

The ratio of isomers (XXX) and (XXXI) shows that the ability to migrate decreases in the sequence H ≫ C_6H_5 > CH_3, i.e. in the sequence mentioned above for cyclopentadienes. It has been reported[88] that the transformations (XXIX) → (XXX) and (XXIX) → (XXXI) are first-order reactions. Thus one must assume that the 1,5-shift reaction in the indene series has virtually the same features as for the cyclopentadienes.

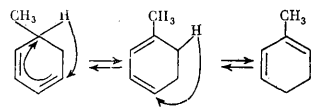
IV. CYCLOHEXA-1,3-DIENES

1. The 1,5-Shift of Hydrogen

The interconversions of cyclohexa-1,3-dienes isomeric with respect to the position of the system of endocyclic double bonds were first observed in 1950 [89] in relation to the reversible isomerisation of 1,5,5,6- and 1,2,6,6-tetramethylcyclohexa-1,3-dienes (XXXII) and (XXXIII) at 350 °C, but the reaction mechanism was not investigated†:

(XXXII), (XXXIV) (XXXIII), (XXXV)

(XXXII), (XXXIII): R = CH_3



(XXXIV), (XXXV): R = H

The reversible isomerisation of 1,5,5- and 2,6,6-trimethylcyclohexa-1,3-dienes (XXXIV) and (XXV) at 300–400 °C was described[90] in 1956. It was suggested that the reaction proceeds via a "biallyl biradical" mechanism, which, in terms of modern terminology, involves ring rupture (with formation of a substituted hexatriene), the 1,7-shift of hydrogen in the resulting triene, and subsequent recyclisation (see below)#. In relation to the type of isomerisation considered, this mechanism aroused serious doubts, because it implied a change in the type of substitution during the reaction and the possibility of the degeneracy of the rearrangement to "automerisation" or a transformation without a change in the structure of the substance, for example, in the case of 5-methylcyclohexa-1,3-diene or 1,5,5-trimethylcyclohexa-1,3-diene (the isomerisation of the latter was observed in the same study[90]).

By analogy with the known behaviour of cyclopentadienes, it was later suggested[95] that the above reaction proceeds via the 1,5-shift of hydrogen and is completed by the attainment of thermodynamic equilibrium [(XXXIV) : (XXXV) ≅ 1 : 1]. An analogous hypothesis had been put forward in an earlier study[93].

In 1971 the migration of the system of double bonds in the cyclohexa-1,3-diene ring was investigated by the authors of this review[96,97]. All three possible isomeric methylcyclohexadienes with a high degree of purity were synthesised and their thermal transformations were investigated[96–98]. It was established[96,97] that the reversible isomerisation of 1-, 2-, and 5-methylcyclohexadienes (XXXVI), (XXXIII), and (XXXVIII) takes place at 300–420 °C and that each diene gives rise to the same equilibrium mixture: 57% (XXXVI), 30% (XXXVII), and 13% (XXXVIII)§.

A study of the compositions of mixtures of methylcyclohexa-1,3-dienes at various equilibration stages starting from the individual dienes (XXXVI)–(XXXVIII) showed[96] that the isomers are interconverted consecutively:

(XXXVIII) (XXXVI) (XXXVII)

The above sequence of transformations is typical for the 1,5-shift of hydrogen, which enabled the authors[96,97] to consider precisely this reaction mechanism. The following kinetic parameters of the isomerisation (XXXVIII) ⇌ (XXXVI) have been obtained[98] for the temperature range 230–250 °C: $\Delta H_1^{\neq} = 38.8$ kcal mol^{-1} and $\Delta S_1^{\neq} = -11.2$ e.u. for the reaction (XXXVIII) → (XXXVI) and $\Delta H_2^{\neq} = 38.5$ kcal mol^{-1} and $\Delta S_2^{\neq} = -14.5$ e.u. for the reaction (XXXVI) → (XXXVIII). In another study[106], where the isomerisation (XXXVIII) → (XXXVII) was regarded as an irreversible reaction, $\Delta G^{\neq} = 35.2$ kcal mol^{-1} and $\lg A = 11.2$ were obtained for the temperature range 300–360 °C. The high negative entropies of activation permitted the conclusion[98] that the reaction has a sigmatropic mechanism with a rigorously ordered transition state and the "biallyl biradical" mechanism could be ruled out[90,107], since if the latter operated the first and rate-limiting stage should have been ring opening with formation of acyclic trienes, to which positive values of $\Delta S^{\neq}$ would have corresponded.

It is striking that for significantly different rates of the reactions (XXXVIII) → (XXXVI) and (XXXVI) → (XXXVIII) (for example, the corresponding rate constants at 230 °C are 5.3×10^{-5} s^{-1} and 2×10^{-5} s^{-1}) the enthalpies of activation for the reactions are the same to within a high degree of accuracy. It has therefore been suggested[98] that the difference between the rates of the interconversions of cyclic dienes isomeric with respect to the position of the system of double bonds is determined almost entirely by the entropy factor.

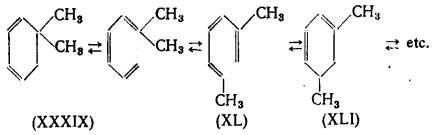
Simultaneously with the above investigations[96,97] and independently of them, it has been shown[108] that mixtures of isomeric methylcyclohexa-1,3-dienes undergo a change in composition at 300–350 °C, i.e. the dienes isomerise under the experimental conditions. It has been suggested[108] that such isomerisation involves the 1,5-shift of hydrogen but no

† The formation in the synthesis of cyclohexa-1,3-dienes of isomers whose structures differ from that expected on the basis of the reaction mechanism has been observed[91–94].

The isomerisation of acyclic 3-*cis*-1,3,5-trienes to cyclohexa-1,3-dienes is one of the most thoroughly investigated electrocyclic reactions[99–104]; the process takes place quantitatively at 100–200 °C. The possibility of the reverse reaction under the conditions of the pyrolysis has been confirmed indirectly by data[105] for the conversion of cyclohexa-1,3-diene into 3-*trans*-hexa-1,3,5-triene (530 °C, yield 1%).

§ Under the given conditions, the isomerisation is not accompanied by the formation of appreciable amounts of side products; among side reactions, the aromatisation of methylcyclohexadienes via their thermal dehydrogenation[96] becomes appreciable only at 450 °C and above.

arguments in support of this have been adduced. It has also been suggested[108] that the process should lead to the establishment of thermodynamic equilibrium between the isomers, but this was not attained.

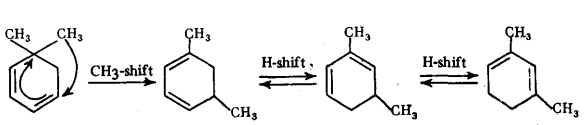


In subsequent studies[109–111] the 1,5-shift was widely used to account for the isomeric transformations of cyclohexa-1,3-dienes.

The information about the composition of the equilibrium mixtures of substituted cyclohexa-1,3-dienes is at present extremely limited, but the data available on this problem[94–96, 111] show that it is close to that of the equilibrium mixtures in the series of cyclopentadienes, which has been much more thoroughly investigated.

It is known that the isomeric transformations of cyclohexadienes can be catalysed by both acids[112] and bases[113], but in both cases the reaction mechanism is evidently different from the 1,5-shift of hydrogen.

2. The 1,5-Shift of the Substituent



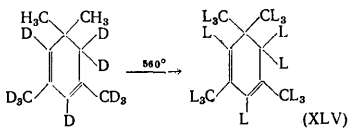
The migration of an alkyl group in the series of cyclohexa-1,3-dienes was first observed in 1956.[90,107] It was established[90] that 5,5-dimethylcyclohexa-1,3-diene (XXXIX) isomerises at 500 °C to 1,3-disubstituted cyclohexadienes, the process being accompanied by aromatisation (to the extent of ~25%; the aromatic fraction contained 33% of toluene and 67% of *m*-xylene). Analogous transformations are undergone by 1,5,5- and 2,6,6-trimethylcyclohexa-1,3-dienes (XXXIV) and (XXXV), forming 1,3,5-trimethyl-substituted cyclohexadienes, mesitylene, and *m*-xylene. The biallyl biradical mechanism has been proposed for the above skeletal isomerisation[90,107]:

(XXXIX) (XL) (XLI)

A characteristic feature of the process involving this mechanism should be a change in the type of substitution and the incorporation of the carbon atom of the side chain in the ring. It was believed that the ability of 5-ethylcyclohexa-1,3-diene (XLII) also to undergo skeletal isomerisation at 450–500 °C, leading to mixtures of 1,2- and 1,4-dimethyl-cyclohexa-1,3-dienes and the corresponding aromatic compounds, constitutes confirmation of this mechanism. It is noteworthy that the degree of conversion of the diene (XLII) into its skeletal isomer is extremely low (not more than 30% at 500 °C, including xylenes).

In 1971 the authors of this review[114,115] carried out an experimental test of the mechanism of the skeletal isomerisation of 5,5-disubstituted cyclohexadienes and established that at 430–530 °C 1,5- and 1,3-dimethylcyclohexa-1,3-dienes (XLI) and (XLII) are formed from the diene (XXXIX) as a result of the consecutive transformations (XXXIX) → (XLI) → (XLIII), corresponding to a mechanism involving the 1,5-shift of the methyl group:

(XXXIX) (XLI) (XLII) (XLIII)



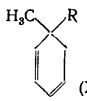
In the concluding stage of the reaction the diene (XLI) formed initially is converted as a result of the 1,5-shift of hydrogen (see above) into an equilibrium mixture of isomers, in which the diene (XLIII) predominates. The reaction is accompanied by aromatisation, toluene being formed from the initial diene (XXXIX) as a result of thermal demethylation and *m*-xylene being formed from the isomerisation products.

It has been noted[114] that the potential barrier to skeletal isomerisation in the series of cyclohexa-1,3-dienes exceeds only slightly the barrier to the hydrogen shift (in contrast to cyclopentadienes). Bearing in mind that, under the conditions of the hydrogen shift, ring opening is known not to occur (see above), presumably the skeletal isomerisation occurring under virtually the same conditions does not involve a ring opening–recyclisation mechanism[90,107] but proceeds via the 1,5-shift of the substituent.

In 1972 Spangler and Bolos[116] arrived independently at the same conclusions. As an additional argument against the ring rupture–recyclisation mechanism, they quoted the observation that the reaction products do not contain any acyclic derivatives of hexatriene. Furthermore, a special synthesis of the triene (XL) (in a mixture with the *trans,trans*-isomer), which might have been an intermediate in the ring dissociation–recyclisation process, was carried out and it was observed that during pyrolysis under identical conditions the diene (XXXIX) and the triene (XL) give rise to completely different mixtures of products[116].

Thus it was established that the irreversible 1,5-shift of the alkyl substituent takes place in 5,5-disubstituted cyclohexa-1,3-dienes in the temperature range 400–500 °C and leads to the elimination of geminal substitution, being completed by the 1,5-shift of hydrogen.

It has been observed[117] that the pyrolysis products of 1,3,5,5-tetramethylcyclohexa-1,3-diene (XLIV) with deuterium atoms in all the positions except for the two geminal methyl groups contain at 560 °C only 19% of the diene (XLV) (the rest consists of mesitylene and methylbenzenes). According to mass spectrometric data, in the absence of hydrogen exchange between the molecules the label is redistributed among the possible positions:



(XLIV) $L = {}^3/_8H + {}^5/_8D$. (XLV)

The above phenomenon was regarded[117] as proof of the ring dissociation–recyclisation mechanism for thermal transformations of the diene (XLIV). However, it is striking that the migration of the alkyl group in the cyclohexa-1,3-diene series takes place at an incomparably higher temperature than in the given experiment. We may note that the results of the above study[117] confirm unambiguously an intramolecular mechanism of the isomerisation of cyclohexadienes even under the very severe conditions used.

According to Schiess and Dinkel[118], the rate of the thermal isomerisation of 5,5-diethylcyclohexa-1,3-diene is 8 times higher than for the dimethyl analogue. At 500 °C (1 s) the reaction is accompanied by a change in the type of substituent; as a result of this (as well as aromatisation), the mixture obtained contains not less than 30 components. The change in the type of substituent can be associated in this instance solely with the rupture of the ring and recyclisation. However, the problem of the nature of the given skeletal isomerisation at 300–400 °C, i.e. under what conditions it should occur if the comparative data of Schiess and Dinkel[118] concerning its rate are correct [cf. the above considerations for the diene (XXXIX)], remains open.

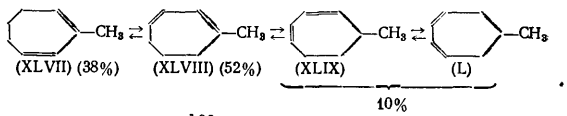
At 300–500 °C non-alkyl groups, for example, the formyl, acetyl, and methoxycarbonyl groups, are capable of migrating in the ring of cyclohexa-1,3-diene.[119] The reaction

results in a mixture of products corresponding to a mechanism involving the 1,5-shift of the substituent with a subsequent 1,5-shift of hydrogen and is accompanied by extensive aromatisation (particularly on prolonged heating). Kinetic measurements[106], the results of which are presented in Table 2, permitted the conclusion that the formyl group in the cyclohexadiene ring migrates at a higher rate than hydrogen, while the methoxycarbonyl and acetyl groups migrate at a lower rate (the rate of migration of the methyl groups is lower still). The pre-exponential factors obtained[106] correspond to a high negative entropy of activation for the reaction, characteristic of the 1,5-shift.

(XLVI)

R = $COOCH_3$(a), $COCH_3$(b), CHO (c), or C_6H_5 (d).

Table 2. Kinetic parameters of the thermal isomerisation of 5,5-disubstituted cyclohexa-1,3-dienes[106].



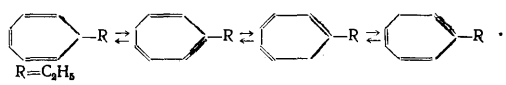
Compound	R	t, °C	$\Delta G^{\neq}$, kcal mol^{-1}	lg$A$
(XLVIa)	$COOCH_3$	270—304	40.8	11.8
(CLVIb)	$COCH_3$	200—240	35.9	12.1
(XLVIc)	CHO	150—200	31.0	11.5

The pyrolysis of 5-methyl-5-methoxycarbonyl- and 5-methyl-5-phenyl-cyclohexa-1,3-dienes (XLVI, a and d), containing a ^{13}C atom in the methyl group in the 5-position, has been investigated[118]. It was established[118] that the label in the methyl group of the diene (XLVIa) is retained to the extent of 85% at 300 °C (1 h in heptane) and 75% at 520 °C (1 s). On the other hand, in the pyrolysis products of compound (XLVId) at 550 °C (1 s) 96% of the label is concentrated in the main ring (disregarding the substituents) and only 4% in the methyl group. On the basis of foregoing, the authors[118] concluded that the migration of the substituents via the 1,5-shift mechanism takes place only when its rate is as high as for a hydrogen atom or a carbonyl group; otherwise the ring dissociation—recyclisation mechanism operates preferentially. However, the experimental data quoted by the authors[118] for the diene (XLVId) involve an evident error: in the statistical distribution of the label in the cyclohexadiene ring and in the methyl group as a result of repeated ring dissociation—recyclisation steps the content of the label in the methyl group cannot be less than ~14% (for a system comprising seven carbon atoms). Bearing in mind the above experimental error, one must suppose that above 500 °C some of the labelled carbon atoms of the methyl group enter the cyclohexadiene ring in the isomerisation process [at 530 °C this fraction is much smaller for the diene (XLVIa) than would be expected for a statistical distribution]. This agrees satisfactorily with the data described above[117].

Thus in 5,5-disubstituted cyclohexa-1,3-dienes different substituents, including alkyl substituents and those containing the carbonyl group, particularly the formyl substituent, should migrate via the 1,5-shift mechanism. Above 500 °C the reaction involves ring dissociation—recyclisation (with a 1,7-shift of hydrogen in the intermediate acyclic triene structure). It is reasonable to regard the latter process as a side reaction and not a parallel reaction, since the 1,5-shift of the substituent takes place already at 400 °C. The concluding stage of the process is in this instance the 1,5-shift of hydrogen in the resulting structures which do not contain geminal substituents.

V. CYCLOHEPTA-1,3-DIENES

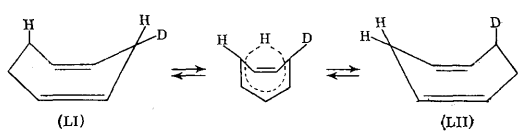
In 1970 Mironov and coworkers[120–123] described the synthesis and isomeric transformations of methyl- and monodeuterocyclohepta-1,3-dienes and established that at 120–160 °C in the liquid or gas phase 2-methylcyclohepta-1,3-diene (XLVII) undergoes reversible thermal isomerisation leading to the formation of an equilibrium mixture of the 1-, 2-, 5-, and 6-isomers (XLVIII), (XLVII), (XLIX), and (L). Here the initial product is the diene (XLVIII) and the reaction proceeds via a mechanism corresponding to the 1,5-shift of hydrogen:



(XLVII) (38%) (XLVIII) (52%) (XLIX) (L)

10%

It has been established[122] that the reactions (XLVII) ⇌ (XLVIII) are of first order and have the following kinetic parameters: $\Delta H_1^{\neq} = 29.5$ kcal mol^{-1} and $\Delta S_2^{\neq} = -7.4$ e.u. for the reaction (XLVII) → (XLVIII) and $\Delta H_2^{\neq} = 28.6$ kcal mol^{-1} and $\Delta S_2^{\neq} = -9.9$ e.u. for the reaction (XLVIII) → (XLVII). Heating 2-deuterocyclohepta-1,3-diene at 140 °C leads[120,123] to a uniform distribution of deuterium between the possible positions in cycloheptadiene in the absence of hydrogen exchange between the molecules, which demonstrates an intramolecular reaction mechanism[123]. Thus it has been established unambiguously[120–123] that a reversible thermal intramolecular 1,5-shift of hydrogen takes place in the ring of cyclohepta-1,3-diene above 120 °C, leading to the establishment of thermodynamic equilibrium between the isomers with respect to the position of the system of endocyclic double bonds.



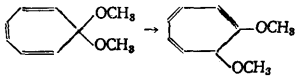
VI. CYCLOHEPTATRIENES

It has been established[124] that the pyrolysis of 7-ethylcycloheptatriene at 400 °C results in the formation of a mixture of all four possible isomers:

R=C_2H_5

A 1,5-shift of hydrogen, accompanied by the migration of the system of two double bonds, has been suggested. This mechanism has been convincingly confirmed[125,126] and it has been shown that, on heating 7-deuterocyclohepta-1,3,5-triene (LI) at 100–140 °C, the deuterium is distributed between the four possible positions. This transformation takes place via an intramolecular mechanism (there is no hydrogen exchange between molecules) and the initial isomerisation product of the triene (LI) is the 3-deutero-isomer (LII). It has been suggested[125] that a non-planar symmetrical structure is formed in the transition state:

(LI) (LII)

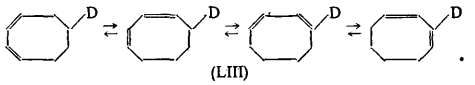


Subsequently the sequence of transformations of isomeric monosubstituted cycloheptatrienes (1,5-shift) was confirmed in a whole series of studies[127–137] dealing with the compositions of the equilibrium mixtures of cycloheptatrienes containing various substitutents [CH_3, C_6H_5, CN, OCH_3, SCH_3, $N(CH_3)_2$, p-$(CH_3)_2NC_6H_4$, COOH, or COOR]; a general tendency was demonstrated—the 7-isomers are energetically more favourable. It has been noted[129] that the presence of groups such as OCH_3 and particularly $N(CH_3)_2$ leads to a sharp increase of the rate of isomeric transformations. A thermal intramolecular 1,5-shift of hydrogen has also been observed in hexamethylcycloheptatrienes[138], in condensed systems containing the cycloheptatriene ring[139,140], in 1,4-di-(7-cycloheptatrienyl)benzene[141], and also in dihydrotropones[142].

The kinetic parameters of the thermal 1,5-shift of hydrogen in a series of cycloheptatrienes are presented in Table 3; a study was made of the transformation of the 7-isomer into the 3-isomer, which was regarded as irreversible. It has been noted[127,128] that the nature of the solvent does not affect the rate of isomerisation. In all the instances investigated the isomerisation was a first-order reaction. The extremely high negative entropy of activation for the reaction confirms the symmetry of the structure of the transition state. Thus it has been shown convincingly that a 1,5-shift of hydrogen takes place in cycloheptatrienes and involves only two of the three double bonds in the ring. The fairly close kinetic parameters of the isomerisation of methylcycloheptadienes and methylcycloheptatrienes constitute an additional confirmation of this fact.

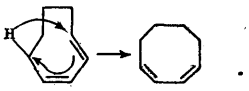
Table 3. Kinetic parameters of the 1,5-shift of hydrogen in the series of cycloheptatrienes (7-isomer → 3-isomer).

Compound	$\Delta H^{\neq}$, kcal mol^{-1}	$\Delta S^{\neq}$, e.u.	Refs.
7-Deuterocycloheptatriene	31	−10	[125]
7-Methylcycloheptatriene	33.3	−4.9	[136]
7-Phenylcycloheptatriene	27.6	−11.6	[127]
7-Methoxycycloheptatriene	25.7	−15	[137]
7-(4-Dimethylaminophenyl)-cycloheptatriene	27.6	−9.3	[130]
1,4-Di(7-cycloheptatrienyl)benzene	29.8	−3.9	[141]



It has been established[143,144] that oxygen-containing substituents can migrate in cycloheptatrienes at 80–150 °C, for example:

This transformation has been observed[145] also in the ethylene ketal of cyclohepta-2,4,6-trien-1-one ($\Delta H^{\neq} = 23.2$ kcal mol^{-1} and $\Delta S^{\neq} = -23$ e.u.). The rate of migration of the methoxy-group in 7,7-disubstituted cycloheptatrienes exceeds, according to Hoffmann et al.[144], the rate of migration of hydrogen. The migration of the methoxy-group from the 7-position of the cycloheptatriene ring in trienes without geminal substituents has also been observed[144]. The combination of the shifts of a substitutent and hydrogen leads to the formation of extremely complex mixtures of compounds. According to some data[143–145], the migration of the alkoxy-group involves the 1,7-shift mechanism, i.e. all three double bonds of the cycloheptatriene ring participate in the transformation, which indicates a sharp difference between this reaction and the shift of substituents in related systems.

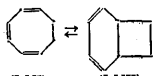


VII. CYCLO-OCTA-1,3-DIENES

In the study of the thermal transformations of 5-deutero-cyclo-octa-1,3-diene (LIII) in 1966 it was established[146] that the system of double bonds in the ring of cyclo-octa-1,3-diene migrates at 130–150 °C, which leads to the attainment of thermodynamic equilibrium between the isomers:

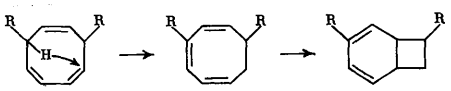
(LIII)

It has been shown[146] that the reaction is not accompanied by hydrogen exchange and that the sequence of the interconversions of the isomers corresponds to the scheme presented above. It has been noted that the reaction proceeds at comparable rates in the liquid and gas phases. The study of the kinetics of the isomerisation of the diene (LIII) in the temperature range 125–150 °C yielded $\Delta H^{\neq} = 29.3$ kcal mol^{-1} and $\Delta S^{\neq} = -10$ e.u. From the foregoing, it was concluded[146] that the reversible thermal intramolecular 1,5-shift of hydrogen takes place in cyclo-octa-1,3-dienes. In subsequent studies[147] of the quenching of the fluorescence of naphthalene under the influence of *cis,trans*-octa-1,3-diene (LIV) it was established that the observed phenomenon is due to the transformation of the diene (LIV) into its *cis,cis*-isomer (LV):



(LIV) (LV)

The authors[147] suggest that the isomerisation (LIV) → (LV) proceeds via the 1,5-shift of hydrogen ($\Delta G^{\neq} = 33$ kcal mol^{-1}).



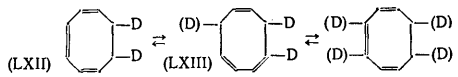
VIII. CYCLO-OCTATRIENES

The study of the migration of the system of double bonds in cyclo-octatrienes is complicated by the fact that the 1,3,5-isomer (LVI) readily undergoes the electrocyclisation reaction: as a result of the reversible reaction at 80–100 °C, equilibrium is established between the triene (LVI) (85%) and its valence tautomer—bicyclo[4,2,0]octa-2,4-diene (LVII) (15%):[148,149]

(LVI) (LVII)

The thermal isomerisation of 5,8-di(α-cyanoisopropyl)-cyclo-octa-1,3,6-triene (LVIII) to the corresponding bicyclic compound (LIX) in boiling xylene (20 h) or benzene (75 h) has been observed[150]:

(LVIII) (LX) (LIX)



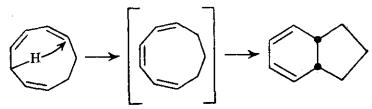
R = —C(CH$_3$)$_2$(C≡N)

The thermal isomerisation of the initial 1,3,6-triene (LVIII) to the 1,3,5-triene (LX) was regarded[150] as the intermediate stage of the reaction¶. By analogy with the isomerisation of

¶ The isolation of the homogeneous diene (LIX) from the reaction products is evidently associated with the loss of the isomer (LX) in the crystallisation process.

cycloheptatrienes described above, it was assumed that the reaction proceeds via the 1,5-hydrogen shift mechanism. The examination of a model of the initial compound led the authors[150] to the conclusion that the distance between the migrating H atom (at $C_{(5)}$) and the corresponding $C_{(1)}=C_{(2)}$ double bond is only 1.5 Å.

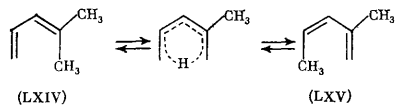
The reversible thermal isomerisation of cyclo-octa-1,3,6-triene (LXI) and cyclo-octa-1,3,5-triene (LVI) at 100–130 °C, leading to the formation of their equilibrium mixture containing slight (0.5–1%), but susceptible to determination amounts of the triene, (LXI), was described almost simultaneously[151]. The kinetic process parameters have been obtained (first reaction order, $\Delta H^{\neq} = 27.3$ kcal mol^{-1}, $\Delta S^{\neq} = -8$ e.u.[151], $\Delta G^{\neq} = 28.9$ kcal mol^{-1}, and $\lg A = 11.74$ [152]); it was shown[151] that the reaction proceeds at comparable rates in the liquid and gas phases. The 1,5-shift of hydrogen was considered as the reaction mechanism. This mechanism was subsequently confirmed by elegant experiments[152,153]. Thus the isomerisation of 7,8-dideuterocyclo-octatriene (LXII) [152] via the 1,5-hydrogen shift mechanism should lead to a redistribution of deuterium only between the 7(8)- and 3(4)-positions, while a redistribution of deuterium between all possible positions should correspond to the 1,3-shift of hydrogen. It has been established[152] that isomerisation results in the attainment of thermodynamic equilibrium between the trienes (LXII) and (LXIII) (isomer ratio 43.7 : 1 at 225 °C). The redistribution of deuterium takes place already at 180 °C, but even at 270 °C the label is located solely in the 3(4)- and 7(8)-positions:



Analogous conclusions were reached in a study[153] of the thermal transformations of 5,8-dideuterocyclo-octa-1,3,6-triene as a result of the isomerisation of which the distribution of the label in the 1,3,5-triene formed also corresponds to 1,5-shift of hydrogen. The absence of hydrogen exchange between the molecules in both cases[152,153] confirms the intramolecular reaction mechanism. It has been established[152,153] that a high primary kinetic isotope effect ($k_H/k_D = 5.0$) corresponds to the isomerisation of cyclo-octatrienes with a slight secondary isotope effect (1.02–0.2). Thus the double bonds in cyclo-octatriene migrate via the 1,5-hydrogen shift mechanism.

It has been reported that the isomerisation of cyclo-octa-1,3-triene to the 1,3,5-isomer (mixed with its bicyclic valence tautomer) takes place in t-butyl alcohol in the presence of potassium t-butoxide (2 h, 90 °C) [148,149,154] or under the influence of an alcoholic solution of potassium hydroxide (4 h, 90–100 °C).[149] However, comparison with the thermal isomerisation conditions does not permit an unambiguous claim that in this case the process is vigorously catalysed by bases.

IX. CYCLONONATRIENES



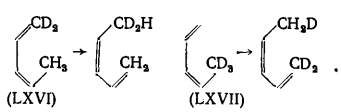
The thermal isomerisation of *cis,cis,cis*-cyclonona-1,3,6-triene to bicyclo[4,3,0]nona-2,4-diene at 200 °C was observed in 1963:[155]

The 1,5-shift of hydrogen was regarded as a hypothetical intermediate stage in the reaction[155].

X. ACYCLIC DIENES

The reversible thermal isomerisation of 4-methylpenta-1,3-diene (LXIV) to *cis*-2-methylpenta-1,3-diene (LXV) in the vapour phase at 350–450 °C (contact time ~1 s) has been described[156]:

It was concluded[156] that the transformation takes place via the 1,5-shift of hydrogen and the migration of two double bonds; a planar six-membered cyclic system was considered as the transition state in the reaction. *trans*-Dienes, incapable of forming a cyclic transition state (for example, *trans*-2-methylpenta-1,3-diene and *trans*-2,5-dimethylhexa-1,3-diene), are thermally stable. According to Wolinsky et al.[156], the (LXIV) + (LXV) equilibrium mixture contains ~80% of the diene (LXIV). Subsequently these results were reproduced[157] and it was shown that at 200 °C the equilibrium mixture contains 93% of compound (LXIV) and at 400 °C its content is 81%.

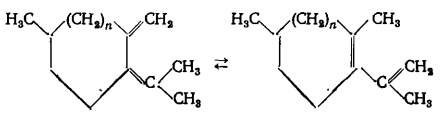


The kinetic data obtained for isomerisations of this type are presented in Table 4. In all the instances investigated the reaction is of first order and has an activation entropy characteristic of the 1,5-shift.

Table 4. Kinetic parameters of the 1,5-shift of hydrogen in the series of acyclic dienes (200–250 °C).

Compound	Reaction product	$\Delta G^{\neq}$, kcal mol^{-1}	$\lg A$	Refs.
2-Methyl-*cis*-penta-1,3-diene	4-methylpenta-1,3-diene	32.8	11.24*	[157]
2-Ethyl-*cis*-penta-1,3-diene	4-methyl-*trans*-hexa-1,3-diene	31.6	10.77	[159]
4-Methyl-*trans*-hexa-1,3-diene	2-ethyl-*cis*-penta-1,3-diene	34.5	11.03	[159]
cis-Hexa-1,3-diene	*cis, trans*-hexa-2,4-diene	32.5	10.80**	[160]
2,3-Dimethyl-*cis*-penta-1,3-diene	3,4-dimethylpenta-1,3-diene	33.8	11.13	[161]
3,4-Dimethylpenta-1,3-diene	1,3-dimethyl-*cis*-penta-1,3-diene	33.3	10.97	[161]

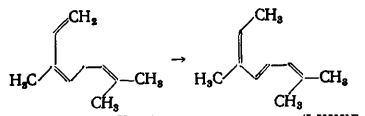
*$\Delta S^{\neq} \cong -8$ e.u.
**$\Delta S^{\neq} \cong -12$ e.u.



The thermal transformations of 1,1-dideutero- and 5,5,5-trideutero-*cis*-penta-1,3-dienes (LXVI) and (LXVII) have been investigated[158]:

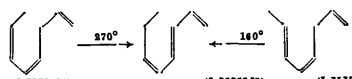
The above reactions are not accompanied by hydrogen exchange between the molecules (intermolecular mechanism) and are not base-catalysed. Comparison of the results of kinetic measurements for the isomerisation of the diene (LXVI) ($\Delta H^{\neq} = 35.4$ kcal mol^{-1}, $\Delta S^{\neq} = -7.1$ e.u., migration of hydrogen) and the diene (LXVII) (migration of deuterium in the same system) led to $k_H/k_D = 12.2$, which agrees well with a cyclic highly symmetrical transition state.

Thus a typical 1,5-shift of hydrogen can occur in acyclic *cis*-diene systems with a chain length corresponding to more than 5 carbon atoms. We may note that the rate of isomerisation is close to that of cycloheptadienes.



Isomerisation of a similar type also takes place in dienes with two exocyclic double bonds; for example, the reversible transformations (LXVIII)⇌(LXIX) and (LXX)⇌(LXXI) have been observed[156]:

(LXVIII), (LXX) (LXIX), (LXXI)

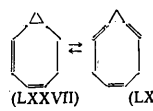


(LXVIII), (LXIX): $n = 0$ in equilibrium with ~80% (LXIX)
(LXX), (LXXI): $n = 1$ in equilibrium with ~90% (LXXI).

Two double bonds can migrate via the 1,5-shift mechanism in acyclic polyene systems; for example, the isomerisation of natural ocimene [3,7-dimethylocta-1,3,6-triene (LXXII)] to allo-ocimene [2,6-dimethylocta-2,4,6-triene (LXXIII)], which takes place at 160–190 °C, can be readily explained from these standpoints[162–164]:

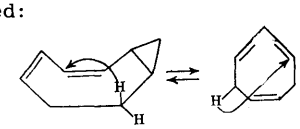
(LXXII) (LXXIII)

It has been reported[165] that two double bonds in 6-*cis*,4-*cis*- and 6-*trans*,4-*cis*-octa-1,4,6-trienes (LXXIV) migrate with formation of octa-1,3,5-triene (LXXIV):



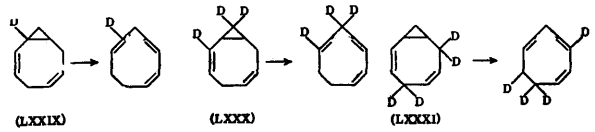
(LXXIV) (LXXVI) (LXXV)

The triene (LXXV) isomerises much more readily than its geometrical isomer (LXXIV) (at 160 °C instead of 270 °C) and the centres involved in the reaction are therefore distributed more readily in a single plane.



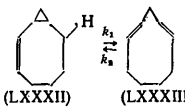
XI. HOMODIENYL SYSTEMS

Isomerisation of a similar type can occur in cyclic systems where one of the double bonds is replaced by a three-membered ring (homodienyl systems). It has been observed[151] that at 150–180 °C bicyclo[6,1,0]nona-2,4-diene (LXXVII) is converted into cyclonona-1,4,7-triene (LXXVIII):



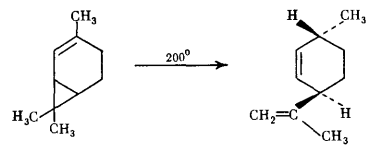
(LXXVII) (LXXVIII)

It has been established that this reaction is reversible; the equilibrium mixture contains 8–9% of compound (LXXVII). The 1,5-shift of hydrogen was considered as the reaction mechanism and the conformational proximity of the migration centres was noted:



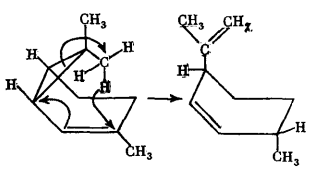
The isomerisation of bicyclo[6,1,0]nona-2,5-diene takes place similarly and the direction of the reaction (the 1,5-shift of hydrogen) has been convincingly confirmed by the study of the position of deuterium in the products of the thermal transformations of the three labelled compounds (LXXIX), (LXXX), and (LXXXI):[166]

(LXXIX) (LXXX) (LXXXI)



A similar reaction has been observed[146] in relation to bicyclo[6,1,0]non-2-ene (LXXXII) at 150–170 °C:

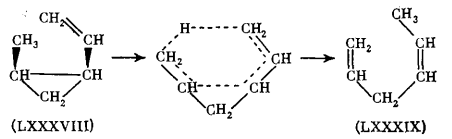
(LXXXII) (LXXXIII)



The equilibrium constant $K = k_1/k_2 = 82.3$. $\Delta H_1^{\neq} = 31.4$ kcal mol^{-1} and $\Delta S_1^{\neq} = -6$ e.u. have been obtained for the reaction (LXXXII) → (LXXXIII), which differs insignificantly from data for the 1,5-shift of hydrogen in the corresponding diene system. The rate constants for the isomerisation (LXXXII) → (LXXXIII) in the liquid and gas phases have similar values. The same isomerisation occurs[167] in *exo*-9-hydroxymethylbicyclo[6,1,0]non-2-ene at 240–340 °C, leading to the 3-hydroxymethylnona-1,4-diene. The 1,5-shift of hydrogen has also been observed in the bicyclo[5,1,0]oct-2-ene system (LXXXIV) at 180–300 °C, cyclo-octa-1,4-diene (LXXXV) being formed as a result of the reversible reaction[168]. The equilibrium constant $K = 36$; kinetic measurements led to $\Delta G^{\neq} = 38.6$ kcal mol^{-1} and $\lg A = 13.17$. It is noteworthy that a common feature of the 1,5-shift in homodienyl systems is the opening of the three-membered ring with formation of dienes containing isolated (1,4) double bonds†.

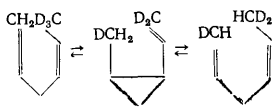
An interesting example of isomerisation in homodienyl systems with a six-membered main ring is provided by the transformations of 3,7,7-trimethylbicyclo[4,1,0]hept-2-ene (LXXXVI) (Δ^4-carene) and its derivatives into non-conjugated dienes [isolimonene (XXXVII)], which are rigorously stereospecific[174,175]:

(LXXXVI) ($a_D^{20} = +92.7°$) (LXXXVII) ($a_D^{20} = +119.5°$)



The kinetic parameters obtained for this reaction[174] are typical for the 1,5-shift of hydrogen: $\Delta H^{\neq} = 27.2$ kcal mol^{-1} and $\Delta S^{\neq} = -17.2$ e.u. The isomerisation of (+)-3-hydroxymethyl-Δ^4-carene is just as stereospecific[176]. Transformations of this type also evidently involve a transannular 1,5-shift of hydrogen, in which the hydrogen atom of the *endo*-methyl group in the 7-position, conformationally close to that of the second migration centre, is involved:

† In homodienyl systems with a smaller main ring (C_6 and smaller) the opening of the three-membered ring proceeds via a mechanism differing from the 1,5-shift[109,169–173].

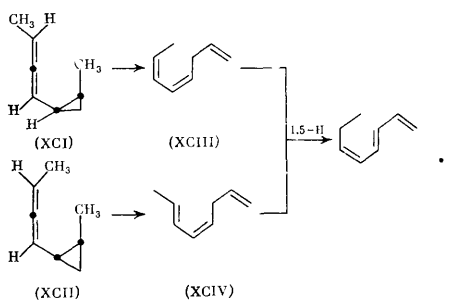


The absence of the 1,5-shift in homodienyl systems with a six-membered main ring but without an *endo*-substituent in the three-membered ring is probably due precisely to conformational factors or, in other words, to the remoteness of the hydrogen atom in the 5-position from the corresponding p-π-orbital of the double bond (in the 3-position).

In methylvinylcyclopropane systems the mechanism of the thermal transformations also depends on their configuration. Thus it has been established[177,178] that at temperatures above 160 °C *cis*-1-methyl-2-vinylcyclopropane (LXXXVIII) isomerises quantitatively to *cis*-hexa-1,4-diene (LXXXIX); under these conditions, *trans*-1-methyl-2-vinylcyclopropane is thermally stable:

(LXXXVIII) (LXXXIX)

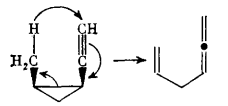
The kinetic parameters of the reaction (LXXXVIII) → (LXXXIX) ($\Delta G^{\neq} = 31.2$ kcal mol^{-1} and lg $A = 11.03$ according to the data of Ellis and Frey[177] and $\Delta H^{\neq} = 30.2$ kcal mol^{-1} and $\Delta S^{\neq} = -11$ e.u. according to the data of Roth and Konig[179]) are satisfactorily consistent with the 1,5-hydrogen shift mechanism. This mechanism was subsequently convincingly confirmed[179] by a study of the thermal isomerisation of 6,6,6-trideutero-*cis*-hexa-1,4-diene (XV):



(XC)

The redistribution of deuterium between the terminal C atoms of the system can be accounted for in this instance solely by a reversible intramolecular 1,5-shift of hydrogen.

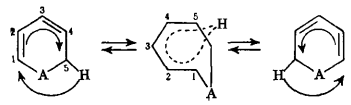
Thus the necessary and sufficient condition for the 1,5-shift of hydrogen in conjugated homodienyl systems is the coplanarity of the five C atoms which are potential participants in the reaction and the spatial proximity of the terminal C atoms in this system.



The 1,5-homodienyl shift of hydrogen has been observed recently[165] in compounds where the double bond is part of the allene system. One of the diastereoisomers of the substituted cyclopropylallene (XCI) readily isomerises in the form of a 5% solution in benzene at 125 °C to *cis*-octa-1,3,5-triene (XCIII), while the isomerisation of the other diastereoisomer (XCII) to the triene (XCVI) takes place at 160 °C at a much lower rate[165]:

(XCI) (XCIII)

(XCII) (XCIV)



The only instance of the 1,5-shift in a system containing a triple bond is the thermal isomerisation of *cis*-2-ethynyl-1-methylcyclopropane above 350 °C; the initial product is hexa-1,2,5-triene[180]:

XII. GENERAL AND CHARACTERISTIC FEATURES OF THE REACTION AND ITS MECHANISM

The experimental data examined above show that the 1,5-shift of hydrogen or a substituent is an extremely common phenomenon in organic chemistry. This reaction is evidently characteristic of any *cis*-1,3-diene or polyene system including cyclic, acyclic, and homodienyl systems.

In general the 1,5-shift involves the displacement of a system of two double bonds to a neighbouring carbon atom (at the 5-position) and the migration of hydrogen (or a substituent) from this atom to the $C_{(1)}$ atom of the initial diene system:

(XCV)

Only the 1,3-diene system exhibits the ability to migrate, since it is well known that cyclohexa-1,4-diene[181] and cyclohepta-1,4-diene[182] do not undergo thermal isomerisation. In 1,4-dienes with C_9 and larger rings the 1,5-shift of hydrogen leads to the closure of a three-membered ring (to a slight extent as a reversible reaction). 1,4-Homodienyl systems are also thermally stable up to 500 °C, which has been established in relation to bicyclo[4,1,0]hept-3-ene[172] and 3,7,7-trimethylbicyclo[4,1,0]hept-3-ene.[175,183]

The migrating system of double bonds must have the *cis*-configuration, since the *trans*-dienes in the acyclic series (see above) as well as cyclic dienes with a fixed transoid system of double bonds do not enter into the reaction under consideration[74,96].

It has been established reliably for each of the cases discussed above that the thermal isomerisation proceeds precisely as the 1,5-shift and not the 1,3-shift, involving the migration of one of the double bonds; the latter would have led to a sequence of interconversions of isomers which has been reliably ruled out by experimental data.

In polyene chains or rings only two double bonds participate in the reaction, i.e. the thermal isomerisation involves the 1,5- and not the 1,7-shift. The migration of the alkoxy-group in the series of cycloheptatrienes (the 1,7-shift) is one of the few exceptions known at the present time.

Reactions proceeding via a stage involving the elimination of a proton, particularly in the series of cyclopenta-, cyclohexa-, and cyclohepta-dienes capable of forming the corresponding anions, can formally lead to the same final results as the 1,5-shift of hydogen (i.e. to the establishment of thermodynamic equilibrium between the isomers). However, in relation to such reactions the 1,5-shift has the following clear-cut distinctive features:

(1) The absence of hydrogen exchange in the isomerisation process (intramolecular mechanism).

(2) Comparable rates of reaction in the liquid and gas phases.

(3) A high (in absolute magnitude) negative entropy of activation ($\Delta S^{\neq} = -8$ – -12 e.u.).

(4) A high primary kinetic isotope effect $k_H/k_D \geq 6$ (for the migration of hydrogen).

(5) Stereospecificity of the reaction.

The above features of the isomerisation of diene and polyene systems make it possible to classify it unambiguously as the 1,5-shift.

The rate of isomerisation decreases in the sequence cyclopentadiene–cyclohepta-1,3-diene–cyclohexa-1,3-diene ($C_5 > C_7 \gg C_6$); comparison with the acidity sequence of hydrocarbons ($C_5 > C_6 \cong C_7$) shows that there is no charge separation in the transition state. This conclusion has also been confirmed by the weak dependence of the rate of reaction on the nature of the solvent and by the comparable rates of reaction in the liquid and gas phases. Thus the 1,5-shift is a process proceeding as a "reaction without a mechanism".

The transition state of the reaction is cyclic, rigorously ordered, and highly symmetrical, the migrating hydrogen atom being approximately equidistant from the migration centres (the 1- and 5-positions). This has been confirmed by the high negative entropies of activation for the reaction and the high primary kinetic isotope effect. This transition state corresponds to a synchronous shift of hydrogen and the double bonds. In the transition state the five carbon atoms participating in the reaction form a planar or almost planar system of the type of (XCV). A mechanism of this type is referred to as sigmatropic, since it is based on the migration of a σ-bonded hydrogen atom, which interacts in the transition state with the two ends of a 4π-electron system. The total number of electrons in the system constitutes a sextet, i.e. the most stable (according to the Hückel rule) system is formed. As a result of the reaction the π orbital of the carbon atom in the 1-position is converted into the sp^3-hybrid orbital of the new C–H bond, while the sp^3-orbital of the $C_{(5)}$–H bond is converted into the π orbital of the diene (polyene) system. A similar mechanism has been discussed in a number of studies[184–187] and has been confirmed by quantum-mechanical calculations[188].

From the standpoint of the conservation of orbital symmetry, considered in detail, for example, by Woodward and Hoffmann[187] and Gilchrist and Storr[189], the fact that the isomerisation of diene and polyene systems takes place as the 1,5-shift has been explained on the basis of selection rules. This mode of reaction is of the suprafacial type[187,189], i.e. the *s* orbital of hydrogen overlaps a lobe of the *p* orbital of carbon in the 1-position located on the same side of the plane; this overlap makes the given process allowed for the thermal reaction. In the same systems the 1,3- and 1,7-shifts should proceed via an antarafacial pathway with participation of the *p* orbital on the opposite side of the plane of the system. In the 1,3-shift such overlap requires a considerable angular strain in the molecule and it does not therefore occur under the conditions of the thermal reaction. For the 1,7-shift, the antarafacial pathway in the thermal reaction is in principle possible, but in this case the potential barrier to the reaction is much higher than for the 1,5-shift.

The velocity of the 1,5-shift of hydrogen in different systems varies within fairly broad limits. The reaction takes place most readily in cyclopentadienes ($\Delta G^{\neq} \cong 20$ kcal mol^{-1}) and with the greatest difficulty in cyclohexadienes ($\Delta G^{\neq} \cong 39$ kcal mol^{-1}); for cycloheptadienes as well as dienes and trienes with large rings, $\Delta G^{\neq} = 29$–31 kcal mol^{-1}. Presumably the above differences are associated with the distance between the $C_{(1)}$ and $C_{(5)}$ migration centres; in other words, the ease of isomerisation is determined by the conformational proximity of the $C_{(5)}$–H bond and the π orbital of the $C_{(1)}$ atom. Cyclopentadiene is known to have a planar conformation[190–192], the cyclohexa-1,3-diene molecule is almost planar[193], while the cyclohepta-1,3-diene[194] and cyclo-octa-1,3-diene molecules[50,195–197] are non-planar and have a large dihedral angle; for higher cyclodienes, a non-planar configuration is apparently also typical. An approximate estimate of the distances between the migration centres (the 1- and 5-positions) in cyclopenta-, cyclohexa-, and cyclohepta-dienes in the given conformations shows that, in terms of this distance, the cyclic dienes can be arranged in the sequence $C_5 < C_7–C_9 \ll C_6$, which is satisfactorily correlated with the sequence based on decreasing rates of isomerisation.

The 1,5-shift of substituents in all the cases investigated takes place under more severe conditions than the 1,5-shift of hydrogen; the greater the ease of migration of hydrogen in the given system, the greater the difference between the rates of migration of hydrogen and substituents. Evidently the shift of substituents takes place fundamentally via the same pathway as the shift of hydrogen. The lower rate of migration of alkyl groups is apparently due to the fact that the ability of the *s* orbital of hydrogen to form a "bridge"[189] bond in the transition state is greater than that of the sp^3-hybrid orbital of the alkyl group. The more pronounced *s* character of the sp^2-hybrid orbital in the phenyl group can account for the greater rate of its migration compared with that of the alkyl group.

In all cases the 1,5-shift of hydrogen is completed by the establishment of thermodynamic equilibrium between the isomers with respect to the position of the system of endocyclic double bonds. The composition of the equilibrium mixture is determined by the operation of thermodynamic factors alone. Two limiting cases are possible in principle: (1) if the difference between the free energies of the isomers is close to zero, their concentrations in the equilibrium mixture are practically equal; examples of such mixtures are provided by deutero-derivatives of dienes and polyenes; (2) if one of the isomers is much more favoured by energy factors ($\Delta\Delta G > 1.5$ kcal mole^{-1}), than its concentration in the equilibrium mixture is close to 100%; examples of such systems are provided by 1,2,3- and 1,2,4-trimethylcyclopentadienes (see above).

Comparison of the compositions of the equilibrium mixtures in different series revealed general features; (a) a lower stability of isomers containing a substituent in the methylene groups; (b) comparable thermodynamic stabilities of isomers differing in the position of an alkyl group attached to the system of double bonds; (c) the fact that isomers containing a substituent which lengthens the conjugation chain inthe 1-position are preferred. These features should apparently hold for the substituted *cis*-dienes which have not yet been investigated.

For cyclic diene systems, the main contribution to the difference between the free energies of the isomers comes from the entropy factor. Hence one may conclude that the composition of the equilibrium mixtures of cyclic dienes and polyenes should vary insignificantly within wide temperature limits, since the temperature dependent term in the equation defining the equilibrium constant is either small or close to zero. The temperature dependence of the composition of the equilibrium mixtures has been hardly investigated, but comparison of the ratios of the isomeric 1,2,3,4-, 1,2,3,5-, and 1,2,4,5-tetramethylcyclopentadienes at 20 °C (79 : 10 : 11)[21,77] and 500 °C (79 : 5 : 16)[77] confirms this hypothesis.

Systems in which there is a possibility of a 1,5-shift of hydrogen or a substituent are naturally not exhausted by those listed above. Presumably transformations of this type will be discovered in the immediate future for other representatives of the class of *cis*-diene and polyene structures, including homodienyl structures. In particular, the 1,5-shift of substituents, especially functional groups, has been virtually uninvestigated for systems with more than seven carbon atoms in the ring.

In conclusion one should note that the possibility of a 1,5-shift, particularly the 1,5-shift of hydrogen, should be taken into account in the study of any chemical reactions of dienes and polyenes.

Metallotropic Tautomeric Transformations of the σ,σ-Type in Organometallic and Complex Compounds

L.A.Fedorov, D.N.Kravtsov, and A.S.Peregudov

The review is devoted to the consideration of studies in the field of metallotropy—a new type of tautomeric transformations of organometallic and complex compounds involving the intramolecular and intermolecular migration of metal-containing groups.
The bibliography includes 221 references.

I. INTRODUCTION

The problems of tautomerism constitute one of the most important branches of theoretical chemistry and have attracted the constant attention of investigators throughout many years. The foundations of the science of tautomerism were laid as early as the end of the past century by A.M.Butlerov. Until the end of the 1950's, the most thoroughly investigated type of tautomerism involved prototropic transformations accompanied by the dissociation of σ-bonds and the migration of the hydrogen atom between cation-accepting centres. The study of these processes enabled M.I.Kabachnik to create a quantitative theory of prototropic equilibrium.

At the beginning of the 1960's a qualitative jump occurred in the study of tautomerism. It was caused, on the one hand, by the discovery of tautomeric processes associated with the dissociation of donor–acceptor σ- or π-bonds and processes involving the migration of groups containing a metal, metalloid, or carbon key atom and, on the other hand, the extensive application of the NMR method. All these factors led to the vigorous accumulation of qualitatively new facts and to the development of fundamentally new ideas in the theory of tautomeric processes.

This review deals with studies in the field of metallotropic transformations of organometallic and complex compounds. If the phenomenon under consideration is defined more vigorously, then one must assume that metallotropic transitions occur as a result of a change in the relative positions of two fragments of the compound—cationoid and anionoid, accompanied by the dissociation of some bonds and the formation of others between the metal and the ligand and in many instances also by a redistribution of the multiple bonds of the latter. Here the cationoid residue may be the metal or the organometallic group or another metal-containing species, where the metal forms a bond with the anionoid residue before and after the metallotropic transition. The anionoid residue can consist of a bifunctional (in the general case a polyfunctional) ligand capable, in principle, of forming several variants of the chemical bond with the same metal atom of the cationoid residue.

Initially[1-17] the problem of metallotropy was formulated and solved in relation to derivatives of prototropic tautomeric systems in which a "mobile" hydrogen atom has been replaced by an organometallic group. Among other features, in these studies the specific characteristics of the phenomenon, associated with the replacement of H by MR_n, were discovered. It was found that metallotropic systems are in all cases analogues of the corresponding prototropic models (as regards their structure and the process mechanism) and have many interesting, frequently fundamental, characteristic features.

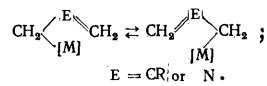
It was subsequently discovered that, in principle, metallotropic transitions can occur in systems of very many types, including those very remote from the prototropic analogues. In particular, various types of metallotropic transformations in π-complexes of transition metals have been observed and in many cases investigated in detail.

If this classification of the phenomenon of metallotropy is based on the nature of the bond formed by the metal, it is possible to distinguish three main types of metallotropic transitions: σ,σ- transitions, π,π-transitions, and σ,π-transitions. For tautomeric transformations of the σ,σ-type (sigmatropic transitions), it is postulated that before and after the rearrangement the metal forms localised (principle-valence or coordinate)σ-bonds with topologically different atoms of the anionoid residue of the given or another molecule. Transitions of the π,π-type consist in the migration of the metal from the system of multiple bonds, with which the π-bond had been formed initially, to a topologically different system in the given or another similar molecule. For transitions of the σ,π-type, it is suggested that in the initial and final states the metal forms bonds of different types with the ligand. The metallotropic π,π- and σ,π-transitions do not have prototropic analogues, while many (but not all) σ,σ-transitions are formally analogous to the corresponding prototropic systems. Studies on metallotropic π,π- and σ,π-transformations have been reviewed[18]. This review therefore deals mainly with the advances in recent years in the study of sigmatropic transitions of metal-containing groups.

A particular feature of the phenomenon considered must be emphasised. Metallotropic transitions can occur not only intramolecularly but are frequently also intermolecular. We shall adopt the convention that the intramolecular transformations are those in which the cationoid metal-containing group migrates between atoms of the same anionoid residue and which are not accompanied by the decomposition of the

given compound into kinetically independent species. On the other hand, in intermolecular metallotropic transitions the metal-containing species is separated for a short time from the anionoid residue and is attached to a "transferring agent" or passes into the bulk of the solution, as a result of which after the metallotropic transition the cationoid species is bound not to its "own" anionoid residue but to a "foreign" one. In terms of purely external features, the intermolecular metallotropic transitions may not differ from exchange processes in which the metal-containing species migrates from one anionoid residue to another. We shall therefore adopt the convention that metallotropic transitions will be assumed to be only those where the intermolecular migrations of the cationoid residues take place between bifunctional or polyfunctional ligands [process (I)]; and henceforth the symbol [M] denotes a metal-containing species, its organoelemental analogue, or a proton (cationoid residue), which is bound via the M–E σ-bond to the anionoid residue [E]. On the other hand, the transitions of metal-containing species between monofunctional ligands will be classified as exchange reactions [process (II)]:

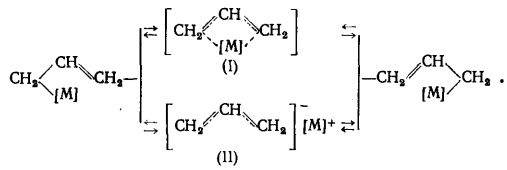
$$[M]-[E]-\rightleftarrows [M]-[E^*]- \quad (1)$$
$$[E^*]- \qquad\qquad [E]-$$



$$[M]-[E]+[M^*]-[E^*] \rightleftarrows [M]-[E^*]+[M^*]-[E]\,. \quad (2)$$

Mainly infrared and ultraviolet spectroscopic methods were used initially in studies of metallotropy and the equilibrium position in metallotropic systems[1–8]. However, subsequently high-resolution NMR, particularly dynamic NMR, began to be used on a wider scale for these purposes[9–17]. With the aid of the latter, it is often possible to obtain the kinetic characteristics of metallotropic processes, which permits a successful analysis of their mechanisms. This is because metallotropic transitions, like tautomeric transformations in general, frequently take place at rates comparable to the NMR time scale, which makes it possible to investigate not only the ratios of the possible tautomers but also the dynamics of their transformations. In view of these factors, a further consideration of the phenomenon of metallotropy will be based mainly on NMR results, but if necessary other data will also be employed.

The first experimental evidence in support of the occurrence of metallotropic transitions in organometallic compounds of non-transition metals was apparently obtained in 1960 by Nasmeyanov and Kravtsov[1] in an infrared and ultraviolet spectroscopic study of solutions of arylmercury derivatives of *p*-nitrosophenols in aprotic media. In a series of subsequent studies other instances of the migration of metal-containing groups between carbon atoms or heteroatoms of the corresponding molecule were investigated or simply discovered: however, one should note that these studies, including those by NMR, have been by no means systematic for all the models; the review of the relevant studies is therefore unfortunately somewhat fragmentary. In order to overcome this deficiency to some extent, in the analysis of certain model structures, for which the migration of metal-containing groups is as yet unknown, has been little studied, or may be impossible, we considered instances of E,E-transitions (E = C,N,O,S,etc.) with participation of cationoid species such as SiR_3 and GeR_3, which are organoelemental analogues of the groups R_3Sn and R_3Pb, as well as organometallic groups involving transition and light non-transition metals.

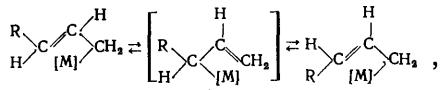


II. METALLOTROPIC C,C-TRANSITIONS

Among "purely carbon" systems, where there is a possibility of C,C-transitions of metal-containing groups accompanied by the dissociation of old and the formation of new metal–carbon bonds, one must first consider the simplest three carbon system $-\underset{|}{\overset{|}{C}}-C=C-$, whose prototropic analogue has a
[M]
relatively low mobility (as well as the related azomethine triad $-\underset{|}{\overset{|}{C}}-N=C-$ with a central nitrogen atom, which has not been
[M]
investigated at all from the standpoint of metallotropic transitions):

(3)

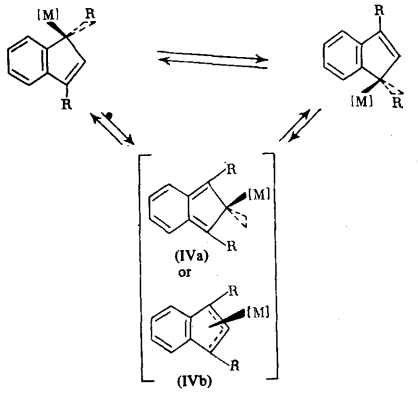
Although the occurrence of metallotropic 1,3-transitions [reaction (3)] with E=CR has usually been considered for a fairly wide range of allyl derivatives, we believe it is correct to discuss here only those examples in which the existence under specific conditions of a localised C_3H_5–[M] σ-bond has been demonstrated reliably. When the migration is retarded by the protons of the allyl group, the ^1H NMR spectrum shows the corresponding $AKLX_2$ system, which in a case of sufficiently rapid intramolecular or intermolecular C,C-transitions [reaction (4)], involving the C–M bond, degenerates to AX_4 (the corresponding spin systems are observed also for substituted allyl radicals). This phenomenon has been observed, in particular, in NMR studies of the compounds C_3H_5HgX[19,20], $(C_3H_5)_2Zn$[21,22], and $(C_3H_5)_3B$[23]:



(4)

It has been suggested that the 1,3-transitions [reaction (4)] take place with the intermediate formation of either the transition state (I) or of ionic structures, for example of type (II). In the case of $(C_3H_5)_2Zn$[21,22] and asymmetric allyl derivatives of mercury[19,20], reaction (4) is intermolecular and that involving allyl derivatives of boron is intramolecular[23].

The occurrence of process (4) was first postulated in an attempt to explain the NMR spectra of allyl derivatives of magnesium[24]. However, one should note that the spectral pattern corresponding to the inhibition of the metallotropic transition has not so far been observed in the NMR spectra of the asymmetric derivatives C_3H_5MgX and $RCH{=}CHCH_2MgX$ even at very low temperatures[21–30], so that the question of the occurrence of migration processes in these systems has in essence remained open. In the study of the ^1H NMR spectra of the asymmetric compound $(t\text{-}C_4H_9CH_2CH{=}CHCH_2)_2Mg$ it was shown recently[31] that, at sufficiently low temperatures, both the *cis*- and *trans*-forms of this compound with C–Mg σ-bonds exist simultaneously in solvating media, while at higher temperatures they undergo an interconversion. These results suggested that the *cis–trans* isomerisation [reaction (5)] is preceded by the formation of structure (III)



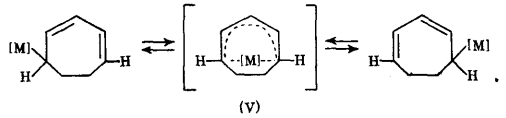
for a short time, evidently as a result of the metallotropic 1,3-transition

(III)
R = t-$C_4H_9CH_2$ (5)

where [M] = $MgCH_2CH{=}CHCH_2C(CH_3)_3$.

The indenyl organometallic compounds in which the C,C-metallotropic transformations [reaction (6)] can proceed not only via 1,3-transitions but also via two consecutive 1,2-shifts with formation of the intermediates (IVa) or (IVb), are an unusual example of a carbon triad:

(IVa) or (IVb) (6)



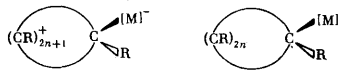
Changes in the ^1H and ^{13}C NMR spectra consistent with metallotropic C,C-transitions [reaction (6)] have been observed in the study of $(C_9H_7)_2Hg$,[10,32] $C_9H_7Sn(CH_3)_3$,[12,33-35] and other indenyl compounds[12,35-37], and it has been shown for a series of derivatives that this process takes place intramolecularly. The available NMR data for metallotropic transitions (6) indicate the dependence of the rate on the nature of [M] and make it possible to set up series based on the relative ease of metallotropic transformations as a function of the nature of the metal [series (7)] and the nature of the substituents in the group [M] [series (8)][35,38]:

$$R, H < Si(CH_3)_3 < Ge(CH_3)_3 < Sn(CH_3)_3 < HgC_9H_7; \quad (7)$$

$$Si(OCH_3)_3 < SiCl_3 < Si(CH_3)Cl_2 < Si(CH_3)_2Cl < Si(CH_3)_2C_6H_5 < Si(CH_3)_3. \quad (8)$$

As regards the mechanism of C,C-transitions (6), the results of the vast majority of the experimental and theoretical[39-41] studies support the view that they do not involve a 1,3-shift but proceed via consecutive 1,2-transitions. In particular, comparison of the energy characteristics of the C,C-transitions in indenyl and cyclopentadienyl (see below) organometallic compounds shows that in all cases the transition from $C_5H_5[M]$ to $C_9H_7[M]$ is accompanied by an increase of E_a by approximately 8.5 kcal mol^{-1}.[35] Bearing in mind that this quantity is close to the difference between the energies of the indenyl and isoindenyl structures, amounting to approximately 9 kcal mol^{-1} according to estimates[42], one can assume that the metallotropic transitions in indenyl derivatives take place via two consecutive 1,2-shifts with the intermediate formation of compound (IVa) or (IVb), which are not detectable by NMR.† Among other pieces of evidence in support of this mechanism, we may point to NMR data[12] for indenyl derivatives of tin with [M] = $Sn(CH_3)_2C_6H_5$ (R = H or CH_3). The authors[12] found that, in the absence of a dynamic system, the signals corresponding to the two CH_3Sn groups in [M] are shielded in different ways and can merge when the C,C-transitions are accelerated with increase of temperature. They interpreted this result as proof of the mechanism with a 1,2-shift, within the framework of which the intermediates (IVa) and (IVb) have a mirror symmetry plane, transforming one CH_3Sn group into the other, which is consistent with the averaging of their shielding (in the case of the 1,3-transition with inversion at the metal atom the two CH_3Sn groups should remain non-equivalent). The authors[12] noted, however, that the less probable 1,3-transition, with retention of the configuration at the tin atom and inversion of that at the asymmetric carbon atom, is also consistent with the experimental facts.

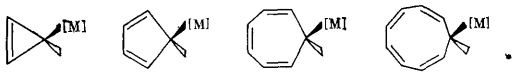
The occurrence of metallotropic C,C-transitions in allyl and indenyl derivatives is promoted by, among other things, appropriate geometrical factors. The detection of metallotropic transitions between more remote carbon atoms, particularly in pentad systems of type (9), is therefore important. The possibility of such transitions has been confirmed in an NMR study of the corresponding R_3Sn derivatives ($R = CH_3C_6H_5$).[49,50] The averaging of the shielding of the indicator nuclei in the 1- and 5-positions, associated with the acceleration of the C,C-transitions (9) via the 1,5-migration mechanism, apparently with the intermediate formation of the transition state (V), has been observed at fairly high temperatures in the ^1H and ^{13}C NMR spectra:



(V) (9)

The carbon systems with C,C-transitions (4), (6) and (9) can be conventionally referred to as "open" (in the sense used here they can evidently include also cyclic structures), because only "vibrational" transitions between two or more cation-accepting centres (degenerate or non-degenerate) are possible in them. Metallotropic systems of the "closed" type, in which there is a possibility of not only "vibrational" C,C-transitions but also of migrations of organometallic groups accompanied by the formation of a C–M bond in succession with all the carbon atoms of the system, have also been widely investigated. There is no point in considering the

† In making a choice between the two possible intermediates—the isoindenyl intermediate (IVa) and the π-allyl intermediates (IVb), one should apparently resort to the available NMR or other data concerning the structure of the σ-allyl derivatives of mercury, tin, germanium, and silicon[43-47]. Since tautomeric 1,3-transitions in these derivatives, accompanied by the intermediate formation of the π-structure (IVb), are unknown under non-catalytic conditions (the energy characteristics of the 1,3-transition in the π-allyl derivatives of silicon[48] show that the process is a rearrangement and not a tautomeric transformation), it is logical to give preference to the isoindenyl intermediate (IVa) when the 1,3-migration in indenyl organometallic compounds is considered.



prototropic analogues of the "closed" systems because the relevant processes in such systems are clearly slow:

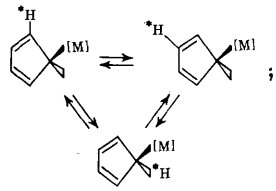
(VI) (VII)

(a) $n=1$, (b) $n=2$, (c) $n=3$, (d) $n=4$.

In the simplest "closed" systems the occurrence of metallotropic C,C-transitions appears to be most probable in even derivatives of type (VI) and in odd derivatives of type (VII).[18] Among structures (VII), σ-cyclopropenyl compounds (VIIa) ($n=1$, carbon triad) have so far not been investigated at all and the C,C-migration in σ-cycloheptatrienyl derivatives (VIIc) ($n=3$) and σ-cyclononatetraenyl derivatives (VIId) ($n=4$, R=H) of non-transition metals has been studied by NMR only for individual examples of organotin compounds[16, 50-52]. Thus the greatest number of publications deal with C,C-transitions in σ-cyclopentadienyl and related compounds (VIIb) ($n=2$, R=H or R≠H; carbon pentad)[11,32,35,41,53-81] (see also the relevant reviews concerning this problem[41,82,83]). The even charged structures (VI) have so far been investigated for the case with $n=1$ ($R=CH_3$)[84-86]:

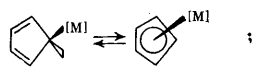
(VIIa) (VIIb) (VIIc) (VIId)

The first convincing evidence in support of the occurrence of C,C-metallotropic transitions in σ-cyclopentadienyl compounds was obtained in 1965–1966 in a low-temperature NMR study of σ-cyclopentadienyl derivatives of iron[53], silicon, and germanium[54]. Subsequently analogous results were obtained in studies of compounds of a number of non-transition and transition metals[11,32,35,42,55-81]. In the ^1H NMR spectra of the C_5H_5 ligand in these compounds at fairly low temperatures a multiplet of the type AA'BB'X (or ABCDX for compounds with a lower symmetry) has been observed. The corresponding set of signals has been noted also in the ^{13}CNMR spectra. These results are consistent with the presence of a localised C_5H_5–M bond and have been confirmed in many instances in structural studies by diffraction methods[54, 59,87,88]. With increase of temperature, a number of patterns of an intermediate type are observed in the spectra and at still higher temperatures there is a single signal corresponding to the situation where all five ^1H or ^{13}C ring nuclei are equivalent as a consequence of the time averaging of their shielding.



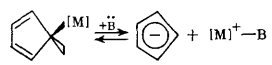
The change in the structure of the cyclopentadienyl compounds (VIIb) has an appreciable effect on the rates of metallotropic transitions in them. In particular, data referring to the derivatives of Group IVB elements[35,38,77] established the series (10)–(12) based on the relative changes in the rates of the processes as a function of the structure [M], which coincide with the corresponding series (7) and (8) established for indenyl organometallic derivatives:

$$R < Si(CH_3)_3 < Ge(CH_3)_3 < Sn(CH_3)_3, \quad (10)$$



$$SiCl_3 < Si(CH_3)Cl_2 < Si(CH_3)_2Cl < Si(CH_3)_3, \quad (11)$$

$$Ge(OCH_3)_3 < GeCl_3 < Ge(GH_3)_3. \quad (12)$$

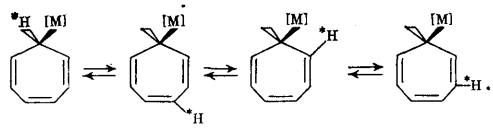


Three mechanisms for the migration of the organometallic group, leading to the averaging of the shielding of the nuclei in the NMR spectra, have been proposed: the intramolecular mechanisms (13) and (14) and the intermolecular mechanism (15) in highly basic media. Piper and Wilkinson[91], who were the first to suggest the possibility of sigmatropic C,C-transitions of the organometallic group in σ-cyclopentadienyl compounds of metals, pointed out that these transitions can proceed via the intramolecular migration of the metal along the perimeter of the ligand [reaction (13)]. Subsequently mechanism (14), postulating that the type of the C_5H_5–M bond changes in the course of intramolecular metallotropic transitions (σ,π-transitions[52]), was also proposed. Each of these mechanisms is consistent with the fundamental characteristics of the NMR spectra. The study of more detailed changes in the spectrum showed that the 1,2-shift mechanism (13) is preferable for intramolecular processes[53,60,61,92]; it presupposes the migration of the metal via the shortest path to a neighbouring carbon atom (and constitutes, as it were, a form of σ,π-conjugation: the opposed dynamic movement of electrons and the organometallic species). However, the available experimental data[52,63] do not allow the possibility of mechanism (14) to be rejected. The Woodward–Hoffmann rules have been extended to the study of the mechanism of sigmatropic migration in derivatives (VIIb)[39-41]:

(13)

(14)

(15)



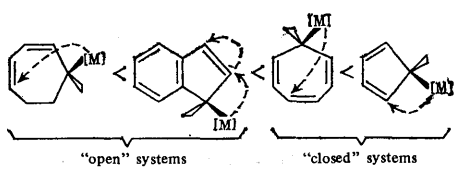
Certain factors complicating the analysis of the NMR spectra of the compounds C_5H_5–M must be emphasised. Firstly, in the study of the properties of cyclopentadienyl compounds of different metals the presence of the C_5H_5–[M] σ-bond is as a rule postulated in an explicit or implicit form (if, by virtue of its "electronic requirements", the metal can, in principle, form an M–C σ-bond) and hence a σ,σ-mechanism of the migration of metal-containing groups. However, the available data show that such hypotheses cannot be regarded as sufficiently correct in the absence of additional unambiguous confirmation (for example, the observation in the low-temperature ^1H NMR spectra of compounds C_5H_5-M of the spin system AA'BB'X, the observation of a localised bond in the study of compounds by diffraction methods, etc.). Secondly convincing evidence for the intramolecular character of the C,C-transitions of organometallic groups has been by no means obtained in all cases (the intramolecular nature of the transitions has been established, for example, for σ-cyclopentadienyl derivatives of Group IVB elements—Si, Ge, and Sn#)[35,62,69-73]. There are also more general difficulties associated with the existence of additional factors: the possibility of a change in the nature of the C_5H_5–M bond under the influence of solvents with a high solvating capacity[93-96], the ability of the cyclopentadienyl ligand to participate in the formation of a bridge bond with certain metals[97], the possibility of the retention of dynamic features in the C_5H_5–M fragment, even in a crystal[98], etc.

The fact that in organometallic derivatives of the type C_5H_5–M (in those compounds where the presence of a C,M σ-bond has been confirmed and in which the C,C-transitions

It has recently been found[92] that in highly basic media organotin groups can migrate also via the intermolecular mechanism (5).

are intramolecular) the existence of 1,2-transitions has been demonstrated led to an interesting theoretical problem. Indeed, among derivatives of type (VII) the mechanism of the C,C-migration satisfies two conditions simultaneously only in compounds (VIIb)—the intuitive idea that migration to the nearest atom (the 1,2-shift) is preferred and the orbital symmetry conservation rules (satisfied when the C,C-transition takes place via the 1,5-mechanism), because the 1,2- and 1,5-transitions are identical only in cyclopentadienyl compounds (VIIb).

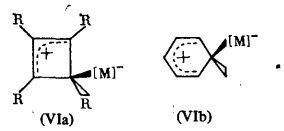
Because of this, C,C-transitions have been investigated in some studies[16,50,99] in compounds (VIIc) with [M] = $Sn(C_6H_5)_3$, for which the 1,2- and 1,5-transitions do not coincide and can be fully distinguished by dynamic NMR:



(16)

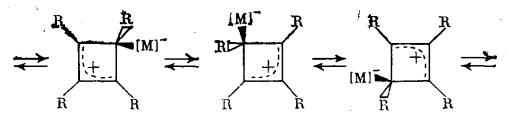
At low temperatures the ^1H and ^{13}C NMR spectra of this derivative correspond to a fixed structure with a localised C–M bond, which is consistent with data obtained in a study of this compound by a diffraction method in the crystalline state[99]. At higher temperatures the ^1H NMR spectrum shows a single signal corresponding to the seven protons of the cycloheptarrienyl ring with averaged chemical shifts. Analysis of the temperature-induced changes in the form of the NMR line led to the conclusion that the C,C-transitions within the limits of the seven-numbered ring take place via the 1,5-shift mechanism (16). Structure (VIII) has been proposed as a transition state in this process[49]. The possible formation of the centrally symmetrical structure (IX), at least at temperatures not exceeding 30 °C, has been rejected[16] on the grounds that the changes in the ^1H NMR spectrum are asymmetric. Thus the C,C-transitions of the organometallic group in derivatives (VIIc) do not take place in the direction of the shortest pathway (as in cyclopentadienyl compounds) but in the direction predicted by symmetry conditions. We may note, however, that, according to ^{13}C NMR data, the C,C-migrations of the organotin group in the σ-cyclononatetraenyl derivatives (VIId) take place preferentially in the direction of the shortest pathway[51].

(VIII) (IX)



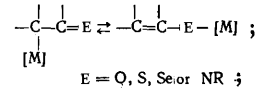
Summarising the data obtained hitherto for the C,C-transitions of organotin groups, we may quote the series (17), formulated by Curtis and Fink[49] and based on the increasing rates of metallotropic transformations as a function of the structure of the anionoid hydrocarbon residue:

"open" systems "closed" systems (17)



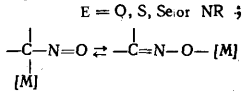
We may note that in all cases these are in essence sigmatropic 1,5-transitions (in terms of the classification of Woodward and Hoffmann[100]). In addition, the fact that the transitions in these systems are, from the point of view of their velocities, rearrangements rather than tautomeric transformations considered here when [M] = H appears to be significant. Thus the migration of organometallic groups in the systems analysed is promoted by additional factors, as a result of which the potential barrier is lower for heavier cationoid species. The principal factor appears to be the greater length of the C–M bond compared with the C–H bond and the presence in the metal atom of a vacant orbital, which is larger and has a lower energy than the potentially active vacant 2p orbitals of the hydrogen atom[101,102].

An analysis carried out as above in relation to the odd structures (VII) is in principle possible also for the even charged structures (VI):



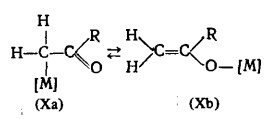
(VIa) (VIb)

Such analysis has been carried out hitherto only for the σ-complexes of cyclobutadiene–structure (VIa), $n = 1$, $R = CH_3$, $[M] = AlCl_3$.[84–86] Analysis of the ^1H and ^{13}C NMR spectra of the corresponding compounds over a wide range of conditions enabled a number of investigators[79–81] to find that in this case the intramolecular dynamics involves mainly (if not exclusively) the 1,2-shifts of the group $AlCl_3$ along the ring perimeter;



III. C,E-TRANSITIONS (E = O, S, Se, or NR)

Among non-degenerate C,E-triads, for which there is a possibility of the observation of metallotropic transitions, we shall point to two which are of particular interest—of the keto-enol type (18) and the nitroso-isonitroso type (19). In the corresponding non-metallated systems the reversible equilibrium prototropic transitions, which are rapid in terms of the NMR time scale, are as a rule observed extremely rarely[103]. However, in the study of the C,E-transitions in similar triads by procedures including the NMR method, certain advances have already been made, although in each individual case there is a probability of a shift of equilibrium (18) to one side, which precludes the simultaneous observation of both tautomeric forms in solution;

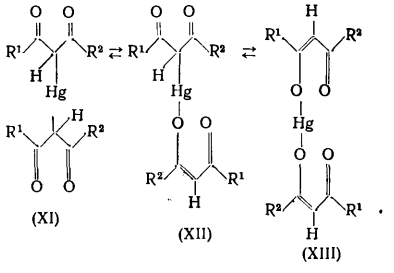


(18)

E = O, S, Se or NR;

(19)

The results of studies of keto-enol transformations (18) by procedures including infrared and NMR spectroscopy have been reported[14,104,105] for $[M] = R_3Sn$, R_3Ge, and E = O. The ratio of the tautomers in these systems depends on a number of factors, including the solvent and the presence of catalytic admixtures of certain compounds:

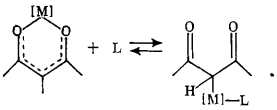


(Xa) (Xb) (20)

In the study of the ^1H NMR spectra of the $(CH_3)_3Sn$ derivative of acetone (X, $R = CH_3$)[14] the averaging of the signals due to the CH_2 groups of the O- and C-isomers was observed even in the absence of the catalysts, which indicates the

occurrence of fairly rapid C,O-transitions of the group $(CH_3)_3Sn$. The observed changes in the chemical shifts of the signals due to the CH_2 protons as a function of temperature permitted the conclusion that a change of temperature entails a displacement of tautomeric equilibrium (20) in the compound. The merging of the signals corresponding to different isomers and observed separately at lower temperatures has also been observed at 150 °C in chlorobenzene in the spectrum of the analogous derivative of acetophenone (X, $R = C_6H_5$).

C,O-Transitions of organomercury groups have been studied in connection with the analysis of the NMR spectra of a series of acetylacetonato-derivatives of mercury[15,106,107]:

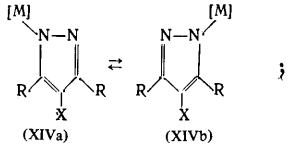


(21)

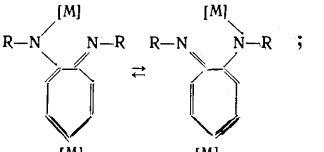
A study[15] of the keto-compound (XI, $R^1 = R^2 = t\text{-}C_4H_9$) in $CHCl_3$ showed that at room temperature the ^1H NMR spectrum does not exhibit signals corresponding to the $^{199}Hg-C-^1H$ spin–spin interaction, while at lower temperatures not only these satellites but also the methylidyne signal, corresponding to approximately a 3% content of one of the enol isomers (XII) or (XIII), are observed. This result can be explained by postulating that the organomercury group undergoes fairly rapid metallotropic C,O-transitions (21) in solution [in the crystal the compound exists only in the keto-form (XI)[106,108]]. It was subsequently found that[10] the C,O-transformations in this system are rapidly accelerated when ethanol-d_6 is used as the solvent.

A quantitative study of the keto–enol transitions (21) has been carried out[107] by dynamic NMR with the acac derivative of mercury, in which a high stabilisation of the enolic form ($R^1 = n\text{-}C_3F_7$ and $R^2 = t\text{-}C_4H_9$) has been achieved by introducing the electronegative group $n\text{-}C_3F_7$§. Apart from the main isomer (XI) in solution [in the crystal the compound exist only in the keto-form (XII)] comparable amounts have also been found of the enolic isomer (XII) and under certain conditions the two isomers are interconverted at a fairly high rate [isomer (XIII) with $R^1 = n\text{-}C_3F_7$ and $R^2 = t\text{-}C_4H_9$ is not formed, which facilitated the interpretation of the results by the authors[107]].

Analysis of the ^1H NMR line form of the compound in deuteroacetone in the temperature range from −60 °C, where the spectrum shows only the signal due to the proton of the methylidyne group of the keto-form (XI) and two signals due to the methylidyne protons of the enolic form (XII), to +40 °C, where all three signals merge into one, made it possible to determine the necessary thermodynamic parameters of the process ($E_a = 9.9$ kcal mol^{-1}).[107] Special experiments established that the metallotropic C,O-transitions take place intramolecularly in this instance (at least in the temperature range from −60° to +10 °C). It was noted that a change in the nature of the solvent influences the rate of the C,O-transitions but has almost no effect on the equilibrium position. Finally, analysis of the NMR data available for the acac derivatives of other metals capable of forming a C–M bond (platinum[110] and gold[111,112]) enabled the authors[107] to conclude that, among these metals, mercury is the most labile in relation to metallotropic C,O-transitions:

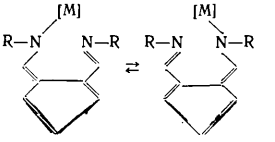


(22)



It has recently been reported[113] that the C,O-transition (22) has been detected by NMR in acetylacetonato-derivatives of gold with $[M] = Au(CH_3)_2$ and $L = PR_3$, in the course of which the acac ligand behaves either as a bidentate O-derivative or as a monodentate C-derivative. Reaction takes place when phosphines, which are necessary for the retention of the coordination number of the metal in the course of the process, are added to the solution.

IV. N,N-TRANSITIONS IN TRADITIONAL TAUTOMERIC SYSTEMS



Among the traditional structures in which metallotropic N,N-transitions are possible, in principle, we may point in the first place to several even systems—the diad system (23), the tetrad system (24), and the hexad system (25).

(23)

(24)

(25)

Hypotheses concerning the possibility of the tautomeric transformations (23)–(25) for $[M] = H$ have been frequently put forward on the basis of various considerations including NMR data[114–122]. In particular, it has been possible[116] to "freeze" by dynamic NMR the prototropic N,N-transitions (25) and to discover the asymmetric structure of the fragment N...H–N. However, in terms of the phenomenon considered here the study of the N,N-transitions of the cationoid species $[M] \neq H$ has been developed to a definite extent only in the field of pyrazoles (23).

The occurrence of metallotropic N,N-transitions (23) has been demonstrated[17] in relation to *N*-arylmercury derivatives of pyrazoles and also[123–125] for $[M] = SiR_3$ and $Ge(CH_3)_3$. The case with $[M] = Sn(C_4H_9\text{-}n)_3$ has also been investigated recently[126].

N-Phenylmercury derivatives of 3,5-dimethyl-4-X-pyrazoles (XIV), where $[M] = HgC_6H_5$, $R = CH_3$, and X = Cl, Br, or NO_2, have been chosen[17] as model systems and the corresponding non-metallated compounds with $[M] = H$ were used

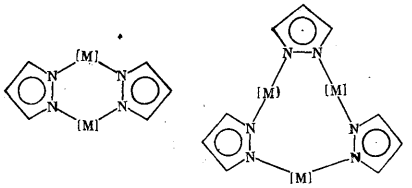
§ It must be emphasised that the acac derivatives of mercury can have, in principle, different and frequently unexpected structures[109], since kinetic study of their rearrangements, including C,O-transitions, is virtually impossible without a preliminary unambiguous determination of the structure of the substance.

for comparison. In the fixed isomers (XIVb), which are detected at fairly low temperatures, the degrees of shielding of the 3- and 5-CH_3 groups in the case of [M] = HgC_6H_5 differ appreciably. In contrast to organomercury derivatives, the separation of the signals due to the methyl protons is not observed in the ^1H NMR spectra of the initial pyrazoles {[M] = H} up to −110 °C.[17] This may be caused either by the higher mobility of the tautomeric system with [M] = H or by the unduly small difference between the degrees of shielding of the 3- and 5-methyl groups in the fixed tautomers. The data obtained in studies[121,122] where the splitting of the signals due to the $C_{(3)}$ and $C_{(5)}$ nuclei in compounds (XIV) with [M] = H and R = X = H, was observed in solvating solvents by $^{13}C-\{^1H\}$ NMR (at −110 °C in a mixture of diethylether and tetrahydrofuran[121] and at −17 °C in hexamethylphosphoramide[122]) apparently also support the first hypothesis.

Different mechanisms of the metallotropic transitions in the series of pyrazoles have been analysed[17]. In particular, the intermolecular N,N-transitions can occur in principle via both bimolecular and ionic mechanisms. However, the bimolecular mechanism of the formation of phenylmercury derivatives of pyrazoles tends to be disproved by the fact that the parameters of the ^1H NMR spectrum of compound (XIV, R = CH_3 and X = Cl) are independent of the concentration of this compound. Data concerning the influence of polar additives on the rate of the process may be evidence against the intermolecular transfer of the organometallic group via an ionic mechanism. It has been found that, when the polar nitromethane is added to a mixture of methylene chloride and chloroform, chosen as the main solvent, the migration of the phenylmercury group is accelerated slightly[17]. The use of a solvating agent such as pyridine as the additive also does not entail appreciable changes [which is analogous to the absence of a dependence of the rate of N,N-transitions on the solvent, observed in an NMR study of the $(CH_3)_3Si$ derivatives of pyrazole[125]].

Thus the most acceptable explanation of the ^1H NMR data obtained by Kravtsov et al.[17] is that the organomercury groups migrate between nitrogen atoms via the intramolecular 1,2-transitions (23). This mechanism presupposes the coordination of the mercury atom in its transition state to both nitrogen atoms of the heterocycle.

Solvating solvents exert different types of influence on the prototropic and metallotropic N,N-transitions in pyrazoles. Thus the addition of the polar nitromethane to a solution of compound (XIV) with [M] = H and X = Cl[116] as well as [M] = HgC_6H_5[17] has only an insignificant influence on the process. However, the addition of pyridine leads to a sharp acceleration of the prototropic process although this type of influence by pyridine has not been observed for [M] = HgC_6H_5. These findings apparently indicate a difference between the mechanisms of the N,N-transitions in the solvents employed. For cationoid species of other types, for example, [M] = SiR_3 and $Ge(CH_3)_3$, the results of studies by dynamic NMR[123-125] show that, as for [M] = HgC_6H_5, the N,N-transitions take place intramolecularly. These NMR data make it possible to set up sequences (26) and (27) based on the relative increase of the mobilities of the cationoid species in the series of pyrazoles as a function of their nature[26,27]:

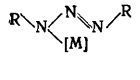


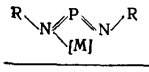
$$Si(OC_6H_5)_3 < Si(CH_3)_3 \sim Si(C_2H_5)_3 < Ge(CH_3)_3 < Sn(C_4H_{9}\text{-}n)_3 \quad (26)$$

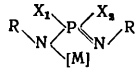
$$SiR_3 < Ge(CH_3)_3 < HgC_6H_5 . \quad (27)$$

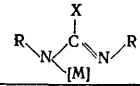
The available NMR data also permit certain inferences concerning the influence of substituents in the anionoid residue on the rates of the N,N-transitions. For example, an increase of the electron-donating capacity of the substituents in the 3- and 5-positions is accompanied by the acceleration of the 1,2-transitions of the organosilicon and organogermanium groups:

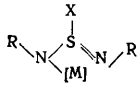
$$CF_3 < H < CH_3 . \quad (28)$$









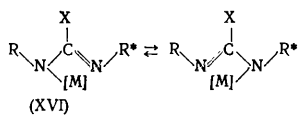


In conclusion we emphasise that the intramolecular mechanism formulated for the group of cationoid species considered, [M] = HgR, SnR_3, GeR_3, and SiR_3, for which the compounds (XIVa) are monomeric, cannot be transferred mechanically to pyrazoles with cationoid species of other types:

(XVa) (XVb)

The simplest example of explicit differences is provided by the case with [M] = H for which the trimeric structure (XVb) has been postulated[21], in the ground or transition states and for the description of the N,N-transitions of which one evidently cannot use mechanism (20). The pyrazole derivatives of univalent gold, [M] = Au, have an analogous structure in the ground state[127,128]. The dimeric structure (XVa) in the ground state has been established for yet another group of cationoid species with [M] = BR_2, AlR_2, GaR_2, or TlR_2,[129-132] and all the M–N bonds in these compounds are virtually equivalent[129].

Table 1. Certain degenerate metallotropic 1,3-transitions between nitrogen atoms in triad systems (according to NMR data).



Tautomeric system	X	[M]	R	Solvent	*t*, °C*	Refs.
	—	HgC_6H_5	FC_6H_4	Py + THF + $CHCl_3$ (3:2:2)	<−120	[139]
	—	$Si(CH_3)_3$	CH_3	C_6H_6	>80	[140]
	—	$Si(OCH_3)_3$	CH_3	CH_2Cl_2	18	[141]

	CH_3	$Si(CH_3)_3$	$Si(CH_3)_3$	$(C_2H_5)_2O$	<−50	[144]

* The temperature at which the signals of the indicator nuclei merge.

Among the odd systems, in which there is a possibility of N,N-transitions of organometallic species in principle, we shall point out, for example, the amidine triad (29) and the

diazoamine triad (30). The prototropic transformations (degenerate and non-degenerate) in the corresponding initial structures with [M] = H have so far been inadequately investigated by NMR[133-139]. There are also few data concerning the metallotropic transitions[9,139-142]. Table 1 gives a compilation of the available information about the degenerate metallotropic 1,3-transitions between nitrogen atoms in these and certain other triad systems, which have so far been established by NMR. It also includes data obtained for [M] = $Si(CH_3)_3$, because they make it possible to discover certain tendencies useful in the analysis of metallotropic transitions proper.

Degenerate metallotropic N,N-transitions of the amidine type were first observed in 1968[9] in the study of the ^1H NMR spectra of N,N-dimethylbenzamidine derivatives (XVI) with [M] = $Sn(CH_3)_3$ or $Si(CH_3)_3$, R = CH_3, and X = C_6H_5.[9]

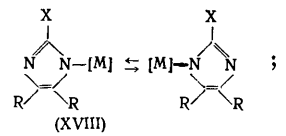
(XVI) (29)

(30)

It has been found that the signals of the non-equivalent *N*-methyl groups observed separately at −60 °C merge into a singlet with increase of temperature, which indicates acceleration of the N,N-transitions (29). This migration apparently takes place intramolecularly, which can be inferred from the absence of a dependence of the NMR spectra on the concentrations of the compounds and also from the observation in the case of [M] = $Sn(CH_3)_3$ even under fast dynamic conditions of satellites due to the spin–spin interaction of the ^{117}Sn and ^{119}Sn nuclei with the protons of the N–CH_3 groups[9]. For [M] = H, a singlet due to the indicator protons has also been observed at room temperature.

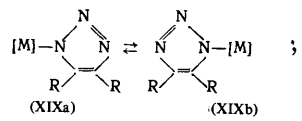
The results of a study[142] in which an attempt was made to observe N,N-transitions (29) of organomercury groups in compounds (XVI) with [M] = HgC_6H_5 or $HgCH_3$, X = H, and R = aryl permit additional conclusions. The ^1H NMR spectra of these compounds at temperatures up to −100 °C do not exhibit a splitting of the signals due to the indicator group protons (Table 1), which can be explained either by the unduly high rate of the N,N-transitions (29) or by the symmetrical structure of the compound in which the metal atom is linked simultaneously to both nitrogen atoms. Bearing in mind that the latter hypothesis conflicts with X-ray diffraction data[142], presumably the 1,3-N,N-transitions (29) of the organomercury groups in the amidine triad are appreciably faster than the transitions of the organotin groups.

The proton N,N-transitions in the open diazoamine systems (XVII) have been investigated frequently by NMR, but the majority of these studies refer to non-degenerate transformations with [M] = H and R ≠ R*. The retardation of the proton transitions (30) in the degenerate case has been noted in only one study[138].



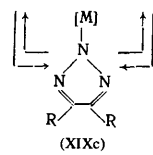
The study of degenerate metallotropic N,N-transitions (30) has begun only recently. Thus it has been observed[139] that, in contrast to di-(4-fluorophenyl)triazenes, the N,N-transitions (30) in their phenylmercury derivatives (XVII) with [M] = HgC_6H_5 and R = 4-FC_6H_5 are so fast that even in the temperature range from −90° to −120 °C only a consecutive broadening of the fluorine signal is observed, which may be evidence in support of some retardation of the intramolecular metallotropic transitions (the intermolecular migration of the phenylmercury groups takes place at higher temperatures). It is interesting to compare these results with data obtained for the N,N-transitions of organosilicon groups[140,141]. For [M] = SiR_3, the N,N-transitions (30) are also intramolecular and their rate depends significantly on the structure of the groups in [M]:

$$SiCH_3(C_2H_5)_2 < Si(CH_3)_3 < Si(CH_3)_2OCH_3 < SiCH_3(OCH_3)_2 < Si(OCH_3)_3 < \\ < Si(CH_3)_2Cl < Si(CH_3)Cl_2 < HgC_6H_5 \quad (31)$$



Presumably sequence (31) is associated with the increase in the same order of the coordinating capacity of the key element (Si or Hg), which facilitates the formation of the transition state.

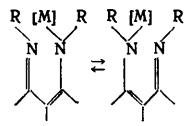
The results of the NMR study of dynamic processes also in the series of derivatives of certain transition metals are available[149-153], but, bearing in mind the fact that the triazene ligand in transition metal complexes can behave not only (and not so much) as a monodentate species but also as a bidentate or bridging species[153-156], it is natural to suppose that the correct interpretation of these results requires the determination of independent data on the structure of the compounds, particularly on the type of bond between the organometallic group and the anionoid residue.



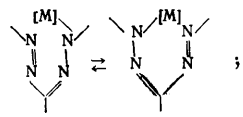
Among cyclic systems, imidazoles (XVIII) and vicinal 1,2,3-triazoles (XIX) are the simplest and most natural analogues of triads of the amidine and diazoamine types. As regards the possible metallotropic N,N-transitions, the most interesting feature of these nitrogen heterocycles is that, in contrast to the amidine and diazoamine triads (29) and (30), a planar four-unit cyclic transition state incorporating the M atom and three atoms of the triad cannot be formed in such systems:

(XVIII) (32)

(XIXa) (XIXb) (33)

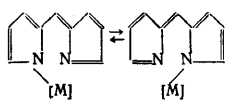


(XIXc)



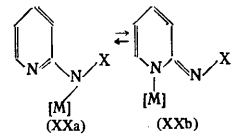
The question of the possible metallotropy in imidazoles can be considered in relation to cationoid groups such as $Si(CH_3)_3$ and $Ge(CH_3)_3$. Thus a study[157] of the ^{13}C NMR spectrum of trimethylsilyl derivatives of imidazole (X = CH_3, R = H) in the absence of a solvent demonstrated the non-equivalence of the $C_{(4)}$ and $C_{(5)}$ atoms even at room temperature. An analogous phenomenon has been observed in the study of the ^1H and ^{13}C NMR spectra of *N*-trimethylsilylimidazole and the ^{13}C NMR spectrum of an *N*-trimethylsilyl derivative of 2-methylimidazole in triethylamine. These results showed that, for [M] = $Si(CH_3)_3$, intramolecular 1,3-transitions (32) do not occur in imidazole. However, it has been established[157] that traces of water, usually present even in highly purified specimens of trimethylsilylimidazoles, catalyse intermolecular

N,N-transitions of the $(CH_3)_3Si$ groups¶. This conclusion was confirmed by the measurement of "frozen" ^1H and ^{13}C NMR spectra of trimethylsilyl derivatives of imidazoles and 2-methylimidazole in the study of each in triethylamine and by the acceleration of N,N-transitions following the addition of water. The intermolecular nature of the N,N-transitions was confirmed in the study of the ^{13}C NMR spectra of a mixture of trimethylsilyl derivatives of imidazole and 2-methylimidazole.

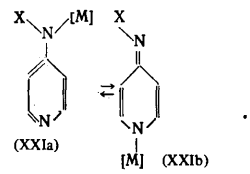


From the standpoint of metallotropic N,N-transitions, vicinal 1,2,3-triazoles (XIX) have yet another feature which distinguishes them from triazenes and is associated with the indefinite nature of the "instantaneous" structure of these compounds for different [M]. In particular, the fact that the ^{13}C NMR signals corresponding to the $C_{(4)}$ and $C_{(5)}$ nuclei are not resolved up to −50 °C for $[M]=SnR_3$[158] can be accounted for by the symmetrical structure of compound (XIXc) (all these compounds are monomeric in solution) and not by the rapid migration of the SnR_3 group between the nitrogen atoms via process (33). Although the authors themselves[158] are inclined towards the first hypothesis, the second explanation is no less ligitimate. Thus further study of the metallotropic transitions in the series of vicinal triazoles should be preceded by an unambiguous determination of their "instantaneous" structure:

(34)



(35)



(36)

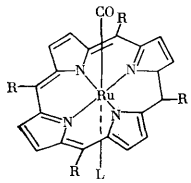
Only a few studies have been made on the question of the N,N-transitions of cationoid species in the pentads (34)–(36) and mainly for the case where [M] = H. In particular, low-temperature NMR measurements do not permit the detection of the prototropic transitions (36).[159] It has been suggested[160] on the basis of NMR data that, for $[M]=Tl(CH_3)_2$, the organometallic species is linked simultaneously to both nitrogen atoms. Although this conclusion is entirely likely, a more rigorous treatment requires the corresponding low-temperature measurements in order to throw more light on the question of the "instantaneous" structure of the compound with $[M]=Tl(CH_3)_2$: whether the metal in this derivative is tetracoordinate or tricoordinate and whether it executes rapid N,N-transitions:

(37)

An instance of non-degenerate N,N-transitions has been found[4,5] in an ultraviolet spectroscopic study of solutions of phenylmercury derivatives of 2- and 4-phenylsulphonylaminopyridines (representing respectively an aminopyridine triad and pentad). The simultaneous existence in solution in acetonitrile of the two possible tautomeric forms of these compounds—the aminopyridine form (XXa) or (XXIa) and the pyridone imine form (XXb) or (XXIb)—and their interconversion via non-degenerate metallotropic transitions of the amidine type (37) or (38) for $[M]=HgC_6H_5$ and $X=SO_2Ar$, has been demonstrated. A dependence of the tautomer ratio on the nature of the medium has been established. In particular, in dioxan equilibria (37) and (38) are almost wholly displaced towards the aminopyridine form:

(38)

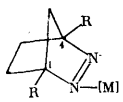
The influences of various factors on the shifts of the tautomeric equilibria (37) and (38) have been compared for two different cationoid groups, namely [M] = H and HgC_6H_5.[4,5] It was found that, for [M] = H, the pyridone imine forms (XXb) and (XXIb) are more stable than for $[M]=HgC_6H_5$, particularly in solvents of low polarity. The substituents in the *para*-position of the benzene ring of the SOAr group have the same effect on the position of the tautomeric equilibrium involving both 2- or 4-arenesulphonylaminopyridines and their phenylmercury derivatives.

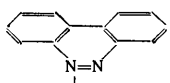


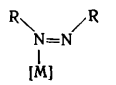
V. METALLOTROPIC N,N-TRANSITIONS IN SYSTEMS WITH M–N COORDINATE BONDS

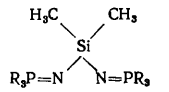
In the tautomeric systems considered the metallotropic N,N-transitions of metal-containing species are accompanied by a rearrangement of the system of multiple bonds in the molecules. However, in principle, in organometallic derivatives one cannot rule out the possibility of the existence of tautomeric systems in which the metallotropic transition between two states does not require a redistribution of the multiple bonds. One of the types of structures of this kind can evidently consist of compounds in which [M] migrates between the heteroatoms N,O,S, etc., subject to the condition that the M–E bond is a coordinate linkage and that two or more equivalent or different atoms able to behave as donors of an unshared electron pair are available for its formation.

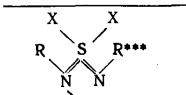
Such tautomeric systems have indeed been found in recent years. The first report of "non-traditional" metallotropic 1,3-transitions between nitrogen atoms appeared in 1967[161,162] and that of intramolecular 1,2-transitions was published in 1972.[163] Hitherto this phenomenon has been observed and investigated for an extremely wide variety of nitrogen-containing systems[164–183]. Several examples of degenerate

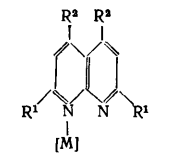












¶ In the light of these results, the results of a dynamic NMR study of imidazole derivatives, carried out for [M] = $Ge(CH_3)_3$, R = H or CH_3 and X = H by Cotton and Ciappenelli[124] and for $[M]=Si(CH_3)_3$ and R = X = H carried out by Torocheshnikov et al.,[125] apparently become more understandable. The studies were performed without taking into account the possibility of catalysis by traces of water and led the authors[124,125] to somewhat different conclusions, although they observed experimentally the same result—the identical shielding of the $H_{(4)}$ and $H_{(5)}$ nuclei as well as $C_{(4)}$ and $C_{(5)}$ nuclei over the entire temperature range accessible to investigation.

N,N-transitions of the 1,2- and 1,3-types in compounds with heterocyclic and other anionoid residues are presented in Table 2.

(XXII)

Table 2. Certain degenerate metallotropic 1,2- and 1,3-transitions between nitrogen atoms in non-traditional tautomeric systems (according to NMR data).

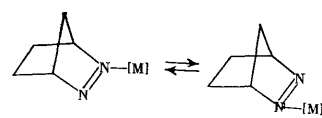
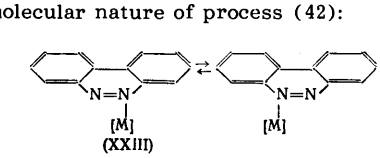
**** X = Hal, OCN, etc.



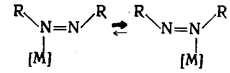
Eaton et al.[163] investigated by dynamic ^1H NMR several complexes of type (XXII), where R = iso-C_3H and L = mono- or di-nitrogen heterocyclic ligand. It was found that in the case where L = 4,5- or 3,6-dimethylpyridazine, 1,2-transitions can occur intramolecularly:

(39)



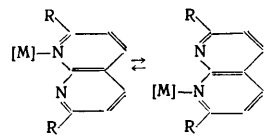
In particular, when L = 4,5-dimethylpyridazine at solution temperatures below approximately 12 °C, the signals corresponding to the indicator methyl groups are observed separately. With increase of temperature the signals broaden, approach one another, and finally merge into a single signal. The temperature dependence of the NMR line form for the complex in the presence of an excess of the free ligand permitted the conclusion that, in the range from −24° to +40 °C, process (39) is intramolecular, while at temperatures in the range 30–150 °C it also becomes intermolecular. Analogous results have been obtained in the study of the ruthenium complex of 3,6-dimethylpyridazine. In this case the process proceeds intramolecularly at lower temperatures, while above −43 °C it can also take place intermolecularly[163].

A study[170] of compounds of the type $CrAr(CO)_2L$, where L = 2,3-diazabicyclo[2,2,1]hept-2-ene, demonstrated a temperature dependence of the signal due to the 1,4-protons, which indicated the identical shielding of these protons at high temperatures and their different shielding at low temperatures. The authors suggested that these spectral changes are related to intramolecular 1,2-transitions (40) of the group [M] = $Cr(CO)_2Ar$ between the bicyclic nitrogen atoms. The study of process (40) using different aromatic ligands in [M] revealed a dependence of the free energy of activation for the process on the structure of the aromatic π-ring: $(CH_3)_6C < 1,3,5\text{-}(CH_3)_3C_6H_3 < C_6H_6 < 1,4\text{-}[CH_3OC(O)]_2.C_6H_4$.



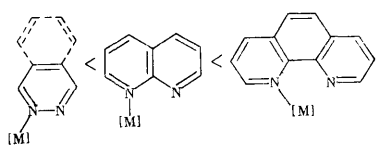
(40)

Additional information about the 1,2-transitions of groups containing transition metals has been obtained in a number of studies[176–179]. In particular, in a study of compounds (XXIII) by ^{13}C and ^1H NMR it was found that, for [M] = $Cr(CO)_5$ and $W(CO)_5$, process (41) takes place fairly rapidly at room temperature. The study of the $W(CO)_5$-complexes of the *cis*- and *trans*-isomers of 2-azopropane showed that N,N-transitions take place only in the *cis*-compounds {[M] = $W(CO)_5$, R = iso-C_3H_7; process (42)}. In this case the proximity of the neighbouring nitrogen atom reduces the activation energy for the intramolecular transition so much that the formation of a new W–N bond in the transition state requires a preliminary dissociation of the old bond. A series of pieces of evidence have been adduced in support of the intramolecular nature of process (42):



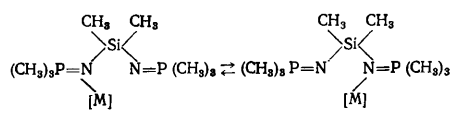
(XXIII)

(41)



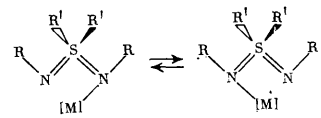
(42)

(43)



A thorough study has been made[167] of the metallotropic 1,3-N,N-transitions (43) in a series of 1,8-naphthyridine derivatives with [M] = $(CH_3)_2AuX$, X = Hal, OCN, or SeCN, and R = CH_3. At room temperature in weakly solvating solvents the ^1H NMR spectra of the compounds show that the non-equivalent methyl groups of the ligand are equally shielded, while at −90 °C their signals are converted into two separate singlets of equal intensity. The corresponding changes have been observed for aromatic protons in the 3,4- and 5,6-positions. Special experiments have established that the dynamic process is intramolecular (its characteristics are independent of the concentration of the test substance and of the addition of an excess of free 1,8-naphthyridine). This fact and also the monomeric nature of the compound permitted the conclusion that the changes in the NMR spectra are caused by metallotropic 1,3-transitions of the organogold group between the nitrogen atoms of the 1,8-naphthyridine ring. Yet another feature of process (43) should be noted: changes in the substituent X in the organogold group hardly alter the free energy of activation for the process.

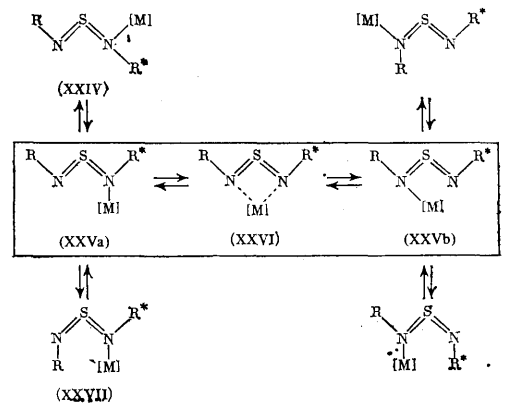
Transitions of type (43) have also been studied for [M] = $MCl(PR_3)_2$, R = H, and M = Pt or Pd.[180-183] Furthermore, studies have been made of the 1,4-transitions of these metal-containing groups in a 1,10-phenanthroline complex and of the 1,2-transitions in the pyridazine and phthalazine complexes. Comparative analysis of the NMR data led to the conclusion that the rate of the N,N-transitions of the metal-containing group increases in the sequence:



The increase takes place as the orientation of the unshared electron pair of the non-coordinated nitrogen atom becomes more favourable for the formation of a transition state in which both nitrogen atoms are linked simultaneously to the metal atom. In the palladium derivatives the rate of the process is higher than in the platinum compounds.

A comparative study has been made[161,162] of the 1,3-N,N-transitions (44) of the organometallic groups [M] = $Al(CH_3)_3$, $Ga(CH_3)_3$, and $In(CH_3)_3$:

(44)



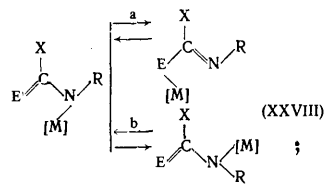
The ^1H NMR spectra of these derivatives at room temperature showed, as for the free ligand, a single doublet signal corresponding to the protons of the $(CH_3)_3P$ group. With decrease of temperature the signal broadens and in the case of the aluminium and gallium derivatives is split into two doublets of equal intensity; for the indium compound the splitting is not achieved even at −70 °C. The authors[152] concluded that they observed intramolecular 1,3-N,N-transitions (44) (their rate is independent of the addition of the non-coordinated ligand) of the groups $M(CH_3)_3$, whose rate increases in the sequence $Al(CH_3)_3 < Ga(CH_3)_3 < In(CH_3)_3$. Presumably this sequence is due to the increasing size of the vacant orbital of the metal with increase of its atomic number, which facilitates the formation of the transition state in which the metal forms a new bond before the dissociation of the old one:

(45)

Data have been published[166] on the metallotropic N,N-transitions (45) in bis-*S*-alkyl derivatives of sulphodi-imide, where [M] = $Al(CH_3)_3$, R = $(CH_3)_3Ge$ or $(CH_3)_3Si$ and R′ = CH_3 or C_2H_5. At room temperature the ^1H NMR spectra exhibited a single signal corresponding to the indicator groups R; at lower temperatures the signal is split into two components of equal intensity. The authors[166] interpreted these results from the standpoint of fairly rapid N,N-transitions (45) of the organoaluminium group in the system. As regards the mechanism of these transitions, they occur mainly intramolecularly at fairly low temperatures, while at higher temperatures they can also take place intermolecularly.

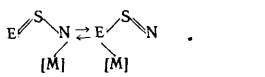
A series of studies[171-175] have been devoted to the structure of and dynamic, including metallotropic, processes in sulphodi-imide derivatives of transition metals without substituents at the sulphur atom. Sulphodi-imides non-alkylated at the sulphur atom themselves undergo intramolecular dynamic transformations in the temperature range investigated by the authors (mainly as a result of the internal rotation about the S = N bond). This complicated the interpretation of the phenomena concerning the NMR spectra of the sulphodi-imide complexes of transition metals. Furthermore, one must take into account the fact that, on formation of these complexes, the sulphodi-imides can function not only as N-donors but also as S-donors or chelates, depending on the nature of the metal-containing group:

(46)



In the interpretation of the ^1H and ^{13}C NMR spectra of the sulphodi-imide derivatives of platinum(II), palladium(II), rhodium(I), and iridium(I) the authors considered several possible types of transformations, mainly intramolecular ones [the processes (XXIV) ⇌ (XXVa), (XXVII) ⇌ (XXVa), and (XXVa) ⇌ (XXVI) ⇌ (XXVb) via mechanism (46)]. Among these, only the reaction (XXVa) ⇌ (XXVb) is a metallotropic N,N-transition, which involves the intermediate formation of the transition state (XXVI) and which proved to be extremely sensitive to different structural factors. It has been found that the N,N-transitions depend appreciably on the properties of the metal and its environment and begin to be observed in the NMR spectra at temperatures from −45° to +60 °C; their rate decreases in the sequence Rh^I, Ir^I > neutral Pd^{II}, cationic Pt^{II} > neutral Pt^{II}.

A number of workers[172,174,175] were able to find several compounds in which the ligand exists mainly in the *trans, trans*-form (XXV) (and in which the dynamic processes observed by NMR can be explained exclusively by metallotropic N,N-transitions), in particular, a number of bivalent platinum complexes. A distinct separation of the signals corresponding to the indicator aryl groups is observed at −20 °C in the ^1H and ^{13}C NMR spectra of the complexes (XXV) with R = Ar and [M] = *trans*-$PtCl_2L$, while at 0 °C these signals have already merged. The N,N-transitions (46), whereby the authors[172] explained the observed spectral changes, proved to be intramolecular, because their rates were independent of either the concentration of the platinum complex or of the addition of the free ligand to the solution; however, above 30 °C the process was found to take place also via an intermolecular mechanism.

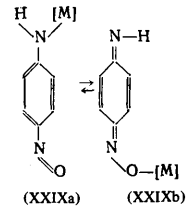


Among other features of reaction (46), the following have been noted. Firstly, it has been found that the rate of the N,N-transitions of platinum in diarylsulphodi-imides increases with decrease of the electron-donating capacity of the ligand L: $PR'_3 > AsR'_3 > SbR'_3$. Secondly, the rate of the process increases on enhancement of the electron-accepting properties of the aryl substituents and is therefore greater for R = Ar than for R = Alk. According to the authors, these results can be explained by the fact that the electron-accepting constituents are capable of stabilising the transition state (XXVI).

VI. N,E-TRANSITIONS (E = O, S, or Se)

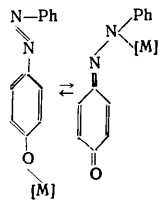
Fairly numerous studies have been made of the dynamic transformations in the triads (47)[184-200] and (48)[201,202] (E = O or S). The interpretation of the results is in many instances difficult because of the possibility of dynamic changes of two types in these compounds—the 1,3-N,E-transition (47a) of the cationoid group and the internal rotation (47b) about the C–N bond in the amide(thioamide) form:

(XXVIII) (47)



(48)

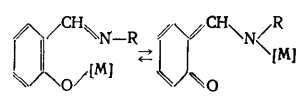
In particular, when E = O, processes (47) were investigated in relation to different cationoid species and the occurrence of the amido-amidol N,O-tautomerism was noted for [M] = $Al(CH_3)_2$,[184] BR_2,[185] and SiR_3.[175]



It has been shown for [M] = $Si(CH_3)_3$ and X = CH_3 that the N,O-transitions (47a) take place intramolecularly and that the *para*-substituents in R = aryl alter appreciably the ratio of the tautomers, promoting a shift of the equilibrium in the direction of the imidol form (XXVIII) in the sequence[197] $OCH_3 < CH_3 < H < Cl < NO_2$.

The 1,3-migration (47a) and the internal rotation (47b) have also been investigated for E = S, but in relation to a smaller number of examples.

A study has been made[2] of several potentially tautomeric systems in which there is a possibility of the metallotropic N,O-transitions (49) and (50)—nitrosoanilines (XXIX), hydroxyazo-compounds (XXX), and quinone phenylhydrazones:

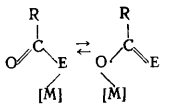


(XXIXa) (XXIXb) (49)

(XXXa) (XXXb) (50)

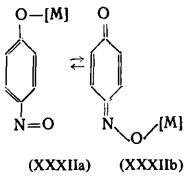
In the study of nitrosoanilines, nitrosonaphthylamines, and their arylmercury derivatives a similarity was observed in the behaviour of cationoid species such as [M] = H and [M] = HgC_6H_5 from the standpoint of the tautomeric equilibrium (49); both organometallic derivatives and their unsubstituted analogues have the nitrosoamine structure (XXIXa) in solution (in contrast to nitrosophenols, for which the quinonoid form predominates). However, in the sodium salts of nitrosoanilines and nitrosonaphthylamines the anions exist in the quinonoid form. Similar results have been obtained in the study of hydroxyazo-compounds and their arylmercury derivatives (XXX). For cationoid species of both types—[M] = H and [M] = HgAr—the benzenoid structure (XXXa) is typical both in solution and in the solid state.

Yet another example of metallotropic tautomeric systems is provided by the organometallic derivatives of *o*- and *p*-hydroxyarylaldimines[203]. In particular, analysis of electronic and luminescence spectroscopic data for o-compounds of type (XXXI) with [M] = $HgCH_3$, HgC_6H_5, or $Tl(C_2H_5)_2$ led to the discovery of non-degenerate O,N-transitions (51). As for [M] = H, in non-polar solvents equilibrium (51) is almost wholly displaced towards the benzenoid O-form (XXXIa), while in solvating media the content of the quinonoid tautomers (XXXIb) also becomes appreciable. A shift towards the quinonoid form is likewise observed following a decrease of temperature. It is striking that in the crystalline state compound (XXXI) with [M] = HgC_6H_5 exists entirely in the quinonoid N-form[204]. The occurrence of O,N-transitions has also been observed in the phenylmercury derivative of *p*-hydroxyarylaldimine[203]:



(XXXIa) (XXXIb) (51)

VII. O,E-TRANSITIONS (E = O, S, or Se)

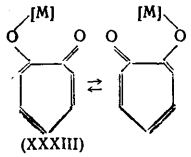


There are virtually no NMR data on degenerate metallotropic O,O-transitions in triads such as [M]–O–N=O and R–C(=O)–O–[M] and their determination will be limited by the

degree of development of the ^{17}O NMR method. It is methodologically simpler to investigate the non-degenerate tautomeric transitions (52) in triads of this kind, which can occur, for example, when $E \neq O$. Such a process has been investigated, in particular, for $E = Se$, $R = CH_3$, and $[M] = SiH_3$[205, 206]. By varying the conditions of the measurement, it was possible to observe in the ^1H NMR spectra both possible states of the system—either two sets of signals due to the SiH_3 group and the indicator group R, corresponding to slow O,Se-transitions of the SiH_3 group within the framework of non-degenerate interconversions of the O- and Se-isomers, or a single set of signals corresponding to the indistinguishability of the isomers owing to their rapid interconversion. Special experiments showed that reaction (52) is intramolecular:

(52)

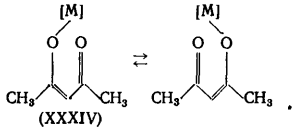
An example of non-degenerate O,E-transitions can also be provided by the O,O-transitions in compounds with structurally non-equivalent oxygen atoms. Such compounds have been studied, in particular, in the investigation of Nesmeyanov and Kravtsov[1] mentioned above and in a subsequent investigation[7]. The authors studied the absorption spectra of organometallic derivatives of *p*-nitrosophenols (XXXII) with $[M] = HgC_6H_5$, $Sn(C_6H_5)_3$, or $Pb(C_6H_5)_3$. The set of infrared and ultraviolet spectroscopic data obtained showed that, in contrast to the solid state, where the organometallic derivatives of nitrosophenols have only the quinone oxime structure, in solution they exist in both forms—the quinone oxime form (XXXIIb) and the nitroso-form (XXXIIa). Thus the interconversion of the tautomeric forms of these compounds in solution takes place via the rapid non-degenerate metallotropic O,O-rearrangement (53):



(XXXIIa) (XXXIIb)

(53)

The position of equilibrium (53) depends on a number of factors. In particular, for $[M] = Sn(C_6H_5)_3$ and $Pb(C_6H_5)_3$ in pyridine, THF, and acetone, the content of the nitroso-form is high, while in chloroform it is low. The nature of the organometallic group does not influence appreciably the position of equilibrium (53), which has been tested in relation to $[M] = HgAr$. On the other hand, the introduction of substituents into the aromatic ring of nitrosophenol lowers the content of the nitroso-form for derivatives with $[M] = Sn(C_6H_5)_3$ and $Pb(C_6H_5)_3$, as well as the initial nitrosophenols.

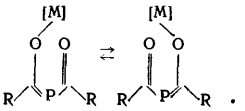


Among tetra- and penta-atomic systems, for which degenerate O,O-transitions of cationoid species have already been investigated by NMR, we shall mention the derivatives of tropolone and the enolic form of acetylacetone. However, these investigations are limited by the fact that, in relation to the majority of univalent organometallic groups, the anionoid residues of tropolone and acetylacetone behave as bidentate ligands. There are also structural difficulties associated with the inadequate knowledge about many potentially metallotropic systems. As a result, the data available at present about the O,O-dynamic processes (54) and (55) refer mainly to the case where $[M] = SiR_3$:[207-209]

(XXXIII)

(54)

Thus, in the study of compound (XXXIII) with $[M] = Si(CH_3)_2CH(CH_3)CH_2CH_3$ the $^{13}C-\{^1H\}$ NMR spectrum of the ring at 0 °C showed only four carbon signals instead of the expected seven. This result was interpreted as evidence for rapid O,O-transitions (54), which was confirmed in subsequent low-temperature measurements. Thus, for $[M] = SiR_3$ the enol–enol O,O-transitions in tropolones are comparatively rapid, in agreement with the conclusion already reached using the ^1H and ^{17}O NMR methods for $[M] = H$:[209]



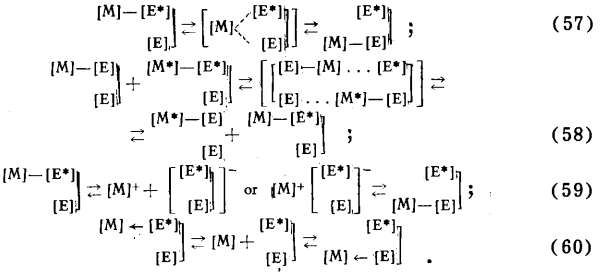
(XXXIV)

(55)

Analogous results were obtained in the study of the acetylacetonato-derivatives (XXXIV) with $[M] = Si(CH_3)_2R$[207] or $Si(CH_3)_2CH(CH_3)CH_2CH_3$.[208] Their ^1H or $^{13}C-\{^1H\}$ NMR spectra exhibit in the corresponding temperature ranges the entire set of spectral features corresponding to the dynamic process (55). The rate of transitions (55) in *cis*-acac-$Si(CH_3)_2R$ is higher than in tropolone and, depending on the nature of the group R, it increases in the sequence $CH(CH_3)CH_2CH_3 < n\text{-}C_4H_9 < C_2H_5 < CH_3 < CH_2=CH$, $C_6H_5 < CF_3CH_2CH_3$.

Certain observations have been made on the mechanism of degenerate enol–enol O,O-transitions (54) and (55) of organosilicon groups[208]. It has been found for $[M] = Si(CH_3)_2CH(CH_3)CH_2CH_3$ that both $SiCH_3$ groups give rise to separate signals in the $^{13}C-\{^1H\}$ NMR spectra in the temperature range where the occurrence of processes (54) and (55) was noted on the basis of NMR spectra. This enabled the authors[208] to conclude that the configuration at the silicon atom is preserved in the O,O-transitions of organosilicon groups and to postulate transition states for these processes. In our view, this result can also serve as evidence for the intramolecular mechanism of processes (54) and (55):

(56)

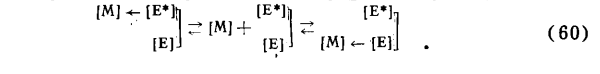


Finally, a recent communication[210] concerning the observation by NMR of O,O-transitions in a series of diacylphosphines should be mentioned {process (56), $[M] = Si(CH_3)_3$, $R = C(CH_3)_3$}.

VIII. THE MECHANISM OF METALLOTROPIC E,E-TRANSITIONS

The study of metallotropic tautomeric transformations is in essence only just beginning. It is therefore as yet difficult to expect a fairly complete understanding of the mechanism of this interesting and fairly unusual group of reactions. At present one can only attempt an initial survey of the available data, to assign them to certain most probable schemes, and to discover a series of common features of the influence of various factors on the rate of the process. Additional conclusions will evidently follow when the necessary

experimental data have been obtained. However, even the data already available on the metallotropic E,E-transitions are of theoretical value and can stimulate more far-reaching, including quantum-chemical, generalisations.



In considering the mechanism of metallotropic tautomeric transformations, one can restrict the treatment of a first approximation to four most suitable possibilities differing mainly in the characteristics of the elementary reaction steps and the form in which the cationoid and anionoid species exist:

(57)

(58)

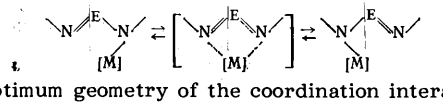
(59)

(60)

Firstly, the metallotropic E,E-transitions can take place via the intramolecular mechanism (57). This variant of the reactions is observed in many systems with cation-accepting centres in close proximity in space, particularly in different triads.

The second possibility involves the intermolecular transfer of the cationoid species [M] in the synchronous transition in the course of the interaction of two or more molecules. This mechanism [for example, mechanism (58)] does not presuppose the dissociation of the molecules into individual cationoid and anionoid residues, but after the metallotropic transition step the species[M] is bound to the residue of the partner-molecule and not to its "own" anionoid residue.

Some derivatives can dissociate into kinetically independent species. For compounds with fairly ionic [M]–[E] bonds, these are usually the ions $[M]^+$ and $[\overline{E\ E}]^-$ or their ion pairs, including solvent separated pairs. In the latter case the metallotropic transition (59) consists in the fact that the cationoid species can be linked to an anionoid residue, but this time a "foreign" one and not its "own" residue.



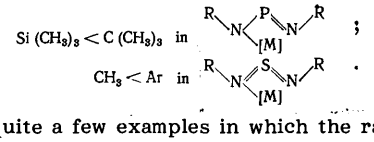
Finally the fourth possibility consists in the decomposition of the compound into neutral independent species, which are subsequently rejoined, and involves the metallotropic transition (60). This variant of the mechanism is characteristic of derivatives in which the coordinate bonds M ← E is formed between the groups [M] and $[\overline{E\ E}^*]$. In this case the anionoid and cationoid residues of the compound are stable neutral formations and can therefore exist independently in solution for a long time.

Within the framework of modern ideas[211,212], the first two mechanisms are of the associative type and the last two are of the dissociative type. We may note that the metallotropic transitions (59) are relatively atypical for the organometallic derivatives considered. On the other hand, the E,E-transitions (60) are already known in many instances (Section V). However, these data are so far insufficient for the interpretation of the characteristics of the decomposition of compounds into kinetically independent species, which is the rate-limiting stage of the metallotropic transition.

The structure of the compounds in which the intramolecular metallotropic transitions discovered hitherto take place in most cases is such that the metal atom forms a bond with one of the E atoms of the anionoid residue $[\overline{E\ E}^*]$ (E = N, O, S etc.) and is at the same time fairly close to the other E atom. Here it is envisaged that in the ground state of these compounds the distance between M and E* can be fairly large, but the relative positions of the three atoms in the given molecule—M, E, and E*—ensure the formation of a new M...E* bond and the transition state  even before the complete dissociation of the old M–E bond. In other words the elementary step of the intramolecular E,E-transition involves the virtually simultaneously dissociation of the old M–E bond and the formation of a new M–E* bond in which the potential barrier is overcome, but the system does not dissociate into kinetically independent species.

It must be emphasised that the "principle of geometrical proximity" formulated in this way, which presupposes the spatial proximity of the cation-accepting centres between which [M] migrates, constitutes a necessary but not sufficient condition for the intramolecular mechanism of metallotropic transitions. Apart from this, certain other factors, which also promote the transitions of the groups [M], are likewise important: the flexibility of the anionoid residue, facilitating the mutual approach of the cation-accepting centres, the marked electron-accepting properties of [M] and the electron-donating properties of E, and the correspondence between the geometry of the transition state and the optimum geometry of the coordination interactions for the given metal atom. However, ultimately all these factors are in some way related to the decrease of the barrier height on the potential energy curve for the E...M...E* system, which must be overcome in order to form the transition state without the dissociation of the system into kinetically independent species.

The postulate of a cyclic structure for the transition state may be adopted as one of the hypotheses concerning the elementary step in intramolecular metallotropic transitions. For example, the 1,2-transitions in pyrazoles and in general any 1,2-transitions, as well as many but by no means all 1,*n*-transitions satisfy this condition. In particular, the limitation may refer to systems of the triad type in which the atoms comprising the triad form part of the ring. This last refinement is associated with the virtual impossibility of ensuring the planarity of the transition state in small rings, as has been shown, for example, by a comparison of data for metallotropic transformations of the imidazole [reaction (32)] and amidine [reaction (29)] types. As mentioned above, in imidazoles the 1,3-transitions (32) take place only intermolecularly if at all[157], while in amidine derivatives the intramolecular process (29) takes place very readily[142], as in the case of the diazoamine triad (30). Evidently this clear difference is associated with the possibility of the formation in the latter case of a planar four-membered transition state, so that in this instance the fundamental step in the metallotropic transformation is a synchronous transformation of the bond system (E = N or CR):



The optimum geometry of the coordination interactions for the given organometallic group may also be important[213]. Thus, the high migratory capacity of RHg groups compared with R_3Sn in intramolecular metallotropic processes can be partly attributed to the fact that a T-shaped geometry of the coordination interactions, close to the geometry of the coordination interactions in the formation of a cyclic transition state in intramolecular metallotropic processes, is optimum for the compounds RHgX,[214] while for the compounds R_3SnX the optimum geometry of coordination interactions is trigonal bipyramidal[215], in which the additional ligand occupies an axial position and which does not correspond to the coordination geometry of a cyclic transition state.

It must be emphasised that it is useful to consider metallotropic E,E-transitions only in structures where a mesomeric structure with delocalised bonds is not formed for geometrical or other reasons, as a result of which the potential of the E...M...E* system requires a single-well configuration in the structures considered, of the kind observed, for example, in dimeric derivatives of pyrazole $\{[M]-L\}_2$ with $[M]=TlR_2$, etc., and not a two-well configuration.

We shall consider in relation to known examples certain factors tending to accelerate the intramolecular metallotropic transitions.

In many instances the important factor determining the rate of E,E-transitions is the lability of the dissociating M–E bond, which increases with increase of its polarity and depends in its turn on the difference between the electronegativities of the atoms E and M and on the polar effects of the substituents. This is indicated, in particular, by the series characterising the influence of substituents attached directly to the metal in the cationoid species [M] on the rate of 1,2-transitions in pyrazoles and indenes (see Sections II and IV); $OCH_3 < Cl < C_6H_5 < CH_3$. In this case the σ-electron-accepting substituents, which reduce the polarity of the M–E bond, lower the capacity of the group [M] for migration, while electron-donating substituents increase it.

An analogous conclusion can apparently be reached by considering the influence of the substituents in the anionoid residue attached directly to the atom E. In contrast to the previous case, in the anionoid residue the polarity of the M–E bond decreases under the influence of electron-donating and not electron-accepting substituents. This influence of the substituents R has in fact been found experimentally[147, 148,171,172] for certain 1,3-transitions:

There are quite a few examples in which the rate of metallotropic E,E-transitions depends greatly on the ease of formation of the new bond. In this case the Lewis acidity of the metal in the cationoid species [M] and the basicity of the second cation-accepting centre can be regarded as the driving forces of the metallotropic tautomeric transformations. Indeed, data for the metallotropic C,C- and N,N-transitions in many organometallic systems have shown that the mobilities of different groups [M] in the E,E-transitions under consideration give rise to the following sequence: $R < SiR_3 < GeR_3 < SnR_3 < HgR$. Bearing in mind that the Lewis acidity of the metal atom in [M] increases in the same sequence, presumably the enhancement of the acidity of the metal tends to decrease the height of the potential barrier in the formation of the transition state and hence to facilitate the metallotropic transitions. An analogous conclusion follows from data for the influence of substituents in the cationoid residues of tautomeric systems such as triazenes and acetylacetonates[207,208]. In this case the substituent series, $C_4H_9 < C_2H_5 < CH_3 < OCH_3 < Cl$, is the opposite to that found for pyrazoles and indenes. An evident cause of this difference may be the difference between the geometries of these two groups of compounds. Whereas in the case of pyrazoles and indenes, which have a rigid geometry, the polarity of the dissociating M–E bond is more important, in compounds with a more flexible structure, such as, for example, triazenes and acetylacetonates, the rate of the process depends to a great extent on the ease of formation of the new M–E* bond. As a result, the enhancement of the electron-accepting properties of the substituents in [M], which renders the atom M more acid, is accompanied by the acceleration of the metallotropic transitions and not their retardation. It is natural to suppose that in this instance the substituent effects refer not so much to the M–E bonds as to a change in the acidity of the atom M, which facilitates or hinders the formation of the new M–E* bond.

Data concerning the ratio of the rates of the E,E-transitions of cationoid species such as $[M]\neq H$ and $[M]=H$ in related systems show that, whereas intramolecular tautomeric transformations are more characteristic of metallotropic transitions, intermolecular transformations of the synchronous type—bimolecular and in general n-molecular—are encountered much more frequently than in prototropic systems. In particular, O,O-transitions in acetylacetonate and tropolone derivatives with $[M]=H$ take place much faster than for $[M]=SiR_3$[207–209] {we may note that the C,C-transitions, which proceed via an intramolecular mechanism for both $[M]\neq H$ and $[M]=H$, are faster than the proton transitions for $[M]=HgR$, SnR_3, GeR_3, SiR_3, etc.}.

This may be caused also by the different capacities of the compounds considered for dimer formation and by their structural differences in the dimeric state. Many experimental data have shown that prototropic systems with bidentate anionoid residues form fairly frequently, if only for a short time, dimeric structures with non-equivalent bonds[216–218]:

$$\begin{bmatrix}[E]-H\ldots[E]\\ [E^*]\ldots H-[E^*]\end{bmatrix}\quad\begin{bmatrix}[E]\ldots H-[E]\\ [E^*]-H\ldots[E^*]\end{bmatrix}$$

These apparently include also tropolone and acetylacetonate derivatives, since prototropic transitions in these systems can proceed via an intermolecular mechanism, within the framework of the hydrogen bonds arising on formation of the dimer, and not via an intramolecular mechanism {as for $[M]=SiR_3$}. A similar explanation can be put forward in the interpretation of the results of the study of N,N-transitions in diaryltriazenes.

It is noteworthy that the capacity for the formation of associated species is characteristic also of the derivatives of certain metals among those considered here, in particular, tin, cadmium, and thallium, but in many instances, for example for $[M]=Tl$, the bonds are equivalent in the dimerisation process by virtue of geometrical and other causes, as a result of which the potential surface for the [E]–[M]–[E*] fragment is a single well:

$$\begin{bmatrix}[E]-[M]-[E^*]\\ [E^*]-[M]-[E]\end{bmatrix}$$

and the metallotropic transition considered here correspondingly loses its significance.

Certain preliminary considerations concerning the possible nature of the influence of the solvent on the rates of metallotropic processes can also be formulated. Thus it is to be expected that polar but weakly coordinating solvents will facilitate intramolecular and intermolecular metallotropic processes as a result of the polarisation, ionisation, or dissociation of the M–E bonds. Weakly polar coordinating solvents, which do not induce the ionisation or dissociation of the M–E bonds, should hinder intramolecular metallotropic processes and processes proceeding via a bimolecular mechanism by blocking the vacant orbitals of the metal atom. Finally, solvents exhibiting both a high coordinating capacity and a high polarity and capable of inducing the dissociation of the M–E bonds[219–221] should accelerate metallotropic processes, facilitating their occurrence via the intermolecular dissociative mechanism.

The Applications of Quantum-chemical Methods to Spectroscopic Studies on Organic Compounds

P.P.Shorygin and K.Ya.Burshtein

The ways of using quantum-chemical methods in the spectro-chemistry of organic compounds are considered and the advances in the calculation of electronic and vibrational spectra are characterised. The effectiveness of the combined application of quantum-chemical and spectroscopic methods and the possibility of using LCAO-MO methods for the interpretation of ultraviolet, infrared, and Raman spectroscopic data in the study of molecular structure in the ground and excited states are demonstrated in relation to a number of examples.
The bibliography includes 134 references.

I. INTRODUCTION

A fairly complete utilisation of the potential of molecular spectroscopy, including infrared, ultraviolet, and Raman spectroscopy, can be achieved if it is possible to establish the origin of the spectral lines (bands). Useful information about the line assignments and molecular structure can be obtained from purely empirical correlations. Different variants of the additive scheme involve wider possibilities; they relate the spectra of complex molecules to the conventional parameters attributed to individual fragments, for example, chemical bonds (force constants, "electro-optical constants" of the bonds, etc.). However, in the most interesting cases—when there is a significant interaction between the fragments of the molecule—the additive scheme is greatly complicated and the possibility of an unambiguous, non-empirical, determination of the bond parameters and their physical significance are lost.

The application of quantum-chemical methods, which are based in some way on the ideas concerning the interaction of nuclei and electrons, made it possible to proceed to better-founded calculations of line frequencies and intensities with

a considerable limitation of empirical elements. Thus it has been possible to achieve a more complete and a better-founded interpretation of the spectra and to explain on this basis the characteristic features of a series of chemical and physical properties of many compounds, to obtain additional data for the description of molecular-optical phenomena, and to make semiquantitative predictions of the spectra and of the behaviour of systems which are not readily susceptible to experiments (for example, unstable intermediates).

In view of the multiplicity and non-equivalence of the quantum-chemical methods, it is useful to characterise the specific possibilities of each, to note their advantages and disadvantages, and to assess the prospects for the development of their application in molecular spectroscopy.

II. QUANTUM-CHEMICAL METHODS FOR THE CALCULATION OF SPECTROSCOPIC PARAMETERS

In the calculations of the parameters of electronic and vibrational spectra the Hartree–Fock approximation is usually employed[1]. The many-electron wave function of the molecule is found in the form of the antisymmetrical product of the one-electron wave functions—molecular orbitals (MO) $\phi_m(\mu)$—multiplied by the spin wave functions α or β of the corresponding electron:

$$\Phi_0 = \mathscr{A}\det|\varphi_1(1)\alpha(1)\varphi_1(1')\beta(1')\ldots\varphi_n(n')\beta(n')|, \qquad (1)$$

where $2n$ is the number of electrons and μ the ordinal number of the given electron. The coefficient $\mathscr{A}$ is determined by the condition governing the normalisation of $|\Phi_0|^2$ to unity.

The molecular orbitals are sought in the form of linear combinations of atomic orbitals (LCAO)

$$\varphi_m(\mu) = \sum_i C_{mi}\chi_i(\mu), \qquad (2)$$

where the C_{mi} are the required coefficients; thus the set of atomic orbitals $\chi_i(\mu)$ constitutes the basis set for the construction of the wave function ϕ_m. The principal requirement which must be met by the basis set of atomic orbitals consists in the fact that it must represent with adequate accuracy the distribution of electron density in the molecule, i.e. the basis set must be sufficiently complete. Unfortunately it is very difficult to satisfy this condition in practice. The atomic orbitals constitute an approximate representation of the electron density in isolated atoms, but their use in calculations of the electronic wave functions of molecules leads to additional errors associated with the impossibility of reproducing certain features of the changes in electron distribution on formation of valence bonds. It is therefore necessary to expand the basis sets χ_i by including additional functions in them.

The coefficients C_{mi} in Eqn.(2) are determined by a variational procedure with minimisation of the total electronic energy of the molecule E. Roothaan[2] showed that the coefficients C_{mi} corresponding to the minimum value of E can be determined from the following equations:

$$\sum_j (F_{ij} - \varepsilon_m S_{ij})\, C_{mj} = 0, \quad \sum_{ij} C_{mi}C_{mj}S_{ij} = 1, \qquad (3)$$

where

$$F_{ij} = H_{ij} + \sum_{kl} P_{kl}\left(\langle ij|kl\rangle - \frac{1}{2}\langle ik|jl\rangle\right). \qquad (4)$$

Here the summation was carried out over all the atomic orbitals k and l in the basis set. S_{ij} is the overlap integral of the atomic orbitals i and j, ε_m the energy of the electron in the mth molecular orbital, H_{ij} the one-electron Hamiltonian, P_{kl} the matrix of the bond charges and orders, and $\langle ij/kl\rangle$ the matrix element of the Coulombic interaction of electrons in the atomic orbitals χ_i, χ_j, χ_k, and χ_l:

$$\langle ij|kl\rangle = \iint \chi_i(\mu)\chi_j(\mu)\, R_{\mu\varkappa}^{-1}\, \chi_k(\varkappa)\chi_l(\varkappa)\, d\tau_\mu d\tau_\varkappa.$$

In this expression the integration is carried out with respect to the entire space of the Cartesian coordinates and $R_{\mu\kappa}$ is the distance between the electrons μ and κ.

The self-consistent field (SCF) method is used to solve the non-linear system of Eqns.(3) and (4). The set of coefficients C_{mi}, the choice of which can be fairly arbitrary, is then used as the zeroth approximation; in semiempirical methods C_{mi} are usually calculated by a procedure similar to the extended Hückel method. The matrix F_{ij} is constructed from the zeroth-approximation coefficients determined in this way and is then used, on solving Eqn.(3), to find a new set of the C_{mi}, from which a new matrix F_{ij} is constructed, etc., until the matrix elements F_{ij} and the coefficients C_{mi} cease to vary.

In practice both semiempirical and non-empirical calculations by the LCAO-MO SCF method are used.

Among the *semiempirical* procedures, the CNDO (complete neglect of differential overlap of atomic orbitals) and INDO (incomplete neglect of differential overlap) methods are commonest[3–7]. In these methods, the wave functions are calculated only for the valence electrons and the inner shells are included in the molecular skeleton; a minimal Slater basis set is used and a part of the Coulombic interaction between the electrons is neglected. In the CNDO approximation account is taken of one- and two-centre matrix elements of the Coulombic interaction of electrons only of the type $\langle ii/kk\rangle$, while in the INDO approximation the one-centre matrix elements $\langle ij/kl\rangle$, in which the i, j, k, and l orbitals belong to a single atom, are also introduced. In order to calculate all the one-centre matrix elements, the atomic spectra are used, while the two-centre integrals are evaluated from empirical formulae reflecting the dependence of the interaction between the electrons and nuclei on the relative positions of the atomic orbitals. In the second case the parameters in the empirical formulae indicated must be determined from data not only for atoms but also for small molecules; the solution of the problem is then not unambiguous and the differences between the selection procedures are characterised by modifications of the CNDO and INDO methods. A rational selection of parameters makes it possible to diminish the disadvantages of the CNDO and INDO approximations and also of the SCF method.

The CNDO/2,[5,6] INDO[7], MINDO/2,[8,9] and MINDO/3 [10] (modified INDO approximations) are most widely used to calculate the properties of the ground states of organic molecules, while electronic absorption spectra are calculated by the CNDO/S method[11,12]. A further improvement of the semiempirical methods can be achieved in terms of the more rigorous null diatomic differential overlap (NDDO) approximation.

As regards *non-empirical* calculations, here all the matrix elements of the interaction between the electrons and nuclei are evaluated by the analytical calculations of the necessary integrals in terms of a basis set of atomic orbitals. The atomic orbitals are usually Gaussian functions, which ensure a relative simplicity of the calculations but lead to a fairly poor representation of the distribution of electron density, so that one has to use many more functions than for Slater basis sets. The OST-3GF basis set—the minimal basis set of Slater orbitals each of which can be fitted by a linear combination of three Gaussian functions, is very widely

used. In the OST-4-31GF basis set, each Slater orbital for the electrons in the inner shell is described by a linear combination of four Gaussian functions and that for valence electrons is described by a combination of three and one Gaussian functions. The use of two (instead of one) linear combinations, whose coefficients in Eqn.(2) are varied independently, makes it possible to take into account the changes in the atomic orbitals on formation of different valence bonds.

The results of the calculations depend greatly on the choice of the basis set. Generally speaking, it is desirable to expand the basis set until the attainment of the Hartree–Fock limit, whereupon its further expansion no longer alters the result. However, this can be done only for the simplest molecules, for example, for CH_4 and NH_3. For more complex molecules, it is necessary to restrict the treatment to small basis sets, but their selection introduces a considerable arbitrary element into the calculation; the treatment is not universal and different basis sets must be used for different properties of the molecule. We may also note that the employment of the Hartree–Fock approximation (the SCF method) can also introduce a large error and further refinement of the electronic wave function (allowance for electron correlation) constitutes a very complex problem.

The methods described above are most widely used in quantum-chemical calculations of molecular spectra. However, their application to complex molecules is hindered by the large amount of computer time required. At the present time calculations by non-empirical methods are in practice possible for molecules consisting of not more than 6–10 atoms (20–30 electrons); semiempirical methods of the CNDO or INDO type are applicable to molecules consisting of several tens of atoms (up to 50–100 electrons). The amount of computation for more complex objects is too great even for the most efficient computers. In recent years attempts have therefore been made again to employ combined methods based on the π-electron approximation[13]. In order to take into account σ-electrons, a special empirical quadratic function was introduced, being added to the π-electronic energy of the molecule. This function contains parameters similar to the equilibrium geometrical parameters and force constants; the parameters were chosen so that the molecular geometry can be calculated by minimising the expression for the total energy of the molecule and the force constants can be calculated by differentiating the energy with respect to the atomic coordinates. Although the scope of such calculations is in many respects limited, they make it possible to investigate the spectroscopic characteristics of very large molecules.

Calculations by non-empirical methods on molecules with heavy atoms require a very large amount of computer time. The latter can be reduced by resorting to the pseudopotential method. In this approximate method one calculates the wave functions of the outer electrons only, assuming that the latter exist in the resultant electric field of the charges of the nuclei and inner electrons; the field is introduced into the Hamiltonian in the form of an empirical potential function—the pseudopotential. Calculations by this method (see, for example, Sachs and Hinze[14] and Abarenkov[15]) are much less accurate than the usual non-empirical calculations, but a successful selection of the empirical function can lead to a significant improvement of the results.

Relativistic effects, associated primarily with the high velocity of the electrons of the inner shells (involving an increase in the mass of the electron and a lag in the Coulombic potential) and with the spin–orbital interaction, play an appreciable role in the properties of molecules with heavy atoms; the shielding of the nuclear charges by inner electrons is then altered, which influences indirectly the valence electrons. Allowance for the relativistic effects increases the amount of calculation severalfold. The relevant methods for semiempirical and non-empirical calculations in LCAO-MO SCF schemes have been described in detail in a review[16].

The SCF Xα scattered wave method, the principle of which differs fundamentally from that of the widely used LCAO-MO SCF method, has been applied in recent years to the calculation of electronic absorption spectra. In the Xα method each atom is assumed to be surrounded by a sphere (different variants either do or do not allow for the overlap of the spheres of adjacant atoms); in the space between the spheres the electronic wave function is specified by planar waves and within the spheres it is sought by solving the Schrödinger equation with an empirical potential (for further details, see the relevant review[17]). The method is usually classified as non-empirical, although the specification of the potential within the spheres surrounding the atoms is partly empirical.

The Xα method makes it possible to carry out faster calculations than by the non-empirical LCAO-MO SCF methods. It is particularly effective in the study of molecules with heavy atoms containing a large number of electrons in the inner shells, since the computation time depends in this instance only slightly on the number of electrons in the atom. However, the region of applicability of this method in spectroscopy is at present largely limited to the determination of the positions of the occupied electronic levels (which are particularly important for photoelectron and X-ray electronic spectroscopy); the electronic absorption spectra are calculated much more rarely (resorting to the extremely artificial "transition state" procedure) and only the energies of transitions averaged with respect to the multiplet (!), intermediate between singlet and triplet transitions, are usually calculated, although in principle the possibility of allowing for the multiplicity is not ruled out.

III. THE FORCE CONSTANTS OF CHEMICAL BONDS AND INTRAMOLECULAR VIBRATION FREQUENCIES

The force constant of a chemical bond $K(i)$, equal to the second derivative of the potential energy of the molecule with respect to the increase in the length of the given bond: $(\partial^2 V/\partial q_1^2)_{q_j=\text{const.}}$, is perhaps the main characteristic of the mechanical properties of the bond. For like bonds in different molecules of a similar type, it varies within narrow limits; its semiquantitative correlations with the bond length and order and also certain relations with the dissociation energy are known. However, one should note that the usual force constants depend to some extent on the arbitrary element in the selection of the internal coordinate system in the molecule; the "independent force constants" d^2V/dq_1^2, which characterise the bond strength under the conditions where an external force is applied to only one (*i*th bond), are free from this disadvantage[18]. It is even more significant that the chemical bond in a polyatomic molecule cannot be, strictly speaking, characterised by a single force coefficient. For this purpose, one must introduce a whole matrix of coefficients including those related to the interaction of the given bond with all other bonds, i.e. with non-diagonal elements $K(ij) = \partial^2 V/\partial q_i \partial q_j$.[19,20] The latter determine the appearance of forces acting in the *j*th bonds as a result of the extension of the *i*th bond. The non-diagonal elements are as a rule small, but they are of primary importance for certain problems.

If the structural formula of the compound is known and the necessary set of force constants is available, it is possible to calculate fairly simply, for the conformation investigated, the frequencies ω of all the normal atomic vibrations manifested in the infrared and Raman spectra as well as vibronic absorption and secondary emission spectra, to determine the vibrational modes, and to characterise the force field in a molecule deformed in any way. These possibilities are limited in practice by the inadequacy of the information about the force constants themselves (which is particularly restricted for electronically excited states).

The total amount of information required for an exact calculation of the frequencies ω in complex molecules is extremely large and the available data must be supplemented using analogies and approximate assumptions. Under these conditions, the invocation of additional sources of information appears very important; quantum chemistry occupies a special place here, since it not only makes it possible to estimate, in principle, any force constants for both the ground and electronically excited states but it can also elucidate the origin of individual coefficients and their relation to the structure of the electron shell (unfortunately, sufficient attention has not been paid to this factor hitherto).

It is known that the solution of the converse problem—the calculation of the force coefficients from experimental frequencies ω—requires extensive and laborious preparatory work involving the synthesis of isotopic models. In many cases the solution is not unambiguous and the choice between sets of coefficients satisfying the initial system of equations is frequently based on intuition. The application of MO methods places at the disposal of the investigator independent criteria for such a choice. One can add to this that the quantum-chemical calculation of "independent force constants" does not involve any additional difficulties.

Both semiempirical and non-empirical quantum-chemical methods are used to calculate the force constants. In all cases the molecular geometry is optimised initially, i.e. the most stable form corresponding to the total energy minimum is specified; the second derivatives of the energy with respect to the Cartesian or natural coordinates (force constants) and if necessary also cubic and biquadratic terms are then found at the minimum.

The choice of the basis set has a significant influence on the results of non-empirical calculations of force constants (particularly, non-diagonal elements). Thus, when a minimal Slater basis set is used, an extremely indirect agreement with experiment is obtained. The agreement improves significantly on passing to an extended basis set (OST-4-31G, etc.), but a further extension of the latter is no longer very effective—even when the Hartree–Fock limit is reached the force constant prove to be too high by 10–20%.[21] The accuracy of the calculation of the non-diagonal elements is then much lower. Thus K(C–O, C–O′) for the CO_2 molecule was found to be too high almost by a factor of two[22]. Allowance for electron correlation improves the results[23,24], but this is virtually impossible for polyatomic molecules.

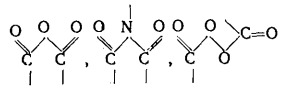
A characteristic feature of the semiempirical methods is that the deformation vibration frequencies are lower than the stretching vibration frequencies. In the CNDO/2 method the values of ω for deformation vibrations agree with experiment without the introduction of corrections, while the data for stretching modes are found to be too high. On the other hand, in the MINDO/2 method the latter are close to the experimental data, but the deformation vibration frequencies are too low. The MINDO/3 method yields results of an intermediate type; the errors are on average the same as in non-empirical calculations without allowance for electron correlation.

Since the errors are in most cases systematic, they can be greatly reduced by introducing empirically selected correcting scale factors for the determination of the types of force constant (for example, for the C–C bonds, C–C–H angles, etc.) or increments which are added to the calculated frequencies.

For calculations in terms of the MINDO/3 approximation, Dewar and Ford[25] selected a system of increments specific to stretching, deformation, and torsional vibrations of specific atomic groups or bonds; the satisfactory accuracy of the results was demonstrated in relation to a large number of examples, but the wide variety of the normal vibrational modes, which in a complex molecule include the vibrations of many bonds and angles, and the impossibility of a clear-cut separation of stretching and deformation modes limit the prospects for correcting frequencies in terms of the types of vibrations.

It appears more logical to correct the force constants and positive results have been achieved on these lines. In a non-empirical calculation of the vibrational spectra of ethylene in terms of the OST-4-31G basis set the introduction of four correcting factors (of the order of 0.75...1.0) for the diagonal force constants and of yet another correcting factor for all the non-diagonal force constants diminished the average discrepancy with 12 experimental frequencies severalfold and the latter amounted to ~7 cm^{-1}.[26] Similar results were obtained also for ethane, propane, propene, and dimethyl ether, but the corrections were chosen individually for each type of compound[27,28]. We may note that a simple determination of the frequencies from the set of coefficients $K(ij)$ obtained experimentally for other molecules of a similar type yields approximately the same accuracy in the absence of conjugation.

In the calculation of the spectra of hydrocarbons by the CNDO/2 method the following correcting factors must be introduced for the force constants[29]: 0.38 for valence bonds, 1.80 for angles in the molecular plane, and 0.62 for angles of displacement from the plane. The same corrections have been used for glyoxal and acroleine[30]. A set of scale factors for organic compounds containing N and O atoms has been recommended and tested[31]; the standard error in a series of fairly complex triazoles did not then exceed 30 cm^{-1}. We recall that the experimental error is ~±1 cm^{-1}, but the effect of the medium (solvent), which is difficult to eliminate, is an order of magnitude greater.



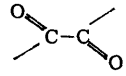
In selecting the scale factors or increments, the problem of their reproducibility in a series of different molecules naturally arises. It can be shown that it is similar to the problem of the possibility of transferring an experimental force constant, but in reality the causes of the limited universality in these two instances are completely different; in the first case such limitation arises from the significant irregularity of the errors of the selected computational method, while in the second the force field for particular test molecules has real specific features which are in themselves of extremely great interest and important for chemistry and are in addition susceptible to investigation by quantum-chemical methods.

The wide variety of procedures and correction factors reflects the subjective approach of different workers to this problem. The best results are obtained when the corrections are made specific to the maximum extent, although this inevitably reduces (and in the limit completely vitiates) the significance of the initial calculation itself.

As regards the calculations of *non-diagonal* force coefficients $K(ij)$, the latter are frequently subject to large errors and for polyatomic molecules the estimation of the accuracy of the calculations by comparison with values evaluated from experimental data is very difficult owing

to the unreliability of the latter. Practical experience with calculations has shown that semiempirical methods lead to incorrect signs of the non-diagonal coefficients characterising the interaction of the C–H bonds with adjacant valence bonds; the absolute values of these constants are low and they therefore have little effect on the frequencies, but the relative positions of the stretching vibration lines for the CH_2 and CH_3 groups depend on them. In other cases qualitatively satisfactory results were obtained. However, the non-diagonal elements were corrected by extremely arbitrary (relatively unjustified) procedures[26–31]; the correction factors were varied in the range from 0.3 to 1 (depending on the investigator who carried out the calculation and on the method used).

For non-adjacent bonds, the coefficients $K(ij)$ are extremely small and in the calculation of the frequencies ω they are therefore usually disregarded; however, in certain molecules in the presence of conjugation they proved to be fairly large, contrary to expectation. In the systems



they are to a large extent responsible for the anomalously large splitting of $\omega_{C=O}$ into components corresponding to the in-phase and out-of-phase vibrations of the C=O groups[19,32]; the splitting (up to 70 cm^{-1}) and the values of $K(C=O, C=O')$ proved in this instance to be several times greater than for the system  [32,33] although seemingly the opposite should have been expected.

Table 1. The force field in terms of the symmetry coordinates for the ethane molecule (K, δ, and ρ are the stretching, deformation, and torsional force constants; subscripts S and d denote the values for symmetrical degenerate vibrations).

Calculation of the principal non-diagonal coefficients for acetic anhydride by the CNDO/2 method[34] confirmed the ideas concerning the interaction of two C=O groups in the vibrational process, as a result of which $K(C=O, C=O')$ for the anhydride is much greater than for a similar molecule with a methylene bridge (pentane-2,4-dione); however, calculation revealed a feature which could not be established from experimental data, namely the significance and large contribution to the splitting of $\omega_{C=O}$ by the coefficients $K(C=O, C-O)$, which are much greater than $K(C=O, C-C)$ for pentanedione.

Certain ideas concerning the accuracy of the results obtained by different computational methods and also the coefficients $K(i)$ and $K(ij)$ themselves are provided by Tables 1 and 2, which include also fairly reliable data determined from observed frequencies; the computational methods used yielded approximately equivalent results.

It follows both from the calculation and experiment (Table 2) that the non-diagonal coefficients $K(ij)$ for a molecule with conjugated NC–CN bonds are much greater than in saturated hydrocarbons. The negative sign of $K(C\equiv N, C\equiv N')$ means that the extension of one C≡N bond favours an increase in the length of another. The diagonal coefficient $K(C\equiv N)$ is in this case lower (as for the H_2N–CN and $H_2C=CH$–CN molecules[35]) than for acetonitrile by ~3% due to conjugation, while $K(C-C)$ is in fact appreciably higher.

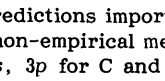

Table 2. The force constants (mdyn $Å^{-1}$) of dicyanogen and acetonitrile[35,126,127].

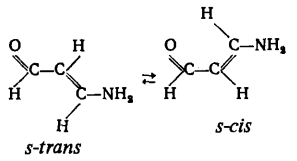
*Calculation by a non-empirical method in terms of a moderate basis set.



**Calculation by a non-empirical method in terms of a large basis set.

In individual studies attempts were made to investigate the accompanying molecular forms which cannot be isolated from the equilibrium system. In the communication quoted above[30] interesting data are presented for the semiempirical calculation of the spectra of the *s-cis*-conformers of butadiene and glyoxal, for which limited and unreliable information was available. According to the results[30,33], the force constants of the double bonds in the *s-cis*- and *s-trans*-conformers are virtually the same, but $K(C-C)$ for *cis*-glyoxal is appreciably smaller than for the *trans*-isomer, as a result of which ω_{C-C} is lower by 100–200 cm^{-1}. The interaction coefficients of the double bonds are in all cases small, but the symmetric vibration frequency of the double bonds in the *s-cis*-form (in contrast to the *s-trans*-form) should be lower than the antisymmetric frequency.

Detailed information has been obtained for the rotational isomers of formic acid[33]. The spectrum of the *s-cis*-conformer  was unknown and the calculation yielded predictions important for experiment. The application of a non-empirical method with a fairly large basis set (9*s*, 5*p*/5*s*, 3*p* for C and O) yielded the following force constants for the *s-cis*-conformer (*s-trans*-conformer): $K(C=O) = 14.6$ (14.1) mdyn $Å^{-1}$; $K(C-O) = 6.9$ (7.2) mdyn $Å^{-1}$; $K(O-H) = 8.8$ (7.9) mdyn $Å^{-1}$; $K(C=O, C-O) =$ 1.9 (1.3) mdyn $Å^{-1}$. In conformity with the differences between bond strengths in the *s-cis*-form, $\omega_{C=O}$ should be higher by 50 cm^{-1} and ω_{O-H} should be higher by 200 cm^{-1}. The data obtained make it possible to estimate the zero-point vibration energy and to revise the calculations of the

heats of chemical reations; on the other hand they enable one to supplement the available information about the interrelations between the $K(i)$ and the chemical bond lengths.

In the infrared spectra of certain aminocarbonyl compounds with conjugated C=C and C=O bonds, a third band, whose origin is obscure, appears in the region of 1610 cm^{-1} in addition to the bands at ~1650 cm^{-1} ($\omega_{C=O}$) and ~1570 cm^{-1} ($\omega_{C=C}$) usually observed. Calculations of the spectrum of animopropenyl[36] showed that the band is associated with the second rotational isomer and at the same time that $K(C=O)$ increases in *cis–trans*-isomerisation:

(15.0 mdyn $Å^{-1}$ for the *s-cis*-isomer and 16.1 mdyn $Å^{-1}$ for the *s-trans*-isomer), while the C=C bond changes little (36); unfortunately the authors did not estimate K(C–C) and K(C=C, C=O).

The non-empirical calculation of the force constants for methylamine and a series of other simple molecules[37–39] permitted the assignment of certain lines concerning which contradictory view had been expressed or at least to reject the earlier explanations; for example it was established that the 777 cm^{-1} band in the spectrum of HNCO refers to an out-of-plane vibration, while in the hydroxylamine spectrum the torsional vibration band should be in the region of ~1300 cm^{-1}.

The estimates of the strengths of bonds involving the metal atom in salts in the absence of intermolecular interaction are of interest. According to calculated data[40], the coefficient K(Li–C) for an isolated LiCN molecule should be lower by a factor of 3–4 than for the bonds with the cyano-group in the H–CN, Cl–CN, and H_3C–CN molecules.

According to Schlegel et al.[21], the force constants differ significantly for the C–H bonds oriented in different ways relative to the unshared electron pair of the neighbouring heteroatom. Predictions of the spectrum of vinylborane, which is virtually impossible to determine experimentally, have been made on the basis of the calculated force constants and frequencies[41].

During recent years attempts were made to use quantum-chemical calculations of vibrational frequencies for the evaluation of the partition functions and for the determination from the latter of the entropy contribution to the free energy. The spectra of stable molecules can be most simply determined experimentally, but quantum-chemical methods are applicable also to unstable compounds and to transition states (see, for example, Yoshioka et al.[43]); at the same time they can yield information about the frequencies of unobserved transitions. Thus the entropy contribution to the activation energy can be estimated from calculated frequencies and extremely fine kinetic effects can be interpreted. The first studies showed that the accuracy of the method is entirely sufficient for this purpose; thus data have been obtained for the primary kinetic isotope effect in the reaction $CH_2=CH-CH_2COOH \rightarrow CH_3CH=CH_2 + CO_2$, which agreed well with experiment[25].

In connection with the foregoing, it must be emphasised that the results of quantum-chemical calculations cannot as yet characterise the force field and the frequencies ω with an accuracy equal to that of the experimental determination, but they are extremely useful for line assignments and the combination of calculated and experimental data leads to a more complete and reliable description of the spectrum. The calculated *relative* values are more reliable and can assist in interpreting the comparatively small differences between the frequencies of similar molecules, which cannot always be done by other methods.

By combining quantum-chemical methods with the usual methods involving calculation from experimental frequencies, it is possible to achieve a significant refinement of the force field (see the examples in the literature[42,44,55]).

IV. THE INTENSITIES OF INFRARED ABSORPTION BANDS

The integral intensity of a fundamental infrared absorption band is known to be proportional to the square of the derivative of the molecular dipole moment $\partial\mu/\partial Q$. The origin of the dependence of the dipole moment on Q is associated both with the displacement of the atoms carrying a charge and with the changes in the charges themselves (or in the populations of the atomic orbitals).

In order to calculate the intensity, it is sufficient to evaluate the dipole moments for the equilibrium and non-equilibrium values of Q, which does not present significant technical difficulties, although it does require the knowledge of the vibrational mode. Among the semiempirical methods, best agreement with experiment is achieved with the aid of the CNDO/2 method and a somewhat worse agreement is obtained using the MINDO/3 and INDO methods. An important feature of the quantum-chemical methods is the possibility of determining the signs of the derivatives of the dipole moment. If the derivatives are fairly large, their signs are found to be the same whatever the method, including the non-empirical methods, and they can be regarded as more or less reliable; the differences in sign have been obtained only for certain deformation vibrations of the C–H bonds.

Table 3. Derivatives of the dipole moments with respect to symmetry coordinates (D $Å^{-1}$).

*Calculation by a non-empirical method in terms of a large basis set.

The results of calculations by different methods for methane and ethylene (Table 3) and other compounds[45–50] have shown that the quantum-chemical methods make it possible to obtain a semi-quantitative agreement with experiment and to determine which lines should be intense, which should be weak, and which should not be observed at all. Such data are sufficient for the solution of many spectrochemical problems. The differences between the intensities of lines associated with isotypical vibrations can

be calculated with a high degree of accuracy for a series of molecules with similar structures. Thus a fairly satisfactory correlation with experiment has been obtained for the C=C stretching vibration bands in the spectra of different ethylene derivatives $H_2C=CHX$, although the intensities differed in this instance by a factor of 5–10;[51] here it would be appropriate to take the next step and to give a well-founded explanation of the higher intensity of the bands of molecules containing electron-donating groups X.

The simplest but as yet insufficiently tested procedure for increasing the accuracy of the calculation of the line intensities involves the selection of scale factors or increments. This method has been used to find derivatives of the dipole moments of acetylene, ethylene, and ethane. In calculations by the non-empirical method in terms of a minimal basis set the derivatives were found to be too low to approximately the same extent; their multiplication by 1.2 led to quite acceptable results and to an adequate agreement with experiment[52].

Problems of increasing the accuracy of the calculation of the vibrational mode for the atoms and of extending the basis set for the calculation of the wave functions by including polarising orbitals in the set (p orbitals for the H atom and d orbitals for the C and O atoms) and also of allowing for electron correlation stand in the way towards a more rigorous and accurate calculation of the infrared band intensities (without introducing corrections)[53].

V. PROCEDURES FOR THE INVESTIGATION OF THE STRUCTURES OF MOLECULES IN ELECTRONICALLY EXCITED STATES

The available information about the electronic structures and properties of organic molecules in excited states is extremely scanty. Such substances are comparatively unsusceptible to experimental study and the possibility of resorting to quantum-chemical methods is very important. It is noteworthy that the study of excited states is very important not only for the characterisation of the optical properties of molecules but also for understanding the characteristics and mechanisms of many chemical (primarily photochemical) reactions.

The Hartree–Fock approximation for molecules with closed shells, described in Section II, makes it possible to calculate the electronic wave function of the ground state Φ_0. In the study of electronically excited states, certain modifications must be introduced into the computational scheme. The simplest modification is the approximation of virtual orbitals[54], in which all the one-electron molecular orbitals are calculated by the standard Hartree–Fock method for the ground state, each occupied molecular orbital containing a pair of electrons with opposed spins. After the calculation of the coefficients (adjusted for self-consistency) of the expansion of the molecular orbitals with respect to atomic orbitals the energy of the molecular orbital, and the total molecular energy, one of the electrons is "transferred" from the occupied to the vacant orbital. The energy of this transition ($m \to r$) is calculated as the difference between the energies of the electron in these orbitals, since all the remaining molecular orbitals are assumed to be unaltered (which can be regarded as a fairly rough approximation).

In order to take into account the changes in the molecular orbitals of electronic excitation, we shall make use of the method of configuration interaction (CI). In this method the wave functions $\Phi_{m \to r}$ of excited singlet states, calculated in terms of the approximation of virtual orbitals

$$\Phi_{m\to r} = \text{const} \cdot \det|\varphi_1(1)\alpha(1')\varphi_1(1')\beta(1')\ldots\varphi_{m-1}(m-1)\times \cdot\times\alpha(m-1)\varphi_{m-1}(m-1)'\beta(m-1)'\varphi_m(m')\beta(m')\ldots \ldots\varphi_n(n)\alpha(n)\varphi_n(n')\beta(n')\varphi_r(r)\alpha(r)|$$

constitute the basis set. Linear combinations of these functions

$$\Psi_{q\to t} = \sum_{mr} C_{mr}^{qt}\Phi_{m\to r}$$

give rise to more accurate wave functions of the excited states. The subscripts and superscripts m, r, q, and t can vary from 1 to N, where N is the number of atomic orbitals in the basis set adopted. The coefficients C_{mr}^{qt} are determined by the diagonalisation of the matrix made up of the elements $\langle\Phi_{m\to r}|H|\Phi_{m'\to r'}\rangle$. The functions $\Phi_{m\to r}$ are of the one-determinant type, while the functions $\Psi_{q\to t}$, with CI, are of the multideterminant type. However, for the majority of excited states the main contribution to $\Psi_{q\to t}$ comes from only a single one-determinant function $\Phi_{m\to r}$, while others introduce only a small correction reflecting the changes in the molecular orbital on excitation.

Other methods widely used to study the geometry and electronic structure of molecules in the excited state are the restricted and unrestricted Hartree–Fock methods for open shells and the Dewar half-electron method.

In calculations by the restricted Hartree–Fock method on systems with open shells equations of types (3) and (4) include non-diagonal Lagrange coefficients[2], and their solution is more complex than for systems with closed shells. However, entirely acceptable procedures have been proposed for their solution[56–59], which made it possible to apply the method on a fairly large scale in non-empirical calculations of the geometry of excited states.

When the unrestricted Hartree–Fock method is used, two different sets of linear combinations of atomic orbitals, corresponding to electrons of different spins, are introduced for each electron pair. Each electronic state is described by a specific set of coefficients defining the electron population of the molecular orbitals. The coefficients of the expansion of MO and AO are determined from the system of equations obtained by Pople and Nesbet[60]. The principal deficiency of the method consists in the fact that the wave function obtained does not, strictly speaking, represent the eigenfunction of the square of the spin operator and is an inaccurate solution, which can be improved only by introducing an additional laborious procedure.

The Dewar half-electron method[61] is based on the standard Roothaan equations for molecules with closed shells (where there are two electrons in each molecular orbital) but with an altered number of electrons in two molecular orbitals in the calculation of the bond charge and order matrix P_{ij}. This description of the excited state with retention of Eqn.(4) for F_{ij} implies in essence that the molecular orbitals, occupied by a single electron in the standard Roothaan method, are populated by two "halves" of an electron with opposed spins. F_{ij} then incorporates the matrix elements of the Coulombic interaction of the electron halves and the exchange interaction between the unpaired electrons is incorrectly taken into account. The necessary corrections for this can be introduced into the final total energies, retaining the standard Roothaan expressions for F_{ij}. In this case the usual programs for molecules with closed shells are less altered on passing to the study of excited states. In the determination of the coefficients for the expansion of the molecular orbitals with respect to the basis set of atomic

orbitals one then minimises an inaccurate expression for the total energy, but the associated errors are small and do not have a significant influence on the results of the calculation.

The advantages and disadvantages of each of the above methods have not yet been adequately investigated, but they are apparently entirely suitable for calculations of the geometries and electronic structures of excited molecules. Examples of calculations of the geometries of excited singlet states are presented in Table 4. It is noteworthy that Table 4 lists the absolute geometrical parameters, whereas for spectroscopic purposes their changes on excitation are mainly required; the latter are reproduced much less accurately by quantum-chemical methods. For other examples, see the literature[62-68]. From the standpoint of computer time, the Dewar half-electron method[68] is the most economical among those enumerated above and can be recommended for calculations on large molecules.

VI. QUANTUM-CHEMICAL CALCULATIONS OF THE FREQUENCIES AND PROBABILITIES OF ELECTRONIC TRANSITIONS

The quantum-chemical calculations of the geometry and of the distribution of electron density for excited states, examined above, can be regarded as successful, since even semiquantitative results are extremely useful. However, for the calculation of electronic absorption spectra, it is necessary to have more accurate wave functions and, despite their laborious nature, variants taking into account the configuration interaction are used nowadays for this purpose.

Calculations in terms of the CNDO/S valence approximation with allowance for CI are most widely used to investigate the electronic absorption spectra of molecules containing systems of conjugated π-bonds[11,12]. Several modifications of the method have been proposed, differing slightly from one another in the choice of the empirical parameters but leading to fairly similar final results. The errors in practical calculations of the energies of $\pi \rightarrow \pi^*$ electronic transitions do not exceed several tenths of electron-volts even for fairly complex molecules (Table 5). The accuracy is lower for the $n \rightarrow \pi^*$ transitions and the energies obtained are in most cases too low. The latter is apparently associated with the use of the CNDO approximation in which no account is taken of a series of interaction integrals between electrons making a significant contribution to the energy of the $n \rightarrow \pi^*$ transitions. The singlet–triplet splitting for n, π^* excited states is then found to be zero, although in reality for certain compounds it reaches 1 eV.

Table 5. Calculation of the electronic absorption spectra by the CNDO/S method[11,12].

Semiempirical methods have been little used for the calculation of the energies of $\sigma \rightarrow \sigma^*$ transitions; the accuracy obtained using the existing parametrisations should be low and one may expect qualitative rather than quantitative results. One should remember that in semiempirical methods one normally employs a minimal basis set and this precludes the calculation of the parameters of the Rydberg transitions (to orbitals with large quantum numbers), which usually occur in the region of $\sigma \rightarrow \sigma^*$ electronic transitions and can be mixed with them.

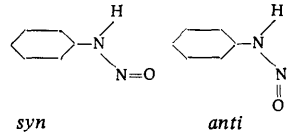
In calculations on the excited states and electronic absorption spectra by non-empirical methods one has to have much larger basis sets than for the calculation of the properties of the molecular ground state. The attempts to select small basis sets have led to agreement with experiment only for individual electronic transitions in a limited range of compounds. This is because the change in the distribution of electron density on excitation is not reproduced with the necessary accuracy by a simple alteration of the population of the molecular orbitals or even by a transition to their linear combinations. In other words, the basis set of atomic orbitals selected for the ground state is unsatisfactory for the excited state. On excitation, the electron cloud usually expands and this has a marked influence on the matrix elements for the interaction of electrons and nuclei. In order that the wave function expanded in terms of the basis set of atomic orbitals (i.e. represented by a linear combination of atomic orbitals) should reproduce this expansion, the basis set must be modified—the orbital exponents must be altered somewhat or additional diffuse orbitals must be included. The nature of the expansion of the electron cloud is specific to each $0 \rightarrow e$ electronic transition and the only rational method of improving the basis set involves an increase of the number of atomic orbitals.

The introduction of very large basis sets and allowance for the contributions of all singly and doubly excited configurations greatly extend the scope of the calculation and make it possible to evaluate the energies of electronic transitions to within 0.2–0.5 eV. However, at the present time this is possible only for small molecules, since the difficulty of the calculations increases very rapidly with increase of the number of atoms. The results of such calculations of the spectra of ethylene, butadiene, benzene, and certain other compounds with simple molecules have been published in a review[69].

Non-empirical methods are most widely applied in calculations on Rydberg transitions[69–72]. For simple molecules, it has been possible to calculate, in good agreement with experiment (±0.1 eV), the positions of the absorption bands, but their assignments are not always reliable, since the Rydberg bands are very close to one another (even in triatomic–penta-atomic molecules up to 10 transitions may be located in the region of 7–8 eV). The non-empirical methods lead to appreciably high energies of the lowest $\pi \rightarrow \pi^*$ transitions (error up to 1 eV).

In practice calculations of the electronic absorption spectra of organic compounds extend over a region of not more than 8–10 eV. For a more remote region, the difficulty of the calculations increases greatly owing to the necessity to take into account highly excited configurations.

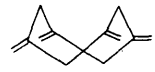
The oscillator strengths of the electronic transitions are calculated less accurately in all the methods than the transition energies and the results can differ severalfold from the experimental data. The requirements for the accuracy of the wavefunctions are then particularly stringent and the small errors associated with the selection of the basis set can be markedly reflected in the results; in practice it is necessary to take into account the contributions of a still greater number of excited configurations. However, the oscillator strengths of the observed $0 \rightarrow e$ transitions can differ by several orders of magnitude; under these conditions, even semiquantitative estimates are sufficient for the prediction of the overall form of the absorption spectrum and for the interpretation of the individual bands.



The results of the calculation can usually be compared with experiment only for a few (long-wavelength) electronic transitions. The majority of transitions are located in a region difficult to investigate experimentally (<1500 Å) and the lack of experimental data for such transitions hinders the direct estimation of the accuracy of the computational methods. However, indirect procedures can be used for this purpose. The electronic polarisability can be evaluated from the oscillator strengths and frequencies ν_e of the $0 \rightarrow e$ transitions calculated by a quantum-chemical method and the results can be compared with experimental data. Polarisability calculations have been carried out for many types of molecules[70–75] and for the majority of these a sufficient agreement with experiment has been obtained, which shows indirectly a satisfactory accuracy of the calculation of the parameters of the absorption bands over a wide range of the spectrum.

When the results of the calculation of oscillator strengths are used to infer the structure of complex molecules, one must not underestimate their approximate nature. In this connection mention should be made of calculations for 4-nitro-*N*-benzylideneaniline[76]; within the framework of the comparison made, the results correspond to the arrangement of the two benzene rings in perpendicular planes, which is extremely unlikely. Examples of the application of calculations of oscillator strengths, dipolar and quadrupolar polarisabilities, and hyperpolarisability have been described[77–82].

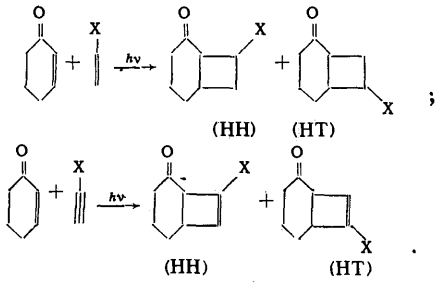
VII. THE APPLICATIONS OF QUANTUM-CHEMICAL CALCULATIONS TO THE EXCITED STATES OF ORGANIC MOLECULES



The quantum-chemical calculations of the electronic structures and geometries of electronically excited molecules are widely used to interpret experimental data and to assign ultraviolet absorption bands, to establish a relation between absorption spectra and the structure of the molecule and its conformation, and also to investigate the reactivities of electronically excited molecules in photochemical processes[83–90].

We shall consider several examples. In the absorption spectra of certain organic compounds the characteristic long-wavelength bands were previously tentatively assigned to charge-transfer transitions but this could be proved and the contribution of charge transfer could be estimated only by quantum-chemical calculations. In particular, it has been established for *N*-alkyl-*N*-nitrosoaniline and its alkyl derivatives[83] that excitation in the first (long-wavelength) absorption band leads to an electronic transition in the benzene ring (^1L_b), while excitation in the second band leads to an electronic transition mainly in the NNO group; the absorption of light whose frequency corresponds to the third band gives rise to an electron density distribution with transfer of more than half of the electronic charge from the NNO group to the benzene ring, while absorption in the fourth band modifies the wave functions in the region of the benzene ring (^1L_a). It follows from the calculation that the charge-transfer band should be observed experimentally only for the *anti*-isomer, while for the *syn*-isomer it should be close to the more intense ^1L_a band and should be masked by the latter:

syn *anti*



The experiments have shown that certain non-conjugated polyene compounds (adamantane derivatives) with a fixed relative orientation of two double bonds of the type

have an intense absorption band at ~230 nm (while for monoolefins the first intense band is located in the region <200 nm). Non-empirical calculations have led Braverman et al.[84] to the conclusion that this band is due to the electronic transition between the components of the split π and π^* levels, caused by the mutual influence of the double bonds through space. This influence also leads to the stabilisation of the excited state, while interaction via methylene bridges (with participation of the σ orbitals of the C–H bonds) affects the energies of the highest occupied orbitals and the symmetries of the molecular wave functions; the latter explains the high intensity of the absorption band. A simpler system with two weakly interacting C=C bonds (norbornadiene) has been investigated[85]; the contributions of charge transfer were estimated for each excitation level and the influence of hyperconjugation involving the bridging atoms on the $^1A_1 \rightarrow {}^1B_2$ transition was noted.

No less interesting results can be obtained in the study of photochemical reactivity. Thus the stereospecificity of the photochemical addition of acetylene and ethylene derivatives (HC≡CX and $H_2C=CHX$) to α,β-unsaturated

ketones has been considered[86]. Experimental studies on the reaction led to unusual results; it was found that certain acetylene and ethylene derivatives form products in which the carbonyl group of the ketone and the substituent X are directed to one side ("head to head", HH), while in others, i.e. in the presence of a second substituent X, they are directed to different sides ("head to tail", HT); in the third case the stereospecificity vanishes; examples of the reaction mechanisms are given below:

According to the results of the calculations the ground and excited (triplet) states by the CNDO/2 method, the above difference can be accounted for by the fact that the stereospecificity of the reaction of ethylene derivatives is due mainly to the interaction between the π-electron orbitals of the C=C bonds of the reacting molecules, while in the case of acetylene derivatives it is caused by the dipole–dipole interaction. The absence of stereospecificity in the addition of acetylene derivatives containing only the highly polar CHO and COOH substituents is associated with the fact that the component of the dipole moment perpendicular to the direction of the C ≡ C bond predominates in these derivatives[86].

Interesting data concerning the changes in molecular geometry on electronic excitation have been obtained with the aid of non-empirical methods (Fig.1). It is at present impossible to obtain such information in other ways. In another investigation[89] it has been shown that all the bond lengths in the pyrazine ring increase as a result of the $\pi \rightarrow \pi_1^*$ electronic transition, while in the $n \rightarrow \pi_1^*$ transition the C–C bonds become shorter.

The use of quantum-chemical methods in the study of optical activity is particularly appropriate for molecules with conjugated or highly interacting bonds where the approximation of weakly bound subsystems (molecular fragments) is unsuitable. As an example, we may note the calculations of the rotatory power of the $n \rightarrow \pi^*$ electronic transitions in dioxan-1,4-dione and its methyl derivatives, as a result of which it was possible to estimate separately the contributions of the asymmetric substitution in the ring and of the dissymmetry (chirality) of the ring itself in each conformer[87].

VIII. THE INTENSITIES OF THE COMPONENTS OF VIBRONIC TRANSITIONS

The calculation of the intensities of the components of the vibrational structure is of primary important for the characterisation of the overall form of the bands in the electronic absorption and fluorescence spectra and also for the calculation of the Raman line intensities.

In specific calculations it is usually assumed that, in the overall wave function of a molecule, it is possible to distinguish the electronic and vibrational components Ψ_e and $\prod_a u(Q_a)$. The transition moment $00 \rightarrow ev$ involving a change in the electronic and vibrational states can then be represented by the following expression of:

$$\mathbf{M}^{00\rightarrow ev} = \int \ldots \int \prod_a u_{00}(Q_a)\, M^{0e}\, u_{ev}(Q_a)\, \mathrm{d}Q_i, \qquad (7)$$

in which the integration is carried out with respect to all the Q_a, M^{0e} is the moment of the $0 \rightarrow e$ transition determined by the function Ψ_0 and Ψ_e, and u_{00} and u_{ev} are the nuclear wave functions of the initial (00) and final (ev) states. In principle, M^{0e} is a function of the normal nuclear coordinates; M^{0e} can be expanded in series in powers of Q, retaining only its first terms in view of the rapid convergence of the series. The dependence of M^{0e} on the coordinates Q_{as} of the antisymmetric atomic vibrations largely determines the distribution of intensities in the series of components $\nu_{e0} + n\nu_{as}$ of the absorption band. However, for symmetrical modes, this type of dependence is of secondary importance and is frequently disregarded; the calculation of the intensities of the components of vibronic transitions then requires the calculation of M^{0e}, the molecular geometry, the frequencies and modes of the atomic vibrations, and the nuclear wave functions for the ground and excited states.

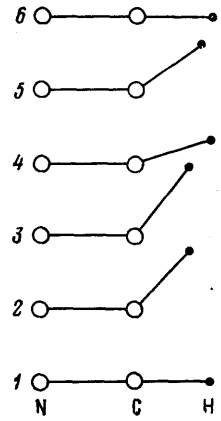


Figure 1. The geometry of the HCN molecule in the ground and excited states (the energies of the states are given in brackets in eV): *1*) ground state (0.0); *2*) $^1A''$ (6.48); *3*) $2^1A'$ (6.78); *4*) $2^1A''$ (7.52); *5*) $3^1A'$ (7.85); *6*) $3^1A''$ (8.97).[80]

Calculations of the intensity taking into account the $M^{0e}(Q)$ relation and, if necessary, the differences between the potential energy curves for the molecule in the ground and excited electronic states, carried out by non-empirical methods for formaldehyde and other molecules[91–94] and by semiempirical methods for benzene, naphthalene, benzoperylene, formaldehyde, and benzaldehyde[95–100], led to a fairly satisfactory agreement with experimental data (Table 6). The results made it possible to interpret certain vibronic bands in the absorption spectra; in particular, it has been shown[92] that the electronic transition $n \rightarrow \pi^*$ in the N_2H_2 molecule is combined with the excitation not only of the fully symmetrical modes but also of the antisymmetric stretching vibration of the N–H bonds, giving rise to a whole series of the corresponding components in the vibrational structure of the absorption band.

According to Herzberg and Teller, the $M^{0e}(Q)$ relation can be expressed in terms of a set of coefficients h_{es}, which determine the mixing of the wave functions Ψ for different electronic states (e and s) as the normal coordinate Q is varied. In this connection, some workers arrived at the erroneous idea that a simple quantum-chemical calculation of the probability of vibronic transitions in terms of mixing coefficients is possible. However, such calculation requires the evaluation of the overlap integrals of the multideterminant electronic wave function of the excited state of a deformed molecule (i.e. for $Q \neq 0$) and the wave functions of all other states corresponding to the equilibrium positions of the atoms in the ground state ($Q = 0$). The exact evaluation of these integrals is difficult owing to the incompleteness of the sets of atomic orbitals used in practice, so that the molecular orbitals corresponding to $Q = 0$ and $Q \neq 0$ are constructed in terms of different basis sets (displaced relative to one another). Under these conditions, it is generally speaking impossible to expand the function Ψ of a deformed molecule in terms of the atomic orbitals corresponding to the equilibrium molecular geometry. In order to calculate the coefficients h_{es}, it is therefore necessary to introduce a series of approximate assumptions[95]. On the other hand, direct calculation of the derivatives $\partial M^{0e}/\partial Q$ does not require the introduction of additional assumptions and is fairly easy[97].

Table 6. Calculation of the oscillator strengths of vibronic transitions ($00 \rightarrow ev$) corresponding to four vibrational modes in benzene by the CNDO/S method (the results of calculations with the aid of the Herzberg–Teller expansion described by Roche and Jaffe[95] are indicated in brackets).

IX. CALCULATION OF LINE INTENSITIES IN RAMAN SPECTRA UNDER CONDITIONS REMOTE FROM AND CLOSE TO RESONANCE

The intensity of the Raman lines and the line excitation spectra (the dependence of the intensity on the frequency of the exciting light ν) can be calculated subject to greater or smaller limitations, using the classical, semi-classical, or quantum theories. In the "polarisability theory" designed for cases very remote from resonance the line intensity I_a is determined by the set of derivatives of the components of the molecular electronic polarisability tensor α with respect to the coordinate Q_a. The polarisability theory treats α as a single-valued function of Q (and corresponds to ideas concerning a molecule with stationary nuclei in any specified positions Q) but it does not define the origin of the $\alpha(Q)$ relation. The latter is described within the framework of the semiclassical theory[101] as a consequence of the dependence on Q of (a) the Cartesian components $M^{0e}(Q)$ of the dipole moment of the electronic transition $0 \rightarrow e$ made up of the electronic wave functions $\Psi(Q)$ and (b) the frequency ν_e. The contributions of all the electronic excitation levels e are then added together (cf. the book of Tang and Albrecht[102] where incorrect information is given on this subject).

The origin of the $M^{0e}(Q)$ relation in the vibronic theory of Tang and Albrecht[102] is inferred by considering the matrix of the coefficients h_{es}, which describes the mixing of the electronic wave functions of the levels e and s when the nuclei are displaced from the equilibrium positions (see below). In the simplest case

$$M^{0e}(Q) \simeq M^{0e}(0) + Q \sum_{s \neq e} \frac{h_{es} M^{0s}(0)}{E_e(0) - E_s(0)},$$

where $E_e(0)$ and $E_s(0)$ are the molecular energies in the states e and s for $Q = 0$.[103]

All the Cartesian components $(\rho\sigma)$ of the polarisability tensor for any positions of the atomic nuclei can be calculated in terms of the adiabatic approximation of the second order perturbation theory by the formula

$$\alpha_{\rho\sigma}(Q) = \frac{1}{h} \sum_e \left[\frac{M_\sigma^{0e} M_\rho^{e0}}{\nu_e - \nu} + \frac{M_\rho^{0e} M_\sigma^{e0}}{\nu_e + \nu} \right]. \quad (8)$$

The introduction of the dependence of M^{0e} and ν_e on Q compensates to some extent the lack of summation of the contributions of the individual vibrational sublevels ev. The wave functions Ψ necessary for the calculation of the polarisability are determined by quantum-chemical methods; the derivatives with respect to Q are usually found by numerical differentiation.

Calculations of the Raman line intensity by Eqn.(8), which reflect in some form the factors of the semiclassical theory $\nu_e(Q)$ and $M^{0e}(Q)$, have been carried out for many simple molecules (H_2, Cl_2, methane, ethane, ethylene, acetylene, dimethyl ether, etc.). Analysis of the results obtained by different LCAO-MO SCF methods[26,29,70,104–110] showed that for polyatomic molecules they reproduce the distribution of intensities in a manner which is qualitatively correct but extremely approximate, and that non-empirical methods in terms of basis sets of moderate size of the type of OST-4-31GF do not result in a perceptible increase of accuracy compared with semiempirical methods.

More accurate but more laborious non-empirical calculations, using extended basis sets with polarisable orbitals and taking into account electronic correlation, have led to a very satisfactory agreement with experiment for the simplest molecules[111,112]; thus the derivatives of the polarisability of the hydrogen molecule[111] are $\alpha'_\parallel = 1.78$ and $\alpha'_\perp = 0.83$, while the corresponding experimental values are 1.69 and 0.85 respectively. The closeness to the experimental data is not surprising, since virtually exact wave functions were obtained in the relevant investigation[111]; unfortunately such calculations are virtually impossible for complex molecules.

Studies on the simplest hydrocarbons (methane and ethylene) by CNDO/2 methods resorting to the vibronic theory[113,114] led to the conclusion that the $\nu_e(Q)$ relation predominates for lines associated with symmetrical vibrations and also that the mixing of the electronic wave functions Ψ_e with the function Ψ_0 of the ground state (which is usually neglected) makes a significant contribution. However, the polarisability derivatives obtained are in poor agreement with experimental data and at the same time differ markedly from the results of the calculation within the framework of the polarisability theory. The

discrepancies with experiment are to a large extent associated with the insufficiency of information about the highest levels e and with the approximate nature of the calculation of the coefficients h_{es} from the formula of Murrell and Pople[95,115].

Regardless of the foregoing, one may state in a more general form that the application of the vibronic theory in the quantum-chemical calculations of Raman line intensities is undesirable, since the $M^{0e}(Q)$ relation can be calculated directly and much more readily and accurately without introducing the h_{es} matrix and without any additional approximations by evaluating analytically or numerically all the necessary integrals in Eqn.(8); this does not require information about all the levels s, which can be mixed with the level e. However, the calculation of h_{es} is necessary if it is required to elucidate the origin of the $M^{0e}(Q)$ relation.

Thus, in order to calculate the intensity, it is sufficient to carry out independent calculations of M^{0e} and ν_e for several values of Q and to estimate from these data their derivatives with respect to Q and then calculate the derivatives of the polarisability from the formula of the semiclassical theory. Similar calculations for ethylene in the CNDO/S valence approximation with allowance for the contributions of all the singly excited configurations[109] led to estimates of the form of the Raman line excitation spectra and by no means fully confirmed the conclusions of the study quoted above[114]; it follows from the calculations of Burshtein and Shorygin[109] that, following Raman excitation in the visible part of the spectrum, the $M^{0e}(Q)$ relation predominates for all the C–H lines, while the $\nu_e(Q)$ relation predominates for the C=C line. The main contribution for the C=C line comes from the long-wavelength electronic transitions $\pi \rightarrow \pi_1^*$, while for other lines the transitions in the region of ~1000 Å, localised predominantly at the C–H bonds, are the most significant.

Calculations of polarisability for several values of Q for each molecule require a large amount of computer time. To reduce it, it has been suggested that one calculates the derivatives with respect to the external electric field strength of the gradient (with respect to Q) of the potential energy of the molecule present in this field; these derivatives are found only for the equilibrium geometry of the molecule[116].

We may note that the calculation of the derivatives is generally speaking not obligatory; one can resort to the relation $2\alpha_{01} \cong \alpha(Q_0) - \alpha(-Q_0)$, which leads to a somewhat greater accuracy and requires the calculation of α for only two values of $Q = \pm Q_0$, where Q_0 is the zero point amplitude[117].

The use of a minimal basis set in calculations of the polarisability and intensity is fairly problematical. Some investigators[110] insist on introducing extended basis sets of atomic orbitals with inclusion of polarising atomic orbitals (2p and 3p for hydrogen atoms and d for atoms of elements in the Second and Third Periods) and diffuse orbitals. One must agree with this if one is dealing with non-empirical calculations; however, when semiempirical methods are employed, a rational selection of the parameters determining the interaction of the nuclei and electrons makes it possible to compensate to a large extent for the incompleteness of the basis set, because ultimately one needs to determine not the atomic wave functions themselves but the matrix elements calculated using these functions. Whereas in the non-empirical methods of calculation the selection of the basis set to a large extent determines the set and magnitudes of the matrix elements for the interactions of the electrons and nuclei, in semiempirical methods the selection of the basis set is less significant in this respect and the extension of the basis set is associated with a certain arbitrary element in the choice of the parameters for atomic orbitals with large quantum numbers (polarising orbitals) and at the same time does not lead to an appreciable improvement of the results; for these reasons, it is not desirable.

Instead of introducing polarising functions into the computational scheme, it is possible to introduce at some stage corrections in the form of atomic increments[75]. In principle, it is thus possible to correct, for example, the matrix elements of the interaction, but it is simpler to select polarisability increments. The latter are most significant for hydrogen atoms and they can be determined in this instance from experimental data for the H_2 molecule. In calculations using the minimal basis set (without corrections) the perpendicular components of the polarisability of H_2 and its derivative are found to be zero and their true values, determined experimentally, are used as the increments.

The principal difficulty in the calculation of the polarisability by Eqn.(8) consists in the need to calculate the parameters of all the electronically excited states—the energies, the wave functions Ψ_e, and the matrix elements M^{0e}. This difficulty can be in many instances obviated by resorting to the finite perturbation theory[104–106] or by using a variational procedure[118,119], for which it is sufficient to know the wave function Ψ_0 of the ground state. Bearing in mind that calculations by the LCAO-MO method are more accurate for Ψ_0 than for Ψ_e, under certain conditions it is possible to count on a higher accuracy of the determination of the polarisability[120].

Only the tensor of the *static* electronic polarisability can be calculated by the finite field methods in the perturbation theory. To evaluate this tensor, an electric field is introduced into the electronic Hamiltonian of the molecule. In the CNDO valence approximation it is sufficient for this purpose to add to the diagonal elements of the Fock matrix terms of the type $-eE_x x_a$ and to the non-diagonal elements of the type $-eE_x\langle s_a|z|p_{xa}\rangle$, where E is the electric field strength and s_a and p_{xa} are atomic orbitals of the s and p type of the atom a. Having calculated in this way all the Cartesian components of the dipole moment of the molecule in the ground state with (μ^*) and without (μ^0) an external field, we obtain the following expression for the specified positions of the atoms:

$$\alpha_{\rho\sigma}(Q) = (\mu_\rho^* - \mu_\rho^0)/E_\sigma.$$

The Raman line intensities for methane, ethylene, tetrachloroethylene, and other simple molecules were calculated from the polarisabilities and their derivatives found by this procedure. The calculations of μ were performed within the framework of the extended Hückel method, by the CNDO/2 and INDO methods, and also by non-empirical methods in terms of very large Gaussian basis sets with polarising functions[104–106,116].

The applications of the finite perturbation theory are not associated with cumbersome calculations and they can therefore be extended to more complex polyatomic organic molecules. The results for cyclopropenone are compared with experimental data in Fig.2.

It must be emphasised that static polarisability data can be used only when the frequency of the exciting light is very remote from ν_e; the Raman intensities calculated directly via derivatives of the static polarisability have generally speaking no physical significance although they can differ only slightly from values found for low frequencies of the exciting light ($\nu \ll \nu_e$). The latter factor justifies the application of the finite field method

in the study of the spectra of saturated hydrocarbons and certain other compounds without conjugated bonds and having absorption bands only in the far ultraviolet.

The variational method, which can be regarded as an alternative to the method of perturbation theory, makes it possible, at least under conditions remote from resonance, when $\nu \ll \nu_e$, to calculate the molecular dynamic electronic polarisability tensor without evaluating the contribution of each excited state[119,120]. Some information about these states is then introduced in the form of the wave functions of the singly and doubly excited configurations.

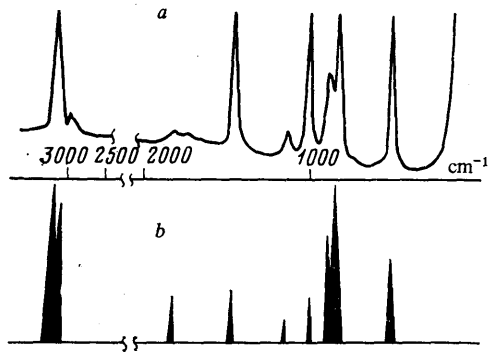

Figure 2. Raman spectra of cyclopropenone: *a*) experiment; *b*) calculation by the CNDO/2 method[105].

Within the framework of the method indicated, the sums of the first and second components of the binomial terms in Eqn.(8) are calculated by the variational procedure. Thus, in order to find the $\sigma\sigma$ component, the following expression is minimised in the first place at a specified frequency ν:

$$B_{\sigma\sigma}(Q, \nu) = \langle f|H - E_0 - h\nu|f\rangle + 2\langle\psi_0|\mu_\sigma|f\rangle, \qquad (9)$$

where f is the function to be varied, which is sought in the form of a linear combination of the wave functions of all the singly excited configurations, μ_σ the σ component of the dipole moment operator, H the electronic Hamiltonian, and E_0 and Ψ_0 are the energy and electronic wave function of the ground state, which are found by the usual quantum-chemical methods. At the minimum $f = f_0$ and $B_{\sigma\sigma}(Q, \nu)$ is close to the sum in Eqn.(8) being sought. Next the expression

$$\langle g|H - E_0|g\rangle + 2\langle g|\mu_\sigma|f_0\rangle, \qquad (10)$$

is minimised and g_0 for the function g being varied is found in the form of a linear combination of doubly excited configurations. Then

$$\frac{1}{h}\sum_e \frac{M_\sigma^{0e} M_\sigma^{e0}}{\nu_e - \nu} = B_{\sigma\sigma}(Q,\nu) + 2\langle g_0|H - E_0|\varphi_0\rangle, \qquad (11)$$

where $B_{\sigma\sigma}(Q, \nu)$ is calculated by Eqn.(9) with $f = f_0$.

Similar calculations (in each case for several values of the coordinate Q) by the CNDO/2 method enabled Svendsen and Tangaa[121] to calculate the first and second derivatives of the polarisabilities of methane, ethane, ethylene, and acetylene. An entirely satisfactory accuracy was achieved and the second order correction determined by Eqn.(10) proved to be small (≤10–20%). In addition, data were obtained for ethylene at several exciting light frequencies ν, which indicate, in conformity with the conclusions of the semiclassical theory, a faster increase of the intensity of the overtone with increase of ν; however, in the region of the resonance the calculations are merely conventional.

Selective allowance for the excited configurations in terms of the symmetry type led the authors[121] to estimates of the contributions of σ and π electrons; according to these estimates, the latter determine the polarisability of the ethylene molecule to the extent of 2/3, the derivative with respect to the symmetry coordinate of C–H to the extent of 12%, and the derivative with respect to the C=C coordinate to the extent of 95%.

The Raman line intensity corresponding to the vibrational transition $0 \to f$ is proportional to $\sum_{\rho\sigma} |(\alpha_{\rho\sigma})_{0f}|^2$ according to the quantum theory, where $(\alpha_{\rho\sigma})_{0f}$ is the Cartesian component of the electronic polarisability tensor.

When account is taken of the contributions of the sublevels ev, one can write the following equality for each tensor component:

$$(\alpha_{\rho\sigma})_{0f} = \text{const} \sum_{ev} \left[\frac{\langle 0|M_\rho^{0e}|v\rangle\langle v|M_\rho^{e0}|f\rangle}{\nu_{ev} - \nu} + \frac{\langle 0|M_\sigma^{e}|v\rangle\langle v|M_\rho^{e0}|f\rangle}{\nu_{ev} + \nu} \right], \qquad (12)$$

where 0, ν, and f are the quantum numbers of the vibrational sublevels of the ground, intermediate, and final states, M_σ^{0e} and M_ρ^{0e} are the Cartesian components of the vector of the dipole moment of the electronic transition $0 \to e$, ν_{ev} the frequency of the $00 \to ev$ transition, and ν the frequency of the incident light, which generally speaking should occur in a region far from or close to resonance with the frequency ν_{ev}. M_σ^{0e} and M_ρ^{0e} are usually regarded as functions of Q; the use of corrected quantities of the type of M^{0ev} is an alternative.

If there are many effective intermediate levels ev, it is more convenient to replace Eqn.(12) by the evaluation of the integral $\langle 00|G|0f\rangle$, where G is a Green function in which the functions Ψ_e and summation with respect to ev are used; thus one carries out initially the summation and then integration with respect to the coordinates of the electrons and nuclei[122].

The relation between the quantum and simple classical theories as regards the non-resonance Raman lines of the fundamental band can be determined by the direct proportionality between the matrix element $(\alpha_{\sigma\sigma})_{01}$ and the derivative $\partial\alpha_{\sigma\sigma}(Q)/\partial Q$. In certain investigations (including those quoted above[113,114]) the quantity $(\alpha_{\rho\sigma})_{0f}$ is set equal to the sum of the contributions of the derivatives of the polarisability with respect to all the normal coordinates Q (or the sum of the corresponding matrix elements of the polarisability), which, however, lacks any justification.

It is noteworthy that in a more sophisticated version of the classical theory the polarisability is not a single-valued function of Q and is replaced by the more general transmission function $\mathcal{K}(\nu, t)$, where t is the time; the latter includes an expression similar to Eqn.(12) with the corresponding decay constants[123].

Eqn.(12) describes the response of a system in a fixed initial position i. If a statistical description of a mixed *ensemble* of molecules and of its time variation is required, one can go over to the use of the density matrix ρ. The intensity of the secondary emission is then proportional to $\sum_i \rho_{ii} |\alpha_{if}|^2$, where the square of the modulus is averaged with respect to the *ensemble*.

The matrix elements $(\alpha_{\rho\sigma})_{0f}$ are calculated in the same way as in the calculation of the vibrational structure of the electronic transition $00 \rightarrow ev$ (see Section VIII) and requires information about the frequencies and modes of the atomic vibrations and the molecular geometry for the ground and all the excited states. The determination of these parameters is very laborious and is virtually impossible for complex molecules. For resonance Raman excitation, the treatment may be restricted to the contribution of a single electronic level e in Eqn.(12), but decay constants must be introduced.

If the linear term of the expansion of Ψ_e in series in terms of powers of Q by the Herzberg–Teller method is used for the calculation of the matrix elements $\langle 0|M^{0e}(Q)|v\rangle$ in Eqn.(12) or of M^{0e} in Eqn.(8), then we go over to the vibronic theory of Tang and Albrecht[102]. Specific calculations have not been made by Eqn.(12) within the framework of this theory and calculations by Eqn.(8) have already been described above.

The intensity of the Raman lines and the excitation spectra of these lines in the pre-resonance and resonance regions for butadiene and certain polyenes have been calculated[124] by Eqn.(12) but with allowance for only one first excited state π, π_1^*. In order to reduce the amount of computer time, the authors[124] used the approximate combined method proposed by Warshel and Karplus (see Section II) and obtained good results. They concluded that in the region of resonance the dominant Raman mechanism involves a process which, in terms of the semiclassical theory, is referred to as the modulation of the electronic transition frequency and is determined by the derivatives of ν_e.

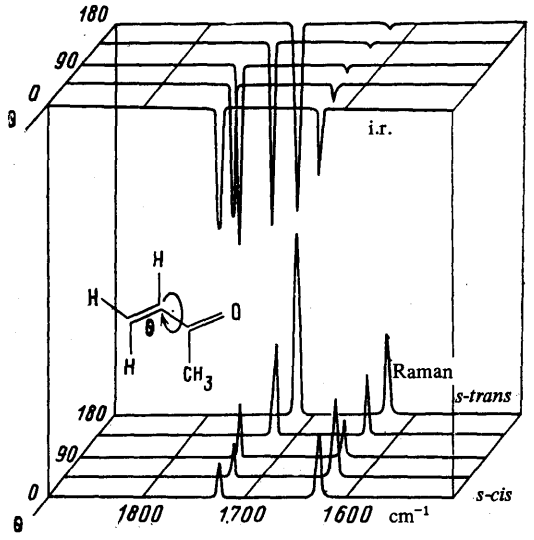

Figure 3. The line intensities associated with the stretching vibrations of the C=C and C=O bonds in the infrared and Raman spectra of methyl vinyl ketone, calculated by the CNDO/2 method[129] as a function of the angle θ of internal rotation about the central C–C bond.

The changes in the intensities of the Raman and infrared lines as well as the spectroscopic features of the conjugation of the C=C and C=O double bonds with a smooth variation of the angle of rotation θ about the C–C bond have been calculated[129] by the CNDO/2 method; the results are presented in Fig.3 (taking into account the data of other workers). The susceptibility of systems with any specified angle θ to calculation greatly extends the scope of the experiments. Other examples of calculations of the intensity have also been published[130–134].

The data presented above demonstrate the wide variety of methods used to calculate the Raman line intensities. Comparison of the results for ethylene obtained by different procedures (Table 7) shows that in most cases a satisfactory agreement with experiment was achieved; discrepancies with experiment by a factor of 2–4 have been noted for individual lines, but this accuracy is sufficient for the qualitative analysis of experimental data. In comparisons of this kind, one should bear in mind that the results of the calculation may vary by a factor of 2–3 owing to the inaccuracy of the atomic vibrational modes on which they are based.

Table 7. The relative Raman line intensities for ethylene on excitation under conditions remote from resonance in the visible region.

**Non-empirical calculation in terms of the OST-4-31G basis set.

X. CONCLUSION

The susceptibility of the electronic wave functions and of the energy of excited molecules to calculation in terms of LCAO schemes permits the invocation of molecular orbital methods in the study of virtualiy any molecular-orbital phenomena; among them, one can note also those which have begun to be investigated only in recent years, for example, the Raman-induced Kerr effect, the Raman-optical activity, simultaneous electronic (or vibrational) transitions in components of the mixture, the beats in the secondary emission of light by molecules associated with the interference of electronic states, non-linear optical phenomena, the manifestation of the anharmonic interaction of the modes and of non-adiabatic conditions, etc.

In principle, one can predict the overall form (and interpret) the absorption and emission spectra of simple molecules, complexes, ions, radicals, and molecular crystals and to infer the dependence of the spectra on the conformation, on the initial electronic state, or on additional perturbations. At the same time it is possible to refine and supplement the available information about the force field, to determine the signs of the derivatives of the polarisability and the dipole moment, to estimate

the frequencies of the unobserved transitions, to characterise the potential energy curves for excited states, etc.

The accuracy of the calculations of the spectral parameters is at present much lower than the experimental accuracy but is sufficient for the solution of many spectrochemical problems; the combination of calculated and experimental data leads to a more complete and reliable description of the spectrum.

The use of quantum-chemical methods makes it possible to increase the amount of information derivable from spectroscopic studies, to discover the principles underlying the empirical relations between the spectra and various physical and chemical properties of molecules, and to elucidate the nature of the interaction between the atomic groups in complex molecules on the basis of the idea of the interaction of electrons and nuclei.

Further advances in the application of quantum-chemical methods to spectroscopy will be evidently closely related to progress in computer techniques. The development of fast computers will extend the scope for taking into account more fully the electron correlation (particularly as a result of the inclusion of highly excited configurations in the SCF method) and will permit the abandonment of many simplifications, for example,the appreciable limitation of the size of sets of basis functions and the neglect of the contributions of the *d* and *f* atomic orbitals of the elements in the first two Periods, the empirical selection of certain parameters, the restriction to models simulating a small fragment (for example, an active centre) of a complex molecule, etc. On the other hand, one can count on considerable progress in the study of molecular systems and processes as a function of time.

It is noteworthy that compounds both with and without heavy atoms are being successfully studied in experimental spectrochemistry. The compounds with heavy atoms are not susceptible to investigation by the majority of quantum-chemical methods. The accumulation of experience in the parametrisation of such systems will undoubtedly diminish the gap between the scopes of the experimental and theoretical methods. At the same time, one may expect further successes in the development of ways of taking into account relativistic effects, which in certain systems can appreciably alter the disposition of electronic levels, the transition probabilities, and the frequencies ω; the influence of these effects increases very rapidly with increase of the effective nuclear charge and can therefore prove comparable to, for example, the result of the Coulombic interaction and can be much greater than the influence of the usual conjugation of double bonds.

Progress in the development of computational methods is closely related to the endeavour to develop more universal and more accurate but sufficiently compact versions and, on the other hand, to limit the elements of subjectivity and uncertainty, which are expressed, for example, in the selection of a variant of the computational method leading to the best result in the solution of a specific problem, in the adaptation of parameters, and in the introduction of corrections specific to a particular type. As a result of these features, the application of even non-empirical methods proved to be far from free from empirical characteristics.

The alternatives to the LCAO approximation, which resemble the usual schemes as regards their conventional aspect, are of great interest, but hitherto fairly modest advances have been made on these lines, being limited by the imperfection of the proposed schemes and the large amount of computer time required.

Bearing in mind all the data described here, one can say in conclusion that the combination of the methods of experimental spectroscopy and quantum chemistry will greatly increase the effectiveness of the studies of molecular structures and the mechanisms of chemical processes and will extend the scope of practical chemical applications of spectroscopy.

Enzyme Catalysis in Organic Synthesis

K.Martinek and A.N.Semenov

The present state of enzyme catalysis and the prospects for its introduction in organic synthesis are examined. The physicochemical approaches whereby the yield of the desired product can be increased under conditions favourable for biocatalysis (at the optimum of the catalytic activity and stability of the enzyme) are analysed. Together with classical equilibrium and kinetic preparative methods, the thermodynamic features and general methodological aspects of a new approach—enzymatic synthesis in two-phase systems comprising water and a water-immiscible organic solvent—are discussed in detail.
The bibliography includes 170 references.

I. INTRODUCTION

The application of biological catalysts (enzymes) in organic synthesis appears to be extremely promising and in many instances has a number of significant advantages over the classical methods of synthetic chemistry. This is due primarily to the fact that enzymes exhibit a unique specificity (selectivity), i.e. the reactions which they catalyse proceed as a rule via a single pathway without side processes. Furthermore, the unsurpassed catalytic activity of enzymes ensures synthesis under mild conditions. Consequently the practical application of biocatalysis might result in the saving of energy and resources and in addition might decrease the damage caused by modern chemical technology to the environment.

Despite the evident advantages of enzyme catalysis, the decisive steps in this field were outlined only the last 10–15 years. This is due, firstly, to the general progress in the study of the properties, structure, and functions of enzymes (see, for example, Refs.1–4), and, secondly, to the introduction of immobilised enzymes[5,6]. As a result of immobilisation (for example, the covalent attachment of the enzyme to a water-insoluble particle, the encapsulation of the enzyme in a gel, and the adsorption of the enzyme on a carrier), it is possible to separate the heterogeneous catalyst from the reaction medium and to use it again. Furthermore, immobilisation constitutes a method of the specific modification (improvement) of practically important properties of enzymes[5-7] and in the first place of their stability[8-11]. Thirdly and finally, enzymes have become available in large amounts in connection with the development of methods for their microbiological synthesis and isolation[12,13].

The successes achieved using biocatalysis in preparative organic synthesis as well as the likely prospects for their applications have been discussed in a number of reviews[5,6,14-27]. The vast majority of enzymatic processes have been developed only on a laboratory scale: typical examples are presented in two publications by the authors of this review[8,9]. However, certain processes have already been applied on an industrial scale[14,15].

Nevertheless there exists one factor which limits the application of enzymes in preparative organic synthesis on a wider scale. The point is that enzymes retain their unique catalytic properties only over a fairly narrow range of conditions, at neutral or nearly neutral pH and at not unduly high temperatures. However, the equilibria in many reactions of practical importance are displaced towards the initial reactants under these conditions. In other words, when biocatalysis is employed, a situation frequently arises where the conditions necessary for the retention of the catalytic properties of the enzyme are incompatible with the optimum thermodynamic conditions for the attainment of a high yield in the catalysed reaction.

The conflict between the relatively "severe" conditions under which the chemical reaction should take place and the "fragile" nature of the biocatalyst (its relatively labile structure) can be resolved in principle. One of the ways involves the stabilisation of the enzyme in relation to the inactivating influences of increased temperature, extreme pH values, organic solvents, etc. Significant advances have already been made on these lines[8-11] and the relevant studies are being continued (see, for example, Martinek et al.[16]). It is to be hoped therefore that in the future the classical approaches of preparative organic synthesis (alteration of temperature and pH, selection of reaction medium) will become common also in enzymatic reactions. This review deals with fundamentally different solutions of the given problem, namely physicochemical approaches which make it possible to increase the yield of the desired product without the stabilisation of the enzyme, directly under conditions favourably for biocatalysis.

II. EQUILIBRIUM APPROACHES

The approaches whereby the yield of the desired product (in enzyme-catalysed thermodynamically unfavourable synthetic reactions) can be improved by a shift of the chemical equilibrium will be referred to as equilibrium approaches.

1. The Method Based on the Low Solubility of the Product

The shift of the chemical equilibrium in a favourable direction may be caused by the poor solubility in water of one or several final products (under the reaction conditions), which

precipitate. The physicochemical essence of this phenomenon will be considered in relation to the reaction

$$A + B \rightleftharpoons C\downarrow (ppt). \quad (1)$$

The effective equilibrium constant $K_{eff} = [C]_{soln} + [C]_{ppt}/[A][B]$ is

$$K_{eff} = \frac{K}{[C]_{soln}} \left\{ [A]_0 (K/[C]_{soln})^{1/2} - 1 \right\}, \quad (2)$$

provided that the true equilibrium constant (in the absence of the precipitate) is given by $K = [C]/[A][B]$ and the material balance equation is of the form $[A]_0 = [A] + [C]_{soln} + [C]_{ppt}$ for $[A]_0 = [B]_0$, where $[A]_0$ and $[B]_0$ are the initial concentrations of the initial reactants, [A], [B], and [C] are the equilibrium concentrations of the reactants in solution, $[C]_{soln}$ is the maximum concentration of the dissolved product (solubility), and $[C]_{ppt}$ the concentration of the precipitated reactant (referred to the volume of the entire system). Eqn.(2) is valid only in the presence of a precipitate, i.e. for $[A]_0 > [C]_{soln} + [A] = [C]_{soln} + \{[C]_{soln}/K\}^{1/2}$.

It follows from Eqn.(2) that the shift of equilibrium(1) observed when the product precipitates should be more pronounced at high concentrations of the initial reactant and naturally for a lower solubility of the final product.

Applications. The method described is usually employed for the synthesis of the amide (peptide) linkage via the general mechanism

$$R_1COO^- + R_2NH_3^+ \rightleftharpoons R_1CONHR_2 + H_2O.$$

In this reaction the solubility of the product is as a rule significantly lower than those of the initial reactants because two charges disappear during the synthesis (see, for example, the synthesis of anilides[28-31], aminoacid phenylhydrazides[30,32,33], and oligopeptides with a specified sequence[29,30,34-43]). Various proteolytic enzymes are used as catalysts in this instance: α-chymotrypsin, trypsin (see, for example, Isowa et al.[38]), bacterial metalloproteinases[40], papain[43], etc.

Limitations of the method. The method suffers from two significant disadvantages. Firstly, the requirement for a low solubility of the final product greatly limits the choice of compounds which can be synthesised in this way[37]. In order to ensure a sufficiently low solubility of the corresponding product, sometimes the ionogenic groups in the initial reactants must be protected[36,43]. Secondly, the formation of the precipitate in the reaction hinders the application of water-insoluble enzyme derivatives as catalysts.

2. The Application of Consecutive Reactions

The yield of the reaction increases if one of the products is involved in a consecutive (enzymatic or non-enzymatic) thermodynamically favourable reaction, for example:

$$A + B \overset{K}{\rightleftharpoons} C + D, \quad (3)$$

$$D \overset{K_T}{\rightleftharpoons} F. \quad (4)$$

Since reaction (4), additionally introduced into the system, must be thermodynamically favourable, i.e. the condition $\Delta G_T < 0$ must hold, the equilibrium constant of the overall reaction $A + B \rightleftharpoons C + F$ must be greater than the equilibrium constant of the initial synthetic reaction (3):

$$K_\Sigma = \exp\left(-\frac{\Delta G^0 + \Delta G_T^0}{RT}\right) > K = \exp\left(-\frac{\Delta G^0}{RT}\right). \quad (5)$$

Reactions with formation of inorganic pyrophosphate. This method proved to be particularly fruitful in relation to reactions of the type

$$A + B \rightleftharpoons C + PP_i,$$

where PP_i is the organic pyrophosphate. Subsequent hydrolysis of the pyrophosphate, catalysed by the addition of inorganic pyrophosphatase added to the system (II),

$$PP_i \overset{II+H_2O}{\rightleftharpoons} 2P_i, \quad (6)$$

is a thermodynamically very favourable reaction; for example, at pH 7 the free energy of reaction (6) is $\Delta G_T^\circ = -5.27$ kcal mol^{-1}.[44] This ensures a significant shift of the equilibrium of the overall reaction towards the products. For example, in the synthesis of the nucleotide orotidine 5′-monophosphate (OMP) from orotic acid (OA) and 5-phospho-α-D-ribosyl diphosphate (PRPP),

$$OA + PRPP \rightleftharpoons OMP + PP_i, \quad (7)$$

catalysed by phosphoribosyltransferase, it was possible[45] to raise the yield from 54 to 100% by the introduction of the additional process (6). This method, based on the removal of the pyrophosphate side product, has been used in the enzymatic synthesis of NAD,[46] labelled galactoses[47], nucleic acids[48], and β-UDP-acetylglucosamine[49].

Regeneration of the cofactor of the enzymatic reaction. Many enzymatic reactions proceed with participation of cofactors:

$$A + Cof \overset{enzyme}{\rightleftharpoons} B + Cof', \quad (8)$$

where Cof and Cof′ are the initial and "spent" forms of the cofactor respectively[50,51]. The consumption of the cofactor greatly increases the cost of the products and ultimately restricts the wide-scale application of enzymes in organic synthesis. In recent years much effort has therefore been directed to the creation of the so-called cofactor regeneration systems. The regeneration usually takes place as a result of a coupled enzymatic or non-enzymatic reaction (or set of reactions) of the type

$$C + Cof' \rightleftharpoons D + Cof \quad (9)$$

(see the relevant reviews[6,9]). Consequently, in the regeneration of the cofactor, the yield of the product B may be determined by the equilibrium of the overall reaction $A + C \rightleftharpoons B + D$. This has been shown clearly[52] for the modification of steroids:

$$\text{steroid} + NAD \overset{K=2.6\cdot10^{-8}}{\rightleftharpoons} \text{steroid} + NADH, \quad (10)$$

(the steroid fragments are CH–OH and C=O, respectively)

catalysed by 20β-hydroxysteroid dehydrogenase.

The regeneration of the cofactor

$$NADH + \text{pyruvate} \overset{K_T=3.8\cdot10^{11}}{\rightleftharpoons} NAD + \text{lactate}, \quad (11)$$

catalysed by lactate dehydrogenase, is a thermodynamically favourable process. This is why the equilibrium of the overall process (10)–(11) is displaced towards the formation of the product, namely the keto-form of the steroid: $K_\Sigma = KK_T \approx 10^4$.

Other examples. In an analogous system with regeneration of the cofactor

$$\text{steroid} + NADH \xrightarrow{\text{20β-hydroxysteroid dehydrogenase}}$$

(steroid fragment C=O)

$$\rightarrow \text{steroid} + \text{NAD}, \quad (12)$$

$$\text{NAD} + C_2H_5OH \xrightarrow{\text{alcohol dehydrogenase}} \text{NADH} + CH_3CHO, \quad (13)$$

it was found[58] that the overall equilibrium constant is approximately unity. In order to shift the equilibrium towards the formation of the hydroxy-form of the steroid, the familiar reaction involving the strong binding of the acetaldehyde formed as a side product into the semicarbazone was used:

$$CH_3CHO + NH_2NHCONH_2 \rightleftharpoons CH_3CHNNHCONH_2 + H_2O. \quad (14)$$

Thus the additional process accompanying the synthetic reaction and responsible for the shift of the overall equilibrium to the right may be both an *enzymatic* reaction of type (6) and a *non-enzymatic* chemical reaction, for example reaction (14). In principle, this thermodynamically favourable auxiliary process can be also physical. Thus Laskowski and coworkers[54] observed the trypsin-catalysed synthesis of the peptide linkage in the active centre of the soyabean trypsin inhibitor:

$$-^{64}\text{Lys} + {}^{65}\text{Ile} \rightleftharpoons -^{64}\text{Lys}-^{65}\text{Ile} + H_2O. \quad (15)$$

The equilibrium of the synthetic reaction is displaced to the right, because the product forms a stable complex (binding constant approximately 10^8) with trypsin.

3. Enzymatic Synthesis in Water–Organic Solvent Mixtures

The synthesis of compounds such as ethers, esters, amides, and anhydrides, etc. is usually carried out by the reversal of hydrolytic reactions, so that water is one of the products:

$$A + B \overset{K}{\rightleftharpoons} C + H_2O. \quad (16)$$

Under the conditions of the enzymatic reaction (in water), the equilibria of such reactions are therefore as a rule displaced to the left as a consequence of the high concentration of the aqueous component (55.5 M).

Physicochemical (sources) of the shift of the equilibrium. Evidently the yield of the product C can be increased by reducing the concentration of water in the system, because $[C] = K[A][B]/[H_2O]$. For this purpose, it is convenient to carry out the reaction not in water but in a water–organic solvent mixture with a high content of the non-aqueous component: dimethyl sulphoxide, formamide, dimethylformamide, dioxan, acetone, ethylene glycol, glycerol, monohydric alcohols, etc. (see the relevant reviews[9,11,55]).

Together with this trivial "concentration" effect, equilibrium (16) is influenced also by factors associated with the medium, such as the change in the dielectric constant or polarity, etc. Among specific effects of this kind, the shift of the equilibrium caused by the change in the pK of the acids (and/or) bases involved in the reaction must be regarded as extremely common.

We shall consider this phenomenon in relation to the synthesis of the amide linkage:

$$\begin{array}{ccccc} R_1COOH & + & R_2NH_2 & \rightleftharpoons & R_1CONHR_2 + H_2O. \\ \downarrow\uparrow K_a & & \downarrow\uparrow K_b & & \\ R_1COO^- & & R_2NH_2^+ & & \end{array} \quad (17)$$

In water (at any pH) the equilibrium in this reaction is displaced to the left primarily due to thermodynamically favourable ionisation processes involving at least one of the initial reactants. On passing to a water–organic solvent mixture with a high content of the non-aqueous component steady shifts of the observed pK_a and pK_b take place due to both electrostatic and solvation effects[56]. As a rule the pK_a for the acid changes most significantly: it increases, i.e. the ionisation equilibrium shifts towards the uncharged form. As a result, the equilibrium of the entire reaction (17) is displaced towards the product being synthesised[57,58]. For example, on passing from water to an 85% solution of butane-1,4-diol, the equilibrium constant for the synthesis of the peptide linkage increased by a factor of 80.[57]

The systems investigated. Water–organic solvent mixtures with a high content of the non-aqueous component have been used to synthesise the ethyl and glyceryl esters of *N*-acetyl-L-tyrosine[59], urea[60], glycerophosphate[61], aliphatic acid esters[62,63], dipeptides[57,64], and human insulin[64,65], as well as for the resynthesis of the hydrolysed peptide linkage in ribonuclease[58]. An unsuccessful attempt has also been made to synthesise sucrose from glucose and fructose[66].

Limitations of the method. A significant disadvantage of the method is that, in the presence of high concentrations of organic solvents, an appreciable impairment of important characteristics of enzymes such as catalytic activity, specificity, and stability is as a rule observed (see paper of Klibanov et al.[61] and the references therein as well as Butler's review[55]). Frequent attempts have therefore been made to protect the enzyme from inactivation by organic solvents via immobilisation (see the discussion in the papers by Martinek and coworkers[67,68]). However, this approach has still not let to sufficiently stable enzyme preparations. For this reason, investigators usually select simply by trial and error conditions (organic solvent and its concentration) such that the shift of the equilibrium towards synthesis is sufficient and at the same time an appreciable inactivation of the enzyme is not observed.

In contrast to these empirical approaches, a criterion, based on scientific principles, has been recently formulated[61] for the selection of the organic solvent as the component of the medium in enzymatic (including synthetic) reactions. Nevertheless, even under optimum conditions, it is not possible to reduce the concentration of water in the system by a factor greater than 10–20, which naturally restricts the scope of the method.

Criterion for the selection of the optimum solvent (from the standpoint of its influence on the enzyme). Such a criterion can be justified on the basis of general ideas concerning the relative role of the forces maintaining the native structure of the protein molecules in aqueous solutions: "hydrophobic interactions" play a dominant role[69,70] (despite recent doubts[71,72]). Consequently, a "good" solvent for the protein should not affect such interactions.

In order to answer the question which solvents have this property, we turned[61] to the results obtained for the information of micelles by surfactants in various solvents. Thus Ray[73] concluded that hydrophobic interactions constitute merely a special case of solvophobic interactions.

In terms of their capacity to undergo solvophobic interactions, all solvents can be divided into three classes: the first class includes water, glycerol, ethylene glycol, aminoethanol, formamide and certain others, the second class includes methylformamide and dimethylformamide, and the third includes methanol, ethanol, and toluene. Solvophobic interaction occur to the greatest extent in the solvents belonging to the first class (thus detergent micelles are formed only in these solvents); they are manifested much less in the solvents of the second class and are virtually

absent in solvents of the third class. According to Ray[73], this difference is caused by the fact that solvents of the first class contain in their molecules at least two or three fragments capable of forming hydrogen bonds. As a result of intermolecular interactions, hydrogen bonds give rise to rigid (thermodynamically unfavourable) skeletal solvent structures around the solvophobic solute molecules. This leads to solvophobic (or, in the special case of water, hydrophobic) interactions. In a series of solvents of the first class solvophobic interactions occur most effectively (this has been inferred from the critical micelle-formation concentrations) in water and glycerol; in the remaining solvents this capacity is significantly smaller.

These data enabled us to formulate[61] a criterion for the selection of the optimum solvent. The criterion is universal, because the effectiveness of solvophobic as well as hydrophobic[74] interactions is not determined by the nature of the interacting molecules but depends primarily on the nature of the solvent. Consequently, if it is assumed that the main role in the maintainence of the structure of the protein molecules is that of hydrophobic interactions, one must recognise that the best solvents for enzymatic reactions must be those of the first class and among them water (which is used in nature) and glycerol. In this connection it is appropriate to mention that in certain studies it has indeed been found experimentally that solvents of the first class, particularly glycerol and to a lesser extent ethylene glycol, denature proteins to a much lesser extent than others. This empirical finding has found a physicochemical explanation[61,73].

In order to confirm the above views, we investigated[61,75] the dependence of the catalytic activities of certain enzymes (acid phosphatase, α-chymotrypsin, formate dehydrogenase, and penicillin amidase) on concentration in aqueous solutions of certain organic solvents. It was found[61,75] that glycerol and ethylene glycol (which belong to the first class) inactivate enzymes to a lesser extent than dimethylformamide (second class) or ethanol (third class). The same conclusion follows from a comparative study carried out recently by Butler[55] on acid phosphatase in aqueous solutions of ethylene glycol (first class) and methanol (third class). These facts are in good agreement with the concept developed by ourselves[61], according to which the native structure of protein molecules (and hence their catalytic activity) are maintained in those solvents which are capable of solvophobic interactions. At the same time one should note that the three-dimensional structure of protein molecules is maintained not only by hydrophobic interactions but also by other types of bonding—electrostatic or hydrogen, etc.[69]; therefore the replacement of water by another solvent cannot be totally "ignored" by the protein. This also probably explains the decrease of the catalytic activity at an unduly high glycerol concentration[61,75] (see also the discussion of the criteria for the selection of the solvent in Butler's review[55]). Nevertheless, in many instances water–glycerol mixtures (or mixtures of water and a solvent of the first class) are entirely suitable as media for synthetic reactions[59,61,76–82]. We shall consider one example.

Enzymatic synthesis of glycerophosphate. In water (at pH 5) the equilibrium constant "does not favour" the synthesis of glycerophosphate[83]. For example, at glycerol and inorganic phosphate concentrations of 2 mM the yield of glycerophosphate should be approximately only 0.01%. The situation is different in 95% glycerol. Fig.1 (curve 3) illustrates the kinetics of the accumulation of glycerophosphate in its enzymatic synthesis from glycerol and phosphate[61]. The same level of glycerophosphate in the system can be reached also in the solvolysis of α-glycerophosphate (curve 1) or β-glycerophosphate (curve 2) by acid phosphatase, which shows that the level of accumulation of glycerophosphate attained corresponds to true thermodynamic equilibrium in the system and is not limited, for example, by the inactivation of the enzyme in the water–organic solvent mixture. Fig.1 shows that the yield of glycerophosphate in 95% glycerol is approximately 35%, which is entirely acceptable for preparative purposes.

III. NON-EQUILIBRIUM (KINETIC) APPROACHES

In certain cases it is possible to attain a concentration of the desired product so high that it does not correspond to the thermodynamic state of the system and arises and persists for a specific time as a result of purely kinetic factors. This approach is widely used to increase the yield of products in enzyme-catalysed thermodynamically unfavourable synthetic reactions.

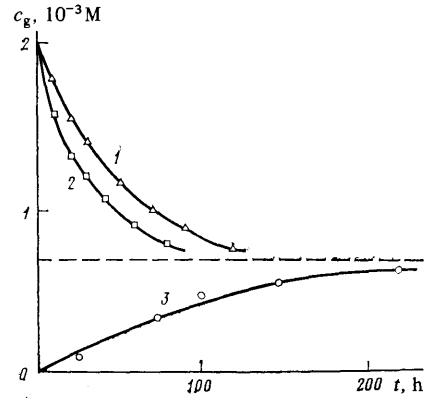

Figure 1. Kinetic curves for the acid phosphatase-catalysed hydrolysis (curves *1* and *2*) and synthesis (curve *3*) of glycerophosphate in 95% glycerol (c_g = glycerophosphate concentration): 1) α-glycerophosphate; 2) β-glycerophosphate. The dashed line represents the equilibrium glycerophosphate concentration[61].

1. Transfer Reactions Catalysed by Hydrolytic Enzymes

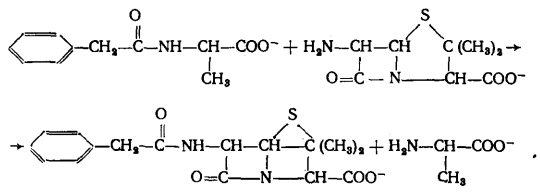
If the equilibrium in the reaction

$$\text{Acyl—OH} + \text{Nucl—H} \rightleftharpoons \text{Acyl—Nucl} + \text{H}_2\text{O}$$

is displaced towards the initial reactants, the yield of the product Acyl–Nucl can be increased significantly with the aid of the kinetic procedure described above.

The essential physicochemical nature of the method. For example, suppose that it is necessary to synthesise a derivative Acyl–X, which, together with the inevitable hydrolysis, can interact effectively with a nucleophile (Nucl–H):

$$\begin{array}{l} \text{Acyl—X} \xrightarrow{\text{H}_2\text{O}} \text{Acyl—OH} + \text{HX}, \\ \quad -\text{XH}\downarrow\ +\text{Nucl—H} \\ \text{Acyl—Nucl} \xrightarrow{\text{H}_2\text{O}} \text{Acyl—OH} + \text{Nucl—H}. \end{array} \qquad (18)$$



The desired product Acyl–Nucl will then be formed in the reaction mixture as an intermediate, which subsequently hydrolyses. Evidently the time variation of the concentration of the intermediate Acyl–Nucl should be represented by a curve with a maximum (see the kinetics of consecutive reactions[84]). It is important that, for certain ratios of the concentrations of the reactants and the rate constants for the individual stages, the maximum concentration of Acyl–Nucl may prove to be significantly higher than the equilibrium value.

We shall consider reaction (18) in greater detail under catalytic conditions (with participation of a hydrolase). The mechanism of catalysis by many enzymes of the class of hydrolases includes the formation of an intermediate covalent compound comprising the acyl component of the substrate and the enzyme—the acylenzyme[3,85]. In subsequent stages the acylenzyme decomposes under the influence of water with regeneration of the catalytically active enzyme (E) and the formation of the corresponding acid [stages (I) and (II)]:

$$\begin{array}{l} \text{Acyl–X} \xrightarrow[-\text{X}]{\text{E; (I)}} \text{Acyl–E} \xrightarrow[-\text{E}]{\text{H}_2\text{O; (II)}} \text{Acyl–OH} \\ \qquad\qquad -\text{E}\downarrow\ (\text{III})\ \uparrow +\text{Nucl} \qquad\qquad \text{H}_2\text{O}\uparrow\ (\text{V})\ \downarrow -\text{E} \\ \text{Acyl–Nucl} \xrightarrow[-\text{Nucl}]{\text{E; (IV)}} \text{Acyl–E} \end{array} \qquad (19)$$

However, when a nucleophile (Nucl), capable of competing effectively with water, is present in the system, there is a possibility of a parallel reaction [(I) and (III)] and the intermediate Acyl–Nucl will be formed in the reaction mixture and will be subsequently hydrolysed enzymatically in stages (IV) and (V).[3,86]

The kinetics of the accumulation and hydrolysis of the product Acyl–Nucl are described by a system of differential equations which cannot be solved in the general case in an analytical form and its solution requires the application of numerical integration methods on a computer. The kinetics of the enzymatic transfer of the acyl residue to the nucleophile have been investigated in very great detail[87,88]. Fig. 2 shows as an example how benzylpenicillin accumulates in the reaction mixture in its synthesis from phenylacetylglycine and 6-aminopenicillanic acid:

(20)

The reaction was catalysed[87] by penicillin amidase. Fig. 2 shows that the concentration of the product at the kinetic optimum greatly exceeds the equilibrium level (dashed line).

For the further development of the given kinetic method, it is important that the experimental results are fully described by the theoretical curve plotted using kinetic and equilibrium constants determined from independent experiments[87,88], which leads to the possibility of predicting the maximum yield and hence of optimising the synthetic process.

Application. Botvinnik and coworkers were some of the first investigators to apply the above method in the stereospecific synthesis of oligopeptides with a specific sequence (using α-chymotrypsin as the catalyst)[89,90]; later, the synthesis of peptides was investigated in detail by Japanese workers[91,92]. The method has also been used for the penicillin amidase-catalysed synthesis of β-lactam antibiotics[87,88,93], phosphatidylserine[94], and phosphatidylethanolamine[95] (using phospholipase as the catalyst).

Limitations of the method and prospects. The application of the method is limited by the fact that it is necessary to select (and synthesise) an initial substrate Acyl–X which is hydrolysed fairly slowly via the catalytic pathway (II) [see reaction (19)] and reacts vary effectively (rapidly) with the added nucleophile [stage (III)]. The maximum yield of the product Acyl–Nucl is also limited by its subsequent hydrolysis [stages (IV) and (V)]. In principle, both these hydrolytic "obstacles" to the given method can be at least partially suppressed by carrying out the synthesis under conditions ensuring the precipitation of the product[89–92]. In future investigations an attempt may be made to reduce the undesirable hydrolysis of the initial reactant Acyl–X and the product Acyl–Nucl by carrying out the synthesis in a water–organic solvent mixture, with a high content of the non-aqueous component, rather than in water. For the same purpose, to increase the kinetically controlled yield, the application of two-phase systems comprising water and a water-immiscible organic solvent can also prove useful (see below).

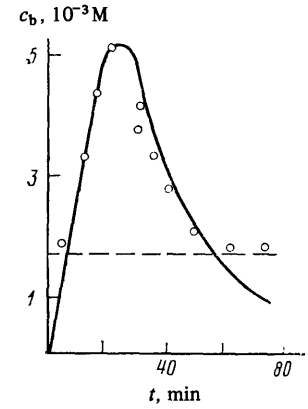


Figure 2. Kinetic curve for the accumulation of the product in the synthesis of benzylpenicillin (c_b = benzylpenicillin concentration) from phenylacetylglycine and 6-aminopenicillanic acid catalysed by penicillin amidase. Circles—experimental data; continuous curve—the result of the solution of a system of differential equations by numerical integration on a computer[87].

2. Kinetically Controlled Equilibrium

An extremely interesting phenomenon has been observed recently[96]: the hydrolysis of the ethyl ester of *N*-acetyl-L-tyrosine catalysed by α-chymotrypsin immobilised on charged carriers (Sephadexes) does not go to completion at pH 8 (only to the extent of 60–90% depending on the conditions). Furthermore, the synthesis of the ester from the corresponding acid and alcohol takes place under the same conditions (in water in the presence of an enzyme immobilised on a carrier):

$$\text{N–Acet–}L\text{-TyrOH} + \text{EtOH} \rightleftharpoons \text{N–Acet–}L\text{-TyrOEt} + \text{H}_2\text{O}$$

(Fig. 3). As a result, it is possible to attain the same composition of the reaction mixture both from the side of synthesis and from the side of hydrolysis. This limiting composition does not change for a long time. At the same time, the above

state of the system does not correspond to the true thermodynamic equilibrium. Thus, when a certain amount of free (non-immobilised) enzyme is added to the system, the concentration of the ester falls almost to zero.

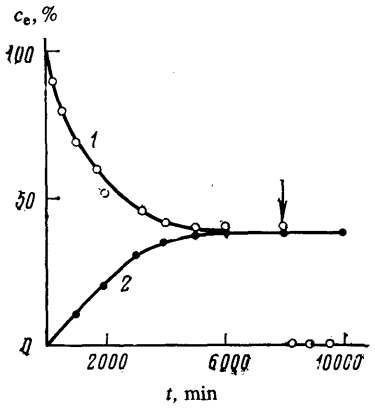

Figure 3. Kinetic curves for the hydrolysis (curve *1*) and synthesis (curve *2*) of the ethyl ester of *N*-acetyl-L-tyrosine (c_e = ester concentration) catalysed by α-chymotrypsin immobilised on charged carriers (sephadexes). The arrow denotes the instant of the addition of the non-immobilised enzyme[96].

It is believed[96] that the phenomenon is associated with the fact that the free energy of the chemical reaction changes in the electrical double layer (EDL) on the surface of the carrier (relative to the free energy of the same reaction in the absence of the electric field) due to the orientation energy of the reactant dipoles. Ultimately it may turn out that within the EDL the reaction equilibrium favours the synthesis of the product to a greater extent than in water. Naturally the volume of the EDL on the surface of the carrier constitutes only a fraction of the total volume of the system and the shift of the equilibrium in it should have a very insignificant effect on the overall equilibrium composition of the reactants throughout the entire system. However, if the rates of reaction in the bulk phase of the system are low compared with the corresponding rates in the EDL, i.e. if the reaction equilibrium in the entire system is established solely via the EDL, the observed equilibrium composition of the reactants may be kinetically controlled by the equilibrium of the reaction in the electrical double layer. This is why the authors[96] proposed the term "kinetically controlled equilibrium" for phenomena of this kind.

The kinetic control of the equilibrium can be achieved, for example, *catalytically* if the catalyst is incorporated within the EDL. In this case the rate of reaction within the EDL is naturally higher than in the bulk phase of the system and for this reason (if the equilibrium within the EDL favours synthesis) it is possible to achieve a fairly high yield of the product, which naturally does not correspond to equilibrium in the bulk phase of the entire system. This situation is believed[96] to occur precisely in the example discussed above.

From the same standpoint, it is apparently possible to explain also the finding that the hydrolysis of the same substrate (the ethyl ester of *N*-acetyl-L-tyrosine) takes place only to the extent of 60% when the reaction is catalysed by α-chymotrypsin immobilised on a spiropyran matrix[97]; the synthesis from the acid and alcohol takes place correspondingly to the extent of 40% (Fig.4). It is of interest to note that this effect occurs only under illumination; in the dark the synthetic reaction does not occur, while the hydrolysis proceeds to the extent of 100%. Fig.4 shows that, as a consequence of this, there is a possibility of regulating the position of the "kinetically controlled equilibrium" with light. Japanese workers explain this phenomenon by the fact that the properties of the matrix, which apparently determine the chemical reaction equilibrium near or within it, are different in the dark and in the light[97].

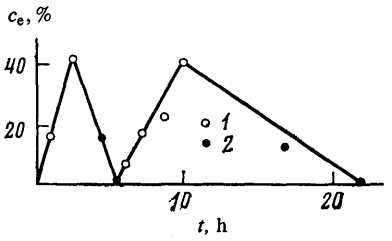

Figure 4. Kinetic curves for the synthesis (curve *1*) and hydrolysis (curve *2*) of the ethyl ester of *N*-acetyl-L-tyrosine catalysed by α-chymotrypsin immobilised on a spiropyran matrix: 1) illuminated system; 2) system in the dark[97].

Both systems were discovered quite recently (they were reported in 1978 and 1979 respectively), have been comparatively little investigated (the mechanism and reaction of the second system are still not entirely clear), and it is therefore difficult to assess their advantages and disadvantages and also the potential possibilities of their applications in enzymatic organic synthesis.

IV. ENZYMATIC SYNTHESIS IN TWO-PHASE SYSTEMS COMPRISING WATER AND A WATER-IMMISCIBLE ORGANIC SOLVENT

Each of the methods described above, which makes it possible to displace the equilibrium (or in the general case to increase the yield of the desired product) in enzyme-catalysed thermodynamically unfavourable synthetic reactions, is applicable in only a limited number of instances. An equilibrium approach has been proposed recently, which apparently constitutes a more general solution of the problem. Its essential feature is that the reaction is carried out in a two-phase system water–water-immiscible organic solvent[67,68]. The enzyme is present in the aqueous phase and it is therefore unnecessary to solve the traditional problem of stabilising the enzyme with respect to denaturation by the organic solvent. The added substrates, dissolved in the organic phase, diffuse from the latter into water, react chemically under the influence of the enzyme, and the products diffuse from water back to the organic phase. Thus, the thermodynamic equilibrium in the given reaction is established throughout the water–organic solvent system via water (with the aid of the enzyme present in water). The volume fraction of the organic phase can be in principle as close to unity as is necessary (the water content must be only sufficient to dissolve the required amount of the enzyme with retention of catalytic activity). Consequently the equilibrium conditions

in such a system can be as close as required to the equilibrium in the pure organic medium.

An enzymatic two-phase system can be created either in the form of two immiscible layers, or as an emulsion of an aqueous solution of the enzyme in the organic phase, or, finally, by the incorporation of the enzyme in the inverted micelles of the surfactant[16,98] (see also the relevant reviews[8-11]) or in liquid membranes[99]. However a suspension of particles (porous glass or ceramic, whole fibres, gel grains, microcapsules, etc.) impregnated with an aqueous solution of the enzyme is much more convenient for technological purposes. The enzyme can be used in both free and immobilised states.

The essential physicochemical features of the shift of the chemical equilibrium. On passing from water (as the reaction medium) to a two-phase system with a low content of the aqueous component, a significant shift of the chemical equilibrium was observed[67,68]. One of the causes of the shift of the equilibrium, observed in reactions of the type $A + B \rightleftharpoons C + H_2O$ (where one of the products is water) is self-evident; this is a concentration effect due to the decrease of the concentration of the aqueous reactant in the two-phase system. However, there exists yet another more general source of the shift, namely the change in the effective equilibrium constant as a result of the partition of the reactants between the phases. We shall consider the quantitative characteristics of this phenomenon in relation to certain simple reactions.

The reaction $A \rightleftharpoons B$. In a two-phase system the reactants are partitioned between water and the organic solvent:

$$\begin{array}{ccc} (A & \xrightleftharpoons{K_w} & B)_{aq} \\ \Big\uparrow P_A & & \Big\uparrow P_B \\ (A & \xrightleftharpoons{K_o} & B)_{org} \end{array} \qquad (21)$$

Here the subscripts w and o refer respectively to water and the organic solvent. The effective equilibrium constant of reaction (21), which is equal to the ratio of the overall concentrations of reactants A and B referred to the volume of the entire two-phase system, i.e. $K_{eff} = [B]_{tot}/[A]_{tot}$, can be formulated as follows[100-102]:

$$K_{eff} = K_w \frac{1 + \alpha P_B}{1 + \alpha P_A}, \qquad (22)$$

or

$$K_{eff} = K_o \frac{1 + 1/\alpha P_A}{1 + 1/\alpha P_B}, \qquad (23)$$

where K_W and K_O are the equilibrium constants of reaction (21) in water and in the organic solvent respectively, $\alpha = V_o/V_w$ the ratio of the volumes of the organic and aqueous phases, $P_A = [A]_o/[A]_w$ and $P_B = [B]_o/[B]_w$ are the partition coefficients of the reactants between the phases.

Eqn.(22) shows that K_{eff} changes monotonically with increase of α, namely, depending on the choice of the organic solvent, it can either increase (for $P_A < P_B$) or decrease (for $P_A > P_B$). For fairly high values of α (when the content of the aqueous phase is extremely low), the equilibrium constant tends to a limit $K_W P_B/P_A \equiv K_O$. The partition coefficients of organic compounds between water and commercially available organic solvents are usually between 10^{-4} and 10^4.[103,104] Consequently the limiting shift of the equilibrium (K_{eff}/K_w) can be very considerable in principle.

As an example we shall consider the oxidation of isobutyl alcohol catalysed by alcohol dehydrogenase:

$$\begin{array}{ccc} \{(CH_3)_2CHCH_2OH + NAD \rightleftharpoons (CH_3)_2CHCHO + NADH\}_{water} & & \\ \Big\downarrow P_{alcohol} \qquad\qquad \Big\downarrow P_{aldehyde} & & \\ \{(CH_3)_2CHCH_2OH \qquad\qquad (CH_3)_2CHCHO\}_{org} & & \end{array}$$

This reaction has been thoroughly investigated in water[105]. In a two-phase system[100-102] the position of the equilibrium in this reaction is described by an equation analogous to Eqn.(22), because the cofactor employed does not pass from water to the organic solvent in either the oxidised or in the reduced form (being electrostatically charged).

Consequently the partition coefficients of NAD and NADH are virtually zero. Thus

$$K_{eff} \simeq K_w \frac{1 + \alpha P_{aldehyde}}{1 + \alpha P_{alcohol}}. \qquad (24)$$

The experimental results are presented in Fig.5. Two factors should be noted for the system considered. Firstly, the reaction investigated constitutes a system in which the difference between the hydrophobic properties of the initial and final reactants is very slight. Thus in the water–octanol classical system the partition coefficients of the aldehyde and alcoholic groups differ only by 12%.[103] Nevertheless, it is possible to select a solvent (see Fig.5) such that the partition coefficients of the initial and final reactants differ fairly considerably (for example, due to specific solvation effects). As a result, by varying the nature of the organic phase, it was possible to alter the effective equilibrium constant within very wide limits (by a factor of approximately 100). Secondly, Fig.5 shows that the theoretical curve *1* [plotted on the basis of Eqn.(24) using the partition coefficients of isobutyl alcohol and isobutyraldehyde found in an independent experiment] is in satisfactory agreement with experiment.

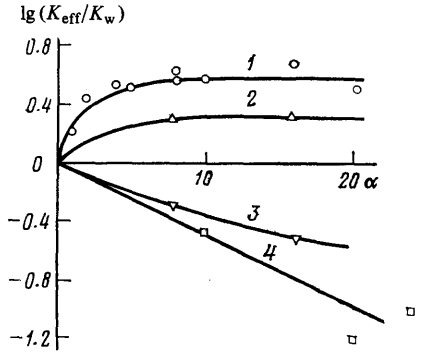

Figure 5. Dependence of the effective constant (K_{eff}) of the reaction involving the oxidation of isobutyl alcohol to isobutyraldehyde catalysed by alcohol dehydrogenase in a two-phase water–organic solvent system on the phase volume ratio α and on the composition of the ethyl acetate–hexane organic phase (ethyl acetate, %): 1) 0; 2) 12.5; 3) 50; 4) 100 (Semenov et al.[100,101]).

The reaction $A + B \quad C + D$. The dependence of the effective equilibrium constants on the ratio of the volumes of the organic and aqueous phases (α), i.e.

$$K_{eff} = K_w \frac{(1 + \alpha P_C)(1 + \alpha P_D)}{(1 + \alpha P_A)(1 + \alpha P_B)}, \qquad (25)$$

is more complex[100-102] than for the previous first-order reaction. Typical instances are presented in Fig.6.

The limiting shift of the equilibrium observed in a two-phase system in the presence of an extremely low water content can be in principle even greater than in the simple reaction A ⇌ B (see above). This is evident because the expression for the limiting shift $K_{eff}/K_w = P_C P_D / P_A P_B$ (at $\alpha \to +\infty$) includes a large number of partition coefficients. However, a more important feature of chemical equilibria involving second order reactions is that the dependence of K_{eff} on α for specific ratios of the partition coefficients can have an extremum (Fig.6). In other words, in a system of two immiscible solvents the effective equilibrium constant may be greater (or correspondingly smaller) than the limiting values characterising the equilibria in each phase. This factor must be taken into account in selecting the optimum conditions for the chemical synthesis (for further details, see below).

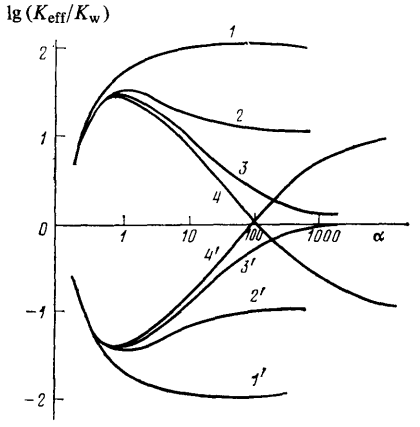

Figure 6. Dependence of K_{eff} for a reaction of the type A + B ⇌ C + D in a water–organic solvent two-phase system on α for certain values of the partition coefficients: 1)–4) $P_A = P_B = 1$, $P_C = 10^2$ [P_D: 1) 1; 2) 10^{-1}; 3) 10^{-2}; 4) 10^{-3}]; 1')–4') $P_C = P_D = 1$, $P_A = 10^2$ [P_B: 1') 1; 2') 10^{-1}; 3') 10^{-2}; 4') 10^{-3}] (Taken from Refs.100–102).

The essential physicochemical nature of this phenomenon (the presence of an extremum) can be discovered very clearly in relation to the following example. We shall assume that the initial reactants are distributed between the phases in such a way that one of them (A) is located fully in one of the phases (water), while the other (B) is located fully in the other (organic solvent). Then the reaction equilibrium in the two-phase system is completely displaced to the left ($K_{eff} = 0$) whatever the equilibrium constant in each phase separately. The reason for this is evidently that the reactants A and B, being separated in space, cannot interact. On the other hand, the equilibrium is fully displaced to the right ($K_{eff} \to \infty$ regardless of the final equilibrium constants in a particular phase) if the final products prove to be completely separated from one another, i.e. when one of the products (for example C) is concentrated entirely in water, while the other (D) passes to the organic solvent.

The extremum of the equilibrium in the two-phase system has been observed experimentally (by varying the ratio of the volumes of the aqueous and organic phases) in relation to the α-chymotrypsin-catalysed synthesis of the ethyl ester of *N*-benzoyl-L-phenylalanine (from ethanol and the corresponding acid)[100-102]. In water the yield of the ester is negligible[106,107]. At the same time in a two-phase system (for the optimum ratio of the volumes of water and the organic solvent) the yield was 80, 64, 62, and 26% for chloroform, benzene, carbon tetrachloride, and diethyl ether respectively[100-102]. Thus, as a result of using two-phase systems, it is possible to increase the yield of the ester virtually from zero to a preparative level.

Decrease of the concentration of the aqueous reactant. In reactions such as the synthesis of ethers, esters, amides, peptides, etc. of the type A + B ⇌ C + H_2O one of the products is water. Therefore in aqueous solution their equilibrium is displaced towards the initial reactants as a consequence of the high concentration of water in the system (55.5 M). On passing to two-phase systems, the water content diminishes; as a result of this, the yield of the product C should in principle increase.

However, one should bear in mind that in a two-phase system the yield of the product C depends on the concentration of water in two ways: not only via the Law of Mass Action, i.e. $[C]_{tot} = K_{eff}[A]_{tot}[B]_{tot}/[H_2O]_{tot}$, but also via the equilibrium constant determined by a function of the type of (25) and hence depending on α. Ultimately we have[100-102]

$$[C] = K_{eff}\frac{[A][B]}{[H_2O]} = K_w\frac{[A][B](1+\alpha P_C)(1+\alpha)}{55.5(1+\alpha P_A)(1+\alpha P_B)}. \quad (26)$$

According to this equation, the dependence of [C] on α can be very complex (Fig.7). In particular, for certain ratios of the partition coefficients there is actually a decrease of the yield of the product C with decrease of the concentration of the second product (water) in the system. This is because the effective equilibrium constant diminishes to a greater extent with increasing α than the overall concentration of water in the system [see Eqn.(26)].

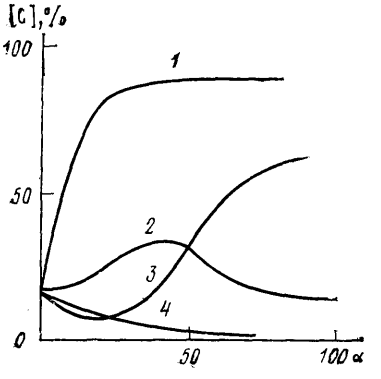

Figure 7. Dependence of the yield of the product C in a reaction of the type A + B ⇌ C + H_2O in a two-phase water–organic solvent system on α for the following partition coefficients: 1) $P_A = P_B = 1$, $P_C = 50$; 2) $P_A = P_B = 0.1$, $P_C = 0.01$; 3) $P_A = 10$, $P_B = 0.01$, $P_C = 1$. 4) $P_A = P_B = 1$, $P_C = 0.1$; it was assumed that $K_W = 10$ (from Martinek et al.[102]) in all cases.

The shift of ionic equilibria. The occurrence of many reactions involves the ionisation of the reactants, for example,

$$\left.\begin{aligned} HA + B &\underset{K'_{eq}}{\overset{K_{eq}}{\rightleftharpoons}} C + D, \text{ where } HA \overset{K_a}{\rightleftharpoons} H^+ + A^- \\ A + B &\underset{K'_{eq}}{\overset{K_{eq}}{\rightleftharpoons}} C + D, \text{where } B + H^+ \overset{K_b}{\rightleftharpoons} BH^+. \end{aligned}\right\} \quad (27)$$

On passing from water to two-phase systems, a change is to be expected not only in the equilibrium constant of the chemical reaction proper (K_{eq}) but also in the equilibrium constants of the ionisation processes (K_a or K_b). As a result, the shift of the equilibrium of the overall process will be evidently determined by the changes in all the constants and will therefore depend on the pH.

In this Section we shall analyse the physicochemical causes of the changes in the constants of ionic equilibria in two-phase water–organic solvent systems relative to aqueous solutions and we shall also consider the possibilities arising in this instance for increasing the yield of products in enzyme-catalysed thermodynamically unfavourable synthetic reactions.

We shall consider, for example, the ionisation of an acid in a two-phase water–organic solvent system[108,109]:

$$\begin{array}{l}(HA \underset{}{\overset{K_a}{\rightleftharpoons}} H^+ + A^-)_{aq} \\ \downarrow\uparrow P_{HA} \\ (HA)_{org}\end{array} \quad . \tag{28}$$

Here we shall assume that virtually only the uncharged form of the acid or base dissolves in the organic phase. This hypothesis is as a rule valid (see for example, Leo et al.[103]). The only exceptions are the highly polar solvents which are capable of extracting from water charged compounds in the form of ion pairs[110].

The ionisation constant of an acid in a two-phase system will be defined in the usual way by the Henderson–Hasselbach equation:

$$(pK_a)_{eff} = pH - \lg \frac{[A^-]_{tot}}{[HA]_{tot}},$$

where $[A^-]_{tot}$ and $[HA]_{tot}$ are the overall concentrations of the ionised and unionised forms of the acid respectively, calculated relative to the volume of the entire two-phase systems, and the pH characterises the aqueous phase. We then have[108,109]

$$(pK_a)_{eff} = pK_a + \lg(1 + \alpha P_{HA}). \tag{29}$$

Similarly for the protonation of a base B in a two-phase system we have

$$\begin{array}{l}(B + H^+ \underset{}{\overset{K_b}{\rightleftharpoons}} BH^+)_{aq} \\ \downarrow\uparrow P_B \\ (B)_{org}\end{array} \tag{30}$$

and we obtain[108,109] the following expression for the effective equilibrium constant:

$$(pK_b)_{eff} = pK_b - \lg(1 + \alpha P_B). \tag{31}$$

Thus in two-phase water–organic solvent systems, the pK_a for the acid increases by an amount $\lg(1 + \alpha P_{HA})$ and the pK_b for the base decreases correspondingly by an amount $\lg(1 + \alpha P_B)$. The partition coefficients of organic acids and bases can reach[103,104] (10^2–10^4). Consequently, in a system containing, for example, 1 vol% of water ($\alpha = 100$) the shift of the effective pK can amount to 4–6 pH units.

The ionisation equilibria of the model compounds 2,4-dinitrophenyltryptophan (acid) and Neutral Red(base) have been investigated[108] in two-phase water–organic solvent systems. It has been shown that, firstly, the effective pK in such systems is indeed displaced relative to aqueous solutions and the experimental shift reaches five or more pH units. Secondly, the experimental dependence of $pK_{b,two\text{-}phase}$ of Neutral Red on α is described satisfactorily by the theoretical curve based on Eqn.(31) using the partition coefficient P_B found in an independent experiment.

We shall now consider how the shift of the pK of the reactants can influence the equilibria of the chemical reactions occurring in two-phase water–organic solvent systems and what possibilities arise in this instance for increasing the yield of the desired product.

The attainment of the coincidence of the pH optima of the efficiency of the catalyst and of the equilibrium of the catalysed reaction. The situation frequently arises where the pH optimum of the stability and catalytic activity of the enzyme is significantly removed from the pH values which favour thermodynamically the synthesis of the given product. As an example, one may point to the synthesis of β-lactam antibiotics (the thermodynamic pH optimum is in the range 3–5),[88] 4-p-nitroanilides (with a pH optimum of 2–3), and esters of *N*-substituted aminoacids whose synthesis is favoured by pH values below 3.[106,107,111] At the same time the majority of enzymes capable of catalysing these synthetic reactions (penicillin amidase, trypsin, α-chymotrypsin, and other proteases) are active and stable only at neutral (or nearly neutral) pH. This contradiction can be resolved by employing two-phase water–organic solvent systems rather than water as the reaction medium.

As an example, we shall consider the synthesis of the ethyl ester of *N*-benzoyl-L-phenylalanine catalysed by α-chymotrypsin:

$$\begin{array}{l}R{-}COOH + EtOH \rightleftharpoons R{-}COOEt + H_2O \\ \downarrow\uparrow K_a \\ R{-}COO^-\end{array} \tag{32}$$

Fig.8 illustrates the pH dependence of the equilibrium constant of this reaction in water (curve *1*).[106] Evidently the synthesis is favoured only by pH values below 3, while at neutral and nearly neutral pH (i.e. under the conditions where α-chymotrypsin functions) the equilibrium is almost wholly displaced towards the initial substances; the fact that one of the reactants (the acid) is dissociated under the given conditions plays a significant role in this instance. Thus in water the enzymatic reaction is of no preparative value.

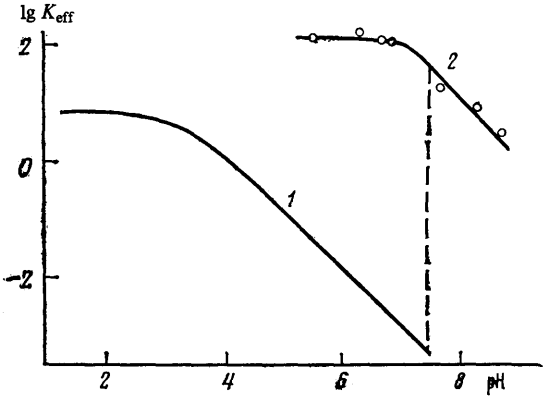

Figure 8. pH dependence of the equilibrium constant of the reaction involving the synthesis of the ethyl ester of *N*-benzoyl-L-phenylalanine in water (curve *1*) and in the chloroform—5 vol.% of water two-phase system (curve *2*)[108,112].

On passing to two-phase water–organic solvent systems[108,112,113], the effective pK_a for the acid increases [see Eqn.(29)], so that the pH dependence of the equilibrium constant shifts towards neutral or alkaline pH. Fig.8 illustrates the pH dependence of the equilibrium constant of reaction (32) in the chloroform +5 vol.% of water two-phase system (curve *2*).

Evidently, compared with aqueous solutions, the pK for the acid has increased by more than three units (see the shift of curve *2* to the right along the abscissa axis compared with curve *1*). As a result, it was possible to achieve the coincidence of the pH thermodynamically favourable for the synthesis and the pH optimum of the catalytic activity and stability of α-chymotrypsin (see the dashed line, pH 7.5). In addition, the limiting, i.e. pH-independent, equilibrium constant has also increased (by more than an order of magnitude) (see the upwards shift of curve *2* along the ordinate axis). The reason for this is that the product (the ester) is preferentially extracted from water into the organic phase. Ultimately the overall change in the equilibrium constant at pH 7.5 (dashed line in Fig.8) is by approximately five orders of magnitude. This is why it has become possible to drive the hydrolytic reaction almost wholly towards synthesis at neutral pH. Thus the yield of the ester in the given system is 80–100% (depending on the reactant concentrations) while in water it does not exceed 0.01%.

Peptide synthesis. An example of reactions involving di-iogenic compounds may be the synthesis of the peptide linkage:

$$\begin{array}{ccc} R_1COOH + R_2NH_2 & \rightleftharpoons & R_1CONHR_2 + H_2O \\ \downarrow\uparrow K_a \quad\quad \downarrow\uparrow K_b & & \\ R_1COO^- \quad R_2NH_2^+ & & \end{array} \qquad (33)$$

The pK_a for carboxylic acids are usually in the range 3–4 and the pK_b for amines are 8–10.[50,107,114] Consequently, in water, over the entire pH range, at least one of the initial reactants exists almost entirely in a charged form. As a result, the equilibrium of the overall reaction is almost wholly displaced to the left, towards hydrolysis[107].

On passing to two-phase water–organic solvent systems, the effective pK_a for the acid as a rule increases and the pK_b for the base diminishes (see above), which implies that at neutral pH the fraction of the uncharged forms of both the acid and the amine increases to some extent[108,109]. Consequently the equilibrium of reaction (33) should be displaced to the right, towards synthesis. The second source of the shift of the equilibrium is that the peptide is as a rule extracted from water to the organic solvent more effectively than the initial reactants. Thirdly and finally, the equilibrium yield of the product in reaction (33) in a two-phase water–organic solvent system should also increase owing to the decrease of the water content.

We tested this approach[108,109,115,116] in relation to the α-chymotrypsin-catalysed synthesis of *N*-acetyl-L-tryptophanyl-L-leucine amide:

$$\text{N—Ac—}L\text{-Trp} + L\text{-LeuNH}_2 \rightleftharpoons \text{L—Ac—}L\text{-Trp—}L\text{-LeuNH}_2 + H_2O.$$

On passing from water to the two-phase system ethyl acetate + 2 vol.% of water, the equilibrium constant of the synthetic reaction increased by more than three orders of magnitude (cf. curves *1* and *3* in Fig.9). As a result, the reaction equilibrium was displaced considerably to the right, which made it possible to synthesise the dipeptide almost quantitatively in water the yield does not exceed 0.1% other conditions being equal.

Synthesis of ionic products. It would appear that the two-phase approach to preparative organic synthesis is inapplicable to reactions where the products are ions because they would not pass from water to the organic phase and hence would not be distributed throughout the system. However, this difficulty can be overcome by selecting for the ionic reactants hydrophobic counterions, as is done, for example, in the chemistry of nucleotides[117] and has also proved useful in the radioactive analytical method[118]. We tested this approach in relation to the synthesis of glycerophosphate from inorganic phosphate and glycerol[67]. The reaction was catalysed by alkaline phosphatase using tetrabutylammonium as the hydrophobic counterion for the phosphates. In the chloroform–water two-phase system the yield of glycerophosphate was more than 30%,[67] while in water (in the absence of the organic phase but otherwise under the same conditions) the yield was negligible[83].

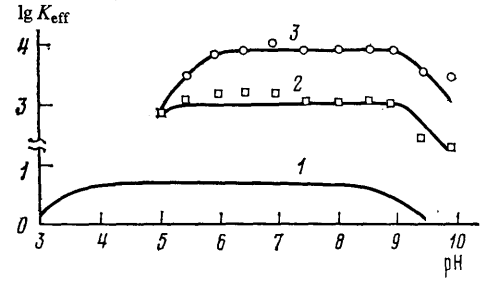

Figure 9. pH dependence of the equilibrium constant of the reaction involving the synthesis of *N*-acetyl-L-tryptophanyl-L-leucine amide in water (curve *1*) and in the ethyl acetate–water two-phase system containing 17 vol.% (curve *2*) and 2 vol.% (curve *3*) of water[108,115].

The enzymatic two-phase method is also applicable to other processes of practical importance involving ionic products, such as the modification of antibiotics[119], the synthesis of a dipeptide from free aminoacids[120], and the separation of a racemic mixture of free aminoacids[121].

General remarks concerning the choice of experimental conditions. Theoretical study[100–102] of the equilibria of chemical reactions in two-phase water–organic solvent systems permits the following conclusion: the equilibrium of a chemical reaction in a two-phase system is in general determined by the equilibrium constant of this reaction in one of the phases, the partition coefficients of the initial and final reactants, and the ratio of the volumes of the organic and aqueous phases. Consequently, knowing the equation describing the equilibria of the reactions in the two-phase systems and the partition coefficients (from the literature or from independent experiments), it is possible to calculate K_{eff} and hence the yield of the reaction products [see, for example, Eqns.(22), (25), and (26)]. Unfortunately the amount of information in the literature about the partition coefficients of various substances is at present inadequate and the available information is not always reliable[103,104]. In addition one must bear in mind that at high concentrations of reactants the latter can themselves alter the reaction medium and the distribution of the reactants (and hence the effective reaction equilibrium) will exhibit deviations from a simple (ideal) model[122].

It is important to be able to predict the mode and extent of the change in the equilibrium in a two-phase system relative to water because the dependence of K_{eff} (and of the yield of the chemical reaction products) in a two-phase system on the volume ratio of the phases (α) can be fairly complex. Consequently it can hinder the selection of the experimental conditions for the synthesis. In this connection, we draw attention to two factors.

1. For certain ratios of the partition coefficients, K_{eff} for reaction (4), observed in a two-phase system, can be significantly greater (Fig.6, curves 2–4) or correspondingly smaller (Fig.6, curves 2′–4′) than the equilibrium constants of the same reaction in each phase. We shall analyse this phenomenon in greater detail (quantitatively) in relation to a two-phase system where $K_W = K_O$, i.e. we shall assume that the equilibrium constant is the same in both immiscible solvents. The partition coefficients will be varied in the range of reasonable values from 10^{-5} to 10^5 (cf. Leo et al.[103]).

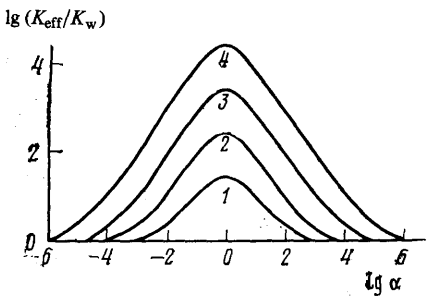

Figure 10. The extremum in the relation between K_{eff} for a reaction of the type A + B ⇌ C + D in the water–organic solvent two-phase system on the phase volume ratio (α) for the following partition coefficients: 1) $P_A = P_B = 1$, $P_C = 10^2$, $P_D = 10^{-2}$; 2) $P_C = 10^3$, $P_D = 10^{-3}$; 3) $P_C = 10^4$, $P_D = 10^{-4}$; 4) $P_C = 10^5$, $P_B = 10^{-5}$ (from Martinek et al.[102]).

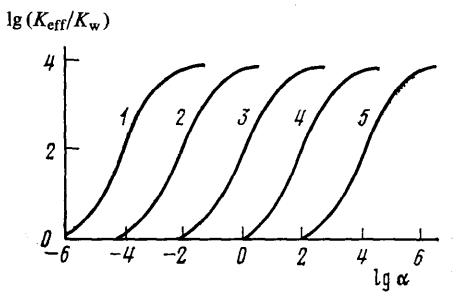

Figure 11. Examples of the S-shaped relation between K_{eff} for a reaction of the type A + B ⇌ C + D in a two-phase water–organic solvent system on α for the following partition coefficients: 1) $P_A = P_B = 10^3$, $P_C = P_D = 10^5$; 2) $P_A = P_B = 10$, $P_C = P_D = 10^3$; 3) $P_A = P_B = 0.1$, $P_C = P_D = 10$; 4) $P_A = P_B = 10^{-3}$, $P_C = P_D = 0.1$; 5) $P_A = P_B = 10^{-5}$, $P_C = P_D = 10^{-3}$ (from Martinek et al.[102]).

Fig.10 shows how the effective value of K_{eff} varies in a particular instance with the phase volume ratio α. Evidently the maximum effective equilibrium constant, observed for a reaction of the type A + B ⇌ C + D in a two-phase system, can exceed by a factor greater than 10^4 the corresponding equilibrium constants for the same reaction in each of the phases. Consequently the application of two-phase systems as reaction media can be particularly useful for increasing the yield of the desired product in reactions (not necessarily enzymatic) where the equilibrium is not displaced in the required direction in any of the solvents which are available and suitable for the given reaction.

2. In selecting the conditions for the synthesis, one should also bear in mind that the dependence of K_{eff} on α may be S-shaped (even in terms of non-logarithmic coordinates)[102], i.e. over a certain range of values of α the reaction equilibrium is as it were insensitive to a change in the medium. This can be seen from Fig.11, where we analysed the case where $10^4 K_W = K_O$. Evidently, depending on the partition coefficients (which were varied in the range of reasonable values from 10^{-5} to 10^5),[103] the shift of the chemical equilibrium is observed both for a negligible content of the organic phase ($\alpha = V_O/V_W \cong 10^{-5}$, curve 1) and for comparable amounts of the phases ($\alpha \cong 1$, curves 3), or even, finally, in the absence of water from the system ($\alpha \cong 10^5$, curve 5). In each case it is convenient to employ different methodological procedures to establish the two-phase system. Thus two-phase systems can be formed in the following way.

(a) For systems with a low content of the organic phase ($\alpha \ll 1$), this can be, for example, an aqueous solution of a surfactant forming micelles†; the internal (hydrophobic) region of the micelles can serve as the organic phase[123].

(b) For systems with a low water content ($\alpha \gg 1$), the enzymes should apparently be enclosed in "inverted" micelles of surfactants in an organic solvent[16,98,125].

(c) Systems containing comparable amounts of the organic and aqueous phases can be set up, as already mentioned above (see Section I), in the form of an emulsion of an aqueous solution of the enzyme in an organic solvent or as a suspension in the same solvent of porous particles impregnated with an aqueous solution of the enzyme. When an emulsion is used, the question of the specific interface is extremely important: the greater the specific interface, the faster the diffusion of the reactants through the interface, which has a favourable influence on the reaction kinetics; on the other hand, under these conditions the inactivation of the catalyst (enzyme) can be accelerated as a result of its adsorption at the interface[126]. In this instance one can employ a simple two-layer system.

Generally speaking, any substance capable of forming a two-phase (or pseudo-two-phase system) can be used as the "organic" phase. For example, a water-insoluble polymer can be used for this purpose[127,128].

V. THE PRESENT STATE OF ENZYME CATALYSIS AND THE PROSPECTS FOR ITS INTRODUCTION INTO ORGANIC SYNTHESIS

It is seen from the above survey that enzymes have been used very successfully without additional stabilisation (in relation to denaturation by the reaction medium) in a whole series of synthetic reactions. This has also been promoted by the development of physicochemical approaches whereby the yield of the product can be increased directly under conditions favourable (optimal) for biocatalysis.

It follows from the data in the present review that for the purposes of organic synthesis about 50 enzymes have already proved useful, mainly in the following processes (references are given only to reviews and the latest surveys).

†In the case of micellar systems it is possible to speak of the presence of two phases only as a matter of convention because there is no visible interface. It is therefore more appropriate to speak of "pseudo-two-phase" systems[123]. Nevertheless all the characteristics of the shift discussed above obtain in this instance (see, for example, Martinek and coworkers[124,125]).

1. The Synthesis of Oligo- and Poly-nucleotides

The methods for the chemical synthesis of the internucleotide linkage have been as yet inadequately developed and it is virtually impossible to synthesise a polynucleotide containing several tens of units by a purely chemical procedure[129]. Much attention is therefore devoted in the literature to enzymatic methods for the synthesis of oligo- and polynucleotides. In the synthesis of oligoribonucleotides and oligodeoxyribonucleotides use is therefore made of ribonuclease[24,129–132]:

$$N{>}p + N' \xrightarrow{\text{RNAase}} NpN', \qquad (34)$$

polynucleotide phosphorylase[24,129,130,133]:

$$I + NDP \xrightarrow{\text{PNPase}} IpN + P_i \qquad (35)$$

or RNA ligase[129,134]:

$$NpN' + pN''pN'''p \xrightarrow{\text{RNA ligase + ATP}} NpN'pN''pN'''p\ . \qquad (36)$$

Here N >p is the nucleotide 2′,3′-cyclic phosphate, N the nucleoside, NDP the nucleoside diphosphate, NpN′ the dinucleoside monophosphate, and I the initiator (primer) molecule (usually a dinucleotide).

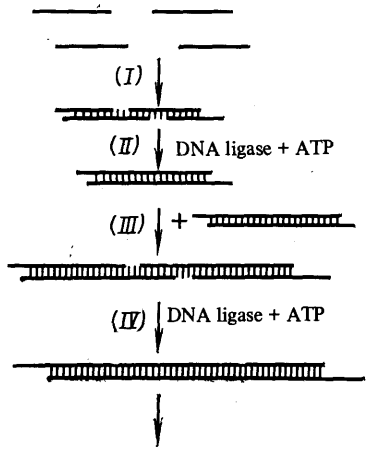

Figure 12. Illustration of the "method of sticky ends". Horizontal lines—sequence of nucleotides joined by covalent bonds; vertical lines—complementary non-covalent (hydrogen) bonds.

For reaction (34), preference is given to non-specific ribonucleases as the catalyst. This makes it possible to synthesise oligonucleotides containing a wide variety of nucleosides, including some which are not encountered in nature. Reaction (35) may involve the extremely undesirable polymerisation process and several approaches have been developed for its suppression[24]. Reaction (36) has been discovered comparatively recently and so far has been hardly used.

Khorana and coworkers[135,136] developed a method for the synthesis of double-stranded polynucleotides with a definite sequence, which has come to be called the "method of sticky ends". His idea can be understood from Fig.12. According to this method, in the first stage the initial oligonucleotides (with a length equivalent to 5–15 units) form a double-stranded complex as a result of complementary non-covalent interactions [stage (1)]. Next, the 3′- and 5′-ends in the resulting complex, which have approached one another in space, are joined by covalent linkages under the influence of DNA ligase [stage(II)]. All the fragments from which the final polynucleotide is to be made up are synthesised in this way and are linked initially via complementary non-covalent interactions [stage (III)] and then also by covalent bonds [stage (IV)]. Using this scheme, Khorana and coworkers synthesised the structural gene of alanine tRNA [135] and the complete gene of suppressor tyrosine tRNA.[136]

2. Regeneration of ATP

Adenosine 5′-triphosphate (ATP) is the substrate of many enzymatic reactions and is widely used in research and in recent years also in enzymatic organic synthesis. In connection with the latter factor, the problem of the regeneration of ATP from ADP and (or) AMP arose.

Among the fairly large number of systems proposed for this purpose, two reactions, catalysed either by acetylphosphokinase[137–139], i.e.

$$ADP + \text{acetylphosphate} \xrightarrow{\text{acetylphosphokinase}} ATP + \text{acetate},$$

or by carbamoyl phosphate kinase[140],

$$ADP + \text{carbamoyl phosphate} \xrightarrow{\text{carbamoyl phosphote kinase}} ATP + \text{carbamate},$$

must be recognised at present as the most suitable.

If AMP is used as the initial reactant, then adenylate kinase must also be introduced into the system[137]:

$$AMP + ATP \xrightarrow{\text{adenylate kinase}} 2ADP.$$

Laboratory devices for the regeneration of ATP have been constructed on the basis of acetylphosphokinase and adenylate kinase immobilised on Sepharose and carbamoyl phosphokinase immobilised on glass[138,140].

3. Synthesis of Labelled Compounds

Compounds containing heavy or radioactive atoms in specific positions within their molecules have found extensive applications in chemistry and biology for the investigation of the mechanisms of chemical and enzymatic reactions, metabolic pathways, molecular structures, etc. Enzymes have been used on an increasing scale in recent years for the synthesis of compounds of this kind. The application of enzymes has the following principal advantages.

Firstly, *specificity*. In the synthesis of labelled compounds it is extremely important to introduce the label into rigorously defined positions within the molecule. The unique specificity of enzymes as a rule permits this. Apart from the high purity of the desired product, the expensive radioactive material is not consumed on side reactions in enzymatic synthesis.

Secondly, *high rate*. At the present time it appears extremely promising to use as labels the so-called short-lived isotopes, for example ^{11}C (half-life $T_{1/2} = 20.3$ min), ^{13}N ($T_{1/2} = 10$ min), ^{15}O ($T_{1/2} = 2$ min), and others. However, as a consequence of the high rate of decomposition of such isotopes, purely chemical synthetic methods were frequently ineffective. The synthesis of compounds containing short-lived isotopes became possible as a result of the employment of enzymes[141].

Thirdly, *mild conditions*. Enzymatic reactions proceed under mild, as a rule, physiological conditions. This is significant, for example, in the synthesis of labelled amino-acids (there is no racemisation) or proteins (there is no denaturation).

Tens of examples of the successful employment of enzymes for the synthesis of various labelled compounds have now been described.

Proteins. The following system is normally used in the synthesis of labelled protein derivatives[142-144]:

$$\text{protein} + K^{125}I + H_2O_2 \xrightarrow{\text{peroxidase}} \text{protein} - {}^{125}I.$$

The enzyme is used in the soluble or (better) immobilised[144] form.

Aminoacids. The initial reactants for the synthesis of labelled aminoacids are α-ketoacids and $\overset{*}{N}H_3$:[141,145-149]

$$R{-}\underset{\underset{O}{\|}}{C}{-}COOH + \overset{*}{N}H_3 + NADH \rightleftarrows L\text{-}R{-}\underset{\underset{{}^*NH_2}{|}}{CH}{-}COOH + NAD^+.$$

The reaction is catalysed by glutamate dehydrogenase obtained from ox heart, which (in contrast to the enzyme from other sources) exhibits a broad substrate specificity.

Nucleoside triphosphates. The problem of the synthesis of nucleoside triphosphates containing ^{32}P in the α-, β-, or γ-positions only has been solved with the aid of enzymes[150-153].

Sugars. Enzymes have been used to synthesise certain commercially unavailable sugars from commercial preparations of labelled glucose[47,154].

4. Synthesis of Oligopeptides

In the 1930's Bergmann showed for the first time that proteolytic enzymes can affect not only the hydrolysis but also the synthesis of peptides. In recent years the number of publications on this topic has increased sharply, since enzymatic or combined (enzymatic plus chemical) methods came to be regarded as a serious alternative to purely chemical synthesis of the peptide linkage. The advantages of the enzymatic method include the following: (a) the absence of racemisation; (b) mild reaction conditions which rule out degradation of labile compounds; (c) the absence of the need to protect the functional groups in the aminoacid side chains: (d) the absence of the need to activate the reacting groups.

Apart from the large number of model oligopeptides[29,30,34-42,57,58,64,65,89-92], important biologically active compounds such as angiotensin[39], encephalins[42,155], and human insulin[64,65] have been synthesised with the aid of enzymes.

The range of enzymes employed has been greatly extended: whereas up to 1970 only papain and chymotrypsin were used as catalysts, nowadays trypsin, pepsin, subtilisin, ficin, bromelain, carboxypeptidase (for the removal of protecting groups[156]), thermolysin, and bacterial metalloproteinases have also found applications.

5. The Synthesis and Modification of β-Lactam Antibiotics

The enzymatic method for the modification of β-lactam antibiotics in order to improve their properties, developed on a wide scale in recent years, appears to be extremely promising. According to this procedure[5,15], in the first stage the natural β-lactam antibiotics are subjected to penicillin amidase-catalysed hydrolysis in order to obtain the so-called nucleus of the antibiotic: 6-aminopenicillanic acid (in the case of penicillins) or 7-aminocephalosporanic acid) (in the case of cephalosporins). In the second stage the nucleus of the antibiotic is acylated (using penicillin amidase as the catalyst):

$$R^1{-}\underset{\underset{O}{\|}}{C}{-}N{-}\underline{\overline{\text{nucleus}}} \underset{-R^1COOH}{\overset{+H_2O}{\rightleftarrows}} H_2N{-}\underline{\overline{\text{nucleus}}} \xrightarrow{+R^2COOH} R^2{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{H}{|}}{N}{-}\underline{\overline{\text{nucleus}}} \quad (37)$$

In the second, acylation stage the yield of the product can be increased by carrying out the reaction in a weakly acid medium (a pH of 4.5–5.0 is optimum for the synthesis in most instances) or using as the acylating agent not the free acid but its activated derivatives.

By varying the acyl group R^2, it is possible to improve specifically the properties of antibiotics—to extend the spectrum of their activity, to increase their stability in the organism, and to reduce their allergenic effect. Several tens of "semisynthetic" antibiotics have been obtained in this way[5,15,87,88,157].

6. Modification of Steriods

Enzymes, cells, or unpurified extracts are also used for the modification of steroids[158-164].

7. Industrial Processes

Together with the laboratory developments discussed above, a series of technological (industrial) processes involving immobilised enzymes have been set up recently: (a) the synthesis of L-aspartic acid using immobilised microbial cells containing aspartase[14]; (b) the synthesis of L-malic acid using immobilised microbial cells containing fumarase[15]; (c) the synthesis of 6-aminopenicillanic acid using immobilised penicillin amidase[15]; (d) the separation with the aid of immobilised aminoacylase of racemic mixtures of aminoacids (obtained by a chemical, non-enzymatic procedure)[15,19]; (e) the synthesis of D-aminoacid derivatives with the aid of immobilised hydantoinase[15].

There are also large-scale industrial processes which go beyond the classical framework of organic synthesis and are more in the nature of the industrial manufacture of food products; (f) the preparation of glucose–fructose syrups using immobilised glucose isomerase[165,166]; (g) decomposition of lactose (the preparation of lactose-free milk) with the aid of lactase[15].

Certain processes have been developed only on pilot apparatus: (h) the synthesis of glucose from partial starch hydrolysates using immobilised glucoamylase[167]; (i) the synthesis of glucose and (or) ethanol from cellulose using cellulase[168]; (j) the preparation of glucose–fructose syrups from sucrose with the aid of immobilised invertase[15].

The Table, which we took from Sweigart and Dale[14] and supplemented by Klesov's data[169], gives a list of organisations which have set up these industrial (or pilot) processes.

It may seem surprising that a review of organic syntheses includes also the "food" processes (f)–(j). The need for this combined approach to the analysis of the present state of the problem (the introduction of enzymes into industrial processes) arises partly from the fact that enzyme catalysts have long been used in the food industry and at the present time (1976–1979) the food industry is the main consumer of the manufactured enzymes[13]. However, the principal factors which led us to consider, as far as possible, the most complete picture of the technological processes catalysed by enzymes are as follows. Firstly, the use of enzymes is beginning to break up the usual framework of organic synthesis. Secondly, any enzymatic food process (processes) gives rise to

new prospects for the large-scale preparation of raw material for chemical engineering, namely ethanol (and possibly also glucose). Finally, on the basis of processes already introduced, it is easier to predict certain economic factors. Evidently modern microbiological industry is already (1976) able to ensure the manufacture of enzymes in amounts running into hundreds of tons annually (at a cost of approximately 150 million dollars)[13]. However, the contribution of the ensyme to the overall cost of the product is in many instances insignificant[13,14].

The use of immobilised enzymes in large-scale (industrial) (L) and pilot plant (P).

*For the classification of the processes, see text.

For the introduction of biocatalysis into industrial processes (in which economic factors play a decisive role) on a wider scale, it is naturally necessary to improve further processes involving the microbiological synthesis and isolation of enzymes, methods for the preparation of carriers and the immobilisation of enzymes on them, enzymatic reactors, etc. However, the key problems at the present stage are the stabilisation of enzymes (see, for example, Martinek and Berezin[170]) and then the regeneration of cofactors, the use of polyenzyme systems, and the immobilisation of micro-organisms.

Polyfluorinated Arenonium Ions

V.D.Shteingarts

This novel type of arenonium ions plays a key role in the isomerisation and electrophilic reactions of aromatic compounds. Methods for their generation, the investigation of their electronic structure by means of fluorine-19 nuclear magnetic resonance, and the influence of structural factors on their relative stability are discussed. Results on the chemical reactions of polyfluorinated arenonium ions, opening up paths for their synthetic use, are summarised. A list of 74 references is included.

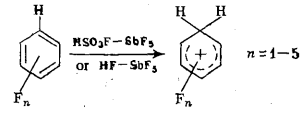
I. INTRODUCTION

A most important stage in studying the mechanism of the reactions of aromatic compounds with electrophilic agents, which has been responsible for a recently established and extremely fertile direction of research in this field, has been the development of methods for generating long-lived arenonium ions that in some degree model intermediate species in these reactions. The progress made[1] has provided an experimental basis for earlier views on the intermediate formation of σ-complexes during electrophilic reactions of aromatic compounds and has revealed the role of isomerisation of these species as one factor governing the dependence of the final result on the reaction conditions; in particular, the isomeric composition of the reaction products depends on the contribution made to the total change by addition of an electrophilic species to a substituted aromatic ring carbon atom (*ipso*-reactions[2]).

ipso-Reactions with electrophilic agents have recently been studied in particular on aromatic polyfluoro-compounds. The immense possibilities for the synthesis of diverse polyfluorinated compounds opened up by the discovery of reactions of this type (those between aromatic polyfluoro-compounds and nitrating reagents have been reviewed[3]) and the trend to their directed use have made necessary a more profound study of the reaction mechanism.

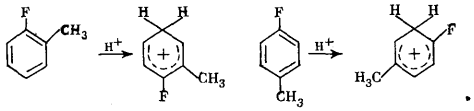


The mechanism of *ipso*-electrophilic reactions of aromatic polyfluoro-compounds suggested initially involves addition of the electrophilic species at a position in the aromatic ring occupied by such an electronegative substitutent as a fluorine atom[3]. The arenonium ion assumed to be formed possesses structural characteristics that are extremely unfavourable for its stability: it contains a large number of fluorine atoms at positions in the unsaturated portion at which the substituent plays no effective part in charge delocalisation by a conjugation mechanism (non-resonance positions†), and also two electronegative substituents together at an sp^3-hybridised site. At the time at which this scheme was proposed stable arenonium ions having such characteristics were unknown. Therefore the generation of ions of this type under "long-lived" conditions, with the aim of demonstrating the very possibility of their existence, would provide one of the most fundamental pieces of experimental evidence in support of the scheme. Results thus obtained are obviously of value not only in studying the chemistry of aromatic polyfluoro-compounds: they are important for understanding the properties of carbocations—species that have a fundamental role in organic chemistry.

† We shall regard as resonance positions those that are involved in delocalisation of the positive charge when the distribution of π-electron density is described in terms of limiting ("resonance") structures.

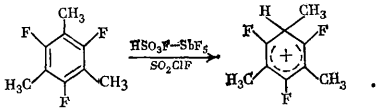
II. GENERATION OF POLYFLUORINATED ARENONIUM IONS

1. Protonation of Partly Fluorinated Aromatic Compounds



The first polyfluorinated arenonium ions were obtained by this reaction, which was most widely used in the initial state of development of the chemistry of these species (during 1967–1968). The weak basicity of aromatic polyfluoro-compounds required the use of a "superacid"—a solution of antimony(V) fluoride in fluorosulphuric acid—to achieve a sufficient degree of protonation. Both hydrogen and fluorine-19 nuclear magnetic resonance spectroscopy were used to record the formation of benzenonium ions having two hydrogen atoms as geminal substituents[4–6] when incompletely substituted fluorinated benzenes were dissolved in this acid system:

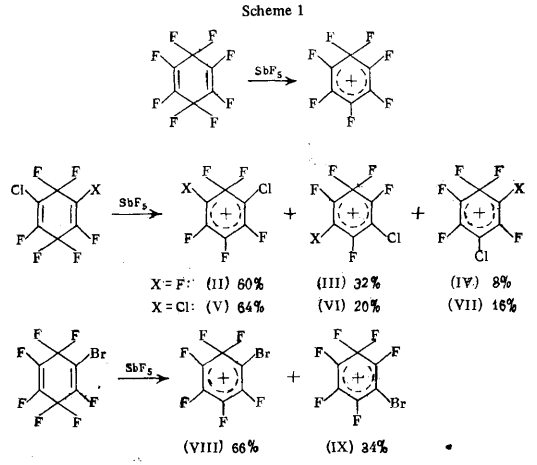
The orientation of addition of the proton then corresponds to decrease in stability of the arenonium ions as the position of the fluorine atom in the unsaturated part varies in the sequence *para* > *ortho* ≫ *meta*. *o*-Difluorobenzene, 1,2,3,4- and 1,2,4,5-tetrafluorobenzenes, and pentafluorobenzene are hardly protonated at all in this acid system, owing to the strong destabilisation of arenonium ions by a *meta*-fluorine atom. Protonation of these compounds required the use of a stronger acid—a solution of antimony(V) fluoride in hydrofluoric acid—but hexafluorobenzene is not protonated even in this case[7]. Such difficulty of *ipso*-protonation according to the position occupied by a fluorine atom is consistent with subsequent quantum-chemical calculations of the relative stability of fluorobenzenonium ions[8].



Fluorine-containing methylbenzenes are also protonated at unsubstituted positions[5,6,9]. In cases in which the *ortho*–*para* orienting effects of methyl group and fluorine atom do not coincide the fluorine atom in the resulting arenonium ion

is located in a resonance position, predominantly *para*, while the methyl group occupies the non-resonance *meta*-position[5]:

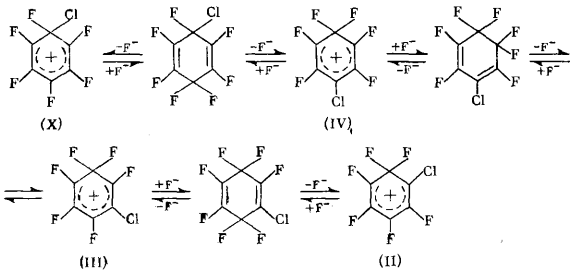
Because of the high rate of interconversion of isomeric arenonium ions corresponding to protonation of aromatic compounds the above rules apply to equilibrium proportions of isomers. However, isomeric ions differ in the nature of the substitutents at two or more positions, so that the relative effects of substituents at any one of them on the stability of the ion cannot be assessed. Therefore the orientation involved in the protonation of *o*- and *p*-fluorotoluenes cannot be interpreted as indicating that a fluorine atom has a stronger stabilising influence than a methyl group in the resonance arrangement. Determination of the relative stabilising effects of these substituents by comparing the relative stabilities of arenonium ions differing in the substituent at only one position (Section III) has shown that the methyl group has the stronger stabilising influence.



The only example of an aromatic polyfluoro-compound that is completely substituted in the ring and is converted into an arenonium ion on protonation is trifluoromesitylene. In this case, however, a benzenonium ion is formed in which all the fluorine atoms are located in the unsaturated portion[5]:

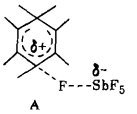
The above examples show that the arenonium ions containing a fluorine atom attached to an sp^3-hybridised carbon atom cannot be obtained by the protonation of aromatic fluoro-compounds. Such ions have been obtained by using less traditional methods of generating arenonium ions.

2. Action of Antimony(V) Fluoride on Polyfluorinated Dihydro-aromatic Compounds



Scheme 1

An approach made earlier to obtain alkyl cations[10,11] has proved useful for generating polyfluorinated arenonium ions having fluorine atoms in an sp^3-hybride node: a fluoride anion is detached by antimony(V) fluoride from the corresponding precursor, in the present case from the polyfluorinated dihydro-aromatic compound. The perfluorobenzenonium ion (I) and its analogues (II)–(IX) containing chlorine or bromine atoms in the unsaturated portion have been generated from polyfluorinated cyclohexadienes in antimony(V) fluoride[12,13] and in sulphuryl chloride fluoride[14–16]. Scheme 1 gives for these analogues the equilibrium proportions established in antimony(V) fluoride solution at 20–40 °C.

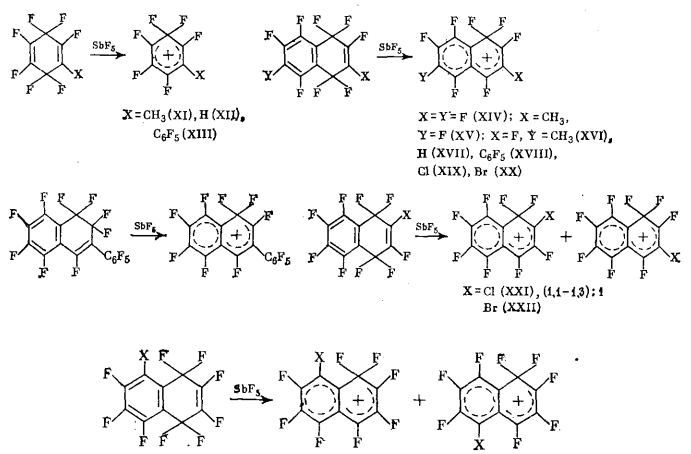


Ions containing a *p*-chloro-substitutent cannont be formed directly from percursors. Their presence in the reaction mixtures indicates the possibility of interconversion of isomeric ions, which apparently occurs by a series of reversible transformations of benzenonium ions into cyclohexadienes[13,14]. The equilibrium character of the proportions given in Scheme 1 is supported by formation of the ion (IV) and of the 1-chlorohexafluorobenzenonium ion (X) in the proportions 9 : 1 when antimony(V) fluoride acts on 3-chloroheptafluorocyclohexa-1,4-diene in sulphuryl chloride fluoride at −90 °C (the latter ion (X) is generated also by the chlorination of hexafluorobenzene—see below). With rise in temperature to −40 °C the ion (X) is converted into (IV), which at −20 °C is in turn converted into the ions (II) and (III), between which the above relation is established. The sequence of interconversions of chlorohexafluorobenzenonium ions when the solution "thaws out" (Scheme 2) indicates the greater ease of addition of a nucleophilic species at the *para*-position in the benzenonium ion [transition from (X) to (IV)] than at an *ortho*-position [conversion of (IV) into (III) and then into (II)], and may well represent the relative electrophilic strengths of the two resonance positions in the cyclohexadienyl fragment[14].

Scheme 2

It follows from the above results that between −90 and −80 °C the addition of a fluoride ion at the *para*-position and hence also the isomerisation of polyfluorinated arenonium ions are slow processes. This means that the proportions in which isomers are formed at these temperatures are kinetically controlled. The action[17] of antimony(V) fluoride on hexafluoro-1-halogenocyclohexa-1,4-dienes in sulphuryl chloride fluoride at −90 °C yields the corresponding hexafluoro-2- and -3-halogenobenzenonium ions in the proportions 1 : 2 and 1 : 3 when the halogen is respectively chlorine and bromine; these differ from the equilibrium proportions of the same ions (Scheme 1) established at −60 °C. In the case of the chloro-compounds complete equilibrium involving the isomer (IV) is established at −20 °C.[17]

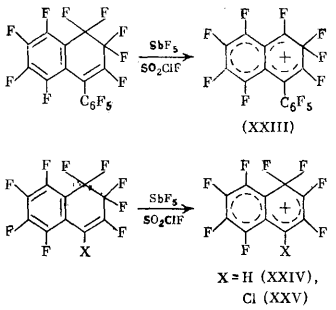
If the transition state corresponding to the detachment of a fluoride anion from a cyclohexadiene molecule is assumed to be of the type



A

the discrepancy between the kinetically controlled and the equilibrium ratios of isomeric ions may indicate that the increase in the positive charge in the cyclohexadienyl system accompanying transformation of the transition state into an

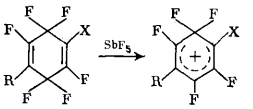
arenonium ion leads to a change in the relative stabilising effects of *o*- and *m*-halogeno-substitutents with respect to the sp^3-hybridised carbon atom[17].



The ions 1,1,2,4,5,6-hexafluro-3-methylbenzenonium (XI),[18] 1,1,2,3,4,6-hexafluorobenzenonium (XII),[16] perfluoro-3-phenylbenzenonium (XIII),[19] and perfluoro-1-naphthalenonium (XIV)[12,13] and many of its substituted analogues[17-19] have been generated by the action of antimony(V) fluoride on the corresponding polyfluorinated cyclohexadienes (Scheme 3).

Scheme 3

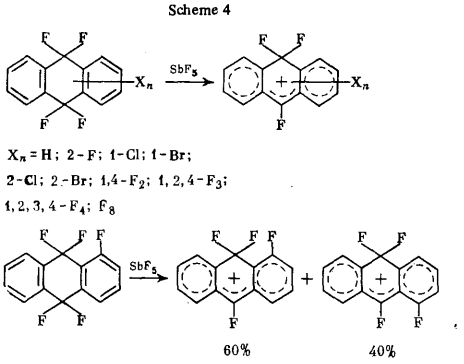
The formation of ions (XI), (XV), and (XVI) corresponds to the tendency mentioned in subsection 1 for the methyl group to occupy a non-resonance position if that will make a resonance arrangement of the fluorine atom possible[18]. This also partly explains the preferential non-resonance orientation of the pentafluorophenyl group. In the latter case, however, another possible factor is that resonance involvement of the pentafluorophenyl group in charge delocalisation is apparently diminished by its non-coplanarity with respect to the remainder of the ion, which causes steric interaction of fluorine atoms situated near together[19,20].



The net effect of these factors is that, with a pentafluorophenyl group substituted on an α-carbon atom in the cyclohexadienyl fragment of a naphthalenonium ion, the napthalen-2-onium ion (XXIII) is formed[21], whereas naphtalen-1-onium ions are usually more stable than naphthalen-2-onium ions[1] (cf. formation of the ions (XXIV) and (XXV) from the corresponding precursors[22]):

The relative stabilising effects of so closely related substituents as the halogen atoms are apparently very sensitively dependent on the structure of the arenonium ion, primarily on the distribution of positive charge in it (cf. the above data on the discrepancy between kinetically controlled and equilibrium proportions of halogenohexafluorobenzenonium ions).

This is evident e.g. in the conclusion from the equilibrium ratios of isomeric 1,1-difluorobenzenonium and 1,1-difluoronaphthalen-1-onium ions that a chlorine or a fluorine atom in a cyclohexadienyl fragment occupies preferentially a resonance position (predominance of the ions (II), (V), (XIII), (XXI), and (XXII) over their isomers), whereas halogen atoms in a β-position in the benzene fragment of naphthalen-1-onium ions are characterised by the opposite tendency (ions (XIX) and (XX)—see above).

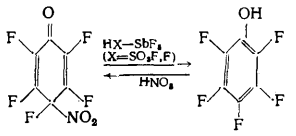


The possibility of generating 5-R-pentafluoro-2-halogenobenzenonium ions (R = CH_3, H) from the corresponding cyclohexadienes was predicted from the above results and then realised[15]:

R = CH_3, X = Cl, Br, CH_3; R = H, X = Cl, Br, H, CH_3 .

The action of antimony(V) fluoride in sulphur dioxide at −20 °C on 9,9,10,10-tetrafluoro-9,10-dihydroanthracenes yields the 9,9,10-trifluoroanthracenonium ion and the corresponding halogen derivatives, including polyfluorinated analogues[23,24] (Scheme 4).

Scheme 4

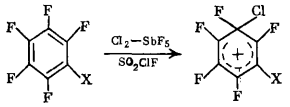


The predominance of the 1-X-9,9,10-trifluoroanthracenonium ions (X = F, Cl, Br) over their 4-X-isomers is obviously a consequence of the occurrence in the latter of destabilising interaction between halogen atoms present in the spatially contiguous resonance positions 4 and 10.

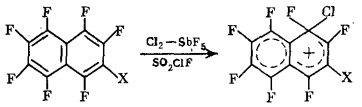
3. Protonation of Polyfluorinated Cyclohexadienones

Cyclohexadienones are conjugated bases of hydroxyarenonium ions, and their protonation has long been used to generate the latter. Koptyug et al.[1] have obtained by this method several hydroxyarenonium ions containing an electronegative atom or group (F, Cl, Br, OH, OCH_3, $OCOCH_3$, NO_2) attached to an sp^3-hybridised carbon atom.

This method has been used to generate polyfluorinated arenonium ions containing as geminal substitutents not only fluorine but also other halogen atoms[25-27]. Ions of the latter type simulate intermediate species in the electrophilic *ipso*-halogenation of aromatic polyfluoro-compounds at positions occupied by fluorine atoms. The ability, revealed by these examples, of chlorine and bromine atoms to be retained at an sp^3-hybrid atom of an arenonium ion in a geminal position with respect to a fluorine atom has served as experimental basis for the generation of polyfluorinated arenonium ions by the direct electrophilic halogenation of aromatic polyfluoro-compounds (below).



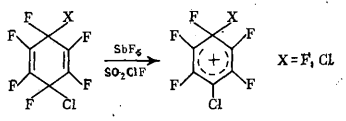
In attempts to generate an arenonium ion containing a nitro-group as substituent located geminally with respect to a fluorine atom, in contrast, pentafluoro-4-nitrocyclohexa-2,5-dien-1-one when dissolved in the systems $HSO_3F-SbF_5-SO_2$ and $HF-SbF_5-SO_2ClF$ is converted into pentafluorophenol, with the dependence of the degree of conversion on the quantity of the pentafluoride corresponding to a stoichiometric ratio of two moles of the latter per mole of the ketone. In the absence of antimony(V) fluoride the reaction does not take place, but nor does protonation of the ketone[28]. Thus introduction of antimony pentafluoride into the system leads to reversal of the *ipso*-nitration of pentafluorophenol[28,29], which may be due to involvement of a nitronium cation in specific complex formation in such systems:



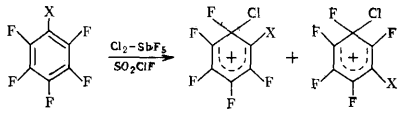
4. Action of Electrophilic Agents on Aromatic Polyfluoro-compounds

Generation of arenonium ions by direct electrophilic attack on aromatic compounds is obviously the most fundamental method for experimental testing of the generally accepted schemes of interaction between aromatic compounds and electrophilic agents. For a long time arenonium ions corresponding to reactions involving addition of an electrophile to an aromatic ring by means of an electronegative heteroatom could not be generated in this way[1]. Success was achieved independently by groups of workers headed by Olah in the USA [30] and by Koptyug in the USSR,[31-33] who used polymethylated aromatic compounds as substrates and strong protic acids as media. These researches, as well as the above results on the fixation of polyfluorinated hydroxyarenonium ions with chlorine and bromine atoms as substituents geminal with respect to a fluorine atom, initiated attempts to generate polyfluorinated arenomium ions by the direct electrophilic halogenation of aromatic polyfluoro-compounds.

The action of molecular chlorine and antimony(V) fluoride on aromatic polyfluoro-compounds in sulphuryl chloride fluoride between −80 and −60 °C forms polyfluorinated 1-chloro-1-fluoroarenonium ions[14,34,35]:

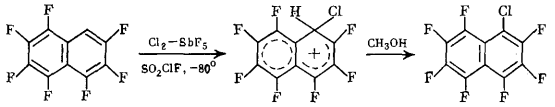


X = F, CH_3, C_6F_5



X = F, H, CH_3

With respect to the reaction mechanism, an alternative to direct electrophilic attack on the polyfluoro-aromatic ring would be addition of molecular chlorine on chlorine fluoride followed by reaction between the resulting cyclohexadienes containing a chlorofluoromethylene group and antimony(V) fluroide. Such a possibility is refuted, at least for the chlorination of hexafluorobenzene, by the abstraction of a fluoride anion from the halogenated methylene group when antimony(V) fluoride acts on cyclohexadienes of the above type[14]:

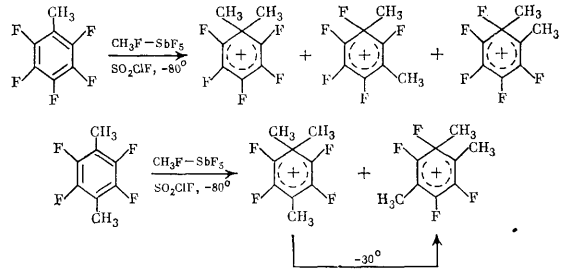


In most of the above cases of the chlorination of aromatic polyfluoro-compounds the orientation of addition of the chlorine cation is consistent with the relative stability of the isomeric polyfluorinated 1,1-difluorobenzenonium and 1,1-difluoronaphthalenonium ions formed by the action of antimony(V) fluoride on polyfluorinated cyclohexadienes or dihydronaphthanlenes (Section III). The only exception is the chlorination of chloro- and bromo-pentafluorobenzenes, with preferential formation of 3-X-1-chloropentafluorobenzenonium ions (X = Cl, Br). Since there are grounds for supposing that at least with polyfluorinated 1-chloro-1-fluorobenzenonium ions, such orientation corresponds to the equilibrium ratios of the isomeric ions (in virtue of the ease of migration of the chlorine atom—Section III), this exception indicates a change in the relative stability of 2- and 3-X-substituted isomers (X = Cl, Br) on passing from 1,1-difluorobenzenonium ions to their 1-chloro-1-fluoro-substituted analogues (Scheme 5). Such a change may be due both to increase in steric strain in the 2-X-isomer with increase in the bulk of the geminal substitutent and to change in the distribution of electron density in the unsaturated portion of the ion under the influence of change in the electronic effect of the substituent at the sp^3-hybridised atom[28,36].

Scheme 5

X = Cl:	33%	67%
X = Br:	20%	80%

Pentafluorobenzene and 1-H-heptafluoronaphthalene are chlorinated under the above conditions at the unsubstituted position. However, whereas in the former case only chloropentafluorobenzene is formed, in the latter a rare example of formation of an arenonium ion corresponding to substitution of hydrogen could be observed:



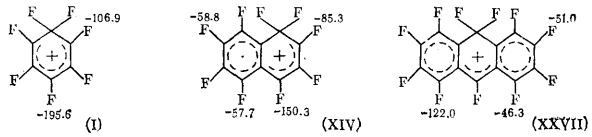
(XXVI)

The chief product of methanolysis of a solution containing this ion is 1-chloroheptafluoronaphthalene. The comparative stability of the ion (XXVI) with respect to detachment of a proton is apparently due to steric hindrance caused by *peri*-interaction when a chlorine atom is situated in the plane of the naphthalene ring system[35].

Attempts have also been made to generate arenonium ions by electrophilic bromination and nitration of aromatic polyfluoro-compounds. Bromination has proved successful with pentafluorotoluene, addition of which to a solution of bromine and antimony(V) fluoride in sulphuryl chloride fluoride at −60 °C forms a 1-X-3 methylpentafluorobenzenonium ion, in which X appears from the chemical shifts of atoms in its immediate vicinity to be a bromine atom[22,36]. However, formation of polyfluorinated arenonium ions could not be detected from the ^{19}F n.m.r. spectra in the action on polyfluorinated

benzenes of nitrating systems containing nitronium fluoroborate or nitrosyl chloride together with fluorosulphuric acid or antimony pentafluoride in sulphur dioxide or sulphuryl chloride fluoride, which recalls the above unsuccessful attempts to generate the 4-hydroxy-1-nitropentafluorobenzenonium ion by protonating the corresponding nitrocyclohexadienone[28].

Scheme 6

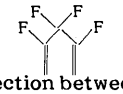


It has recently been discovered that the complex of fluoromethane and antimony(V) fluoride is able to methylate aromatic polyfluoro-compounds at positions occupied by either a fluorine atom or a methyl group, with formation of the corresponding arenonium ions[37]. This method has been used to generate 1,1-, 1,2-, and 1,3-dimethylpentafluorobenzenonium ions in sulphuryl chloride fluoride at −80 °C. The methylation of tetrafluoro-*m*-xylene under similar conditions occurs predominantly at a position occupied by a methyl group, and to a less extent at position 5 occupied by a fluorine atom. With tetrafluoro-*p*-xylene approximately equal quantities of 1,1,4- and 1,2,5-trimethyltetrafluorobenzenonium ions are formed. When the temperature of the solution rises from −80 to −30 °C, the ion containing two geminal methyl groups isomerises with migration of one of them to an adjacent position (Scheme 6).

III. PROPERTIES OF POLYFLUORINATED ARENONIUM IONS

1. Nuclear Magnetic Resonance Spectra and Structure

A most important experimental advance making a considerable contribution to the development of research on polyfluorinated carbocations and on arenonium ions in particular is the possibility of using ^{19}F n.m.r. spectroscopy to detect the formation and study the electronic structure of these species. The great sensitivity of the degree of shielding of fluorine nuclei to structural characteristics of a molecule, producing a change in the chemical shifts of fluorine atoms δ_F over a range of $\sim 10^{-8}$, makes this method a powerful tool for determining the structure of molecules containing fluorine. Furthermore, the predominantly π-electronic character of the variation in shielding of fluorine atoms in series of structurally similar unsaturated compounds makes it theorectically possible to use δ_F values to characterise the influence of structural factors, in particular of substituents quite remote from the given fluorine atom, on the π-electron density distribution. The spin–spin coupling constants between fluorine nuclei are also extremely informative.



Despite the admittedly approximate character of such an approach, there are grounds for supposing that it gives a qualitatively correct picture of the dependence of the delocalisation of positive charge in polyfluorinated carbocations on their structure. This is indicated, for example, by the decrease in $\Delta\delta_F$ in the series of arenonium ions[14,22,23]

(I) (XIV) (XXVII)

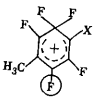
i.e. with gradual increase in extent of the π-electron system (here $\Delta\delta_F$ is the chemical shift of a fluorine atom in the arenonium ion relative to the corresponding fluorine atom in the polyfluoroaromatic precursor, which in this case corresponds to formal removal of one of the geminal fluorine atoms as a cation). The relations between the $\Delta\delta_F$ values for different fluorine atoms in each of these arenonium ions correspond qualitatively with quantum-chemical calculations of the distribution of π-electron density in fluorine-containing arenonium ions[38]. Finally, the $\Delta\delta$ values for fluorine atoms and the carbon atoms to which they are attached in these three ions vary in parallel, in conformity with the equation $\Delta\delta_C = 0.135\,\Delta\delta_F$. Such a correlation apparently indicates that the ratio between the fractional charges on carbon and fluorine atoms remains approximately constant for a given cyclic C–F group, despite variation within wide limits in the degree of delocalisation of the charge[39].

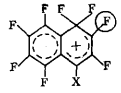
An analysis[40] of $\Delta\delta_F$ values# in a series of arenonium ions generated by protonation of partly fluorinated benzenes[4,7] leads to the conclusion that accumulation of fluorine atoms in the unsaturated part of the ion is apparently accompanied by a redistribution of electron density involving increase in the electron deficiency of the *para*-position but diminution in the deficiency at the *ortho*-positions. Comparison of $\Delta\delta_F$ values for protonated pentafluorobenzene[7] and for the ion (I)[14] shows that replacement of hydrogen by fluorine atoms at an sp^3-hybridised site leads to further increase in the fractional positive charge at the *para*-position, so that the π-electronic structure of ion (I) can be represented to a first approximation by the limiting structure

(B)

The existence of a connection between $\Delta\delta_F$ values of the type of π-electron density distribution reveals the tempting prospect

These tendencies are supported by quantum-chemical calculations[38].

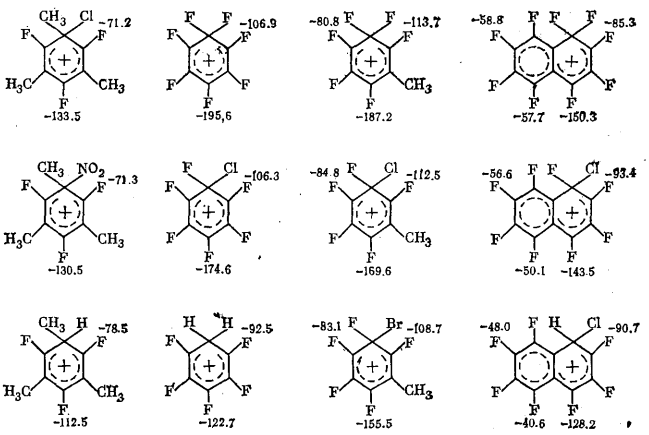




The existence of a connection between $\Delta\delta_F$ values and the type of π-electron density distribution reveals the tempting prospect of elucidating the relations between the electronic effects of substituents. The Table gives values of $\Delta\delta_F$ for series of polyfluorinated arenonium ions differing in the nature of a substituent in a given position. Inspection of these data indicates that the ratio of the $\Delta\delta_F$ values for structurally similar polyfluorinated arenonium and hydroxyarenonium ions is consistent with the generally accepted relation between the electron-donor resonance effects of the hydroxy-group and the fluroine atom. Yet the dependence of $\Delta\delta_F$ for an *o*-fluorine atom in the cyclohexadienyl fragment on the nature of the substitutent X in series of 4-X-hexafluorobenzenonium (X = F, Cl), 4-X-2,3,5,6-tetrafluorobenzenonium (X = F, Cl, Br, H), and 4-X-octafluoronaphthalen-1-onium (X = F, Cl, H)

This analysis is based on an assignment of signals, somewhat different from that of Ref.7, in the ^{19}F n.m.r. spectra of several of the ions.

ions conforms to electron-donor effects of halogens located in the resonance *para*-position diminishing on the whole in the sequence Br > Cl > F.[13,17,20]



The same laws are revealed by a comparison of $\Delta\delta_F$ values for *p*-fluorine atoms in the cyclohexadienyl fragment of 2-X-hexafluorobenzenonium (X = F, Cl, Br),[13,16] 2-X-5-R-pentafluorobenzenonium (R = CH_3: X = F, Cl, Br; R = H: X = F, Cl, Br, H),[15] and 2-X-octafluoronaphthalen-1-onium (X = F, Cl, Br)[13,17] ions. In 2-X-substituted benzenonium ions, however, substituents X located in resonance positions have different effects on $\Delta\delta_F$ for chlorine atoms in the other two resonance positions, *para* and *ortho*. As the electronic structure of polyfluorinated benzenonium ions closely resembles a limiting structure of type (B), it may be supposed that the relation between the π-electronic effects of substituents X should be evident in the influence of the nature of X on the value of $\Delta\delta_F$ for the *para*-fluorine atom, not for the fluorine atom located in the other *ortho*-position, especially as it coincides qualitatively with the effect of *p*-X-substituents on the shielding of the fluorine atoms in other resonance positions in 4-X-hexafluorobenzenonium[13] and 4-X-2,3,5,6-tetrafluorobenzenonium[20] ions, as well as polyfluorinated arylmethyl cations[41].

Values of $\Delta\delta_F$ for polyfluorinated arenonium ions[15,20,22,25] (for the circled fluorine atom in each formula).

Arenonium ion	X	$\Delta\delta_F$, ppm	Arenonium ion	X	$\Delta\delta_F$, ppm
	F	−106.9		F	−187.2
	Cl	−88.5		Cl	−170.5
	OH	−64.2		Br	−164.7
	H	−96.3			
	F	−92.5		H	−185.6
	Cl	−84.8		F	−186.8
	Br	−81.7		Cl	−170.8
	H	−89.1		Br	−164.8
	F	−85.3		F	−106.9
	Cl	−71.0		Cl	−93.7
	OH	−59.8		Br	−89.6
				H	−83.1
	F	−195.6			
	Cl	−173.9			
	Br	−165.7			

It is extremely important whether the sequence Br > Cl > F of variation in the influence of halogen atoms on the shielding of fluorine atoms in resonance positions actually represents the relation between their resonant electron-donor effects (the influence of *p*-halogen atoms in non-fluorinated benzenonium ions on the $\delta_{^{13}C}$ values of ring *ortho*-carbon atoms is characterised by an analogous series[42]. Indeed, although all halogen atoms exert a greater shielding effect than does a hydrogen atom, which corresponds to predominance of the electron-donor resonance component in their total electronic effects, differences in effects of halogen atoms may be connected mainly with their inductive effects[43] (see discussion of these results in Ref. 44). Sufficiently accurate results obtained by quantum-chemical calculations on the ions are necessary to solve this problem. The influence of substituents in non-resonance positions in the unsaturated part of polyfluorinated arenonium ions on the shielding of fluorine atoms in remote resonance positions is represented by the sequence CH_3 > H > Br > Cl > F, which coincides qualitatively with the generally accepted relation between their inductive effects[15].

Scheme 7

Important data have been obtained on the effects of substituents at the sp^3-hybridised site on the distribution of electron density in, and on the stability of, arenonium ions. The laws governing the reactions of aromatic compounds with various electrophiles[45] and also the actual possibility of generating the arenonium ions that are intermediate species in such reactions may depend on this effect. Such information can be obtained in a series of polyfluorinated arenonium ions by comparing $\Delta\delta_F$ values for ions formed by the protonation of pentafluorobenzene[7,20], the protonation, nitration, and halogenation of trifluoromesitylene[5,31], the halogenation of aromatic polyfluoro-compounds[14,33], and the action of antimony(V) fluoride on polyfluorinated cyclohexadienes[15,20,22]. The data in Scheme 7, illustrating the variation in $\Delta\delta_F$ in series of arenonium ions differing in the nature of the geminal substituents, indicate that decrease in electronegativity of a geminal substituent is accompanied by increase in shielding of the $F_{(4)}$ atom in benzenonium or of $F_{(4)}$, $F_{(5)}$, and $F_{(7)}$ atoms in naphthalen-1-onium ions, which apparently represents diminution in the fractional positive charge in the corresponding C−F groups. It is reasonable to expect an accompanying increase in the fractional positive charge at the *ortho*-position and hence the deshielding of *o*-fluorine atoms. This does actually occur in a series of benzenonium ions generated from trifluoromesitylene. Analogous changes are observed in the ^{13}C n.m.r. spectra of polymethylated benzenonium ions differing in the nature of substitutents at the sp^3-hybridised site[45]. In the remaining series, however, no unambiguous correspondence is observed between variation in $\Delta\delta_F$ for an *o*-fluorine atom and the electronegativity of a substituent at an sp^3-hybrid site. The apparent reason is that changes in $\Delta\delta_F$ observed for *o*-fluorine atoms are largely due to variation in the shielding effect of geminal substituents that is transmitted directly through space. Analogous laws are observed with variation in the nature of geminal substituents in polyfluorinated hydroxyarenonium ions[26].

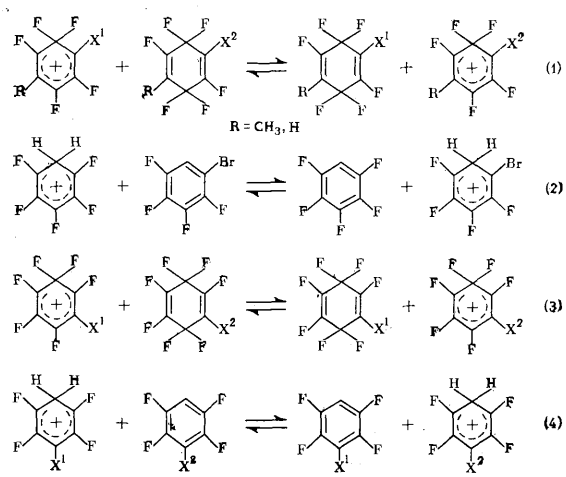
The $\Delta\delta_F$ values for fluorine atoms at non-resonance positions in the unsaturated part of arenonium ions and also at the sp^3-hybridised site apparently do not reflect the character of the distribution of positive charge. It is sufficient to mention that the signals of geminal fluorine atoms are displaced upfield on passing from polyfluorinated dihydro-aromatic compounds to the corresponding polyfluorinated

arenonium ions[13], which may be due to change specific to this process in the so called van der Waals contribution to the shielding constant[46]. Fluorine atoms at non-resonance positions in the unsaturated part of ions are apparently subject to the deshielding influence of fluorine atoms at neighbouring resonance positions, which bear considerable fractions of the positive charge. This is most likely due to a downfield shift in the signals of fluorine atoms at non-resonance positions relative to the corresponding signals in the ^{19}F n.m.r. spectra of the precursors[13]. An analogous explanation was given for the mutually deshielding influence of *peri*-fluorine atoms in polyfluorinated anthracenonium ions[23].

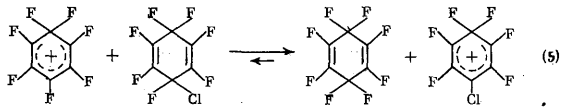
Even in the early work on the generation of polyfluorinated arenonium ions by the protonation of polyfluorobenzenes[4-6], and later by the action of antimony(V) fluoride on polyfluorinated cyclohexadienes or dihydronaphthalenes[12,13], it had already been shown that *o*- and *p*-fluorine atoms in a cyclohexadienyl fragment are characterised by unusually large absolute values of the spin–spin coupling constants between them, far exceeding those of J_{FF} for similarly oriented fluorine atoms in neutral compounds[47]. This phenomenon was interpreted qualitatively[13], in view of the close similarity of the π-electron system to a limiting structure of type (B), on the basis of effective interaction between the *o*- and *p*-fluorine atoms by a mechanism of conjugation.

From analogous considerations a similar increase in J_{FF} values in polyfluorinated naphthalenonium and anthracenonium ions relative to neutral compounds may be expected for the interaction between fluorine atoms in other resonance positions. In fact values of $J^{5,7}_{FF} \cong 50$ Hz are observed for naphthalene-1-onium ions[13], $J^{2,4}_{FF}$ 35–40 Hz for anthracen-9-onium ions[23], and $J_{FF} = 20-25$ Hz for the interaction of $F_{(2)}$ and $F_{(4)}$ with $F_{(5)}$ and $F_{(7)}$ in naphthalen-1-onium ions[18]. It is significant that the interaction between the spatially contiguous $F_{(3)}$ and $F_{(4)}$ atoms in polyfluorinated benzenonium ions corresponds to values of $J^{3,4}_{FF} = 25-30$ Hz only slightly exceeding those of J^{ortho}_{FF} for neutral fluoro-aromatic compounds[47], whereas the interaction of $F_{(2)}$ with $F_{(3)}$ is characterised by values $J^{2,3}_{FF} = 4-6$ Hz typical of the interaction of vicinal fluorine atoms located at a double bond in a cycloalkene[48], which is consistent with the close similarity of the cyclohexadienyl fragment in a polyfluorinated arenonium ion to the structure (B).

The above generalisations suggest that values of J_{FF} for interaction between fluorine atoms in resonance positions should be extremely sensitive to the type of the delocalisation of positive charge in arenonium ions. In conformity with this a parallelism in the variation of J_{FF} values and chemical shifts of the corresponding fluorine atoms is observed for polyfluorinated arenonium ions[13,23] and also the related arylmethyl cations[41]. From this point of view it is reasonable that the interaction of *peri*-fluorine atoms in naphthalen-1-onium and anthracene-9-onium ions corresponds to values of $J_{FF} = 130-150$ Hz,[13,23] since in neutral derivatives of naphthalene and anthracene such interaction is characterised by values of 60–80 Hz.[49,50] When a hydroxy-group, which exerts a stronger electron-donor effect than does a fluorine atom, is introduced into a resonance position in a polyfluorinated benzenonium or naphthalenonium ion, values of J_{FF} for interaction between fluorine atoms involved in resonance charge delocalisation decrease significantly, as is to be expected[27].



All the results at present available show that the possibility of parallel application of ^{19}F and ^{13}C n.m.r. spectroscopy makes polyfluorinated arenonium ions, and more generally polyfluorinated carbocations of various structural types, extremely interesting subjects for investigation. Detailed study of the dependence of the electronic structure of carbocations on their molecular structure and in particular elucidation of the relations between the electronic effects of substituents become theoretically possible. It may be supposed that, in contrast to the established practice of assessing these relations from the influence of substituents on the relative stability of carbocations or from their rate of formation in solution, such an approach will yield a picture uncomplicated by solvation interactions. The most reliable information can apparently be obtained from a combination of spectral data with results of quantum-chemical calculations.



2. Equilibrium Proportions of Polyfluorinated Arenonium Ions and the Stabilising Influence of Substituents

Elucidation of the factors governing the relation between the relative stability of carbocations and their structure is of decisive importance for study of the mechanism of many reactions involving intermediate formation of species of this type. When applied to arenonium ions, this general task becomes the particular problem of establishing a theory of the influence of substituents on the rate and the orientation of reactions of aromatic compounds with electrophilic agents. Polyfluorinated arenonium ions are no exception in this respect, since a considerable volume of data have now accumulated on orientation in electrophilic reactions of aromatic polyfluoro-compounds of two main types—substitution of a hydrogen atom and addition[3,16,51-63].

Although papers on the generation of polyfluorinated arenonium ions contain numerous data on the equilibrium proportions of isomeric ions of this type, they cannot provide information on the relative stabilising effects of substituents at individual positions, since the isomeric ions differ in the nature of substituents at more than one position. In some cases these relations can be assessed from a comparison of the conditions of protonation of the corresponding fluorinated benzenes (Section II). The structure of the resulting benzenonium ions indicates that the *para*-position of a fluorine atom is most favourable to the stability of the ion, whereas the *meta*-position provides the greatest destabilising effect. These results are consistent with quantum-chemical calculations predicting that carbocations with fluorine atoms in resonance positions will be more stable than isomers having a different arrangement of the same substituents[54,55].

Scheme 8

(5)

The traditional approach to elucidating the relative stabilising effects of substituents at individual positions in carbocations is to study the dependence of the equilibrium formation constants of the ions fron neutral precursors on the nature of the substituents[56]. Among polyfluorinated arenonium ions such an approach has been adopted for the equilibrium systems in Scheme 8, formed by the action of a deficiency of a Lewis or a protic acid (depending on the mode of regeneration) on a mixture of equivalent quantities of two precursors[15,20].

The positions of equilibrium in systems (1) and (2) indicate that the stabilising effect of *ortho*-substitutents diminishes the sequence $CH_3 > Br > Cl > H > F$. Similarly, series (3) gives the stability sequence of benzenonium ions with different *meta*-substituents $CH_3 > H > Br > Cl > F$.[15] Relations established in series (4) correspond to variation in the stabilising influence of *para*-substituents in the sequence $CH_3 > F > Br > Cl > H$.[15]

It must be noted that the attempt[20] to assess the relative stabilising effects of *p*-fluorine and *p*-chlorine atoms in corresponding 4-X-hexafluorobenzenonium ions from equilibrium constants in system (5) (with simultaneous generation of the ions by the action of antimony(V) fluoride on a mixture of two cyclohexadienes) gave a relation between chlorine and fluorine opposited to that found for series (4). However, this apparently does not represent the true relation between the stabilising effects of *p*-chlorine and *p*-fluorine atoms in polyfluorinated arenonium ions, since the requirement that structural differences should be remote from the bond undergoing rupture in the precursors is not met[57]. In such a situation differences in the equilibrium position may be due to structural features not so much of the ions as of their precursors, so that the observed relations cannot be interpreted in terms of effects of substituents in the ions themselves. The decisive role may be played by differences in steric stress or in strength of the carbon–fluorine bond in difluoro- and chlorofluoro-methylene groups of the cyclohexadiene precursors (see Refs.58 and 59 for the effect of the accumulation of geminal fluorine atoms on the carbon–fluorine bond strength).

Nevertheless, it must borne in mind that the relative stabilising effects of halogen atoms are apparently very sensitive to other structural characteristics of arenonium ions. Thus in series (1) differences in the relative stability of *o*-bromo- and *o*-fluoro-ions correspond to equilibrium constants of concurrent generation of the ions $K \geq 300$. In the concurrent protonation of 1-bromo-2,3,4,5-tetrafluorobenzene and pentafluorobenzene (system 2) the difference is characterised by the value $K = 1.5$ [15] with preservation of the qualitative relation between the stabilising effects of *o*-bromine and *o*-fluorine atoms.

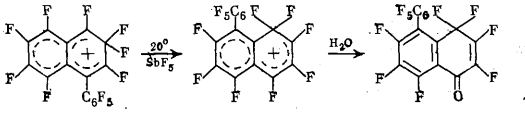
In view of the correspondence between the influence of substituents on the relative stability of cations and on the shielding of a fluorine atom in a resonance position remote from the substituents in 4-fluorinated di- and tri-phenylmethyl cations and related zwitterions[60,61], considerable interest attaches to a comparison of the above data on the influence of substituents on the ^{19}F n.m.r. spectra and on the relative stability of polyfluorinated arenonium ions. In series (3) the ions exhibit a complete qualitative correspondence between the influence of 3-substituents on $\Delta\delta_F$ for the $F_{(6)}$ atom and on the relative stability of the ion, the relations in both cases being consistent with the generally accepted sequence of variation in inductive effects in the series of substituents[15]. In series (1) and (2) there is similarly a qualitative correspondence between the effects of *o*-halogen or *o*-hydrogen atoms in the benzenonium ion on $\Delta\delta_F$ for a *p*-fluorine atom and on the relative stability of the ion. Such parallelism is characteristic of arenonium ions formed by the protonation of 1-X-2,3,4,5-tetrafluorobenzenes (X = F, Br).[15] If the variation in shielding effect of substituents in this sequence actually represents their relative electron-donor resonance effects (other possible reasons for the observed relationship with halogen atoms have been given in this Section), it may be supposed that these effects are mainly responsible also for the observed variation in stabilising influence.

It is noteworthy that such correspondence does not exist with *p*-substituents and an *o*-fluorine atom acting as indicator: although the shielding sequence of *p*-halogen and *p*-hydrogen atoms for series (4) coincides qualitatively with that of the *same* substituents located at *ortho*-positions in series (1) and (2), the stabilising effects of halogen atoms in series (4) vary in the different sequence $F > Br > Cl$.[20] The absence of such parallelism may mean that for the given substituents the order of variation in electron-donor resonance effect does not coincide with that in stabilising effect. The main contribution to the relation between the stabilising effects of halogen atoms as substituents bearing considerable fractions of the positive charge may then be made by their solvation interaction with surrounding species[20] (cf. discussion in Ref.62 on the solvation of carbocations). Such solvation effects may also be responsible to some extent for the fact that, as already noted[1,63], halogenated arenonium ions appear more stable in superacid media than could be expected from the effects of halogen atoms in the usual reactions of halogenobenzenes with electrophilic reagents.

In view of the above considerations it is noteworthy that resuits on the shielding and stabilising effects of *p*-halogen atoms in benzyl cations related to arenonium ions indicate that the parallelism between these effects may break down when hydrogen atoms are completely replaced by fluorine atoms[41]. With such modification the shielding effects of halogen atoms are reversed ($F > Cl > Br > H$ for αα-difluoro-*p*-halogenobenzyl cations[64] and $Br > Cl > F > H$ for hexafluoro-*p*-halogenobenzyl cations[41]), while their stabilising effects merely level off. This also may indicate that some factor other than the electronic effect of the substituent may make a significant contribution to the stabilising influence of *p*-halogen atoms, with the qualitative sequence of *p*-substituents apparently maintained with respect to this component of the stabilising effect on passing from αα-difluoro- to hexafluoro-*p*-halogenated benzyl cations[20]. A significant influence of solvation on the relative stabilising effects of halogen atoms may be indicated also by the diminution in stability of benzyl cations in the sequence of *p*-substituents $H > F > Cl$ suggested by the ionisation potentials of the benzyl radicals[65], whereas in antimony(V) fluoride with sulphuryl chloride fluoride *p*-halogen atoms are more strongly stabilising substituents of αα-difluorobenzyl cations than is a hydrogen atom[20].

In series (1), (3), and (4) in Scheme 8 polyfluorinated arenonium ions are considerably more strongly stabilised by a methyl group than by halogen atoms. With *meta*-orientation (series 3) this corresponds to the position occupied by methyl in the shielding sequence of substituents; with *ortho*- or *para*-orientation of this substituent—series (1) and (4)—such correspondence is absent. This apparently indicates that both shielding and stabilising effects of a methyl group differ significantly in nature from the corresponding effects of halogen atoms when these substituents are located in resonance positions.

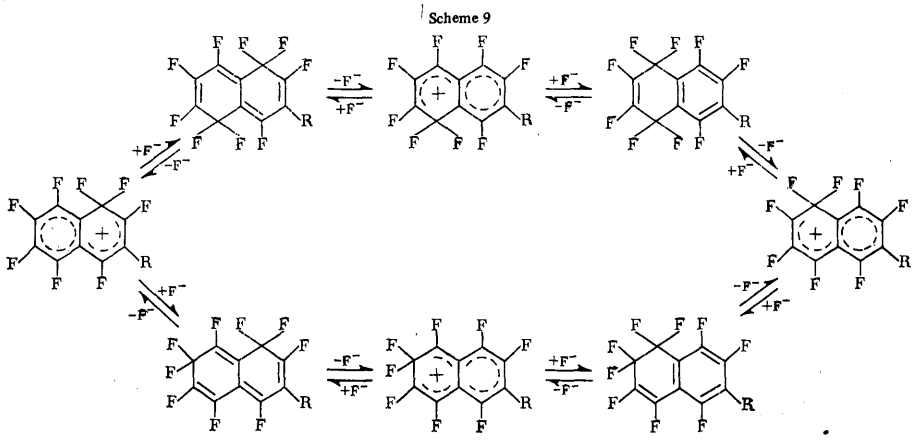
The relations between the stabilising effects of substituents at individual positions in polyfluorinated arenonium ions revealed in series (1)–(4) provide an approach to an understanding of certain factors predetermining the equilibrium isomeric composition of ions generated by the action of antimony(V) fluoride on polyfluorinated cyclohexadienes (Section II). For example, the formation of *m*-methyl isomers in series (1) in no way means that *meta*-orientation is preferable to *ortho*- or *para*-orientation, but rather is due to a tendency to avoid the destabilising influence of a *m*-halogen atom. An indication of this is that, when a hydrogen atom and a methyl group are present in the same series as substituents other than fluorine atoms, the latter occupies an *ortho*- not a *meta*-position in the corresponding ion. On the other hand, the obvious reason for the strongly marked tendency of a fluorine atom to occupy the *para*-position is that only then is it a stronger stabilising substituent than other halogen atoms.



A method of concurrent generation has provided data on the influence of the accumulation of fluorine atoms on the relative stability of 9,9,10-trifluoroanthracenonium ions[66]. Introduction of a fluorine atom at position 2 somewhat stabilises the ion, whereas simultaneous introduction of fluorine atoms at positions 1 and 4 leads to its destabilisation. Further decrease in relative stability occurs on the complete replacement of hydrogen by fluorine atoms, initially in one and then in both benzene rings of the anthracene-9-onium ion. All these changes are consistent with the influence of the structural modifications on the shielding of fluorine atoms, apparently representing a redistribution of π-electron density[23].

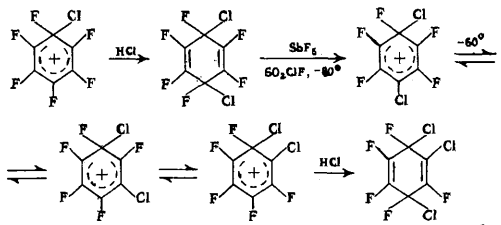
3. Isomerisation of Polyfluorinated Arenonium Ions

An urgent task in the investigation of arenonium ions is to study their isomerisation, the importance of which extends far beyond the chemistry of such ions[1,67]. Polyfluorinated arenonium ions undergo several types of isomerisation. In Section II we have already mentioned their reversible isomerisation, involving successive addition and detachment of a fluoride anion with intermediate formation of polyfluorinated dihydro-aromatic compounds. Isomeric polyfluorinated naphthalenonium ions containing the sp^3-hybridised site and the substituent other than fluorine in different rings undergo analogous interconversions. These processes take place under appreciably more severe conditions than does isomerisation in which the positions of the substituent and the sp^3-hybridised site vary within the same ring. The reason is obviously that addition of a fluoride anion to the benzene ring of a naphthalenonium ion entails complete loss of aromaticity[17–19] (Scheme 9).



The investigation of such processes broadens significantly our ideas on the thermodynamics of polyfluorinated naphthalenonium ions. Thus 6-X-octafluoronaphthalen-1-onium ions in which X = CH_3, H are completely converted into the corresponding 3-X-isomers[17,18], but with X = C_6F_5 the equilibrium ratio 3-X : 6-X = 2 : 1 is established[19]. When X = Cl, Br, the substituent is also located preferentially at a β-position in the cyclohexadienyl fragment—not in the benzene ring—of the polyfluorinated naphthalene-1-onium ion[17]. In all these cases transfer of the substituent X from the benzene to the cyclohexadienyl ring is accompanied by the reverse migration of the fluorine atom, which, situated *ortho* or *meta* in the cyclohexadienyl fragment, is the most destabilising of the substituents examined (see data in subsection 2 on relative stabilising effects of substituents at individual positions in polyfluorinated benzenonium ions). Therefore the thermodynamic relations displaced in these examples can obviously be linked with the greater effect, on the relative stability of the ion, of substituents present in the cyclohexadienyl fragment than of those located in the benzene ring.

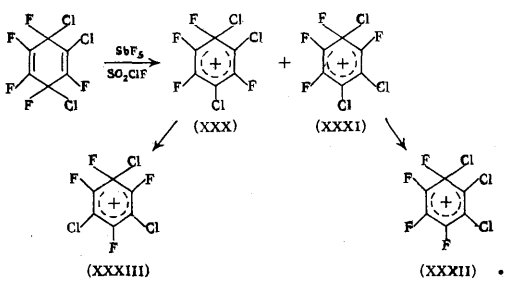
Somewhat different relations hold when a substituent other than fluoro occupies an α-position in a polyfluorinated naphthalenonium ion. For example, the perfluoro-4-phenylnaphthalen-2-onium ion passes into the perfluoro-8-phenylnaphthalen-1-onium ion, as is indicated by the isolation of dodecafluoro-1,4-dihydro-5-phenylnaphthalen-1-one from the products of hydrolysis of the reaction mixture[21]:



The first example of migration of a geminal substitutent in polyfluorinated arenonium ions was observed in those formed by addition of a proton to an unsubstituted carbon atom in fluorobenzene, *o*- and *p*-difluorobenzenes, and also 1,2,3,4-tetrafluorobenzene. These processes involve those isomers between which transition can be achieved only by 1,2-migration of a hydrogen atom from one unsubstituted ring position to another. The temperature conditions under which changes due to these intramolecular processes are detected in the n.m.r. spectra indicate that 4-mono- and 3,4-di-fluorobenzenonium ions are considerably more stable than their isomers[7]. Such a substantial difference in ease of occurrence of individual stages in 1,2-migration of a hydrogen atom as occurs with protonated fluorobenzenes is not observed with toluene and *o*-oxylene. This is because differences in energy between isomeric benzenonium ions distinguished by the position of a methyl group in the unsaturated part of the ion are not so large as with isomers differing in the position of a fluorine atom[7].

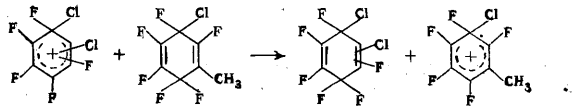
Scheme 9

Recent years have seen the discovery of isomeric changes in arenonium ions involving migration of various electronegative heteroatomic groups corresponding to active attacking species in electrophilic reactions of aromatic compounds[1,68]. A series of polyfluorinated arenonium ions have undergone isomerisation as a result of migration of a chlorine atom, which, unlike the proton in the above examples, is able to pass from one to another geminal position relative to a fluorine atom. Thus the 1,4-dichloropentafluorobezenonium ion, generated as in Scheme 10, is converted with rise in temperature of the solution from −80 to −60 °C into a mixture of 1,4-, 1,3-, and 1,2-dichloropentafluorobenzenonium ions (5%, 62%, and 33% respectively). Treatment of this mixture with hydrogen chloride yields 1,3,6-trichloropentafluorocyclohexa-1,4-diene[69] (Scheme 10).



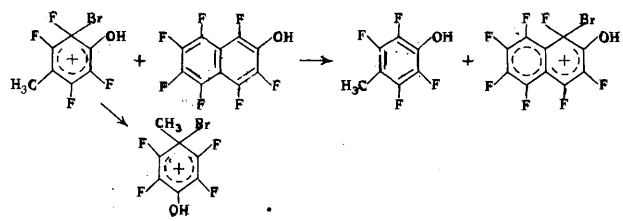
Scheme 10

(XXVIII) (XXIX)



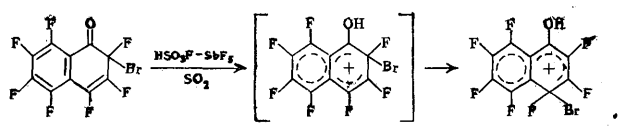
Reaction of this diene with antimony(V) fluoride in sulphuryl chloride fluoride at −90 °C yields not only the primary products of detachment of a fluoride anion—1,2,4- and 1,3,4-trichlorotetrafluorobenzenonium ions (XXX) and (XXXI)—but also two other ions, the 1,2,3- and 1,3,5-trichlorotetrafluorobenzenonium ions (XXXII) and (XXXII), having a different relative arrangement of chlorine atoms than in the original diene (Scheme 11). With rise in temperature to −70 °C the signals of the initially formed ions (XXX) and (XXXI) disappear from the ^{19}F n.m.r. spectrum of the solution, and only those of their isomerisation products (XXXII) and (XXXIII) in the proportions 1 : 1.3 remain. It is interesting that these two ions are extremely stable: right up to −30 °C they are not converted into isomers having two fluorine atoms at the sp^3-hybridised site[36], in contrast to other polyfluorinated benzenonium ions containing chlorofluoromethylene as geminal group (Section II). This may be due to improvement in the stability of polyfluorinated arenonium ions relative to their cyclohexadiene precursors as fluorine atoms in the unsaturated part of the ion are replaced by chlorine atoms, with a consequent raising of the energy barrier to addition of a fluoride anion at resonance positions in the arenonium ion.

Scheme 11

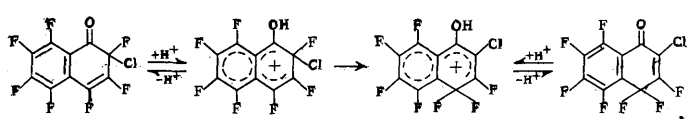


(XXXIII) (XXXII)

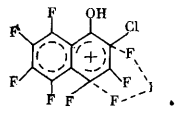
In the above cases isomerisation apparently occurs by intramolecular migration of a chlorine atom. This is indicated by absence of transfer of chlorine to pentafluorotoluene or pentafluorobenzene added to the reaction medium under conditions for isomerisation of the dichloropentafluoro- and trichlorotetrafluoro-benzenonium ions, although both additives are chlorinated by a mixture of molecular chlorine and antimony(V) fluoride in sulphuryl chloride fluoride, with formation respectively of the 1-chloro-3-methylpentafluorobenzenonium ion[14] and chloropentafluorobenzene[35]. The absence of such transfer to added pentafluorotoluene cannot be attributed to displacement of the equilibrium towards the ions (XXVIII)–(XXXIII), since addition of 3-chloro-1-methylhexafluorocyclohexa-1,4-diene to a solution containing the ions (XXVIII) and (XXIX) shifts the equilibrium towards an ion that is a chlorination product of pentafluorotoluene[69]:



This result was to be expected from the relations elucidated[15] between the stabilising effects of halogen atoms and the methyl group as substituents in polyfluorinated arenonium ions.



In contrast to this, conversion of the 1-bromo-1,3,4,6-tetrafluoro-2-hydroxy-5-methylbenzenonium ion into the 1-bromo-4-hydroxy-1-methyl isomer occurs most probably by intermolecular migration of the bromine atom, since addition of heptafluoro-2-naphthol yields the 1-bromoheptafluoro-2-hydroxynaphthalen-1-onium ion and tetrafluoro-*p*-cresol[27]:

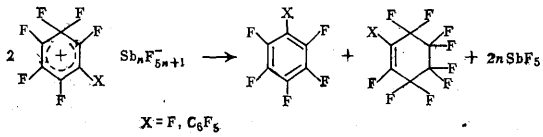


In an attempt to protonate 2-bromoheptafluoro-1,2-dihydronaphthanlen -1-one in the HSO_3F–SbF_5–SO_2ClF system between −70 and −40 °C formation of the corresponding 1-hydroxynaphthalen-2-onium ion could not be observed at all. Its isomer—the 1-bromoheptafluoro-4-hydroxynaphthalen-1-onium ion—was detected, undoubtedly as a consequence both of the greater stability of the naphthalen-1-onium than of the naphthalen-2-onium ion and of the ease of migration of the bromine atom[27]:

It is interesting that the 2-chloroheptafluoro-1-hydroxynaphthalen-2-onium ion, corresponding to protonation of 2-chloroheptafluoro-1,2-dihydronaphthanlen-1-one, could be detected. This also isomerises into the more stable 4-hydroxynaphthalen-1-onium ion, not by migration of the chlorine atom, as might have been expected from the relative tendencies of chloro- and fluoro-aromatic compounds to undergo isomerisation[67], but formally by transfer of a fluorine atom[27]:

This process is due to isomerisation either of the ion or of the precursor in equilibrium with it, apparently by a specific mechanism[70] involving hydrogen fluoride and a cyclic transition state of the type

(C)

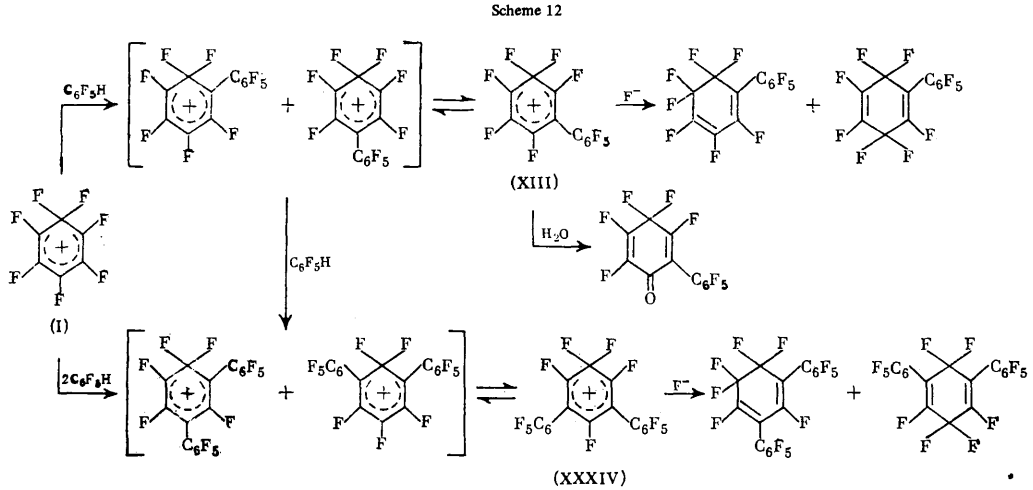


Thus known processes involving the isomerisation of polyfluorinated arenonium ions are at present limited to the transfer of hydrogen, chlorine, and bromine atoms. Apparently only in the case of the chlorine atom does intramolecular migraton occur from one position occupied by a fluorine atom to another. Determination of the relative tendencies of various groups to migrate for arenonium ions in the broad sense is important for interpreting the factors responsible for the orientation observed in reactions of aromatic compounds with electrophilic agents.

The most thoroughly studied reactions of this type in polyfluoro-aromatic compounds are those with nitrating agents, during which attack by the nitronium cation can be directed either at an unsaturated position in the aromatic ring or at those occupied by various substituents, including fluoro[3]. In this connection special interest attaches to the ability of a nitro-group to migrate "around the framework of the polyfluorinated molecule", a problem whose solution is prevented by the lack of methods for generating stable arenonium ions containing geminal fluorine atom and nitro-group at the sp^3-hybridised site. The only known fluorine-containing arenonium ion corresponding to addition of a nitronium cation to the aromatic ring—the 2,4,6,-trifluoro-1,3,5-trimethyl-1-nitrobenzenonium ion—exhibits no tendency to undergo rearrangement, whereas its completely methylated analogue—the hexamethyl-1-nitrobenzenonium ion—readily automerises as a result of intramolecular migration of the nitro-group[30]. The absence of rearrangement in the former case is apparently due to the significantly lower stability of the isomer corresponding to addition of the nitronium cation to trifluoromesitylene at a position occupied by a fluorine atom: this results in a considerably lower activation barrier to movement of the nitro-group from a position occupied by a methyl group to a neighbouring position.

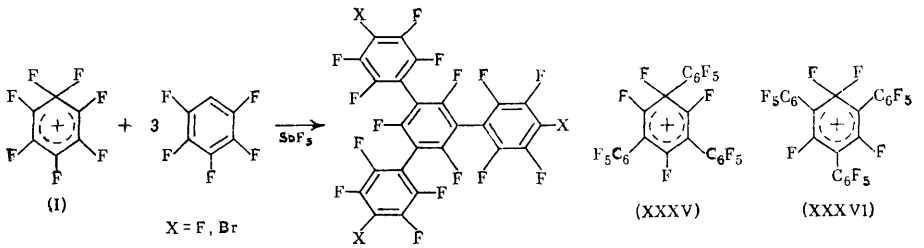
4. Transformations of Polyfluorinated Arenonium Ions in the presence of or in Antimony(V) Fluoride

Progress made during recent years in the development of methods for generating arenonium ions under "long life" conditions not only has extended the possibility of solving various theoretical problems associated with the properties of these species but has also enabled their synthetic utilisation to be envisaged. In this category we can include results obtained in studying the reactions of polyfluorinated arenonium ions in the presence of or in antimony(V) fluoride.



Perhaps the most interesting feature of these reactions is the capacity of polyfluorinated arenonium ions in many cases to undergo aromatisation by formal removal of a fluorine cation from the sp^3-hybridised site. Thus heptafluorobenzenonium hexafluoroantimonate disproportionates in solution to form equal quantities of hexafluorobenzene and decafluorocyclohexene[71]. Perfluoro-3-phenylbenzenonium hexafluoroantimonate undergoes an analogous transformation, but in this case the reaction is apparently complicated by fluorination by antimony(V) fluoride of phenylcyclohexadiene present in equilibrium with the benzenonium ion, so that perfluorophenylcyclohexene predominates over perfluorobiphenyl among the reaction products[19]:

X = F, C_6F_5

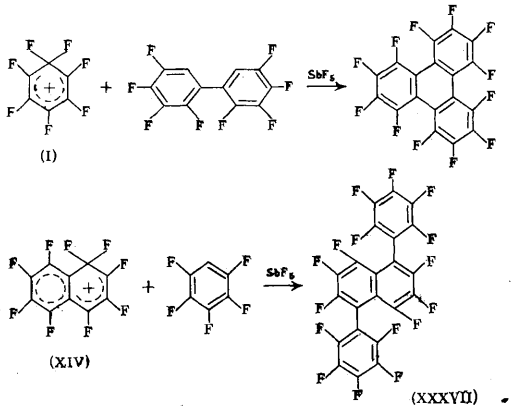


Aromatisation of polyfluorinated arenonium ions has been observed also when they react with partly fluorinated aromatic compounds in antimony(V) fluoride. Reaction of the ion (I) with one equivalent of pentafluorobenzene yields the perfluoro-3-phenylbenzenonium ion (XIII) [Scheme 12]. A mechanism has been suggested involving electrophilic attack on pentafluorobenzene by the most electrophilic centre in the heptafluorobenzenonium ion—the *p*-carbon atom—followed by a series of interconversions of polyfluorinated phenylated cyclohexadienes and benzenonium ions[19]. Addition of a second equivalent of pentafluorobenzene to (XIII) or interaction of (I) with two equivalents of pentafluorobenzene yields the perfluoro-3,5-diphenylbenzenonium ion (XXXIV).

Scheme 12

(XXXIV)

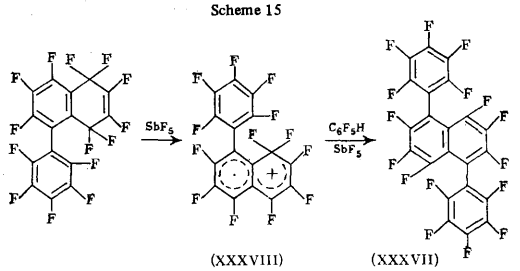
Scheme 13



The structure of the latter indicates that the second equivalent probably interacts not with (XIII) but with the perfluoro-2-phenylbenzenonium ion, present in low concentration in equilibrium with (XIII), after which the reaction proceeds by a mechanism similar to that suggested to explain formation of the ion (XIII). Hydrolysis of solutions of salts of arenonium ions generated in this way or their dilution with sulphur dioxide yields polyfluorinated phenylated cyclohexadienones or cyclohexadienes respectively[72].

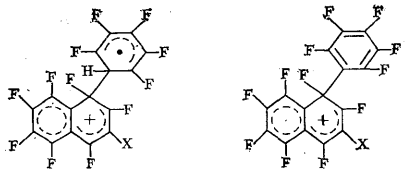
When the ion (I) is treated with three or more equivalents of pentafluorobenzene in antimony(V) fluoride, formation neither of any arenonium ions containing three or more pentafluorophenyl groups nor of compounds corresponding to hydrolysis of these species or their capture by a fluoride anion can be detected. Furthermore, perfluoro-1,3,5-triphenylbenzene is obtained in yields up to 70%. This apparently means that entry of a third pentafluorophenyl group is immediately followed by rapid aromatisation of the cyclohexadienyl fragment of one of the perfluorophenylbenzenonium ions (XXXV) and (XXXVI), a process distinct from the above disproportionation of the hexafluoroantimonates of the ions (I) and (XIII).

The ion (I) reacts similarly with 1-bromo-2,3,5,6-tetrafluorobenzene. Of the two most probable precursors of a polyfluorinated 1,3,5-triphenylbenzene—ions of types (XXXV) and (XXXVI) (Scheme 13)—the former is prefered, since its structure corresponds to the tendency of the pentafluorophenyl group to occupy a *meta*-position in the unsaturated part of the ion. Furthermore, no aromatisation processes other than the above disproportionation have been observed for benzenonium ions containing two fluorine atoms attached to the sp^3-hybridised carbon atom, which include ions of type (XXXVI).[72]



Reactions of this type are obviously of interest as routes for the synthesis of difficultly accessible polyfluorinates polycyclic aromatic compounds. This is illustrated by the syntheses of perfluorotriphenylene from (I) and 2,2',3,3',4,4',5,5'-octafluorobiphenyl[72] and of perfluoro-1,5-diphenylnaphthalene (XXXVII) from the perfluoronaphthalen-1-onium ion (XIV) and pentafluorobenzene[21,73] [Scheme 14].

Scheme 14



The second reaction apparently involves electrophilic attack on pentafluorobenzene by the 4-carbon atom in (XIV), followed by a series of isomeric conversions of polyfluorinated phenylnaphthalenonium ions yielding the perfluoro-8-phenylnaphthalene-1-onium ion (XXXVIII). This reacts with a second equivalent of pentafluorobenzene to form the compound (XXXVII). The reality of this transformation is confirmed by the formation of (XXXVII) by the action of pentafluorobenzene on the precursor of the ion (XXXVIII)—perfluoro-1,4-dihydro-5-phenylnaphthalene (Section II)—in the presence of antimony(V) fluoride[21] (Scheme 15).

Scheme 15

Those of the isomeric ions in which a fluorine atom and a pentafluorophenyl group are geminal substituents are probably responsible for aromatisation of the cyclohexadienyl fragment in polyfluorinated arenonium ions during the above reactions. This hypothesis has found some support in the formation of polyfluorinated 1-mono- and 1,5-di-phenylnaphthalenes also in the reactions of stable radical-cations of 2-X-heptafluoronaphthalenes (X = F, H, CH_3) with pentafluorobenzene[21] and with tetrafluorobenzenes[74] in antimony(V) fluoride. In terms of the schemes usually employed to describe the oxidative condensation of aromatic compounds involving radical-cations these reactions suggest, in view of the orientation for X = H, CH_3 (cf. data in Section II on relative stabilities of isomeric polyfluorinated arenonium ions containing these substituents), intermediate formation of species of type (XXXIX) and/or (XL), with the former perhaps being converted into the latter[21].

Examples of the reactions of polyfluorinated arenonium ions given in the present Review form only a small fraction of the results illustrating the opening of a new chapter in organic synthesis with the development of methods for generating and studying the properties of stable carbocations. The ensuing possibilities are difficult to overestimate, and at the present time we are witnessing the initial stage of their realisation.

The Mössbauer Spectroscopy of Tin Halide Complexes with Organophosphorus Ligands

Sh.Sh.Bashkirov, I.Ya.Kuramshin, A.S.Khramov, and A.N.Pudovik

The Mössbauer parameters (the isomer shift δ, the quadrupole splitting ΔE, and the probability of recoilless absorption f') have been analysed for a large number (more than 200) of complexes of mono- and bi-dentate organophosphorus complexes with tetra-alkyltin and alkyltin halides. It is shown that the Mössbauer method can be used to determine the localisation centres of the donor-acceptor bond in complexes of organophosphorus compounds with tin tetrahalides and to determine the geometrical structures of the complexes. It has been observed that the quantities δ, ΔE, and f' for the compounds $[R'R''R'''P(Y)]_{2(1)}SnR_nX_{4-n}$ are definitely influenced by the nature of the substituents in the ligand and in the acceptor. This influence can be described with the aid of the reaction constants of the substituents σ^{ph} and σ^*.
The bibliography includes 110 references.

I. INTRODUCTION

The Mössbauer effect or nuclear gamma resonance (NGR) have been used recently on an extremely wide scale in a wide variety of fields of science and technology. Mössbauer spectroscopy has found the most extensive applications in chemistry: in physical chemistry, in the chemistry of coordination compounds, in nuclear chemistry, etc.[1]

The extensive and effective applications of Mössbauer spectroscopy in chemistry, particularly in the chemistry of organoelemental compounds, are due to the fact that the Mössbauer isotopes ^{57}Fe and ^{119}Sn have come to be most widely used in Mössbauer spectroscopy (these isotopes are relatively readily available and sources based on them are simple to prepare and to use in experiments). On the other hand, as a consequence of the enormous importance of iron- and tin-containing compounds in science and technology, the chemistry of these elements has been studied in extremely great detail. This happy coincidence led to the intensive employment of the Mössbauer effect for studies on organoelemental compounds.

The accumulation of extensive experimental data on Mössbauer spectroscopy during the last twenty years (the effect was discovered by Mössbauer in 1958[2]) entailed the appearance of a whole series of monographs and reviews in which the principles and applications of Mössbauer spectroscopy are described fairly completely[1,3,4]. However, unfortunately none of these publications deals with studies of the class of organoelemental compounds comprising the complexes of tin halides with organophosphorus ligands.

On the other hand, the interest in the coordination compounds of phosphorus is due to the fact that the wide variety of organoelemental compounds containing phosphorus and the unique set of their properties make these substances extremely valuable both for science and for practical purposes. Among organophosphorus compounds (OPC) and their complexes, effective medicinal substances have been found and many OPC are flotation agents, additives to oils, and plasticisers. Coordination compounds of the OPC have found applications in the preparation of materials in various fields (quantum electronics, microelectronics, etc.).

The most important Mössbauer parameters for chemistry are the isomer or chemical shift δ and the quadrupole splitting ΔE, the knowledge of which permits inferences to be drawn about the structure of the electronic valence shell and the geometrical structure of the immediate environment of the Mössbauer atom, about the nature of the chemical bond, etc. Yet another Mössbauer parameter—the probability of recoilless absorption f'—is also of undoubted interest; it permits the study of the dynamic properties of crystals, which depend on the masses of the atoms and on the force constants characterising the interaction between them.

The aim of the present review was to survey the available data on the Mössbauer spectroscopy of tin halide complexes with organophosphorus ligands and to examine the relation between the Mössbauer parameters, the reactivities, and the structures of the compounds. We do not deal with the experimental features of the Mössbauer spectroscopy of ^{119}Sn, which have been described fairly completely elsewhere[1,5-7].

In all cases the isomer shifts, the quadrupole splittings, and the resonance line widths (Γ) are quoted in terms of units of velocity (mm s^{-1}). The isomer shifts are given relative to SnO_2 at room temperature; if the shift is indicated in the original publication relative to another compound, the appropriate recalculation has been made. Since in virtually all studies the accuracy of the determinations of δ, ΔE, and Γ is stated to be in the range $\pm 0.03-0.05$ mm s^{-1}, we shall assume that the experimental error of the determination of these parameters is in this range. The accuracy of the determination is to within ± 0.03. The Mössbauer spectra of the compounds described below have been obtained in the region of liquid nitrogen temperatures (78–90 K) unless otherwise stated.

II. THE ISOMER SHIFT

1. The Influence of the Donor Atom

The isomer or chemical shift is the difference between the energies of the nuclear transitions in the absorbing and emitting nuclei. In the Mössbauer spectra this is manifested

by a shift of the absorption resonance line relative to the emission resonance line (Fig. 1).

In the general case the isomer shift is defined in the following way[1,3,4]:

$$\delta = \frac{4}{5}\pi e^2 z R^2 \frac{\Delta R}{R}\{|\psi(0)|_a^2 - |\psi(0)|_s^2\}, \quad (1)$$

where e is the electronic charge, z the nuclear charge, R the average charge radius of the nucleus, ΔR its change on transition from the ground to the excited state, and $|\psi(0)|_a^2$ and $|\psi(0)|_s^2$ are the electron densities at the nucleus in the absorber and the source respectively. Since the contribution of the inner shells in tin compounds is approximately constant[1,4], δ depends on the population of the valence shell of the Mössbauer atom. Furthermore, theoretical analysis[1,4,8] and numerous experimental results[9-12] showed that in the case of tin(IV) compounds one can neglect to a first approximation the population of the 5p states of the tin atom and the mutual shielding of the s electrons by the p and d electrons.

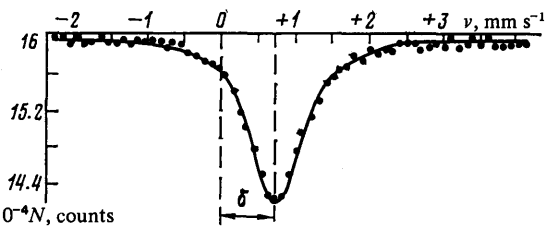

Figure 1. The Mössbauer spectrum of the complex $[(C_2H_5)_2P(S)S]_2SnCl_2$ at 85 K (continuous line—calculation).

Thus the state of the Mössbauer atom in various chemical compounds is determined primarily by the structure of the outer electronic valence shells and the main contribution to δ for tin-containing compounds comes from the difference $|\psi_{5s}(0)|_a^2 - |\psi_{5s}(0)|_s^2$. Consequently the relative change in the population of the valence 5s shells of the tin atom in a series of different absorbers (for a fixed source) can be inferred from the change in δ.

Since $\Delta R/R > 0$ for ^{119}Sn, one can claim unambiguously that, for tin-containing compounds, a large value of δ corresponds to a large population of the 5s shell of the tin atom. Thus if 100% covalent bonding is assumed in α-tin ($\delta = 2.1$ mm s^{-1}), i.e. that the population of the 5s orbital is 1.0–1.2 electrons[5,15,16], and a 50% ionic bond character is assumed for SnF_4 ($\delta = -0.25$ mm s^{-1}),[4] then evidently the closer the value of δ for any tin-containing compound to that for SnF_4, the smaller the population of the 5s shell of the tin atom in the given substance.

Thus the isomer shift permits inferences about the chemical environment of the Mössbauer atom in various compounds. Such analysis is particularly simple for the determination of the valence state of tin. Thus, for bivalent tin, the isomer shift relative to α-tin is greater than zero, while for quadrivalent tin it is less than zero[17]. If the shifts are considered relative to SnO_2 (a generally recognised standard in ^{119}Sn Mössbauer spectroscopy), then $\delta > 2.1$ mm s^{-1} for tin(II) and $\delta < 2.1$ mm s^{-1} for tin(IV). One must note that in certain complexes of the type $LSnCl_3$ the isomer shift ($\delta > 2.1$ mm s^{-1}) does not allow the estimation of the formal valence of tin[18].

Systematic treatment and analysis of the literature data[10-12,19-24] and the authors' own results[25-43], summarised in Tables 1–9, permits the claim that the values of δ for compounds of the type $L_3(L')SnX_4$ and the ratio of the isomer shifts of $L_2(L')SnBr_4$ (δ_{Br}) and $L_2(L')SnCl_4$ (δ_{Cl}) is determined in the first place by the nature of the immediate environment of the tin atom (Table 1) and this makes it possible to use Mössbauer spectroscopy for the determination of the localisation centres of the donor–acceptor bond in complexes of organophosphorus compounds with both tin chloride and tin bromide.

Table 1. The isomer shifts and quadrupole splittings in the Mössbauer spectra of tetra-alkyltin compounds, tetra-aryltin compounds, alkyltin halides, and aryltin halides with mono- and bi-dentate organophosphorus ligands $L_2(L')SnX_4$, $L_2SnR_nX_{4-n}$ ($n = 1,2$), and $LSnR_3Cl$ and of the organotin salts L_2SnX_2 at 78–90 K.[38,40]

* and ** For X = I, $\delta = 0.93$ and 0.40–0.45 mm s^{-1} respectively, $\Delta E = 0$ and 0.65–0.79 mm s^{-1}, and the number of compounds is unity.

*** For $[Cl_3P(O)]_2SnCl_4$, $\Delta E = 1.12$ mm s^{-1}.

The data in Table 1 show that there is a definite relation between δ and the electronegativity χ of the atoms surrounding the Mössbauer isotope, which makes it possible to determine the donor atom in ligands having two and more donor centres and to estimate the sequence in the variation of the isomer shift on passing from tin(IV) chloride to tin(IV) bromide complexes. This relation is described approximately by the following empirical equation[38]

$$\frac{\delta_{Br}}{\delta_{Cl}} = \alpha \frac{\chi_{Br} - \chi_{Sn}}{\chi_{Cl} - \chi_{Sn}} + \beta \frac{\chi_{Br} - \chi_{Sn}}{\chi_{Y} - \chi_{Sn}} , \qquad (2)$$

where α and β are coefficients and χ_Y is the electronegativity of the ligand donor atom.

Note. For complexes 5, 25, 26, 43, 44, 46, and 50, the values of f'_{85} are respectively 0.31, 0.31, 0.15, 0.36, 0.23, 0.26, and 0.29.[96,97]

The data in Table 1 and Eqn.(2) suggest[38] that the complexes $[(C_5H_{10}N)P(S)]_2SnCl_4$ and $[(C_4H_8N)P(S)]_2SnCl_4$, whose isomer shifts are 0.49 and 0.43 mm s^{-1} respectively, are formed as a consequence of the electron-donating properties of the nitrogen atom and not the thiophosphoryl sulphur, as suggested by Carty and Sharma[23]. The above conclusion is confirmed by data obtained for similar systems in ^{35}Cl Mössbauer spectroscopic and vibrational spectroscopic studies[44].

Note. The values of f'_{85K} have been determined for complexes 22 and 25 (0.29 and 0.38).[96,97]

In selecting the coefficients α and β in Eqn.(2), it was found that the optimum agreement between the calculated and experimental δ_{Br}/δ_{Cl} (Table 1) is observed when the ligands are subdivided into groups with similar electronegativities:

(a) the Allred–Rochow electronegativities[45,46]:

Y=O, N, Cl : α=2.61, β=—0.88;
Y=S, P, Br : α=1.69, β=—0.085;

(b) the Pauling electronegativities[45,47,48]:

Y=O, N, Cl : α=2.94, β=—0.85;
Y=S, P, Br : α=2.82, β=—0.055;

(c) the Mulliken electronegativities[23,49–51]:

Y=O, N, Cl : α=4.90, β=—2.89;
Y=S, P, Br : α=2.55, β=—0.48.

Note. X = Br in complexes 18, 24, 25, 34, and 35, while in the remaining cases X = Cl. f'_{85K} = 0.41, 0.31, 0.22, 0.21, 0.25, 0.25, 0.31, and 0.29 for complexes 2,4,6,13,14,16,17, and 30 respectively[96,97].

We may note that the correlations between the isomer shifts and the Mulliken group molecular electronegativities of the ligands (χ_L) in similar complexes has also been mentioned by Carty and Sharma[23]. The use of χ_L from their study[23] in Eqn.(2) instead of χ_Y also leads to satisfactory results.

Together with the Mössbauer spectra of the molecular complexes of tin halides with organophosphorus compounds, Mananov et al.[26] investigated the Mössbauer spectra of the salt products $[R'R''P(Y)Y]_2SnX_2$ (Table 8). The similarity

of the values of δ for the complexes $[R'R''P(O)O_2]SnCl_2$ to those for SnO_2 and $BaSnO_3$ suggests that the immediate environment of the tin atom in these complexes is also octahedral[52,53]. This is possible for the polymeric structure $[R'R''P(O)O]_2SnCl_2$, which is in full agreement with data obtained for the above and similar compounds by vibrational spectroscopic methods[54].

2. The Effects of Substituents

Together with the influence of the immediate environment of the tin atom in the complexes $[R'R''R'''P(Y)]_{2(1)}SnR_nX_{4-n}$, on the isomer shift, the study of the influence of the substituents in $R'R''R'''P(Y)$ and SnR_nX_{4-n} on the isomer shifts of the complexes $L_2SnR_nX_{4-n}$ and the estimation of the degree of their influence on the population of the 5*s* shell of the tin atom are also of undoubted interest. The tendency towards a linear dependence of δ on the sum of the constants of the substituents in the ligand and the acceptor was noted in our earlier studies[26,31,32,40-42,54] and by Khrapov et al.[55] and Ford and Sams[56].

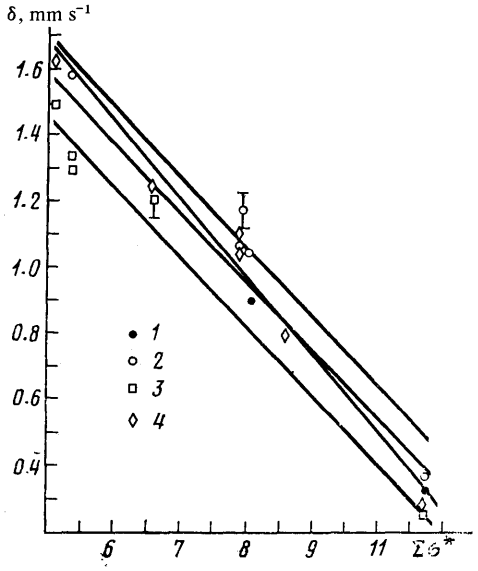

Figure 2. Relations between δ and $\Sigma\sigma^*_{R,Cl}$ for different complexes: 1) $[(CH_3)_2(CH_3O)P(O)]_2Sn(CH_3)_nCl_{4-n}$; 2) $[(CH_3)_2ClP(O)]_2SnR_nCl_{4-n}$ (R = CH_3, C_2H_5, or C_4H_9; 3) $[(n\text{-}C_4H_9)_3P(O)]_2SnR_nCl_{4-n}$ (R = CH_3, C_2H_5, or C_6H_5); 4) $[(C_6H_5)_3P(O)]_2SnR_nCl_{4-n}$ (R = C_4H_9 or C_6H_5).

Analysis of the dependence of δ on the sum of the Taft constants[57,58] of the substituents at the tin atom (Σσ*) leads to the following correlation equations† (Fig. 2):

$$[(CH_3)_2(CH_3O)P(O)]_2Sn(CH_3)_nX_{4-n}\ (n = 0, 1, 2;\ X = Cl, Br) \quad (3a)$$
$$\delta = -0.206\,\Sigma\sigma^* + 2.600\ (r = 0.984,\ S = 0.076,\ P \leqslant 0.0027,\ m = 4),$$

$$[(CH_3)_2ClP(O)]_2SnR_nX_{4-n}\ (n = 0, 1, 2;\ X = Cl, Br;\ R = CH_3, C_2H_5, C_4H_9) \quad (3b)$$
$$\delta = -0.213\,\Sigma\sigma^* + 2.770\ (r = 0.984,\ S = 0.0067,\ P < 0.0005,\ m = 7),$$

$$[(n\text{-}C_4H_9)_3P(O)]_2SnR_nCl_{4-n}\ (n = 0, 1, 2;\ R = CH_3, C_4H_9, C_6H_5) \quad (3c)$$
$$\delta = -0.210\,\Sigma\sigma^* + 2.501\ (r = 0.994,\ S = 0.057,\ P \leqslant 0.0008,\ m = 6),$$

$$[(C_6H_5)_3P(O)]_2SnR_nX_{4-n}\ (n = 0, 1, 2;\ X = Cl, Br;\ R = CH_3, C_4H_9, C_6H_5) \quad (3d)$$
$$\delta = -0.206\,\Sigma\sigma^* + 2.606\ (r = 0.972,\ S = 0.094,\ P < 0.0005,\ m = 8).$$

Evidently the coefficients representing the slopes in Eqns. (3a)–(3d) change insignificantly from series to series. This suggests that the Sn–Cl, Sn–Br, and Sn–C bonds make the main contribution to the population of the 5*s* valence shell of the tin atom in the complexes $[R'R''R'''P(O)]_{2(1)}\cdot SnR_nX_{4-n}$. This conclusion is consistent with those reached from the dependence of δ on χ[23,51] and with X-ray diffraction data[60].

The dependence of δ on Σσ* for the substituents at the tin atom and on the sum of the Kabachnik constants ($\Sigma\sigma^{ph}$)[57,58] for the substituents at the phosphorus atom were examined by ourselves[40] to estimate the influence of the substituents at both tin and phosphorus atoms on the isomer shift in the Mössbauer spectra of the complexes $[R'R''R'''P(O)]_2SnR_nX_{4-n}$#:

$$\delta = -0.208\Sigma\sigma^* + 0.018\Sigma\sigma^{ph} + 2.635\ (r = 0.976,\ S = 0.095,\ P < 0.0005,\ m = 90). \quad (4)$$

Comparison of Eqns. (3) and (4) shows that allowance for the influence on δ by the nature of the substituents at the phosphorus atom together with that of the substituents at the tin atom does not introduce significant changes into the constant term and the coefficient of Σσ*.

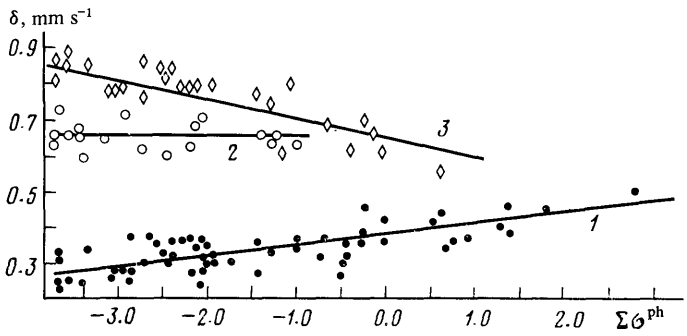

Figure 3. Relations between δ and $\Sigma\sigma^{ph}$ for the complexes $[R'R''R'''P(Y)]_2SnCl$: 1) Y = O; 2) Y = S; 3) Y = LEP.

Examination of the Mössbauer parameters of the complexes $[R'R''R'''P(Y)]_2SnCl_4$ shows that here too there is a tendency towards a linear variation of δ as a function of the sum of the constants of the substituents at the phosphorus atom[32,37,40,54] (Fig. 3):

$$[R'R''R'''P(O)]_2SnCl_4 \quad (5a)$$
$$\delta = 0.030\,\Sigma\sigma^{ph} + 0.381\ (r = 0.78,\ S = 0.039,\ P < 0.0005,\ m = 48),$$

† The two-parameter linear correlation equations have been obtained by the method of least squares[59]. Here and below the following notation has been adopted: *r* is the correlation coefficient, *S* the main error, *P* the level of significance, and *m* the number of experimental points.

Numerous correlation equations have been obtained by the Chebyshev method[61].

$$[R'R''R'''P(S)]_2SnCl_4 \quad (5b)$$
$$\delta = 0.66 \pm 0.06,$$
$$[R'R''R'''P]_2SnCl_4 \quad (5c)$$
$$\delta = 0.056\,\Sigma\sigma^{ph} + 0.646\,(r = 0.75, S = 0.061, P < 0.0005, m = 28),$$
$$[R'R''R'''P]_2SnR_nX_{4-n}\ (X=Cl,\ Br;\ n=0.1;\ R=C_4H_9) \quad (5d)$$
$$\delta = -0.196\,\Sigma\sigma^* - 0.055\,\Sigma\sigma^{ph} + 2.768\,(r = 0.84,$$
$$S = 0.075,\ P < 0.0005,\ m = 32).$$

It is seen from Eqns.(5) that, as the nature of the donor centre varies from Y = O to Y = LEP (lone electron pair), the sign of the slope changes. In the reaction series investigated the sensitivity to the nature of the substituents at the phosphorus atom in the ligand decreases in the sequence $R'R''R'''P > R'R''R'''P(O) > R'R''R'''P(S)$. On the other hand, the sensitivity of the enthalpy of complex formation ΔH to the influence of the substituents decreases in the sequence $> R'R''R'''P(S) > R'R''R'''P > R'R''R'''P(O)$.[62,63] The observed difference can be due to small (in absolute magnitude) changes in ΔH in the series of complexes of thiophosphoryl compounds investigated by Mössbauer spectroscopy ($\Delta\Delta H \leq 5$ kcal mol^{-1}).[62,63]

Since the enthalpies of formation of the complexes increase as the "electron withdrawing" effect of the substituents at the phosphorus atom is reduced for all the $[R'R''R'''P(Y)]_2 \cdot SnX_4$ (Y = O, S, Se, or LEP) investigated[62,63], one of the possible causes of the difference between the values of ρ in Eqns.(4) and (5a) and in Eqns.(5c) and (5d) can apparently be an additional donor–acceptor interaction in $[R'R''R'''P]_2 \cdot SnX_4$ between the lone electron pair of the halogen atom in the acceptor molecule and the vacant d orbitals of the phosphorus atom of the ligand molecule[32,40,63]. With increase of the basicity of the phosphorus atom in $R'R''R'''P$, the strength of this interaction should increase, since the electron density transferred from the donor is concentrated at the halogen atoms[64,65], which leads to an increase of δ.

It is known[1,4,20,23,26,61] that tin halides are capable of forming trigonal-bipyramidal complexes as well as octahedral complexes. We therefore investigated[26,40] the influence of the substituents at the tin atom and of the organophosphorus ligand on δ in pentacoordinate complexes of tin halides. A correlation analysis of the isomer shifts in the Mössbauer spectra of the complexes $LSnR_3Cl$ (Table 5) as a function of the reaction constants of the substituents at the phosphorus and tin atoms was carried out for this purpose. The resulting correlation equations are

$$\delta = -0.076\,\Sigma\sigma^* + 1.648\,(r = 0.892, S = 0.036, P \leq 0.002, m = 8), \quad (6)$$
$$\delta = -0.093\,\Sigma\sigma^* + 0.020\,\Sigma\sigma^{ph} + 1.740\,(r = 0.919, S = 0.031, P < 0.0005,$$
$$m = 8). \quad (7)$$

It is seen from Eqns.(4), (5a), (6), and (7) that in the pentacoordinate compounds the sensitivity of the isomer shift to the nature of the substituents at the tin atom is much smaller than in the octahedral complexes, while the contribution of the organophosphorus ligand to δ remains virtually the same. We believe that the above finding is due to the fact that in the octahedral systems there is a relatively symmetrical distribution of ligands about the nucleus. On the other hand, in trigonal-bipyramidal complexes this symmetry breaks down in the axial plane (L–Sn–Cl), which apparently increases the sensitivity of δ to L.[40,60,67]

Thus the isomer shifts of the compounds $[R'R''R'''P(Y)]_{2(1)} \cdot SnR_nX_{4-n}$ are described satisfactorily in terms of the reaction constants of the substituents at the tin and phosphorus atoms. The correlation equations obtained can be used to predict the isomer shifts in the Mössbauer spectra of similar compounds and their other spectroscopic characteristics[23–44], to estimate the Taft and Kabachnik constants of the substituents in the ligand and acceptor, to determine the 5s valence shell populations of the tin atom in the complexes of tetra-alkyltin compounds and alkyltin halides with organophosphorus ligands, and to determine the coordination number of tin in the compounds investigated. Since the enthalpies of formation of the complexes $[R'R''R'''P(Y)]_{2(1)}SnR_nCl_{4-n}$, characterising the energies of the donor-acceptor interaction, are likewise linearly related to $\Sigma\sigma^*$ and $\Sigma\sigma^{ph}$,[62,63] Mössbauer spectroscopy can be used also to estimate the enthalpies of formation of the complexes of tetra-alkyltin compounds and alkyltin halides with $R'R''R'''P(Y)$.

Note. X = Br in complexes 2,4,12,19, and 22, while in the remaining cases X = Cl. $f'_{85K} = 0.23$, 0.24, 0.22, 0.23, 0.21, and 0.22 for complexes 1,2,9,18, and 24 respectively.

III. THE QUADRUPOLE SPLITTING

1. The Influence of the Geometrical Structure of the Complexes

The electrical quadrupole interaction in the Mössbauer spectra is manifested by a fine structure whose components correspond to the gamma transitions between the split levels. For the ^{57}Fe and ^{119}Sn Mössbauer nuclei, where the spins of the excited and ground states are 3/2 and 1/2 respectively, this hyperfine structure appears in the spectrum in the form of a doublet. The appearance of the doublet is associated with the splitting of only the upper level into two states with spin projections $m_I = \pm 3/2$ and $m_I = \pm 1/2$, while the ground state with a spin of 1/2 is not split[1,4]. A typical Mössbauer spectrum with quadrupole splitting is presented in Fig.4.

The energy gap between the split sublevels (or the quadrupole splitting ΔE) can be represented as follows for ^{57}Fe and ^{119}Sn[1,4]:

$$\Delta E = -\frac{1}{2}e^2qQ\left(1 + \frac{1}{3}\eta^2\right)^{1/2}, \quad (8)$$

where Q is the quadrupole moment of the nucleus, characterising the deviation of the distribution of the averaged nuclear charge density in the state with $I = 3/2$ (for ^{57}Fe and ^{119}Sn) from spherical symmetry, $q = V_{zz}/e$ the electric field gradient (EFG) at the Mössbauer nucleus, $\eta = (V_{xx} - V_{yy})/V_{zz}$ the asymmetry parameter, and V_{xx}, V_{yy}, and V_{zz} are the principal components of the diagonalised EFG tensor chosen so that the condition $|V_{xx}| \leq |V_{yy}| \leq |V_{zz}|$, for which the values of η are in the range $0 \leq \eta \leq 1$, holds.

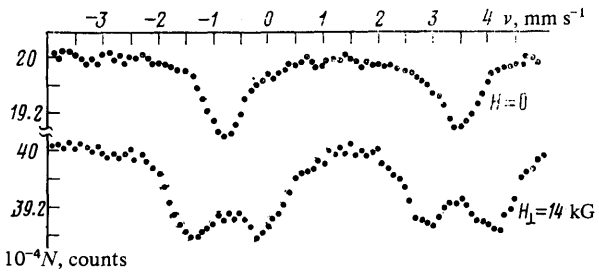

Figure 4. The Mössbauer spectra of $\{[(CH_3)_2N]_3P(O)\}_2 . Sn(CH_3)_2Cl_2$ for $H = 0$ and $H = 14$ kG.

The valence shell of the free tin atom has the structure $5s^25p^2$, but, since s electrons have the spherical symmetry (without taking shielding into account), they do not give rise to an electric field gradient at the nucleus and the EFG for ^{119}Sn depends on the distribution of p electrons. For different types of hybridisation, s and d electrons can contribute to the EFG,[1,4] but the nature of the p bond is decisive; consequently ΔE makes it possible to estimate the electron distribution in the valence p shell.

Like the isomer shift, the quadrupole splitting is a characteristic parameter for the determination of the valence state of the tin atom. In those cases where tin is in the bivalent state the absorption spectra have a doublet structure[1,4,17,68,69] ($\Delta E = 0.5-2.5$ mm s^{-1}) [with the exception of $SnCl_2$,[1,48] owing to the presence of unbalanced p electrons in tin(II) compounds giving rise to an EFG at the nucleus].

In compounds of quadrivalent tin there is a possibility of the formation of four (sp^3 hybridisation) or six (sp^3d^2 hybridisation) equivalent bonds, which ensure equal populations of the p_x, p_y, and p_z states and as a consequence the absence of a field gradient at the ^{119}Sn nucleus. On the other hand, the upper limit of the variation of ΔE for tin(IV) compounds can be greater than for bivalent tin compounds: $\Delta E = 0-5.4$ mm s^{-1}.[1,4,10-12,17-43,70] Table 1 presents the limits of the variation of the quadrupole splitting in the Mössbauer spectra of the complexes $[R'R''R'''P(Y)]_{2(1)} . SnR_nX_{4-n}$.

Analysis of the Mössbauer spectroscopic data in Tables 1–9, combined with data for the geometrical structures[10,26,60,67,71] and the enthalpies of formation[62,63] of the complexes $[R'R''R'''P(Y)]_2SnX_4$ and the complexes of organophosphorus compounds with alkyltin halides, shows that the following factors make the main contributions to the generation of the electric field gradient at the tin nucleus and hence to the quadrupole splitting ΔE for compounds of this type[42]: (1) the geometrical configuration of the complexes (*cis–trans* isomerism), (2) the spatial configuration of the organophosphorus ligand, (3) the electron-donating capacity of the atom Y in the P=Y group and the nature of the substituent R_nX_{4-n} atom.

We shall consider in greater detail the influence of each factor on the ΔE for the compounds investigated.

Analysis of the data in Table 1 shows that, for complexes of organophosphorus compounds with tin halides, the Mössbauer parameters of only the compounds formed as a result of the electron-donating properties of the oxygen of the phosphoryl group, namely $[R'R''R'''P(O)]_2SnX_4$, and of the phosphorus atom, namely $[R'R''R'''P]_2SnX_4$, are sensitive to structural isomerism. For the *trans*-complexes of phosphoryl compounds, the quadrupole splitting varies from 0.5 to 1.6 mm s^{-1}, while for the *cis*–compounds it is as a rule less than 0.5 mm s^{-1} [the *cis*-complexes of tin(IV) chloride with phosphoryl chloride and the dichlorides of phosphoric and phosphonic acid are an exception]. A change in the geometry of the complexes $[R'R''R'''P(O)]_2SnX_4$ from *trans* to *cis* entails a decrease of ΔE by a factor of two[72,73] (subject to the condition that the $\Sigma\sigma^{ph}$ and ΣE_S for the substituents in the ligand are approximately equal). This is illustrated fairly clearly by the Mössbauer spectra of the following complexes (Tables 2 and 3): *cis*-$[(C_4H_9O)_2(SCH_3)P(O)]_2SnCl_4$ ($\Delta E = 0.41$ mm s^{-1}), *trans*-$[(n\text{-}C_3H_7O)_2(SCH_3)P(O)]_2SnCl_4$ ($\Delta E = 0.83$ mm s^{-1}), *cis*-$[(C_6H_5)_2(CH_3)P(O)]_2SnBr_4$ ($\Delta E = 0.37$ mm s^{-1}), and *trans*-$[(C_6H_5)_2(CH_3)P(O)]_2SnCl_4$ ($\Delta E = 0.68$ mm s^{-1}).

For complexes with similar enthalpies of formation (with similar values of $\Sigma\sigma^{ph}$ for the substituents at the phosphorus atom), ΔE increases with increase of the bulk of the substituents at the phosphorus atom—for example, $\Delta E = 0.46$ mm s^{-1} for *trans*-$[(C_2H_5)_2ClP(O)]_2SnCl_4$, $\Delta E = 0.83$ mm s^{-1} for *trans*-$[(n\text{-}C_3H_7O)_2(SCH_3)P(O)]_2SnCl_4$, and $\Delta E = 1.06$ mm s^{-1} for *trans*-$[(iso\text{-}C_3H_7O)_2(SCH_3)P(O)]_2SnCl_4$ (Table 2), i.e. an increase of the bulk of the groups at the phosphorus atom in the ligands $R'R''R'''P(O)$ induces an EFG at the tin nuclei both as a result of the geometrical isomerism of the complexes and the steric effect[11,25,31].

The possibility of using the ΔE for the determination of the geometrical structure of complexes of tetra-alkyltin halides with phosphoryl compounds is also indicated by the finding that the structure of the complexes $[R'R''R'''P(O)]_2 . SnR_nX_{4-n}$ ($n = 0-2$) is described satisfactorily on the basis of the point charge model[22,74]. According to this model, the overall EFG (q) can be represented by the sum of the independent contributions of each ligand[75]. Since $\Delta E \propto q$, the principle of additivity can be extended also to the quadrupole splitting and can be regarded as the sum of the partial quadrupole splittings (*PQS*) of the ligands.

Table 10 presents the values of *PQS* for certain organophosphorus ligands in the complexes $L_2Sn(CH_3)_nCl_{4-n}$, which we calculated by the method proposed previously[75,76], and the ΔE for these complexes. The Table shows that in most cases there is a satisfactory agreement between the calculated and experimental ΔE.

The Mössbauer spectra of the complexes $[R'R''R'''P]_2SnCl_4$ having the *trans*-structure also exhibit quadrupole splitting (Tables 1 and 6). However, in the Mössbauer spectra of the $[R'R''R'''P]_2SnCl_4$ series ΔE diminishes with increase of the bulk of the ligands—for example, $\Delta E = 1.02$ mm s^{-1} for *trans*-$[(n\text{-}C_4H_9)_3P]_2SnCl_4$ and $\Delta E = 0.58$ mm s^{-1} for *trans*-$\{[(CH_3)_2N]_3P\}_2SnCl_4$ (see Table 6), while the opposite behaviour obtains for the complexes $[R'R''R'''P(O)]_2SnCl_4$. The observed difference in the influence of the steric effects of the substituents at the phosphorus atom on the ΔE for the complexes $[R'R''R'''P]_2SnCl_4$ and $[R'R''R'''P(O)]_2SnCl_4$ can also be explained by the additional intramolecular interaction in $[R'R''R'''P]_2SnCl_4$ due to the d orbitals of the phosphorus atom[32,63]. With increase of the bulk of the substituent at the phosphorus atom in $R'R''R'''P$, the strength of this interaction should decrease, which should lead to a decrease of ΔE.

In the Mössbauer spectra of the complexes formed as a result of the electron-donating properties of the S and Se atoms, the quadrupole splitting is small or altogether absent, although the complexes have the *trans*-structure (Tables 1 and 7). Together with geometrical and steric factors the nature of the substituents at the phosphorus and tin atoms in the ligand and acceptor respectively influence significantly the quadrupole splitting.

Table 10. The calculated (ΔE_t) and experimental (ΔE_e) quadrupole splittings for the complexes $L_2Sn(CH_3)_nX_{4-n}$.

No.	L	n	ΔE_e, mm s^{-1}	ΔE_t, mm s^{-1}
1	$(CH_3)_3P(O)$	0	0.51	+0.22
2	$(CH_3)_3P(O)$	2	4.30	+4.32
3	$(CH_3)_2(CH_3O)P(O)$	0	0.25	−0.56 (*trans*) ; +0.28 (*cis*)
4	$(CH_3)_2(CH_3O)P(O)$	0	0.40	+0.26
5	$(CH_3)_2(CH_3O)P(O)$	1	2.20	+2.37
6	$(CH_3)_2(CH_3O)P(O)$	2	4.37	+4.39
7	$(CH_3)_2ClP(O)$	0	0.57	−0.38 (*trans*) ; +0.19 (*cis*)
8	$(CH_3)_2ClP(O)$	0	0.35	−0.34
9	$(CH_3)_2ClP(O)$	1	2.26	+2.25
10	$(CH_3)_2ClP(O)$	2	4.10	+4.28
11	$[(CH_3)_2N]_3P(O)$	0	0.69	−0.52
12	$[(CH_3)_2N]_3P(O)$	0	0.93	−0.48
13	$[(CH_3)_2N]_3P(O)$	1	2.35	+2.34
14	$[(CH_3)_2N]_3P(O)$	2	4.36	+4.36
15	$(n\text{-}C_4H_9)_3P(O)$	0	0.25	+0.16
16	$(n\text{-}C_4H_9)_3P(O)$	0	0.00	+0.14
17	$(n\text{-}C_4H_9)_3P(O)$	2	4.15	+4.25

Note. X = Br in complexes 4,8,12, and 16, while in the remaining cases X = Cl. The *cis*-structure is characteristic of complexes 1 and 15, complexes 3 and 7 consist of mixtures of *cis*- and *trans*-isomers, while the *trans*-structure is characteristic of the remaining complexes[65,66]. The partial quadrupole splittings (PQS_L) for complexes 1,3,7,11, and 15 are respectively −0.10, −0.13, −0.085, −0.12,[22] and −0.07 mm s^{-1}. The values of PQS for CH_3, Cl, and Br are 1.03,[22] 0.01, and 0.00 mm s^{-1} respectively.

Before considering the nature of the influence of the electronic effects of the substituents at the phosphorus and tin atoms on ΔE, we should point out that, as a consequence of the large number of variables determining the ΔE for the compounds investigated, Herber's rule does not hold for the complexes $[R'R''R'''P(Y)]_2SnX_4$.[77] According to this rule, the ratio of the quadrupole splitting to the isomer shift $\rho = \Delta E/\delta$ is determined by the coordination number of tin. If $\rho < 1.8$, then the tin atom is tetracoordinated, while for $\rho > 2.1$ the environment of the tin atom is octahedral or trigonal-bipyramidal. The data summarised in Table 1 show that Herber's rule is valid only for the *trans*-complexes of organophosphorus compounds with tin tetrahalides formed due to the electron-donating properties of the phosphoryl oxygen.

2. Chemical Effects

Since, like the isomer effect, the quadrupole splitting characterises the electronic structure of the Mössbauer atom, it is natural to expect that[26,31,36,41,42,47,49,51,54,77-82] the electronegativity of the ligands and the electronic effects of the substituents in the ligand will exert a definite influence on ΔE.

Fig. 5 illustrates graphically the dependence of ΔE on $\Sigma\chi_{R,X}$ for the complexes $L_2Sn(CH_3)_nCl_{4-n}$. Evidently the quadrupole splitting increases with decrease of $\Sigma\chi_{R,X}$, i.e. the decrease of $\Sigma\chi_{R,X}$ for the substituents at the tin atom in the octahedral complexes $L_2Sn(CH_3)_nCl_{4-n}$ increases the asymmetry of the p electrons at the tin nucleus. The data for the trigonal-bipyramidal complexes $LSnR_3Cl$ deviate from the correlations presented in Fig. 5, which permits the use of ΔE together with δ for the determination of the coordination number of tin in compounds of this type[26,54].

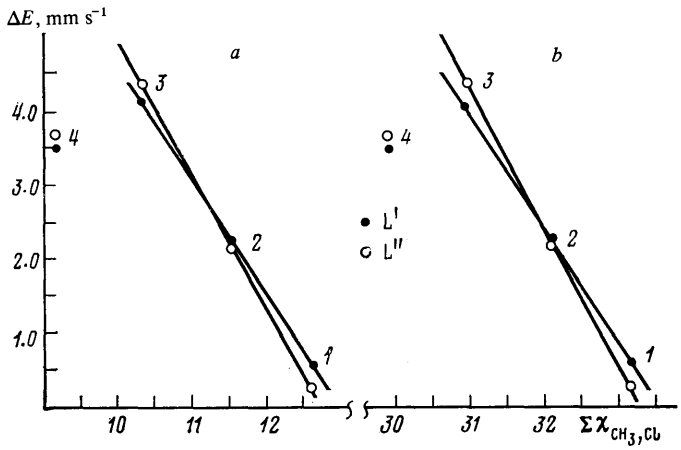

Figure 5. Relations between ΔE and $\Sigma\chi_{R,Cl}$ for the complexes $L_2Sn(CH_3)_nCl_{4-n}$, $n = 0,1,2$ [$L' = (CH_3)_2ClP(O)$; $L'' = (CH_3)_2(CH_3O)P(O)$, $n = 1$ (*1*), 1 (*2*), 2 (*3*), 3 (*4*)]; *a*) Pauling electronegativity; *b*) Mulliken electronegativity.

The influence of the substituents at the tin and phosphorus atoms on the quadrupole splitting can also be described with the aid of the substituent reaction constants σ^* and σ^{ph}.[26, 31,41,42,54,78,80,83,84] The above analysis of the correlation between the ΔE and the constants $\Sigma\sigma^*$ and $\Sigma\sigma^{ph}$ shows that they are linear. The relations between the ΔE and the $\Sigma\sigma^*$ for the complexes $L_2SnR_nCl_{4-n}$ are as follows:

$$[(CH_3)_2(CH_3O)P(O)]_2Sn(CH_3)_nCl_{4-n} (n = 0, 1, 2) \quad (9a)$$

$$\Delta E = -0.77\,\Sigma\sigma^* + 8.44\ (r = 0.995, S = 0.17, P < 0.0025, m = 4),$$
$$[(CH_3)_2ClP(O)]_2SnR_nCl_{4-n} (n = 0, 1, 2; R = CH_3, C_2H_5, C_4H_9) \quad (9b)$$

$$\Delta E = -0.71\,\Sigma\sigma^* + 7.94\ (r = 0.992, S = 0.167, P < 0.0005, m = 6),$$
$$[(n\text{-}C_4H_9)_3P(O)]_2SnR_nCl_{4-n} (n = 0, 1, 2; R = CH_3, C_4H_9, C_6H_5)$$

$$\Delta E = -0.75\,\Sigma\sigma^* + 8.28\ (r = 0.992, S = 0.24, P < 0.0005, m = 6), \quad (9c)$$
$$[(C_6H_5)_3P(O)]_2SnR_nCl_{4-n} (n = 0, 1, 2; R = C_4H_9, C_6H_5) \quad (9d)$$

$$\Delta E = 0.69\,\Sigma\sigma^* + 7.91\ (r = -0.970, S = 0.30, P < 0.001, m = 6).$$

The results show that ΔE is more sensitive to the nature of the organophosphorus ligand than δ.[32]

Since ΔE and δ vary linearly with $\Sigma\sigma^*$, there is also a linear relation between these two Mössbauer parameters[1,4,26, 41,42,54,82]:

$$[(CH_3)_2(CH_3O)P(O)]_2Sn(CH_3)_nCl_{4-n} (n = 0, 1, 2), \quad (10a)$$

$$\delta = 0.28\,\Delta E + 0.27\ (r = 0.997, S = 0.04, P < 0.0025, m = 4),$$
$$[(CH_3)_2ClP(O)]_2SnR_nCl_{4-n} (n = 0, 1, 2; R = CH_3, C_2H_5, C_4H_9) \quad (10b)$$

$$\delta = 0.32\,\Delta E + 0.31\ (r = 0.982, S = 0.08, P < 0.0005, m = 6),$$

$$[(n\text{-}C_4H_9)_3P(O)]_2SnR_nCl_{4-n}\ (n = 0, 2;\ R = CH_3, C_4H_9, C_6H_5) \quad (10c)$$

$$\delta = 0.27\,\Delta E + 0.21\ (r = 0.990, S = 0.07, P < 0.0005, m = 6),$$

$$[(C_6H_5)_3P(O)]_2SnR_nCl_{4-n}\ (n = 0, 1, 2;\ R = C_4H_9, C_6H_5) \quad (10d)$$

$$\delta = 0.32\,\Delta E + 0.21\ (r = 0.943, S = 0.14, P < 0.0025, m = 6).$$

The tendency towards a linear variation of ΔE with $\Sigma\sigma^{ph}$ for the substituents at the phosphorus atom of the ligand has also been observed[36,42,54] for the complexes of tin tetrachloride with R'R"R'"P(Y). Fig.6 illustrates graphically the relations between the ΔE and the $\Sigma\sigma^{ph}$ for the *trans*-complexes $[R'R''R'''P(Y)]_2SnCl_4$ (Y = O or LEP). We may note that the hypothesis of Phillip et al.[10] that the quadrupole splitting for the tin(IV) bromide complexes should be greater than for the tin(IV) chloride complexes does not hold for the tin tetrahalide complexes of R'R"R'"P(Y). In the vast majority of cases the upper limit of the variation of ΔE for the bromides is much smaller than for the chlorides (Tables 1–3).

For the *trans*-complexes of phosphoryl compounds with substituents at the phosphorus atom such as C_2H_5, C_6H_5, and CH_3O the quantity ΔE is almost independent of the strength of the donor–acceptor interaction (Y=O) (see Fig.6*a*, lower straight line):

$$\Delta E = 0.50 \pm 0.10\ (m = 28). \quad (11a)$$

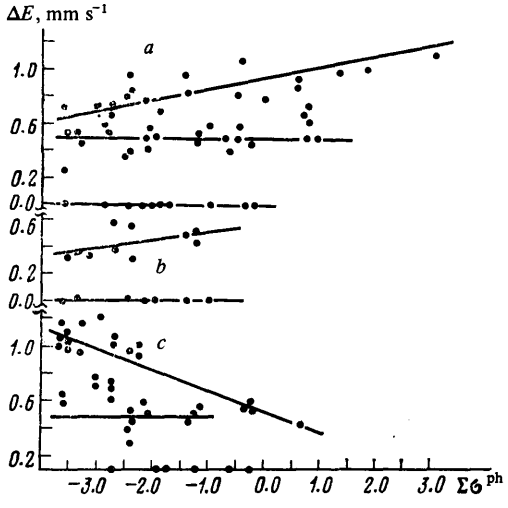

Figure 6. Relations between ΔE and $\Sigma\sigma^{ph}$ for the complexes $[R'R''R'''P(Y)]_2SnCl_4$: *a*) Y = O; *b*) Y = S; *c*) Y = LEP.

The absence of an influence by the nature of the substituents at the phosphorus atom on ΔE has been noted (see Fig.6*c*) also for certain complexes formed owing to the electron-donating properties of the phosphorus atom for Y=LEP:

$$\Delta E = 0.48 \pm 0.10\ (m = 17). \quad (11b)$$

On the other hand, for complexes containing the $(CH_3)_2N$, $(CH_3)_2CH$, and $(CH_3)_2CHO$ groups, ΔE varies approximately linearly with the $\Sigma\sigma^{ph}$ for the substituents at the phosphorus atom (Y=O):

$$\Delta E = 0.09\,\Sigma\sigma^{ph} + 0.95\ (r = 0.74, S = 0.15, P < 0.0005, m = 27). \quad (12)$$

On passing from the complexes of phosphoryl compounds to those of thiophosphoryl compounds and the complexes formed owing to the electron-donating properties of the phosphorus atom, the slope (Fig.6*c*) in the correlation equations for Y=LEP diminishes and then changes sign:

$$\Delta E = -0.15\,\Sigma\sigma^{ph} + 0.52\ (r = 0.87, S = 0.12, P < 0.0005, m = 21). \quad (13)$$

However, the behaviour of ΔE and of the isomer shift δ in the Mössbauer spectra of the $[R'R''R'''P(Y)]_2SnCl_4$ series investigated indicates in our view yet again an additional donor–acceptor interaction between the lone electron pair of the halogen atom in the acceptor molecule and the vacant *d* orbitals of the phosphorus atom in the ligand molecule in the complexes $[R'R''R'''P]_2SnCl_4$.[32,63] Comparison of the absolute slopes of the plots of ΔE against $\Sigma\sigma^{ph}$ for different series of complexes shows that the sensitivity of ΔE to the influence of the substituents in different classes of organic compounds is different and varies in the sequence R'R"R'"P > R'R"R'"P(O) > R'R"R'"P(S).

Correlation analysis of the ΔE for the Mössbauer spectra of the trigonal-bipyramidal complexes shows that here too there is a linear variation of the quadrupole splitting with $\Sigma\sigma^*$ and $\Sigma\sigma^{ph}$ and with the isomer shift[41,42]:

$$[R'R''P(O)]\,SnR_3Cl \quad (14a)$$

$$\Delta E = -0.205\,\Sigma\sigma^* + 4.087\ (r = 0.970, S = 0.047, P < 0.0005, m = 8),$$

$$\Delta E = -0.203\,\Sigma\sigma^* + 0.005\,\Sigma\sigma^{ph} + 4.085\ (r = 0.972, S = 0.045, P < 0.0005, m = 8), \quad (14b)$$

$$\delta = 0.30\,\Delta E + 0.37\ (r = 0.730,\ S = 0.06, P < 0.05, m = 6). \quad (15)$$

We may note that the dependence of ΔE on $\Sigma\sigma^*$ agrees, as regards the sign of the slope, with the analogous relation for hexacoordinate compounds [Eqns.(9) and (14)], while the literature data[78,80,83,84] indicate the opposite tendency. On the other hand, the relations between δ and ΔE agree not only as regards sign but also as regards the slopes [see Eqns.(9) and (15)].

The above expressions do not take into account the sign of the EFG. It follows from theoretical and experimental studies[85–91] on other organotin compounds that the quadrupole splitting should be positive for the *trans*-octahedral complexes and negative for the pentacoordinate complexes. The results[42] of a study of the complexes of alkyltin halides with organophosphorus ligands agree with those published previously for the *trans*-octahedral compounds[85–91]. Thus Fig.4 presents the Mössbauer spectrum of the complex $\{[(CH_3)_2N]_3P(O)\}_2Sn(CH_3)_2Cl_2$ with and without superposition of an external magnetic field at right angles to the observation axis. It follows from the resulting spectrum, in conformity with the conclusions of earlier investigations[86,87,89], that the quadrupole splitting for the above compound is greater than zero and the electric field gradient is therefore negative.

IV. THE PROBABILITY OF THE MÖSSBAUER EFFECT

In the vast majority of studies where Mössbauer spectroscopy has been used to solve various problems of coordination and organoelemental compounds, only parameters such as δ and ΔE are discussed; on the other hand, the data for the probability of the recoil-less absorption of γ-quanta (f') available in the literature are extremely limited[1,4,51,92–94]. Two studies have been published on f' in the Mössbauer spectra of complexes of tin tetrahalides with organoelemental ligands[12,92]. The limited nature of the experimental data can be explained both by the complexity of the theoretical interpretation of the results and by certain experimental difficulties[1,4,6,7].

The probability of the Mössbauer effect depends on the dynamics of the crystal lattice, i.e. on its elastic properties, and a specific model of the crystal must be selected for an examination of the dependence of f' on the macroscopic parameters of the solid. It has been shown[1,92,94] that for organometallic compounds the most convenient model of the molecular crystal is one within the framework of which it is assumed that the probability of the Mössbauer effect can be formulated to a first approximation as $f' = f'_M f'_c$, where f'_M and f'_c are the probabilities that the intramolecular and intermolecular vibrations respectively will not be excited[1].

The atomic vibrations in the molecule occur in the high-frequency range; it can be assumed that f'_M is fairly large (~1) at a low temperature and depends only slightly on the latter. The quantity f'_c, described by the Debye model[1,92], depends greatly on the temperature and makes the main contribution to the temperature variation of f'. The probability of the Mössbauer effect then increases and its temperature dependence diminishes when stronger chemical bonds are formed between individual molecules; the formation of such bonds is usually coupled with an increase of the coordination number of tin[9,95].

Thus it is evident that f' makes it possible to infer the relative strengths of the intermolecular interactions and the coordination number of the Mössbauer atom; the principal consequence of the molecular crystal model is a linear dependence of $\ln f'$ on the temperature T in the high-temperature approximation ($T > \theta/2$, where θ is the characteristic temperature of the given crystal), because f'_c is an exponential function of T. Such a dependence of the intensity and area of the Mössbauer spectrum (which depend directly on f') was demonstrated previously for different organotin compounds[51,92-94]. However, the authors[12] failed to observe a linear dependence of $\ln f'$ on T, which led them to the conclusion that the molecular crystal model is inapplicable to complexes of tin halides with organic ligands.

The results of our studies[96,97] on complexes of tin halides with organophosphorus ligands, presented in Tables 2–9, show that the probabilities of the Mössbauer effect for these systems lie within fairly broad limits: 0.15–0.58. Examination of the complexes of tin halides with mono- and bi-dentate ligands shows that the f' for these compounds are approximately the same.

The replacement of tin(IV) chloride as the acceptor by tin(IV) bromide also does not alter appreciably the probability of the Mössbauer effect, while other Mössbauer parameters (δ and ΔE) for the complexes $L_2(L')SnCl_4$ and $L_2(L')SnBr_4$ are significantly different. If the nature of the acceptor does not have an appreciable influence on f', then a tendency towards an increase of f' in the following sequence can be observed when the nature of the donor atom in the $[R'R''R'''P(Y)]_2SnX_4$ and $[R'R''P(Y)Y]_2SnX_2$ compounds investigated is altered: P : ≅ P=O > P=S (for R', R'', R''' = const.). The enthalpies of formation of the compounds vary in the same sequence[62,63].

It is noteworthy that the Mössbauer spectra of the complexes $[R'R''R'''P]_2SnCl_4$ exhibit a parallel variation of f' and ΔE, which is apparently also associated with the occurrence of an additional donor–acceptor interaction in these complexes. The highest value has been observed for the salts $[R_2P(O)O]_2SnX_2$. The probabilities of the recoil-less absorption for these substances are close to the values of f' for octahedral compounds such as SnO_2 and $BaSnO_3$.[98,99] Within the framework of the molecular crystal model, this can be accounted for by the considerable strengthening of the intermolecular bonds in such systems (compared with molecular crystals of the type L_2SnX_4) and we believe serves as additional confirmation of the octahedral structure of the given compounds[96,97].

In the case of the dithio-analogues $[R_2P(S)S]_2SnX_2$, having the octahedral bischelate structure, the probability of the Mössbauer effect is much smaller than for $R_2P(O)O]_2SnX_2$, which is apparently associated with the weaker donor–acceptor interaction in complexes formed via the thiophosphoryl sulphur[63,96,97,100,101] compared with the complexes formed via the phosphoryl oxygen.

We shall now consider the temperature variation of $\ln f'$ presented in Table 11 and in Fig. 7.[97] The data in Table 11 and Fig. 7 show that, in all the instances considered, a linear relation§ between $\ln f'(\ln c_A)$ and T holds with a satisfactory degree of reliability (a high level of significance), i.e. contrary to the data of Varnek et al.,[12] the molecular crystal model is applicable to the compounds $[R'R''R'''P(Y)]_2SnR_n \cdot X_{4-n}$ and $[R'R''P(Y)Y]_2SnX_2$, as well as other organotin compounds[9,50,92-94].

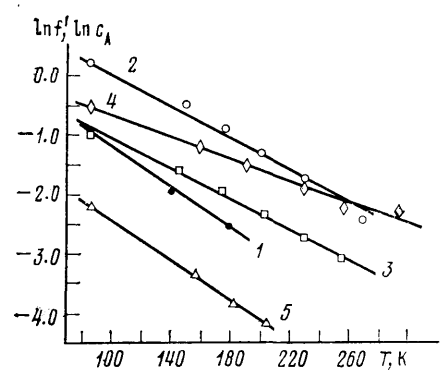

Figure 7. Temperature variation of $\ln f'$ and $\ln c_A$: 1) $\{[(CH_3)_2N]_3P(O)\}SnBr_4$; 2) $\{[(CH_3)_2N](C_6H_5)_2P(S)\}_2SnCl_4$; 3) $[(C_6H_5)_3P]_2SnCl_4$; 4) $[(n\text{-}C_4H_9)_2P(O)O]_2SnCl_4$; 5) $[(iso\text{-}C_3H_7O)_2P(S)S]_2SnCl_2$.

Table 11. The parameters of the correlations $\ln f' = 10^{-3}aT + b$ for the complexes[97].

No.	Compound	t, °C	m	$-a$	b	r	S	P	M
1	$\{[(CH_3)_2N]_3P(O)\}_2SnCl_4$	85—257	6	14.2	0.42	0.975	0.202	≤0.005	619

16	$[(C_2H_5)_2P(S)S]_2SnCl_2$	85—261	5	20.8	0.98	0.974	0.297	0.005	490

Note. M is the molecular weight and DEPB = 2,3-bis(diethylphosphono)butadiene. The relation $\ln c_A = 10^{-3}aT + b'$ is presented for compounds 5, 6, and 14.

§ Here c_A is the effective thickness of the absorber.

As mentioned above, according to this model one can write in terms of the high-temperature approximation[1,92]

$$\ln f' \propto \frac{3E_\gamma^2}{Mc^2} \cdot \frac{T}{k\theta^2}, \qquad (16)$$

where E_γ is the energy of the Mössbauer transition of the nucleus from the excited to the ground state, M the mass of the entire complex structural unit, c the velocity of light, k the Boltzmann constant, and θ the Debye temperature.

According to Eqn.(16), the slope of the $\ln f'(T)$ straight line is

$$a \cdot 10^{-3} = \frac{3E_\gamma^2}{Mc^2} \cdot \frac{1}{k\theta^2}. \qquad (17)$$

Hence it follows that, subject to the condition that the nature of the intermolecular bonds is the same ($\theta_M \cong$ const.), the coefficient representing the slope in the correlation equations should depend on the mass of the structural unit for different compounds. Such relations were observed previously for certain organotin compounds[102,103]. An analogous tendency towards a decrease of the absolute value of the slope with increasing mass may be noted also for certain complexes of tin halides with organophosphorus ligands (Table 11). This is manifested particularly clearly for the compounds $[R_2'P(S)S]_2SnCl_2$.

Comparison of the temperature variations of the $\ln f'$ for the tin(IV) chloride and bromide complexes shows that the probability of the Mössbauer effect for the bromides is more sensitive to temperature, since the corresponding slopes are greater in absolute magnitude than for the corresponding tin(IV) chloride compounds. The relatively small change of the slope as the nature of the acceptor is altered can be understood when account is taken of Eqn.(17). Consequently, despite the identical value of f' at 85 K, analysis of the temperature variations permits the conclusion that the tin(IV) bromide complexes have weaker chemical bonds. This conclusion is consistent with the results of studies by other methods[44,62,63]. The data presented show that, in contrast to f', the temperature variation of the probability of the Mössbauer effect is sensitive both to the nature of the ligand and to the nature of the halogen atom in the acceptor molecules. The sensitivity of the temperature variation of $\ln f'$ to the nature of the ligand varies in the following sequence: $R_2P(S)S^- \geq R'R''R'''P > R'R''R'''P(O) > R'R''P(O)O^-$ (Table 11).

Thus the study of the probability of the recoil-less absorption of gamma-quanta and its temperature variation for the complexes of tetra-alkyltin compounds and alkyltin halides with organophosphorus ligands yields interesting additional information about the properties and structures of these substances.

Radical-Chain Reactions of Acetals in Solution

D.L.Rakhmankulov, S.S.Zlotskii, V.V.Zorin, U.B.Imashev, and R.A.Karakhanov

Experimental results on the liquid-phase radical-chain reactions of acetals are summarised. Factors influencing the rate of formation, structure, and properties of free radicals generated from cyclic and linear acetals are discussed. Attention is paid mainly to the kinetics and the mechanism of the reactions of mono- and di-alkoxyalkyl radicals in solution. The relation between the structure of acetals and their reactivity towards various radicals is examined. Data are given illustrating the possibility of using homolytic liquid-phase reactions of acetals in organic synthesis. A list of 77 references is included.

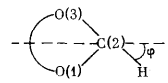
I. INTRODUCTION



During the last 10–15 years much interesting information has been obtained on the chemistry of homolytic liquid-phase reactions of 1,3-dioxacyclanes, which has been surveyed in part[1]. This field has since been widely developed in the chemistry of acetals, and the results surveyed[1] no longer reflect the progress made in the study of radical–chain reactions of 1,1-dialkoxyalkanes, 1,3-dioxacyclanes, and related compounds.

Acetals and their hetero-analogues are successfully employed in the synthesis of various organic compounds, and are also widely used as solvents, plasticisers for polymeric materials, etc. Furthermore, linear and cyclic acetals often serve as subjects for the study of theoretical problems in organic chemistry connected with the interaction of two oxygen atoms separated by a carbon atom. The urgency of systematising and generalising data on radical reactions of acetals in the liquid phase is due to the possibility of their forming the basis of industrial processes for obtaining esters, halogenohydrin ethers, telomeric acetals, etc. from inexpensive and accessible petrochemical products.

Among the tasks of the present Review are to discuss research results on radical–chain reactions of acetals, to analyse the factors determining their reactivity, and to assess the prospects for using homolytic reactions of acetals for organic synthesis. Since an immense quantity of experimental results have been obtained on the liquid-phase oxidation of oxygen-containing organic compounds, in particular acetals, and require separate systematisation and discussion, they will not be considered in the present Review.

II. STRUCTURE OF RADICALS GENERATED FROM CYCLIC AND LINEAR ACETALS

The formation and the three-dimensional structure of mono- and di-alkoxyalkyl radicals generated from linear and cyclic acetals have been investigated by electron spin resonance spectroscopy[2–13]. Analysis of the hyperfine coupling constants of the unpaired electron with an α-hydrogen atom $a(\alpha\text{-H})$ has established[2–4,11] that in cyclic systems the deviation of the bonds of the tervalent carbon atom in dialkoxyalkyl radicals from the planar structure characteristic of alkyl and cycloalkyl radicals increases as the ring becomes smaller. The same effect has been found[13] in calculations by the extended Hückel method of the angles ϕ of distortion of the C–H bond from the plane formed by the $O_{(1)}$–$C_{(2)}$ and $C_{(2)}$–$O_{(3)}$ bonds in cyclic mono- and di-alkoxyalkyl radicals

In the 1,3-dioxacyclohex-2-yl radical the angle ϕ should be 15°, but in 1,3-dioxacyclopent-2-yl 20–25°. The dependence of $a(\alpha\text{-H})$ on ϕ can be approximated by the linear equation $a(\alpha\text{-H}) = -23.1 + 1.44\phi$.[13]

A relation has been identified[8,11] between the structure and the selectivity of formation z of cyclic dialkoxyalkyl radicals (Table 1):

$$z = \left(\frac{[N]}{[M]}\right)_{\dot{N}H_2} / \left(\frac{[N]}{[M]}\right)_{\dot{O}H},$$

where N is the dialkoxyalkyl radical, M is an alkoxyalkyl radical, and $([N]/[M])_{NH_2\cdot}$ and $([N]/[M])_{HO\cdot}$ are the concentration ratios of di- and mono-alkoxyalkyl radicals formed from acetals by the action of $\cdot NH_2$ and HO· radicals respectively.

When an acetal is attacked by different types of radicals (hydroxyl ·OH and aminyl $\cdot NH_2$), preferential formation of the 1,3-dioxacycloalk-2-yl radicals is observed[8] in both cases (Table 1). This indicates that a hydrogen atom is abstracted from the methylene or methine group between the two oxygen atoms more readily than from any other positions in the molecule. Introduction of a methyl group at position 2 or 4 facilitates formation of the corresponding di- and mono-alkoxycycloalkyl radicals (Table 1), which is more clearly evident with aminyl radicals[14].

Examination of the behaviour of cyclic formals reveals the largest difference between rate constants of homolytic cleavage of non-equivalent carbon–hydrogen bonds in 1,3-dioxolan (Table 1). Divergence from a planar structure is about the same in radicals (IX), (XIX), and (XXIV), and their rates of formation by the action of hydroxyl and aminyl radicals should not differ significantly. However, whereas radicals (XVIII) and (XXIII) give negative values of $a(\alpha\text{-H})$, −1.0 and −4.2 oersteds respectively[2], (VIII) gives $a(\alpha\text{-H}) =$ 21.5 oersteds[2,8]: i.e. the orbital of the unpaired electron is more involved in "partial" sp^3-hybridisation in (VIII). On

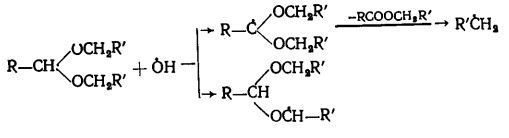
Note. Here d = doublet, m = multiplet, q = quintet, and t = triplet. The respective sources of HO· and H_2O· radicals were[8,11] the $Ti^{III} + H_2O_2$ and $Ti^{III} + NH_2OH$ redox systems.
*Signal of radical in e.s.r. spectrum at noise level.

this basis it was suggested[8] that attainment of the transition state in the abstraction of a hydrogen atom by active hydroxyl and aminyl radicals with homolysis of the $C_{(2)}$–H bond occurs more readily in compound (I) than in (V) and (VII). This provided a satisfactory explanation of the decrease in selectivity z on passing from five-membered to six- and seven-membered 1,3-dioxacyclanes (z respectively 2.5, 2, and 1.3).[8] This effect is also responsible for a somewhat greater selectivity ($z \cong 3$) of formation of the monoalkoxyalkyl radical (XVI) than of the cycloalkyl radical (XVII) in the case of the acetal (VI), when the differences in strength of carbon–hydrogen bonds and in geometry of the resulting radicals are very great in the 1,3-dioxacyclane and cyclopentane fragments.

The e.s.r. spectra of the acetals investigated (I)–(VII) revealed no signals that could have been assigned to acyclic acyloxyalkyl radicals[2,3,8]. At 30–50 °C and also when rearrangement of cyclic dialkoxyalkyl radicals is accompanied by the formation of tertiary acyloxyalkyl radicals, however, signals from the latter are observed in the e.s.r. spectra[11]:



Similar observations have been made[12] on radicals generated by the photodecomposition of t-butyl peroxide. Hence cyclic dialkoxyalkyl radicals are not converted into linear acyloxyalkyl radicals at relatively low temperatures. Such rearrangement becomes appreciable above 60 °C, and causes formation of the corresponding acyclic products in the isomerisation, addition, and telomerisation of cyclic acetals[1].

*Concentrations of di- and mono-alkoxyalkyl radicals N and M relative to concentration of alkyl radicals Alk.

Study of the structure and selectivity of formation of radicals from 1,1-dialkoxyalkanes (linear acetals) had established[8] simultaneous formation of mono- and di-alkoxyalkyl together with alkyl radicals by the action of hydroxyl radicals (Table 2). These last result from breakdown of relatively unstable linear dialkoxyalkyl radicals[12]:

Selectivity of formation of dialkoxyalkyl radicals increases somewhat on passing from formals (XXV)–(XXVIII) to acetals (XXIX) and (XXX). On treatment of diethoxymethane (XXVI) with the less active (than hydroxyl) aminyl radicals the selectivity of formation of diethoxymethyl radicals is approximately doubled[9]. Among the formals (XXV)–(XXVIII) increase in size and branching of the alkoxy-substituent is accompanied by an increase in relative e.s.r. signal intensity of the alkyl radicals (XXXIII), (XXXVI), (XXXIX), and (XLII), which is explained by enhancement of their stability. The concentration of alkyl radicals generated from the acetals (XXIX) and (XXX) is lower than that from the formals (XXV) and (XXVII) (Table 2), owing to the lower rate of rearrangement of tertiary than of secondary dialkoxyalkyl radicals, which is also indicated by other results[13].

III. REACTIVITY OF ACETALS TOWARDS VARIOUS RADICALS

Published data on the activity of acetals in reactions with different kinds of radicals have been obtained mainly by methods of competing reactions. The relative activities of linear, cyclic, and cyclolinear acetals towards t-butoxy-radicals have been studied[15–17], and the partial contributions by individual hydrocarbon groups determined. Table 3 summarises values of the ratio k_a/k_d for linear[15], cyclolinear[16], and cyclic[17] acetals, where k_a ($M^{-1}\ s^{-1}$) is the rate constant for abstraction of a hydrogen atom from a substrate molecule by a t-butoxy-radical

$$t\text{-BuO}^{\cdot} + QH \xrightarrow{k_a} t\text{-BuOH} + Q^{\cdot}$$

and k_d (s^{-1}) the rate constant of fragmentation of the t-butoxy-radical

$$t\text{-BuO}^{\cdot} \xrightarrow{k_d} CH_3COCH_3 + CH_3^{\cdot}\ .$$

Additive analysis of values for the ratio in Refs. 15–17 has shown that the relative partial rate constant for abstraction of a hydrogen atom from a methylene group in a hydrocarbon chain at 130 °C is 0.07–0.15 M^{-1}, and that for the methylene group $OCH(CH_3)$ is ~2.6 M^{-1}. The activation energy of detachment of a hydrogen atom from 1,1-dialkoxyalkanes by t-butoxy-radicals has been estimated[15] as lying in the range 6.5–8.5 kcal $mole^{-1}$.

Differences in reactivity between cyclolinear 2-alkoxyoxans and 2-alkoxyoxolans—(XCII)–(XCVI), (XCIX)–(CII) and (CIII)–(CVI)—are determined by the partial contributions of the alkoxyl substituents[16]. Partial contributions at 130 °C to k_a/k_d are approximately[16] 1.7, 2.8–3.0, and 0.3 M^{-1} for oxan-2-yloxy, oxolan-2-yloxy, and methoxy respectively.

Five-membered are more active than the corresponding six-membered 2-alkoxyoxacyclanes. Ring size has a similar influence among cyclic ethers, cyclic acetals[17], and their hetero-analogues[11]. The activation energy for abstraction of a hydrogen atom from 2-alkoxyoxacycloalkanes has been given[16] as ~7.0 kcal $mole^{-1}$. Abstraction of a hydrogen atom from a carbon atom adjacent to two oxygen atoms takes place most selectively[15–17] in cyclic and less selectively in linear acetals (Table 3); 2-alkoxyoxacycloalkanes occupy an intermediate position.

The ratio of the rate constants for abstraction by an undecyl radical of a hydrogen atom from a substrate molecule and of a chlorine atom from tetrachloromethane

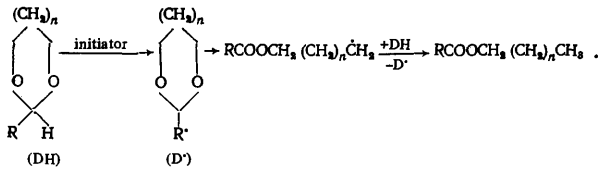
$$C_{11}\dot{H}_{23} + QH \xrightarrow{k_H} C_{11}H_{24} + Q^{\cdot}$$
$$C_{11}H_{23}^{\cdot} + CCl_4 \xrightarrow{k_{Cl}} C_{11}H_{23}Cl + CCl_3^{\cdot}$$

measures the reactivity of the acetal towards the radical (Table 4).[18,19] These results show that cyclic and linear acetals are more reactive than alkylbenzenes (XCVII), (CVII), (CVIII), and carboxylic acids (CX), (CXI) by factors of ten or more.

The ratio k_H/k_{Cl} increases with increase in length of the alkoxyl substituent in 1,1-dialkoxyalkanes and on attachment of an alkyl group to the carbon atom between the two oxygen atoms. The 1,1-dialkoxyethane (XXIX), (LII), (XXX), and (LIII) are about twice as active[18] as the corresponding formals (XXV)–(XXVII) and (XLIX). This indicates that a methyl group increases the activity of the bond between hydrogen and the tertiary carbon atom in acetals relative to the secondary methylenedioxy-links in formals. The 1,1-dialkoxyalkanes (LXIII) and (LXIV), which contain isoalkoxyl substituents, are somewhat less active than the acetals (XXX) and (LIII) with straight-chain alkoxy-groups. Table 5 gives relative rate constants for detachment of a hydrogen atom by undecyl radicals from carbon–hydrogen bonds of various strengths in 1,1-dialkoxyalkanes[18].

With change in size of the heterocyclic ring activity increases from 1,3-dioxacyclohexanes (CXV), (CXVI), (XXXII) through 1,3-dioxacycloheptanes (VII), (CXVII) to 1,3-dioxocyclopentanes (I), (CXIV).[19] These results agree well with data[24] on the influence of ring size on the activity of cyclic

acetals in free-radical isomerisation, in which the limiting stage of abstraction of the hydrogen atom from the 2-carbon atom in the substrate is effected by acyloxyalkyl radicals:



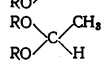


Table 4. Ratio of rate constants k_H/k_{Cl} for abstraction by undecyl radicals at 80 °C of a hydrogen atom from an acetal and of a chlorine atom from tetrachloromethane[18,19].

*From Ref. 23.

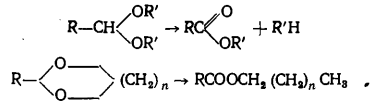
Table 5. Relative partial rate constants for abstraction by undecyl radicals at 80 °C of a hydrogen atom from C–H bonds in 1,1-dialkoxyalkanes[18].

Bond type	$10^2k_H/k_{Cl}$	Bond type	$10^2k_H/k_{Cl}$
	1.0		3.0
CH_3OCH_2-H	1.2		25.0
$-OCH(CH_3)-H$	1.7		

Such a relationship indicates that the transition state is close to the final products[25]. The change in sp^3-hybridisation of the cyclic 2-carbon atom to sp^2, which occurs during detachment of the hydrogen atom, is least advantageous with the six-membered ring, which causes a decrease in the ratio k_H/k_{Cl}. The increase in activity of the 1,3-dioxacyclanes (CXIV), (CXVI), and (CXVII) with introduction of a 2-alkyl substituent into the ring is common to five-, six-, and seven-membered acetals. This effect is less marked with 1,3-dioxacyclopentanes (I) and (CXIV) than with 1,3-dioxacyclohexanes (CXV), (CXVI), and (XXXII) and 1,3-dioxacycloheptanes (VII) and (CXVII). This is attributed[19] to greater divergence of the bonds of the tervalent carbon atom from the planar structure in the resulting 2-alkyl-1,3-dioxacyclopent-2-yl radicals than in 2-alkyl-1,3-dioxacyclohex-2-yl and 2-alkyl-1,3-dioxacycloheptyl-2-yl radicals[2,8,11] and to the stabilising effect on them of the alkyl substituent.

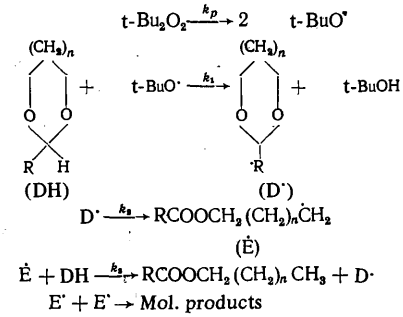
The activities of linear and cyclic acetals towards phenyl radicals (Table 6) have been studied[20,21] by a method of competing reactions

$$C_6H_5^{\cdot} + DH \xrightarrow{k_H} C_6H_6 + D^{\cdot}$$



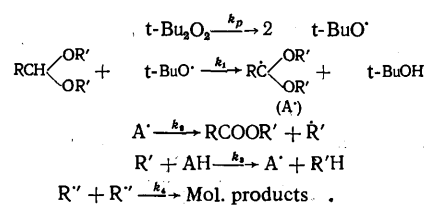
$$C_6H_5^{\cdot} + CCl_4 \xrightarrow{k_{Cl}} C_6H_5Cl + \dot{C}Cl_3$$

where DH is an acetal molecule. The qualitative pattern of relative reactivities and also the relations with the structure of the reactants and the nature of the substituents are on the whole the same as those for the reactions of acetals with undecyl radicals.



Relative partial rate constants for abstraction of a hydrogen atom from carbon–hydrogen bonds of different strengths in 1,1-dialkoxyalkanes and in 1,3-dioxacyclanes have been determined (Table 7).[20,21] The difference in activation energy for abstraction by a phenyl radical of a hydrogen atom from a 1,3-dioxacyclane and a chlorine atom from tetrachloromethane is 3.4–4.0 kcal mole^{-1}.[21]

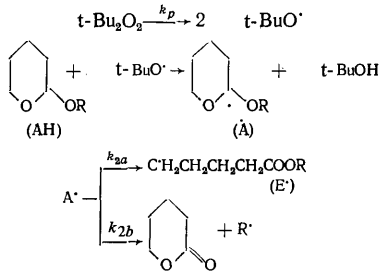
IV. KINETICS AND MECHANISM OF HOMOLYTIC LIQUID-PHASE REACTIONS OF ACETALS



Formation of esters in the presence of radical initiators is a general reaction of linear and cyclic acetals[1,22–27]:

The reason is the greater activity in radical reactions of a carbon–hydrogen bond of a methine or methylene group located between two oxygen atoms. Kinetic study[28,29] of formation of the products has established a mechanism of isomerisation involving the sequence of primary steps—(*a*) in the case of 1,3-dioxacycloalkanes (DH)

or (*b*) in the case of 1,1-dialkoxyalkanes (AH)



The difference in behaviour between cyclic and linear acetals is that a dialkoxycycloalkyl radical rearranges into a linear

acyloxyalkyl radical, whereas an αα-dialkoxyalkyl radical fragments with formation of an ester and an alkyl radical. These two routes are followed simultaneously in the isomerisation of cyclolinear acetals of 2-alkoxyoxans[30-32], when the 2-alkoxyoxacyclohex-2-yl radical formed is converted into an alkyl valerate or δ-valerolactone by rupture of an endocyclic or exocyclic carbon–oxygen bond:

$$(R')E^{\cdot} + AH \xrightarrow{k_3} CH_3CH_2CH_2CH_2COOR + A^{\cdot}$$

$$(R')E^{\cdot} + E^{\cdot}(R') \xrightarrow{k_4} \text{Mol. products}.$$

The variation in activity of the cyclic compounds (Table 8) depends on the size of the ring. Three competing factors—degree of hybridisation, strain in the ring, and polar effects—were taken into account[33] in considering the reactivity of these compounds with respect to isomerisation. The reactivities of the formals (I), (LXXX), (VII), (CXXIX), (XXXVI), and (CXXX) correlate with the rates of formation of carbonium ions and of decomposition of azo-compounds[33], which in view of conclusions in Ref. 34 indicates almost complete rupture of the bond in the rate-determining step. Hence the transition state must be closer in structure to the products than to the initial species. The 2-carbon atom (the reaction centre) passes from sp^3- to sp^2-hybridisation, which weakens the effect of steric hindrance in the case of 1,3-dioxolan (I), but in the reaction with seven-, eight-, and nine-membered structures (VII), (CXXIX), and (CXXX) weakens transannular interaction. When 1,3,6-trioxacyclooctane (XXXVI), in which repulsion between atoms at positions 2 and 6 is not possible, acceleration of the reaction is not observed. In the cyclohexane analogue (LXXX) the reaction is slowed down, since the almost ideal tetrahedral configuration is disrupted on passing to sp^2-hybridisation.

Table 7. Relative partial rate constants for abstraction by phenyl radicals of a hydrogen atom from carbon–hydrogen bonds in 1,1-dialkoxyalkanes at 100 °C and 1,3-dioxacyclanes at 80 °C.[20,21]

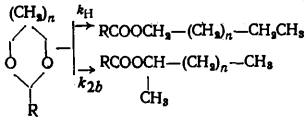
*In a ring.



Differences in activity between the cyclic acetals (LXXVI)–(LXXIX), (LXXXI), (LXXXIII), (LXXXV), and (CXXI) are determined[17,23] by the capacity of the $C_{(2)}$–H bond for homolysis on reaction with primary alkyl radicals (Table 8). All derivatives of aliphatic aldehydes isomerise at rates exceeding the rate of isomerisation of the corresponding formals by factors of 2–3 (allowing for the number of active hydrogen atoms). The introduction of a 2-methyl group causes almost identical increases in the activity of five-, six-, and seven-membered cyclic acetals in the abstraction of a hydrogen atom by t-butoxyl,[17] undecyl,[19] and alkyl [17,23] radicals; this can be attributed to enhancement of the energy of the ground state, which is consistent with data[33] showing that increase in such energy facilitates homolysis of the bonds being broken. The slight increase in reactivity of the benzaldehyde derivative (LXXIX) is explained[35] by the non-planar structure of the 2-phenyl-1,3-dioxacycloalk-2-yl radical.

Table 8. Kinetic parameters for the isomerisation of cyclic acetals [0.3 M $(t\text{-}C_4H_9)_2O_2$].[17,23,36]

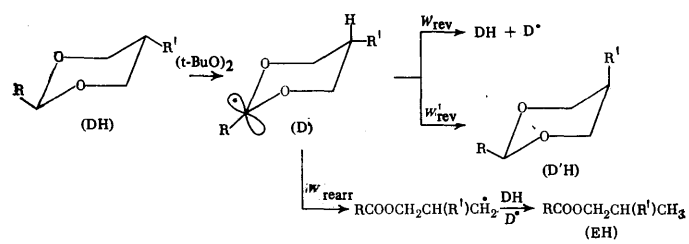
(CXXXIII)	$OCH(CH_3)CH_2CH_2CH(CH_3)OCH_2$	0.88	1.4	2.17	3.36

The lower reactivity of the cyclic acetals (CXXXI)–(CXXXIII) of di-secondary glycols (Table 8) than of their unsubstituted analogues is due not to change in strength of the $C_{(2)}$–H bond undergoing rupture but to differences in activity between the radicals carrying the chain[36].

2,4-Disubstituted 1,3-dioxacyclanes (Table 9) during isomerisation form esters of primary and secondary alcohols[17,37]:

Preferential formation of straight-chain esters is due[11,13,17,37] to the greater rate of formation of a secondary than of a primary radical on ring opening in a cyclic radical. Isomerisation of the 1,3-dioxans (CXXXIV), (CXXXV), and (CXXXVIII) into straight-chain esters is more selective than that of the 1,3-dioxolans (CXXXVI) and (CXXXVII) probably because the transition state is closer to the final products in the rearrangement of a six-membered than of a five-membered ring[17,37].



The only product of isomerisation of 4,4-dimethyl-1,3-dioxan—a formal of a primary–tertiary glycol—under the influence of t-butyl peroxide is isopentyl formate[17]. This indicates that the rate constant of rearrangement of a cyclic dialkoxyalkyl radical into a tertiary formyloxyalkyl radical exceeds the rate constant of rearrangement into a primary radical by factors of ten or more[13].

Table 9. Isomerisation of 2,4-disubstituted 1,3-dioxacyclanes[17,37].

No.	Acetal formula	k_H/k_i			ΔE^*, kcal mole^{-1}

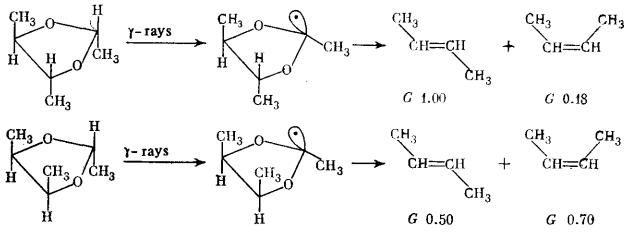
*From Ref. 40, at 135 °C.
**$\Delta E = E_H - E_i$.

In the reaction initiated by t-butyl peroxide individual stereoisomers of 2,5-dialkyl-1,3-dioxacyclohexanes not only form the corresponding esters but also undergo configurational isomerisation[11,38]:

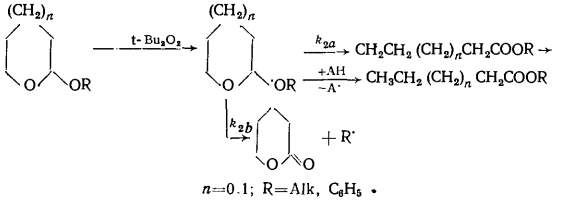


The reverse transition—from stereoisomers having an equatorial–axial arrangement of groups to isomers with a diequatorial arrangement of alkyl substituents—is also possible (DH′ → DH). It is noteworthy that at 135 °C the rate of rearrangement of 2,5-dialkyl-1,3-dioxacyclohex-2-yl radicals w_{rearr} exceeds the rate of epimerisation w'_{rev} by factors of 4–7.

Radical epimerisation of 1,3-dioxacyclanes can involve alkoxycycloalkyl radicals. Thus reaction between the low-boiling stereoisomer of 2-isopropyl-2,4-dimethyl-1,3-dioxacycloheptane (DH) and t-butyl perbenzoate at 100 °C yields methyl propyl and isopropyl methyl ketones together with the high-boiling isomer (D′H):[39]

Comparison of results in Refs. 11, 38, and 39 indicates that the ring breaks down more rapidly when dialkoxyalkyl radicals are involved. This is because rearrangement of a cyclic dialkoxyalkyl radical with formation of a carboxy-group is energetically more advantageous than is rearrangement of a cyclic monoalkoxyalkyl radical with formation of a carbonyl group[39].

1,3-Dioxacyclopent-2-yl radicals generated in aqueous medium by γ-irradiation may break down by a concerted mechanism with simultaneous rupture of two bonds[40]. Thus radiolysis of *trans*- and *cis*-2,4,5-trimethyl-1,3-dioxolans forms both *cis*- and *trans*-but-2-enes:



where *G* is the quantum yield. The initial *trans*-isomer gives predominantly *trans*-but-2-ene, and the *cis*-isomer gives mainly *cis*-but-2-ene.

*$k_2 = k_{2a} + k_{2b}$.

The type of reaction and the relative activity of 2-alkoxyoxacycloalkanes (Table 10) depend on the structure of the alkoxy-substituent and on the size of the ring[30-32]. 2-Alkoxyoxolans (CVI) are more active than the corresponding oxans (XCV):[30]

Derivatives of primary alcohols—especially of methanol (XCII)—give predominantly the isomeric linear esters, whereas derivatives of tertiary alcohols mainly fragment with formation of δ-valerolactone[30,32]. Under otherwise similar conditions the ratio of ester to lactone is higher in the case of oxans (XCV) than with their five-membered analogues (CVI),[30] since the rate of rearrangement of cyclic dialkoxyalkyl radicals increases with ring size[11,13,41]. 2-Methoxyoxan (XCII) and 2-methyl-1,3-dioxan (LXXXI) are closely similar in reactivity. The factor determining the reactivity of cyclic acetals, independently of their structure, is obviously the presence of two oxygen atoms located α to the ruptured carbon–hydrogen bond[1].

2,2-Dialkyl-4-methyl-1,3-dioxacyclanes—cyclic ketals of primary–secondary glycols—are converted into carbonyl compounds under the influence of radical initiators, with ring cleavage at the two carbon–oxygen bonds[17,42]:

Here the reaction centre is a methine group adjacent to one oxygen atom. The reactivity of ketals, like that of acetals, is determined by the size of the ring, the presence of substituents promoting homolysis of the $C_{(4)}$–H bond, and the activity of the radicals carrying the chain.

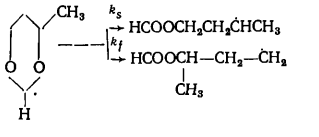
*Pre-exponential factor.

Kinetic study of the homolytic reactions of 1,1-dialkoxyalkanes[22-27] has established that their activity increases in the sequence diethoxymethane < 1,1-diethoxyethane < phenyldiethoxymethane (Table 11). Hence groups capable of delocalising the unpaired electron and thereby stabilising the intermediate dialkoxyalkyl radical enhance the reactivity of acetals.

The activity of 1,1-dialkoxyalkanes in homolytic liquid-phase reactions depends little on the size of the alkoxy-group[25].

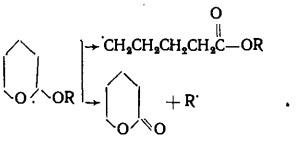
The lower activity of 1,1-dialkoxyalkanes than of 1,3-dioxacyclanes is attributed to greater stability of carbon–hydrogen bonds in linear than in cyclic acetals, and also to the greater advantage for cyclic systems of change to an sp^2-state of the sp^3-hybridised carbon atom between the two oxygen atoms[24,25].

Formation of carbonyl compounds and ethers in the course of homolytic liquid-phase reactions is characteristic of derivatives of higher aliphatic alcohols[25]. Their rates of accumulation are lower than that of the formation of esters by factors of 2–3 and 8–10 respectively. Ethers and carbonyl compounds are formed as a result of one- and two-stage fragmentations of monoalkoxyalkyl radicals:



The selectivity of formation of esters diminishes on passing from derivatives of primary to those of secondary alcohols[24–26], owing to the decrease in the difference in reactivity of carbon–hydrogen bonds adjacent to one or two oxygen atoms. The difference in activation energy of rupture of such bonds by alkyl radicals is 1.0–2.5 kcal mole^{-1}.[24–26]

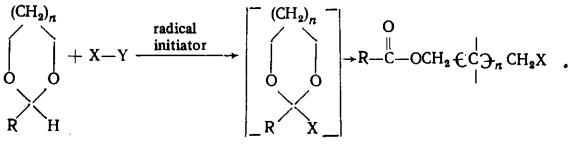
The rate of accumulation of ethers $R'CH_2OR$ is lower than that of formation of carbonyl compounds R'CHO by factors of 3–6. This indicates that the rate of unimolecular breakdown of monoalkoxyalkyl radicals exceeds the rate of abstraction of a hydrogen atom from a substrate molecule[24].



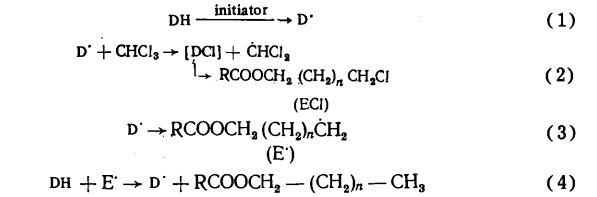
Formation of esters is also observed when reactions of 1,1-dialkoxyalkanes (XLIX) and (CXLI) are initiated by the photochemical decomposition of t-butyl peroxide (at 20 °C), but their rate of accumulation is far lower than the rate of initiation, and over a wide range is independent of the substrate concentration[43]. Under these conditions chain termination takes place mainly on dialkoxyalkyl radicals, fragmentation of which is the rate-determining stage. The rate constant of rearrangement (at 20 °C) of dialkoxyalkyl radicals $\cdot C(OR)_2CH_3$ (R = n-C_4H_9, n-C_6H_{13}) including primary alkoxy-substituents is $k_2 \approx 10$ s^{-1}.[24,43]

The influence of high pressure on the kinetics and the mechanism of the homolytic conversion of acetals into esters has been studied[11,27,30,44–47]. In the isomerisation of 2-isopropyl-1,3-dioxolan (LXXVII) the kinetic parameter $k_3/k_4^{1/2}$ remains almost unchanged with increase in pressure[11,44]. The reason is that abstraction of a hydrogen atom by primary alkyl radicals is only slightly accelerated with increase in pressure (this effect is more typical of secondary and tertiary radicals[48]), while recombination, governed by the rate of interaction of radicals in the cage, may be enhanced[44].

In the isomerisation of 4-methyl-1,3-dioxan (CXXXV) the chain is carried mainly by secondary alkyl radicals, and increasing the pressure to 7500 atm increases $k_3/k_4^{1/2}$ by factors of 2.0–2.5.[11,45] The selectivity of formation of a straight-chain ester in the isomerisation of 4-methyl-1,3-dioxolan increases with pressure, for the transition state is closer to the initial state along the reaction coordinate for the formation of a secondary than of a primary alkyl radical:



The stage of rearrangement of the 4-methyl-1,3-dioxacyclohex-2-yl radical differs little in volume of activation depending on whether a primary or a secondary acyloxyalkyl radical is formed: $\Delta V_{sf}^{\neq} \approx 3$ cm^3 mole^{-1}.[45] The direction of homolytic transformation of 2-alkoxyoxans is more noticeably influenced by pressure[30,46,47], rise in which increases the proportion of δ-valerolactone relative to the ester. The explanation is that rearrangement in both directions is slowed down[30,46], but the ring-opening rate constant is more strongly lowered:

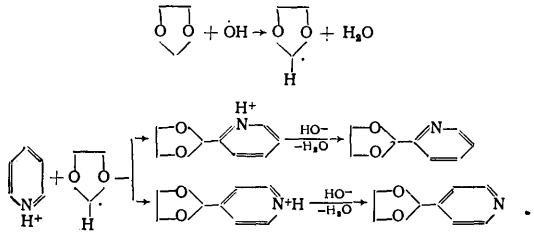


In conversion of the 1,1-dialkoxyalkanes (LXI) and (LXIV) into esters[27] the ratio of the rates of formation of isobutyl acetate and formate increases with pressure, as a consequence of the difference in reactivity towards homolytic cleavage between the secondary and tertiary carbon–hydrogen bonds in (LXI) and (LXIV). This agrees well with data showing that rise in pressure accelerates more strongly the reaction that takes place more rapidly under normal conditions[49,50].

There is much published information[1,38,51–56] indicating that 1,3-dioxacyclanes are converted under the influence of radical initiators in the presence of halogenating agents X–Y (chlorine, *N*-bromosuccinimide, polyhalogenoalkanes) into the corresponding halogenated carboxylic esters:

Formation of the latter involves[1,51–53] an intermediate unstable[53] cyclic dialkoxyalkyl halide, which rapidly isomerises into the corresponding halogenated ester. Isomerisation of the halide entails intramolecular nucleophilic substitution as a result of attack by an X^- anion at a carbon atom attached to an oxygen atom. The photolysis of optically active 2-methyl-4-phenyl-1,3-dioxolan in the presence of trichlorofluoromethane, sensitised by benzophenone, yields α-chlorophenethyl acetate with complete inversion of configuration[5].

When 1,3-dioxacyclanes undergo homolytic isomerisation in halogenoalkanes (tetrachloromethane, chloroform, bromotrichloromethane, etc.), formation of esters is accompanied by that of halogenated carboxylates[38,54–57], the latter by chain transfer to the halogenoalkane[54]. Kinetic study of the accumulation of chloroesters in chloroform suggested[38,55–57] for their formation the mechanism

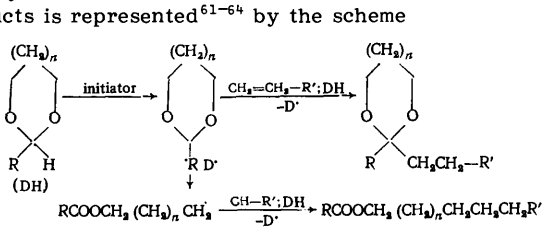


The cyclic dialkoxyalkyl radical formed is consumed in two ways: bimolecular abstraction of a chlorine atom from chloroform gives an unstable[53] 2-chloro-1,3-dioxacyclane DCl, which under the reaction conditions undergoes unimolecular conversion into the chloroester; and unimolecular rearrangement (3) into linear acyloxyalkyl radicals, which then abstract a chlorine atom from chloroform (5), finally gives the chloroester. The relative contributions of reactions (2) and (5) to

the kinetics of accumulation of the chloroester depend on the temperature[38]: at 130 °C (with t-butyl peroxide as initiator) the chloroester accumulates by both reactions, whereas at 80 °C (initiator benzoyl peroxide) reaction (2) is the chief pathway for the formation of ECl; unchlorinated esters are not found[38].

The rate-determining stage is rupture of a carbon–hydrogen bond by a dichloromethyl radical[38]. Termination takes place on such radicals. The reactivity of 1,3-dioxacyclanes towards conversion into chlorinated esters has been studied[38, 55–57]. Values of the kinetic parameter $k_3/k_4^{1/2}$, which characterise the activity of acetals towards the dichloromethyl radical at 80 °C, show[38] that it is comparable with their reactivity towards alkyl radicals only at 120–130 °C. The reason given[38] for the enhanced reactivity of dichloromethyl radicals is that a carbon–hydrogen bond is stronger in dichloromethane than in the methyl group of a normal hydrocarbon by 1.5–2.0 kcal mole^{-1}. [58,59] The nature of the substituent has little effect on the strength of the ruptured $C_{(2)}$–H bond.

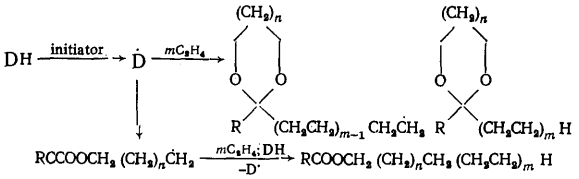
Results fully consistent with these conclusions have been obtained for the conversion of 1,3-dioxacyclanes into chloroesters in the presence of 1,1,1-trichloroethane. Dichloromethyl and 1,1-dichloroethyl radicals show the same tendency to abstract a hydrogen atom. The presence of two halogenating agents[60] (e.g. tetrachloromethane with *N*-bromosuccinimide or with bromotrichloromethane) leads to parallel formation of bromo- and chloro-esters. Preferential formation of the former is attributed[60] to greater stability of the carbon–chlorine bond.



A hydrogen atom located between two oxygen atoms in 1,3-dioxolan can be replaced by a pyridine residue[61]. Thus reaction between protonated pyridine and 1,3-dioxolan in the presence of iron(II) sulphate together with hydrogen peroxide to supply hydroxyl radicals gives 2- and 4-(1,3-dioxacyclopent-2-yl)pyridines:

The 2-isomer is formed preferentially, which is on the whole characteristic of homolytic substitution of protonated heteroaromatic bases under the influence of nucleophilic carbon-centred radicals.

V. RADICAL ADDITION OF ACETALS TO ALK-1-ENES

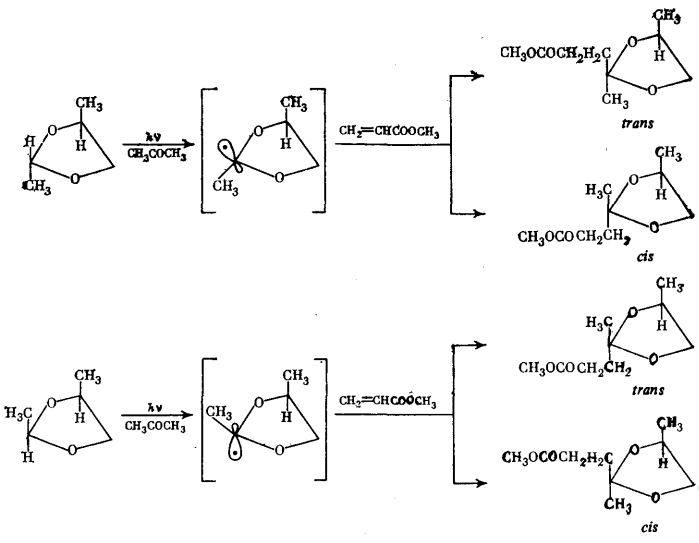


Addition of 1,3-dioxacyclanes to terminal alkenes (hexene, octene, ethylene) yields the corresponding 2-alkylated 1,3-dioxacyclanes and esters[62–70]. The formation of addition products is represented[61–64] by the scheme

$n = 0, 1, 2$; R′ = H, C_4H_9, or C_6H_{13}; R = H, or Alk.

The relative proportions of linear and cyclic products depend[41,61] on the temperature and the structure of the dioxacyclane. Below 50 °C the main products are 2-alkyl-1,3-dioxacyclanes. With rise in temperature the yield of esters increases. Increase in ring size has a similar effect, which is explained[61] by increase in the rate of unimolecular rearrangement of dialkoxyalkyl radicals on passing from five- to seven-membered rings[11,13]. The yield of cyclic products increases on passing from formals to acetals, owing[61,62] to the lower rate of unimolecular rearrangement of tertiary than of secondary dialkoxycycloalkyl radicals[11,13,41]. Substituents capable of delocalising the unpaired electron at position 2 in the 1,3-dioxacyclane somewhat increase the yield of 2-alkyl-1,3-dioxacyclane[61].

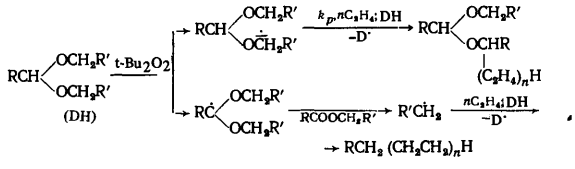
Two series of products—ester telomer-homologues and 2-alkyl-1,3-dioxacyclanes—have been identified[65–70] in the radical telomerisation of ethylene by cyclic acetals at 50° to 150 °C. The mechanism



was suggested[65–70] for the formation of these products. The cyclic dialkoxyalkyl radical adds to ethylene or else gives a linear acyloxyalkyl radical by intramolecular rearrangement. The latter adds to ethylene to form esters. The values found[65–68] for the partial chain-transfer constants ($C_n \cong 0.1$ to 0.3) characterise 1,3-dioxacyclanes as telogens of medium activity. The fact that C_n is independent of the number T_n of monomer units already added to the growing radical indicates that the 1,3-dioxacyclane substituent exerts no polar effect.

Telomerisation of a five-membered cyclic formal, 1,3-dioxolan, is accompanied by formation of a new series of products, 2-alkyl-2-butyl-1,3-dioxolans[65,69], which is attributed[69] to rearrangement of the growing radical T_n ($n = 2$) with 1,5-migration of a hydrogen atom. Such transfer is made possible by an unstrained transition state having a six-membered ring structure[65,69].

The radical telomerisation of ethylene by 2,4-dimethyl-1,3-dioxan (VI) (in the presence of dicyclohexyl peroxodicarbonate at 50 °C) yields stereoisomeric 2-alkyl-2,4-dimethyl-1,3-dioxans[71]. Isomers having an axial—equatorial arrangement of methyl groups are formed preferentially. This is assumed[71] to be due to the shielding effect of the axial $H_{(1)}$–$H_{(6)}$ atoms or to the non-planar structure[11,14,23] of the 2,4-dimethyl-1,3-dioxacyclohex-2-yl radical (XX). The telomerisation of ethylene by 4-methyl-1,3-dioxolan (benzoyl peroxide at 80 °C) also yields predominantly *trans*-2-alkyl-4-methyl-1,3-dioxolans, which is attributed[72] to the same causes[71].

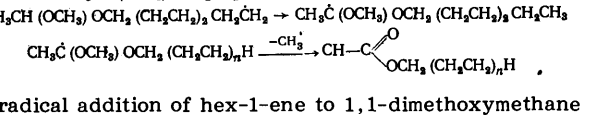


Photochemical addition of *cis*- or *trans*-2,4-dimethyl-1,3-dioxolan to methyl acrylate (at −78 °C) gives a mixture of geometric isomers, in which that with a *cis*- or *trans*-

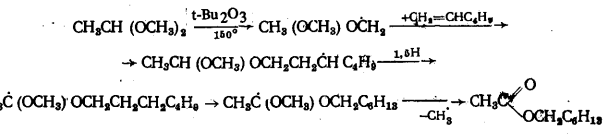
arrangement of the methyl groups respectively predominates[73]:

Such stereoselective addition of methyl acrylate is attributed[73] to the pyramidal structure of the 2,4-dimethyl-1,3-dioxacyclopent-2-yl radical, which under the reaction conditions (−78 °C) partly retains the original structure. With rise in temperature above 20 °C the *cis*-dimethyl isomer is formed preferentially. Inversion of the pyramid of the tervalent carbon atom apparently occurs readily with rise in temperature, and the stereoselectivity of addition is determined by the presence of the 4-methyl group.

The radical telomerisation of ethylene by 1,1-dialkoxyalkanes[74–77] gives unsymmetrical linear acetals formed by the addition of monoalkoxyalkyl radicals to ethylene; esters and unsaturated hydrocarbons are also formed. The latter results from addition to ethylene of fragmentation products from the 1,1-dialkoxyalkanes. The telomerisation of ethylene by 1,1-dialkoxyalkanes initiated by t-butyl peroxide is represented[74–77] by the scheme



Products of the addition of dialkoxyalkyl radicals to ethylene are not detected, for linear radicals of this type are unstable[13]. Even at 20 °C they break down unimolecularly to form esters and alkyl radicals[9,23,76,77].



The radical telomerisation of ethylene by 1,1-dialkoxyalkanes is characterised[76,77] by partial chain-transfer constants $C_n = k_n/k_p$; for example, the values of these constants for diethoxymethane are[76]

$$C_1 = 0.18 \pm 0.02;\ C_2 = 0.19 \pm 0.02;\ C_3 = 0.19 \pm 0.02 \text{ (Ref.76)}.$$

Hence linear acetals are comparatively ineffective reaction-chain carriers and are telogens of moderate activity. Since C_n is independent of the number n of monomer units, the acetal radical exerts no polar effect on chain transfer[76]. In the telomerisation of ethylene by 1,1-dimethoxymethane not only unsymmetrical linear acetals but also propyl and heptyl acetates (n = 1, 3) have been identified, though pentyl acetate (n = 2) was not detected in the reaction mixture[76,77]. The selective formation of propyl and heptyl acetates is explained[76,77] by the novel process (for this reaction) of rearrangement of the first and third growing radicals (n = 1, 3) with 1,5- and 1,9-migration of a hydrogen atom:

The radical addition of hex-1-ene to 1,1-dimethoxymethane initiated by the thermal decomposition of t-butyl peroxide (at 150 °C) is also accompanied by rearrangement with 1,5-migration of a hydrogen atom[76,77]:

The ease with which such migration takes place is due to the unstrained character of the transition state, whose geometry is similar to that of the cyclohexane ring.

---o0o---

On the whole the above features of homolytic liquid-phase reactions of cyclic and linear acetals and related compounds are due to the presence of carbon–hydrogen bonds activated by oxygen atoms. The selectivity of formation of dialkoxyalkyl radicals and their reactivity towards various reagents mainly determine the rate and direction of transformation of acetals in solution.

The information surveyed on the homolytic reactions of acetals in solution demonstrates the prospects for using such reactions to generate substituted carbon-centred radicals and employing them in organic synthesis.

The Crystal Structures of Potentially Tautomeric Compounds

N.G.Furmanova

Data on the structures of potentially proto-, metallo-, and carbono-tropic compounds, obtained mainly by X-ray diffraction, are surveyed. The results of neutron and electron diffraction studies have also been partly used. It is shown that a characteristic feature of all the systems considered is the formation of hydrogen or secondary bonds ensuring the contribution of both possible tautomeric forms to the structure. Systematic consideration of the experimental data leads to the conclusion that there is a close relation between the crystal structure and the dynamic behaviour of the molecules in solution and that secondary and hydrogen bonds play a significant role in the tautomeric transition.
The bibliography includes 152 references.

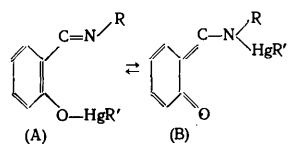
I. INTRODUCTION

Among the physical methods for the investigation of molecular structure, X-ray diffraction analysis, which makes it possible to determine the structure objectively without any *a priori* models, occupies the principal place. Systematic consideration of the enormous amount of experimental data obtained by this method shows that in the crystals of the vast majority of organic and organometallic compounds the distances between atoms of the given kind can be divided into two groups: the distances between atoms joined by a chemical bond (they are characterised by the sum of the covalent radii) and the distances between atoms not linked by chemical bonds, the shortest of which are usually close to the sums of the van der Waals radii. Since the van der Waals radii are greater by ~0.8 Å than in the covalent radii, in the spectrum of interatomic distances there is a "gap" separating valence distances from non-valence distances.



However, in the last few years an increasing number of interatomic distances occupying precisely this gap have been observed. The accumulation of experimental data on structures of this type suggests the possibility of applying X-ray diffraction not only to the determination of the geometrical characteristics of the initial substances and reaction products but also to the solution of certain problems concerning chemical processes. This field is undergoing an increasing development at the present time. In particular, systematic studies are being prosecuted in Switzerland in Bürgi's group[1]. Burgi believes that any chemical reaction involving the dissociation of some bond and the formation of others should be characterised by structural data demonstrating a continuous transition between the covalent bond and the van der Waals contact.

Bürgi and coworkers carried out X-ray diffraction studies on a series of alkaloids and related compounds containing a tertiary amino-group and a carbonyl group. A set of these structures, in which a correlation has been found between the shortening of the intramolecular N...C contact and the breakdown of the coplanarity of the covalent bonds involving the C atom, constitutes a model of the nucleophilic addition to the carbonyl group involving the formation of an intermediate with a tetrahedral carbon atom. An analogous correlation has also been observed for the O...C=O contacts[2].

This review deals with the application of X-ray diffraction analysis to the study of elemento- and proto-tropic systems.

II. DERIVATIVES OF SALICYLALDEHYDE

In the determination of the crystal structures of tautomeric (or potentially tautomeric) compounds the problem of which of the two possible molecular forms exist in the crystal arises in the first place. Thus Minkin and coworkers demonstrated[3] by electronic absorption and luminescence spectroscopy that phenyl- and methylmercury derivatives of *o*-hydroxyarylaldimines exist in solution in the form of an equilibrium mixture of benzenoid and quinonoid tautomers, whose ratio varies with temperature and solvent polarity:

(A) (B)

X-Ray diffraction analysis showed[4] that in the crystal the phenylmercury *N*-methylsilicylideneaminate molecule is an *N*-derivative with the *cis*-configuration relative to the C(2)–C(3) exocyclic bond (Fig.1). This configuration is favourable for intramolecular coordination and the Hg...O distance [2.44 (3) Å] in this molecule is indeed smaller by ~0.5 Å than the sum of the van der Waals radii of these atoms, which indicates a coordination interaction (a secondary Hg...O bond). Coordination leads to the breakdown of the linearity of the N–Hg–C fragment: the angle between the covalent bonds involving the Hg atom is 167(1)°.

The detection of the Hg–N covalent bond, which has the usual length, implies that the molecular structure is best described in terms of the quinonoid form B, but the strong

intramolecular Hg...O interaction indicates a considerable contribution of the benzeneoid structure A also. The interatomic distances in the salicylideneaminate ligand can therefore be intermediate between the distances in A and B, but the accuracy with which the location of the carbon atoms can be specified in the presence of a heavy metal such as mercury is insufficient for the consideration of such fine structural details.

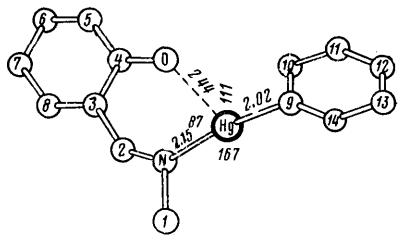


Figure 1.

In contrast to this structure, in the dimethyltin *N*-(2-hydroxyphenyl)salicylideneaminate molecule[5] the Sn...O distance in the salicylideneaminate chelate ring [2.130(7) Å] is somewhat shorter than the Sn–N distance [2.225(8) Å], which indicates that the benzenoid *O*-form predominates (Fig.2). The distribution of bond lengths in this chelate ring is also consistent with the above treatment. At the same time, the shortening of the C–O bond to 1.30(1) Å compared with the C–O bond in the hydroxyphenyl fragment of the same molecule [1.35(1) Å] and with the value usual for phenols (1.38 Å) as well as the shortening of the C–C(=N) bond to 1.45(1) Å indicate a contribution of the quinonoid *N*-form.

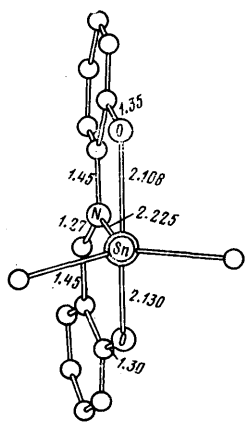

Figure 2.

In *N*,*N'*-ethylenebis-salicylideneaniline[6] (Fig.3) and *N*-*N'*-(*o*-phenylene)bis-salicylideneaniline[7] the salicylideneamine fragment exists in the benzenoid form, although the O–H...N intramolecular hydrogen bond, analogous to the secondary Hg...O bond in the phenylmercury derivative, ensures some contribution (albeit very small) of the quinonoid structure. In transition metal complexes the salicylideneaminate ligand has an intermediate structure, all its interatomic distances being close to the lengths of aromatic bonds (see, for example, Lingafelter and Braun[8]).

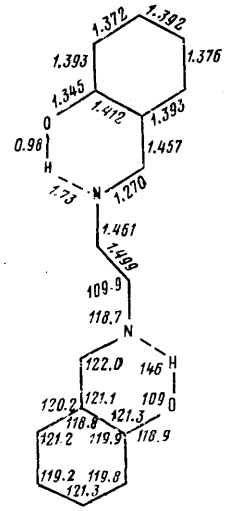

Figure 3.

The structure of the salicylaldehyde complex of diethylthallium[9] is also best described in terms of the benzenoid form: the Tl–O(1) distance involving the phenolic oxygen atom (2.46 Å) is much shorter than Tl–O(2) (2.61 Å); the C(1)–O(2) bond (1.23 Å) is close to the normal double bond and the C(2)–O(1) bond (1.32 Å) is close to a single bond.

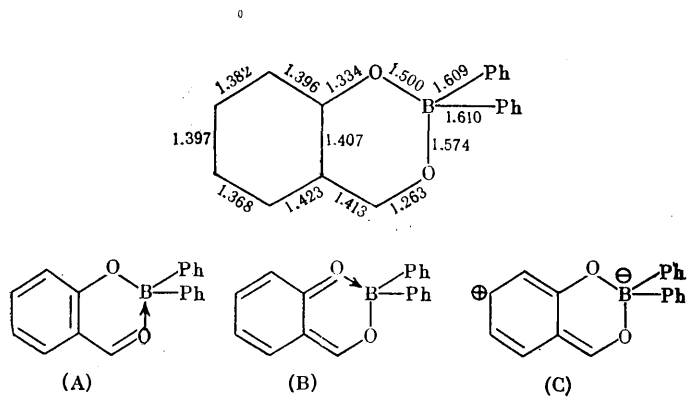

Figure 4.

The salicylaldehyde complex of diphenylboron has an analogous structure[10] (Fig.4). The B–O bond lengths in this molecule are significantly non-equivalent: 1.500 and 1.574 Å, which leads to the conclusion that the contribution of the benzenoid form A to the structure predominates, but even the shorter of these bonds is somewhat longer than

the usual value 1.477 Å. The absence of heavy atoms from this molecule made it possible to determine the structure with a higher accuracy and to discover the real distribution of bond lengths, indicating a significant contribution of the three resonance forms—benzenoid (A), *o*-quinonoid (B), and *p*-quinonoid (C)—to the structure.

A similar distribution of bond lengths has been found in the *o*-vanilline molecule[11]†, where a strong intramolecular hydrogen bond was observed (Fig.5*a*), but, judging from the C–O and C–C (exocyclic) bonds, the contribution of the benzenoid form is in this case somewhat greater than in the boron compound. The bond lengths in the aldehyde group are significantly different from the corresponding values in 2-nitrobenzaldehyde[13] (Fig.5*b*), where there is no hydrogen bond. Similar structures are characteristic also of the salicylic acid molecule (determined by X-ray diffraction[14] and neutron diffraction[15]) and the 2-amino-3-methylbenzoic acid molecule[16].

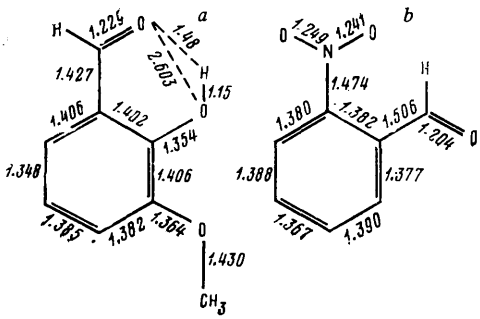

Figure 5.

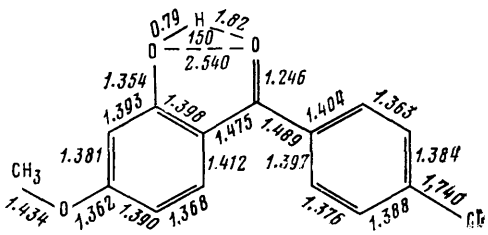

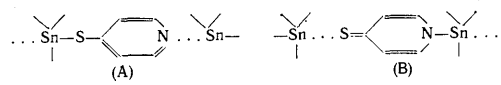

Figure 6.

The quinoid form makes a significant contribution to the structures of 2-hydroxy-4-methoxybenzophenone[17] and 4-chloro-2-hydroxy-4'-methoxybenzophenone[18] (Fig.6), where a six-membered ring is also formed as a result of an intramolecular hydrogen bond. In the 2,4-dihydroxybenzophenone crystal[19] there is an intermolecular as well as an intramolecular hydrogen bond, so that both the *o*-quinonoid and *p*-quinonoid forms should contribute to the resultant structure. As a result of this, although the C=O, C–O, and C–C (exocyclic) bonds are similar in all three structures, in the benzene ring of the last structure only one bond is distinctly shortened, namely that which should be double in both *o*- and *p*-quinonoid structures.

†The structure of the unsubstituted salicylaldehyde was investigated only in 1953 [12] and the accuracy of its determination is insufficient for the consideration of fine structural details.

III. HYDROXY-, MERCAPTO-, AND AMINO-PYRIDINES

Potentially metallotropic compounds can also form systems with intermolecular coordination in the crystalline state. In particular, the triphenyltin derivative of 4-thiopyridone has such a structure. In principle, its structure can be described in terms of one of two forms: the mercaptopyridine form (A), or the thiopyridone form (B), or a resonance hybrid of forms (A) and (B) with equal contributions by each:

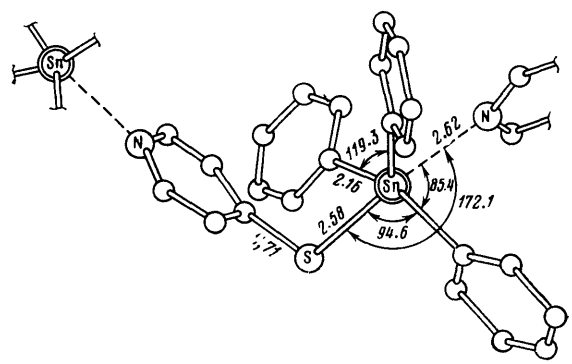

Figure 7.

X-Ray diffraction analysis showed[20] that the crystal is made up of infinite zig-zag chains (Fig.7) with trigonal-bipyramidal coordination of the tin atom. The Sn–S and Sn–N distances are longer than the corresponding single bonds but are appreciably shorter than the normal van der Waals contacts, which indicates a strong intermolecular coordination. However, the contributions of the two limiting forms to the given structure are nevertheless not the same. The Sn–S distance (2.58 Å) exceeds the length of the single bond by only 0.14 Å (the sum of the covalent radii is 2.44 Å [21]), while the Sn...N distance (2.62 Å) exceeds the single bond length by 0.52 Å (the sum of the covalent radii is 2.10 Å). Furthermore, the S–Sn–C valence angles (the average angle is 94.6°) are greater than the N...Sn–C angles (85.4°) and smaller than the ideal value for a trigonal bipyramid (90°), i.e. there is a tendency towards the retention of a tetrahedron at the Sn atom with participation of the S atom. Thus the structure of the test compound in the crystal is best described in terms of the mercaptopyridine form (A), although the contribution of form (B) is considerable. Apart from the lengthening of the Sn–S bond already mentioned, this is indicated by the shortening of the S–C bond to 1.71 Å compared with the normal value (1.78 Å). The triphenyl-lead derivative of 4-thiopyridone has a very similar structure[22].

In contrast to these compounds, which are S-derivatives in the crystal, the isothiocyanate $(CH_3)_2Sn(NCS)_2$ [23] and $(CH_3)_3SnNCS$ [24] are N-derivatives: their Sn–N bond lengths are respectively 2.14 and 2.15 Å, while the Sn...S distances are 3.20 and 3.13 Å.

For both salicylaldehyde and pyridone (hydroxypyridine) derivatives, a considerable similarity of the crystal structures of the metallotropic compounds and their prototropic analogues has been observed. Unfortunately, unsubstituted 4-thiopyridone has not been investigated by X-ray diffraction, but the structures of a series of 4-pyridone derivatives are known. Comparison of the structures of the 2,3,5,6-tetrachloro-derivative (I) [25] and the 3,5-dichloro-2,6-dimethyl derivative (II) [25,26] is of greatest interest. In both compound (I) and compound (II) hydrogen bonds connecting the molecules into infinite chains have been discovered, but compound (I) is a hydroxypyridine tautomer, while compound (II) is a pyridone tautomer (Fig.8).

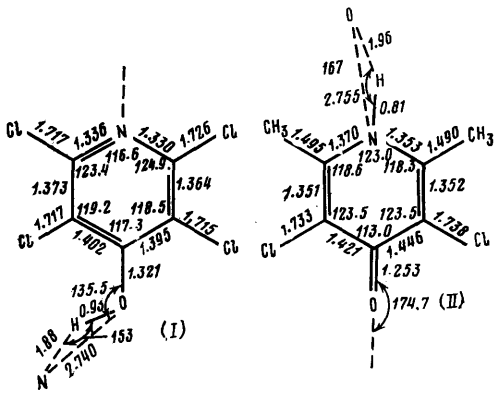

Figure 8.

The main evidence for this comes from the location of the hydrogen atoms in the two structures: the O–H...N hydrogen bond with an O–H distance of 0.93 Å, an H...N distance of 1.88 Å, and an O–H...N angle of 153° is formed in compound (I); in compound (II) the N–H...O bond has an N–H length of 0.81 Å, an H...O length of 1.96 Å, and an N–H...O angle of 167°. The lengths of the valence bonds and the angles also indicate the presence of hydroxy- and oxo-tautomers. It is known (see, for example, Singh[27]) that in six-membered heterocycles the endocyclic bond at an N atom linked to an H atom is much greater (>120°) than at an N atom not linked to an H atom (<120°), which agrees with the values observed for structures (I) and (II). Furthermore the C–O bond length in compound (II) approaches the value of 1.215 Å in aldehydes and ketones[28], while in compound (I) it is close to the value (1.36–1.38 Å) characteristic of aromatic alcohols, although the former is appreciably lengthened while the latter is actually shortened. Finally the bonds in the ring of compound (II) indicate an appreciable localisation, while in compound (I) they are close to the corresponding values for pyridine (the N–C and C–C bond lengths are 1.340 and 1.394 Å respectively[28]).

The stabilisation of the hydroxypyridine form of compound (I) is due to the presence of electron-accepting substituents in the α-position relative to the N atom: by increasing the acidity of the pyridone form and reducing the basicity of the N atom in the hydroxypyridine form, these substituents promote a shift of the tautomeric equilibrium towards the hydroxypyridine form[29]. However, one should note that, although both the intermolecular coordination involving the metal atom and the hydrogen bond lead to the generation in the crystal of forms intermediate between the two limiting forms (which is manifested particularly by the lengthening of the C=O bonds and the shortening of the C–O bonds in pyridone derivatives), the structure of the organotin derivative of 4-thiopyridone is much closer to the resonance hybrid of the two forms than all the known structures of organic analogues.

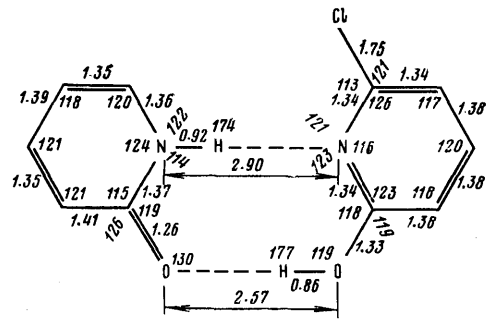

Figure 9.

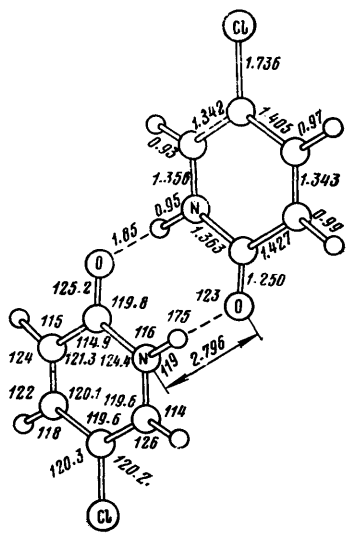

Figure 10.

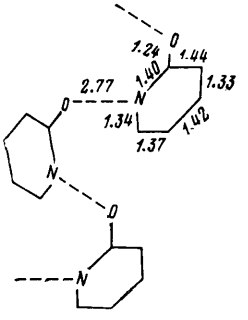
A significant substituent influence on the stabilisation of a particular tautomeric form has been observed also in 2-pyridone derivatives: 2-pyridone and its 6-chloro-derivative form a molecular complex in which the unsubstituted molecule is in the pyridone form, while the substituted molecule is in the hydroxypyridine form[30] (Fig.9). α-Pyridone itself[31], 5-chloro-2-pyridone[32], α-thiopyridone[33], and 3-hydroxy-6-methyl-2-thiopyridone[34] exist in the crystal

in the pyridone form, while 6-chloro- [35] and 6-bromo-2-hydroxypyridine[36] exist in the hydroxypyridine form. In all these structures the hydrogen bonds are intermolecular. The structural unit in both the pyridone and hydroxypyridine forms is in most cases a centrosymmetric dimer (Fig.10) and only in the α-pyridone crystal have infinite helical chains been found (Fig.11). Intramolecular hydrogen bonds are not formed in these systems, since the geometrical conditions (the closure of a three-membered ring) are very unfavourable for them.



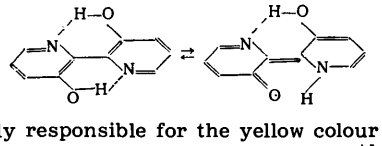


Figure 11.

However, when a hydrogen atom is replaced by a tin atom, a chelate structure becomes possible. Dichlorobis(2-pyridinethiolato)tin has such a structure[37]. In contrast to triphenyltin pyridine-4-thiolate[20] (see above), the Sn–S bonds in these molecules (with an average length of 2.464 Å) are slightly lengthened compared with the normal single bond; at the same time the Sn–N bond length (2.264 Å) also exceed the sum of the covalent radii only by 0.16 Å. This behaviour can be explained by the enhancement of the coordinating capacity of the metal atom and the enhancement of the electron-accepting properties of the substituents, which has been frequently quoted in the literature (see, for example, Furmanova et al.[38]). The distribution of bond lengths in the nucleus is intermediate between those for the mercaptopyridine and thiopyridone forms: the C–S bond lengths are 1.74 Å, the average lengths of the formally double C=C bond in the ring (for the *o*-quinonoid structure) are 1.37 Å, and the lengths of single bonds are 1.41 Å.

In hexakis(2-pyridone)copper perchlorate[39] the complex includes pyridone molecules which have retained the H atoms of their NH groups (the positions of these atoms have been determined objectively by X-ray diffraction) and accordingly exist in a distinctly pyridone form (Fig.12). A somewhat different quinonoid form contributes to the structure of 2,2′-bis-6-methyl-3-pyridinol[40] (Fig.13):

It is apparently responsible for the yellow colour of the compound. In the crystals of 2-aminopyridine[41] and 2-amino-5-chloropyridine [according to the data of Kvick and Backens[42] (X-ray diffraction) and Kvick et al.[43] (neutron diffraction)], as well as in the structures of 2-hydroxypyridine derivatives the molecules form centrosymmetric dimers via N–H...N hydrogen bonds with lengths of 3.071 and 3.058 Å. The C–NH_2 bonds in both molecules [1.351(2) and 1.357(2) Å] are shorter than in the 3-aminopyridine molecule [(1.384(4) Å] incapable of giving rise to the quinonoid form[44].

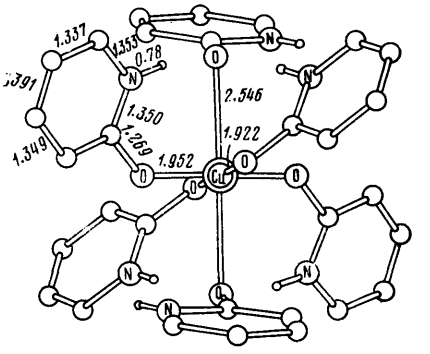

Figure 12.

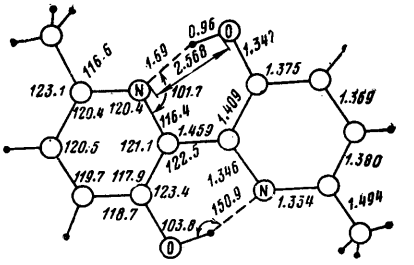

Figure 13.

IV. QUINONE OXIMES AND AMINOQUINONES

An equalised structure, which precludes a conclusion about the predominance of a particular form, obtains in the crystal of triphenyl-lead 2-fluoro-4-nitrosophenoxide[45]. The crystal is made up of infinite chains (Fig.14). The Pb atom has a trigonal-bipyramidal coordination with the O atoms in the axial positions. The difference between the Pb–O bond lengths (2.43 and 2.50 Å) is close to the error in their determination. Three Pb–C bonds are coplanar: the sum of the C–Pb–C angles is 359.9° and the average O(1)–Pb–C and O(2′)–Pb–C angles are 89.8° and 90.4°. Thus, neither the Pb–O distances nor the valence angles at the Pb atom indicate the predominance of a particular form and the structure is best described as a resonance hybrid with equal contributions by the quinone oxime and nitrosophenol forms.

Infinite chains formed via hydrogen bonds have also been found in the structure of free *p*-quinone oxime[46], but the molecule of this compound exists in the crystal as a distinct quinone oxime form (Fig.15). On the other hand, the C=N bond (1.309 Å) is longer and the N–O bond (1.374 Å) is shorter than in cyclohexane-1,4-dione dioxime (1.276 and

1.411 Å respectively[47]), although the H atom of the oxime groups of the latter molecule are also involved in the formation of hydrogen bonds. Thus a partial redistribution of the π-bonds is manifested distinctly only for the *p*-quinone oxime system capable of a tautomeric transformation.

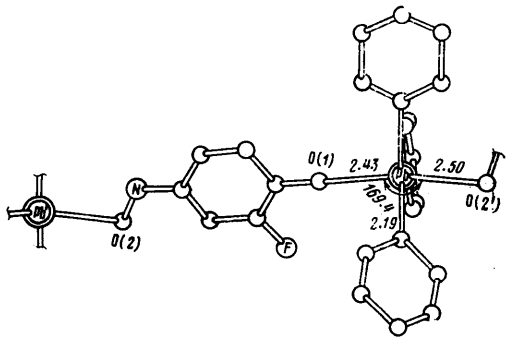

Figure 14.

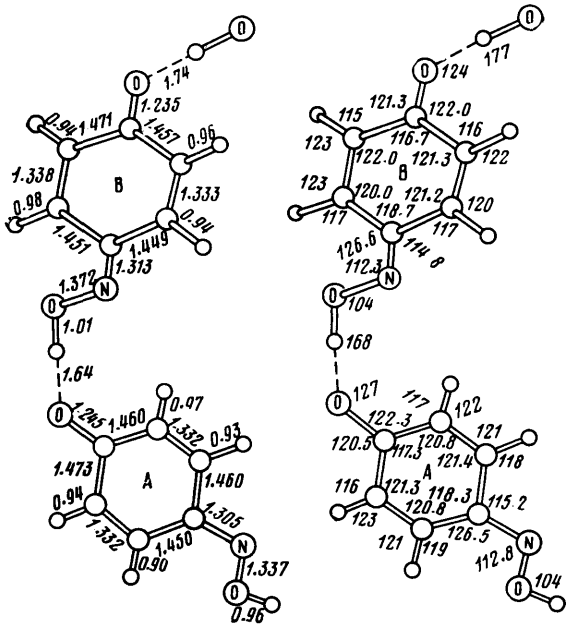

Figure 15.

6-Chloro-3-methyl-*p*-nitrosophenol, 6-bromo-3-methyl-*p*-nitrosophenol, and 3-chloro-*p*-nitrosophenol, investigated previously on the basis of projections, have similar structures[48,49]. It would be of interest to compare the structures of these compounds with those of their analogues incapable of association in the crystal. Unfortunately, although such structures are known—the acetates of *syn*- and *anti*-2-bromo-*p*-benzoquinone oximes and 2-chloro-*p*-benzoquinone oxime[50,51]—the low accuracy of their determination precludes a detailed analysis of the geometrical parameters of the molecules (such a comparison has been carried out for amino-derivatives of β-naphthoquinones—see below).

An oxime structure with a small contribution of the nitroso-form is also characteristic of *syn*- and *anti*-pyridine-4-carboxaldehyde oximes[52,53] and *syn*- and *anti*-pyrimidine-4-carboxaldehyde oximes[54,55]. As in the structures of *p*-benzoquinone oximes, in the crystal the molecules of these compounds form infinite chains via hydrogen bonds.

o-Quinone oximes were investigated approximately 20 years ago and the accuracy of these studies is unfortunately not very high. These compounds crystallise in two forms—orange and green. On the basis of spectroscopic and crystal-optical data, it was suggested that the more stable orange α-form corresponds to the quinone oxime structure and the green β-form corresponds to the nitrosophenol structure. The structure of the orange form was determined (on the basis of projections) for 5-methoxy-*o*-quinone 2-oxime[56]. Its molecules do indeed exist in the *anti*-configuration of the quinone oxime form and are linked into infinite chains via hydrogen bonds (Fig.16); the consideration of specific geometrical parameters would not be justified in view of the accuracy obtained. The structure of the green β-form of 5-n-propoxy-*o*-quinone 2-oxime has been determined[57] and it was found that in this case the quinone oxime form predominates (Fig.17), although the molecule has the *syn*-configuration with a strong intramolecular hydrogen bond. The nature of the absorption spectrum, which does not correspond to the oxime structure, can apparently be accounted for by the presence of this bond and a significant contribution of the nitrosophenol form.

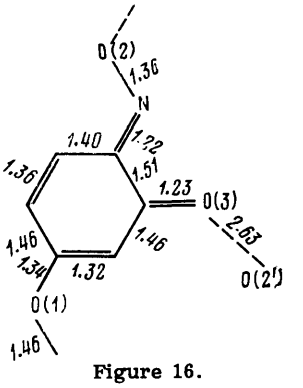

Figure 16.

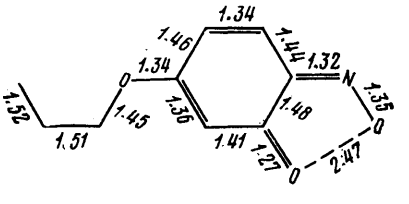

Figure 17.

The crystals of potassium *p*-nitrosophenoxide monohydrate (green)[58], magnesium *p*-nitrosophenoxide hexahydrate (reddish green)[59], and sodium *p*-nitrosophenoxide trihydrate (pale red)[60] also have different colours.

Unfortunately the accuracy of the determination of the structure of the potassium salt is insufficient for the analysis of the electronic structure of the anion. On the other hand, comparison of the geometrical parameters of the *p*-nitrosophenoxide anion in the sodium (Fig.18*a*) and magnesium (Fig.18*b*) salts showed that, as in *o*-quinone oximes, the green colour is associated with a large contribution of the nitrosophenol form, although the latter does not predominate. Comparison of these three structures also shows how much the electronic structure of the *p*-nitrosophenoxide anion depends on the nature of the cation and the system of hydrogen bonds in the crystal.

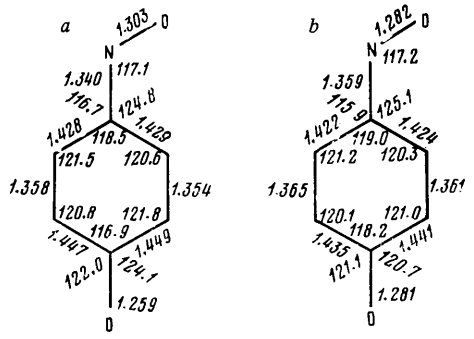

Figure 18.

In all the structures examined in this section (with the possible exception of that of triphenyl-lead 2-fluoro-4-nitrosophenoxide) the quinone oxime form predominates. The nitrosophenol structure has been found only in the molecule of 5-nitrososalicylic acid[61], where the H atom of the hydroxy-group is involved in a strong hydrogen bond with the carboxy-group, as in salicylic acid itself (Fig.19).

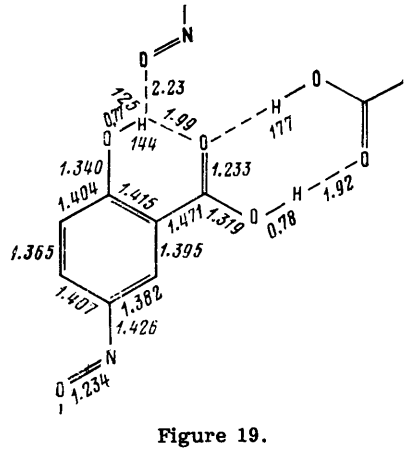

Figure 19.

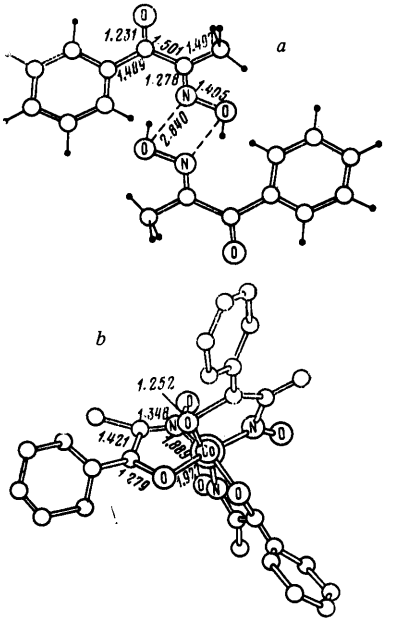
1,2-Naphthoquinone 1-oxime[62] and its 6-t-butyl derivative[63] have the quinone oxime structure and the *syn*-configuration with an intramolecular hydrogen bond. On the other hand, in the metal (Ni, Cu, Hg) complexes of 1,2-naphthoquinone oximes a five-membered ring is formed in which the NO group coordinates the metal atom via the N and not the O atom, rather than a six-membered chelate ring; the ligand has the *anti*-configuration[64-67]. The copper, nickel, and zinc complexes with 1,2-naphthoquinone oxime ligands containing sulpho-groups in the 4- or 5-position have analogous structures[68-70]. The sulpho-derivatives of 1,2-naphthoquinone oximes themselves (with the sulpho-groups in the 5-, 7-, or 8-position) have the *anti*-configuration, in contrast to their analogues without sulpho-groups[71-75]; the H atom of the oxime group in these structures forms an intermolecular hydrogen bond with an O atom of the sulpho-group. The molecule of 7-hydroxyimino-8-oxoquinoline-5-sulphonic acid in the crystal[76] and its anion in the structure of the disodium salt[76] also exist in the *anti*-configuration.

It is noteworthy that in the naphthoquinone oxime molecules examined above, in both the *syn*- and *anti*-configurations, the quinone oxime tautomeric form is very pronounced: the bond lengths vary in the ranges 1.20 to 1.25 Å for C–O, 1.30–1.31 Å for C–N, 1.35–1.39 Å for N–O, and 1.47–1.52 Å for C–C (between the carbonyl and oxime groups). In the quinone oximate anion[76] the contribution of the nitroso-form is somewhat greater: the bond lengths (1.28 Å for C–O, 1.35 Å for C–N, 1.28 Å for N–O, and 1.44 Å for C–C) are close to those found in sodium *p*-nitrosophenoxide[60] (see above). The quinone oximato-ligand has similar geometrical parameters also in the metal complexes.



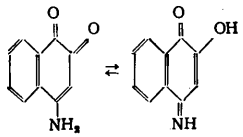


Figure 20.

The oxime form is very distinct also in the structure of 1-phenylpropane-1,2-dione 2-oxime[77] (Fig.20*a*), where the molecules are combined into centrosymmetric dimers via O–H...N hydrogen bonds, while in the cobalt complex[78] this ligand assumes an intermediate structure, like the naphthoquinone oximato-ligand (Fig.20*b*).

The example of naphthoquinone oximes shows that, although the structures with a hydrogen bond between two nucleophilic centres of potentially tautomeric systems are the main ones, they are not the only ones possible for such crystals: when the molecule contains other nucleophilic centres, for example, the sulpho-group, the *a priori* prediction of the structure requires estimates of the energies of the different variants of the resultant structure.

It must also be emphasised that the delocalisation of π-electrons, which is so characteristic of potentially tautomeric systems with hydrogen or secondary (coordinate) bonds, can be observed also in structures where such bonds are absent. The structures of 4-amino-1,2-naphthoquinones[79], where tautomerism is possible in principle, may serve as a good illustration:

The structures of 4-amino-3-bromo-1,2-naphthoquinone, its monohydrate, and methanol solvate, as well as the structures of the monohydrate of 4-amino-3-methyl-1,2-naphthoquinone, 4-diethylamino-1,2-naphthoquinone, and 4-dimethylamino-1,2-naphthoquinone have been determined[79]. In the first four structures there are intermolecular N–H...O hydrogen bonds between the NH_2 group and the CO group in the β-position. The average bond lengths in the N–C=C–C=O chain in these molecules are 1.322, 1.392, 1.405, and 1.246 Å. In the last two structures there are no hydrogen bonds, but the π-bonds are nevertheless delocalised, reflecting the significant contribution of the dipolar form $H_2\overset{+}{N}=C-C=C-\bar{O}$; however, the average bond lengths (1.358, 1.376, 1.418, and 1.237 Å) show that the delocalisation is appreciably weakened in the absence of hydrogen bonds.

V. FORMAMIDINES AND TRIAZENES

If the tautomeric rearrangement is degenerate, then X-ray diffraction makes it possible to distinguish a rapid exchange process from the symmetrical structure equalised as a result of chelate formation in those cases where the NMR method cannot provide an unambiguous answer to this question. An example of such a structure is *N*-phenylmercuri-*N*,*N'*-ditolylformamidine[80]. In the ^1H, ^{19}F, and ^{13}C NMR spectra of this and related compounds the signals of the indicator groups in the *p*-positions of the aromatic rings consist of singlets and the protons of the rings themselves give rise to a symmetrical quartet A_2B_2.

The structures of two crystallographically independent molecules, found by X-ray diffraction, are illustrated in Fig.21. The bond between the phenylmercuri-residue and the formamidine fragment is different in them: in the A molecule the Hg atom forms a normal covalent bond with the N(1) atom, having a length of 2.13(3) Å. The Hg...N(2) distance (2.68 Å) is shortened compared with the sum of the van der Waals radii by ~0.5 Å and indicates the occurrence of coordination interaction. In the B molecule the Hg'...N(2') distance (3.19 Å) is significantly greater than in the A molecule and is virtually equal to the sum of the van der Waals radii, i.e. in the B molecule the coordination interaction is either absent or very weak. At the same time, there is a weak intermolecular interaction between neighbouring type B molecules [the Hg'...N(2'') distance is 3.08 Å]. Thus the characteristics of the spectra of the *N*-phenylmercuri-derivatives of *N*,*N'*-diarylformamidines are due to the rapid reversible intramolecular exchange of the phenylmercuri-residue between the N atoms of the amidine triad. Such exchange is facilitated by the intramolecular coordination observed in the A molecule.

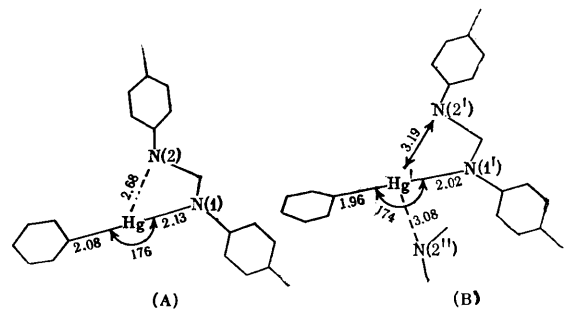

Figure 21.

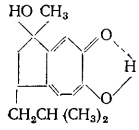
In the molecule of the phenylmercuri-derivative of 2-chlorodiazoaminobenzene[81] the Hg atom forms a covalent bond with one N atom of the triazene system (Hg–N = 2.14 Å) and is coordinated to the other atom (Hg...N = 2.46 Å). The geometries of the triazene and formamidine systems are not very favourable for the formation of a secondary Hg...N bond, because the N–Hg...N angle is much smaller than the ideal value for the Hg atom (90°). Systems of this type are even more unfavourable for the formation of an intramolecular hydrogen bond.

Indeed the binding of the molecules into helical chains by N–H...N intermolecular hydrogen bonds is characteristic of the diazoaminobenzene structures. The crystals of the α- and β-modifications of diazoaminobenzene[82,83], the β-modification of *p*-bromodiazoaminobenzene[84,85], the *p*-methyl- and *p*-chlorodiazoaminobenzenes[86], and *p*,*p'*-dimethyl, *p*,*p'*-dichloro-, and *p*,*p'*-dibromodiazoaminobenzenes[87,88] are constructed in this way. Cyclic dimers are formed via N–H...N hydrogen bonds only in the α-modification of the *p*-bromodiazoaminobenzene molecule[85]. In two structures—those of *p*-nitrodiazoaminobenzene[89] and 2,4-dibromodiazoaminobenzene[90]—the N–H...N hydrogen atoms are absent. The packing of the molecules in the former structure is determined by the N–H...O hydrogen bonds with the nitro-group; a short N...Br contact has been found in the latter molecule, which may also correspond to a hydrogen bond.



Unfortunately the accuracy of the results of all these studies is low and precludes a conclusion concerning the distribution of hydrogen atoms and bond lengths in the triazene chain.

VI. TROPOLONES

Structures with chelate rings are known for mercury (but not in its organic derivatives). Mercury tropolonate, for example, has such a structure[91]: both tropolonate ligands form chelate rings with Hg–O distances of 2.30 Å; the planes of the two ligands form an angle of 85° relative to one another. Tropolone forms symmetrical chelate complexes, similar to the mercury complex described by Allman et al.[91],

also with other metals, for example iron[92], zirconium[93], and copper[94].

Tropolone itself is a tautomeric system[95] and the independence of the signal of the hydroxyl proton in the ^{1}H NMR spectrum of concentration indicates an intramolecular process mechanism[95,96]. However, the geometry of the tropolone molecule is not optimal for the formation of a chelate ring via an intramolecular hydrogen bond and in the crystal tropolone molecules form dimers with a forked hydrogen bond incorporating both intramolecular and intermolecular components[97] (Fig.22). Dimers with a similar structure have also been discovered in the crystals of 4-isopropyltropolone[98,99], 5-isopropyltropolone[100], 3,7-dibromo-6-isopropyltropolone[100], and 5,7-dibromo-4-isopropyltropolone[101]. According to electron diffraction data[102], in the gas phase an asymmetric hydrogen bond is formed in the tropolone molecule. An intramolecular hydrogen bond is apparently also formed in 3,5,7-tribromo-6-isopropyltropolone[103] and chanootin[104]:

In the crystal of ditropolonylfuran[105] dimers having a forked hydrogen bond are formed with participation of one tropolone ring, while in the other ring only an intramolecular hydrogen bond is produced.

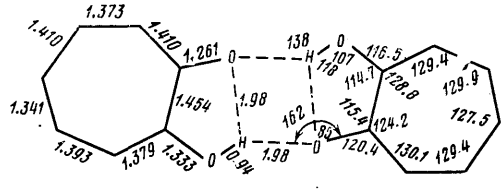


Figure 22.

Carbonotropic systems have been recently synthesised in the series of tropolone derivatives[106,107] (Fig.23). It has been shown by dynamic NMR that the activation barrier to the rearrangement A ⇌ B in solution amounts to 26 kcal mol^{-1} for the *p*-nitrophenyl ether (I). On passing to the 2,4-dinitrophenyl ether (II), it decreases to 11.7 kcal mol^{-1} and for the 2,6-dinitrophenyl ether (III) it becomes so low that, in terms of the ^{1}H NMR time scale, the molecule has an effective C_{2v} symmetry, i.e. a type (B) structure, although the electronic absorption spectra of solutions indicate an asymmetric molecular structure; the 2,4,6-trinitrophenyl derivative has a true symmetrical structure (BIV), i.e. is the first example of a zwitter-ionic Meisenheimer σ-spiro-complex. The (BIV) structure has been confirmed by X-ray diffraction[108]. The molecule in the crystal is located on a two-fold axis (Fig.24). The plane of the cyclohexadienyl ring is almost perpendicular to the remaining portion of the molecule, the angle between them amounting to 85.8°. The C(4) atom is tetrahedral, the angles at the latter varying in the range 101.9–112.4°. The bond lengths in the seven-membered ring are equalised (1.379–1.401 Å), which is characteristic of the tropylium cation. In the six-membered ring the C(3)–C(4) bond length is 1.486 Å, which is appreciably greater than the aromatic bond lengths (1.394 Å) and approaches the length of a single C(sp^2)–C(sp^3) bond (1.510 Å).[28] The lengths of the remaining C–C and C–N bonds indicate the delocalisation of the negative charge over the ring and the nitro-groups.

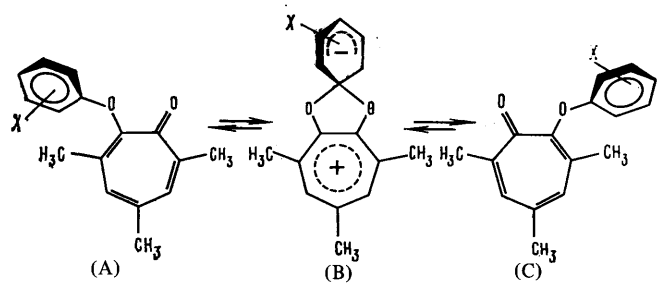

Figure 23.

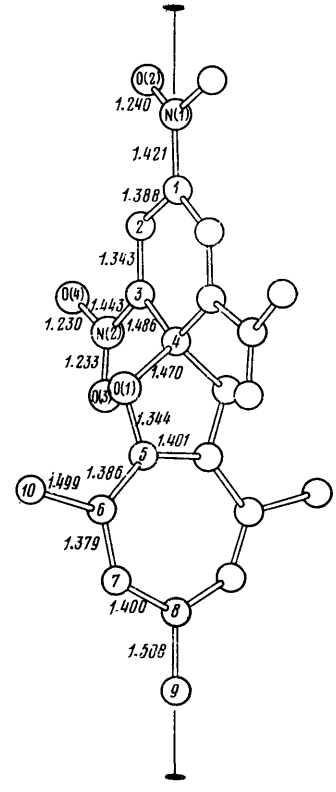

Figure 24.

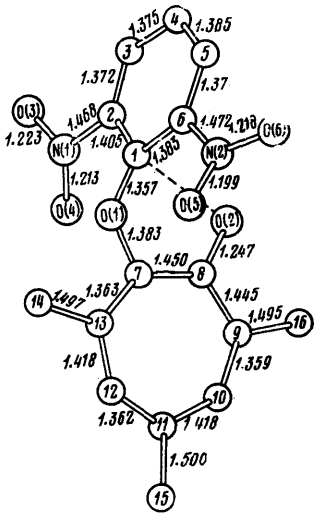
X-Ray diffraction analysis of the (AIII) structure yielded particularly interesting results[108]. Despite the possibility of rotation about the O(1)–C(7) and O(1)–C(1) bonds (Fig.25), the molecule assumes a conformation in which the C(1) atom approaches to the maximum possible extent

the O(2) atom and the C(1)...O(2) distance, which is 2.451 Å, is significantly shorter than the sum of the van der Waals radii (~3.2 Å).[21] As in the (BIV) structure, the plane of the six-membered ring is almost perpendicular to that of the tropolone system (the angle between them is 84.9°), i.e. the conformation of the (AIII) molecule is optimal for the closure of a five-membered ring with formation of a spiro-structure of type (BIV). Furthermore, the C(1) atom is displaced by 0.09 Å from the plane of the three atoms linked to it, in the direction of the O(2) atom, while the C(1)...O(2) line is approximately perpendicular to the O(1)C(1)C(2)C(3) fragment. All these geometrical features show that a configuration fairly close to the structure of the transition state in the first stage (A ⇌ B) of the intramolecular rearrangement A ⇌ C obtains in the (AIII) structure. These geometrical features actually explain the exceptionally high frequency of the migration of the 2,6-dinitrophenyl group in (AIII) solutions.



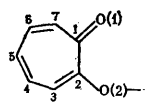


Figure 25.

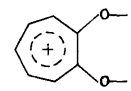
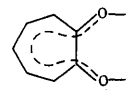


The observed molecular conformation is possible only in the presence of a strong C(1)...O(2) interaction. In the absence of such interaction, the molecule assumes a transoid configuration relative to the C–O bond, as, for example, in *p*-chlorobenzoyltropolone[109]. It is noteworthy that the energy barriers to the *O,O'*-aroyl migrations in tropolone derivatives are much higher than the barriers to the migrations of the 2,6-dinitrophenyl group[106] and there is thus a direct relation between the structure of the molecule and its dynamic behaviour. At the same time it must be emphasised that the occurrence of an intermediate state with a strong intramolecular C(1)...O(2) interaction in the (AIII) crystal proved to be possible as a result of a particularly favourable geometry of this system[107].

Comparison of data for tropolone derivatives makes it possible to distinguish three limiting types of their electronic structure. Type I is a structure with localised double bonds:



The structure of *p*-chlorobenzoyltropolone[109] with the bond lengths C=O = 1.225, C–O = 1.388, and C(1)–C(2) = 1.459 Å, while the average values of the remaining bonds are C–C = 1.419 Å and C=C = 1.338 Å, is closest to this type.

Type II is the structure of the tropylium cation (a six-electron π-system) with delocalisation of the π-electrons over the ring:

A type II structure obtains in tropolone hydrochloride[110] (with the bond lengths C–O = 1.365 and C–C = 1.38–1.41 Å) and the 2,4,6-trinitrophenyl ether of tropolone[108] (C–O = 1.344 Å and C–C = 1.379–1.401 Å).

Finally type III is a structure with a delocalised π-electron system not including the C(1)–C(2) bond but including the C–O bond (a ten-electron π-system):

Sodium tropolonate[111,112] (C–O = 1.278 Å, C(1)–C(2) = 1.478 and with the remaining C–C bond lengths of 1.388–1.426 Å) and the metal complexes mentioned above have this structure. This form makes some contribution to the structures of numerous hydrogen-bonded tropolone derivatives, which is manifested primarily by a lengthening of the C=O bond (~1.25–1.26 Å) and a shortening of the C–O bond (~1.33–1.35 Å); the C(1)–C(2) bond length is 1.45–1.50 Å, the remaining C–C bond lengths in the ring are 1.40–1.44 Å, and the C=C bond lengths are 1.35 to 1.37 Å.

The considerable delocalisation of the π-electrons in these systems, as in the systems discussed previously, is due precisely to the formation of a hydrogen bond. SCF–MO calculation[113] without allowance for this bond leads to a more delocalised system [C=O = 1.258 Å, C–O = 1.389 Å, C–C = 1.452–1.462 Å, and C=C = 1.355–1.357 Å; the C(1)–C(2) bond length does not differ from that of the other C–C bonds in the ring].

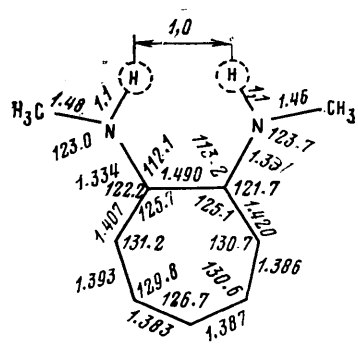


Figure 26.

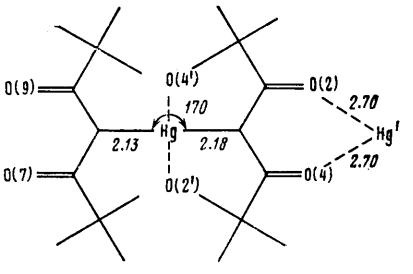
In contrast to these derivatives, the nitrogen analogue of tropolone—1-methylamino-7-methyliminocyclohepta-1,3,5-triene—has a type III structure in an almost pure form[114]. According to X-ray diffraction data (Fig.26), a hydrogen

atom in the molecule is distributed between two equivalent positions at a distance of ~1.0 Å from one another and at a distance of ~1.1 Å from the nearest N atom. A detailed analysis of thermal vibrations showed that this structure is not a result of a disordered statistical superposition of two "tautomers" but corresponds to a symmetrical system with a very low energy barrier to the transition of the H atom from one potential well to another. This description is consistent with infrared spectra[115] and with ^{1}H NMR spectra[114], in which the protons of the CH_3 groups give rise to a singlet signal even at −80 °C.

VII. β-DIKETONES

β-Diketones also form symmetrical chelate rings with the bond lengths C−C ≅ 1.39 Å and C−O ≅ 1.27 Å in complexes with most metals (see, for example, Lingafelter and Braun[8]). The acetylacetonate anion in the potassium salt also has a structure with delocalised bonds[116]. However, β-diketones can also give rise to a C-form with an Hg atom, which has not been found for tropolonate complexes.



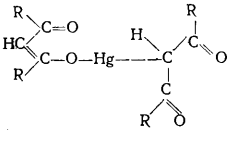


Figure 27.

Mercury bispivaloylmethanate has such a structure in the crystalline state[117,118] (Fig. 27). The Hg atom in this molecule forms somewhat lengthened Hg−C bonds (2.13 and 2.18 Å) with the two dipivaloylmethanate groups (the normal Hg−C bond length is 2.07−2.11 Å) and weak coordinate bonds having a length of 2.70 Å with the two oxygen atoms of a neighbouring dipivaloylmethanate group (the length of the covalent Hg−O bond is 2.03−2.07 Å. The ^{1}H NMR spectra showed that in solution in chloroform the molecules of this compound are monomeric, but a weak signal at 5.75 p.p.m. indicates the presence of ~5% of the enolic form together with the initial diketo-form. According to Fish[119], the content of the enolic form in solution in ethanol rises to 50% and the molecular structure is described by the formula

The molecules of (nonane-4,6-dionyl)trimethylplatinum are dimeric both in the crystal and in solution[118]. In this dimer (Fig. 28) the Pt−O bonds (2.14 and 2.16 Å) (the normal value is 1.97 Å) may be regarded as the main ones, while the Pt−C bond (2.39 Å) is "additional" (the normal length of the Pt−C σ-bond is 2.02 Å), i.e. the bonds are more equalised in this structure.

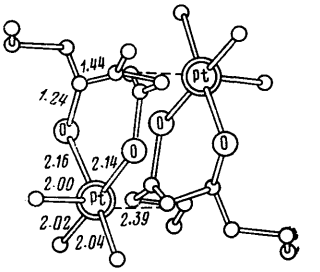

Figure 28.

According to X-ray diffraction studies, the non-coordinated β-diketone molecules exist in the enolic form and have a cisoid conformation with a very strong intramolecular hydrogen bond. Depending on the nature of the substituents, both an almost symmetrical structure with approximately equalised bonds, for example, in benzoylacetone according to X-ray diffraction data[120] and neutron diffraction data[121], and a highly asymmetric structure with a distinct predominance of one of two enolic forms, for example, in 1-(2-thienyl)-4,4,4-trifluorobutane-1,3-dione[122] (Figs. 29*a* and 29*b*), can obtain.

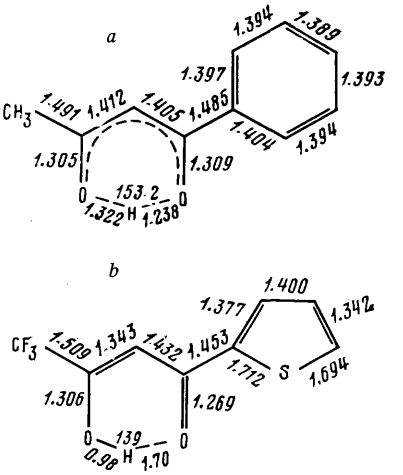

Figure 29.

The structure of the last compound agrees with the results of a calculation by the CNDO/2 method[123], which showed that the proton should be localised at the carbonyl group with the more electronegative β-substituent. However, a fully equalised structure with a highly symmetrical hydrogen bond has not been found among β-diketones. In all the structures

where the position of the hydrogen atom has been determined fairly reliably from X-ray or neutron diffraction data (see, for example, Refs.124–129), the atom is displaced towards one of the oxygen atoms and this displacement is correlated with the difference between the C–C and C–O bond lengths. It is noteworthy that there is no fundamental difference between symmetrical and slightly asymmetric hydrogen bonds[130]. The adiabatic potential of a hydrogen atom involved in very strong hydrogen bonds has a broad and shallow minimum and even the very weak perturbations due to the asymmetry of the environment of the molecule in the crystal are sufficient to infringe the symmetry of this bond[131].

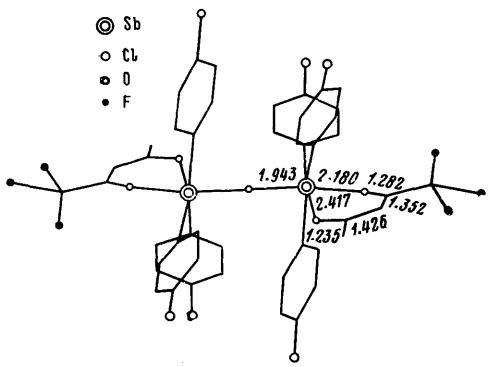

Figure 30.

A strong intramolecular O–H...S bond is formed in 3-mercapto-1,3-diphenylprop-2-en-1-ol [132] (according to neutron diffraction data, the bond lengths are O–H = 1.024 Å, H...S = 1.904 Å, and O...S = 2.865 Å), i.e. the compound exists in the crystal in the enolic (and not the thioenolic) form; the C–O bond (1.321 Å) is comparatively long, while the length of the C–S bond (1.675 Å) is close to that of a double bond. The chelate ring in μ-oxobis[tris(*p*-chlorophenyl)(1,1,1-trifluoropentane-2,4-dionato)antimony] has a highly asymmetric structure[133] (Fig.30), while in the octahedral acetylacetonate complexes [(acac)CH_3SbCl_3], [(acac)$(CH_3)_2SbBr_2$], and [(acac)Ph_2SbCl_2] [134] the chelate rings are symmetrical. In (1,3-diphenylpropene-1,3-dionato)triphenyltin[135], with a trigonal-bipyramidal coordination of the metal atom, the equatorial Sn–O(1) bond (2.094 Å) is shorter than the axial Sn–O(2) bond (2.276 Å). Accordingly the bonds in the diketonate ligand are also non-equivalent: the lengths of the bonds closest to O(1) are C–O = 1.29 Å and C–C = 1.36 Å, while those of the bonds closest to O(2) are C–O = 1.26 Å and C–C = 1.40 Å.

Phosphonia-β-diketones have a somewhat different structure. The α-triphenylphosphoniabenzoylacetone cations also exist in the enolic form in the crystal but have the *trans*-configuration, forming a hydrogen bond with Cl^- (Fig.31) or BF_4^- ions[136,137]. The chloride of α-triphenylphosphoniaacetoacetic ester has a similar structure[138]. In contrast to the *cis*-enols, in the *trans*-enols the planarity of the enolic system is appreciably infringed and the bond lengths are closer to the standard values: C–C = 1.49–1.56 Å, C=C = 1.31–1.37 Å, C–O = 1.32–1.33 Å, and C=O = 1.17–1.24 Å.

Acetylacetone has been investigated by electron diffraction in the gas phase and it has been observed that at the experimental temperature (~105 °C) the content of the enolic form in the gas is 66%.[139] The geometrical parameters of the enolic and diketo-forms are presented in Fig.32. At room temperature the equilibrium is displaced towards the symmetrical enolic form according to electron diffraction data[140]. The electron diffraction data for trifluoroacetylacetone[140] and hexafluoroacetylacetone[141] also agree best with the symmetrical enolic structure.

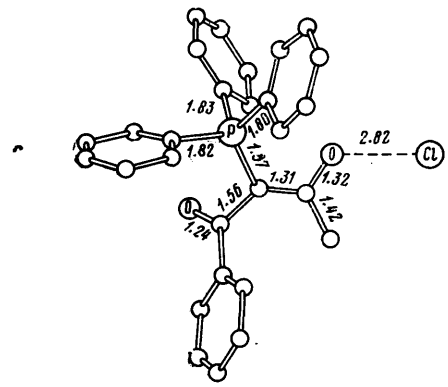

Figure 31.

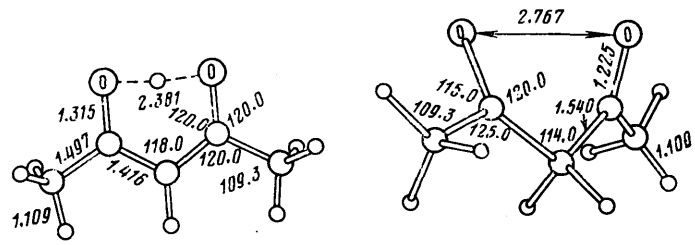

Figure 32.

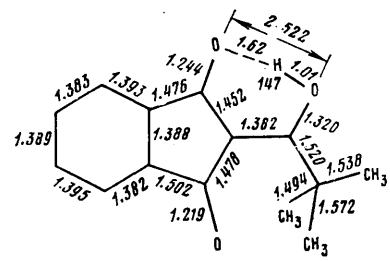

Figure 33.

In the 2-pivaloylindan-1,3-dione molecule[142] one of the carbonyl groups is involved in a keto–enol system with a strong intramolecular hydrogen bond, while the other remains free (Fig.33). This structure makes it possible to observe particularly distinctly the lengthening of the C=O bond in the chelate ring and the shortening of the C–C bond in

the latter, in conformity with the partial contribution of the second tautomeric form to the structure.

In the series of acetylacetone derivatives, as in the tropolone series, carbonotropic tautomerism has also been observed[107], but there are virtually no X-ray diffraction data for compounds of this class. X-Ray diffraction analysis of the picryl derivative of acetylacetone *N,N'*-dimethyldiimine[143], on the basis of which the intramolecular migration of the picryl group between the two N atoms might have been postulated (Fig.34), showed that this compound is a *C*-derivative (formula C).

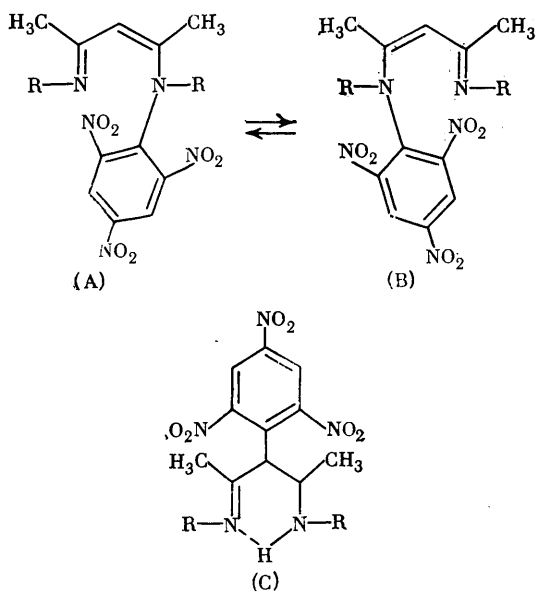

Figure 34.

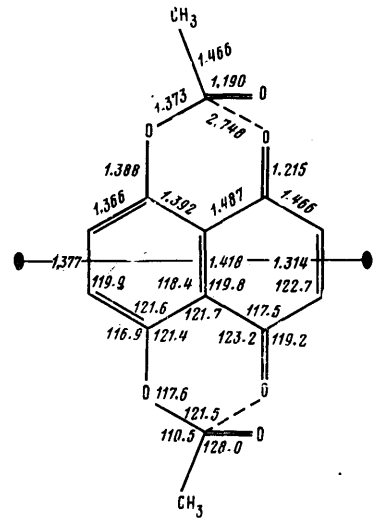
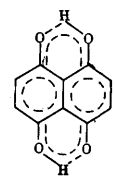
VIII. MOLECULAR GEOMETRY AND INTRAMOLECULAR REARRANGEMENTS

Thus the formation of hydrogen (in the case of prototropism) or secondary (in the case of metallo- and carbono-tropism) bonds is characteristic of all tautomeric and potentially tautomeric systems. The relation between the geometries of the molecules and their capacity for intramolecular rearrangements has been traced for some of the examples described above.

The relation between the geometry of the molecule and its ability to undergo the *trans*-acylation reaction has been noted in X-ray diffraction studies on naphthazarine[144] (Fig.35) and tetramethylnaphthazarine[145] diacetates. In these molecules the planes of the acetyl groups are almost perpendicular to the plane of the naphthazarine ring, but are nevertheless somewhat inclined towards the quinonoid oxygen atom, which shortens the C...O distances to 2.68–2.75 Å, although, at least for the first molecule, there is a possibility of the deviation of this group in the opposite direction. Thus even in the ground states of these molecules there exists a basis for the transfer of the acyl group to the neighbouring O atom. However the C...O interaction in these systems is weak and does not distort the C=O and C–O bond lengths.





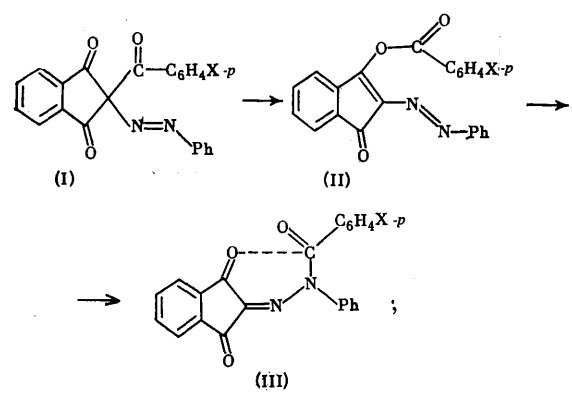


Figure 35.

In naphthazarine itself there is a strong slightly asymmetric O–H...O hydrogen bond, so that the structure is nearly mesomeric, but with a slight predominant contribution of the 4,8-dihydroxy-1,5-naphthoquinone form[146]. Shortened intramolecular C...O distances between the carbon atom of the benzoyl group and the oxygen atom of the carbonyl group (2.673, 2.638, and 2.835 Å) have also been found in the structures of the 2-(*N*-benzoyl-*N*-phenylhydrazones) of indan-1,2,3-trione (III),[147,148] which are formed instead of the expected enol benzoates (II) on thermal rearrangement of the corresponding azo-compounds (I):

X = H (*a*), Br (*b*), or t-Bu (*c*).

In the crystal these molecules can exist both in the *syn*-configuration [compound (IIIa) and one of the independent molecules of compound (IIIb)] and in the *anti*-configuration [the second independent molecule of compound (IIIb) (?) and compound (IIIc)], the unusual stability of the sterically

strained *syn*-form being probably caused by the C...O interaction mentioned above. This interaction creates almost ideal conditions for the rearrangement (III) ⇌ (II), which apparently makes the (II) → (III) transition very rapid during the reaction and precludes the observation of the intermediate formation of (II). One should note that the C...O interaction observed in these structures is fairly weak and does not alter appreciably the bond lengths in the *syn*-form compared with the *anti*-form.

IX. FULVENES

The derivatives of pentafulvenes are also interesting keto-enol systems. 6-Hydroxyfulvene-1-carboxaldehyde has been investigated by X-ray and neutron diffraction[149]; two of its nitro-derivatives—2,3-diacetyl- and 2,3-dibenzoyl-5-nitrocyclopentadiene—have also been subjected to X-ray diffraction analysis[150]. The diketo-form (I) (Fig.36), a tautomeric equilibrium between the enolic fulvene forms (II) (which appears most probable on the basis of spectroscopic data), or a delocalised symmetrical structure (IV) are possible in principle for these compounds. The ^{1}H NMR data for the nitro-derivative also do not conflict with structure (III). Studies[149,150] have shown that in the crystals of all three compounds structure (IV) is formed.

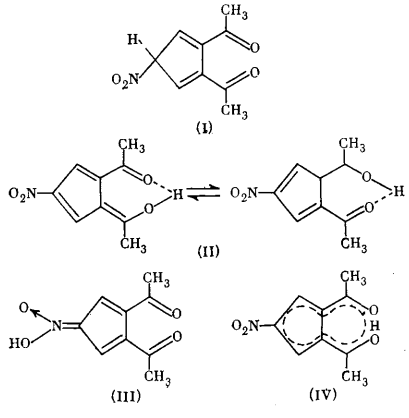

Figure 36.

The enolic hydrogen atom is located at approximately equal distances from both oxygen atoms (although in an X-ray diffraction study of 6-hydroxyfulvene-1-carboxaldehyde the hydrogen atom gave rise to a double electron density peak, but in the remaining cases the location of this atom was unambiguous) and the molecular symmetry is close to C_{2v}. The length of the central C–C bond is 1.462–1.467 Å, which is close to that of a single bond in cyclo-octatetraene (1.462 Å), while the lengths of the remaining C–C and C–O bonds are close to values correspondng to a bond order of 1.5, i.e. the delocalisation involves mainly the outer ring and affects the central bond to only a slight extent. Quantum-chemical calculations have led to an analogous conclusion[150].

In the crystal of the nitrogen analogue—*N*,*N*'-diphenyl-6-aminopentafulvene-2-aldimine[151]—the hydrogen atom is distributed between two positions (Fig.37), which can be a result of either a statistical superposition of two asymmetric forms, which can undergo tautomeric transitions only in solution, or of the migration of the hydrogen atom between two equilibrium positions also in the crystal. Analysis of thermal vibrations suggests that preference should be given to the last variant.

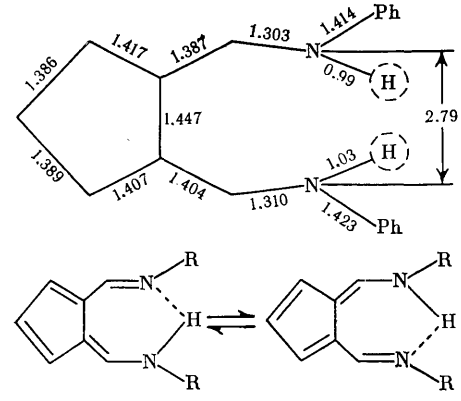

Figure 37.

* *
*

Thus the data examined have shown that in all cases of potentially tautomeric systems without exception a coordination interaction has been observed (a hydrogen bond in prototropic systems), resulting in a greater or smaller contribution of both possible tautomeric forms to the structure and ultimately in a resonance hybrid with equal contributions of both forms. The occurrence of hybrid forms in the crystal implies that their formation in the tautomeric transition requires a minimal energy expenditure. One can therefore assume that in systems where there is a possibility of intramolecular coordination, the tautomeric transformation in solution also proceeds via the formation of hybrid forms with this type of coordination.

One can also assume that in systems with highly asymmetric secondary (hydrogen) bonds, the tautomeric transition takes place more readily the stronger this bond. On the other hand, if a structure close to a resonance hybrid of two tautomeric forms obtains in the crystal, it is most likely to be stable also in solution, i.e. the system is not tautomeric. The latter is valid, for example, for the Meisenheimer tropolone spiro-complex discussed in this review. In order to confirm the general nature of the relations indicated and to obtain quantitative estimates, joint systematic studies on the geometry and tautomeric behaviour of the molecules, which are virtually completely lacking at the present time (particularly for metallotropic compounds), are necessary.

For systems with intermolecular coordination, the appearance of a hybrid transition state requires the formation of associated species, apparently with a cyclic structure, and kinetic studies are necessary for the solution of the problem of the mechanism of the transition. There is as yet no direct confirmation of the mechanism of tautomeric transitions via associated molecular species but the characteristics of certain exchange reactions (the inverse dependence of the reaction rate on temperature, overall reaction order of ~4) can be accounted for precisely by the formation of associated

species. The exchange reaction between trimethyltin phenoxide and thiophenoxide can serve as an example[152].

The solution of this and many other problems of tautomeric transformations requires further joint structural and kinetic investigations.

Sorption Mechanism of Metal Ions on the Salts of Heteropoly Acids

L.K.Neudachina and V.F.Barkovskii

Published data on the sorption properties of insoluble salts of heteropoly acids (HPA) are discussed in terms of recent views on the structure of HPA salts and on the tendency of ions to form heteropoly compounds, and a classification of ions which can be sorbed on HPA salts is proposed. The special features of the sorption mechanism of specific groups of ions are discussed, and sorption on HPA salts is shown to be a complex process, influenced by properties of the ions such as radius, ionic potential, state of the ion in solution, and tendency to form complexes. The sorption of ions which can form heteropoly compounds is a multi-step process, accompanied by interaction of the sorbed ions with the molybdophosphate anion. 111 references.

I. INTRODUCTION

The ion-exchange properties of the salts of heteropoly acids (HPA) were discovered by Baxter and Griffin in 1905 when washing with potassium salt solutions a precipitate of ammonium molybdophosphate (AMP) used for the gravimetric determination of phosphorus[1]. However, this phenomenon was not widely used until the late 1950's and early 1960's, when it was applied to the concentration and separation of alkali metal ions[1-26], and to the determination of caesium in sea water and in effluents[27-30] and in biological materials[31-33]. It was then realised that insoluble HPA salts are valuable inorganic ion exchangers: they are cheap, readily available, and easily prepared in any laboratory. They can be used in theoretical studies of ion exchange processes[8] because they are monofunctional when suitably prepared and, like zeolites, they do not swell significantly in aqueous solutions.

Together with the experimental papers began to appear papers on the mechanism of sorption processes HPA salts[7,8,13-20,34-43] as well as review articles[1,2,4,44]. However, the most interesting of these reviews[1] is already more than 10 years old, and more recent reviews are either too sketchy[2,4] or inaccessible[44].

Furthermore, all the reviews published so far adopt a formal classification of the sorbed ions into univalent, bivalent, and multivalent to describe the mechanism of sorption processes. Univalent and bivalent ions have almost identical sorption mechanisms, and the substantial differences in sorption behaviour of the other ions are not revealed by classifying them all as "multivalent". We have therefore attempted to develop a more rational description of the sorption mechanism of various ions on HPA salts by combining two types of information: published data on the structure, formation conditions, and stability of the heteropoly compounds of different

elements, and observations on the sorption properties of HPA salts.

II. STRUCTURAL PROPERTIES OF THE HPA SALTS USED AS INORGANIC SORBENTS

Insoluble salts of heteropoly acids are inorganic sorbents with a fairly complex crystal structure[1-4]. The structural features of the initial heteropoly compounds (HPC) are responsible for the complexity of the processes at the sorbent–solution interface, and they should not be overlooked when the experimental results are analysed. We shall therefore examine the structure of a range of heteropoly compounds before attempting to describe the mechanism of ion exchange on HPA salts.

Of the many sparingly soluble HPA salts, ammonium molybdophosphate is most widely used as a sorbent. It is a HPC of the 12th series[45], having the Keggin structure[46-48]. Ammonium molybdophosphate is precipitated from aqueous solutions as fine yellow crystals of the neutral salt $(NH_4)_3 \cdot PMo_{12}O_{40} \cdot nH_2O$ or of the acid salt $(NH_4)_2HPMo_{12}O_{40} \cdot nH_2O$ (depending on the ratio of molybdophosphoric acid to ammonium salt)[49].

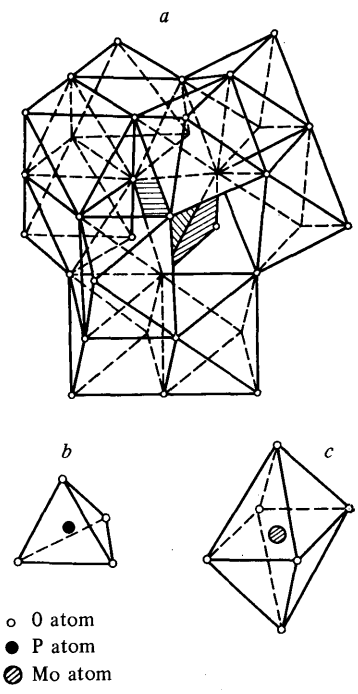

Figure 1. Structure of the $PMo_{12}O_{40}^{3-}$ ion[46]: (*a*) overall shape of the anion, (*b*) PO_4 tetrahedron, (*c*) MoO_6 octahedron.

Heteropoly compounds differ from ordinary coordination compounds in not having discrete ligands coordinated to a central atom. Therefore the coordination sphere of the HPC can be treated as a single complex ligand. At the centre of a ligand anion having the Keggin structure we find a PO_4 [46-48] tetrahedron (Fig.1), surrounded by twelve MoO_6 octahedra arranged in four groups of three: within each triplet the octahedra are edge-sharing, and the triplets are interconnected by sharing corners. Because of the electrostatic interaction between the atoms the octahedra are distorted, with different Mo–O distances. The structure is characterised by the presence of twelve Mo=O double bonds (oxygen end-atoms), and twelve almost linear and twelve angular Mo–O–Mo bridging bonds (bridging oxygen atoms). The HPA anion as a whole is an almost spherical particle with a negative charge (–3) on its surface. In the crystalline state there is no direct bond between the anions: the structure is stabilised by hydrogen bonds, or by the cations. All HPC can form a variety of crystal hydrates, in which the amount of water is often difficult to determine exactly[47,48]. Heteropoly acids and their salts with a Keggin structure crystallise in the cubic system[46,50]. The HPA anions retain their high symmetry in aqueous solutions[48,51]. In the crystalline salts the cations are accommodated in the spaces between anions, and they can exchange with cations in solution if their size allows[1,48].

Heteropoly compounds with the Keggin structure have the general formula[48] $E^{x+}M_{12}O_{40}^{x-8}$, where M is usually Mo or W, and E = B, Si, P, As, Cr, Mn, Fe, Co, Cu, Zn, Ti, Zr, Ga.

In addition to the simpler heteropoly compounds, a whole series of mixed HPC (in which one or more molybdenum atoms are replaced by Tungsten, vanadium, or another metal) has been synthesised[48]. The formation of mixed compounds is due to the general tendency of these ions to combine in polymeric structures, giving compounds which in most cases can be classified as complexes with the Keggin structure.

Triple complexes[48] are formed when highly charged ions (for example, Zr^{IV}, Ti^{IV}, Th^{IV}, Nb^{V}) are added to heteropoly acids in solution. The i.r. spectra of the solid complexes[52,53] show that zirconium, titanium, and thorium can replace molybdenum in the coordination sphere, forming mixed heteropoly complexes. Under these conditions the Keggin structure is retained.

Furthermore, we know from the chemistry of heteropoly compounds[48,54] that addition of alkali to a solution of (say) 12-tungstophosphoric acid produces an 11-tungstophosphate. These "unsaturated" compounds, for example the anion $EW_{11}O_{39}^{n-}$, have an incomplete Keggin structure in which one tungsten atom and one oxygen end-atom are missing[55]. The charge on the anion is always increased by four units. Some lanthanide and actinide ions can form stable complexes with unsaturated heteropoly complexes: the formation of these complexes with thorium[56], cerium[55], and other elements[57] has been reported.

Thus, several variants of the interaction of sorbed ions with ammonium molybdophosphate or other sparingly soluble salts of a HPC of the 12th series are possible.

1. As stated above, the cations in the salt structure are located in the spaces between the anions, and they can (if their size allows it) exchange with cations in the bulk of the solution[1]. Therefore, one variant of the interaction is the replacement of cations from the outer sphere of the sorbent by sorbed ions (i.e. the normal ion exchange reaction).

2. Since the HPA anions are not inert as a matrix, the sorption of ions tending to form mixed complexes with the molybdenum or tungsten of the coordination sphere can cause replacement of molybdenum or tungsten atoms by the corresponding metal atom.

3. Another possible variant is the adsorption of a metal ion on the surface of the anion in a geometrically favourable position, due to interaction with an oxygen end-atom. This interaction should be enhanced by the partial decomposition of the 12th-series HPA anion at high pH, giving a small amount of 11th-series HPA anions.

The most frequently used sorbents are sparingly soluble salts of 12th-series heteropoly acids with a Keggin structure: on these materials differences in sorption properties, and hence also in the possibility of separating various ions, are

determined mainly by the properties of the ions being sorbed, both physical (ionic radius, ionic potential) and chemical (state of the ion in solution, tendency to form complexes in general, and formation of heteropoly compounds in particular).

On the basis of their ability to form heteropoly compounds the inorganic ions can be classified into three groups.

I. The first group includes the ions which cannot normally act as complex-forming hetero-atoms, or form the coordination sphere of HPA, but which form salts with heteropoly acid anions. These are the ions of the alkali and alkaline-earth metals, many doubly charged ions such as Zn^{2+}, Cu^{2+}, Co^{2+}, Ni^{2+}, Mn^{2+}, and Cd^{2+}, and some triply charged ions. These ions, if their size allows it, can exchange with the cations of sparingly soluble HPA salts, which behave towards them as ordinary strongly acidic cation exchangers.

II. The second group consists of ions which can act as the central atom in HPC. They include Ge^{IV}, Ti^{IV}, Zr^{IV}, Th^{IV}, Ce^{IV}, Te^{IV}, Se^{IV}, Ga^{IV}, Cr^{III}, Fe^{III}, Co^{II}, etc. Typical complex-forming ions with a high charge and a small radius, such as Ti^{IV}, Zr^{IV}, Th^{IV}, Ce^{IV}, Te^{IV}, etc., can interact with the anionic part of the sorbent by an addition reaction, especially in the presence of structural defects on the surface (partial degradation of the 12th-series HPA with formation of unsaturated compounds). The sorption of ions such as selenium, able to form highly stable HPC, can lead to reconstruction of the whole surface structure of the sorbent. However, all these ions can also take part in exchange in the outer sphere of the HPA salts as one of the steps in the sorption process.

III. The third group consists of ions able to form the coordination sphere of heteropoly compounds, such as molybdenum(VI), tungsten(VI), vanadium(V), and chromium(VI). Sorption of these ions by HPA salts is often accompanied by the formation of mixed heteropoly compounds.

This classification is not absolute, because some ions could be assigned to two of the groups with equal justification. For example, in the case of iron(III), salt formation with HPA anions has been reported[45] as well as the formation of heteropoly complexes in which the iron is the central atom[48]. Niobium can act as the central atom, forming molybdenum–niobium HPA,[48] but it can also form heteropoly compounds by entering the coordination sphere[47]. We should also note that in real systems it is rare to find one of the above types of interaction in a pure form: sorption process on HPA salts are usually complex. This statement is consistent with a large volume of recently published work.

III. SORPTION OF METAL IONS ABLE TO FORM SALTS WITH HPA ANIONS

Many salts of heteropoly acids have been described[45]. In the case of molybdophosphoric acid (MPA) and tungstophosphoric acid (TPA) the salts of the alkali and alkaline earth metals, and those of silver, thallium, and mercury(I) are known, as well as those of manganese, cobalt, nickel, cadmium, copper(I), iron(III), and zinc. All these ions can be assumed to undergo exchange, to varying extents, on the insoluble salts of heteropoly acids. For the separation and concentration of ions the product of the interaction of the sorbed ion with the initial, sparingly soluble HPA salts must also be insoluble, i.e. the ammonium ions in the AMP structure can be exchanged to a significant extent only for metal ions which form HPA salts insoluble in water[7].

Healy's work[49,58,59] is highly relevant to the identification of the range of ions which can form sparingly soluble salts with HPA anions: he prepared and analysed the neutral and the acid salts of the alkali metals, silver, thallium(I), mercury(I), and barium, and also some mixed salts of alkali metals and of barium with aluminium, iron(III), and some rare-earth elements, with the anions of MPA, TPA, and tungstosilicic acid. Healy concludes from a study of the solubility of these salts[59] that mixed salts prepared by exchange of ions in the outer sphere of HPA are sparingly soluble if two of the three hydrogen atoms in the MPA or TPA are replaced by a heavy alkali metal, while the third hydrogen atom can be replaced by a light ("soluble") or a heavy ("insoluble") alkali metal. For example, the salts $K_2LiW_{12}O_{40}$ and $K_2RbW_{12}O_{40}$ have a very low solubility in water. Salts of the alkaline-earth metals are more soluble in water(and even more so in acids) than the salts of the heavy alkali metals, and therefore they are not absorbed by tungstophosphates at acidities above 0.3 M, though they can be easily removed from solutions at pH 1–4.[59]

From the point of view of solubility the most effective use of the ammonium salts of HPA is exchange with heavy alkali metal ions such as K^+, Rb^+, and Cs^+, or with the Tl^+, Ag^+, and Hg_2^{2+} ions, which form the least soluble salts with HPA.[49] For this reason HPA salts were first used as ion exchangers in the concentration and separation of heavy alkali metal ions[5–9]. A large amount of experimental information on the exchange of alkali metal ions on MPA and TPA salts is now available, and the mechanism of these processes has been studied in detail.

Smit and coworkers[5–8] carried out one of the first and most fundamental studies of this problem by synthesising the ammonium salts of various HPA,[7] calculating the distribution coefficients of several alkali metal anions, and analysing the results[7,8]. They established[7] that for a given HPA salt the distribution coefficient increases with the atomic number (or ionic radius) of the alkali metal, i.e. in the same order as in the case of strongly acidic organic ion exchangers. The higher distribution coefficients of Ag^+ and Tl^+ (as compared to alkali metal ions of the same size) are ascribed by Smit to the partial covalency of the bond between Ag^+ or Tl^+ ions and the HPA anions. The separation factors for pairs of alkali metal ions (defined as the ratio of the distribution coefficients under similar experimental conditions) are much higher for the ammonium salts of HPA than for the Dowex-50 resin. The selectivity of AMP towards heavy alkali metals is so great that small amounts of the larger alkali metal ions (Cs^+ and Rb^+) can always be selectively adsorbed from solutions containing amounts of the smaller alkali ions several times greater than the maximum capacity of the column[8]. Thus, 19 mg of Rb^+ can be quantitatively separated from 600 mg of K^+ on a column containing 1 g of AMP and 0.5 g of asbestos. The first attempt at relating the cation exchange properties of AMP and other HPA salts to their crystal structure was reported by Smit.

The basic parameter which determines the exchange of a univalent cation on AMP is, according to Smit, the ionic radius. The large alkali metal cations can be stably accommodated in the holes of the lattice and lower the lattice energy sufficiently to form sparingly soluble salts. It is suggested[7] that because of the pore structure of the HPA salts ion exchange can take place over the whole of the crystal lattice, and not just on the surface of the crystals. However, large organic cations cannot move freely through the lattice, and they are exchanged on the crystal surface only.

The validity of the law of mass action for exchange processes on MPA has been tested[8] by a study of the Rb^+–NH_4^+ exchange. By analysing the elution curves it was shown that not all the ammonium ions in AMP can be exchanged: ~60% of the ammonium ions can be replaced by caesium, and ~80% by rubidium. Smit explains this observation by postulating that caesium ions (and, to a lesser extent,

rubidium ions) can block the channels of the ions exchanger, thus hindering the diffusion of ions in the lattice.

However, subsequent work on the exchange properties of HPA salts has shown that the sorption of alkali metal is a more complex process. Thus, Krtil established[13-19,36] that in most cases the results apply to the acid salts of HPA. When the initial salts have the composition $(NH_4)_{2.67}H_{0.33}(PW_{12}O_{40})\cdot 9.8H_2O$ or $(NH_4)_{2.95}H_{0.05}(PMo_{12}O_{40})\cdot 11.6H_2O$ treatment with acid causes exchange of NH_4^+ ions by hydrogen ions, with formation of a more acid salt[9]. Later work showed[13,15,36] that the sorption of alkali metal ions on the salts of heteropoly acids can involve three independent processes: a) exchange of ammonium ions by alkali metal ions, b) exchange of hydrogen ions from the sorbent by alkali metal ions, c) exchange of ammonium ions from the sorbent by hydrogen ions from the acid solution.

The equilibrium constant for all these processes have been determined[36], and it has been shown that the exchange of alkali metal ions on HPA salts obeys the law of mass action. Mathematical treatment of sorption data using this law can be carried out relatively simply only when the sorbed ion is present in trace amounts (as compared with the ammonium ion or the acidic hydrogen of the sorbent[1]). In this case the plots of $\lg D$ against pH and $\lg D$ against $[NH_4]$ should be straight lines of unit slope. This expectation has been confirmed experimentally in studies of the sorption of alkali metal ions on HPA salts[5-36].

Table 1. Distribution coefficients D of different cations on AMP in 0.1 M NH_4NO_3.[34]

Cation	Li+	Na+	K+	Rb+	Cs+	Ag+	Tl+	H_3O^+
r, Å	0.60	0.95	1.33	1.48	1.69	1.26	1.40	—
D	0.57	0.78	4.7	266	4024	54	3939	0.84
θ_{max} %	20.9	26.4	48.7	53.6	45.3	64.8	45.8	—

Though the general features of the sorption of alkali metal ions on HPA salts are generally agreed, different workers report different experimental values of the distribution coefficients D and of the maximum extent of exchange of the ammonium ion in HPA salts by alkali metal ions. Thus, Krtil[18] determined the maximum sorption capacity of AMP and ammonium tungstophosphate (ATP) towards caesium: the results (1.0 and 0.66 mg-equiv Cs g^{-1} respectively) indicate the formation of the dicaesium salt of the HPA in both cases. On the other hand, measurements of the maximum extent of exchange (θ_{max}) of the ammonium ions by alkali metal ions under dynamic conditions[34] did not give values of 33.3 and 66.6%, corresponding to the exchange of one or two ammonium ions (Table 1). The differences between the D values obtained by different workers[8,15,18,34,36] can be ascribed to different experimental methods and different procedures for the preparation of the sorbent.

A detailed study[18] of the sorption of caesium and rubidium on normal and on acid ammonium and thallium salts of MPA and TPA revealed some interesting features: thus, caesium in weakly acidic solutions (0.01 M HNO_3) has a lower affinity for the acid salt than for the normal salt. A possible explanation is that in normal ammonium salts of HPA the caesium can be exchanged only by ammonium ions, whereas in acid salts it can be exchanged by NH_4^+ and H^+ ions. Measurements of the pH dependence of the sorption of caesium on acid salts at constant concentration of ammonium ions have shown that the process is influenced by hydrogen ions only at acidities ≥1 M (in HNO_3). Hence, caesium can exchange with hydrogen ions only in strongly acid solutions.

Attempts have been made[34,35] to relate the sorption of alkali metal ions to various physicochemical characteristics of AMP and of the sorbed ions. Thus, it has been shown[35], by analysing the solubilities of the corresponding HPA salts and their crystal lattice energies, that the separation of alkali metal ions on AMP is possible in principle. The affinity series obtained from that work, $Cs^+ > Rb^+ > K^+$, is consistent with the more general sequence[34]

$$Cs^+ = Tl^+ > Rb^+ > Ag^+ > K^+ > H^+ > Na^+ > Li^+,$$

shown in Table 1. Furthermore, we note a linear relationship between $\lg K'$ (where K' is the equilibrium constant of the exchange reaction) and ΔH (the energy of hydration) for Cs^+, Rb^+, and K^+, whereas the smaller ions Na^+ and Li^+ have unexpectedly high values of $\lg K'$. It is suggested[34] that the smaller alkali metal ions undergo exchange in a partially hydrated form (Fig.2). By applying the law of mass action to the experimental exchange isotherms for the alkali metal ions an isotherm equation valid over a wide range of concentration has been obtained[34]. It assumes that the activity of the ammonium ions in the crystal is equal to the mole fraction of exchangeable ammonium ions, and that the ions in the solid phase are in an ideal solution. Thus, the equation is an analogue of the Langmuir isotherm[60]. The agreement between experimental and calculated results is satisfactory.

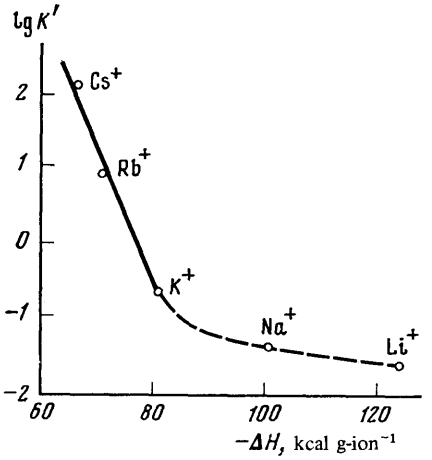

Figure 2. Logarithm of the equilibrium constant of the exchange reaction against hydration energy of the alkali metal ions[34].

One of the early publications[6] suggested the following mechanism for the exchange of bivalent ions (in particular, barium) on AMP:

$$Ba^{2+} + H_2O \rightleftarrows Ba(OH)^+ + H^+ \quad (1)$$

$$RNH_4 + Ba(OH)^+ \rightleftarrows RBa(OH) + NH_4^+ \quad (2)$$

where R is a molybdophosphate anion. The evidence for this conclusion was that only large univalent cations are readily exchanged with the ammonium ions of AMP, and the ion $Ba(OH)^+$ satisfies both conditions (univalence, and large crystallographic radius). Furthermore, this reaction scheme

explains the dependence of the sorption of barium on the concentration of ammonium ions as well as on the acidity of the medium.

More recent work[14,27,61] in different laboratories on the sorption of ^{90}Sr on various HPA salts led to the conclusion[14] that $\lg D$ for strontium varies linearly with pH at pH < 3, with a slope of −2 (i.e. one strontium ion is exchanged for two hydrogen ions). These experimental facts cannot be explained by Smit's mechanism[18]. Healy[59] critically examined Smit's mechanism, and pointed out that a species such as $Ba(OH)^+$ is highly unstable, and very unlikely to exist in bivalent cation salt solutions under the conditions used for sorption on AMP. Smid himself came to the same conclusion in a later paper[62]. Referring to Stockdale's results[63], Smit pointed out that even in weakly acid solutions the sorbent is in the form of an acid salt of MPA, of composition intermediate between the doubly and the triply substituted salt. The pure doubly substituted salt can be prepared by washing the exchanger with acid[58,63]. Smit concluded from these observations that bivalent ions are sorbed reversibly on AMP by exchanging with ammonium ions or with the oxonium ions remaining in the AMP precipitate in spite of thorough washing with ammonium nitrate:

$$2\,(NH_4)_2\,(H_3O,\,NH_4,\,Na\ \text{ etc.})\,MP + Ba^{2+} \rightleftarrows \rightleftarrows [(NH_4)_2\,MP]_2\,Ba + 2\,(H_3O^+,\,NH_4^+,\,Na^+\ \text{etc.}) \qquad (3)$$

This reaction scheme is consistent with the dependence of the sorption of bivalent ions on pH and on the concentration of ammonium ions, and also with the slope of the plots of $\lg D$. Furthermore, it is clear that the exchange mechanisms of univalent and bivalent ions on HPA salts must be similar, and there are no grounds for involing specific mechanisms in the two cases as is often done in the literature[1,6,62,64]. However, there is a difference in the sorption and elution conditions of the two types of ion, and this difference has been used in the separation of ^{137}Cs and ^{90}Sr.[6,14,27,36,61,62] It is probably associated with the differences in solubility of the exchange products in water and in acid solutions[49,58,59].

Table 2. pH of the equilibrium solutions before (pH_1) and after (pH_2) contact with AMP.[64]

M^{2+}	Mg^{2+}	Ca^{2+}	Sr^{2+}	Ba^{2+}	Mn^{2+}	Co^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+}	Cd^{2+}
pH_1	5.89	6.20	6.30	6.54	6.37	6.19	6.33	4.88	5.37	6.14
pH_2	3.87	3.55	3.41	3.03	3.74	3.50	3.49	3.26	3.48	3.53

The sorption of Be^{2+}, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, and Hg^{2+} has been studied[64] under both static and dynamic conditions. The D values are independent of acidity at pH > 3 for practically all the listed ions, and in more strongly acidic solutions they increase with pH. The variation of $\lg D$ with $\lg [NH_4NO_3]$ is a straight line of unit slope. From these observations the authors conclude[64] that the exchange with ammonium ions involves a singly charged particle, possibly $M(OH)^+$: in other words, they revert to the Smit mechanism[6], described by Eqns.(1) and (2). Though the $M(OH)^+$ complexes are unstable for most of these ions, it is suggested[64] that the equilibrium of their formation reaction (1) is shifted towards the right by the sorption of $M(OH)^+$ particles on the AMP. The observed decrease in pH of the equilibrium solutions during sorption of bivalent ions on AMP (Table 2) is quoted[64] as evidence for the validity of Eqns.(1) and (2).

However, a lowering of the pH of the equilibrium solution can be produced also by the exchange mechanism corresponding to Eqn.(3) if the sorbent is an acid salt of MPA. The authors[64] had worked with a normal salt, and therefore they excluded the possibility of exchange by the mechanism (3). However, they controlled the composition of their sorbents by determining the AMP content alkalimetrically rather than by determining the ammonia content. Because of the large molecular weight of the molybdophosphate anion (as compared to NH_4^+, and even more so as compared to the hydrogen ion) this approach cannot give accurate results. The most convincing argument in favour of exchange by Eqns.(1) and (2) is the slope of the plots of $\lg D$ against $\lg [NH_4NO_3]$, and also the pH value of the solutions before sorption (greater than 5 in every case, see Table 2). The $M(OH)^+$ particles may be relatively stable under these conditions.

Table 3. Distribution coefficients of trace amounts of doubly charged cations on AMP in 0.1 M NH_4NO_3 solution[64].

M^{2+}	D	M^{2+}	D	M^{2+}	D
Mg^{2+}	0.81	Mn^{2+}	1.34	Cu^{2+}	1.92
Ca^{2+}	1.48	Co^{2+}	1.38	Zn^{2+}	4.28
Sr^{2+}	1.34	Ni^{2+}	1.77	Cd^{2+}	2.21
Ba^{2+}	3.68				

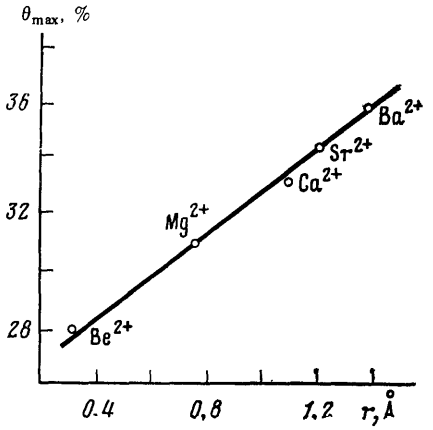

Figure 3. Maximum exchange (θ_{max}) of alkaline-earth ions against ionic radius[64].

The stoichiometry of the exchange was tested[64] by a series of dynamic experiments aimed at determining the maximum capacity of the column for different bivalent cations: the result was that different cations can replace different amounts of ammonium ions in AMP. For example, in the exchange of Hg^{2+} ions ~10% of the ammonium ions are replaced, as compared to 27% in the exchange of Zn^{2+}, 23.5% in the exchange of Co^{2+}, etc. These values differ very substantially from the values (33.3 and 66.6%) corresponding to the stoichiometric exchange of one or two ammonium ions. With the alkaline-earth metal ions a direct proportionality is found between the maximum degree of exchange and the ionic radius (Fig.3), but not with other ions.

The distribution coefficients for trace amounts of bivalent[64] and univalent ions[34] have also been determined (under otherwise identical conditions). We note (Table 3) that the distribution coefficients for bivalent ions are much smaller than those for the heavy univalent ions. From the experimental results the bivalent ions can be arranged in the following affinity series:

$$Zn^{2+} > Ba^{2+} > Cd^{2+} > Cu^{2+} > Ni^{2+} > Ca^{2+} > Mn^{2+} \sim Sr^{2+} \sim Co^{2+} > Mg^{2+}.$$

IV. SORPTION OF IONS ABLE TO ACT AS THE CENTRAL ATOM IN HETEROPOLY COMPOUNDS

This is the most extensive group of ions in our classification. As was pointed out in Section II, it includes the typical complex-forming ions, such as Ce^{III}, Y^{III}, Sc^{III}, Fe^{III}, Cr^{III}, Ti^{IV}, Zr^{IV}, Th^{IV}, Ce^{IV}, Te^{IV}, Ga^{IV}, Nb^{V}, U^{VI}, U^{IV}, Np^{IV}, etc. Many of these ions carry a high charge and have a small radius, i.e. they have a high ionic potential, which explains their highly developed tendency to form complexes. All these ions can act as the central atom in heteropoly compounds. The heteropoly complexes of Ti^{IV}, Zr^{IV}, Cr^{III}, and Fe^{III} have the Keggin structure[48,65].

Hexamolybdenum and hexatungsten compounds with octahedral coordination of the central atom, of general formula $E^{x+}M_6O_{24}^{x-12}$, are formed by ions such as Te^{IV}, Al^{III}, Cr^{III}, Fe^{III}, Ga^{III}, etc.[48,66,67]

The structure of the heteropoly complexes of Ce^{IV}, Th^{IV}, U^{IV}, and Np^{IV} has been described[48,68-71]. It has one special feature: the central atom has icosahedral surroundings. This structure is now called the Dexter–Silverton structure[72], and the anion has the general formula $E^{4+}M_{12}O_{42}^{8-}$. "Triple" heteropoly complexes have been described for many ions of this group. They have been used in the spectrophotometric determination of titanium[73-77], thorium[78,79], zirconium[80], niobium[81,82], hafnium[83], yttrium[84], nickel[85], and other elements. Opinions as to the location of the second hetero-atom in such a structure have varied. The earlier papers[73-75,80,81,83] suggested that the third component occupies a special place in the coordination sphere rather than replacing molybdenum, thus acting (with the phosphorus) as a second central atom. More recently the most generally held view has been that the triple complexes are mixed heteropoly compounds, in which some of the molybdenum is replaced by another element[48].

On the other hand, some of the ions listed above can also form salts with HPA anions. In particular, Healy[59] has described the formation of mixed cerium–caesium $[(Cs_2PW_{12}O_{40})_3Ce]$, aluminium–caesium $[(Cs_2PW_{12}O_{40})_3Al]$, and iron–caesium $[(Cs_2PW_{12}O_{40})_3Fe]$ salts of tungstophosphoric acid. The same paper describes the formation of mixed salts of ammonium and caesium with cerium, praseodymium, and europium during the sorption of the latter elements on precipitated ammonium and caesium molybdophosphates.

The cations do not occupy a fixed position in the structure of the heteropoly acid salts[47,48,86], and they are merely accommodated in the space between the anions. If their size allows, they can be exchanged for cations from the external solution[1,7,8]. Hence, the first step in the sorption of cations on sparingly soluble heteropoly acid salts is diffusion into the crystal and exchange with the cations of the salt. In the first group of cations, discussed in Section II of this review, these steps conclude the process, and mixed salts of the appropriate HPA are formed. On the other hand when the sorbed ions can act as the hetero-atom in an HPA it can also (under suitable conditions) interact further with the anion, which can no longer be treated as an inert matrix (as in the exchange of alkali or alkaline-earth metals).

Before discussing the possible types of interaction between the sorbed ions and the anions of HPA salts we should examine the experimental information on the sorption of these ions on molybdophosphates and tungstophosphates. The sorption of ions in this group has been studied for many years merely from the standpoint of separating these ions from alkali metal ions (for example, in the preparation of radiochemically pure caesium-137 [6,11,17,19,22] or potassium-42.[24]) Krtil[36] and Smit[62] were among the first to study the sorption mechanism of tervalent ions.

Krtil believes[36] that the interaction of yttrium(III) and cerium(III) with ammonium tungstophosphate is based on ion exchange with the ammonium or hydrogen ions of the sorbent. At nitric acid concentrations of 0.2–1 M Krtil observed a linear relationship between $\lg D$ and $\lg c_{HNO_3}$, with a slope of 3, from which he concluded that yttrium and cerium(III) are exchanged for three hydrogen ions at these acidities. The bond between the sorbed ions and the sorbent is relatively weak, since these ions can be displaced by hydrogen ions. The pH for maximum sorption is ~1. Furthermore, Krtil suggests that the sorption of these ions (in contrast to the sorption of alkali metal ions) does not depend on diffusion of sorbate into the sorbent lattice, since all the processes are confined to the surface of the sorbent.

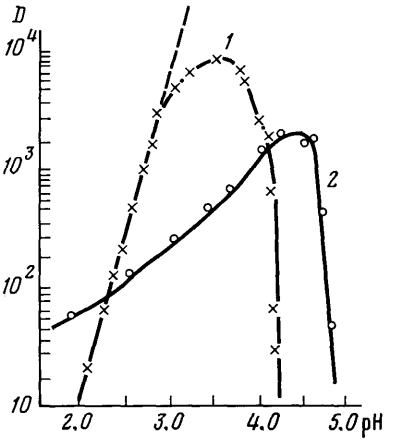

Figure 4. Distribution coefficient of yttrium from 0.1 M NH_4NO_3 solution against acidity of the medium[62]: *1*) on AMP, *2*) on ATP.

Smit[62] studied the pH dependence of the sorption of yttrium on AMP and ATP. Like Krtil[14], he found a fairly complex dependence (Fig. 4), the slope in the pH region 2–3 (curve *1*) being 2.72 instead of the expected 3.0. The distribution coefficients were determined after stirring the yttrium solution with the sorbent for 10–12 h. As Fig. 4 shows, when the pH of the equilibrium solution is increased above 3 the sorption of yttrium on AMP falls off sharply. By comparing these results with those of dynamic experiments Smit discovered some interesting discrepancies. In the dynamic experiments some of the yttrium sorbed at pH < 4 can be eluted (together with strontium) by a 1 M solution of NH_4NO_3, whereas elution of the remainder requires a solution

of 1 M NH_4NO_3 + 1 M HNO_3. On the other hand, after sorption on AMP from an acetate buffer solution at pH 4.5 the whole of the yttrium is in a form which cannot be eluted by 1 M NH_4NO_3. This can be exploited for the separation of strontium from yttrium. The process is not easily reversible: rapid elution of the yttrium requires at least a 0.5 M solution of HNO_3. Smit believes that the yttrium which cannot be eluted by NH_4NO_3 is adsorbed on an unusual type of exchange centre, or by a special mechanism, so that the ion exchange reaction is complicated by some additional interaction in this case. It is suggested[62] that complex formation between the sorbed ions and various decomposition products of the heteropoly anion (or even the 12th series HPA themselves, structurally modified) can occur in the solid phase.

As stated, in Smit's experiments the equilibrium sorption fell off steeply at pH > 3, which at first sight cannot be reconciled with the results of dynamic experiments. However, it was shown that if the equilibrium experiments at pH > 3 are carried out in 1 min rather than 10–12 h the D values no longer decrease with increase of pH, but lie on an extension of the left-hand branch of curve *1* in Fig. 4 (broken line). The decrease in the distribution coefficients of yttrium at high pH values after relatively long equilibration times is ascribed[62] to complex formation between ytrrium in the aqueous phase and the soluble decomposition products of the 12-AMP (which may include the 11-molybdophosphate anion).

Unfortunately, kinetic sorption curves for yttrium are not given in Ref. 62, but the results of the following experiment are quoted. A sample of AMP was left overnight in contact with a 0.1 M solution of NH_4NO_3 in a pH 4.5 buffer (sodium acetate). The water phase (which had developed a yellow colour) was then separated, a trace of yttrium was added to it, and the solution was allowed to contact a fresh portion of AMP for 1 min. Under these conditions practically no sorption of yttrium was observed. On the other hand, when the first sample of AMP was immersed for 1 min in a fresh buffer solution (at pH 4.5) containing a trace of yttrium unusually high D values for yttrium were obtained.

It is suggested[62] that this experiment demonstrates the formation of water-soluble complexes which cannot be adsorbed on AMP. X-Ray diffraction patterns of AMP samples exposed for 20 h to a pH 4.5 buffer solution are taken as evidence that the AMP samples are unchanged. The present writers find this evidence unconvincing, since one of the most likely decomposition products of 12-molybdophosphate is the 11th series anion, which consists (see Section 1) of an incomplete Keggin structure with a missing molybdenum atom and oxygen end-atom[55]. The presence of a few structural defects of this type on the sorbent surface can hardly be detected by X-ray diffraction analysis. Therefore, we believe that the type of interaction between yttrium and the molybdophosphate anion in the solid phase is still an open question.

As regards the other ions of this group, the sorption of titanium, thorium, uranium, neptunium, zirconium, niobium, selenium, and tellurium on various heteropoly acid salts has been investigated[37–43,87–93]. Sorption processes involving these elements may be even more complex than with yttrium, because these multiply charged ions tend to hydrolyse in aqueous solutions as well as forming many types of complex with anions of different acids. Allowance for all these factors (in addition to the possible interactions with the anionic part of the sorbent) must be made in studies of the sorption processes for these ions.

Thus, in a study of the behaviour of uranium(VI) during sorption on AMP the hydrolysis of the ion and the formation of nitrato and sulphato complexes had to be allowed for[38]. At low concentrations of HNO_3 (<10^{-2} M) and NH_4NO_3 (<5 × 10^{-3} M) the distribution coefficient of the uranyl ion on AMP ($\lg D$) was found[38] to be independent of the concentration of HNO_3 and NH_4NO_3, but at higher concentrations a linear relationship with a slope of unity was observed. These results led to the conclusion[38] that in the ion exchange reaction a univalent ion replaces an ammonium ion, the most probable exchanging particle in this case being UO_2OH^+. Exchange of the $UO_2NO_3^+$ particle is said to be impossible, because its formation occurs at higher concentrations of nitric acid than those used in this work (0.01–0.25 M). The sorption mechanism of the UO_2OH^+ ion is equated[38] to that of alkali metal ions, an ammonium or hydrogen ion in the AMP being replaced by the UO_2OH^+ ion. The law of mass action was shown to apply to exchange equilibria involving uranyl ions present in solution in different forms. The sorption of uranium is reversible: under dynamic conditions the uranium is sorbed from a 10^{-3} M solution of nitric acid and eluted in 100% yield by a 1 M solution of the acid.

The sorption of elements such as zirconium and niobium has been studied for many years merely with the aim of optimising their separation from caesium-137.[17,19,22,36] It was shown[17,36] that the behaviour of zirconium and niobium differs very substantially from that of the other fission products. Though the plot of $\lg D$ against $\lg c_{HNO_3}$ is linear, its slope is fractional. Krtil suggests[36] that in this case molecular sorption of neutral complexes or hydrated forms of the elements must be taking place. Because of the low solubility of zirconium phosphates he concludes that the anomalous behaviour of zirconium and niobium is due to chemisorption. Under the conditions used for the sorption of alkali metal ions the sorption of zirconium and niobium is partially irreversible. If the initial solution contains hydrofluoric acid, the elements are converted into fluoro complexes and are sorbed with difficulty: only 0.01% of a ^{95}Zr–^{95}Nb mixture is extracted under these conditions[19]. Solutions containing tartaric acid[22] as well as HF are recommended to minimise the sorption of these isotopes.

In a more recent paper[89] the same workers describe in detail the sorption mechanism of zirconium and niobium, allowing for the formation of hydrolysed and polymerised forms of these elements in aqueous solutions. Both elements give rise, in acid solutions, to chemical forms which can be sorbed on AMP both by ion exchange (cations) and by adsorption (neutral molecules, and colloidal particles). Addition of neutral salts was found to affect the sorption of zirconium and niobium on MPA, the distribution coefficients increasing with the concentration of ammonium and sodium ions, whereas under ion exchange conditions ammonium ions lower the sorption coefficients by taking part in the exchange equilibrium. Hence, the sorption of trace quantities of zirconium and niobium on AMP involves adsorption of hydrolysed or polymeric forms of these elements rather than ion exchange (as in the case of caesium). Complexing agents decrease the sorption of both elements by hindering the formation of strongly sorbed polymeric forms. The effect of complexing agents on the sorption of ^{95}Zr increases in the sequence $NO_3^- \ll$ tartrate ≅ citrate ≅ $SO_4^{2-} < F^- \cong$ oxalate, and for ^{95}Nb the series is citrate ≅ tartrate ≅ $NO_3^- \ll SO_4^{2-} < F^- \cong$ oxalate.

The sorption of microgramme quantities of niobium on the caesium and ammonium salts of MPA was first studied[87] with the aim of separating niobium from a large excess of titanium. As in the case of trace amounts of ^{95}Nb,[89] the niobium is not desorbed by solutions of mineral acids, but it can be eluted quantitatively by 40 ml of a solution of NH_4F (0.2 M) at pH 2. Hence, and also in view of the considerable sorption of niobium from acid solutions and of the failure of ammonium

and sodium ions to influence the sorption, the interaction of niobium with HPA salts cannot be purely by ion exchange. Titanium is less strongly held by caesium molybdophosphate: it is not sorbed at an acidity >0.5 M HCl, and it can be desorbed quantitatively by a 5 M solution of HCl. The differences in behaviour of niobium and titanium can be used to separate these isotopes[87].

The sorption of thorium on ammonium molybdophosphate was first described by Ganzerli-Valentini and coworkers[37]. Their measurements (under static conditions at room temperature) included the effect of factors such as the concentration of nitric acid, time, and the concentration of ammonium nitrate on the distribution coefficient of thorium (D_{Th}) on AMP. By studying the dependence of D_{Th} on the time of shaking the solution with the sorbent it was found that equilibrium in solutions 10^{-3} M and 0.7 M with respect to HNO_3 is reached in 12 and 8 h respectively. The plot of $\lg D_{Th}$ against concentration of nitric acid is fairly complex (Fig.5): at nitric acid concentrations below 0.3 M the dependence is non-linear, but the experimental points for 0.3–1 M HNO_3 lie on a straight line of slope −3.7. The maximum value of D_{Th} is 13500. The linearity of the plot of $\lg D_{Th}$ against $\lg [HNO_3]$ denotes that in this region of $[HNO_3]$ values of Th^{4+} ion is replacing the acidic hydrogen of AMP by an ion exchange mechanism. The deviation of the slope from an integral value was first ascribed[37] to experimental error, but in view of the reproducibility of the measurements the authors then concluded that the activity of thorium in solution may be affected by the concentration of nitric acid through the formation of nitrato complexes.

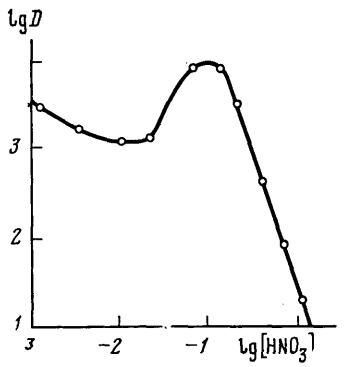

Figure 5. Distribution coefficient of thorium on AMP against the acidity of the medium[37].

The authors[37] do not reach a firm conclusion on the sorption mechanism of thorium for $[HNO_3] < 0.3$ M, though they suggest the possibility of formation of thorium hydrolysis products, or of complexes of thorium with molybdophosphoric acid or its decomposition products. It is not stated whether these complexes are formed in the liquid phase or in the ion exchanger, but nevertheless the slow equilibration in a 10^{-3} M HNO_3 solution (as compared with 0.7 M HNO_3) is ascribed to the formation of these complexes.

The following dependence of $\lg D_{Th}$ on the concentration of ammonium nitrate was observed (Fig.6): between 5×10^{-3} and 1.5×10^{-2} M NH_4NO_3 the plot is linear, with a slope of −4, confirming that the interaction of thorium with AMP is by an ion exchange mechanism, but for $[NH_4NO_3] > 1.5 \times 10^{-2}$ M there is a change in slope which the authors[37] ascribe (as in the case of nitric acid) to a change in the activity of thorium ions in solution. In all the equilibrium experiments the pH was measured in the initial solutions as well as at equilibrium. In every case the pH of the equilibrium solution was found to be lower by ~0.1 pH unit, confirming that the acidic hydrogen of the sorbent is involved in the exchange.

With thorium, uranium, and neptunium the experiments under dynamic conditions show a hysteresis effect[40] which had been briefly mentioned in Ref.37. Whereas thorium is sorbed on AMP from 10^{-3} M HNO_3, its removal from the column begins at a concentration of 0.5 M HNO_3, and does not go to completion. A mixture of 1 M HNO_3 + 1 M NH_4NO_3 removes 70% of the thorium, and a 2 M HNO_3 + 1 M NH_4NO_3 solution removes 90%. Increasing the concentration of ammonium nitrate has little effect on the elution of the thorium, but by increasing the concentration of acid we can remove the thorium from the column quantitatively (at 8 M HNO_3). If sulphuric acid is used as the eluent the thorium can be washed out of the column at a lower concentration of the acid.

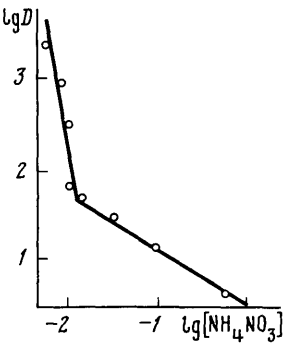

Figure 6. Distribution coefficient of thorium on AMP against concentration of NH_4NO_3 (in 0.1 M HNO_3). [37]

Np(IV) behaves in many ways like Th(IV) during sorption on AMP. The shift of the linear portion of the $\lg D_{Np}$ against $\lg [HNO_3]$ plot towards acidities greater than in the case of thorium is explained[39] by a higher tendency towards hydrolysis. In the region of 0.5–2.5 M HNO_3 the slope of the linear portion denotes exchange of a Np(IV) particle. However, at lower acidities the sorption of Np(IV) is no longer described by an ion-exchange reaction. Experiments under dynamic conditions[40] have shown that the sorption of Np(IV) on AMP is even more irreversible than that of thorium: even 14 M nitric acid cannot elute more than 87% of the neptunium.

It has been confirmed experimentally[40] that thorium, neptunium, and (to some extent) uranium can form complexes with molybdophosphate or its decomposition products under the conditions needed for the sorption of these elements on AMP. It is not stated[40] whether these complexes are formed in the solid or in the liquid phase. However, it is suggested that the AMP lattice may be distorted by the small size and high charge of the Np(IV) and Th(IV) ions, causing an increase in the rate of decomposition of the AMP, but the influence of these changes on the distribution coefficients of the sorbed ions is not made clear.

The maximum in the plot of the sorption of neptunium(IV) against time of contact between the phases (Fig.7) is explained[39] by postulating that the Np(IV) ions initially adsorbed on the AMP surface can form complexes with the heteropoly anions which are then returned (in part) to the solution. The possibility of complex formation in the solid phase is specifically mentioned in order to explain the difference between the slope (−2) of the plot of $\lg D_{Np}$ against $\lg [NH_4NO_3]$ and the expected value (−4), and also the almost total irreversibility of the sorption of Np(IV) under dynamic conditions[40].

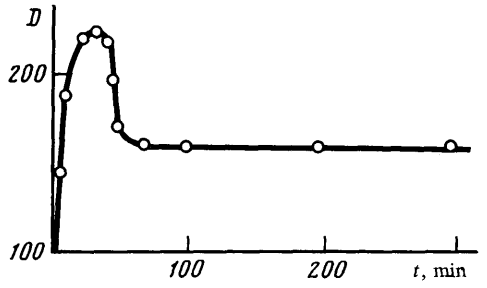

Figure 7. Distribution coefficient of neptunium(IV) on AMP against time of contact between the phases[39].

In an attempt to clarify the treatment of the sorption mechanism of thorium on AMP the writers have shown[43] that the dominant process at pH 0–1.15 is ion exchange of the thorium for the ammonium or the acidic hydrogen of the sorbent. Further evidence for this conclusion comes from the dependence of the distribution coefficient of thorium on AMP on the concentration of phosphate and molybdate ions in solution at pH 0.7: the phosphate ions have almost no effect on the sorption of thorium, whereas addition of molybdate ions to the solution gives a lower value of D_{Th}. This can be explained by postulating the formation by thorium in aqueous solutions of molybdenum–thorium heteropoly complexes of an anionic type[69], which cannot be sorbed in the outer sphere of the AMP.

Simultaneously present phosphate and molybdate ions have a more marked effect than molybdate ions alone. The measurements were made at pH 0.7, which corresponds to the optimum conditions for the formation of the soluble thorium–phosphorus–molybdenum triple complex[78] (of the anionic type). Since under the present conditions the triple complex is more stable than the double (thorium–molybdenum) complex, the sorption of thorium on AMP is almost totally suppressed by the presence of the phosphomolybdate reagent. Hence, the sorption of thorium on AMP is hindered by the formation of heteropoly complexes in the aqueous phase. From the sorption isotherms on AMP at different temperatures[43] we find that the sorption of thorium on AMP increases with temperature, in contrast to the behaviour of true ion exchange systems. This effect sets in at high concentrations of thorium.

Thus, the ion exchange process is complicated by the interaction of thorium with the anionic part of the sorbent. In order to establish whether molybdenum is displaced from the coordination sphere of the AMP, or whether the metal is adsorbed on the anion surface as a result of interaction with an oxygen end-atom, the equilibrium solutions were analysed for molybdenum and phosphorus during the measurement of the isotherms. No correlation between the amount of sorbed thorium and the amount of molybdenum in solution could be found, and therefore any interaction between the thorium and the anionic part of the sorbent can only be of the addition type.

As was stated above, an increase in pH favours the decomposition of heteropoly compounds of the 12th series with formation of compounds of the 11th series[48,54]. Thorium can form relatively stable compounds with the latter[56]. Therefore we cannot exclude the possibility of an equilibrium between 11th- and 12th-series compounds on the surface of the sorbent in contact with the solution, the presence of the 11th-series compounds enabling the thorium to form complexes with the anionic part of the sorbent.

In the case of selenium and tellurium—the next members of this group of ions—kinetic measurements have shown[41] that sorption is accompanied by chemical interaction with the anionic part of the sorbent. The experimental results obey the equation for diffusion within the grain. In order to identify the rate-limiting step unequivocally the activation energies for the sorption of Se(IV) and Te(IV) on AMP were calculated (18.4 and 7.7 kcal $mole^{-1}$ respectively). These values confirm that diffusion in the grain is the slowest step in the process. When the chemical interaction between the ions and the sorbent is unhindered (small ionic radii, high concentration of sorbed ions, and long contact times between the sorbent and the solution) the kinetic curves no longer obey the diffusion equations. The presence of chemical interactions between the anion of the sorbent and the sorbed ion is confirmed by the lack of dependence of the rate of sorption of Se(IV) on the nature of the cation of the sorbent and on the concentration of electrolyte.

Studies of the sorption of Se(IV) and Te(IV) on AMP under equilibrium conditions have shown[42] that the hydrogen ions in the sorbent can contribute to the ion exchange process if the acidity of the solution is high enough. At higher pH values the value of D is unaffected by changes in acidity, suggesting chemical interaction between the sorbed ion and the sorbent matrix.

The exchange constants and thermodynamic exchange functions have been calculated from the sorption isotherms. The change in the thermodynamic Gibbs potential ($\Delta\Phi$) is negative for both Se(IV) and Te(IV), indicating that the sorption of both elements is selective on AMP. This is due mainly to the increase in the entropy of the system, since the enthalpy factor is unfavourable in this case ($\Delta H > 0$). The conditions for optimum sorption of selenium and tellurium coincide with the existence region[94–97] of the known double and triple complexes of Se(IV) and Te(IV) with molybdate and molybdophosphate: therefore, the concentrations of molybdenum and phosphorus in the equilibrium solutions were determined[42] during the measurement of the sorption isotherms under equilibrium conditions in order to clarify the interaction between these ions and the sorbent matrix. As the concentration of Te(IV) on the sorbent is increased, the amount of Mo(VI) and P(V) in solution is unchanged, but in the sorption of selenium it increases in proportion to the concentration of Se(IV), the average P : Mo ratio in solution being 1 : 12, i.e. the sorption of selenium is accompanied by a reconstruction of the sorbent matrix, leading to the transfer of molybdophosphate ions into the solution. Thus, published data on the mechanism of sorption lead to the conclusion that the sorption of ions of the second group on heteropoly acid salts is a multi-step process[42,43,98].

Step 1. Penetration of the sorbed ions into the macropores of the sorbent grain and ion exchange with a cation or acidic hydrogen of the sparingly soluble HPA salt.

Step 2. Sorption of the ions on the surface through interaction with the oxygen end-atoms of the anion structure, giving E–O–Mo bonds. This step is most marked when the sorbed ion has a strong tendency to form heteropoly acids. By comparing HPA stability data[69,99–102] with the conditions conducive to sorption of the corresponding ions[37–43,62,87–89,93,103] we arrive at the following affinity series:

$$Y^{III} < UO_2^{II} < Th^{IV} \simeq Ce^{IV} < Te^{IV} < Ti^{IV} < Zr^{IV} < Nb^{V}.$$

Step 3. In the case of ions with a high ionic potential the chemical interaction with the surface results in the removal of some of the molybdophosphate ions from the surface [as in the sorption of Se(IV)].

V. SORPTION OF IONS ABLE TO FORM THE COORDINATION SPHERE OF HETEROPOLY COMPOUNDS

Very little has been published on the sorption of molybdenum(VI), tungsten(VI), vanadium(V), and chromium(VI) ions on HPA series. However, we know[48] that these ions (in solutions) have a strong tendency to combine into polymeric structures, giving "mixed" heteropoly compounds. The best known of these are the mixed HPA of vanadium and molybdenum[104–107] and those of molybdenum and tungsten[108,109]. Some indirect information was obtained in studies of the coprecipitation of vanadium(V) with ammonium molybdophosphate[110,111]. The dependence of the extent of coprecipitation of vanadium on the amount of coprecipitant was found to vary with the concentration of vanadium in solution, i.e. to depend on the vanadium to phosphorus ratio. The incorporation of vanadium(V) into the precipitate is a maximum only when the conditions in the solution (acidity, excess of molybdate ions) are favourable to complex formation between phosphate, vanadate, and molybdate. Tsyganok and coworkers[111] have shown, by the molar ratio and isomolar series method, that a complex with a ratio of P : V = 1 : 1 is formed in solution during coprecipitation. Hence they concluded that the co-crystallisation process plays a dominant role in this system, since the replacement of one molybdenum atom by vanadium does not affect the structure of the heteropoly anion. The $PMo_{12}O_{40}^{3-}$ and $PMo_{11}VO_{40}^{4-}$ anions are isomorphous. The coprecipitation of vanadium on a pre-existing AMP precipitate has also been studied, and found to be less complete than coprecipitation during formation of the precipitate.

Thus, published data on the sorption mechanism of various ions on HPA salts lead us to conclude that more comprehensive studies of complex formation between the sorbed ions and the HPA anions are needed, under different conditions and in the presence of the components found in real mixtures, before the application of heteropoly acid salts in the separation and concentration of radioactive or stable isotopes can be further extended.

The Mechanism of the Aromatisation of Paraffinic Hydrocarbons on Oxide Catalysts

G.V.Isagulyants, Yu.G.Dubinskii, and M.I.Rozengart

Data obtained in studies on the mechanism of the aromatisation of paraffinic hydrocarbons are examined. Attention is concentrated on studies carried out by isotope methods. It is shown that aromatic hydrocarbons are formed from paraffins on oxide catalysts via a single pathway—the successive dehydrogenation of the aliphatic hydrocarbon with formation of a six-membered ring (cyclodiene) as a result of the thermal cyclisation of a triene.
The bibliography includes 148 references.

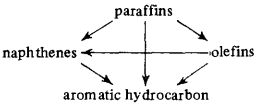
I Introduction 805
II. The mechanism of the aromatisation of paraffins on oxide catalysts 805

I. INTRODUCTION

The aromatisation reaction was discovered independently in 1936 by three groups of Soviet chemists on catalysts of different kinds[1-4]. This reaction, which makes it possible to obtain comparatively simple aromatic compounds from paraffinic hydrocarbons, has naturally attracted the attention of investigators in all countries with a developed petroleum processing industry. The interest in the reaction was due not only to the likelihood of the creation of a new industrial process for the synthesis of aromatic raw materials but also to the possibility of determining the nature of the cyclising effect of the catalyst and the cyclisation mechanism by studying the reaction, i.e. due to the possibility of elucidating a series of new fundamental catalytic laws.

Numerous studies devoted to the aromatisation reaction have been published in Soviet and foreign literature, but its mechanism was elucidated only in the last decade. It was found that no special cyclising functions are required from aromatising oxide catalysts. In the available reviews[5-9] attention has been concentrated on the technological aspects of the process (the composition and properties of the catalysts, the methods for their treatment and modification, etc.), but the reaction mechanism proper has been considered relatively little; furthermore, in most instances it is treated erroneously from the standpoint of modern ideas[10-11].



Although aliphatic hydrocarbons are aromatised on oxide catalysts in a fairly complex manner, the process can serve as a model reaction. Thus many characteristics of the aromatisation of paraffins established on oxide catalysts hold also for the platforming processes, the dehydrogenation of higher paraffins, etc.

The aim of the present review is to analyse the development and the present state of the ideas on the mechanism of the conversion of aliphatic hydrocarbons under aromatisation conditions on oxide catalysts mainly on the basis of the latest experimental data and information obtained with the aid of isotope research techniques.

II. THE MECHANISM OF THE AROMATISATION OF PARAFFINS ON OXIDE CATALYSTS

The first detailed discussion of the mechanism of the aromatisation reaction was held in 1939 at a session of the Faraday Society. A certain amount of experimental data had accumulated by that time, which permitted certain generalisations. It was established that aromatisation proceeds on chromium oxide and a number of other oxides in the temperature range 500–520 °C and on a platinum catalyst at a temperature 200° lower[12-17]. In the catalytic reaction mixtures obtained on oxides olefins were always present in addition to aromatic hydrocarbons[2-4,18], their content depending on the contact time[19]. The yield of aromatic products formed from olefins is higher than the yield obtained from the corresponding paraffins[20,21]. Paraffins and olefins without a straight six-carbon chain hardly form aromatic hydrocarbons.

Hoog et al.[21] proposed a scheme for the aromatisation reaction having included in the latter all the reaction pathways imaginable at the time. The scheme postulated the formation of olefins or cyclanes as intermediates:

(1)

According to the experimental data of Hoog et al.[21], the aromatisation of paraffins proceeds at least partially via a stage involving dehydrogenation to the corresponding olefins.

Consideration of thermodynamic data led to the conclusion[22] that the direct formation of benzene from hexane, by-passing any intermediates, i.e. the pathway leading to the conversion of paraffins into aromatic hydrocarbons in Scheme 1, is energetically the most favourable. From this standpoint (subsequently it was supported also by a series of other investigators), olefins are regarded as side products.

Pitkethly and Steiner[23] favoured two other mechanisms of the formation of aromatic hydrocarbons: via olefins as intermediates, by their cyclisation to a cycloparaffin and subsequent dehydrogenation of the latter to an aromatic hydrocarbon, or by the direct cyclisation of the paraffin to a naphthene via a stage involving a semihydrogenated state, which can also give rise to an olefin as a side product.

Both these mechanisms presuppose in one way or another the formation of a six-membered naphthene as an obligatory reaction stage. Probably at that time it was difficult to imagine the transformation of a paraffin into an aromatic hydrocarbon via a procedure other than the formation of a hexamethylene ring. Its further conversion into an aromatic hydrocarbon had been thoroughly investigated. It is noteworthy that the data of Pitkethly and Steiner with Hoog's correction[24] definitely indicated the intermediate formation of olefins, at least in the first reaction stage. Herington and Rideal[25] suggested that the first stage in the reaction is the obligatory cyclisation of the paraffin to a six-membered naphthene. They believe that the reaction is

possible only when at least one of the carbon atoms involved in cyclisation is located on the catalyst surface. Having calculated the probability of such cyclisation-promoting adsorption for different configurations of the hydrocarbon on the catalyst surface and having assumed that the degree of adsorption is proportional to the rate of reaction, the authors[25] found that these quantities agree with the experimental yields of aromatic hydrocarbons from the corresponding paraffins. They proposed the same mechanism also for the formation of aromatic hydrocarbons from olefins. However, this mechanism did not explain how *m*- and *p*-xylenes present in n-octane catalytic reaction mixtures are formed. In order to account for the origin of *m*- and *p*-xylenes (they cannot be obtained by the direct cyclisation of the paraffin to a six-membered naphthene), the authors[25] had to consider the formation of bicyclo-octanes of different structures, whose decomposition can give rise to the corresponding six-membered cyclanes.

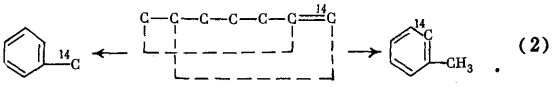
At the same time studies in which olefins were detected among the reaction products continued to be published: the investigators discussed their role as intermediates[26-29]. As regards cyclohexane hydrocarbons, none of the investigators was able to detect them. This was explained by the fact that under aromatisation conditions the rate of dehydrogenation of cyclohexanes (according to the data of Kazanskii and Liberman[16]) greatly exceeds the rate of aromatisation of the corresponding paraffins. Komarevsky and Shand[30] attempted to detect *gem*-dimethylcyclohexane in the catalytic reaction mixtures obtained in the aromatisation of 2,2-dimethylhexane on an alumina–chromium oxide catalyst, assuming that it should not be dehydrogenated to an aromatic hydrocarbon. However, only *m*-xylene was found in the reaction products.

Nevertheless this result was insufficiently convincing to abandon the idea of the intermediate formation of cyclohexane in the aromatisation of paraffins[31-35], particularly since Kazanskii et al.[36] detected by Raman spectroscopy *gem*-dimethylcyclohexane in the catalytic reaction mixture obtained in the aromatisation of 3,3-dimethylhexane on platinised carbon, which indicated immediately the possibility of the direct cyclisation of the paraffin on a platinum catalyst. Comparison of the results of the studies of Komarevsky and Shand[30] with those of Kazanskii et al.[36] might have served as a basis for the hypothesis of significant differences between the mechanisms of the aromatisation of paraffins and oxide and metallic catalysts.

In subsequent years the attention of investigators was concentrated on oxide aromatisation catalysts, which appeared more promising at the time since new low-percentage alumina–platinum catalysts had not yet been introduced into practice. In Steiner's review[7], which deals exclusively with studies carried out on oxides, predominantly chromium oxide, catalysts, it is concluded that olefins must be formed as intermediates in the first stage of the aromatisation reaction on oxide catalysts.

However the kinetic evidence presented by Steiner[19,23,26,28,37] apparently proved to be insufficiently convincing to many other investigators and the latter continued to assume that olefins are formed as side products[31,35,38-41].

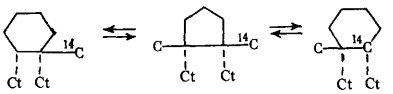
Inspection of the studies in the first stage of the research into the aromatisation reaction shows that mainly three possible reaction pathways were considered:



(1) the cyclisation of the paraffin to a six-membered naphthene in the first reaction stage followed by its dehydrogenation to an aromatic hydrocarbon;

(2) the formation of an olefin, which is subsequently converted into an aromatic hydrocarbon, also via a naphthene;

(3) direct transformation of the paraffin into an aromatic hydrocarbon on the catalyst surface.



One should bear in mind that during the period when the above studies were carried out the methods for the analysis and separation of hydrocarbon mixtures were extremely complex and relatively uninformative. Studies involving a large number of analyses in the course of the experiment were therefore difficult. As soon as it became possible to use radioisotopes for the investigation of the mechanisms of chemical reactions, the latter were employed also in the investigation of the aromatisation of paraffins. These studies, involving the application of the method of tracer atoms[42], were begun as early as the 1950's and have continued up to the present time.

A study[43] of the transformation of [1-^{14}C]hept-1-ene over a chromium oxide catalyst revealed the presence of 50% of the radioactive label in the methyl group of the resulting toluene, which corresponds to the formation of aromatic hydrocarbons by the simple cyclisation of the aliphatic hydrocarbon via the mechanism

(2)

However only 26–29% of the label was found in the methyl group of toluene obtained[44] in the aromatisation of [1-^{14}C]heptane (depending on the degree of reaction). In order to account for these results, it was necessary to resort to more complex reaction mechanisms: with formation of a bicycloheptane (according to Herington and Rideal[25]) or with formation on the surface of the catalyst (Ct) of a cyclopentane-like adsorbed complex, which then isomerises to a six-membered cyclic compound and is subsequently dehydrogenated:

(3)

The formation of intermediate cyclopentanes was not confirmed experimentally[44].

In a study of the transformation of 2,2-dimethyl-4-[^{14}C]methylpentane, Cannings et al.[45] obtained *p*-xylene (yield 14%) and toluene (yield 3%) as the aromatisation products; the methyl groups of the xylene contained 50% of the label, while that of toluene contained 23–25% of the label. According to the authors, the reaction proceeds via a stage involving skeletal isomerisation with subsequent ring closure by the aliphatic molecule to give a six-membered cyclic compound.

The mechanism of the aromatisation reaction has been investigated in detail by the tracer atom method in studies by Pines and coworkers[46-60]. Three catalysts were used in studies during the period from 1959 to 1965:[46] chromium oxide (without a carrier), chromium oxide deposited on alumina with distinct acidic properties (type A), and chromium oxide deposited on alumina without pronounced acidic properties (type B). In the aromatisation of [1-^{14}C]-n-heptane it was observed[46-50] that the content of the label in the methyl group of toluene depends on the nature of the catalyst and varies during the experiment. In experiments with pure chromium oxide 44–47% of the radioactivity was detected in the methyl group of the toluene. In experiments with chromium oxide deposited on alumina the content of the label in the methyl group was 39 and 17% (for aluminas of types A and B respectively), increasing appreciably after several hours of the operation

of the catalyst. An analogous study has been carried out on the aromatisation of [1-^{14}C]-n-octane.

Since the results could not be explained on the basis of the known mechanisms, Pines suggested the intermediate formation of five-, seven-, and eight-membered rings, in addition to the six-membered rings, which then undergo isomerisation of the "contraction–expansion" type to give the six-membered rings. Pines and coworkers investigated the transformations of cyclanes—methylcyclopentane, substituted cyclohexanes[48], methylcycloheptane[47], and cyclo-octane[49], as well as paraffins for which these cyclanes might be aromatisation intermediates—and noted a similarity in the products of the aromatisation of paraffins and the corresponding cyclanes. The same analogy was noted in the distribution of the label in the hydrocarbon molecules when the products of the reactions of linear and the corresponding cyclic hydrocarbons were compared[49,51,59]. The authors regard this analogy as proof that the C_5, C_7, and C_8 cyclanes are intermediates in the aromatisation of the corresponding alkanes. They suggest that the size of the intermediate ring depends on the acidity of the catalyst. On chromium oxide and an acid catalyst of type A, five- and six-membered rings are formed preferentially, while on the "non-acid" catalyst of type B seven- and eight-membered rings predominate.

According to Pines' hypothesis, the distribution of the radioactive label in the aromatisation products should not depend on the position of the label in the initial paraffin, for example, in n-octane. Indeed, the site at which the contraction of the eight-membered ring begins involves any bond of the ring with equal probability. However, a comparative study of the aromatisation of [1-^{14}C]octane and [4-^{14}C]octane on a type B catalyst[48,49,51–53] showed that the distribution of the label in ethylbenzene and xylenes depends significantly on its position in the initial octane. Thus the content of the label in the aromatic rings of ethylbenzene and *o*-xylene obtained from [4-^{14}C]octane is from 92 to 97%, while the contents of the label in the same products obtained from [1-^{14}C]octane are respectively 68–50% and 39–8%.

Having considered next the possible distribution of the label under the conditions of the formation of an intermediate five-, six-, seven-, or eight-membered ring or even a bicyclic compound (according to Herington and Rideal[25]), Pines and coworkers concluded that the formation of only one of these intermediates cannot fully account for the experimental data. However, the combination of two or even three mechanisms involving the formation of intermediate rings of different structures can explain all the experimental results[51]. The studies by Pines have shown that the formation of cyclanes, including the six-membered cyclane, as aromatisation intermediates was not questioned in any way; other aromatisation pathways with participation of other intermediates were not in essence considered. Nor was the role of unsaturated hydrocarbons, particularly olefins, in the formation of aromatic hydrocarbons considered, although Pines and coworkers used gas–liquid chromatography for analysis and not only olefins but also dienes were detected in the catalytic aromatisation reaction products[49,51].

Thus the use of radioisotopes at this stage of the investigation helped little in elucidating the pathways leading to the transformation of paraffins under aromatisation conditions. This can probably be explained by the fact that the tracer atom method, which deals only with the location of the label in the starting materials and final reaction products, does not permit a conclusion concerning the nature of the intermediates. Experiment only indicated the location or transfer of the label to a particular position in the final product without any indication of the pathways leading to this transition.

In a study of the aromatisation of [4-^{14}C]heptane on catalysts of types A and B (in Pines' terminology), Feighan and Davis[61] observed that the bulk of the radioactive label is present in the $C_{(3)}$ position in toluene, but the $C_{(2)}$ and $C_{(1)}$ atoms as well as the carbon atom of the methyl group also proved to be radioactive. Comparison of the data obtained in a comparative study of the aromatisation of heptanes labelled in the 1- and 4-positions yielded a picture analogous to that obtained earlier by Pines for [1-^{14}C]- and [4-^{14}C]-octanes[62]. Feighan and Davis[61] suggested that, together with the direct cyclisation of heptane, there is also partial skeletal isomerisation of heptenes. The subsequent cyclisation of the iso-olefin can explain the transfer of the label from [4-^{14}C]heptane to the methyl group of toluene.

To demonstrate the direct cyclisation of the paraffin, Davis and coworkers[63,64] compared the products obtained on chromium oxide and alumina–platinum catalysts. Assuming that the possibility of the direct cyclisation on platinum has been demonstrated[36], the author claims that the difference which he nevertheless observed can be accounted for by the greater isomerising capacity of the chromium oxide catalyst compared with the platinum catalyst. For example, on the platinum catalyst Davis obtained toluene as the main product from *gem*-dimethylcyclohexane and 2,2-dimethylhexane. On the chromium oxide catalyst, toluene was also obtained from *gem*-dimethylcyclohexane, but 2,2-dimethylhexane gave rise to *m*- and *p*-xylenes and not the demethylated product. If the cyclohexane hydrocarbon had undergone isomerisation, the naphthene and paraffin aromatisation products would have been identical. Consequently Davis's results confirm the possibility of the skeletal isomerisation of the aliphatic molecule, but they do not demonstrate the existence of an intermediate naphthene. Thus in these studies too the role of unsaturated hydrocarbons was in essence not considered.

In a study of the formation of olefins from paraffins on the chromium oxide catalyst Timofeeva and coworkers[65–75] demonstrated with extensive experimental data that aromatic hydrocarbons are also always formed under these conditions. A small amount of olefins is then obtained from alkanes with a straight-chain structure, the amount of aromatic hydrocarbon being large, while isoalkanes (which are incapable of forming a six-membered ring without isomerisation) produced mainly olefins. Dienes were detected in the catalysts in both cases[70–72].

Studies[76–79] of the aromatisation of a series of paraffins and olefins ranging from C_6 to C_9 [77] on the alumina–chromium oxide–sodium oxide catalyst and of cyclanes ranging from C_5 to C_7 [78] and isoparaffins[79] also demonstrated, with a large number of examples, that the yield of aromatic hydrocarbons produced from olefins (particularly from alk-2-enes and alk-3-enes) is always greater than the yield obtained from paraffins. Furthermore, in the aromatisation of paraffins a sharp increment of the yield of aromatic hydrocarbons with increase of reaction temperature always follows the maximum content of olefins in the catalytic reaction mixture. On this basis, it has been concluded[76–79] that olefins play the role of intermediates in the aromatisation of paraffins. The above workers believe that the next stage of the reaction is cyclisation, preferentially the cyclisation of a C_6 olefin, since, according to their data, methylcyclopentane and methylcyclopentene give rise to very low yields of benzene under these conditions. However, Perrée and Blouri[77] did not detect either C_5 or C_6 hydrocarbons (other than

aromatic hydrocarbons) in the catalytic aromatisation reaction mixtures, but did find traces of dienes.

On the hypothesis that the rate of aromatisation must follow a first-order equation and that olefins must be formed as intermediates, Penchenkov and Zhorov[80-82] derived a kinetic equation for the two-stage reaction paraffins → olefins → aromatic hydrocarbons. Comparison of the experimental and calculated yields of heptane, octane, and nonane aromatisation products revealed a very great similarity[80,81]. It was observed that under these conditions the isomerisation of olefins with differing double bond positions proceeds faster than dehydrogenation[82]. Thus virtually an equilibrium mixture of isomeric olefins undergoes aromatisation and the olefin aromatisation reaction has been shown to be 7–8 times faster than the dehydrogenation of a paraffin.

Having used in the study of aromatisation mixtures of non-radioactiveheptane and heptanes with one of the carbon atoms replaced by the ^{14}C radioactive label, Lipovich and coworkers[83-86] showed definitely that heptenes are intermediates in the formation of toluene.

Thus the above group of studies again indicated the intermediate formation of olefins in the aromatisation of paraffins. However, subsequent olefin transformation pathways were virtually uninvestigated.

A new stage in the study of the mechanism of the aromatisation reaction became possible as a result of the application of a pulsed technique in combination with gas-chromatographic analytical methods. Rozengart et al.[87] investigated the composition of the heptene aromatisation products as a function of contact time on an alumina–chromium oxide–potassium oxide catalyst and observed that heptadienes were present in the catalytic reaction mixtures. It was found that, with increase of contact time, their contact passes through a maximum. For short contact times, the concentration of heptadienes is greater than that of toluene and the maximum heptadiene content occurs at the same time as the point of inflection in the S-shaped toluene curve. These data are fully consistent with the characteristics of consecutive reactions.

Since heptadienes can be regarded as intermediates, the authors[88-90] subsequently investigated kinetically the transformation of hepta-1,3-diene and observed that heptatrienes are present in the catalytic reaction mixtures. It was found that their content also passes through a maximum with increasing contact time, although the content of trienes is lower than that of toluene even for the shortest contact times. These results as well as data obtained in the study of the reactions of heptatriene and methylcyclohexadiene suggested[88] that the aromatisation of the paraffin proceeds via the successive dehydrogenation of the aliphatic molecule to trienes. Trienes readily undergo thermal cyclisation[91-93] with formation of cyclodienes, which are then dehydrogenated to the aromatic hydrocarbon: paraffin → olefin → diene → triene → alkylcyclohexadiene → aromatic hydrocarbon. In contrast to the previous schemes, this scheme does not postulate the intermediate formation of cyclohexane hydrocarbons.

It was necessary to test the reliability of this scheme by independent methods and to determine whether or not it constitutes the only pathway, the main pathway, or only one of many pathways to the transformation of alkanes into aromatic hydrocarbons.

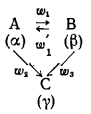
The kinetic isotope method proposed by Neiman[94-97] and widely used in studies of the mechanisms of heterogeneous-catalytic reactions[42,98-113] was employed in subsequent investigations. In contrast to the tracer atom method, the kinetic isotope method is not concerned with the position of the label within the molecule, the molecule as a whole being treated as radioactive and the distribution of the label between the reaction products being estimated.

In order to determine whether or not cyclohexane hydrocarbons are intermediates in the aromatisation of a paraffin, for example, hexane, a study has been made[114] of the aromatisation on an alumina–chromium oxide–potassium oxide catalyst of mixtures of hexane and cyclohexane in which cyclohexane contained the radioactive label. If cyclohexanes were an intermediate in the reaction involving the conversion of hexane into benzene, one would expect a decrease of the molar radioactivity of cyclohexane in the catalytic reaction mixture relative to the initial value as a consequence of the formation of non-radioactive cyclohexane from n-hexane. This decrease should have been greater the lower the content of [^{14}C]cyclohexane in the initial mixture and the greater the degree of conversion of n-hexane. However, even in the case where the benzene content in the catalytic reaction mixture was many times greater than the cyclohexane content in the mixture, no decrease in the activity of cyclohexane was observed. Thus cyclohexane is not an intermediate in the aromatisation of n-hexane under the given conditions.

In order to elucidate the role of olefins, a study was made of the transformation of mixtures of n-hexane and hex-1-ene in which one of the components contained the radioactive label. In the aromatisation of non-radioactive hexane with added labelled hex-1-ene (with a molar radioactivity β) the benzene formed in the reaction was also radioactive (with a molar radioactivity γ). If hexene plays the role of an intermediate in this reaction, β should decrease in the course of the process (as a result of the formation of non-radioactive hexene from n-hexane), remaining, in conformity with the postulates of the kinetic isotope method[42], below the radioactivity of benzene:

$$\beta < \gamma. \qquad (4)$$

On the other hand, when the aromatisation of radioactive hexane mixed with unlabelled hexene is investigated, then the radioactivities of benzene and hexene should increase in the course of the reaction, but the increase should be such that the following condition is maintained:



$$\beta > \gamma. \qquad (5)$$

The maintenance of this condition would suggest that hexene is indeed a precursor of benzene in the aromatisation of hexane. If other intermediates are formed during the reaction from the olefin, their molar radioactivities should have values intermedate between β and γ according to the postulates of the kinetic isotope method.

A study of the aromatisation of a mixture of hexane and [1-^{14}C]hexene showed[115] that the change in the radioactivities of hexenes and benzene during the reaction does indeed obey the rule indicated by inequality (4) (see Table). Thus, in contrast to cyclohexane, hexene is undoubtedly an intermediate in the aromatisation reaction. The tabulated data show that the radioactivity of hexadienes is intermediate between those of hexene and benzene. Consequently hexadienes are also obligatory intermediates in the aromatisation reaction.

Although it has been shown[114] that hexane does not undergo catalytic cyclisation in the first reaction stage, one cannot claim that cyclisation does not occur in the stages involving the formation of olefins or dienes. Furthermore, the results of the two studies quoted above do not rule out the possibility of the reaction on the surface of the catalyst without the liberation of intermediates into the reaction space—in the way imagined, for example, by Taylor and Turkevich[22].

An answer may be obtained to these questions by employing in the investigation the method involving the calculation and comparison of the reaction rates proposed by Balandin and coworkers[101–103]. Each multistage reaction can be represented by the triangular scheme

(6)

where A, B, and C are the initial reactant, the intermediate, and the final product respectively and α, β, and γ are their molar radioactivities. The reaction rates w_1, w_1', w_2, and w_3 via different pathways are calculated by the equations of the kinetic isotope method from the changes in the concentrations and molar radioactivities of the reaction components. The rate of accumulation of the final product $d[C]/dt$ is calculated wholly from the change in its concentration. It follows from Scheme (6) that, when $w_2 = 0$, the reaction is consecutive and involves the intermediate B; if $w_3 = 0$, then B is a side product; when $w_2 \neq 0$ and $w_3 \neq 0$, the reaction proceeds via the two pathways simultaneously.

Results of experiments on the aromatisation of the hexane–[^{14}C]hex-1-ene mixture (530 °C).[115]

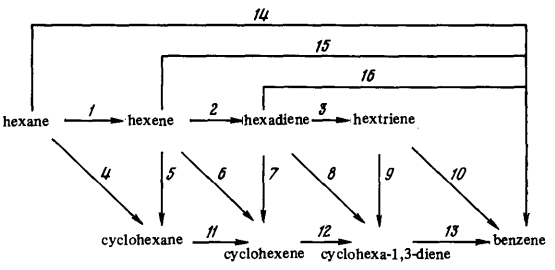
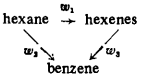
*The radioactivity was not estimated quantitatively.



**The sum of all the isomers detected in the catalytic reaction mixture.

***The molar radioactivity of the products was calculated as a percentage relative to the molar radioactivity of the hexenes in the initial mixture.



Evidently the reaction is in reality more complex than suggested by Scheme 6, because each stage also involves the adsorption and desorption of the reaction components on the surface of the catalyst. However, it is known[98–100] that the consecutive nature of the reaction, established with the aid of the kinetic isotope method, also implies that the desorption and adsorption of the reaction components are faster than the reaction itself.

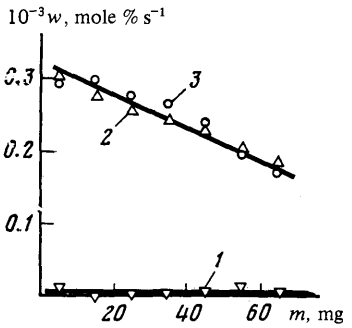
We shall now consider the conversion of hexane into benzene from the standpoint of Scheme (6). Comparison of the literature data and the present author's results[114,115] makes it possible to set up a model of the hexane transformation reaction, which includes the three main aromatisation pathways (see Scheme A). Transformation via stages *1–3*, *9*, and *13* is consistent with the scheme proposed by Rozengart et al.[88] The cyclisation of hexane or of the successive intermediates corresponds to reactions *4–10*. Any other pathways leading to the transformation of hexane into benzene are included in pathways *14–16*.

Scheme A

The kinetic isotope method makes it possible to consider and investigate the pathways involved in the transformation of the reaction components at each stage. The first stage can then be represented as follows:

(7)

If $w_2 \neq 0$, the implication is that benzene can be formed from hexane not only via hexenes but also via some other pathway. Cyclohexane is ruled out as an intermediate[114], but there may be other intermediates which have not been detected in catalytic reaction mixtures for one reason or another. Furthermore, aromatisation can occur on the surface of the catalyst without the desorption of the intermediates into the reaction space. On the other hand, if hexane is converted into benzene via a single pathway, then evidently $w_2 = 0$ and w_3 and the rate of accumulation of benzene in the system $d[C]/dt$ should be equal.



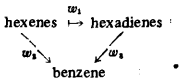


Figure 1. Variation of the rates of transformation of the components of the hexane–[^{14}C]hex-1-ene–benzene mixture with increasing contact time (catalyst sample):[117] *1)* w_2; *2)* dc/dt; *3)* w_3 [for the significance of the symbols, see Scheme (7)].

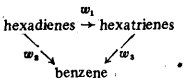
All these hypotheses have been tested[116,117] by investigating the aromatisation of the hexane–[^{14}C]hex-1-ene–benzene ternary system. The results of the calculation of the rates of reaction by the equations of the kinetic isotope method, in conformity with Scheme (6), from the experimental data of the above studies are presented in Fig.1. It was found that the rates of accumulation of benzene $\{d[C]/dt\}$ and of conversion of hexene into benzene (w_3) are the same within the limits of the accuracy of the calculation, while the rate w_2 of the transformation of hexane into



benzene by-passing hexene is virtually zero. Consequently there is no pathway other than that via hexene in the transformation of hexane into benzene and the possibility of reaction via pathway *14* is ruled out.

The same method was then used to investigate the transformations of hexenes and hexadienes:

(8)

It was found that only the dehydrogenation of hexenes to hexadienes takes place in the second stage of the reaction[118,119]. The results of the calculation of the rates in this system are illustrated in Fig.2. Furthermore, special experiments with [^{14}C]cyclohexane showed that there is no cyclisation of hexenes to cyclohexane or cyclohexene[119]. The transformations of hexadienes into hexatrienes† also proceed via a single pathway [see Scheme (9) and Fig.3]:[119]

(9)

There is no cyclisation at this stage, although the possibility of the direct transformation of hexadienes into cyclohexa-1,3-diene has been discussed in the literature as one of the probable cyclisation pathways[120].

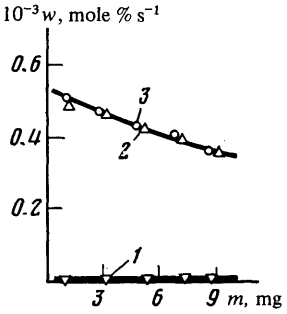


Figure 2. Variation of the rates of transformation of the components of the [^{14}C]hex-1-ene–hexadienes mixture with increasing contact time[119]: *1)* w_2; *2)* dc/dt; *3)* w_3 [see Scheme (8)].

Consequently pathways *5–8* and *15–16* (Scheme A), postulating the catalytic cyclisation or direct transformation of hexanes and hexadienes into benzene, do not occur.

An aliphatic molecule is dehydrogenated in the aromatisation reaction to the triene stage. Scheme A postulates two possible reaction pathways for the triene: thermal cyclisation to cyclohexa-1,3-diene with its subsequent dehydrogenation to benzene (pathways *9* and *13*) or direct transformation of the triene into benzene by-passing the cyclohexadiene formation stage *10*.

As was to be expected, hexatriene mixed with [^{14}C]hexadienes reacts wholly at 520 °C after very short contact times (Fig.4) [118] and is almost completely converted into cyclohexa-1,3-diene, the concentration curve of which has a distinct maximum. With increase of contact time, the concentrations of cyclodiene and benzene vary in opposition. The molar radioactivity of benzene is lower than that of cyclohexadienes and both increase with increasing contact time.

If the molar radioactivities of the hexadienes, cyclodienes, and benzene, are denoted by α, β, and γ respectively, then, taking into account the transformation of hexadienes into hexatrienes demonstrated above[119], one can set up the following sequence:

$$\alpha > \beta > \gamma.$$

This type of sequence for a mixture in which the first component is radioactive indicates, according to the kinetic isotope method, that the transformations of hydrocarbons investigated constitute a single chain: hexadiene → hexatriene → cyclohexa-1,3-diene → benzene. Returning now to Scheme A, one may conclude that the transformation proceeds via pathways *9* and *13*, while pathway *10* does not operate.

Thus, in considering the set of consecutive stages of the transformation of hexane into benzene, it is seen that, under the conditions of aromatisation on the alumina–chromium oxide–potassium oxide catalyst, neither hexane, nor hexene, nor hexadiene undergo catalytic cyclisation. Only the triene is converted into a cyclic product, but a catalyst is not required for this stage. All the remaining reactions constitute stages involving the dehydrogenation of the aliphatic molecule and then of cyclohexadiene. Presumably there are no pathways leading to the formation of the aromatic hydrocarbon on the chromium oxide catalyst other than those indicated below in Scheme (10).

hexane → hexenes → hexadienes → hexatriene → cyclohexa-1,3-diene → benzene. (10)

This scheme explains not only the obligatory presence of olefins and dienes in the catalytic reaction mixtures obtained on oxides but also the high yields of aromatic hydrocarbons from olefins. According to this scheme, hydrocarbons without a straight six-carbon chain can be aromatised only after passing through a skeletal isomerisation stage; consequently in this case one cannot expect high yields of aromatic compounds. It also becomes understandable why no investigators were able to detect cyclohexane hydrocarbons in the catalytic aromatisation reaction mixtures—they are not formed in this reaction.

The same scheme makes it possible to explain also the experimental data obtained in the study of the aromatisation of n-octane on the alumina–chromium oxide catalyst[121–128]. The question of the origin of *m*- and *p*-xylenes produced from n-octane is known to be the most complex in this instance. To account for their origin, the idea of the formation and isomerisation of cyclanes in the aromatisation process was in fact resorted to. However, the formation of isomeric xylenes can be readily understood if the aromatisation of n-octane is considered from the standpoint of the successive dehydrogenation scheme.

It has been shown that the isomerisation of aromatic C_8 hydrocarbons does not occur[46,47,53,121,122], so that the formation of structures leading to these xylenes takes place at intermediate stages of the reaction. If the formation of cyclanes constitutes this intermediate stage, then the ratio of *o*-xylene and ethylbenzene, on the one hand, and *m*- and *p*-xylenes, on the other, in the cyclane aromatisation products should be the same as in the aromatisation of n-octane. Furthermore, the content of *m*- and *p*-xylenes obtained in the aromatisation of 1,2-dimethylcyclohexane and ethylcyclohexane proved to be 3–100 smaller than in the aromatisation of n-octane[128]. Thus the isomerisation of

†Owing to the high reactivity of hexatriene, these experiments were performed at a temperature 100° lower than in the previous study.

the aliphatic intermediate actually accounts for the formation of *m*- and *p*-xylenes. The occurrence of this skeletal isomerisation of the aliphatic molecule under the conditions of the aromatisation on the chromium oxide catalyst is indeed confirmed by the presence of iso-octanes in the catalytic aromatisation reaction mixtures obtained from n-octane[121,122] and isohexadienes and in the catalytic reaction mixtures obtained from n-hexane[129], and it has been shown in the latter case that the skeletal isomerisation can be undergone not only by the unsaturated hydrocarbon but also by the alkane molecule. The increase of the yields of ethylbenzene and styrene with increasing temperature or degree of dilution of the reaction mixture by the inert carrier gas[125] can also be accounted for within the framework of this mechanism[88].

Subsequent studies showed that the kinetic picture observed in the aromatisation of n-hexane in the presence of molybdenum[139,140], vanadium[141], titanium[141], and tungsten[142] oxides deposited on alumina is fully consistent with the consecutive reaction and that the mechanism of aromatisation on these catalysts is the same as on the chromium oxide catalysts. Evidently the above scheme, involving the successive dehydrogenation of the aliphatic hydrocarbon, is applicable to the description of the aromatisation not only on chromium oxide but also on other oxide catalysts.

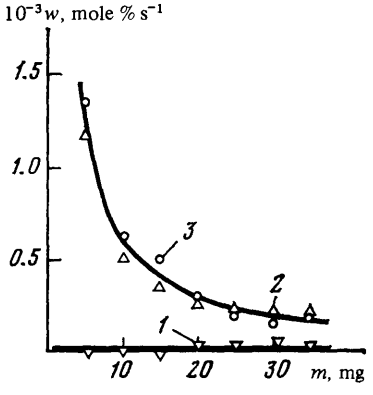

Figure 3. Variation of the rates of transformation of the components of the [^{14}C]hexadienes–hexatrienes mixtures with increasing contact time[119]: *1*) w_2; *2*) dc/dt; *3*) w_3 [see Scheme (9)].

It is noteworthy that in recent years studies have been published in which other aromatisation mechanisms have been put forward which in our view are not adequately supported. Thus, in studies[130,131] of the kinetics of aromatisation, the partial pressure of hexane in the system was varied by adding diluent gases (He, N_2, CH_4 and H_2) to a constant stream of hydrocarbon vapour. It was observed that the decrease of the partial pressure of hexane in a stream of helium, nitrogen, and methane hardly affects the yield of benzene, but reduces the yield of hexenes by a factor of 2. On the other hand, in a stream of hydrogen the yield of benzene decreases sharply, while the yield of hexenes increases somewhat. On the other hand, when the starting material is hexene, then the yield of benzene in a stream of helium, nitrogen, and methane increases with decrease of the partial pressure of hexene.

Being unable to account for these findings on the basis of Scheme (10), Shapchenko and Rudenko[130,131] therefore believe that the aromatisation of hexane on the alumina–chromium oxide–potassium oxide catalyst proceeds via a stage with formation of hexene, which is subsequently converted into a polymolecular complex on the catalyst surface[132,133]. The decomposition of this complex leads to benzene, cracking products, and coke formation. From our point of view, the anomalous results obtained in the above studies[132,133] can be simply explained. The independence of the yields of benzene of the partial pressure of hexane in a stream of helium, nitrogen, and methane observed in these investigations is only apparent, since in the experimental method employed the decrease of the partial pressure of hexane is accompanied by a decrease of contact time. Dilution of the system with a carrier gas (other conditions being equal) enriches the catalyst in benzene[134], while a decrease of contact time reduces its yield. The joint influence of these two factors can create the illusion that the yield of benzene is independent of the partial pressure of hexane.

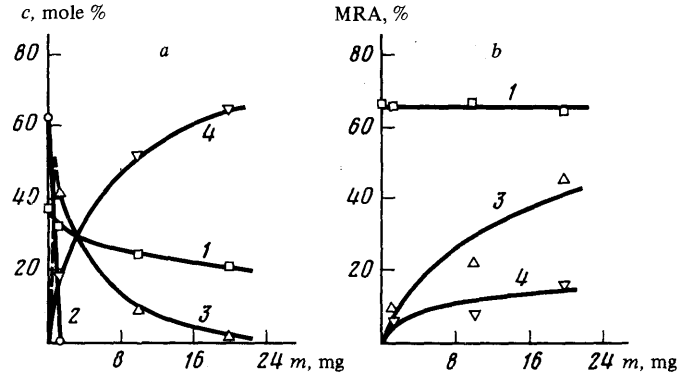

Figure 4. Variation of the concentration *c* (*a*) and the molar radioactivities (MRA) (% relative to the initial radioactivity) (*b*) of the products of the transformation of the [^{14}C]hexadienes–hexatrienes mixture at 530 °C as a function of contact time: *1*) hexadienes; *2*) hexatrienes; *3*) cyclohexa-1,3-diene; *4*) benzene[118].

As regards the influence of the hydrocarbon, which is manifested by an increase of the yield of olefins and a decrease of the yield of aromatic hydrocarbons, the above problem has already been considered and solved[127] in terms of mechanism (10).

Krzywicki and coworkers[135–137] detected cyclohexane and methylcyclohexane in the aromatisation of hexane and heptane on the comparatively little investigated alumina–chromium oxide–iron oxide catalyst[136,137]. The authors believe that these cyclic hydrocarbons are intermediates on the grounds that the curves representing their content in the catalytic reaction mixtures pass through a maximum as a function of time. However, it is difficult to regard this conclusion as sufficiently well founded because the kinetic picture presented by the authors is inconsistent with the kinetics of a consecutive reaction—the maxima are insufficiently distinct and the curve representing the content of the final product is not S-shaped.

Krzywicki et al.[135] did not detect dienes in the catalytic reaction mixtures obtained from paraffins and olefins, which is surprising because the formation of dienes had been detected earlier[138] on the same catalyst (up to 2%) but neither cyclanes nor cyclenes had been found. We therefore studied in greater detail[148] the transformations of hexane, hex-1-ene, and hexa-1,5-diene (on the catalyst prepared as described by Krzywicki and Malinowski[136]) mainly for short contact times. The kinetic picture obtained shows that hexenes and hexadienes are undoubtedly intermediates in the aromatisation of n-hexane on this catalyst.

In recent years studies on the aromatisation of paraffins on oxide catalysts have continued[143-147], but no new experimental facts have been observed which would necessitate a revision of the mechanism of this reaction presented above [Scheme (10)].

* * *

Thus analysis of the experimental data and in particular data obtained by the kinetic isotope method showed that the transformation of paraffins into aromatic hydrocarbons on the oxide catalysts investigated proceeds almost wholly via a single pathway—the successive dehydrogenation of the aliphatic molecule with formation of a six-membered ring by the thermal cyclisation of a triene. Only one function is required from the aromatisation catalyst, namely the ability to effect dehydrogenation.

Evidently this mechanism can be extended also to all other oxide catalysts used for the aromatisation of paraffins. However, the mechanism of the formation of the aromatic hydrocarbon on catalysts containing metals, including platinum group metals, is significantly more complex and therefore requires separate consideration.

Perimidines

A.F.Pozharskii and V.V.Dal'nikovskaya

The review deals with studies devoted to the methods of synthesis, physical and chemical properties, and the practical applications of perimidines—the first class of heteroaromatic compounds with distinct amphoteric chemical properties. i.e. the ability to react readily with both electrophiles and nucleophiles.
The bibliography includes 266 references.

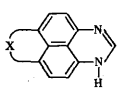
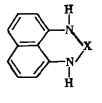
V. Practical applications 831



I. INTRODUCTION

Heteroaromatic systems are known to be very clearly divisible[1-3] into compounds with an excess of π electrons (e.g. pyrrole) and those with a deficiency of π electrons (e.g. pyridine). Electrophilic substitution and oxidation reactions are characteristic of the former, while the latter react mainly with nucleophiles, are difficult to oxidise, but are comparatively readily reduced. Studies in recent years apparently made it possible to discover for the first time a heteroaromatic system exhibiting simultaneously the distinct properties of compounds with an excess and deficiency of π electrons[4]. Such a system is perimidine (I), whose amphoteric chemical properties make it an interesting object of study. In view of the promising nature of such investigations and the increasing number of publications on the chemistry of perimidine, it has become necessary to survey them. The only review on perimidines was published in 1958 [5] when few data were available on their physical properties and reactivity; it therefore included only studies on the methods of their synthesis from 1,8-naphthylenediamines.



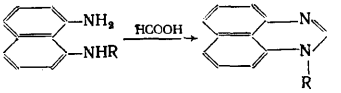
This review provides a compilation of the literature on the perimidine chemistry published up to June, 1980. It includes also data on the chemistry of aceperimidine (II), aceperimidylene (III), and hydrogenated compounds: 2,3-dihydroperimidine (IV) perimidone (V), and thioperimidone (VI).

(I)

(II) X = CH_2CH_2; (III) X = CH=CH

(IV) X = CH_2; (V) X = C=O; (VI) X = C=S.

Perimidine was first obtained and described in detail by Sachs[6] in 1909, while 2-methylperimidine had been described somewhat earlier[7,8]. Individual representatives of perimidines were apparently synthesised as early as the past century[9-11] by the interaction of 1,8-naphthylenediamine with a series of carboxylic acids and their derivatives. However, the compounds could not be obtained in a pure state and their structure could not be established. At the present time the name "perimidine" has been confirmed by IUPAC rules[12], but other names can also be encountered in the literature; 1*H*-naphtho-[1,8-*d*,*e*]pyrimidine, 1*H*-benzo[*d*,*e*]quinazoline, perinaphthimidazole, and 1*H*-1,3-diazaphenalene.



II. METHODS OF SYNTHESIS

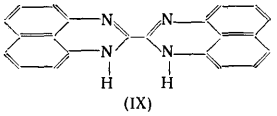
The vast majority of the methods of synthesis of perimidines are based on the reaction of 1,8-naphthylenediamine (VIIa) (NDA) and its derivatives with various compounds containing a carbonyl group. The reaction with carboxylic acids and their derivatives makes it possible to obtain perimidines immediately, while the reaction with aldehydes and ketones leads to 2,3-dehydroperimidines. The latter can be usually readily converted into perimidines. The high reactivity of NDA can be accounted for by the powerful withdrawal of the unshared electron pairs of the two peri-amino-groups (the peri-interaction[13]). On cyclisation, this withdrawal ceases, which is accompanied by an energy gain.

1. Synthesis from 1,8-Naphthylenediamines

(a) Synthesis of Perimidines from NDA and Various Cyclising Agents

Carboxylic acids. This method yields especially satisfactory results when formic acid is used. Thus perimidine[6,14], 1-methylperimidine[15], 1-phenylperimidine[16], and 1-(2,4-dinitrophenyl)perimidine[17] (VIII) are formed in high yields when the diamines (VII) are refluxed with an excess of HCOOH:

(VII) (VIII)

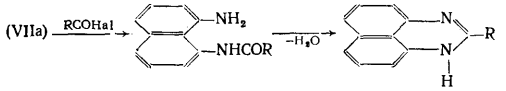


VII: (a) R = H, (b) R = CH_3, (c) R = C_6H_5, (d) R = 2,4-$(NO_2)_2C_6H_3$.

Aceperimidine[18], 1-methylaceperimidine[19], 6-chloroperimidine, 6-bromoperimidine[20], 6-hydroxyperimidine[21], 6-sulphoperimidine, 5,8-disulphoperimidine[22], and 6-phenylazoperimidine[23] have been obtained analogously from NDA derivatives substituted in the naphthalene ring.

The use of other acids does not always give rise to satisfactory results. Thus, when NDA is heated with trifluoroacetic acid[24], acetic acid, and α-, β-, and γ-amino-acids[25], the corresponding-substituted perimidine is formed at best in trace amounts. In order to increase the yield, it has been suggested that the mixture be refluxed in 4 *N* hydrochloric

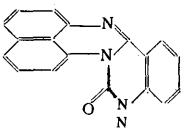
acid[25-27]. Under these conditions, the interaction of NDA with glycolic, mandelic, thioglycolic[25], and lactic[26] acids leads to the formation of 2-hydroxymethyl-, 2-α-hydroxybenzyl-, 2-mercaptomethyl-, and 2-α-hydroxyethyl-perimidines. The first of these compounds can be obtained also in the absence of hydrochloric acid[6]. 2-R-Perimidines are obtained from high-molecular-weight aliphatic acids in low yields even in 4 *N* HCl.[27] On the other hand, when they are fused together with NDA, the products are salts of 2-R-perimidines, from which the free bases can be isolated on treatment with alkali[28] (in an earlier communication[29] it was erroneously stated that only *N,N'*-diacyl derivatives of NDA are formed in this reaction). The interaction of NDA with α-hydroxyphenylacetic acid results in the formation of 2-(α-hydroxybenzhydryl)perimidine[30].



A satisfactory result of the reaction of NDA with aromatic acids has been reported[29,31,32]. When NDA was fused together with quinoline-α-carboxylic acid, 2-(α-quinolinyl)-perimidine was obtained[33]. The individual compounds could not be isolated in the reaction of NDA with pyruvic and phenylpyruvic acids[25].

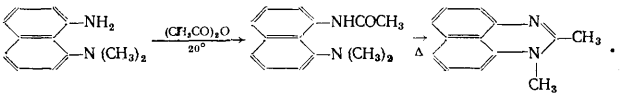
(IX)

With the exception of oxalic and malonic acids, aliphatic dicarboxylic acids react with NDA to form ω-(2-perimidinyl)-alkanecarboxylic acids[27]. Oxalic acid[6,27] gives rise to a mixture of compound (I) and 2,2'-diperimidine (IX), which is a result of the decarboxylation and interaction with NDA of the intermediate perimidine-2-carboxylic acid respectively. The reaction of NDA with malonic acid produces a mixture of 2-methylperimidine and compound (V).[34]



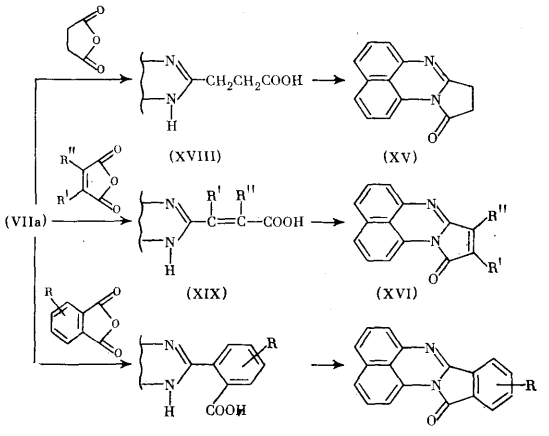
Hydrogen halides. This method is one of the best for the synthesis of 2-substituted perimidines (X). The reaction proceeds via the formation of the monoacyl derivative (XI). The formation of a certain amount of *N,N'*-diacyl derivatives of NDA, which, incidentally, can be readily separated from compounds (X) by virtue of their low solubility, can be regarded as the only disadvantage of the method.

(XI) (X)



In particular, the following derivatives (X) have been obtained by this method; compounds with R = CH_3,[25,35] C_5H_{11}, C_6H_{13},[29] $C_{11}H_{23}$,[25,36] $C_6H_5CH_2$,[6] C_6H_5,[6,25] 4-$CH_3OC_6H_4$,[29,32] 2-, 3-, and 4-$O_2NC_6H_4$, C_6H_5=CH, CH_3CH=CH,[32] CH_2Cl,[37] CH_2F, CHF_2,[166] perfluoroalkyl, C_6F_5,[24,38] 3- and 4-$CF_3C_6H_4$, $CF_3OC_6H_4$, and $CF_3SC_6H_4$.[39] The method is suitable for the synthesis of 1,2-disubstituted perimidines[24,38,166] and also compounds such as 1,4-bis(2-perimidinyl)benzene and 1,5-bis(2-perimidinyl)naphthalene[35]. The only diamine which could not be converted into the corresponding perimidine on treatment with acid chlorides (and anhydrides) proved to be compound (VIId).[17]

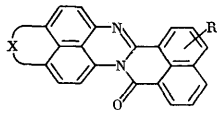
The reaction of NDA with oxalyl chloride[40] leads to the formation of compound (IX) in 95% yield. The symmetrical *N*-substituted[41] and *C*-substituted derivatives (IX) [40] can be obtained similarly. The reaction of NDA with 2-isocyanobenzoyl chloride results in the formation of a derivative of quinazolinoperimidine (XII):[42]



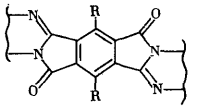
(XII)

Acid anhydrides. Heating NDA with acetic[8,25] and trifluoroacetic[24] anhydrides constitutes the best method of synthesising 2-methyl- and 2-trifluoromethyl-perimidines. The following derivatives (X) have been obtained by this method from NDA and the anhydrides of the corresponding acids: compounds with R = C_2H_5,[6,43] iso-C_3H_7, n-C_4H_9,[32] C_6H_5,[44] and 2-$HO_3SC_6H_4$.[45] The method has been used successfully to synthesise 2-R-aceperimidines[46] and 1,2-disubstituted perimidines[24]. It is of interest that, when 1-amino-8-dimethylaminonaphthalene is refluxed with acetic anhydride, 1,2-dimethylperimidine (XIII) is formed, i.e. the process is accompanied by the elimination of the *N*-methyl group[15]. At room temperature the reaction stops at the stage involving the formation of compound (XIV):

(XIV) (XIII)



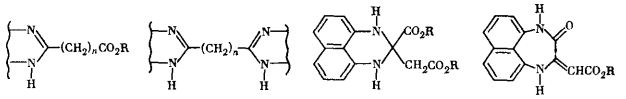
Compounds (XV)–(XVII), which Sachs called perinones, have been obtained by the reaction of NDA with the anhydrides of succinic[6], maleic[6,47,48], and phthalic[6,21,49] acids. The intermediate acids (XVIII)–(XX) can also be isolated:



(XVIII) (XV) (XIX) (XVI) (XX) (XVII)

The synthesis of tetrafluorophthaloperinone by the reaction of NDA with tetrafluorophthalic anhydride has been described. 2-Tetrafluorophenylperimidine is then formed as a side product [as a result of the decarboxylation of an acid of type (XX) [38]]. When NDA [6,50,51] or 5,6-diaminoacenaphthene[18] is heated with naphthalic anhydride and its substituted derivatives, the products are naphthaloperinones (XXI). The reaction of NDA with the dianhydride of pyromellitic acid and its derivatives leads to perinones of type (XXII) [52] [isomers

of compound (XXII) with the *cis*-disposition of the C=O groups are also formed]:

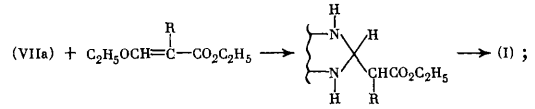


(XXI) R = H, NH_2 or NO_2; X = H_2 or CH_2CH_2

(XXII) R = H, Cl, Br or NH_2.

When NDA interacts with acid anhydrides, *N*,*N'*-diacyl-1,8-naphthalenediamines are also formed in a small amount[24,25,38].

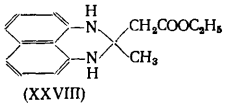
Esters and iminoesters. Perimidines can be relatively readily obtained by treating NDA with carboxylic acid esters. Thus the reaction of NDA with ethyl carbonate leads to 2-ethoxyperimidine in a quantitative yield[53]. 2-Cyanomethylperimidine has been obtained by treating NDA with isobutyl cyanoacetate[54]. The reaction of NDA with dicarboxylic acid esters has been investigated[27]. If the reactants are taken in proportions of 1 : 1, the main product is the ester (XXIII). In the presence of a twofold excess of NDA, the diperimidines (XXIV) are formed in a low yield:



(XXIII) *n* = 0,1 (XXIV) *n* = 0-2 (XXV) (XXVI)

R = CH_3 or C_2H_5.

It has been reported[55,56] that the reaction of NDA with acetylenedicarboxylate esters leads to the formation of dihydroperimidines (XXV) together with diazepins of type (XXVI); the structure of the latter has not been rigorously demonstrated.

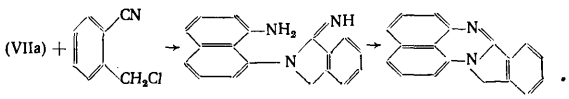


The interaction of NDA with ethoxymethylenemalonic or ethoxymethylenecyanoacetic ester[57] leads to the formation of compound (I). It is believed that cyclisation takes place at the carbon atom to which the ethoxy-group is linked and that the intermediate dihydroperimidine (XXV) splits off a molecule of $RCH_2CO_2C_2H_5$ and is converted into compound (I):

(VIIa) + $C_2H_5OCH{=}C(R){-}CO_2C_2H_5$ → (XXVII) → (I);

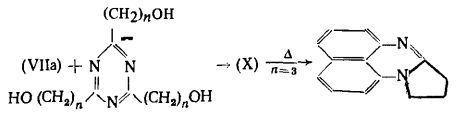
R = $CO_2C_2H_5$ or CN.

The interaction of NDA with acetoacetic ester is of interest. When the two reactants are refluxed without a solvent, 2-acetonylperimidine (X, R = CH_2COCH_3) is formed[6,25]. However, at room temperature the keto-group of acetoacetic ester is involved in cyclisation and the main reaction product is dihydroperimidine (XXVIII).[6] On heating, the latter loses a molecule of ethyl acetate and is converted into 2-methylperimidine:



(XXVIII)

A convenient method of synthesising 2-substituted perimidines, particularly those containing complex and labile groups in the 2-position, involves the interaction of NDA with iminoesters. In particular, the following derivatives (X) have been obtained by this procedure: compounds with R = $CH_2CO_2C_2H_5$,[58] $CH(OC_2H_5)_2$, CH = NOH, CH_2CH_2NHR', *N*-oxo-2-pyridyl, and *N*-oxo-4-pyridyl.[59]

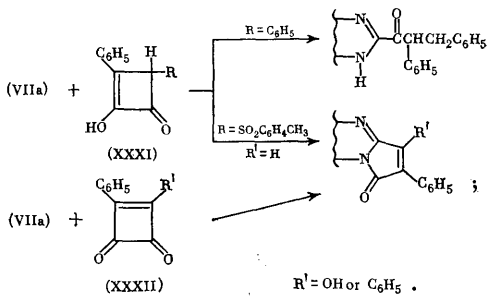


Acid amides and nitriles. There are few data concerning the synthesis of perimidine by the interaction of NDA with carboxylic acid amides and nitriles. Thus, when NDA is heated with caprolactam in the presence of inorganic acids, 2-(ω-aminopentyl)perimidine is formed[60,61]. In the interaction of NDA with ethyl oxamate the cyclisation involves both the ester and amide functional groups, as a result of which a mixture of the amide and the ethyl ester of perimidine-2-carboxylic acid is obtained[25].

At a high temperature acetonitrile and butyronitrile react with NDA dihydrochloride to form 2-methyl- and 2-n-propylperimidines[62]. The following reaction, leading to the perimidine (XXIX), is of interest[63]:

(VIIa) + → (XXIX)

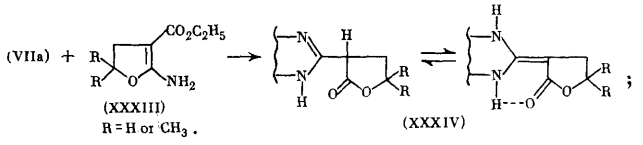
Amidines. The interaction of NDA with formamidine[64] and diphenylformamidine[14] leads to the formation of compound (I). Cyclisation takes place also when NDA is heated with *sym*-triazines, which can be regarded as a kind of cyclic amidines. Thus 2,4,6-tri(ω-hydroxyalkyl)-1,3,5-triazines react with NDA at 220–230 °C to form compound [X, R = $(CH_2)_nOH$];[65] with *n* = 3, this compound cyclises at 250 °C to form the perimidine (XXX):



(VIIa) + → (X) $\xrightarrow[n=3]{\Delta}$ (XXX)

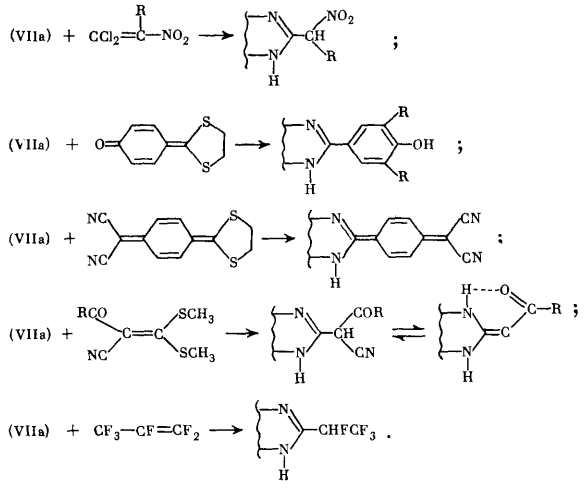
When NDA was heated with 2,4,6-tricyclopropyl-1,3,5-triazine, 2-cyclopropylperimidine was obtained[66]. Triazine itself gives rise to compound (I) in this reaction[67].

Other cyclising agents. 2-Aryl- and 2-heteroaryl-perimidines (X, R = C_6H_5, 4-iso-$C_3H_7C_6H_4$, 4-$CH_3OC_6H_4$, or 2-thienyl) have been obtained by the reaction of NDA with *N*-ethoxycarbonylthioamides[68]. The reaction of NDA with cyanobenzylideneanilines ArN = $C(CN)C_6H_5$ leads to 2-phenylperimidine[69]. 2-Acylindan-1,3-diones, 2-acyl-3-benzofuranones, etc. are effective cyclising agents which give rise to the perimidines (X, R = alkyl or aryl) on interaction with NDA.[70–72] It is of interest to note that these compounds react with *o*-phenylenediamine without the dissociation of the acyl–carbon bond, forming benzodiazepin derivatives.



Reid and coworkers[47,48,73] investigated the reaction of NDA with derivatives of cyclobutenone (XXI) and cyclobutenedione (XXXII). Depending on the nature of the substituent R, the reaction leads to the formation of 2-acylperimidines or perinones:

(VIIa) + (XXXI) R = C_6H_5; R = $SO_2C_6H_4CH_3$, R' = H

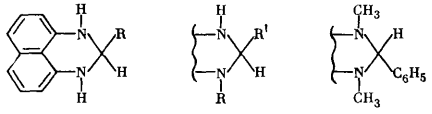


(VIIa) + (XXXII) R' = OH or C_6H_5.

The interaction of NDA with ethyl 2-amino-4,5-dihydrofuran-3-carboxylate (XXXIII) results in the formation of the perimidine (XXXIV), which exists predominantly in the tautomeric form (XXXIVb).[74] It is believed that the site of the μ-carbon atom in compound (XXXIV) is occupied by the carbon atom to which the amino-group is linked in compound (XXXIII), i.e. the reaction involves the recyclisation of compound (XXXIII):

(XXXIII) R = H or CH_3. (XXXIV)

The schemes below show that there is a possibility of the cyclisation of NDA to perimidines with the aid of activated unsaturated compounds: nitroethylenes[75], quinone derivatives[76,77], 1-acyl-1-cyano-2,2-dimethylmercaptoethylenes[78], and hexafluoropropene[79]:

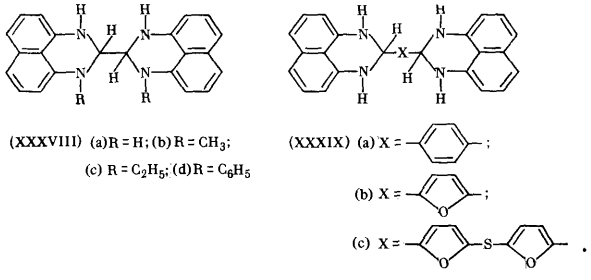


(b) The Synthesis of 2-Amino-, 2-Hydroxy-, and 2-Mercapto-Perimidines

2-Aminoperimidine (X, R = NH_2) is obtained in a high yield by the reaction of NDA with bromocyanogen[80,81] or cyanamide[82]. When NDA is fused together with ammonium thiocyanate[53] or thiourea[16], compound (X, R = NH_2) is formed in a mixture with thioperimidone (VI). The reaction of NDA with *S*-methylisothiourea derivatives leads to perimidine-2-carbamates (X, R = NHCOOR').[83,84] The synthesis of 2-arylamino-[53,85] and 2-dimethylamino-perimidines[86] by the reaction of NDA with aryl isothiocyanates and trichloromethyldimethylamine respectively has been reported.

2-Mercaptoperimidines (which exist in the thione form) are obtained by the reaction of naphthylenediamines with carbon disulphide. Thus compound (VI),[53] 2-mercapto-4,7-dimethylperimidine[87], and 2-mercaptoaceperimidine[18] have been synthesised in this way. It is possible to use potassium xanthate instead of CS_2.[53] Potassium cyanate, carbonate and chlorocarbonate esters[53], phosgene[17,53], and urea[88] are used as cyclising agents for the synthesis of perimidone (V) and its derivatives from NDA; almost all the methods yield satisfactory results. Aceperimidone is obtained similarly[89].

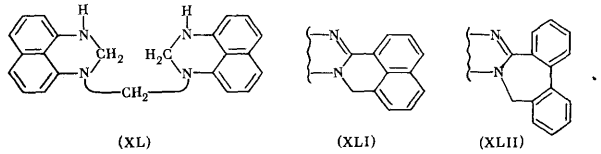
(c) Synthesis of 2,3-Dihydroperimidines from NDA and Aldehydes or Ketones



Aldehydes. Aldehydes interact with NDA in alcohol or benzene with formation of 2,3-dihydroperimidines (XXXV), where R = H, CH_3, CCl_3,[90,91] C_2H_5, n-C_3H_7, iso-C_6H_{13},[92] C_6H_5 [93-95], different halogeno-groups[93,94,96], hydroxy-group,[92-95] methoxy group,[92,94-96] 3,4-methylenedioxy-group,[92] dialkylamino-groups,[15,94] nitrophenyl,[93,94,97] 4-biphenylyl,[94] α-naphthyl,[96] ferrocenyl,[98] 1-propenyl,[95] β-styryl,[95] diethoxymethyl,[92] 2- and 3-pyridyl,[93,97] 2-quinolinyl, 2-pyrrolyl, 3-indolyl, 1-methyl-2-imidazolyl, 1-methyl-2-benzimidazolyl[93], 2-thienyl,[93,96] 2-furyl,[95,96,99] 5-methyl, 5-halogeno-groups, and 5-nitro-2-furyl.[93,99] 2-R-2,3-Dihydroaceperimidines are obtained similarly[100]. The reaction proceeds as a rule with a high yield and terminates after 2 to 3 h even at room temperature.

(XXXV) (XXXVI) (XXXVII)

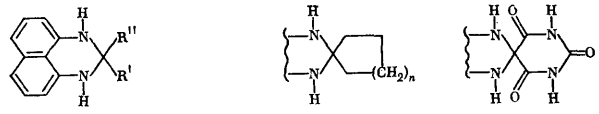
R = CH_3 or C_6H_5; R' = H, Ar, or 2-furyl.



N-Methyl-[97] and *N*-phenyl-substituted[15,90] NDA (VII, b and c) also react with aldehydes to form dihydroperimidines (XXXVI), the reaction involving the amine (VIIc) proceeding with greater difficulty. *N,N'*-Dimethyl-1,8-naphthylenediamine interacts with benzaldehyde, forming compound (XXXVII).[15] The reaction of NDA [90] and its *N*-substituted derivatives[101] with glyoxal leads to hydrogenated bisperimidines (XXXVIII). Compounds (XXXIX) have been obtained analogously from aromatic dialdehydes[97].

(XXXVIII) (a) R = H; (b) R = CH_3; (c) R = C_2H_5; (d) R = C_6H_5

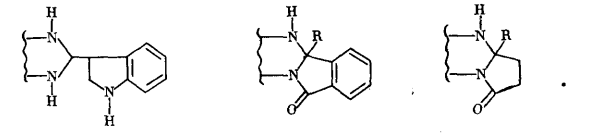
(XXXIX) (a) X = ; (b) X = ; (c) X = .



In a number of instances NDA reacts with aldehydes to form non-standard products. For example, the methane derivative (XL) is obtained together with compound (IV) if equimolar proportions of NDA and formaldehyde are used[90]. The reaction of NDA with phthalaldehyde, naphthalene-1,8-dialdehyde, and biphenyl-2,2'-dialdehyde results in the formation of the aromatised perimidines (XXXIX), (XLI), and (XLII) respectively[102].

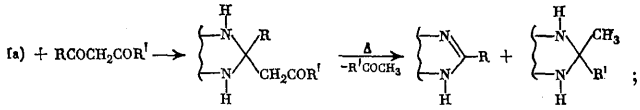
(XL) (XLI) (XLII)

Ketones. Ketones interact with NDA to form 2,2-disubstituted 2,3-dihydroperimidines. Thus the reactions with acetone[8,103] and acetophenone[6] yield compounds (XLIII, a and b) respectively, while the reactions with cyclopentanone and cyclohexanone give rise to compounds (XLIV, a and b).[95]



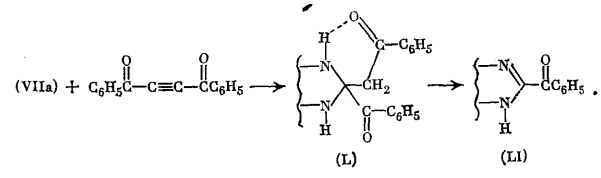
Acetone reacts as readily with NDA derivatives: 2-chloro-,[104] 4-sulpho-,[105] 3,6-dinitro-,[106] and 2,4,5,6-tetranitro-.[107] A method of synthesis of compound (XLIIIa) by the reduction of 1,8-dinitronaphthalene in the presence of the corresponding ketones has been proposed[108]. The reaction of NDA with alloxan and isatin[53] involves the ketone and not the amide carbonyl with formation of compounds (XLV) and (XLVI). The keto-group is also more reactive than the carboxy-group in the reaction of NDA with ω- and *o*-acyl derivatives of propionic and benzoic acids, as a result of which compounds of type (XLVII) and (XLVIII) are produced[109].

(XLIII) (a) $R^I = R^{II} = CH_3$; (b) $R^I = CH_3$, $R^{II} = C_6H_5$; (c) $R^I = CH_3$, $R^{II} = CH_3CO$



(XLIV) (a) $n = 1$; (b) $n = 2$

(XLV)

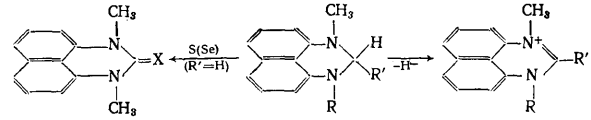


(XLVI) (XLVII) (XLVIII)

The interaction of NDA with diketones has been studied. Diacetyl yields dihydroperimidine (XLIIIc).[53] In the reactions with 1,3-diketones compounds of type (XLIX) are formed initially and are then aromatised on heating with elimination of the $R'COCH_3$ molecule and the formation of a 2-R-perimidine and a 2,2-disubstituted dihydroperimidine (as a result of the interaction of NAD with the eliminated ketone $R'COCH_3$).[53,110] For benzoylacetone, as an example, which gives rise to compound (XLIXb), it is seen that the aliphatic keto-group reacts with NDA more readily than the aromatic group:

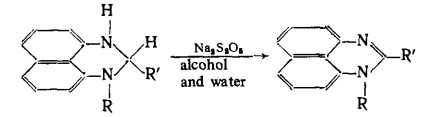
(XLIX) (a) $R = R^I = CH_3$; (b) $R = CH_3$, $R^I = C_6H_5$; (c) $R = R^I = C_6H_5$.

The interaction of NDA with dibenzoylacetylene[111] takes place via one of the carbon atoms of the acetylenic bond. The dihydroperimidine (L) formed readily loses an acetophenone molecule on heating and is converted into 2-benzoylperimidine (LI):



(L) (LI)

Under fairly severe conditions, such aromatisation takes place also for simple 2,2-disubstituted derivatives of 2,3-dihydroperimidine. For example, when a mixture of NDA and benzyl methyl ketone is heated at 315 °C, 2-methylperimidine is formed[112]. The reaction of NDA with diphenyltriketone [1,3-diphenyl-1,2,3-propanetrione] involves the central carbonyl and leads to 2,2-dibenzoyl-2,3-dihydroperimidine[110].



2. Synthesis of Perimidines from 2,3-Dihydroperimidines

The simplicity of the synthesis of 2,3-dihydroperimidines (DHP) and the availability of convenient methods for their dehydrogenation have recently made the reaction of NDA with aldehydes also one of the best methods of synthesising perimidines themselves. A whole series of reagents have been proposed for the aromatisation of DHP, whose choice in a specific instance depends on the nature of the substituents in the dihydroperimidine nucleus. For example, 1,3-disubstituted DHP (LII) are converted into perimidinium salts (LIII) by treatment with iodine[113], trityl perchlorate[114], and 1,3,5-trinitrobenzene[115]. The dehydrogenation of compounds (LII) and their aceperimidine analogues (with $R' = H$) by means of sulphur or selenium leads to the thiones (LIV) or selenones (LV):[113]

(LIV) X = S; (LV) X = Se. (LII) (LIII)

In the dehydrogenation of DHP with unsubstituted NH groups it is best to use sodium pyrosulphite $Na_2S_2O_5$.[97] The reaction is exceptionally clean, has a high yield, and is suitable for the synthesis of many 1- and 2-substituted perimidines (LVI), including those with substituents such as polyhydroxyalkyl groups:

(LVII) (LVI)

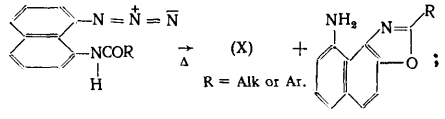
R, R′ = H, alkyl, heteroaryl, etc.

A single-stage synthesis of 2-R-perimidines from NDA and bisulphite adducts of aldehydes is also possible, but it has been achieved only for 2-phenylperimidine[116].

In those relatively few instances where the dehydrogenation with pyrosulphite is unsuccessful (1,2-diaryl- and 2-nitrophenyl derivatives of DHP),[97] it is possible to use palladium on carbon[25,92,98,99], manganese dioxide[117], or sulphur[118]. However, compounds with a nitro-group in the 2-aryl substituent are poorly dehydrogenated also by other dehydrogenating agents[93,97]. The aromatisation of the DHP is significantly hindered also in the presence of the *N*-phenyl [97,115] and *N*-acyl groups[114].

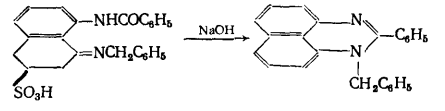
1,2-Disubstituted DHP (LVII) have been successfully aromatised by chloranil[117]. In the case of 2,3-dihydroaceperimidines chloranil dehydrogenates also the CH_2-CH_2 bridge, which results in the formation of aceperimidylenes[119].

The aromatisation of compounds (LVII) can also proceed with elimination of the groups R′ rather than the hydride ion. This is usually promoted by thermolytic conditions or by heating in acetic acid[93,101]. Examples of such aromatisation, in which the $RCRCH_2$ group was eliminated, have already been given above. Similarly, on heating in xylene and particularly in CH_3COOH, heteroaromatic substituents containing a heteroatom of the pyrrole type (pyrrolyl, 3-indolyl, 2-benzimidazolyl, etc.) are readily eliminated from the 2-position in compound (LVII).[93,101] Hydrogenated bisperimidines (XXXVIII) dissociate with rupture of the C–C bond and the formation of perimidines even on dissolution in chloroform[99,101]. This process takes place particularly readily for *N*-alkyl derivatives (XXXVIII, b and c).[101] However, the majority of 2-substituted DHP are resistant to thermolysis[93,



[101]. On the other hand, the thermolysis of 2-(2-pyridyl)- and 2-(2-quinolinyl-2,3-dihydroperimidines leads to the abstraction of a hydride ion and the formation of a 2-(2-pyridyl)- and 2-(2-quinolinyl)perimidines[93,101]. We may note that DHP containing β- and γ-pyridyl and quinolinyl groups in the 2-position are not aromatised in this way; the reason for this is not entirely clear.

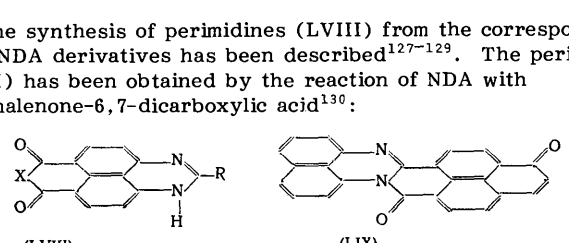
The conversion of *N*-acetylated 2,3-dihydroperimidines into 2-methylperimidine under the influence of hydrochloric acid has been described but unfortunately has been little investigated[120].



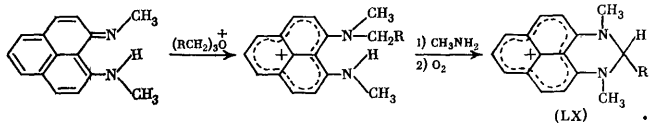
On the whole, DHP exhibit a lower hydride mobility and a greater stability than, for example, benzimidazolines[115], but after prolonged storage DHP gradually darken and decompose.

3. Other Methods of Synthesis of Permidines

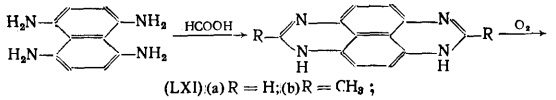
In a number of studies perimidines have been synthesised not from NDA but from other 1,8-disubstituted naphthalenes. Thus, the reduction of 1-acetamido-7-hydroxy-8-nitroso-naphthalene[121] and 1-acetamido-5-hydroxy-8-phenylazo-naphthalene[122] yielded 4(9)-hydroxy- and 6(7)-hydroxy-2-methylperimidines respectively. The possibility of obtaining the *N*-oxide of 2-methylperimidine by the electrochemical reduction of 1-acetamido-8-nitronaphthalene has been reported[123]. Heating of 1-acylamino-8-azidonaphthalenes in trichlorobenzene leads to the formation of a mixture of 2-substituted perimidines and naphthoxazoles in a relatively low yield[124]:



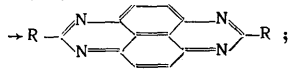
The reaction of the phthaloyl derivative of 1-amino-8-azidonaphthalene gives rise to phthaloperinone. On treatment with iron nonacarbonyl, 1,8-diazidonaphthalene is converted into perimidone in 6% yield[125]. When 8-benzamido-1-benzylimino-1,2,3,4-tetrahydronaphthalene-3-sulphonic acid was heated with alkali, 1-benzyl-2-phenylperimidine was obtained; another product of this reaction was 8-benzimido-1-naphthol[126]:



4. Different Condensed Systems Based on Perimidine

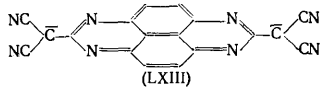


The synthesis of perimidines (LVIII) from the corresponding NDA derivatives has been described[127–129]. The perinone (LIX) has been obtained by the reaction of NDA with phenalenone-6,7-dicarboxylic acid[130]:

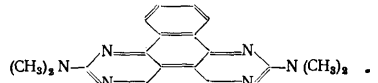


The dihydroperimidine (LX), in which the heteroring is condensed with a phenalenium ion, has been recently synthesised in accordance with the above scheme[131]:

On heating with formic acid, 1,4,5,8-tetra-aminonaphthalene gives rise to the red diperimidine (LXIa), which is extremely readily oxidised by atmospheric oxygen to a slightly greenish tetra-azapyrene (LXIIa).[132,133] The dimethyl derivative (LXIb), obtained by the reaction of 6,7-diamino-2-methylperimidine with acetic anhydride, behaves analogously[134]:



(LXI) (a) R = H; (b) R = CH_3 ;



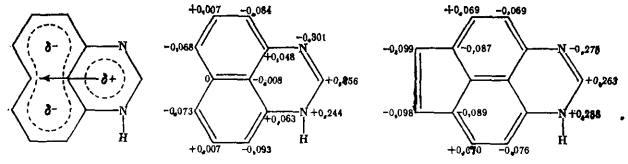
(LXII) (a) R = H; (b) R = CH_3 .

There are also data on the synthesis of tetra-azapyrene derivatives (LXIII) [135] and (LXIV).[136]

(LXIII)

(LXIV)

Polynaphthoperinone has been obtained by the reaction of tetramine with naphthalene-1,4,5,8-tetracarboxylic acid[137].



III. PHYSICAL PROPERTIES

1. Quantum-Mechanical Calculations and Aromaticity

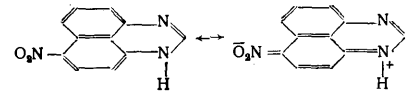
The perimidine molecule is a 14π-electron system, but one of its electrons is not delocalised, which leads to a decrease of aromaticity. Thus the resonance energy per π electron (the REPE index) of perimidine is significantly lower than that of naphthoimidazoles[119]. Another feature of the π-electron structure of the molecule of compound (I) is the formal excess of π electrons in its heteroring in which there are seven π electrons. The expulsion of the "superfluous" super-Hückel electron from the heteroring to the naphthalene fragment of the molecule leads to the polarisation of the π-electron cloud corresponding to structure (LXV).[2] Such a shift has been confirmed by quantum-mechanical calculations [see diagram (LXVI)] regardless of whether one uses the simple Hückel method[138,139], the Pariser–Parr–Pople method[140], or the CNDO/2 method[141,142].

The distribution of electron density in the molecule of compound (I) is so non-uniform that it can be represented as consisting of, as it were, two parts: the μ-carbon atom with an unusually high positive charge and the negatively charged 1,8-naphthylenediamine residue. The transfer of π-electron density from the hetero-ring to the naphthalene system also takes place in naphthoimidazoles[3,139,142], but it is much weaker there. The maximum negative charge in compound (I) is concentrated in the 4- and 9-positions (the *ortho*-positions relative to the heteroring) and in the 6- and 7-positions (*para*-positions), while in the 5- and 8-positions

(*meta*-positions) it is virtually zero. Such alternation of charges can be explained by the alternant nature of the molecule of compound (I). The charge distribution is also very non-uniform in the molecule of aceperimidylene (LXVII), the positive π-charge on the $C_{(2)}$ atom of the latter being higher than in the molecule of compound (I). The maximum negative charge in aceperimidylene is concentrated in the CH=CH bridge[143].

(LXV) (LXVI) (LXVII)

The CNDO/2 method revealed an interesting feature in the polarisation of the electron cloud in perimidine and naphthoimidazoles. In conformity with the foregoing considerations concerning the characteristics of the π-electronic structure of the molecule of compound (I), it was found that the polarisation of the C=N bond in the latter is caused mainly by the shift of π electrons[141], while in naphthoimidazoles[142] and in benzimidazole[141] it is due to a shift of σ electrons.



Quantum-mechanical calculations on 2-phenyl- and 2-2′-hydroxyphenyl-perimidines[138], the perimidinium cation[144], perimidone[145], and 2,3-dihydroperimidine[146] have also been published.

2. Colour and Electronic Spectra

One of the most interesting features of perimidine is its bright yellow colour, which sharply distinguishes it from the colourless naphthoimidazoles. The electronic spectrum of compound (I) consists of three absorption bands in the region of 400, 330, and 235 nm (the α-, β-, and γ-bands)[147]. The last two bands are highly intense ($\lg \varepsilon = 4.1$–4.6) and are also observed in the spectra of 2,3-dihydroperimidines and 1,8-naphthylenediamines[148]. The β-band is undoubtedly related to the transfer of the electron pair of the nitrogen atom to the antibonding π orbital of the naphthalene ring[148], while the γ-band is apparently due to the electronic transitions within the naphthalene ring itself. The absorption α-band, responsible for the colour of the perimidines, is of greatest interest. It has a reduced intensity ($\lg \varepsilon \cong 3.0$) and is usually manifested as a shoulder, which probably explains the lack of attention paid to it by a number of investigators[57,140]. The α-band persists in the spectra of perimidinium salts, i.e. it cannot be attributed to the $n \rightarrow \pi^*$ transition[147].

According to calculated data[138], the origin of the long-wavelength absorption band of perimidines is the π-electron transfer from the naphthalene ring to the heteroring[138]. Thus this band is due to charge transfer between the π-donor and π-acceptor components of the perimidine system, which is consistent with the high π-donor capacity of perimidines (see below) and explains qualitatively the influence of certain substituents on the colour of perimidines. Thus the decrease of the electron deficiency of the heteroring in compound (I) following the introduction of strong electron donors in the 2-position (amino- and alkoxy-groups, etc.) leads to the complete disappearance of colour[147]. Similarly the hydrogenation of the C=N bond leads to colourless compounds (2,3-dihydroperimidines). On the other hand, when strong π-acceptors are present in the 2-position in perimidine, the corresponding compounds are deeply coloured. Thus 2-benzoylperimidine is a dark wine-red[111], while 2-nitrophenyl and 2-nitrofuryl-perimidines are violet[32,93]. One may predict that a deepening of the colour should be observed also after the introduction of electron-donating substituents in the naphthalene ring; it is seen for aceperimidine as an example ($\lambda_{max} = 430$ nm) that this is indeed so.[147] The long-wavelength absorption band in the aceperimidylene spectrum is at 418 nm ($\lg \varepsilon = 4.1$).[143]

When groups containing vacant π orbitals are introduced into the *ortho*- and *para*-positions in the napthalene ring, the electronic spectra of perimidines change significantly and the colour deepens. An intense band due to the $\pi \rightarrow \pi^*$ transition appears in the long-wavelength region, its position depending on the electron-accepting properties of the substituent. For example, λ_{max} for 4-acetyl-1-methyl- and 9-acetyl-permidines are 405 and 416 nm respectively ($\lg \varepsilon =$ 4.11 and 4.0), while the values for 1-methyl-4-nitro- and 9-nitro-perimidines are 445 and 460 nm ($\lg \varepsilon = 3.96$ and 3.99).[148] When these groups are present in the 6- and 7-position, λ_{max} undergoes a further bathochromic shift. It is interesting to note that nitroperimidines are some of the deepest coloured nitro-compounds in the heteroaromatic series. The long-wavelength band in the spectra of these compounds is apparently of the type of the β-band and its strong bathochromic shift is caused by the ease of the transfer of electrons from the heteroring to the acceptor [structure (LXVIIIb)]:

(LXVIIIa) (LXVIIIb)

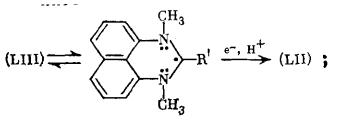
More detailed data on the ultraviolet spectra are given by Pozharskii et al.[149] for nitroperimidines, Minkin et al.[138] for 2-arylperimidines, Pozharskii and coworkers[147,150] for 2-aminoperimidines, and Pozharskii et al.[148] for 2,3-dihydroperimidines, perimidones, and thioperimidones.

3. π-Electron-Donating Properties

Perimidines tend to form deeply coloured charge-transfer complexes (CTC) with various π-acids, including weak acids such as 4-nitrobenzaldehyde[147]. The complexes usually have the 1 : 1 composition in the crystalline state. The charge-transfer bands for the CTC of perimidines and a number of related compounds with 1,3,5-trinitrobenzene (TNB) have been published[142,137,148] together with the ionisation potentials of the donors calculated from these data[147].

The high π-donor capacity of perimidines reflects the low ionisation potential of the electrons in the highest occupied π-MO. Calculations have shown that E^{π}_{HOMO} for the molecule of compound (I) lies appreciably higher than for naphthoimidazole molecules. In terms of the π-donor capacity, perimidines are superior not only to naphthoimidazoles and 1,8-naphthylenediamines but also to a well known π-donor such as phenothiazine. DHP, which apparently have a nearly planar structure in which the conjugation of the electron pairs of the heteroatoms with the aromatic ring is facilitated, exhibit the same π-donor capacity as perimidines[148].

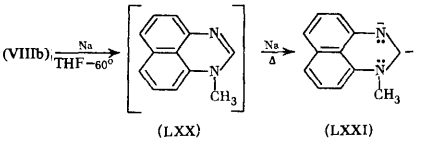
It is of interest to note that, in contrast to the CTC of perimidines and 1,8-naphthylenediamines, the DHP complexes of two charge-transfer bands. In conformity with the experimental data and quantum-mechanical molecular orbital calculations, aceperimidylenes[143], perimidones, thioperimidones, and 2-imino-2,3-dihydroperimidines[148] are inferior as regards the π-donor capacity to perimidines and DHP. For a series of 2,3-dihydroperimidine structures[148], the ionisiation potentials in the gas phase have been measured



by the photoionisation method. The relative π-donor capacities of the perimidines can be estimated from the intensities of the peaks of the doubly charged ions in their mass-spectra[151].

4. Electron-Accepting Properties

In terms of their electron-accepting properties, perimidines occupy a position between azines and imidazoles. Thus perimidinium salts (LIII, R = CH_3) are reduced at the mercury dropping electrode with greater difficulty than the majority of the azinium cations but more readily than benzo- and naphtho-[1,2-*d*]imidazolium cations[152,153]. The ease of reduction of the naphtho[2,3-*d*]imidazolium cation is almost identical to that of the perimidinium cation. A correlation has been observed between the ease of the polarographic reduction of the above cations and the energies of their lowest vacant orbital[152].



Perimidinium and naphtho[2,3-*d*]imidazolium salts are reduced with two single-electron diffusion processes, while benzo- and naphtho-[1,2-*d*]imidazolium salts are reduced with a single two-electron diffusion process. This indicates the relative stability of the radicals formed following the addition of the first electron to the perimidinium and naphtho[2,3-*d*]imidazolium cations. The structure of the radical in the case of perimidine is apparently close to that of (LXIX), i.e. the electron occupies an orbital localised in the heteroring. This is supported by the dependence of $E_{1/2}$ on the nature of the substituents in the heteroring of the perimidinium cation and by its low sensitivity to substituents in the naphthalene ring fragment.

The addition of the second electron leads ultimately to the formation of DHP:[152]

(LXIX) R = CH_3.

1-Alkylperimidine bases are not reduced polarographically, but, on treatment with sodium in tetrahydrofuran (THF) at −60 °C, compound (VIIIb) gives rise to the radical-anion (LXX), whose EPR spectra have been measured and whose spin density distribution has been calculated (it is a maximum in the 2- and 6-positions)[41]. When sodium is replaced by potassium under the same conditions or when sodium is used at a higher temperature, the dianion of 1-methylperimidine, whose structure is probably close to that of (LXXI), is formed:

(LXX) (LXXI)

5. Magnetic Properties and ^{1}H NMR Spectra

Compared with naphthoimidazoles, perimidines have a reduced diamagnetic susceptibility[147], which implies that the molecule of compound (I) is characterised by an appreciable polarisation paramagnetism as a consequence of the asymmetry of its π-electron cloud. The magnetic susceptibility data are consistent with the presence of a single EPR signal with a width of ~7 G for the crystalline specimens of the majority of perimidines; the signal intensity obeys the Curie law and corresponds to a single spin per 5000–10000 molecules[147]. The nature of the signal has been tentatively attributed to the presence at individual crystal lattice sites of local CTC, which is fully consistent with the electronic structure of perimidine.

The advances in the chemistry of perimidine are in many respects due to ^{1}H NMR. ^{1}H NMR data for perimidines are quoted in virtually all publications in recent years. They have been discussed in greatest detail by Pozharskii et al.[147] A characteristic feature of the ^{1}H NMR spectrum of compound (I) is the considerable upfield shift of the aromatic proton signals (on average by 0.8–1.2 p.p.m.) relative to naphthalene and naphthoimidazoles. This phenomenon is apparently due not so much to the weakness of the diamagnetic ring current as to the significant contribution of its paramagnetic component.

The $H_{(4)}$ and $H_{(9)}$ protons, whose signals are significantly displaced upfield compared with those of other protons, can be identified most readily in the ^{1}H NMR spectra of perimidines. As a consequence of the rapid exchange of the NH proton, in perimidines with a free NH group they become equivalent and are manifested by a quartet in a strong field. In 1-alkylperimidines these protons are no longer equivalent and give rise to two well resolved quartets, the quartet due to the $H_{(9)}$ proton being located in a higher field. The disappearance of one of these signals is significant evidence for the introduction of a substituent in the 4- or 9-position[146, 154]. The $H_{(5)}$–$H_{(8)}$ protons in the ^{1}H NMR spectrum of compound (I) give rise to a complex multiplet, which merges with the signal due to the $H_{(2)}$ proton. In the spectra of perimidinium cations the signal of the $H_{(2)}$ proton can be readily identified, since it is displaced downfield to a much greater extent than the signals of the other protons[114,115].

When even one electron-accepting group (acyl-,[144] nitro-,[155] or sulpho-group[156]) is introduced into the naphthalene ring in perimidines, the ^{1}H NMR spectrum is greatly simplified. In particular, this applies to the 6- and 7-positions, because the substituent usually deshields the second peri-proton, displacing its signal downfield and almost reducing to zero the constant J_{meta}. When these groups are in the 4- or 9-position, the structure of the compound is readily determined on the basis of the presence of a strong intramolecular hydrogen bond, the absence of a downfield shift of the signal due to the peri-proton, and by a number of other procedures[144,155]. However, in a few instances (*ortho*- and *para*-chloroperimidines[157]) the interpretation of the ^{1}H NMR spectrum is extremely difficult. The ^{1}H NMR spectra of aceperimidylenes[143] and 2,3-dihydroperimidines[101, 158] have been described. There are data on the ^{13}C NMR spectra of 2-azidoperimidines[159].

6. Infrared Spectra

The infrared spectra of compound (I), 2-methylperimidine, and certain 2-arylperimidines have been briefly discussed[138, 160]. There is information about the characteristic frequencies of other perimidines in almost every paper devoted to their synthesis. Infrared spectroscopy is the most important method for the identification of perimidines, particularly for their differentiation from the DHP, which are formed in many instances as side products or alternative reaction products. The 3100–3500 and 1500–1700 cm^{-1} regions of the spectrum, where the bands due to the stretching vibrations of the NH groups and the C=C and C–N bonds are located, are of greatest analytical importance for compounds of the perimidine series.

In the spectra of crystalline specimens of compound (I) and its 2-substituted derivatives there are no stretching vibration bands due to free NH groups. Instead there is a broad diffuse band extending from 3200 to 2500 cm^{-1}, which indicates the formation of stable associated species via intermolecular hydrogen sharp bonds. Bands due to the free ν(NH) vibrations in the form of a sharp intense peak at 3440 cm^{-1} appear in the infrared spectra of dilute solutions. The appearance of the ν(NH) band as a single sharp, frequently very intense, peak is observed sometimes also for crystalline specimens when the proton of the NH group is involved in an intramolecular hydrogen bond. The relevant data are available for 4(9)-nitro-,[155] 4(9)-acyl-,[144] and 2-(α-quinolinyl)-perimidines and also for 2,2'-diperimidine[101].

2,3-Dihydroperimidines with free NH groups do not undergo such strong association, which is undoubtedly due to their appreciably lower basicity. The ν(NH) stretching vibration bands in their spectra are manifested in both the crystalline state and in solution[101]. In the spectrum of the solution the ν(NH) band is appreciably less intense than for perimidines, is broader, and is displaced by 15–40 cm^{-1} towards lower frequencies.

In the range 1500–1700 cm^{-1} perimidines with a free NH group as a rule have three intense bands, among which the band with the highest wavelength is apparently due to the stretching vibrations of the amidine system. Indeed, in the spectra of perimidinium salts the ν(C$\overset{+}{\cdots}$N) band is displaced by 20–35 cm^{-1} towards higher frequencies, which is typical for cyclic amidines[155]. A very intense doublet is frequently present in the range 1580–1650 cm^{-1} in the spectra of 2-substituted perimidines instead of the triplet; DHP usually have a single intense band near 1600 cm^{-1} in the same region[138].

7. Ionisation Constants

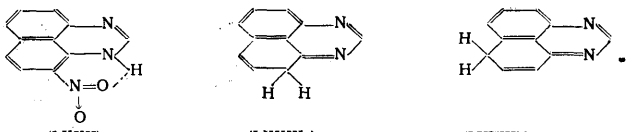
In aqueous solutions $pK_a \cong 6$ for the perimidinium ion and its alkyl-substituted derivatives, i.e. perimidines are stronger bases than benzimidazole, naphthoimidazole and azines[161,162]. The basicity of DHP is lower by approximately two orders of magnitude in water[113] and by five order of magnitude in acetonitrile[163] than that of perimidines[164], which indicates the effective involvement of the electron pairs of both N atoms of DHP in conjugation with the π-electron system of the naphthalene ring and a considerable flattening of the heteroring. Data are available for the basicities of various 1-alkyl-[161,165] and 2-alkylperimidines[163,164,166], 2-arylperimidines[150], nitroperimidines[149], 2,3-dihydroperimidines[113,148], aceperimidines[161], and aceperimidylenes[143]. It is of interest that the basicity of the latter is lower by two orders of magnitude than that of perimidines.

8. Dipole Moments

The dipole moments of seven compounds of the perimidine series have been measured[138]: perimidine (3.18 D), 1-methylperimidine (3.48 and 3.66 D),[142] 2-methylperimidine (3.25 D), 2-phenylperimidine (3.03 D), 2-(4-nitrophenyl)perimidine (3.62 D), 2-(2'-hydroxyphenyl)perimidine (3.82 D), and 2-(2'-methoxyphenyl)perimidine (3.94 D). Quantum-mechanical calculations of the dipole moment of compound (I) have been carried out by the Hückel molecular orbital[138], Pariser–Parr–Pople[140], and CNDO/2 [141,142] methods, the last method yielding the best agreement with experiment. The fairly high dipole moment of compound (I) is consistent with the idea that its electronic structure is highly asymmetric.

9. Mass-Spectra

The mass-spectra of perimidines and 2,3-dihydroperimidine structures, including perimidone and thioperimidone, have been discussed in detail[151]. A distinctive feature of perimidines is their high stability with respect to electron impact and the presence in the mass-spectra of an extremely intense peak of a doubly charged molecular ion.



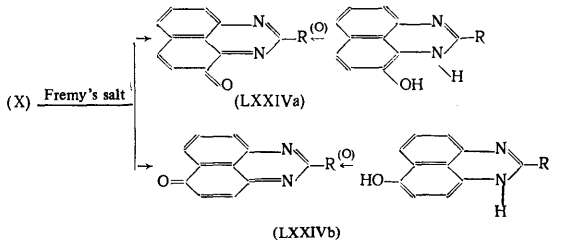
10. Fluorescence Spectra

The fluorescence of compound (I) and some of its derivatives has been studied[35,138]. It has been noted[35] that the overall fluorescence of perimidines is less intense than that of naphthoimidazoles. For the purpose of chromatographic separation, it is useful to know that simple perimidines virtually do not fluoresce on irradiation with u.v. light, while 2,3-dihydroperimidines and 1,8-naphthylenediamines do as a rule fluoresce. An extremely intense fluorescence is shown by 4(9)- and 6(7)-acylperimidines[145] and aceperimidylenes[143].

11. The Tautomerism of Perimidines

The set of all the physicochemical data shows that in perimidines, as in imidazoles, the NH proton rapidly migrates from one nitrogen atom to another (degenerate tautomerism of the amidine type). In monosubstituted permidines containing a substituent in the naphthalene ring there is no degeneracy and the two tautomers should have different properties. These differences are relatively small for 6(7)-substituted perimidines. Thus an estimate[149] based on the pK_a shows that the ratio of the 6- and 7-nitro-isomers in the equilibrium mixture is approximately 35 : 65.

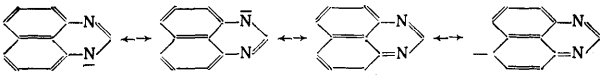
On the other hand, the introduction of a nitro-group[149] or an acyl group[144,147] in the *ortho*-position displaces the equilibrium almost entirely in the direction of the 9-tautomer [for example, in the case of compound (LXXII)] as a result of the formation of a strong intramolecular hydrogen bond. The properties (solubility, basicity, and ultraviolet, infrared, and ^1H NMR spectra) of the 4- and 9-tautomeric forms correspondingly differ markedly. It is of interest that in 4(9)-chloroperimidines an intramolecular hydrogen bond is not formed between the chlorine atom and the NH group[157], apparently as a consequence of the instability of the five-membered chelate. On the other hand, the closure of the five-membered chelate ring in the direction of the 2-substituent has been shown to be possible by the infrared spectra of 2-(α-quinolinyl)perimidine and 2,2'-diperimidine[101]. Tautomerism with migration of the proton to the 4(9)- and 6(7)-positions is theoretically possible for perimidines. Although the 4*H*-perimidines (LXXIIIa) and 6*H*-perimidine (LXXIIIb) have never been detected, the derivatives of these tautomeric forms are known.



(LXXII) (LXXIIIa) (LXXIIIb)

IV. CHEMICAL PROPERTIES

1. Oxidation and Reduction Reactions



As a consequence of their high π-donor capacity, perimidines are extremely sensitive to the action of oxidants. Thus, under mild conditions Fremy's salt converts compound

(I) and its 2-substituted derivatives into a mixture of 4*H*-perimidin-4-one (LXXIVa) and 6*H*-perimidin-6-one (LXXIVb) in a high yield[91]. The ratio of the isomeric one-compounds is ~1 : 1 for 1- and 2-methylperimidines, but in the case of 2-phenylperimidine the 6-oxo-derivative predominates (3 : 1). This reaction has also been carried out for perimidines with alkyl substituents in the naphthalene ring and for certain 2,3-dihydroperimidines[91,168]:

The chemistry of compounds (LXXIV) is of interest particularly their interactions with nucleophiles, leading in many cases to perimidine derivatives which are otherwise extremely difficult to synthesise, e.g. 9-formylperimidines[169]. 4- and 6-Perimidones are also formed on oxidation of 4(9)- and 6(7)-hydroxyperimidines[21,121,122] by atmospheric oxygen or $FeCl_3$. The ease of autoxidation is a characteristic property of all perimidines containing $-E$-substituents in the 4(9)- and 6(7)-positions, where there is an excess of electrons. Apart from hydroxyperimidines, 4(9)- and 6(7)-aminoperimidines are very unstable in the form of bases[134]. If $-E$-substituents are in the 2-position with a deficiency of π electrons, the corresponding perimidines are entirely stable even in the form of bases. There is a qualitative relation between the ease of oxidation of various perimidines and the energy of the HOMO.[134]

The most important property of perimidine and many of its derivatives with a free NH group is the exceptional susceptibility of their N-anions to autoxidation[161]. According to data calculated by the Hückel molecular orbital method, the HOMO of the perimidine N-anion is antibonding ($E_{HOMO} = -0.284\beta$)[161]. This should increase the contribution of structures of type (LXXV, c and d) to the resonance hybrid of the *N*-anion. Presumably the oxidation of the *N*-anion begins with the formation of the corresponding radicals and results in the abstraction of a single electron from the HOMO and subsequent interaction of the radicals with oxygen or with another, as in the oxidative coupling of phenols:

(LXXVa) (LXXVb) (LXXVc) (LXXVd).

It is of interest that electron-accepting substituents in the 2-position (for example, Cl, CF_3, and C_6H_5) do not prevent the autoxidation of the corresponding anions, but, when $+E$-substituents are in the naphthalene ring (NO_2,[155] RCO,[144] SO_3H,[156] and CH=CH in aceperimidylene[143]), then the anion becomes stable in air. The monoanions of perimidone and thioperimidine are also stable, but their dianions undergo autoxidation[170]. In terms of the ease of oxidation of the *N*-anions, only phenothiazines approach perimidines[171]; the *N*-anions of other heterocycles with a pyrrole nitrogen atom are usually stable when acted upon by atmospheric oxygen.

1-Substituted perimidines are readily reduced by sodium in liquid ammonia by the Birch procedure[41], by lithium tetrahydroaluminate[113], or by tetrahydroborates in acid media[172] to 1-R2,3-dihydroperimidines (XXXVI). Perimidinium salts of type (LIII) are quantitatively reduced by alkali metal tetrahydroborates to the DHP (LII).[113]

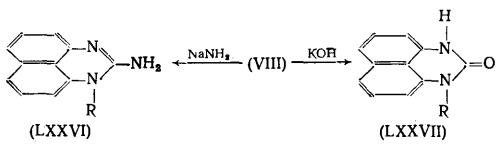
2. *N*-Substitution Reactions at the Nitrogen Atom

Like imidazoles, perimidines are best alkylated in alkaline media and, in view of the possibility of the autoxidation of the *N*-anion, the process must be carried out in an inert atmosphere[161]. Primary alkyl bromides and iodides, including high-molecular-weight compounds, alkylate compound (I) in an alcoholic solution[36,161]. For alkyl halides with the iso-structure (for example, iso-C_3H_7X), the yield of 1-R-perimidine falls sharply[157,161]. Perimidine is also effectively methylated by dimethyl sulphate[172]. The use of methyl toluene-4-sulphonate[161,173] or diazomethane[161] yields less satisfactory results. For less reactive alkyl halides (for example, $ClCH_2CH_2CH_2NMe_2$), higher-boiling solvents (toluene, xylene, etc.) are sometimes used instead of alcohol[16,176].

N-Substitution reactions in the perimidine series are extremely sensitive to steric hindrance by 2- and 4(9)-substituents. Thus, although 2-methyl-, 2-ethyl-, and 2-phenyl-perimidines are methylated[43,46,173,177], they cannot be alkylated by benzyl chloride and isopropyl, allyl, and phenacyl bromides[174,175]. 4(9)-Substituted perimidines are alkylated only at the nitrogen atom remote from the substituent, while 1,4-disubstituted perimidines are not quaternised by methyl iodide even after prolonged heating[144,152,155,174]. The only exception proved to be 4-chloro-1-methylperimidine, which could be converted into a quaternary salt by prolonged refluxing with CH_3I in 18% yield[157].

The alkylation of 6(7)-monosubstituted perimidines gives rise to a mixture of 1,6- and 1,7-isomers which is difficult to separate and in which the 1,6-isomer predominates somewhat[178]. On quaternisation, both isomers yield the same quaternary salt[144,146,155]. The reduced yields of the alkylation products of 4(9)- and 6(7)-nitroperimidines are striking[155]. The explanation is apparently the reduced nucleophilicity of the corresponding anion. The anion of 2-methyl-6,7-dinitroperimidine is not methylated at all under these conditions, while the *N*-methyl derivative of this compound was obtained in a low yield via the silver salt[149]. Nor was it possible to methylate the anion of 2-trifluoromethylperimidine[24].

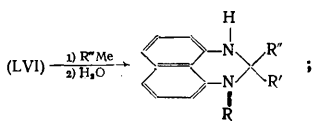
In its reactions with allyl and benzyl halides, the *N*-anion of perimidine exhibits its ambident properties [the contribution of structures of the type (LXXV, c and d) to the resonance hybrid] and the product of *C*-alkylation in the 4(9)-position is formed together with 1-allyl- and 1-benzylperimidines[174]. The best method for the benzylation of compound (I) apparently involves treating the latter with *N*-benzyl-*N*-methylmorpholinium chloride[165]. Another way of avoiding *C*-alkylation in the case of allyl and benzyl halides is to carry out the reaction without an alkaline agent in the presence of twice the amount of perimidine[174], the second equivalent of compound (I) being used to combine with a hydrogen halide molecule from the salt formed initially. This method is preferable when the alkylating agent or the reaction product is unstable in an alkaline medium ($RCOCH_2Br$, CH_3OCH_2Cl, etc.) or when the formation of an anion is difficult, for example, in the series of 9-acylperimidones, and also when the process must be carried out at an elevated temperature, for example, in the alkylation of 2-methyl- and 2-phenyl-perimidines.



In contrast to imidazoles, perimidines do not undergo the Ullman arylation[161] and the only method of synthesising 1-arylperimidines involves the reaction of *N*-aryl-1,8-naphthylenediamines with carboxylic acids and their derivatives[16,17]. Perimidine and its 1- and 2-substituted derivatives undergo *N*-amination with formation of 2-aminoperimidinium salts[179]. Perimidines combine via the NH group with compounds containing multiple bonds; chlorotrifluoroethylene (1-β-chlorotrifluoroethylperimidine is formed)[180], acrylonitrile (1-β-cyanoethylperimidines are formed)[25,181], and formaldehyde

(1-hydroxymethylperimidine is formed)[161]. 2,2′-Diperimidine combines with a styrene molecule via the NH groups[40].

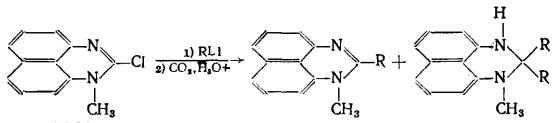
There are also data for the alkylation of aceperimidine[161] and its 2-methyl-,[46] 4-nitro-,[182] and 4-acetyl derivatives[134], [144], aceperimidylene[143], perimidones[183–186], and 1,3-disubstituted DHP.[172] Reactions involving the *N*-acylation of perimidone[183] and 1-R-2,3-dihydroperimidines have been described[114,172,187].



3. Reactions of Perimidines with Nucleophiles

Reactions with nucleophiles are extremely characteristic of *N*-substituted perimidines. They all involve the μ-carbon atom on which a high positive charge is concentrated. Thus 1-alkyl-,[88,188] 1-benzyl-,[88] 1-phenyl-,[16] 1-methoxymethyl-,[88] and 1-dialkylaminoalkyl-perimidines[16,176] undergo amination by sodium amide with formation of high yields of the amines (LXXVI) and hydroxylation by alkali with formation of high yields of the perimidones (LXXVII).[176,186,189] Both reactions are important in the perimidine chemistry. It must be emphasised that, in terms of the ease of hydroxylation, perimidines are superior to all other nitrogen heterocycles introduced into this reaction[186] and, in terms of the ease of amination, they are only slightly inferior to the most active heterocycles—isoquinoline and benzimidazole[190,191]. 1-R-Aceperimidines are also readily aminated[88] and hydroxylated[186]:

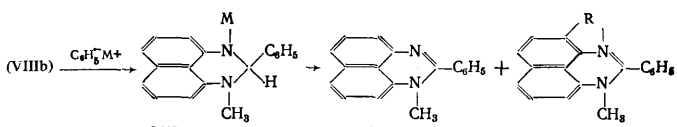
(LXXVI) (LXXVII)



As regards their behaviour with respect to organometallic compounds, perimidines resemble more closely azines, to which organometallic compounds usually add, than heterocycles with an excess of π electrons and azoles (pyrrole, indole, and benzimidazole), which are metallated by these compounds. Thus 1-substituted perimidines[117], aceperimidines, and aceperimidylenes[119] react with organometallic compounds regardless of temperature and solvents, forming 2,3-dihydroperimidines (LXXVIII):

(LXXVIII) R = Alk or Ar; R′ = H, Alk or Ar; R″ = Alk, Ar, or heteroaryl.

Only in one case, in the reaction of compound (VIIIb) with n-butyl-lithium, was the formation of a small amount of the 2-lithio-derivative detected: carboxylation of the reaction mixture led to the isolation of 1-methylperimidine-2-carboxylic acid in 8% yield[117]. It is of interest that the two naphthoimidazoles isomeric with perimidine behave in different ways with organometallic compounds. While the derivative of the linear naphthoimidazole forms adducts with organometallic compounds, derivatives of the angular isomer are metallated by the latter[119]. The addition of organometallic compounds to perimidines is attributed to their reduced aromaticity, the high polarisation of the C=N bond, and the relatively low CH acidity (the rate of base-catalysed deuterium exchange involving the Cμ–H proton has been measured[119]).

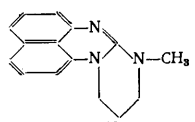


Alkali metal naphthalenides, which readily metallate azole rings, also fail to metallate compound (VIIIb).[141] Thus, treatment of compound (VIIIb) with lithionaphthalene in THF followed by treatment of the mixture with benzophenone or CO_2 gives rise to a mixture consisting of 1-methyl-2,3-dihydroperimidine and 1-methyl-2-(α-naphthyl)perimidine. The interactions of 2-chloro-1-methylperimidine (LXXIX) with butyl- and phenyl-lithium,[117] with alkali metals, and with alkali metal naphthalenides[41] were investigated as other possible synthetic pathways to 2-metalloperimidines. However, in these cases true metallation was not observed. Thus the reaction of compound (LXXIX) with butyl- or phenyl-lithium followed by treatment of the mixture with benzophenone or CO_2 yielded the following products:

(LXXIX)

The products of the interaction of compound (LXXIX) with lithionaphthalene proved to be compound (VIIIb), its 2,3-dihydro-derivative, and 1,1′-dimethyl-2,2′-diperimidine.

The use of benzophenone to bind 2-metalloperimidines which may be formed leads in many instances to extremely unexpected reactions. Thus, whereas compound (VIIIb) reacts with phenylsodium, forming 1-methyl-2-phenyl-2,3-dihydroperimidine in almost quantitative yields, treatment of the final mixture with benzophenone results in the formation of completely different products: 1-methyl-2-phenylperimidine (LXXX) and 1-methyl-2,4-diphenylperimidine (LXXXIa).[154] On the other hand, when phenylsodium is replaced by phenyl-lithium, the yield of compound (LXXX) falls and the main reaction product becomes the carbinol (LXXXb). Compound (XXX) is apparently formed as a result of the elimination of the metal hydride from the intermediate adduct (LXXXII) under the influence of benzophenone:



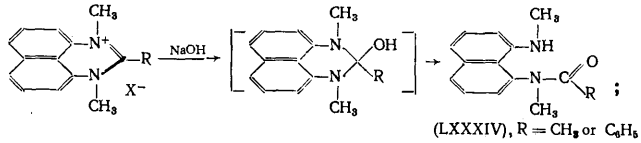
(LXXXII) (LXXX) (LXXXI)

(a) R = C_6H_5; (b) R = $(C_6H_5)_2COH$.

This is the only known reaction involving perimidines in which a nucleophile enters the naphthalene ring with its electron excess and not the 2-position.

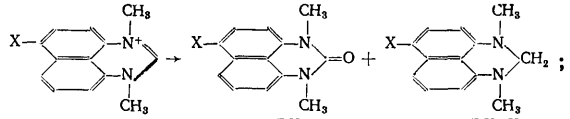
2-Chloroperimidines, obtained by treating perimidones with phosphoryl chloride, are highly reactive in reactions with nucleophiles[88]. Their halogen is readily exchanged for the NH_2 group[88,192] and the primary[16,192] and secondary[176] amine residues can be exchanged for azido-,[147,159,193] alkoxy-, and hydrazino-groups[194]. The rates of the piperidinolysis reactions of 2-chloro-1-methyl derivatives of perimidine, naphtho[2,3-*d*]imidazole, and naphtho[1,2-*d*]imidazole are in the proportions 420 : 33 : 1, which corresponds to the positive charges on the $C_{(2)}$ atoms in these heterocyclic systems[195].

When an attempt was made to synthesise 2-chloro-2-(γ-dimethylaminopropyl)perimidine from the corresponding perimidone and $POCl_3$, the amine (LXXXIII) was obtained unexpectedly[16]:



(LXXXIII)

4. The Interaction of Perimidinium Salts With Nucleophiles

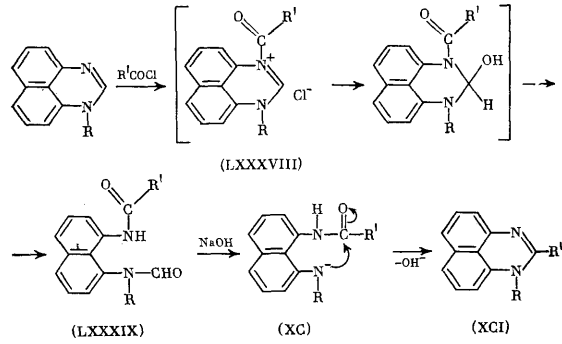


Compared with neutral perimidines, perimidinium salts exhibit a still greater reactivity in relation to nucleophiles. As already stated, they are readily reduced and readily

combine with organometallic compounds to form DHP.[117,196] The most important and interesting reactions of perimidinium salts are those under the influence of alkali agents. The salts substituted in the 2-position are converted into acyclic compounds (LXXXIV) on heating with alkalis, like imidazolium salts[46]:

(LXXXIV), R = CH_3 or C_6H_5.

However, 1,3-dialkylperimidinium salts without a substituent in the 2-position are almost quantitatively converted under these conditions into a mixture with the corresponding perimidone (LXXXVI) and 2,3-dihydroperimidine (LXXXVII), in which the perimidone may predominate somewhat; this reaction is of preparative value[146,156,158,178]:



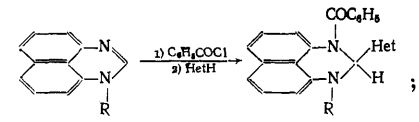
(LXXXV) (LXXXVI) (LXXXVII)

(a) X = H; (b) X = Cl; (c) X = NO_2; (d) X = CH_3CO; (e) X = SO_3^-.

Treatment of the 1,3-dimethylperimidinium cation with one mole of KNH_2 in liquid ammonia leads to results similar to those obtained on treatment with alkali, but the reaction with three moles of KNH_2 leads to the formation of 40% of *N,N'*-dimethyl-1,8-naphthylenediamine together with 1,3-dimethylperimidone[197].

The so-called recyclisation reaction is of very great synthetic importance in the perimidine chemistry[198,199]. Its principle is that treatment of 1-R-perimidines with aromatic, heteroaromatic, or vinylaromatic acids in the presence of mild bases (for example, triethylamine) results in the formation, via a stage involving the formation of *N*-acylperidinium salts (LXXXVIII), of *N*-acyl-*N'*-formyl-1,8-naphthylenediamines (LXXXIX), which recyclise on subsequent heating with alkali with elimination of the formyl group from the pseudo-base (XC) and the formation of a 1,2-disubstituted perimidine (XCI) containing in the 2-position the residue of the acid whose chloride had been used initially:

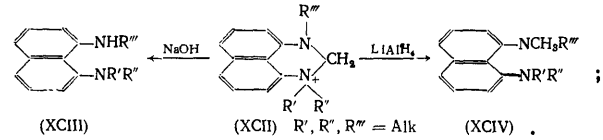
(LXXXVIII)



(LXXXIX) (XC) (XCI)

The reaction proceeds as a rule without side processes and has a high overall yield.

When compounds (LXXXIX) are heated with acids, the aroyl group is split off and the initial perimidine is reformed. On the other hand, when the deformylated pseudo-base (XC) is treated with an acid, it cyclises to compound (XCI), which is important for the synthesis of 1,2-diarylperimidines[165].



Derivatives of 2-phenylperimidine (XCI, R = C_6H_5) containing the following substituents R in the 1-position have been obtained in this way: methyl[198–200], allyl[174], benzyl, acetonyl, phenacyl, phenyl, methoxymethyl[165], and cyanoethyl[181]. The recyclisation of 1-methyl-, 1-(β-dialkylaminoethyl)-, and 1-(γ-dimethylaminopropyl)-perimidines by the chlorides of other carboxylic acids made it possible to introduce in the 2-position the halogenophenyl[38,199,200], methoxyphenyl[198–200], nitrophenyl[200], 3,4-methylenedioxyphenyl[200], α-naphthyl[41], α-furyl, α-thienyl[198,199], styryl, and β-(5-furyl)vinyl groups[198], as well as many other substituents. The recyclisation reaction also takes place with aceperimidines [198,199] and 1,9-trimethyleneperimidine[201]. However, it could not be achieved for benzo- and naphtho-imidazoles as well as perimidines with electron-accepting groups in the naphthalene ring (Cl, NO_2, and RCO).

The salts (LXXXVIII) obtained *in situ* undergo substitution by heteroaryl groups by reaction with heterocycles with an excess of π electrons[187]:

Het = 2-pyrrolyl or 3-indolyl.

1,1,3-Trisubstituted 2,3-dihydroperimidinium salts (XCII) are readily converted into tri-*N*-substituted salts (XCIII) on treatment with an excess of alkali, while their reduction with $LiAlH_4$ leads to tetra-*N*-substituted 1,8-naphthylenediamines (XCIV), which constitutes the best method of synthesising these compounds. For R''' = CH_3CO in the salts (XCII), treatment with alkali is accompanied by the elimination of the acetyl group and the formation of 8-dialkylamino-1-aminonaphthalenes (XCIII, R''' = H):[172]

(XCIII) (XCII) R', R'', R''' = Alk (XCIV).

On heating with elemental sulphur, perimidine and its derivatives are converted into thioperimidones[88,185].

5. Electrophilic Substitution Reactions

Perimidine is one of the most active heterocycles in relation to electrophiles, which can be explained by its high π-donor capacity and high negative π-electronic charge in the *ortho*- and *para*-positions of the naphthalene ring. Electrophilic substitution reactions involve precisely these positions; hitherto attacks by electrophiles on the 5- and 8-positions are unknown.

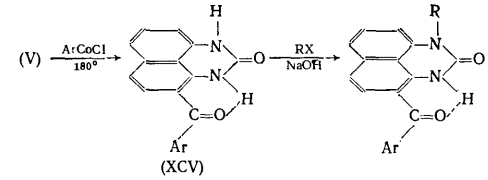
Electrophilic substitution reactions of perimidines are very sensitive to steric hindrance by the *N*-substituent. Very small species (D^+ and with much difficulty Cl^+) can enter the 4- and 9-positions in the presence of neighbouring *N*-methyl groups.

(a) Acid Deuterium Exchange

Perimidine, its 1- and 2-methyl derivatives, and 2-imino-1,3-dimethyl-2,3-dihydroperimidine do not undergo deuterium exchange on prolonged refluxing in CF_3COOD or CD_3COOD, as they exist exclusively in the cationic form under these

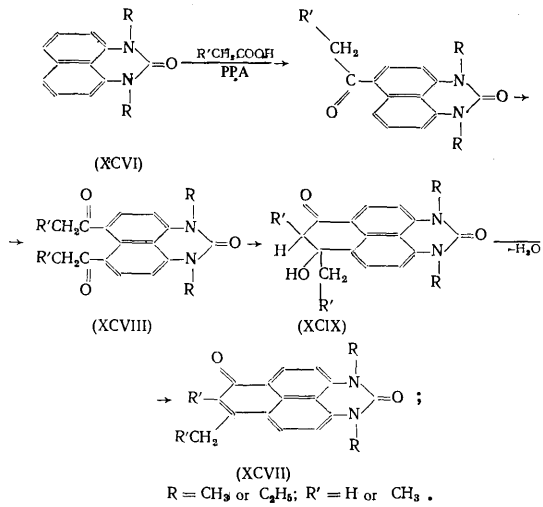
conditions. For deuterium exchange to become possible, the basicity of the compound must be lower than that of compound (I) by at least 2–3 pK_a units. This condition is satisfied particularly by 2-trifluoromethylperimidine (pK_a = 6.64 in acetonitrile) and 2-difluoromethylperimidine (pK_a = 8.90), which slowly exchange protons for deuterium on heating in CD_3COOD, but not by 2-fluoromethylperimidine (pK_a = 11.87), where only the protons of the CH_3 groups are exchanged under these conditions[166].

Deuterium exchange involving compound (I) and its alkyl derivatives takes place in concentrated D_2SO_4, but the reaction is complicated by the simultaneous sulphonation[156]. The H–D exchange involving compound (I) in the naphthalene ring can proceed via the *N*-anion (in C_2H_5OD), using its ambident properties. The reaction is slow and involves only the *ortho*-positions[166].



(b) Acylation

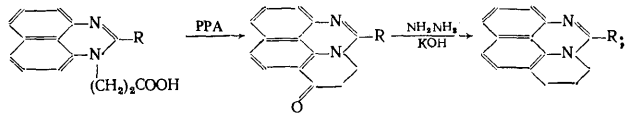
Perimidine is apparently the only heteroaromatic system with a pyridine nitrogen atom which undergoes Friedel–Crafts acylation comparatively readily. It is best to carry out the acylation with the aid of carboxylic acids in polyphosphoric acid (PPA). For compounds with an unsubstituted NH group, the reaction is clearly subject to kinetic and thermodynamic control. Mainly the 6(7)-acyl derivative (55–85%) is formed at 70–85 °C together with a small amount of the 9-isomer. At 120–150 °C the only reaction products become 4(9)-acylperimidines[144]. One of the causes of the increased stability of the latter is the presence of a strong intramolecular hydrogen bond.



1-Methylperimidine is acetylated with formation of a mixture of 6-, 7-, and 4-acetyl derivatives, which is difficult to separate and in which the first two isomers predominate appreciably. 2-Perfluoroalkylperimidines have certain unusual features[163]. They are not acetylated by carboxylic acids in PPA but undergo trifluoroacetylation extremely readily, without a catalyst, by trifluoroacetic anhydride (their acylation by the chlorides of perfluorocarboxylic acids is also possible, but the reaction is slow). Compounds with a free NH group then form only 9-acyl derivatives, while trifluoroacetylation of 1-methyl- and 1-phenyl-2-trifluoromethylperimidines proceeds with a high yield only in the 7-position[163]. On passing from 2-trifluoromethylperimidine to the more basic 2-difluoromethyl- and 2-fluoromethyl-perimidines, the trifluoroacetylation of the naphthalene ring proceeds with increasing difficulty, while compound (I) and its alkyl derivatives are not acylated at all by trifluoroacetic anhydride[163,166]. It is noteworthy that the 1,3-dimethylperimidinium cation is acetylated in the 6(7)-position with the CH_3COOH–PPA mixture under the same conditions as perimidine[178].

1,3-Dimethylperimidone is acylated quantitatively by trifluoroacetic anhydride in the 6-position[163]. The same product is obtained from the thione (LIV) under the same conditions. In the latter case the reaction is apparently also directed to the sulphur atom, after which the thiuronium salts formed hydrolyses to the corresponding perimidone (cf. Borovlev and Pozharskii[145]). On treatment with $(CF_3CO)_2O$, 1,3-dimethyl-2,3-dihydroperimidine chars, but careful acetylation of 1,2,2,3-tetramethyl-2,3-dihydroperimidine made it possible to obtain its 6-trifluoroacetyl derivatives in 21% yield[163].

It has been reported that unsubstituted perimidone (V) is acylated by benzoyl chloride in the presence of $AlCl_3$, but the structure of the product was not established[202]. It was shown later that satisfactory results are obtained in the acylation of compound (V) by aroyl chloride without a catalyst at 180 °C. The reaction product, which is the 4(9)-aroyl derivative (XCV), was subsequently alkylated in order to obtain dyes[183]:



The acylation of compound (V) by carboxylic acids in PPA leads to a mixture of its 4(9)- and 6(7)-acyl derivatives[185]. The acylation of 1,3-dialkylperimidones takes place only in the *para*-positions. When acetic and propionic acids are used, the reaction products are the monoacyl derivatives (XCVI) and phenalenones (XCVII).[145,185] It has been established[145] that phenalenones are formed via stages involving the diacylation and crotonylation of the diacyl derivatives (XCVIII) which, like th aldol (XCIX), could be isolated in special experiments. In those cases where aldol condensation is impossible (for example, in benzoylation), the isolation of a diacyl derivative does not present a problem[145]:

R = CH_3 or C_2H_5; R' = H or CH_3.

Under analogous conditions, 1,3-dimethyl-2,3-dihydroperimidine and the thione (LIV) do not form pericyclisation products and the reaction proceeds only up to the 6(7)-acyl derivative, which is consistent with the lower reactivity of dihydroperimidines and thioperimidones in acylation reactions compared with perimidones[145,185]. Other methods have also been developed for building the phenalenone ring onto perimidones, thioperimidones, and 2,3-dihydroperimidines[145].

In the series of perimidines and perimidones there is a possibility of intramolecular acylation reactions[181,201]; the resulting ketones can be converted by the Wolff–Kishner reaction into bridged systems, for example:

R = H, CH_3 or C_6H_5.

The unsubstituted perimidone undergoes simultaneous acylation by malonic acid diesters in the 1- and 9-positions[203].

The problems concerning the acylation of aceperimidines have been considered[144].

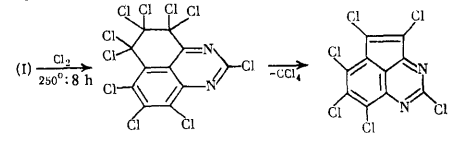
(c) Nitration

Depending on the amount and concentration of nitric acid, perimidines are nitrated (most effectively in acetic acid) to mono-, di-, and tri-, and tetranitro-derivatives[155], while aceperimidines are nitrated to the mono- and di-nitro-derivatives[182]. The initial nitration of perimidines with a free NH group is accompanied by charring, which reduces the yield, particularly for perimidine itself. Thus perimidine is nitrated on treatment with 1 mole of HNO_3 to 4(9)- and 6(7)-nitro-derivatives in proportions of 2.5 : 1 with an overall yield of 30%. Under the same conditions, aceperimidine gives rise to 50% of the 4(9)-nitro-derivative and 17% of the 4,9-dinitro-derivative, while 2-methylperimidine gives rise to the 4(9)- and 6(7)-nitro-derivatives in proportion of 1 : 2.5 with an overall yield of 64%. The nitration of mono-, di-, and tri-nitroperimidines proceeds without charring. When 1- and 2-methylperimidines are nitrated with 2 moles of HNO_3, a mixture of three dinitro-compounds, namely the 6,9-, 6,7-, and 7,9-dinitro-derivatives, is formed in yields of 40, 20, and 10% respectively. Nitration of compound (II) yields 4,9-dinitroaceperimidine. When an eightfold excess of HNO_3 is used, a mixture of 4,6,9- and 6,7,9-trinitroperimidines is formed, in which the second isomer predominates. By heating this mixture with an excess of fuming HNO_3, it is possible to obtain 4,6,7,9-tetranitroperimidines in yields up to 90%.[155,182]

It appears that only the initial nitration of perimidine proceeds via the cation. Indeed the 1,3-dimethylperimidinium cation is nitrated in the 6-position to the mononitro-derivative under the same conditions as perimidine[178]. However, the 6-nitro-1,3-dimethylperimidinium cation gives rise to only traces of the dinitro-compound on prolonged refluxing with fuming HNO_3.[149]

1-Methylperimidine is nitrated mainly in the *para*-positions, the yield of the 4-nitro-derivative amounting to only 9%.[155] The nitration of 1-methyl- and 1,2-dimethyl-aceperimidines[182] and 2-aminoperimidine[204] has also been described.

One of the most interesting features of perimidines and aceperimidines is the possibility of nitrating them with alkali metal nitrates in acetic acid[205]. The reaction takes place readily even at room temperature and makes it possible to introduce up to three nitro-groups into the naphthalene ring. For example, 2-methyl-6,7-dinitroperimidine is converted by 1 mole of $NaNO_2$ into 2-methyl-6,7,9-trinitroperimidine in 79% yield. In mono- and di-nitration the yields are higher owing to charring. The mechanism of the nitration of perimidines by nitrites is not altogether clear. It is striking that this reaction has been encountered also for a number of other polynuclear heterocyclic systems with a π-electron-donating capacity (phenothiazines[206] and porphyrins[207]), which suggests that the proccess may have a possible radical-cation mechanism[206,207]. Perimidines are extemely readily nitrated with nitrogen dioxide as far as the tetranitro-derivatives[205].



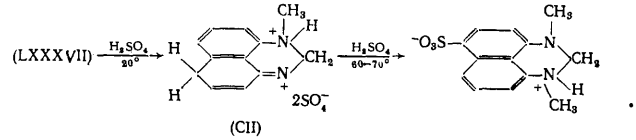
(d) Halogenation

The chlorination of perimidines[157], perimidones, and dihydroperimidines[146] with sulphuryl chloride in acetic acid and with *N*-chlorobenzotriazole (CBT) in an aprotic medium has been investigated. The chlorination of perimidine itself with 1 mole of SO_2Cl_2 leads to the formation of the 6(7)- and 4(9)-chloro-derivatives in proportions of 8 : 1. Treatment with 2 moles of SO_2Cl_2 results in the formation of a complex mixture of mono-, di- and tri-chloroperimidines, while treatment with 3 moles of SO_2Cl_2 gives rise to 4,6,7-trichloroperimidine in a high yield. Tetrachloroperimidine could not be obtained with the aid of SO_2Cl_2, while 2-methylperimidine is chlorinated to the tetrachloro-derivatives with an excess of SO_2Cl_2.

Fundamentally different results have been obtained with CBT. On treatment with CBT, perimidines with a free NH group undergo extensive oxidation, but 1-R-perimidines are chlorinated very smoothly by this reagent. The reaction initially involves the *ortho*-positions and only then are the *para*-positions substituted. Thus the reaction of compound (VIIIb) with 1 mole of CBT in chloroform at 0 °C gives rise to a mixture of 9-chloro-, 4-chloro-, and 4,9-dichloro-derivatives, while the reaction with 2 moles of CBT leads to only the 4,9-dichloro-derivative[157]. Subsequent chlorination yields the 4,7,9-trichloro- and then the 4,6,7,9-tetrachloro-derivatives. Analogous results have been obtained in the chlorination of 1,2-dimethylperimidine and 6,7-dichloro-1-methylperimidine with CBT. The steric hindrance to substitution in the 9-position in 1-isopropylperimidine is too great and the exhaustive chlorination product is 4,6,7-trichloro-1-isopropylperimidine[157].

The sharp difference in the mode of the initial attack between the reactions with SO_2Cl_2 and CBT can apparently be explained by the fact that the reaction proceeds via the cation and the base in the former and latter cases respectively. Indeed the 1,3-dimethylperimidinium cation is chlorinated mainly in the *para*-positions by both reagents[146]. 1,3-Dimethylperimidone is chlorinated with CBT initially also in the 4- and 9-positions and it was impossible to stop the reaction at the monochlorination stage. On treatment with CBT, 1,3-dimethyl-2,3-dihydroperimidine chars, while with the aid of SO_2Cl_2 initially the *ortho*-positions and then the *para*-positions can be chlorinated[146].

The chlorination of perimidine with liquid chlorine in an autoclave at 250 °C has been reported[208]. The reaction product was perchloro-5,6-dihydro-4*H*-perimidine (C), which was subsequently converted into a quinazoline derivative (CI):



(C) (CI)

Very little is known about the bromination of perimidines. When 2-methylperimidine was treated with bromine in acetic acid, only the mono- and di-bromo-derivatives were obtained, but their structure was not established[44]. The nitration of the hydrobromide of 2-aminoperimidine involves the introduction of bromine into the naphthalene ring together with nitro-groups[204].

(e) Sulphonation

Perimidine and its 2-substituted derivatives are sulphonated with concentrated H_2SO_4 even at 20 °C and below. The reaction is rapid and perimidine-6-sulphonic acids, which exist in a betaine form, are formed in a quantitative yield after 10–15 min[36,156]. With increase of reaction time, further sulphonation takes place, but the polysulphonic acids could not be isolated in a pure form[156]. The sulphonation of the 1,3-dimethylperimidinium cation and 1,3-dimethylperimidone also takes place readily, but 1,3-dimethyl-2,3-dihydroperimidine is sulphonated only at a temperature not less than 70–80 °C as a consequence of the formation of the dication (CII):[156]

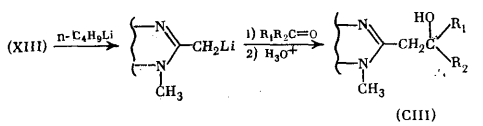
(CII)

(f) Azo-coupling

As shown in an early study by Sachs[6], perimidines are excellent azo-components and give rise to blue azo-derivatives on treatment with diazonium salts. The reaction proceeds in the *para*-positions and has been described for perimidine itself and its 2-substituted derivatives[209], 6(7)-chloroperimidine[20], and 2-aminoperimidine[210].

(g) The Reactivity Indices and the Mode of Electrophilic Attack

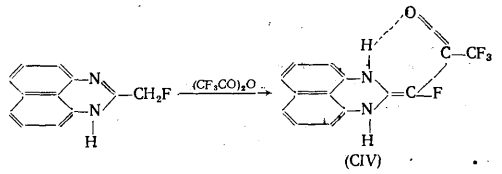
According to quantum-chemical molecular orbital calculations, the *ortho*-positions in the perimidine molecule and in the perimidinium cation have a higher negative π-electronic charge than the *para*-positions (see above). Nevertheless, as can be seen from the foregoing, the vast majority of electrophilic reactions of perimidines take place initially in the 6- and 7-positions. It has therefore been suggested[144] that the electrophilic substitution reactions of perimidines are controlled by the cation localisation energies rather than the π-electronic charges. Indeed, the latter are appreciably smaller than in the *para*-positions both in the perimidine base and in its cation[144]. However, the localisation energies do not explain why the chlorination of perimidines with CBT, which probably proceeds via the uncharged form, is initially directed to the *ortho*-positions. This suggests that the charges nevertheless play a decisive role (in the absence of steric effects) in electrophilic substitution in perimidine bases, while the *ortho*-substitution in the cation is significantly counteracted by the field effect, which is not taken into account in molecular orbital calculations on isolated molecules. The study of other electrophilic substitution reactions involving unsubstituted perimidine is extremely desirable in this connection.



6. The Properties of Certain Functional Groups in Perimidine Derivatives

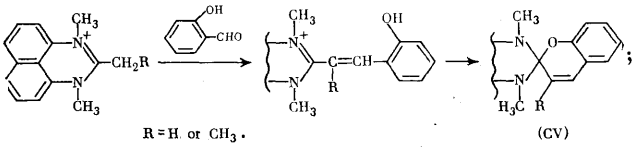
The perimidine nucleus exerts an appreciable influence on the properties of the functional groups linked to it.

(a) 2-Methylperimidines



The hydrogen atoms of the CH_3 group in these compounds are characterised by a considerable mobility. Thus, according to the results of a study of the base-catalysed H–D exchange involving the 2-methyl group in 1,2-dimethylperimidine, the kinetic acidity of the methyl group is higher than in 1,2-dimethyl derivatives of imidazole, naphtho[1,2-*d*]imidazole, benzimidazole, and naphtho[2,3-*d*]imidazole by 3.9, 3.2, 2.3, and 0.3 orders of magnitude respectively[196], which agrees with the decrease of the positive charge on the $C_{(2)}$ atom in the above series.

When compound (XIII) is treated with n-butyl-lithium, the CH_3 group is metallated, which has been used for the synthesis of the carbinols (*CIII*):[196]

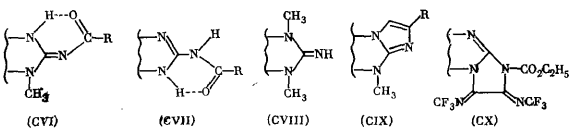


(CIII)

2-Fluoromethylperimidine, where, in contrast to 2-methyl- and 2-difluoromethyl-perimidines, the protons of the CH_2 group exchange for deuterium on heating in CD_3COOD and undergo trifluoroacetylation on treatment with $(CF_3CO)_2O$,[166] exhibits an unexpectedly high reactivity in relation to electrophiles. The product of the last reaction exists in the tautomeric methide form (CIV) stabilised by an intramolecular hydrogen bond. Similar chelates are characteristic also of other perimidines in which one or two protons of the 2-methyl group have been substituted by acidifying substituents:

(CIV)

2-Methylperimidines condense in the absence of a catalyst with various aldehydes, forming 3-styrylperimidines[211–213]. If the aldehyde contains an electron-accepting substituent (e.g. NO_2), the reaction can be stopped at the stage involving the formation of the corresponding carbinols[211]. 2-Methylperimidinium salts have also been introduced into this reaction[173,214]. In particular, the spiropyrans (CV) have been obtained by this method from salicylaldehyde and 2-hydroxy-1-naphthaldehyde[43]:

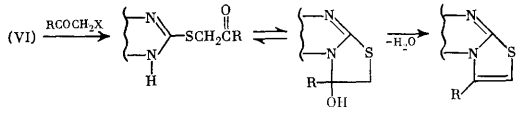


R = H or CH_3. (CV)

5-Nitrosalicylaldehyde forms in this reaction merocyanine, which could not be converted into a spiropyran.

(b) 2-Aminoperimidines

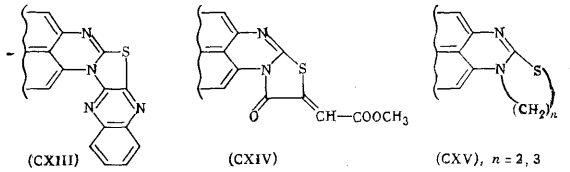
In connection with the amine–imine tautomerism of 2-aminoperimidines, their basicities and electronic and infrared spectra have been investigated[150,192]. At the same time studies have been made of the analogous properties of the fixed amine and imine models. Compared with the majority of other heteroaromatic amines, including 2-aminoimidazoles, 2-aminoperimidines exhibit a much greater tendency towards a shift of the equilibrium in the direction of the imino-form, whose concentration reaches 2%.[150] 1-R-2-Acylaminoperimidines and aceperimidines exist entirely in the imino-form (CVI), but, in the absence of a substituent in the 1-position, the amino-form (CVII) persists[215]. In both cases the preferred tautomer is stabilised by an intramolecular hydrogen bond.



(CVI) (CVII) (CVIII) (CIX) (CX)

In their chemical behaviour 2-aminoperimidines in general resemble other heteroaromatic amines. Their alkylation in a neutral medium involves the pyridine nitrogen atom and makes it possible to obtain imines of type (CVIII).[216] There is also a possibility of the alkylation of the amino-group to 2-alkylamino- or 2-dialkylamino-perimidines, which is achieved by carrying out the reaction in liquid ammonia in the presence of potassium amide[217–219]. 2-Aminoperimidines are acylated at the amino-group with formation of compound (CVI) or (CVII),[192,215] but they form azomethines with a great deal of difficulty[216], while their interaction with α-halogenocarbonyl

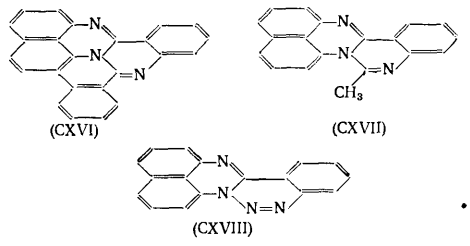
compounds readily converts them into derivatives of imidazo-[1,2-*a*]perimidine (CIX).[220] The synthesis of compounds (CX) from perimidine-2-methylcarbamate has been described[221].



(c) 2-Mercaptoperimidines

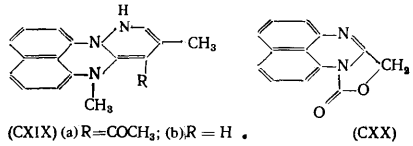
Thioperimidone (VI) is acylated by α-halogenocarbonyl compounds at the sulphur atom with formation of compound (CXI).[222–225] The latter exists predominantly in the acyclic form (CXIa) but the cyclic structure (CXIb) predominates for R = H, CH_3, or C_2H_5.[222] When compound (CXIb) is treated with dehydrating agents, derivatives of thiazolo[3,2-*a*]perimidine (CXII) are formed[223–225]:

(CXIa) (CXIb) (CXII)



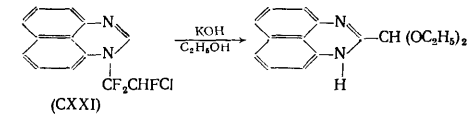
The reaction of compound (VI) with 2,3-dichloroquinoxaline[226], dimethyl acetylenedicarboxylate[227] or α,ω-dihalogenoalkanes[228] leads to the formation of compounds (CXIII)–(CXV) respectively.

(CXIII) (CXIV) (CXV), $n = 2, 3$



(d) Other Compounds

A series of bridged heterocyclic systems (CXVI)–(CXVIII) have been obtained from 2-(2′-aminophenyl)perimidine: compound (CXVI) has been synthesised by heating 2-(2′-benzamidophenyl)perimidine with $AlCl_3$,[229] compound (CXVII) has been obtained by heating 2-(2′-acetamidophenyl)perimidine with acetic anhydride, and compound (CXVIII) has been obtained by diazotising 2-(2′-aminophenyl)perimidine[32]:



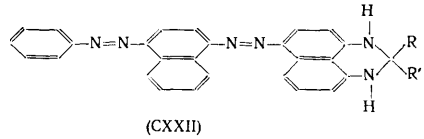
(CXVI) (CXVII) (CXVIII)

On treatment with acetic anhydride in the presence of potassium carbonate, the 1,3-dimethyl-3-aminoperimidinium salt gives rise to a derivative of pyrazolo[2,3-*a*]perimidine (CXIXa), which is deacylated on heating with HCl to form compound (CXIXb).[175] On treatment with chlorocarbonic ester in the presence of NaH, 2-hydroxymethylperimidine is converted into compound (CXIX):[26]

(CXIX) (a) R=$COCH_3$; (b) R = H (CXX)

An interesting recyclisation reaction has been observed on heating compound (CXXI) in an alcoholic solution of KOH:[180]

(CXXI)



The reduction of the ethyl ester of perimidine-1-acetic acid to 1-(β-hydroxyethyl)perimidine and of 2-(2-furyl)perimidine to 2-(2-tetrahydrofuryl)perimidine has been described[25]. The 6(7)-trifluoroacetyl derivatives of perimidones and *N*-substituted perimidines are converted on heating with aqueous alkali into perimidone-6-(7)-carboxylic and perimidine-6(7)-carboxylic acids[166].

Studies of 2-azidoperimidines have shown that they exist in the form of tetrazolo[1,5-*a*]perimidines[159,193].

V. PRACTICAL APPLICATIONS

Numerous patents for the use of alkyl, aryl, azo-, sulpho-, and acyl-derivatives of perimidine, their quaternary salts, and perinones as dyes were issued in the first quarter of the present century. Although the structure attributed to the dyes was incorrect and in many instances still remains unelucidated (for example, the structure of the product of the interaction of 2-methylperimidine with phthalic anhydride)[7], many of them have found practical applications. The bibliography of the publications on this subject up to 1956 can be found in Richmond's review[5]. During the last 25 years, the salts of 2-styrylperimidines[213,230,231] and dispersed dyes based on 4(9)-aroylperimidones[184], *N*-aroylperimidones[232], phthaloylperimidones[233], 6(7)-azoperimidines[209,234], the amides of perimidine-6,7-dicarboxylic acid[127–129,235] and perimidone-6,7-dicarboxylic acid[236], and perinones[130,237] have been proposed as dyes for synthetic fibres.

Azodyes of the type of Sudan Black B with structure (CXXII) have found extensive applications in recent years in the dyeing of various fibres[238–242], as additives to liquid crystal displays[243], and in many other instances[244–249]:

(CXXII)

Phenalenones of type (CXVII) have been proposed as phosphors with a high fluorescence quantum yield[250–252], while perimidine and its 1- and 2-alkyl(aryl)-derivatives have been suggested as cationo-active additives to solutions for contact copper-plating of aluminium[253]. Perimidine-6(7)-sulphonic acids containing in the 2-position hydrophobic groups, a high-molecular-weight alkyl group, or a perfluoroalkyl group exhibit an appreciable antistatic activity[36]. By virtue of the exceptionally low solubility in water of its sulphate and the stability of its colloidal solutions, 2-aminoperimidine has recently found applications as a highly sensitive reagent for the determination of sulphuric acid[254] and sulphates[255] in air (for a complete bibliography, see Ishikawa et al.[79]).

2-Amino-6(7)-[4-acetophenylazo]perimidine[210] has been suggested as a reagent for the determination of microamounts of SO_3^{2-} ions and perimidine itself has been suggested as a reagent for the gravimetric determination of copper[256]. 1,3-Di(β-hydroxyethyl)perimidone is used in the manufacture of polyester fibres[257].

Numerous communications have been devoted in recent years to the biological activity of perimidines. Various 1- and 2-substituted perimidines have been proposed as highly effective antiulcer agents[26,258-265] and neurotropic preparations (both depressants and stimulants of the central nervous system have been discovered[16,109,134,175,177,200]). 2-Arylperimidines exhibit carcinostatic activity[266]. A moderate or weak antimicrobial activity of 2-aminoperimidines[216], the anoretic activity of compounds (CXII) and (CXV),[228] and the antihelminthic activity of 2-acyl-amino-[84] and 2-styryl-perimidines[212] have been reported. Certain perimidines exhibit an extremely marked fungicidal activity[83,191].

The Basicity and Nucleophilicity of Arsenyl Compounds†

V.S.Gamayurova

Data are presented on the nature of the As=O bond in compounds of tetracoordinate arsenic. Problems associated with the manifestation of the electron-donating properties of arsenyl compounds, particularly their basicity in various media as well as their proton-accepting capacity in the formation of hydrogen-bonded complexes, are examined. The electron-donating and proton-accepting capacities of compounds of the type R_nEO, where E=N, P, As, Sb, S, Se, or Te, are compared. The reactions of arsenyl compounds with a wide variety of electrophiles as well as other reactions involving the arsenyl group are discussed. The bibliography includes 172 references.

I. INTRODUCTION

A large amount of scattered data have now accumulated on the physicochemical and chemical properties of tetracoordinate arsenic compounds containing the arsenyl group. There are no reviews wholly devoted to this problem, but compounds containing the arsenyl group have been mentioned in monographs[1-4], reviews[5-18], and dissertations[19,20].

Substances containing the As=O bond constitute one of the most numerous groups of organoarsenic compounds, which play an important role both in laboratory practice and in certain branches of the economy (for example, as extractants in hydrometallurgy, medicinal preparations, herbicides, etc., [21,22]). Furthermore, the characterisation of the structure and properties of arsenyl compounds makes a definite contribution to the understanding of the structure and reactivity of compounds containing the E=O bonds (E=C, Si, P, Se, Te, etc.).

The aim of the present review is to survey the literature data, mainly for the last ten years, concerning the nature of the As=O bond as well as the basicity and nucleophilic reactivity of compounds of tetracoordinate arsenic. The nucleophilic properties of these compounds as well as their basicity, which, according to Edwards and Pearson[23], is a special case of the manifestation of nucleophilic reactivity, are determined by the presence of the arsenyl group. The review does not deal with methods for the synthesis arsenyl compounds, because these have been published in monographs[1-4] or, with their complex formation reactions with various metal salts, since the literature on this problem is extensive and its survey should be the subject of a special review.

Table 1. Certain physical characteristics of the As=O bond.

Type of compound	Compound	r (As=O) (r (As–O)), Å	$\nu_{As=O}$, cm^{-1}	$k_{As=O}$, mdyn Å^{-1}	Bond order	μ, D	$\mu_{As=O}$, D

Remarks: *a*) monohydrate; *b*) the bond lengths r(As=O) and r(As–O) may become equalised as a result of the involvement of the oxygen of the arsenyl bond in a hydrogen bond[34]; *c*) calculated values; *d*) for $Bu_2As(O)OBu$; *e*) for $(EtO)_3AsO$; *f*) for $PhAs(O)(OH)_2$.

Note. Here and in the other tables the numbers in square brackets denote references (Ed.of Translation).

†By analogy with the phosphoryl bond P=O, the term arsenyl bond for As=O is more useful than another term sometimes encountered in the literature.

II. THE NATURE OF THE ARSENYL BOND

The nature of the arsenyl bond has been discussed in numerous studies[19,20,24-30]. All the investigators have concluded that the arsenyl bond is complex and differs from covalent, single, and double bonds and at the same time is not a purely semipolar bond. Certain physical characteristics of the arsenyl bond are listed in Table 1.

Comparison of the As=O and As–O bond lengths shows that the difference between them (up to 0.1 Å) is much smaller than the difference between the sums of the radii of As and O atoms involved in single and double bonds (0.17 Å).[34] Calculation of the lengths of formally double and single bonds, r(As=O) and r(As–O), from the Schomaker-Stevenson formula yields 1.58 and 1.74 Å respectively[29]. Table 1 shows that the experimental value of r(As=O) differs from the above values. Unfortunately the experimental values of r(As=O) refer to the arsenyl group whose oxygen atom is involved in a hydrogen bond.

It has proved convenient to investigate arsenyl compounds by vibrational spectroscopic methods, particularly by infrared spectroscopy[20,24,29,30,35,36,37,41-50]. It has been established that the vibration which is characteristic not only as regards frequency but also as regards mode, corresponds to the arsenyl group in the infrared spectrum. The As=O stretching vibration makes a contribution greater than 95% to the band assigned to the vibration of this bond, while in the case of the As–O bond there is no rigorously characteristic vibration[20,24,36]. Calculations of the stretching vibration frequencies ν(As–O) and ν(As=O) yielded 670 and 1010 cm^{-1}.[29] The calculated and experimental data for the arsenic–oxygen single bond are similar; ν(As=O) is active in the range 600–748 cm^{-1}.[29,50]. The regions where ν(As=O) is active for different derivatives of tetracoordinate arsenic are given in Table 2. Evidently ν(As=O) is active in the range 845–980 cm^{-1} and the experimental values thus differ from the values calculated for the double bond. The influence of substituents on the spectral characteristics of the As=O bond are as a rule additive, as for P=O.[44] A linear relation has been discovered between ν(As=O) and the sum of the constants χ of the substituents at the arsenic atom[29]: $\nu(As=O) = 720 + 30\Sigma\chi$, where χ are the substituent constants (the "group electronegativities" of the substituents derived for phosphoryl compounds). There is a similar relation also for the P=O bond[64]: $\nu(P=O) = 930 + 40\Sigma\chi$.

Such additivity shows that the phosphoryl and arsenyl groups are not directly involved in the resonance interaction with the substituents at the phosphorus and arsenic atoms, which does not, however, rule out the probability of a specific interaction of certain substituents with phosphorus and arsenic atoms[44]. Thus, for "narrow" series, for example, for *para*-substituted phenyl phosphonates and dialkylarylarsine oxides, p-$XC_6H_4P(O)(OEt)_2$ and p-XC_6H_4.$As(O)Et_2$, a linear relation has been found between ν(P=O) and ν(As=O), on the one hand, and the Hammett constants for *para*-substituents, on the other[42]: $\nu(As=O) = 904 + 5\sigma$, $r = 0.98$; $\nu(P=O) = 1260 + 9\sigma$, $r = 0.92$. Since the Hammett constants include a resonance component, the existence of such relations can be treated as evidence for the conjugation of the substituents with the phosphorus and arsenic atoms. Shagidullin[42,44] arrived at the same conclusion in the analysis of ultraviolet spectroscopic data. Analysis of the M=X vibrational frequencies in compounds of the type $R_3M=X$, where M=P, As, or Sb, X=O, S, Se, or Te, and R are alkyl groups, showed[35], that, for identical R, the frequency ν(M=X) depends on the mass of the molecule and the electronegativities of the M and X atoms:

$$\nu_{M=X} = k\left[\frac{\Sigma M}{(m_M\ m_X)}\right]^{1/2} E_M E_X,$$

where M is the mass of the molecule, m the mass of the given atom, and E the electronegativity of the atom.

The differences between the stretching vibration frequencies ν(As=O) in the spectra of various compounds of tetracoordinate arsenic, the differences between the force constants of the As=O bond, and calculations of the order of this bond based on infrared spectroscopic data (Tables 1 and 2) showed, that, depending on the environment of the arsenic atom, the bond multiplicity N varies from 1.4 to approximately 1.8 $N \cong 1.5$ for arsine oxides, $k_{P=O} = 8.25$ and $N \cong 1.9$ for the oxide Me_3PO, and $k_{N\to O} = 3.90$ and $N = 0.65$ for Me_3NO.[30] Many investigators explain such differences in the multiplicities of the NO, PO, and AsO bonds on the basis of the concept of vacant d orbitals[19,20,30,55,56]. Although the NO bond in amine oxides can be regarded as the semipolar $(CH_3)_3\overset{+}{N}-O^-$ linkage, nevertheless calculations of the electronic structures of the compounds X_3NO have shown that there is some displacement of the electrons of the oxygen atom to the nitrogen atom: $p_\pi(O) \to p_\pi(N)$.[56] In phosphorus and arsenic compounds there is a possibility of p_π–d_π interaction between the vacant

Table 2. The regions where the ν(As=O) stretching vibrations are active in the infrared spectra of compounds of tetracoordinate arsenic.

Compound	R_3AsOH ‖ O	RAs(OH)$_2$ ‖ O	R_3AsO	R_3AsOR' ‖ O	RAs(OR′)(NR″$_2$) ‖ O	RAs(OR′)$_2$ ‖ O	(RO)$_2$AsNR′$_2$ ‖ O	(RO)$_3$AsO
$\nu_{As=O}$, cm^{-1}	870 [22]	845–940 [31,51]	880–910 [35,41]	920–930 [48,49]	940–950 [52]	950–960 [29,43]	940–960 [53]	955–978 [24,50]

2*p* orbitals of oxygen and the corresponding 3*d* and 4*d* orbitals of the heteroatoms, which leads to an increase of the multiplicity of the phosphoryl and arsenyl bonds. Since $2p_\pi-3d_\pi$ interaction is energetically more favourable than the $2p_\pi-4d_\pi$ interaction, the above interaction plays a more important role in the phosphorus compounds and leads to a greater increase in the multiplicity of the P=O bond.

This situation has also been confirmed by the dissociation energies of the E=O bonds. The dissociation energy of the arsenyl bond has been determined from thermochemical data for the oxides As_4O_{10} [57] and Ph_3AsO.[58] For comparison, Table 3 presents the dissociation energies of the element–oxygen bonds. It is seen from these data that the dissociation energy of the phosphoryl bond is much higher than for other E=O bonds (cf. also the dissociation energies of the N→O and P=O bonds in F_3NO and F_3PO, which are 410 and 540 kJ mol^{-1} respectively[69]). The difference between the dissociation energies of single element–oxygen bonds is much smaller. If the difference between the dissociation energies of single and double bonds is assumed to be, after Mitchell[55], the contribution of the π-component to the formation of the E=O bond, then, according to the data in Table 3, this contribution is 217–301 kJ mol^{-1} (159 kJ mol^{-1} according to Mitchell[55]) for phosphorus and 88–142 kJ mol^{-1} for arsenic. In the carbonyl group the contribution of the π-component is much greater, amounting to 335–377 kJ mol^{-1}, which can be explained by certain factors, including the shorter length of the CO bond and the more effective $p_\pi-p_\pi$ overlap[55].

Table 3. The element–oxygen bond dissociation energies.

Compound	Bond	Bond energy, kJ mol^{-1}	Compound	Bond	Bond energy, kJ mol^{-1}	Compound	Bond	Bond energy, kJ mol^{-1}
E_4O_6 [57]	P—O	335	E_4O_{10} [57]	P=O	653	Ph_3EO [58]	P=O	552
»	As—O	301	»	As=O	389	»	As=O	443
»	Sb—O	297	»	Sb=O	399	»	Sb=O	439

Measurements of the dipole moments of compounds of tetracoordinate arsenic and calculations of the dipole moments of the As=O bond (see Table 1) indicate a high polarity of this bond. The relative polarity of the As=O bond in tertiary arsine oxides is higher than that of the As=S bond in the analogous sulphides, which can be accounted for by two factors: the stronger $p_\pi-d_\pi$ interaction between the sulphur and arsenic atoms and the smaller charge separation in the σ-bond as a consequence of the lower electronegativity of the sulphur atom[59].

Comparison of the dipole moments of the arsenyl and phosphoryl bonds (Tables 4 and 1) shows that higher values are characteristic of the As=O bond in the analogous compounds and that the difference Δμ increases with the number of electronegative substituents linked to the heteroatom.

The influence of the arsenyl group is reflected in the ^{1}H NMR spectra by a downfield shift of the proton signals of the substituents linked to the arsenic atom[20,25,26,62]. An analogous effect has also been observed for substituents linked to the phosphoryl group[63]. The arsenyl bond exerts a deshielding influence on both methyl and methylene protons (a displacement of the signals by 0.55–0.75 p.p.m.) and on phenyl protons (a displacement by approximately 0.35 p.p.m.). The regions where the proton-containing groups linked to the heteroatom in the tervalent state are manifested correspond to the electronegativities of the heteroatoms of[20] and are similar for arsenic and phosphorus compounds (Table 5). An increase of coordination number from three to four causes an appreciable alteration of the chemical shifts (Δδ, Table 5) for arsenic and phosphorus compounds and, as for the dipole moments (Δμ, Table 4), the difference increases with increase of the number of electronegative substituents (from 0.13 to 0.64 p.p.m.).

Table 4. Comparison of the dipole moments of the phosphoryl and arsenyl bonds: $\Delta\mu = \mu_{As=O} - \mu_{P=O}$.

Compound	$\mu_{P=O}$, D		Δμ, D
Me_3EO	4.3	[60,61]	0.9
$R_2(RO)EO$	1.6	[61]	2.2
$(RO)_3EO$	0.2	[61]	2.3

The increase can be accounted for in terms of the increasing role of $p_\pi-d_\pi$ interaction for phosphorus compounds with increase of the number of electronegative substituents at the phosphorus atom. It is known that, with increase of the positive charge on the atom (P or S), its 3*d* orbitals contract and favourable conditions are created for the overlap with the 2*p* orbitals of oxygen[64,65] (an increase in the multiplicity of the phosphoryl bond leads to a decrease of the dipole moment and of electron-attracting character in the bond to proton-containing substituents).

Table 5. The chemical shifts of the proton-containing groups linked to heteroatoms[20].

Compound	δ_{E-Me} (δ_{E-CH_2}), p.p.m.	Δδ*, p.p.m.	Compound	δ_{E-Me} (δ_{E-CH_2}), p.p.m.	Δδ*, p.p.m.
Me_3As	0.94	—	Me_3NO	3.32	−1.63

*$\Delta\delta = \delta_{As-Me} - \delta_{E-Me}$.

If $\Delta'\delta = \delta_{OEMe} - \delta_{EMe}$ is adopted as characteristic of the change in the charge on the heteroatom, then the charge for different E varies in the sequence N > As > P ($\Delta'\delta$ = 1.2, 0.75, and 0.58 p.p.m. respectively).

X-Ray electronic spectroscopy appears to be extremely promising for the estimation of effective atomic charges in compounds and of the donor-accepter capacity of the ligands[66]. X-Ray spectroscopic methods have been used to investigate the $R_2S-R_2SO-R_2SO_2$ and $R_3NO-R_3PO-R_3AsO$ series[67,68]. X-Ray emission spectra of the sulphur atoms in Me_2SO and Me_2S indicate partial population of the 3*d*

orbital of the sulphur atom in the oxide as a result of $p_\pi-d_\pi$ interaction. The X-ray spectra of the oxygen in R_3EO (E = N, P, or As) also reveal $p_\pi-d_\pi$ interaction in R_3PO. The available data for R_3NO and R_3AsO are insufficient to rule out completely the occurrence of π-bonding in these compounds, but one may conclude that, even if it does occur, it is much weaker than in R_3PO.[67] The determination of the energy of the 1s level of oxygen in the compounds $(C_8H_{17})_3NO$, $(iso\text{-}C_5H_{11})_3PO$, and $(C_8H_{17})_3AsO$ yielded $E(O1s) = 531.3$, 532.2, and 530.0 eV respectively[68]. The energy of the 1s level of oxygen in R_3PO is a maximum, i.e. the negative charge on the oxygen atom in phosphine oxides is a minimum, the value of $E(O1s)$ in phosphine oxides and sulphoxides being similar [$E(O1s)$ = 532.1 eV for R_2SO].[68]

Summarising the investigations of the arsenyl bond, one must conclude that the nature of the arsenyl linkage can be represented by several structures differing in their multiplicity:

$$R_3\overset{\oplus}{As}-\overset{\ominus}{O} \leftrightarrow R_3\overset{\delta+}{As} \cdots \overset{\delta-}{O} \leftrightarrow R_3As{=}O.$$

The multiplicity is influenced by the nature of the substituents linked to the arsenic atom: electron-donating substituents decrease the multiplicity (a semipolar bond), while electron-accepting substituents increase it.

Problems associated with the nature of the arsenyl bond will also be considered in Section III in connection with the basicities of tertiary arsine oxides in water[70] and nitromethane[71]. Proton-containing solvents, including water, reduce the charge on the oxygen atom as a result of the formation of hydrogen bonds with the oxygen of the arsenyl group. In contrast to the behaviour in nitromethane, tertiary arsine oxides are therefore weak bases in water whose pK_a are independent of the length of the hydrocarbon group attached to the arsenic atom[70] (the levelling influence of water).

Thus the arsenyl bond is a complex labile linkage, which varies from a semipolar to a partially multiple bond.

III. THE BASICITY AND PROTON-ACCEPTING CAPACITY OF ARSENYL COMPOUNDS IN THE FORMATION OF HYDROGEN BONDS

The ability of the arsenyl group to participate in complex formation with metal salts, hydrogen bonding, and acid-base interactions is the most important and most characteristic property of arsenyl compounds. The question of the possible classification of all these interactions of the donor–acceptor type and the role of charge transfer in these processes are controversial[72–75]. However, it has come to be assumed that the complexes of oxygen-containing extractants R_nEO with metal salts are formed via the mechanism of electron donor–electron acceptor interactions (EDA).[76] The classification of hydrogen-bonded complexes as EDA complexes has also been receiving increasing recognition[73,74]. Bent's view[77] that the formation of a hydrogen bond is the first stage in acid–base reactions with proton transfer has also been widely accepted[74,75].

Although there exists a view[73] that the pK_a cannot serve as a reliable measure of the electron-donating and electron-accepting molecules, nevertheless the basicity of compounds of the type R_nEO (E = N, P, As, S, or Se), which we shall call for brevity oxa-bases, is at present the best characteristic of the electron-donating capacity of oxygen, since the extracting capacity of these compounds varies in parallel with their basicity[67,75]. It has been shown[75] that the parameters characterising the hydrogen bond should characterise more adequately than the basicity (pK_a) the distribution of electron-density in the molecule in the ground state.

The constants characterising basicity and proton-accepting capacity in the formation of hydrogen bonds are thermodynamic data and cannot yield direct information about reaction mechanisms, but they do have a great advantage over kinetic data, because they can be used directly to compare the structures of the compounds[78].

Numerous studies have been devoted to the determination of the basicities of arsenyl compounds and other oxa-bases, but comparison of the pK_a obtained by different groups of investigators is difficult because of the lack of generally accepted standard methods; this applies particularly to titration in non-aqueous media. When arsenyl compounds are titrated, quaternary arsonium salts are formed ($R_3AsO + H^+ \rightarrow R_3AsOH^+$) and, although the arsenic atom is not involved in the protonation process, the multiplicity of the arsenic–oxygen bond changes[79].

The basicity of derivatives of tetracoordinate arsenic depends on the electronic effects of the substituents at the arsenic atom, which is also a consequence of the lability of the arsenyl bond. Different derivatives of tetracoordinate arsenic give rise to the following series based on the variation of basicity[71]:

$$RAs\begin{matrix}OR' \\ \| \\ O \\ NR''_2\end{matrix} > R_3AsO > R_2As(O)OR' \geqslant R_2As(O)OH >$$
$$> RAs(O)(OR')_2 \geqslant RAs(O)(OH)_2 > (RO)_3AsO \quad .$$

In this series the high basicity of the amidoesters of arsonic acids is due to the protonation of the nitrogen atom of the amido-group[71,78] and does not therefore indicate a high polarity of the arsenyl bond in these compounds.

Numerous correlation equations have now been found for the relation between the pK_a for the arsenyl compounds and the substituent constants σ, σ^+, σ^-,[81] σ^*, σ_I^{Ph}, and σ^{Ph} [49,71,82,83]. The use of σρ-analysis for organoarsenic compounds has been surveyed in a review[79] whose authors concluded that mainly the inductive effects of the substituents are transmitted via the arsenic atom.

The basicities of arsine sulphides and selenides are very much lower than those of arsine oxides[82,84], which, as mentioned above, corresponds to lower polarities of the As = S and As = Se bonds compared with As = O.

The comparison of the basicities and proton-accepting capacities in the formation of hydrogen bonds in the oxa-bases of Group VA and VIA elements incorporating similar functional groups E = O (E → O), responsible for the above properties of these compounds, is of very great interest. In contrast to non-oxidised compounds, examination of the oxa-bases of Group VA and VIA elements makes it possible to eliminate the influence of steric factors from the comparison. Thus analysis of numerous literature data on intermolecular hydrogen bonding involving compounds of Group VA and VIA elements shows that in the compounds R_2EO and R_3EO the influence of steric effects of the substituents is virtually absent, while in the compounds R_2E and R_3E it is large[85].

Hitherto mainly the problem of the involvement of compounds of the type R_2E and R_3E, where E are Group VA and VIA elements, in the formation of hydrogen bonds and acid–base interactions has been discussed in the literature[72,78,86,90]. It has been discovered for a large number of examples that the electron-donating capacities of the compounds R_2E and R_3E, where R is an alkyl substituent, diminish on passing to heavy elements: N > P > As > Sb and

O > S > Se > Te, the greatest differences being observed on passing from elements of the Second Period to those of the Third Period—from nitrogen to phosphorus and from oxygen to sulphur. Within any Period, for example, with increase of the number of the Group, the electron-donating capacity falls: N > O > F; P > S > Cl; As > Se > Br; Sb > Te > I. On passing to aromatic derivatives (R = Ar), complexes involving the π-system of the benzene ring as the proton acceptor appear; in this case there is a possibility of an inversion of the series based on the variation of the electron-donating capacity[86]. Thus the electron-donating capacity within a single Period decreases with increasing electronegativity of the heteroatoms, while within a single Group the electron-donating capacity increases as the electronegativity of the heteroatom increases; this gives rise to difficulties in the analysis of factors determining the electron-donating capacity of compounds.

The direction in which the electron-donating capacity changes within a single Period can be accounted for simply and logically—an increase of the electronegativity of the heteroatom leads to a greater difficulty of the abstraction of valence electrons; this is consistent with the increase of the ionisation potential and with decrease of the electron-donating capacity of the elements[78].

According to modern ideas, the electron-donating capacity of compounds is determined by two factors: the charge transfer from the *np* orbital of the atom E to the antibonding σ orbital of the A–H bond of the proton donor and the overlap of the 1s orbitals of the H atom with the *n* orbitals of the electron donor[72,86]. The increase of I hinders the charge transfer, which entails a decrease of the electron-donating capacity[72]. Since the ability of the orbitals to overlap decreases with increasing diffuseness of the orbitals of the donor *n* electrons, i.e. with increase of the principal quantum number *K*, the influence of the overlap within a single Period can be regarded as constant[86]. Within a single Group, an increase of the atomic number of the element entails a decrease of *I* and an increase of *K*, i.e. both factors (charge transfer and the overlap of the orbitals) exert an influence on the electron-donating capacity of the elements and there is a possibility of partial or complete cancelling of these effects[86].

The data for the basicities of the oxa-bases of Group VA and VIA element of the type R_nEO are presented below.

(1) Acid—H_2SO_4, comparison parameter—pK_a, solvent—water[87]:

$$\underset{4.65}{Me_3NO} > \underset{3.75}{Me_3AsO} > \underset{0.9}{Me_2SO} > \underset{-3.2}{Ph_2MePO} > \underset{-6.15}{PhMeCO}\ .$$

The basicity increases in the sequence N > As > P.

(2) Acid—$HClO_4$, comparison parameter—pK_a, solvent—water[88]:

$$\underset{2.55}{Me_2SeO} > \underset{1.02}{C_5H_5Me_2NO} > \underset{1.01}{Ph_3AsO} > \underset{0.79}{C_5H_5NO} > \underset{0.54}{Ph_2SeO} > \underset{-2.10}{Ph_3PO} > \underset{-2.03}{(PhCH_2)_2SO} > \underset{-3.19}{Ph_2SO}$$

or $Ph_3AsO > C_5H_5NO > Ph_2SeO > Ph_3PO > Ph_2SO$. The basicity decreases in the sequences As > N > P, Se > S, As > Se, and P > S.

(3) Acid—$HClO_4$, comparison parameter—ionisation constant K_i, solvent—acetic acid[88]:

$$\underset{4.60\cdot10^6}{Ph_3AsO} > \underset{2.73\cdot10^6}{C_5H_5Me_2NO} > \underset{4.18\cdot10^5}{Ph_2SeO} > \underset{2.82\cdot10^5}{C_5H_5NO} > \underset{2.72\cdot10^2}{Ph_2PO} > \underset{9.34}{Ph_2SO};\ \underset{10^8}{Me_2SeO} > \underset{3.44\cdot10^3}{Me_3PO} > \underset{3.50\cdot10^2}{Me_2SO}\ .$$

The basicity decreases in the sequences As > N > P, Se > S, As > Se, and P > S.

(4) Comparison parameter—pK_a, solvent—water#:[89]

$$\underset{6}{Me_2TeO} > \underset{5.36}{Me_3SbO} > \underset{4.65}{Me_3NO} > \underset{3.75}{Me_3AsO} > \underset{2.55}{Me_2SeO} > \underset{0}{Me_3PO} \simeq \underset{0}{Me_2SO}\ .$$

The basicity decreases in the sequences Sb > N > As > P, Te > Se > S, Te > Sb, and As > Se.

(5) Acid—$HClO_4$, comparison parameter—pK_a, solvent—nitromethane[84]:

$$\underset{12.76}{Ph_3SbO} \geqslant \underset{12.58}{Ph_3AsO};\ \underset{16.58}{Oct_3SbO} > \underset{16.18}{Oct_3AsO}\ .$$

The basicity decreases in the sequence Sb > As.

Data for the proton-accepting capacities in the formation of hydrogen bonds by the oxa-bases of Group VA and VIA elements of the type R_nEO are presented below.

(1) Proton donor—HSCN, comparison parameter—Δν, solvent—CCl_4:[88]

$$Oct_3PO > Me_3PO > Ph_3PO > Me_2SO > (PhCH_2)_2SO > Ph_2SO\ .$$

The proton-accepting capacity decreases in the sequence P > S.

(2) Proton donor—PhOD, comparison parameter—Δν, solvent—CCl_4:[88]

$$Ph_3AsO > Me_2SeO > C_5H_3(Me)_2NO > Oct_3PO \geqslant Me_3PO > C_5H_5NO > Ph_3PO > Me_2SO > (PhCH_2)_2SO > Ph_2SO\ .$$

The proton-accepting capacity decreases in the sequences As > N > P, Se > S, and P > S.

(3) Proton donor—methanol, comparison parameter—Δν, solvent—CCl_4:[88]

$$Ph_3AsO > Me_2SeO > C_5H_3(Me)_2NO \simeq Oct_3PO > C_2H_5NO > Me_3PO > Ph_2SeO > Ph_3PO > (PhCH_2)_2SO > Ph_2SO\ .$$

The proton-accepting capacity decreases in the sequences As > N > P, Se > S, As > Se, and P > S.

(4) Proton donor—indole, comparison parameter—Δν, solvent—CCl_4:[88]

$$Ph_3AsO > Me_2SeO > Oct_3PO > C_2H_5NO > Me_3PO > Ph_2SeO > Ph_3PO > C_5H_3(Me)_2NO > Me_2SO > (PhCH_2)_2SO > Ph_2SO.$$

The proton-accepting capacity decreases in the sequences As > N > P, Se > S, As > Se, and P > S.

(5) Proton donor—PhN(Me)H, comparison parameter—Δν, solvent—CCl_4:[88]

$$Ph_3AsO > Me_2SeO > Oct_3PO > C_5H_5NO > Me_3PO > C_5H_3(Me)_2NO \simeq Ph_2SeO \simeq Ph_3PO > Me_2SO > (PhCH_2)_2SO > Ph_2SO\ .$$

The proton-accepting capacity decreases in the sequences As > N > P, Se > S, As > Se, and P > S.

(6) Proton donor—HOOCPhX (X = 3-NO_2, 4-NO_2, or 3-Cl), comparison parameter—Δν, crystalline adducts[91]:

$$Ph_3AsO \simeq C_5H_5NO > Ph_3PO\ .$$

The proton-accepting capacity decreases in the sequence As ≅ N > P.

(7) Proton donor—phenol, comparison parameters—Δν, ΔH, and K_d^{298}, solvent—CCl_4:[92,93]:

$$R_3AsO > R_3PO;\ Oct_3AsO > Bu_3AsO > Ph_3AsO\ .$$

The proton-accepting capacity decreases in the sequence As > P.

(8) Donors—Ph_3COH and Ph_3COD, comparison parameters—Δν, crystalline adducts[94]:

$$Ph_3AsO > Ph_2SeO > Ph_2SO\ .$$

#The salts, for example, $R_nEO.HNO_3$, were titrated with alkali[89].

The proton-accepting capacity decreases in the sequences Se > S and As > Se.

(9) Proton donor—water, comparison parameter—$K_{298°}$, solvent—CCl_4:[95,96]

$$Alk_3AsO > Alk_3PO;\ Oct_3AsO > Ph(Oct)_2AsO > Bu_3AsO > Ph_2(Oct)AsO > Et_3AsO\ .$$

The proton-accepting capacity decreases in the sequence As > P.

(10) Proton donor—water, comparison parameters—$\Delta\nu$, E_H, and $\overline{K}$, solvent—CCl_4:[67]

$$Oct_3NO \simeq Oct_3AsO > iso\text{-}Am_3PO > Oct_2SO > (BuO)_3PO\ .$$

The proton-accepting capacity decreases in the sequences N ≅ As > P and P > S.

(11) Proton donor—CF_3COOH, comparison parameter—ΔH, solvent—CCl_4:[97]

$$Oct_3NO > Oct_3AsO > C_5H_5NO > Me(Bu)_2PO > Me_2SO > (BuO_3)PO\ .$$

The proton-accepting capacity decreases in the sequence N > As > P > S.

(12) Proton donor—CF_3COOH, comparison parameter—ΔH, solvent—benzene[98]:

$$Et_3AsO > Ph_3AsO > Et_3AsS\ .$$

(13) Proton donor—CCl_3COOH, comparison parameter—ΔH, solvent—CCl_4:[97]

$$Oct_3AsO > C_5H_5NO > Oct_3PO > (C_6H_{13})_2SO\ .$$

The proton-accepting capacity decreases in the sequence As > P > S.

(14) Proton donor—4-FC_6H_4OH, comparison parameter—ΔH, solvent—CCl_4:[99,100]

$$Me_3NO > Me_3PO \simeq C_5H_5NO > Me_2SO\ .$$

The proton-accepting capacity decreases in the sequence N > P > S.

(15) Proton donor—$CH_2ClCOOH$, comparison parameter—ΔH, solvent—CCl_4:[101]

$$Oct_3PO > Ph_2SeO > Ph_3PO > Me_2SO > Ph_2SO\ .$$

The proton-accepting capacity decreases in the sequences P > S and Se > S.

(16) Proton donor—$CHCl_2COOH$, comparison parameter—ΔH, solvent—CCl_4:[101]

$$Oct_3PO > Ph_2SeO > Ph_3PO > Me_2SO > Ph_2SO\ .$$

The proton-accepting capacity decreases in the sequences P > S and Se > S.

(17) Proton donor—PhC ≡ CH, comparison parameter—$\Delta\nu$, solvent—CCl_4:[88]

$$Ph_3AsO > Me_2SeO > Oct_3PO > Ph_2SeO > C_5H_3(Me)_2NO \simeq \simeq Me_3PO > Ph_3PO > C_5H_5NO \geq Et_2SO \geq Me_2SO > Ph_2SO\ .$$

The proton-accepting capacity decreases in the sequences As > P > N, Se > S, As > Se, and P > S.

Evidently the sequences in which the basicity (pK_a) and the parameters characterising the hydrogen bond ($\Delta\nu$, ΔH, K, and E_H) vary are in most cases the same. It has been stated[88] that a simple relation between the pK_a and the parameters characterising the hydrogen bond holds for strong proton donors. For weak proton donors (for example, phenylacetylene), the pK_a and the parameters characterising the hydrogen bond do not always vary in parallel. Since the main bulk of the available experimental data on the involvement of the oxa-bases R_nEO in hydrogen bonding refer to strong proton donors, i.e., according to the classification adopted by Sergeev[102], these are moderately strong and strong hydrogen bonds, we observe a correspondence between the degree of protonation (i.e. the pK_a) and hydrogen bonding (i.e. $\Delta\nu$, ΔH, K, and E_H).

It is known that charge transfer from the donor to the acceptor molecule assumes an appreciable role in the formation of hydrogen-bonded complexes with strong and moderately strong hydrogen bonds[73,104]; on this basis, the above hydrogen-bonded complexes have been included in the general system for the classification of charge-transfer complexes, i.e. they can be regarded as EDA complexes.

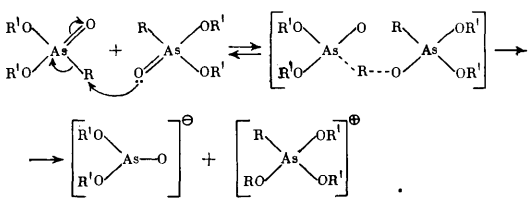
The observed correspondence between the parameters characterising the basicity (pK_a) and the hydrogen bond ($\Delta\nu$, ΔH, E_H, and K) shows that these quantities characterise reliably the electron-donating capacity of the oxa-bases. The possibility of a correlation between the parameters of the hydrogen-bonded complexes and the pK_a has been questioned[73]. It was stated that such correspondence can refer only to a narrow range of analogous complexes, where the acid–base interaction proceeds up to the formation of solvated ions. Evidently, the oxa-bases, which are weak acceptors in ionisation (they are protonated in media with a high acidity[103]) and strong acceptors in hydrogen bonding[88], are precisely the type of compounds whose protonation leads to the formation of solvated ions.

It follows from the data presented that the electron-donating capacity of aliphatic derivatives Alk_nEO is always greater than that of aromatic derivatives Ar_nEO and that the replacement of alkyl groups by alkoxy-groups also entails a decrease of the electron-donating capacity of the oxa-bases. Comparison of the oxa-bases with substituents of the same type is therefore legitimate for the detection of the influence of E on the electron-donating capacity.

Analysis of the data presented permits the following conclusions. The first conclusion is the same as that reached in the analysis of the properties of the oxygen-free bases R_nE formed by Group VA–VIIIA-elements[72,78,86]: within any Period, the electron-donating capacity of the oxa-bases R_nEO decreases with increase of the number of the Group regardless of the Period under consideration. In all cases the basicity and proton-accepting capacity of phosphine oxides are greater than those of the sulphoxides and those of arsine oxides are greater than those of selenoxides. According to Nylen[89], the only exception is that Me_2TeO is somewhat more basic than Me_3SbO, but this requires an experimental test, since the author himself[89] believes that the pK_a for Me_2TeO has been determined only approximately.

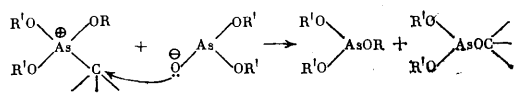
There is a non-monotonic variation of the electron-donating capacities of the oxa-bases R_nEO within a single Group—the oxa-bases of the Second and Fourth Periods are stronger electron-donors than the oxa-bases of the Third Period (always $R_3NO > R_3PO$, $R_3AsO > R_3PO$, and $R_2SeO > R_2SO$); the oxa-bases of the Fifth Period are stronger electron donors than those of the Fourth Period ($R_3SbO \gtrsim R_3AsO$ and $R_2TeO > R_2SeO$).

Thus the following series based on the variation of the electron-donating capacities of the oxa-bases can be set up within Groups VA and VIA: Sb > As > P < N or Sb > As ≅ N > P and Te > Se > S. We may note that the electron-donating capacities of arsine and amine oxides are similar, so that, according to the data presented above, they frequently change places (this finding is also evidence in support of the semipolar nature of the arsenyl bond in arsine oxides). Consequently, partial inversion of the series based on the variation of the electron-donating capacity found for the non-oxidised bases R_nE has been observed for the oxa-bases R_nEO: N > P > As > Sb and O > S > Se > Te.[72,78]



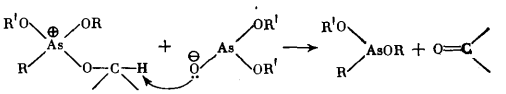
The observed characteristics of the variation of the electron-donating capacities of the oxa-bases R_nEO, where E are Group VA and VIA elements, on the whole agree with the known type of variation of the electronegativities and

the ionisation potentials *I* of these elements: with increase of the number of the Group and with decrease of the atomic number of the element within the Group (i.e. from left to right and from below upwards in the Periodic System), the electronegativity and *I* increase, which should naturally entail a decrease of the electron-donating capacity. The nitrogen atom is an exception in this instance.



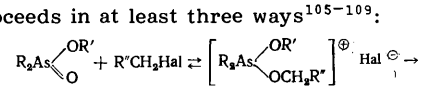
As stated above, the overlap of the 1*s* orbitals of the hydrogen atom with the *n* orbitals of the donor plays an appreciable role in the formation of hydrogen bonds in addition to the charge transfer from the *np* orbital of the donor to the antibonding orbital of the A–H acceptor. When the oxa-bases R_nEO are involved in the formation of hydrogen bonds, the 1*s* orbitals of hydrogen always overlap with the *n* orbitals of oxygen, i.e. the second factor may be regarded as constant. The influence of E on the electron-donating properties of the oxa-bases, which is transmitted via the oxygen atom, evidently reduces to an influence on the charge transfer from the oxygen atom (donor) to the acceptor molecule.

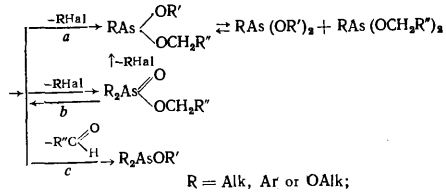
IV. THE NUCLEOPHILIC PROPERTIES OF ARSENYL COMPOUNDS



Many reactions are now known in which the nucleophilic properties of arsenyl compounds in relation not only to the proton but also to the carbon atom are manifested. An example of such reactions is the thermal transformations of arsonic and arsinic acids and arsine oxides. The mechanisms of these fairly complex reactions have been analysed in detail[19]. The pyrolysis of arsenyl compounds apparently begins with the nucleophilic attack by the oxygen of the arsenyl Group on the α-carbon atom attached to the arsenic atom:

Further attack by the anion on the α-carbon atom of the cation leads to isomerisation products:

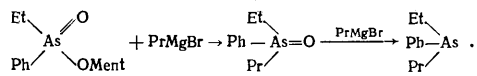




while the reaction involving the hydrogen at the α-carbon atom of the cation leads to the formation of reduction products and aldehydes:

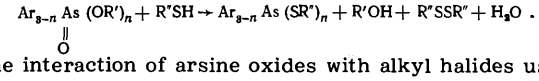
Isomerisation predominates for arsonic acid esters, while reduction predominates for arsine oxides[19].

Together with thermal transformations, the interaction of arsenyl compounds with electrophiles has been studied. The interaction of arsonic and arsinic acid esters with alkyl halides proceeds in at least three ways[105–109]:



(1)

R = Alk, Ar or OAlk;
R′ = Alk; R″ = Alk or Ar .



Nucleophilic attack by the oxygen of the arsenyl group on the α-carbon atom of the alkyl halide leads to the formation of an alkoxyarsonium salt, further reactions of which are determined by the nature of the reactants and the reaction conditions. In the presence of an aliphatic carbon atom linked to arsenic (alkylarsonic and dialkylarsinic acid esters) the attack by the nucleophile is directed to the α-carbon atom of the alkoxyarsonium cation; as a result, a retro-Arbuzov rearrangement of the initial esters takes place (pathway *a*) with formation of a new alkyl halide. The esters of alkyl alkylarsonous and arsenous acids formed under these conditions are usually symmetrised. If the alkyl halide produced in this reaction (RHal) is more reactive than the initial halide ($R''CH_2Hal$), then RHal will subsequently participate in the reaction preferentially and isomerisation products will predominate among the reaction products.

Pathway *b*, i.e. attack by the nucleophile on the α-carbon atom of the calkoxy-group of the alkoxyarsonium cation as a result of which the arsenyl group is regenerated, is characteristic of aromatic derivatives (esters of arylarsonic and diarylarsinic acids). The pathway in which the nucleophile abstracts a proton from the α-carbon atom of the alkoxy-group (α-elimination), which results in the formation of an aldehyde and the product of the reduction of the initial ester, obtains for the same compounds under more severe conditions (on increase of reaction temperature to 180–195 °C).

The menthyl esters of alkylarylarsinic acids react with alkylmagnesium halides with inversion of the configuration and for a molar reactant ratio of 1 : 1 a tertiary arsine oxide is formed, while for a ratio of 1 : 2 reduction to the corresponding arsine takes place[110]:

The reduction of quinquevalent arsenic acid esters is also observed in their reactions with mercaptans, which entails an exchange of the alkoxy-group of the ester for the mercapto-group[111]:

The interaction of arsine oxides with alkyl halides usually leads to the dehydrohalogenation of the alkyl halide by the oxide with formation of 2 : 1 adducts (I), olefins, and hydroxyarsonium salts[70,112–115]:

Adduct (I) has a structure with a symmetrical hydrogen bond between the oxygen atoms and an ionic or covalent bond between the hydrogen atom and the halogen: $[R_3AsO...H...OAsR_3]^{\oplus}\,Hal^{\ominus}$.[116] Analogous products have also been isolated in the reaction of triphenylarsine oxides with monohalogenoacetate esters, chloroacetone, and chloroacetonitrile[117].

If the arsenic atom is linked to even one aliphatic carbon atom, then, together with the reactions indicated above, the retro-Arbuzov rearrangement of the arsine oxides

(yield from 7 to 75%) takes place, as for arsonic and arsinic esters[118–122]:

$$R_3AsO + R'Hal \rightarrow R_3AsOR' .$$

The mechanism of the reaction of arsine oxides with alkyl halides has been studied in many investigations[19,70,123–127] and, although there are certain discrepancies in the treatment of the individual stages of the reaction by different workers, there is no doubt about the first reaction stage—the nucleophilic attack by the oxygen of the arsenyl group on the α-carbon atom of the alkyl halide, leading to the formation of an alkoxyarsonium salt:

$$R_3AsO + HalCR'_2 - CHR''_2 \rightarrow [R_3AsOCR'_2 - CHR''_2]^{\oplus}Hal^{\ominus}.$$

Further reactions of the alkoxyarsonium salt are also determined by the nature of the reactants and the reaction conditions:

$$[R_3AsOCR'_2 - CHR''_2]^{\oplus}Hal^{\ominus} \rightarrow \begin{cases} \xrightarrow{a} R_3AsOCR'_2 - CHR''_2 + RHal \\ \xrightarrow[b]{+R_3AsO} CR'_2 = CR''_2 + [HOAsR_3]^{\oplus}Hal^{\ominus} \rightarrow 2R_3AsO \cdot HHal . \end{cases}$$

The retro-Arbuzov rearrangement (*a*) takes place when the nucleophile attacks the α-carbon atom of the alkoxyarsonium salt, as for arsonic and arsinic acid esters. Pathway (*b*), involving the abstraction of a proton from the β-carbon atom of the alkoxy-group of the arsonium cation by another arsine oxide molecule, obtains only for arsine oxides. Evidently, as a consequence of the higher basicity of arsine oxides compared with other compounds of tetracoordinate arsenic, they are capable of competing with another nucleophile present in the reaction sphere, namely the halide anion. The large size of the nucleophile (arsine oxide) apparently precludes α-elimination accompanied by the formation of aldehydes (as for arsonic and arsinic acid esters), as a result of which β-elimination, leading to the formation of an olefin, takes place.

In the reaction of trialkylarsine oxides with acid halides, there is a rearrangement analogous to the retro-Arbuzov rearrangement (yield 95%):[120]

$$Pr_3AsO + CH_3COCl \rightarrow Pr_3AsOCCH_3 .$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad \| \\ \qquad\qquad\qquad\qquad\qquad\qquad\quad O$$

However, the reactions of triphenylarsine oxide with acetyl bromide and chloride result in the formation of dihalogenoarsoranes[128,129]:

$$Ph_3AsO + CH_3COHal_2 \rightarrow Ph_3AsHal_2 + (CH_3CO)_2O .$$

Such substitution also takes place in the reaction of triphenylarsine oxide with phosgene[130]:

$$Ph_3AsY + COCl_2 \rightarrow Ph_3AsCl_2 + COY ;$$
$$Y = O \text{ or } S$$

and with arsenic trichloride[131].

Depending on the structure, arsine oxides react with hydrogen halides in different ways[132–135]:

$$\underset{(I)}{R_3AsO} + HX \rightleftarrows R_3AsO \ldots \underset{(II)}{HX} \rightarrow \underset{(II)}{[R_3AsOH]^{\oplus}X^{\ominus}} \rightleftarrows \underset{(III)}{R_3AsX_2} + H_2O .$$

The reaction of tertiary arsine oxides, having a comparatively low basicity, for example, the derivatives of dihydrophenarsazine, stops at the first stage involving the formation of hydrogen-bonded adducts (with partial proton transfer[134]). Complete proton transfer to the oxygen of the arsenyl group leads to the formation of a salt-like product (II) [113,133,135,136], which can be dehydrated in the presence of an excess of hydrogen halides with formation of dihalogenoarsorane (III).[132,133].

Summarising the entire complex range of reactions occurring when oxygen-containing compounds of tetracoordinate arsenic interact with electrophiles, one can distinguish four principal pathways: the retro-Arbuzov rearrangement (*a*) characteristic of arsenyl compounds having at least one C_{aliph}–As bond; the protonation of the oxygen of the arsenyl group with formation of a hydroxyarsonium salt (*b*), which can undergo further reactions; the exchange reaction (*c*), which can lead not only to the formation of new arsenyl compounds but also to the regeneration of the initial reactants; the reduction of the initial arsenyl compounds (*d*), which usually occurs at elevated temperatures:

$$R_3AsO + R'X \begin{cases} \xrightarrow{a} R_2AsOR' \\ \xrightarrow{b} [R_3AsOH]X \begin{cases} \xrightarrow{+R'X} R_3AsX_2 \\ \xrightarrow{+R_3AsO} 2R_3AsO \cdot HX ; \end{cases} \\ \underset{c}{\rightleftarrows} R_2AsOR' + RX \\ \qquad\qquad\quad \| \\ \qquad\qquad\quad O \\ \xrightarrow{d} R_3As \end{cases}$$

$R = Ar$, Alk or OAlk; $R' = HAlk$, CH_2COR, CH_2CCN, CH_2CCH_3, AlkMg, CCl_3COOH or $AsCl_3$; $X = Hal$.

In all these reactions the primary step is nucleophilic attack by the oxygen of the arsenyl group on the electrophile, leading to the formation of alkoxyarsonium salts.

Thus onion salts play the main role in the reactions of compounds of tetracoordinate arsenic with electrophiles. Analogous onion salts are also formed in the reactions of other oxa-bases R_nEO with electrophiles. In the reactions of phosphoryl compounds with alkyl halides, quasi-phosphonium salts are formed[137]:

$$\underset{\|}{R_2POR'} + R''Hal \rightarrow [R_2P(OR')(OR'')]^{\oplus}Hal^{\ominus} \rightarrow \underset{\|}{R_2POR''} + R'Hal , \qquad (2)$$
$$O \qquad\qquad\qquad\qquad\qquad\qquad O$$

in the reactions of amine oxides the products are alkoxyammonium salts[138]:

$$R'CH_2Hal + R_3NO \rightarrow [R_3NOCH_2R']^{\oplus}Hal^{\ominus} \rightarrow R'C\begin{matrix} O \\ \diagup\!\!\diagdown \\ H \end{matrix} + R_3N , \qquad (3)$$

and in the reactions of sulphide oxides the products are alkoxysulphonium salts $[R_2SOR']^{\oplus}Hal^{\ominus}$.[65]

Alkoxyarsonium salts are extremely reactive, so that attempts to obtain them by alkylating arsine oxides did not lead to the desired result at −75 °C even when the halide anion was replaced by the less reactive perchlorate and tetrafluoroborate anions[139]. Instead of alkoxyarsonium salts, the adduct of the arsine oxide with the corresponding acid, $2R_3AsO.HX$, was always isolated.

Alkoxyarsonium salts have been obtained by the reaction of tertiary arsines with t-butyl hypohalites at temperatures in the range between −5° and −10 °C [140,141] and by the reaction of methyl dimethylarsinite with methyl iodide[142]. A whole series of products, usually observed in the pyrolysis of arsine oxides[19], were isolated in the thermal decomposition of alkoxyarsonium salts[140]. In addition t-butyl halide and arsine oxide were isolated, which constitutes indirect evidence for the possibility of an exchange reaction when arsine oxides interact with alkyl halides, giving rise to the regeneration of the arsenyl group (this corresponds to pathway *b* in scheme 1), which indicates that processes of the same type occur in the interaction of compounds of tetracoordinate arsenic (arsine oxides and arsonic and arsinic acid esters) with alkyl halides.

Trimethylmethoxyarsonium iodide interacts instantaneously with arsine oxide, forming the usual adduct $2Me_3AsO.HI$,[142] which confirms the hypothesis[124-126] that the rate-limiting stage of the reaction of arsine oxides with alkyl halides is the formation of alkoxyarsonium salts. The report[143] of the synthesis of an alkoxyarsonium salt from tripropylarsine oxide and ethyl bromide on refluxing the components in benzene is evidently erroneous.

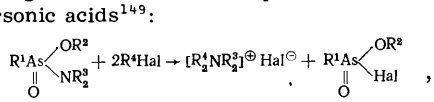
A rearrangement of the type of the retro-Arbuzov rearrangement, which is common for arsenyl compounds, is not characteristic of phosphoryl compounds, for which the bond equilibrium

is displaced towards the tetracoordination form for E = H or C and A = O or S; only for E = P is there a possibility of the existence of both tautomeric forms[144].

The possibility of the retro-Arbuzov rearrangement is determined by the mode of nucleophilic attack on the alkoxyonium cation $[C_{aliph}-E-OC]^{\oplus}$. When E = As, the nucleophile attacks preferentially the α-carbon atom at the arsenic atom, whereas for E = P the attack by the nucleophile is directed to the α-carbon atom of the alkoxy-group. This finding can be explained as follows. Firstly, the strength of the $C_{aliph}-As$ bond is much lower than the strength of the $C_{aliph}-P$ bond in analogous compounds (by 40.2 kJ mol^{-1} and more).[69,145] Secondly the arsonium cation should be stabilised preferentially via an inductive mechanism: $C \rightarrow C \rightarrow As^{\oplus} \leftarrow O \leftarrow C$. The $p_\pi-d_\pi$ interaction of the oxygen and arsenic atoms is then weak or absent, while in the stabilisation of the alkoxyphosphonium cation $p_\pi-d_\pi$ conjugation should play a significant role and should therefore lead to considerable positive polarisation of the α-carbon atom of the alkoxy-group, which facilitates in its turn nucleophilic attack on this atom.

In contrast to the reactions of compounds of tetracoordinate arsenic with electrophiles described above, the reaction of trialkyl arsenates, which have the smallest basicity among arsenyl compounds[71], with electrophiles such as arsenic trihalides and phosphorus trichloride takes place with the retention of the arsenyl group and the formation of tetra-alkyl meta-arsenates[146,147]:

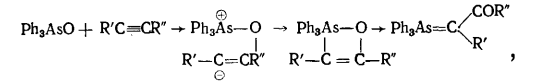
$$2\,(RO)_3AsO + 2AsHal_3 \rightarrow (ROAsO_2)_2 + 2RHal + 2ROAsHal_2\ .$$



The interaction of trialkyl arsenates with phosphorus trichloride is also complicated by an oxidation-reduction reaction in which trialkyl arsenate behaves as an oxidant:

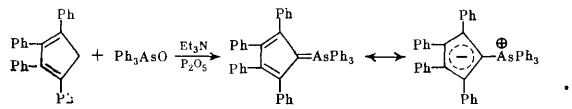
$$(RO)_3AsO + PCl_3 \rightarrow (RO)_3PO + AsCl_3\ .$$

A similar oxidation-reduction reaction has also been observed in the interaction of arsine oxides and tertiary phosphines[148]:



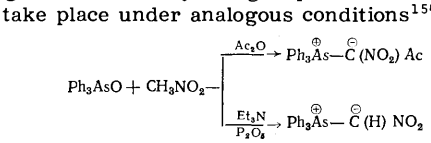
$$R_3AsO + R_3P \rightarrow R_3PO + R_3As\ .$$

In the reactions of amidoesters of arsonic acids with electrophiles (alkyl halides and halogenoesters) a competition might have been expected between the two nucleophilic centres of the amidoester molecule—the oxygen atom of the arsenyl group and the nitrogen atom of the amido-group. However, the study of the products of these reactions showed that the nitrogen atom is the nucleophilic centre in the amidoesters of arsonic acids[149]:

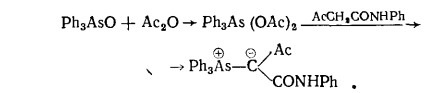


which also agrees with the conclusion that these derivatives are protonated at the nitrogen atom[71,80].

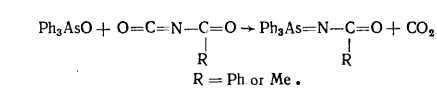
The nucleophilic reactivity of arsenyl compounds in relation to an unsaturated carbon atom is manifested, for example, in the reactions of triphenylarsine oxide with highly electrophilic reagents such as activated acetylenes (dicyanoacetylene and others).[148] It has been suggested that the reaction proceeds via the formation of a zwitterion:



and that the ylid formed as a result of the reaction is resonance-stabilised. Triphenylphosphine oxide is less reactive in this kind of reaction because it reacts only with dicyanoacetylene and at a higher temperature than triphenylarsine oxide[148].

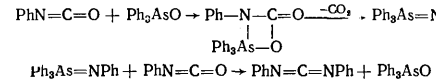


The condensation of triphenylarsine oxide with substituted cyclopentadienes, which takes place in acetic anhydride[150,151] or in triethylamine in the presence of phosphorus pentoxide[152,153], also leads to ylids:

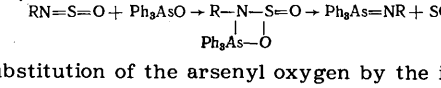


The reactions of tertiary arsine oxides with compounds containing activated methylene groups and also with nitromethane take place under analogous conditions[154]:

The role of acetic anhydride in these reactions reduces to the formation of the intermediate diacetoxyarsorane[153-155], which can subsequently react with compounds containing activated methylene groups, giving rise to the corresponding ylids[155]:

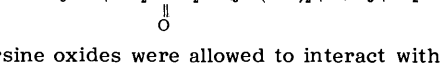


The reactions of stabilised isocyanates with triphenylarsine oxide also lead to the formation of arsine imides[156]:



The benzoyl- and acetyl-arsine imides formed under these conditions are also resonance-stabilised.

The interaction of triphenylarsine oxide with phenyl isocyanate leads to the formation of diphenylcarbodi-imide[157]:



However, under mild conditions the reaction stops at the first stage, involving the formation of arsine imide[158].

N-Sulphinamides react analogously with triphenylarsine oxide[58,159]:

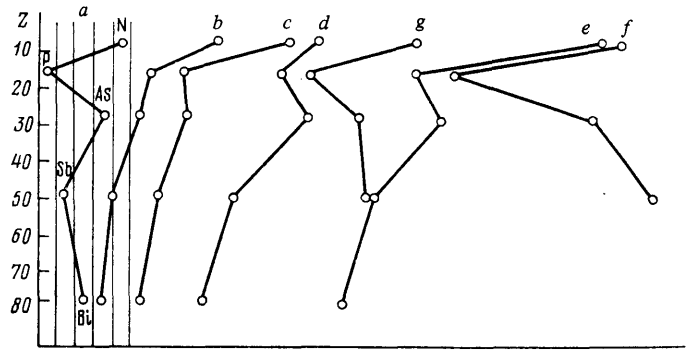
The substitution of the arsenyl oxygen by the isocyanate group takes place in the reactions of tertiary arsine oxides with urea[160,161]:

When arsine oxides were allowed to interact with diols in

benzene with azeotropic distillation of the water formed, cyclic esters of pentacoordinate arsenic—dioxa-arsolanes—were obtained[162]:

$$R_3AsO + \begin{matrix} HO \\ HO \end{matrix} \xrightarrow{-H_2O} R_3As\begin{matrix} O \\ O \end{matrix}$$

Under analogous conditions, phosphine oxides do not form the corresponding dioxaphospholanes. The interaction of stibine oxides with diols also results in the formation of dioxastibolanes[163].



Nucleophilic addition to the carbonyl group is a general reaction for carbonyl-containing compounds; in particular, ketones interact with α-glycols to form quantitatively the corresponding cyclic ketals[164]. By analogy with carbonyl compounds, for which the mechanism of reactions involving nucleophilic addition to the carbonyl group has been studied in detail[165,166], it has been suggested that the mechanism of the reactions of arsine oxides with diols is based on proton transfer from the diols to the oxygen of the arsenyl group with formation of a new arsenic–oxygen bond and subsequent dehydration of the intermediate formed[162].

V. THE PROBLEM OF ANALOGY IN GROUP VA OF THE PERIODIC SYSTEM

Examination of certain physicochemical and chemical properties of arsenyl compounds and their comparison with those of the oxa-bases R_3EO, where E is a Group VA element makes it possible to put forward certain considerations concerning the problem of analogy in Group VA. This problem is closely related to the more general problem of the analogy of the elements within any Group. Examination of the properties of organoelemental compounds on the basis of the properties of the elements and hence of their positions in the Periodic System is extremely important, because it provides a guideline which enables one to become orientated in the enormously wide variety of organoelemental compounds and their properties. It has been mentioned in a number of studies[167–170] that the simplified formulation of the Periodic System, widely used at the present time, in which the elements of the main subgroups are arranged in vertical columns, had led to some 'fetishisation' of the properties of these elements and to the widespread delusion that there is a gradual and smooth increase of the changes in the properties of the elements and their compounds.

Without attempting to consider the historical aspects of the development of various formulations of the Periodic System, we shall confine ourselves to mentioning studies in which the problem of analogy in Group VA was directly involved. Evidently one should mention that in the form of the Periodic System proposed by Mendeleev the elements of the Second Period are displaced relative to the heavier elements, which emphasises their special role. In the pyramidal form of the Periodic System proposed by Nekrasov[171] the elements of the Second and Third Periods are isolated. From the standpoint of Nekrasov's ideas concerning complete and incomplete electronic analogues, nitrogen and phosphorus and also arsenic, antimony, and bismuth are complete electronic analogues, while phosphorus and arsenic are incomplete analogues. This modification of the Periodic System takes into account the electronic structures not only of neutral atoms but also of all the characteristic valence states of the elements.

Subsequent studies in which the problems of the analogy of the elements of the Periodic System were developed and new forms of the Periodic System were proposed, reflecting finer differences between analogous elements, were based on the allowance for the structural and energetic characteristics not only of the outer electron shells of atoms but also of the two electron shells immediately preceeding the outer shell[167–170]. On the basis of the analysis of the energetic characteristics of the atoms (ionisation potentials, electron affinities, orbital radii, etc.), Godovikov[169,170] proposed an improved form of the Periodic System. Two variants of the subdivision of the elements into small subgroups were proposed for Group VA: first variant: VA1(N), VA2(P, As, Sb), VA3(Bi); it agrees well with the analysis of the properties of the oxygen compounds of the elements; second variant: VA1(N), VA2(P), VA3(As, Sb), VA4(Bi); it agrees with the properties of the sulphides.

Dependence of certain parameters of Group VA elements and their compounds on the atomic number Z of the element in the Periodic System: *a*) the arrangement of analogous Group VA elements in the matrix form of the Periodic System[167]; *b*) the first ionisation potentials of the elements[169]; *c*) the change Δr(Å) in the difference between the orbital radius of the atom and the radius of its occupied electron shell immediately preceding the outer shell in analogous elements[169]; *d*) electron affinity[69]; *e*) electronegativity[172]; *f*) pK_a for R_3EO;[89] *g*) E=O bond energy in R_3EO.[58,69].

A similar approach to the construction of the Periodic System with displacements was used by Grigorovich[167,168], who proposed a matrix form of the Periodic System, which provides for the subdivision of the main subgroups of Groups II–VII into five items (see Figure, *a*). This subdivision is based on the variation of the structures of the inner electron shells and the variation of the binding of the outer electrons to the nucleus. Although the matrix form of the Periodic System has not received its due recognition among chemists, nevertheless it reflects most clearly the non-monotonic, frequently zigzag, variation of the physical properties of the elements of the subgroup. This finding is also emphasised in Godovikov's studies[169,170]. The Figure presents plots of the variation of certain properties of Group VA elements and their compounds, illustrating the above postulate. The non-monotonic variation within a subgroup of fundamental properties of the elements such as electronegativities, ionisation potentials, electron affinities, orbital radii, etc., leads to a non-monotonic, frequently zigzag, variation of the physicochemical properties of organoelemental compounds (such as the E=O bond energy and pK_a). This type of variation of the physical and

physicochemical parameters of organoelemental compounds should evidently affect also the variation of their chemical properties.

Analysis of the arrangement of analogous elements within a subgroup, proposed in the matrix form of the Periodic System, explains the similarity of many physicochemical and chemical properties of nitrogen and arsenic compounds which are more likely to be regarded as an anomaly when the usual Periodic System is employed. The similarity of the physicochemical characteristics of the AsO and NO groups as well as of the electron-donating capacities of the oxa-bases R_3NO and R_3AsO was mentioned above. Such similarity has also been observed on comparing the chemical behaviour of the oxa-bases of nitrogen and arsenic, for example, their capacities for the tautomeric transformation

$$R_3EO \rightarrow R_2EOR,$$
$$E = N \text{ or } As.$$

In the N, P, As triad in the matrix form of the Periodic System the phosphorus atom is displaced to the extreme left-hand position (*a*) due to the strong shielding effect of the s^2p^6 electrons, which is greater than that of the $s^2p^6d^{10}$ electrons of arsenic and s^2 electrons of nitrogen. This is evidently also responsible for the specificity of the properties of many phosphorus compounds. The arsenic atom in the matrix form of the Periodic System occupies an intermediate position with some displacement towards nitrogen (see Figure, *a*). This intermediate position of arsenic is reflected in the reactions of the compounds R_3EO with alkyl halides. Comparison of arsenyl compounds in these reactions [scheme (1)] with phosphoryl compounds [scheme (2)] and amine oxides [scheme (3)] shows that arsenyl compounds undergo transformations which are characteristic also of amine oxides—an oxidation-reduction reaction [scheme (1), pathway *a*]—and of phosphoryl compounds—an exchange reaction [scheme (1), pathway *b*].

In the search for similarity, one must not forget the uniqueness of each element of the subgroup. The advantage of the matrix form of the Periodic System also consists in the fact that it reflects not only the similarities but also the differences between the properties of analogous elements caused by the differences between the structures of their inner shells, while the structures of the outer shells are similar.

The problem of the analogy of the elements and their compounds is one of the exciting problems in chemistry. The present review is in essence limited solely to the indication of the new possibilities of the analysis of this problem, which have arisen in connection with the development of new improved formulations of the Periodic System.

The Regularity Bands in the Infrared Spectra of Polymers with Distortions in Structural Periodicity

I.V.Kumpanenko and N.V.Chukanov

Studies of the microstructures of polymers by methods based on the measurement of infrared band intensities are examined. The cluster model, within the framework of which a band classification has been proposed and the possibilities of infrared spectroscopy for the determination of different structural parameters of macromolecules have been analysed, is justified. The bibliography includes 142 references.

I. INTRODUCTION

The latest advances in both practical and theoretical infrared spectroscopy of polymers are associated primarily with the study of the structures and vibrational properties of macromolecules with more or less pronounced distortions in structural periodicity. The interest in these studies is understandable because the vast majority of polymeric materials consist precisely of such macromolecules and the microstructures of polymer chains are known to influence directly or indirectly the physicochemical properties of polymers and to reflect the mechanisms of their formation.

Much attention is devoted in these studies to the analysis of the maximum intensities of the so-called regularity bands; this is mainly because, among all the spectural parameters, this one is perhaps the most sensitive to the degree of order in the macromolecular structure. In the course of its development the modern vibrational spectroscopy of polymers has encountered many problems and it appears useful to begin the review with their brief examination.

II. FUNDAMENTAL PROBLEMS OF THE INFRARED SPECTROSCOPY OF IRREGULAR POLYMERS

For many years infrared spectroscopy remained and still remains one of the most accessible and universal instruments for the investigation of the microstructures of polymers, and empirical methods of interpreting the experimental results still occupy a notable position in it. By varying any structural parameters, for example the length of the entire macromolecule or of its regular component, the degree of tacticity, or the sequence length of the polymer, the investigator is able to discover the spectral changes arising under these conditions, which are then used in the form of calibration relations in the study of the structures of a wider range of compounds.

In the last two decades there has been a growth of interest in the vibratonal spectroscopy of irregular polymers also among theoreticians. A series of new approaches have been created on the basis of the perturbation theory[1,2] and numerical methods[3-5] and attempts have been made to apply the methods of the dynamic theory of defective crystals, which have been well known for a long time in solid state physics, such as the method of Green functions[6-9], the method of negative eigenvalues[10,11], the method of transport matrices[12,13], and the method of moments[14] for the analysis of the vibrational spectra of real macromolecules. There are in general no fundamental obstacles to their application, but there are certain difficulties associated with the large number of vibrational degrees of freedom in the repeating monomeric unit, and, what is more significant from the standpoint of practical applications, with the wide variety of types of distortions in the regularity of the structure within the limits of a single chain.

Procedures widely known in theoretical spectroscopy are used to overcome the first difficulty. For example, in the so-called skeletal approximation[6,7,15,16] some of the atomic groups are replaced by point masses. In the method of bound oscillators[1,17] the repeating monomeric unit is modelled by oscillating dipoles, whose frequencies correspond approximately to the "normal" frequencies of the isolated units. There exist also other approaches[1,2] but we shall not consider them.

In the analysis — both theoretical and experimental — of the spectroscopic manifestations of structural distortions it is possible to proceed via two pathways. The first pathway involves a scrupulous allowance for all the versions of the structure by observing and analysing the spectral lines reflecting the vibrations of the corresponding molecular fragments. The experimental studies based on this approach began to appear literally from the instant of the introduction of infrared spectroscopy into practical laboratory research and nowadays they still make a very considerable contribution. Serious theoretical studies have recently begun to appear in this field. Among these, we may mention as an example studies[10,18] in which determinations were made by the method of negative eigenvalues of the frequency distribution in the spectra of hydrocarbons with different combinations of conformers, both specified artificially and generated at random, or studies[1,19-22] in which calculations were made by the authors' novel method[23-26] of the frequencies and intensities of the infrared bands in the spectra of a series of polymers with different configurational and conformational variants of the chain structure.

The second pathway is associated with the study of the behaviour of the infrared bands reflecting the vibrations of structurally regular frequencies of monomeric units in polymer chains; the nature of the defects terminating these sequencies is then usually not specified and it is implied that

their concentration is fairly small. This pathway is extremely promising, as can be seen from the rapid increase of the number of publications, in which, however, the validity of the application of this approach is usually not analysed.

The differentiation of research trends mentioned above is based on the existence of two types of spectral bands, namely bands due to local vibratons, i.e. vibrations localised in the vicinity of defective units or fragments whose intensity and frequency depend mainly on the nature and concentration of these defects, and bands due to chain vibrations in which the large regular sections of the chain distributed between the defects vibrate as a single whole and whose spectroscopic parameters depend only slightly, in contrast to the previous bands, on the nature of the defects, being determined mainly by the structure and length of the periodic part of the chain.

The sub-division of vibrations into local and chain vibrations is arbitrary: in a vibrating system there is always a greater or smaller mixing of such vibrations but in many instances such mixing is nevertheless insignificant and may be treated as a perturbation and taken into account appropriately. In a more rigorous approach it is also necessary to take into account the possibility of the appearance of quasi-local or resonance vibrations[27,28], the use of which for the analysis of the structure in the sense indicated is incorrect.

The polymer chain can naturally be so disordered that there can be no question of the existence of any chain vibrations embracing large sections of macromolecules. However, many problems of practical importance are associated precisely with the analysis of the microstructures of polymers with molecules containing fairly long regular segments interrupted by individual defective units or small irregular fragments.

The approximation, in which account is taken only of the vibrations of the regular chain sections and the mutual independence of the vibrations of different regular sections within the limits of the same chain is postulated, is referred to as the cluster approximation and plays a very important role in spectroscopic studies. In the majority of investigations by vibrational spectroscopic methods of the stereoregularity of polymers[29-31], the conformations of macromolecules in solution[32-34], the sequence length of copolymers[35-48], and the degree of branching of polymers[49], the cluster approximation is in essence employed, although this is frequently not stipulated. In view of the particular importance of this approximation for the subsequent description, Section III of this review is devoted to a brief analysis of its principles.

The chain vibration bands satisfying the criteria of the cluster approximation are of special interest in our case, since they include the regularity bands according to Zerbi's classification[50]. In a series of studies[29-31,35-48] bands of this type have been referred to as spirality, iso- or syndiotacticity, etc., bands. It is noteworthy that such terms are not entirely unambiguous. For example, the isotacticity band at 998 cm^{-1} in the spectrum of polypropylene can be referred to simultaneously also as the helix band, since the changes it undergoes with decrease of the length of the macromolecular helix observed on fusion of the polymer are broadly the same as those occurring following a decrease of the degree of its isotacticity[30].

In many instances the frequency of the maximum of such a band is independent of or depends only slightly on the regularity of the macromolecule and the band intensity is the structure-sensitive parameter. Henceforth, in speaking of regularity bands, we shall have in mind precisely such bands.

A number of characteristics of the behaviour of regularity bands can be discovered by following the changes in them when the structure of the macrochains is varied. As a rule, these bands appear in the spectra when the regular, in both structural and chemical respects, sequence of monomeric units reaches a critical length, characteristic of precisely this band. For example, the 973 and 998 cm^{-1} bands in the spectra of ethylene–propylene copolymers arise when the isotactic polypropylene sequences reach lengths of 5 and 10 units respectively[35,36], while the 565 and 750 cm^{-1} bands in the spectra of epoxypropane–tetrahydrofuran copolymers refer to the vibrations of polytetrahydrofuran fragments containing at least 4 and 2 units respectively[47].

Another important feature of the regularity bands is the monotonic increase of their intensity with increase of the average length $\bar{N}$ of the regular sequences of units in the polymer and the more or less rapid attainment of a limiting intensity for fairly high values of $\bar{N}$. The increase of the maximum intensity can take place both owing to the increase of the integral band intensity and owing to the decrease of the half-width of the band.

The very fact that the band intensity depends on the length of the regular segments in polymer chains usually leads to the possibility of using this relation to analyse polymer microstructures, in particular, the possibility of measuring the average sequence length of the copolymers and of the degree of tacticity of stereoregular homopolymers. However, the problem of whether such measurements are sufficiently correct and of the nature of the averaging in the experimental determination of these quantities have still not been adequately investigated.

This review is devoted to a detailed analysis of the factors influencing the dependence of the chain vibration band intensities and widths in the infared spectra of polymers on the lengths of structurally regular sequences of units. The criteria governing the choice of regularity bands, both with the aid of a set of empirical features and on the basis of an *a priori* investigation of the structural-force characteristics of macrochains are analysed. Some attention has been devoted to bands containing information about the structure of the helix and to crystallinity bands.

III. THE STRUCTURAL MODEL AND THE CLUSTER APPROXIMATION

A configurationally regular polymer chain is known[51] to be capable of passing under certain conditions to a conformationally regular state. This transition is accompanied by the occurrence of the so-called long-range conformational order in which the chain consists of an ideal helix with the corresponding spatial symmetry. The formation of fairly long helical fragments can be observed in the crystallisation of a polymer or (sometimes) with decrease of the temperature of its solutions.

We shall now assume that under the experimental conditions all the configurationally regular fragments of the macromolecules have passed to the conformationally regular helical state. In this case the fraction of conformationally regular segments attain saturation due solely to the configurational or chemical defects and the distribution of the helices in the specimen with respect to length reflects and to the length distribution of the regular sequences of the monomeric units in the polymer. The necessity for monitoring the conformational defectiveness in the course of spectroscopic measurements becomes clear from the foregoing, since its presence can lead to an apparent decrease of the degree of configurational irregularity of the polymer determined from spectroscopic data.

The main idea of the cluster approximation consists in the fact that, in the analysis of vibrations, the polymer molecule, consisting of alternating regular helical sections and defective regions, is imagined to be ruptured at the sites of the defects and the vibrational spectrum of such a molecule in the frequency range of the chain vibration analysed is represented as a superposition of the vibrational spectra of mutually independent helices.

We emphasise that not all spectral regions satisfy the cluster approximation. The existence of local vibrations of the defects, the occurrence of quasi-local or resonance vibrations—all these can hinder or preclude the application of a given frequency range to structural analysis in terms of the given approximation. A test of the applicability of the cluster approximation in each specific instance can be carried out either experimentally by analysing the spectra of model compounds or theoretically.

The experimental test can consist, for example, in comparing the spectra of polymer specimens differing in the nature of the defects. The application of the cluster approximation is correct for bands whose frequency and intensity vary little in a series of polymers having identical distributions of regular segments with respect to length but containing defects of different types.

In the majority of experimental studies where the cluster approximation has in fact been used for the analysis of polymer microstructures (albeit without the term itself being actually employed), such a test has been carried out in one way or another. Fig.1 illustrates the results of one of the versions of such an investigation for the low-frequency 720 cm^{-1} band for a system of wagging-torsional vibrations of polymethylene fragments in polymer chains of different structure. Evidently the dependence of the relative intensities on the lengths of the regular polymethylene segments in a series of specimens with different types of distortions in structural regularity fits on a single curve, which constitutes an experimental confirmation of the possibility of employing the cluster approximation in the given instance[142].

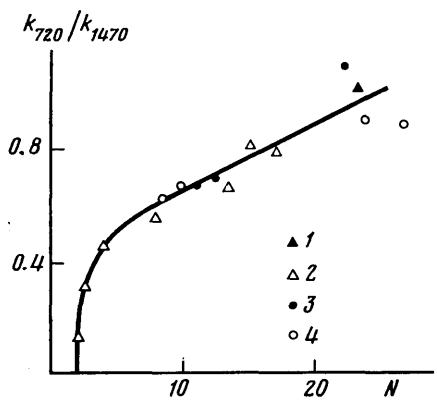

Figure 1. Dependence of the absorption coefficient of the wagging vibration band (720 cm^{-1}), referred to the absorption coefficient of the scissors vibration band (1470 cm^{-1}), on the average length of the polymethylene segments for n-paraffins(1) and copolymers of ethylene with ethylene-d_4(2), but-1-ene(3), and allene(4) at room temperature[142].

Another experimental test is based on the analysis of the form of the dependence of the band intensities on the lengths of regular segments; this will be discussed in detail in Section VI.

The question of the theoretical criteria of the applicability of the cluster approximation has been studied in detail[52] and we shall consider briefly the final results of these studies. The introduction of a defective unit into an initially ideal polymer chain leads in general to complex changes in the vibrational spectrum of the macrochain as a whole. With some approximation, these changes reduce to the appearance of local and resonance vibrations and the mixing of various chain vibrations. At the same time it can be shown that, when certain relations between structural-force parameters of the regular part of the chain and of the defective units are fulfilled, one or several of the chain vibrations of the fragment, located between two defects, can be regarded as independent of all other chain vibrations; it is then immaterial whether the latter refer to the given fragment, to defective units, or to adjacent sections of the chain.

Anticipating, we emphasise that the structure and parameters of the force fields of the majority of real polymeric molecules are such that a fairly large number of bands, referring to this type of independent chain vibrations of regular fragments or, in other words, bands satisfying the criteria of the cluster approximation, can always be found in their vibrational spectra.

These criteria assume the simplest form in terms of the so-called normal coordinates of the repeating unit (NCRU). In terms of these coordinates, the vibrating polymer chain with r degrees of freedom in a repeating unit can be represented by a set of r systems of linked oscillators and each of its r frequency branches forms its own system, which in the case of a defect-free chain is independent of the remaining systems. These coordinates can be referred to as the natural coordinates of the model of linked oscillators. A transformation whereby one can achieve a conversion to such coordinates from any initial coordinates, for example, from cartesian or natural coordinates, has been proposed[53].

The application of this transformation makes it possible to calculate the parameters of systems of linked oscillators modelling any polymer molecule including, among others, an irregular molecule, from its force constants specified in terms of any representation, for example, in the generalised valence force field representation.

The possibility of determining the parameters of the model of linked oscillators in the vicinity of "defective units" of the polymer chain appears to be the most important in this instance. These parameters can then be readily tested for their correspondence to the criteria of the cluster approximation.

Readers interested in further details of this problem are referred to Chukanov and coworkers[52,53]. Here we shall attempt to illustrate the theoretical criteria of the applicability of the cluster approximation in relation to the example of a hypothetical regular polymer molecule with a single defect and two degrees of freedom in the repeating unit. Such a molecule can be brought into correspondence with the model of linked oscillators illustrated schematically in Fig.2. In this model oscillators with intrinsic frequencies ω and ω' are combined into two chains via elastic forces with bond constants α and α'. The interaction between the chains with a force constant δ takes place only via "defective" oscillators, whose frequencies are ω_e and ω_e' and whose linkage to the periodic component of the chains is described by the interaction constants β and β' respectively. The fulfillment of the

conditions

$$\begin{aligned} |\beta| &\ll |\omega^2 - \omega_e^2| \\ |\delta| &\ll |\omega_e^2 - (\omega_e')^2| \\ |\beta'| &\ll |(\omega')^2 - (\omega_e')^2| \end{aligned} \qquad (1)$$

leads to the "breakdown" of such an integral vibrational system into four oscillator chains, each of which vibrates independently of the others[52].

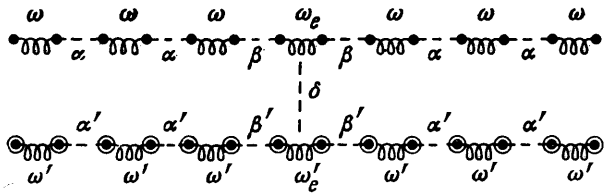

Figure 2. The system of linked oscillators modelling a polymer molecule with two degrees of freedom in the repeating cell and a single defective unit.

We may note that the fulfillment of only the first or only the last relation (1) makes it possible to apply the cluster approximation to oscillator chains with frequencies ω and ω' respectively.

Eqns.(1) thus express the quantitative criteria of the applicability of the cluster approximation to the system considered. In a more general approach one must naturally compare the vibrational frequency of a defective oscillator with the frequency of the chain vibration under consideration and not with the frequency of the intrinsic vibration of an individual non-defective oscillator.

The treatment in all subsequent sections of this review is based on the cluster approximation. Here it is understood that all the spectral bands analysed satisfy the theoretical or experimental criteria of this approximation.

IV. AN EMPIRICAL APPROACH TO THE STUDY OF THE MICROSTRUCTURES OF POLYMERS

Numerous experimental data which have accumulated hitherto indicate the possibility of deriving specific relations for the entire wide variety of spectroscopic manifestations accompanying the structural changes in polymers. Analysis of relations of this kind is very greatly simplified by employing the cluster approximation. Above, it was already noted that the cluster approximation has in fact been used for a long time in experimental studies of polymer spectra. In this section we shall consider studies of this kind, which will be grouped in terms of the types of bands whose intensity is sensitive to particular characteristics of the polymer structure.

Among all the infrared bands, it is reasonable to isolate three large groups from the standpoint of the study of the microstructure: the bands due to the local vibrations of the defects, the characteristic bands of the repeating units, and the regularity bands.

1. The Bands of the Local Vibrations of Defects

The criteria of the cluster approximation (1) at the same time constitute the criteria of the local nature of the vibrations of the defective unit to which correspond oscillators with frequencies ω_e and ω_e' in the NCRU system. However, in practice the demonstration of the local nature of the vibrations does not necessitate the use of Eqns.(1) in each case; it is sufficient to show merely that in a series of polymers with different degrees of regularity the frequency of the given vibration is constant and the intensity of the corresponding band is proportional to the concentration of defects of the given type.

This simplest type of vibration can in fact be used to investigate a whole series of structural characteristics. These include, firstly, the analysis of *the nature and concentration of the terminal functional groups*. The relevant methods have been developed for poly(ethylene terephthalate)[54], poly(ethylene glycol)[34,55], polystyrene (carbonyl groups)[56], and other polymers[34]. In a number of studies the local vibration bands have been used to determine the degree of branching of polyethylene[57,58], poly(vinyl chloride)[59], polycaproamide[60], ethylene-vinyl acetate copolymers[61], and others[34].

The knowledge of the concentration of the functional groups and also of the degree of branching makes it possible to estimate the *functionality* of the oligomer, which is important from the standpoint of its subsequent polymerisation. For a polymer with a known functionality, the concentration of the end groups is unambiguously related to *the molecular weight*. The intensities of the local vibrations of the "contacts" between units of different kinds in the copolymer have been used to determine *the average length of the block* in vinyl chloride–vinylidene chloride[41], epoxyethane–epoxypropane[62], and tetrafluorethylene–chlorotrifluoroethylene[63] copolymers.

It has been shown[27] that single distortions of the *stereoregularity* of isotactic polypropylene lead to the development of local vibrations. The concentration of single polyethylene units in ethylene–propene copolymers has been determined[64] from the intensity of the 733 cm^{-1} band.

2. Characteristic Vibrations of the Repeating Chain Units.

The vibrations of the macrochains for which the frequencies and absorption coefficients of the corresponding bands depend only slightly on the regularity of the polymer structure can be assigned to this class. The intensities of these bands are determined mainly by the content in the polymer of units of the given type and can be used, for example, for the analysis of the composition of the copolymer[65].

The bands can apparently be made more characteristic by measuring the spectra of conformationally irregular copolymers; for example, it is possible to investigate copolymers in the form of solutions at high temperatures or melts.

Calibration curves for the determination of the compositions of ethylene–propene[66], ethylene–but-1-ene[67], propene–but-1-ene and propene–oct-1-ene[68], vinyl acetate–vinyl chloride[69], propene–vinyl chloride[70], ethylene–propene and ethylene–hexene[71], ethylene–vinyl acetate[61], epoxyethane–epoxypropane[55], and many other copolymers have been published. The corresponding references can be found in a monograph[34]. Unfortunately the absence of a dependence of the extinction coefficient on the regularity of the polymer has not been tested in all the investigations.

A number of studies in the same series have been devoted to the *isomeric composition* of the polymers, particularly polybutadiene[72], polypentenamer, and polyoctenamer[73].

3. Regularity Bands

As already mentioned, a characteristic feature of bands of this type is a sharp decrease of their intensity (frequently to zero) in those cases where the average length $\bar{N}$ of the regular sequence of monomeric units falls below a certain threshold value N_0.

The factors determining the average length $\bar{N}$ of a regular sequence of units of a given type may be stereoregularity, conformational order, the extent of the block structure (in the copolymer), the molecular weight, and the degree of crystallinity. Depending on the objects of study, the regularity bands can be divided into several types. According to the classification adopted by Zerbi et al.[50], the conformational bands are those whose frequency and intensity depend on the conformational state of the unit. No account is then taken of the fact that the band parameters depend on the conformational state of the neighbouring units, as suggested, for example, by the complete disappearance of certain conformational bands on fusion of the polymers or when the temperature of their solutions is raised[34,37,75]. The latter implies that a threshold length of the regular sequence exists for such conformational bands, as for regularity bands.

Assuming that the absorption coefficient is independent of the length of the conformationally regular sequence, *the conformational structures* of polyethylene[76], poly(ethylene terephthalate)[77], *trans*-1,4-polybutadiene[78], and a number of other polymers have been analysed. In particular, measurements of the spectra of atactic polystyrene in polarised light[79] made it possible to isolate the spectral contribution of fragments having the *trans*-conformation. However, the hypothesis used in the above study[79] that the vibrations are characteristic requires a rigorous proof and by no means always holds. Thus the spectrum of polystyrene contains a band at 540 cm^{-1}, which is sensitive to sequences containing at least four *trans*-C–C bonds in the main chain[40].

The crystallinity bands have been used to determine *the crystal structures* and *degrees of crystallinity* of polyethylene[80–83], polyesters of the type $[-CO-O-(CH_2)_m-]_n$,[84] polybutadiene[85], isotactic poly(vinyl alcohol)[86], poly(vinyl chloride)[87], poly(vinyl-β,β-d_2 chloride)[88], polytetrafluoroethylene[89], and dextran[90], using simultaneously diffuse bands, assigned to the vibrations of the amorphous regions, in some of the studies[80,82,88,90].

The amorphous structure bands occupy a special place among the structure-sensitive bands. Factors such as the presence of "amorphous" conformations, the infringement of selection rules associated with the helical symmetry of the chain, the scatter of the regular helices with respect to length, and fluctuations of the molecular environment play a role in their formation. Since the amorphous structure bands are not regularity bands in the sense defined above, we shall not consider their analysis.

A method has been proposed[91], for the resolution of the spectrum into components referring to the amorphous and crystalline regions on the assumption that their contributions to the spectrum are additive. Having applied this method to the poly(ethylene terephthalate) spectrum, the authors[91] concluded that, although the *trans*--isomers are present in both phases, their characteristic bands, referring to the amorphous phase, are not manifested in the spectrum, since they are smeared out as a consequence of the marked scatter of the intermolecular interaction energies. However, another explanation of this effect is possible, namely one based on the assumption that the lengths of the sequence of *trans*-isomers in the amorphous phase do not reach the threshold lengths for the regularity bands.

Empirical methods for the analysis of the microtacticity of polypropylene have been developed[30,35]. It has been shown that the 998 and 973 cm^{-1} bands appear in the spectrum for lengths of the isotactic chains greater than those corresponding to 10 and 5 units respectively.

A detailed analysis of bands sensitive to isotactic, syndiotactic, and heterotactic sequences in the polyproylene molecule has been carried out[92]. The 690 cm^{-1} band in the poly(vinyl chloride) spectrum is sensitive to the concentration of the isotactic diads[93]. A method for the determination of the concentration of the diads of polybutadiene units in the 1,4-*cis*- and 1,4-*trans*-configurations has been described[94].

The determination of the sequence length of copolymers constitutes an important problem. In most studies devoted to the determination of this parameter with the aid of regularity bands, the power function method was used, according to which the dependence of the absorption coefficient on the length of the regular segment is described by a function of the type

$$k(N) = \begin{cases} 0 \text{ when } N < N_p \\ k \text{ when } N \geqslant N_p \end{cases}$$

The power function method has been used in the analysis of the sequence length of styrene–methyl methacrylate[38], styrene–butadiene and styrene–acrylonitrile[39,95], methyl methacrylate–acrylonitrile[46], ethylene–propene[30,35,96], propene–propene-1,1,2-d_3, styrene–α-monodeuterostyrene[37], tetrahydrofuran–epoxypropane[47], and epoxyethane–epoxypropane[48] copolymers. It is of interest to note that in almost all cases the threshold length of the sequence of monomeric units analysed is almost independent of the nature of the neighbouring blocks. For example, for all the styrene copolymers enumerated above, $N_p = 3–4$ corresponds to the 543 cm^{-1} band, $N_p = 9–11$ corresponds to the 998 cm^{-1} band of isotactic polypropylene fragments, etc. Furthermore, the intensities of the regularity bands in the spectra of the oligomeric fractions and tetrahydrofuran (THF) copolymers depend on N in the same manner[47]. All this demonstrates the applicability of the cluster approximation to the systems enumerated above.

Table 1 presents the results of studies of the regularity bands–their frequencies and the characteristic lengths of the monomeric unit sequences measured with their aid. The quantity N_0 represents the extrapolated average length of the regular segment for which the given band appears in the spectrum and N_p is the length for which the band intensity reaches half its maximum value. Tables 2 and 3 present the analogous lists for crystallinity and amorphous structure bands.

Despite the fact that the intensities of the regularity bands are extremely sensitive to the polymer microstructure, their use for the analysis of sequence length, stereoregularity, etc. is coupled with certain difficulties.

One of the main difficulties is the absence of model compounds necessary for the derivation of calibration relations between the extraction coefficients and the length of the regular chain. The description of these relations with the aid of a power function[37,47] constitutes a fairly rough approximation.

The need to derive a theoretical expression for the function $k(N)$, which must be fairly general and must contain as few as possible empirically determined parameters, follows from the foregoing. The knowledge of this function would

make it possible to solve yet another problem, namely to establish the type of averaging of the lengths of the regular segments in polymers measured with its aid as well as the place of the average quantities in the series of those generally accepted, namely number-average, weight-average, etc. A detailed examination of these problems is presented below.

Table 1. Regularity bands.

V. DEPENDENCE OF THE INTENSITIES AND WIDTHS OF THE REGULARITY BANDS ON THE LENGTH OF THE MACROMOLECULAR HELIX

In interpreting spectroscopic data, experimenters usually prefer to deal with the absorption coefficients of bands at their maxima (k_{max}), because this spectroscopic parameter is in fact most readily susceptible to direct measurement. At the same time the integral absorption coefficient k and the band width $\Delta\nu$ are known to have a direct physical significance; k_{max} is related to them unambiguously; $k_{max} = Ak/\Delta\nu$, where A is a constant which depends on the units of the quantities in the expression. The factors determining the form of the $k(N)$ and $\Delta\nu(N)$ relations [and hence also of $k_{max}(N)$] are complex and numerous. In particular, one can specify tens of factors influencing the form of the function $\Delta\nu(N)$. They include, for example, the changes in density and refractive index when the microstructure is damaged[34,128], the interaction of vibrations of different types as a consequence of their anharmonicity[129,130], intermolecular interactions[128,129], the resonance of vibrations[131], a non-rigorous validity of the selection rules with respect to the phase parameter[1], polydispersity of the polymer[132], the presence of an amorphous phase and a folded structure in the polymer[34], internal stresses[133], the distribution of the paths traversed by the optical phonon with respect to length[52], band splitting under the influence of the field in the polymer crystal[34], and many others.

Some of these factors are unimportant and in most real cases their influence can be neglected compared with the marked changes in the intensities and widths of the regularity bands (frequently by a factor of several tens) when N is altered. The influence of other factors can be reduced to a minimum by selecting the appropriate experimental conditions. Henceforth we shall deliberately restrict the range of bands considered to those for which the dependence of the intensity on the structure is not complicated by factors difficult to take into account, such as resonance. As a result, there remain a small number of factors whose influence on the $k(N)$ and $\Delta\nu(N)$ relations must be considered[43].

1. Integral Intensity

In order to determine the dependences of the integral intensities of the longitudinal vibration bands on N, it is necessary to take into account first the dilution effect, which arises because the fraction of chain units in the vicinity of the defect have force constants and configurations somewhat different from those for units remote from the defect due to the influence of the latter. The fraction of the energy of the normal vibration corresponding to the units near the defect can then decrease sharply even for an insignificant degree of perturbation[52]. In other words, a chain with a length shorter than the actual length N is effectively involved in the longitudinal chain vibration, which leads to the following dependence of the integral absorption coefficient k on N [43]:

$$k(N) \propto 1 - N_0/N \,. \qquad (2)$$

The $k(N)$ relation for transverse vibration bands is characterised by the presence of maxima and minima. It can be shown[1,52] that in this case the following expression holds for sufficiently high values of N:

$$k(N) \propto \frac{1}{N} \cos^2 \frac{mN\pi}{n} \,, \qquad (3)$$

where n is the number of units of the macromolecule with helical symmetry, corresponding to m turns of the helix. Evidently Eqn.(3) has deep minima which repeat with a period corresponding to n units.

2. Broadening of the Bands

We shall consider initially the case of a dilute polymer solution. There are several theories explaining the broadening of the spectral bands in the liquid phase[5,128,130,134–137]. Among these, the most promising theory, yielding the best agreement with experimental data, is the fluctuation theory developed by Bakhshiev[128]. According to it, the main cause of the broadening of the bands in the spectrum of the liquid phase is the fluctuation of the microdensity of the immediate environment of the molecule.

Allowance for the influence of these fluctuations in the first-order perturbation theory in the NRCU system leads to the following dependence of the chain vibration band width on the chain length and temperature[43]:

$$\Delta\nu \propto (T/N)^{1/4} \,. \qquad (4)$$

This result is not unexpected bearing in mind that the fractional fluctuation of a physical quantity (in this case frequency) for a system consisting of N equivalent objects (in the given case units), whose fluctuations are independent, is inversely proportional to $N^{1/2}$.

The assumption of the independence of the perturbations[138] of the individual units, which is valid in the case of a solution, becomes incorrect in the general case for a polymer in bulk, for example, for a polymer crystal. In the latter case the microdensity fluctuations are caused mainly by the acoustic vibrations of the lattice and hence are to some extent correlated along the chain. The $\Delta\nu(N)$ relation must then be weaker. We shall explain this by a simple example. We shall assume that the perturbing influence of the medium is such that it leads to a synchronous change in the force constants of all the units (the case of maximum correlation). Here the fluctuations in the frequency of the macromolecule, leading to a broadening of the band, are evidently the same as for a single unit, i. e. are independent of N.

In the case of a partial breakdown of the correlation of the acoustic lattice vibrations, as a consequence of anharmonicity, it can be shown[43] that, in the terms of the first-order perturbation theory, the dependence of $\Delta\nu$ on N is

$$\Delta\nu(N) \propto \frac{T^{1/4}}{(N+1)^{3/4}} \left[\sum_{i,j,k=1}^{N} \sum_{k_t=1}^{N_t} \sin^2 \frac{i\pi}{N+1} \cdot \sin^2 \frac{j\pi}{N+1} \times \right.$$
$$\left. \times \sin \frac{ik\pi}{N+1} \cdot \sin \frac{jk\pi}{N+1} \cdot \frac{e^{-|i-j|/N_p^a}}{\omega_{kk_t}^2} \right]^{1/4} , \qquad (5)$$

where N_t is the number of chains constituting the crystal, N_p^a the characteristic length of the section of the chain participating in the correlated acoustic vibrations and having the same physical significance as the average length of the free path of the acoustic phonon, and ω_{kk_t} are the frequencies of the acoustic branch, which are defined by the following relation when account is taken of only the short-range interactions in the NCRU system:

$$\omega_{kk_t}^2 \propto \sin^2 \frac{k\pi}{2(N+1)} + \sigma \sin^2 \frac{k_t\pi}{2(N_t+1)} \,.$$

Here the parameter σ characterises the "interaction" of the oscillators of the neighbouring chains in the NCRU.

Analysis of Eqn.(5) shows that, for low values of N_p^a ($N_p^a < 10$) and high values of σ ($\sigma > 0.5$), the nature of the relation $\Delta\nu(N) \propto N^{-1/2}$ is the same as for a polymer solution [see Eqn.(4)]. Comparison of Eqn.(5) with the experimental $\Delta\nu(N)$ relations shows that this limiting case in fact usually obtains for regularity bands.

Table 4. The form of the $k_{max}(N)$ relations for regularity bands of different types.

Type of vibration	Local vibrations of terminal defects, "contacts", etc.	Characteristic vibrations of repeating units;	Chain vibrations; $N_p^0 \lesssim 1$		
			$\omega(N)$=const		$\omega(N) \neq$ const
			longitudinal	transverse	
$N_p^a \gg 1$ (macromolecule in crystallite)	$k_{max} \sim N^{-1}$ $N \gg 1$	$k_{max}(N)$=const $N > N_p^0$	$k_{max} \sim 1 - N_0/N$ $N < N_0$	$k_{max} \sim \cos^2(\pi mN/n) \cdot N^{-1}$ $N \gg N_0$	Spectral curve has a complex contour
$N_p^a \lesssim 1$ (macromolecule in solution)	$k_{max} \sim N^{-1}$ $N \gg 1$	$k_{max}(N)$=const $N > N_p^0$	$k_{max} \sim N^{1/2}(1 - N_0/N)$ $N_0 < N < N_p^0$	$k_{max} \sim \cos^2(\pi mN/n) \cdot N^{-1/2}$ $N > N_0$	

We may note that a marked breakdown of the correlation of perturbations can then be favoured not only by the anharmonicity of the acoustic vibrations but also by the stationary breakdown of the regularity of the immediate environment of the macromolecule (non-ideality of the crystal structure, defects of the neighbouring molecules, etc.).

3. The Intensities at the Regularity Band Maxima

It follows from Eqns.(2) and (4) that, for longitudinal vibration bands, we have:

$$k_{max}(N) \propto N^{1/2}(1 - N_0/N) \quad . \qquad (6)$$

We may note that Eqns.(4)–(6) do not take into account the finite length of the free path of the optical phonon N_p^0 which amounts for certain regularity bands, as will be shown below, to several tens of units and can be estimated from the value of N for which the experimental $\Delta\nu(N)$ and $k_{max}(N)$ relations deviate from those defined by Eqns.(4)–(6).

VI. CLASSIFICATION OF THE INFRARED BANDS OF POLYMERS

After the principal mechanisms of the influence of the length of the regular segments in macromolecules on the intensities and widths of the infrared bands have been elucidated, it is possible to isolate, within the framework of the cluster approach, groups of bands differing in the nature of the dependence of their absorption coefficients on the length of the segment.

Several attempts have been made at a classification of the structure-sensitive bands in the infrared spectra of polymers, which, however, are only qualitative[50,74]. Our proposed classification is based on the type of dependence of the frequency ω and the absorption coefficient at the band maximum k_{max} on the length of the regular segment N. According to this classification, it is possible to isolate in the infrared spectrum bands which can be more or less definitely assigned to one of the types of vibration of the macromolecular chain: local, characteristic, or chain. In order to make this classification more informative and clearer, we also introduced into consideration parameters characterising the lengths of the paths of the phonons of the optical vibration considered (N_p^0) and the low-frequency acoustic vibrations (N_p^a) with which the given optical vibration interacts. The types of the $k_{max}(N)$ relations and the corresponding values of N_0, N_p^0 and N_p^a as well as the ranges in which N varies and the band polarisations are given in Table 4.

We shall consider the problem of the kind of information about the structure of the polymer contained in each band type. The bands due to the local vibrations of the defects ($k_{max} \propto N^{-1}$) can be used to determine the nature and concentration of the defects, particularly the "contacts" between blocks of different kinds and hence the number-average sequence length or the number-average molecular weight in the case of oligomers.

The characteristic bands of the chain vibrations ($N_p^0 \lesssim 1$, $k_{max} \cong$ const.) can be used to determine the chemical, isomeric, and conformational compositions of the polymers.

The $k_{max}(N)$ relation for the transverse vibration bands at $N_p^0 \gg 1$ contains information about the nature of the helical symmetry of the regular section of the chain (parameters m and n). However, such bands are unsuitable for the determination of the average length $\bar{N}$ of the regular segments as a consequence of the non-monotonic $k_{max}(N)$ relation.

The longitudinal vibration bands for $N_p^0 \gg 1$ and $N_p^a \lesssim 1$, for which there is a strong monotonic dependence of k_{max} on N defined by Eqns.(6), are the most suitable for the determination of the average length of the regular segments in macromolecules. As mentioned above, when these bands are used, the question of the nature of the averaging of the length arises.

VII. THE REGULARITY BANDS AND THE DISTRIBUTION OF THE REGULAR SEGMENTS IN MACROMOLECULES WITH RESPECT TO LENGTH

In conformity with the cluster approximation, each segment makes an independent contribution to the integral absorption coefficient at the specified frequency. Taking this fact into account as well as Eqn.(2), it is easy to obtain an expression for the absorption coefficient of the specimen in terms of the distribution function with respect to the lengths of the segments $w(N)$:

$$k(\bar{N}) \propto \sum_{N=N_0}^{\infty} w(N) \cdot \left(1 - \frac{N_0}{N}\right) \quad .$$

On the other hand, by measuring the optical density of a specimen with an unknown distribution function and using Eqn.(2) as the calibration relation, we obtain

$$1 - \frac{N_0}{\bar{N}} = \sum_{N=N_0}^{\infty} w(N) \cdot \left(1 - \frac{N_0}{N}\right) \quad ,$$

whence

$$\bar{N} = \left(\sum_{N=N_0}^{\infty} \frac{w(N)}{N} \right)^{-1} \equiv \bar{N}_n \quad .$$

Consequently *the integral absorption coefficient of the regularity band contains information about the number-average length of the regular segments.*

The dependence of the absorption coefficient at the regularity band maximum on the function $w(N)$ can be analysed analogously[43]. It follows from Eqn.(6) that

$$k_{max}(\bar{N}) \propto \sum_{N=N_0}^{\infty} w(N) \cdot N^{1/2}\left(1 - \frac{N_0}{N}\right) \quad . \qquad (7)$$

Analysis of Eqn.(7) shows that, for relatively high values of N (for $N \gg N_0$), the square of the experimental optical density is proportional to $\bar{N}_1$ defined by the relation

$$\bar{N}_1 = \left[\sum_{N=N_0}^{\infty} w(N) \cdot N^{1/2}\right]^2 \quad .$$

On the other hand, if values of N in the range $N_0 \leqslant N < 2N_0$ are characteristic of the main bulk of the polymer molecules, the optical density is proportional to $\bar{N}_2$:

$$\bar{N}_2 = \sum_{N=N_0}^{\infty} [w(N)N] - N_0 \equiv \bar{N}_w - N_0 \quad .$$

In the general case the following relation holds for the "spectroscopic average" length $\bar{N}_S$:

$$\bar{N}_n < \bar{N}_1 \leqslant \bar{N}_s \leqslant \bar{N}_2 < \bar{N}_w \quad .$$

where $\bar{N}_n$ and $\bar{N}_w$ are the number-average and the weight-average lengths of the regular segments respectively.

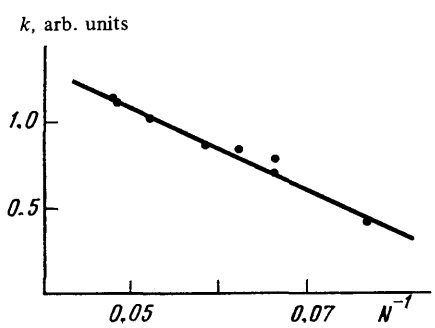

Figure 3. Dependence k on N^{-1} for the wagging vibration band (720 cm^{-1}) of orthorhombic n-paraffins at 173 K.[43]

Thus *the average length of the regular segments in macromolecules determined from the absorption coefficient at the regularity band maximum lies in the range between the number-average and weight-average lengths and usually approaches the latter.*

Finally we may note that the ratio of the average lengths of segments measured on the basis of the peak and integral regularity band intensities $\bar{N}_S/\bar{N}_n$ characterises the width of the distribution $w(N)$.[52,139]

VIII. SOME EXAMPLES OF STUDIES ON THE MICROSTRUCTURES OF POLYMERS WITH THE AID OF REGULARITY BANDS

Since regularity bands can belong to one type or another indicated in Table 4, the dependence of their parameters (k_{max} and $\Delta\nu$) on N (or on T) should have different linearising coordinates defined by Eqns.(2), (4), and (6). We shall quote several typical examples of experimental relations of this kind.

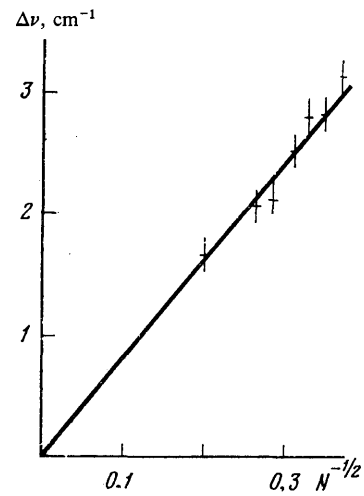

Figure 4. Dependence of $\Delta\nu$ on $N^{-1/2}$ for the forbidden band of the wagging-torsional vibrations of triclinic n-paraffins (735–770 cm^{-1}) at 100 K.[43]

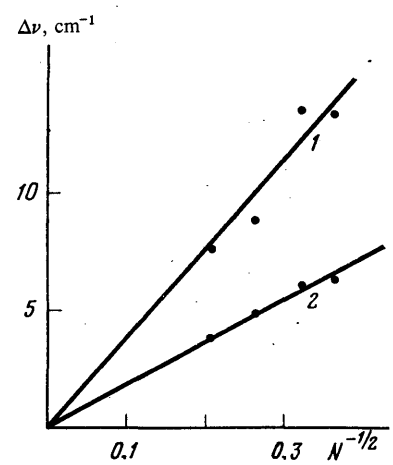

Figure 5. Dependence of $\Delta\nu$ on $N^{-1/2}$ for the C–O stretching vibration and CH_2 wagging vibration bands (845 cm^{-1}, line *1*) and the fanwise CH_2 vibrations (1346 cm^{-1}, line *2*) of the urethanes C_4H_9–NH–CO–O–$(CH_2$–CH_2–O$)_N$–CO–NH–C_4H_9 at 100 K.[52]

Fig. 3 shows that the coordinates (k, N^{-1}) [see Eqn. (2)] are linearising for the band due to the wagging vibrations of n-paraffins.

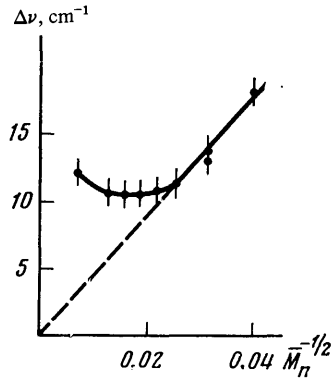

Figure 6. Dependence of $\Delta\nu$ on $\bar{M}_n^{-1/2}$ for the 845 cm^{-1} band in the spectra of crystalline poly(ethylene glycols) at 10 °C.[43]

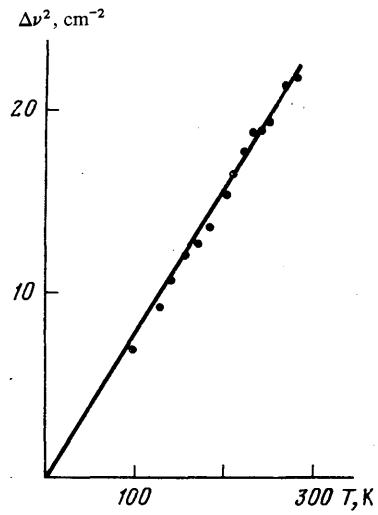

Figure 7. Dependence of $\Delta\nu^2$ on T for the wagging vibration band (720 cm^{-1}) of triclinic n-tetradecane.

When the correlation of the acoustic vibrations undergoes a pronounced distortion in conformity with Eqn. (4), the coordinates $(\Delta\nu, N^{-1/2})$ are also linearising, provided that the chain length does not exceed the length of the free path of the optical phonon N_p^0. Figs. 4 and 5 show that, for not unduly high values of N, the plots of $\Delta\nu$ against $N^{-1/2}$ for certain regularity bands in the spectra of polymers containing polymethylene and polyoxyethylene segments are straight lines passing through the origin of coordinates. The deviation from Eqn. (4) in the case of the 845 cm^{-1} band of poly(ethylene glycols) with molecular weights $\bar{M}_n > 2000$ (Fig. 6) can be accounted for by the finite length of the free path of the optical phonon as a consequence of the anharmonicity of the vibrations or the appearance of a folded structure.

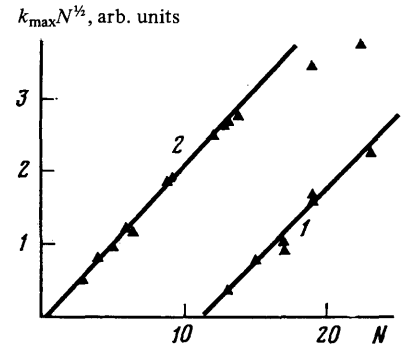

Figure 8. Dependence of $k_{max}N^{1/2}$ on N for different bands: *1*) wagging vibrations (720 cm^{-1}) of orthorhombic n-paraffins at 170 K;[52] *2*) torsional vibrations (1283 cm^{-1}) of glymes, poly(ethylene glycols), and epoxyethane-expoxypropane copolymers at 170 K.[48]

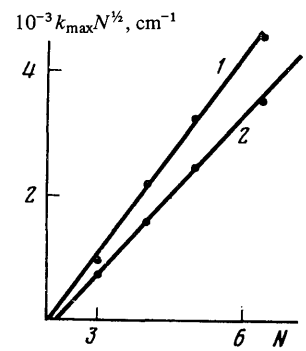

Figure 9. Dependence of $k_{max}N^{1/2}$ on N for the fanwise vibration (1350 cm^{-1}) (line *1*) and torsional vibration (1285 cm^{-1}) (line *2*) bands of glymes and poly(ethylene glycol) with $\bar{M}_n = 300$ at 180 K;[48] solvent-carbon disulphide.

The temperature variation of the regularity bands considered is also described by Eqn. (4). An example of such a relation is presented in Fig. 7.

According to Eqn. (6), the dependence of $k_{max}N^{1/2}$ on N should be linear under the condition $N_p^a \leq 1$ and $N < N_p^0$. The linearity of this relation has been observed for a series of regularity bands of polymers containing polymethylene, polyoxyethylene, and polystyrene sequences of units in the crystalline state and in the form of solutions at low temperatures (see, for example, Figs. 8–10).

However, in some cases the hypothesis of a pronounced distortion of the correlation of perturbations along the chain and Eqns. (4) and (6) derived on this basis do not allow a

satisfactory description of the $k_{max}(N)$ relation. For example, such relations for certain structure-sensitive bands in the spectra of compounds containing polyoxybutylene and polystyrene sequences of units can be described only with the aid of the exact Eqn.(5) for the band width with the optimised parameters N_p^a, σ, and N_0 (Figs.11–13).

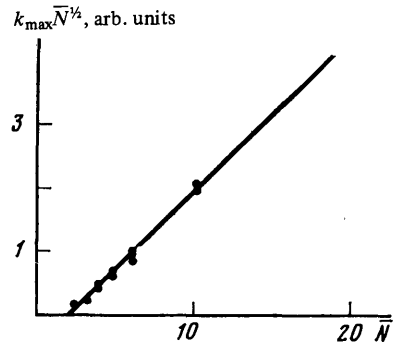

Figure 10. Dependence of $k_{max}\bar{N}^{1/2}$ on $\bar{N}$ for the 1053 cm^{-1} band of the isotactic crystalline styrene–styrene-α-d_1 copolymer[37] ($\bar{N}$ is the average length of the polystyrene segment).

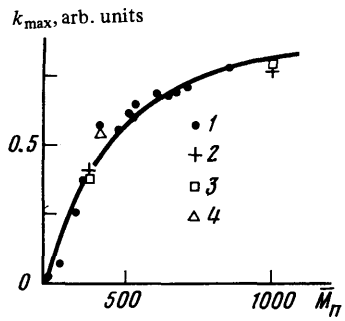

Figure 11. Dependence of k_{max} for the 565 cm^{-1} band on the number-average molecular weight of the polyoxybutylene block for low-temperature solutions in carbon disulphide; *1*) of oligomeric fractions of polytetrahydrofuran; *2*) of initial oligomers; *3*) of acetylated oligomers; *4*) of the tetrahydrofuran–epoxypropane block copolymer[47]. The continuous curve has been calculated by Eqn.(5) with the optimised values of the parameters N_p^a and σ.

1. Analysis of the Helical Structure of Polymer Chains

The bands of transverse vibrations with fairly high values of N_p^0 ($N_p^0 > 2n$, see Table 4) are sensitive to the type of helical symmetry. In order to determine the parameter n of the helix, it is desirable to use bands which correspond to low values of N_p^a; for such bands, the amplitude of the oscillations in the $k_{max}(N)$ relation does not decay unduly rapidly.

In the case of polymethylene chains whose skeleton has a planar zigzag conformation and hence the helical symmetry 2_1 (i.e. two units per turn of the helix), an alternation (with a period of two units) of maxima and minima in the $k_{max}(N)$ curve is to be expected for the transverse vibration bands. Such alternation has indeed been observed for a series of n-paraffins in the region of torsional vibrations (950–1060 cm^{-1}), since the bands corresponding to these vibrations are absent from the spectra of molecules containing an odd number of carbon atoms[124]. For polymers containing regular polyoxyethylene segments with narrow distribution functions with respect to their lengths, the period of the oscillations of the corresponding experimental $k(N)$ relation is equal to seven units (Fig.14). This finding is in good agreement with X-ray diffraction data[140], according to which the polyoxyethylene chain consists of a 7_2 helix.

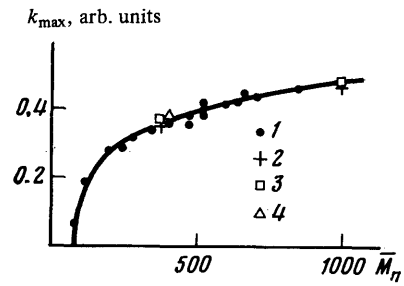

Figure 12. Dependence of k_{max} for the 750 cm^{-1} band in the spectra of low-temperature solutions of model compounds (for legend, see Fig.11) in carbon disulphide on the number-average length of the polyoxybutylene block[47].

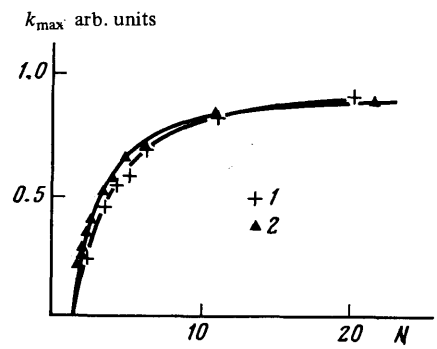

Figure 13. Dependence of k_{max} on the average length of the polystyrene segment for the 1194 cm^{-1} band of the isotactic styrene–styrene-α-d_1 copolymer; *1*) solution in carbon disulphide at −104 °C; *2*) crystalline specimens[37]. The continuous curves have been calculated by Eqn.(5) with optimised values of the parameters N_p^a and σ.

2. The Sequence Length of Tetrahydrofuran-Epoxypropane Copolymers

The structures of such copolymers have been analysed only for polyoxybutylene blocks[47]. Table 5 presents the average lengths $\bar{N}$ of these blocks in copolymers of different composition determined with the aid of the curves illustrated in Figs. 11 and 12. Table 5 also presents the number-average ($\bar{N}_n$) and weight-average ($\bar{N}_w$) lengths calculated from kinetic data[141]. As was to be expected, the lengths determined by the spectroscopic method have intermediate values.

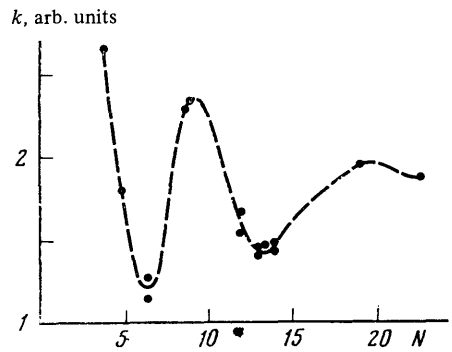

Figure 14. Dependence of k on the length of the polyoxyethylene segment for the 1366 cm^{-1} band in the spectra of glymes, poly(ethylene glycols), and epoxyethane–epoxypropane copolymers at −100 °C.[43]

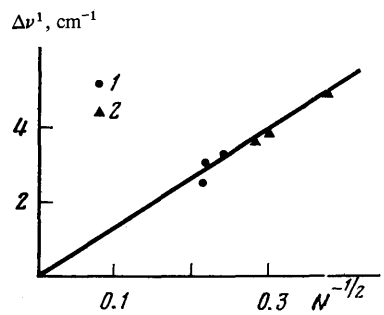

Figure 15. Dependence of the width of the high-frequency wing of the wagging vibration band (730 cm^{-1}) in the spectra of the crystalline component of n-paraffins (1) and ethylene–but-1-ene copolymers (2) on the length of the polymethylene segment[43].

3. The Sequence Length of Epoxyethane–Epoxypropane Copolymers

The Pluronic block copolymers of epoxyethane and epoxypropane (Wyandotte Chemical Co), whose compositions, degrees of block structures, and molecular weights are rigorously correlated with one another, are convenient for testing the spectroscopic method for the analysis of the sequence length. In order to measure the average lengths of the polyoxyethylene POE segments, the dependence of the 1283 cm^{-1} bend intensity on the length of the POE block was used (Fig. 8). Table 6 presents the average lengths of the POE segments measured spectroscopically and determined from the data provided by the Company. Evidently an entirely satisfactory agreement was obtained between these quantities.

Table 5. The lengths of the PTHF sequences in tetrahydrofuran–epoxypropane (EP) copolymers[47].

THF:EP*	$\bar{N}_w$**	$\bar{N}_n$**	$\bar{N}$
1:2	2.2	1.8	2.05
1:1	2.6	2.2	2.5
2:1	3.1	2.4	2.85

* The ratio of the mole fractions of the THF and EP units in the copolymer.

** Kinetic data[141].

Table 6. The lengths of polyoxyethylene (POE) segments in epoxyethane-epoxypropane block-copolymers (Pluronic)[48].

Brand	Average length of POE block	
	Company's data	spectroscopic data
PL-44	9.1	8.8
PL-61	2.2	1.7
PL-62	5.0	4.8
PL-64	12.8	13.7
PL-72	5.9	6.1

4. The Degree of the Block Structure of Ethylene-But-1-ene Copolymers

The development of a method for the measurement of the lengths N of polymethylene blocks is of practical importance in connection with the necessity to investigate the structures of branched polyethylenes. The copolymers of ethylene with other α-olefins can be regarded as models of such polyethylenes.

Fig. 15 shows that the dependence of the half-width of the 730 cm^{-1} band on $N^{-1/2}$ for crystalline copolymers and n-paraffins is described by a single straight line passing through the origin of coordinates, in conformity with Eqn. (4) and the cluster model[43]. The spectra of the crystalline component of the copolymer were obtained by the method of compensations spectroscopy; the spectrum of the polymethylene blocks of the amorphous part of the copolymer was modelled by the spectrum of liquid pentadecane.

---oOo---

In conclusion we may note that we did not mention in this review all the possibilities for structural studies which can be formulated in a wider analysis of regularity bands. For example, one can point to the method based on the analysis

of the temperature variation of the regularity band intensities—the so-called low-temperature spiralisation method[52], which makes it possible to obtain information about the distribution of regular sequences of monomeric units with respect to lengths. Unfortunately, the limited size of the review did not allow us to consider the advantages of the method of analysis using the contour of a complex spectral band whose components are the bands of chain vibrations with frequencies sensitive to the lengths of the regular segments[1,32].

Copolymerisation of Unsaturated Organophosphorus Monomers

S.V.Shulyndin, Ya.A.Levin, and B.E.Ivanov

The present state of the problem of the copolymerisation of unsaturated organophosphorus monomers is considered. Quantitative data on their reactivities in the radical polymerisation processes are surveyed and analysed critically, the place of these monomers among other types of unsaturated compounds is defined, and the organophosphorus monomers most promising from the standpoint of the modification of polymeric materials by copolymerisation methods are specified. The review is based on data published up to the end of 1978.
The bibliography includes 132 references.

VII. Conclusion 875

I. INTRODUCTION

Heat resistance, to which much attention is devoted nowadays, strong adhesion, and the formation of complexes, ion-exchange, and other properties are responsible for the interest in the practical applications of organophosphorus polymers[1]. The majority of polymers of industrial importance burn in air, which constitutes a serious obstacle to their wider and more comprehensive application. Although the introduction of fire-proofing agents into polymers is not able to prevent completely the decomposition of organic polymers on contact with flames, nevertheless it diminishes significantly the rate of propagation of the flame and can even lead to the formation of a self-extinguishing material. The best effect is achieved when chemically active fire-proofing agents[2], particularly organophosphorus monomers (OPM), are used; here the combustion-retarding agent is introduced into the polymer chain, i.e. is an integral part of the polymer. The simplest and most effective method of constructing such a chain involves the copolymerisation of OPM with other unsaturated monomers. Numerous communications devoted to the copolymerisation of unsaturated OPM including reviews and monographs[3-5], have been published hitherto, but the latest review[5] is already more than 10 years old.

Apart from purely practical applications, the copolymerisation method is of interest because it permits a quantitative estimate of the relative reactivities of monomers and polymeric radicals and makes it possible to obtain valuable information for the determination of the mechanisms of radical reactions. Whereas kinetic studies on the homopolymerisation of OPM are as yet restricted to a narrow range of monomers[6-9], the quantitative data on copolymerisation, from which correct conclusions about the influence of the structure of the OPM on their reactivity can be drawn, are fairly extensive. In the present review an attempt is made to survey and interpret critically data on the copolymerisation of OPM precisely from this point of view.

Mainly radical copolymerisation is considered, since problems of the ionic copolymerisation of the OPM have so far been dealt with only in isolated reports[10-12], where it is concluded that the vinyl derivatives of phosphorus have a very low reactivity in anionic and ionic-coordination copolymerisation. Qualitative information about the copolymerisation of unsaturated OPM is discussed only when necessary. The semivinyl copolymerisation of derivatives of tricoordinate phosphorus has been described in a recent review[13]; The semivinyl polymerisation of OPM with SO_2 is dealt with by Faizullin et al.[14]. The properties and applications of the phosphorus-containing copolymers formed will not be considered in this review, since independent reviews have been devoted to these problems[2,15-18].

The polymerisation and copolymerisation of unsaturated OPM lead to carbochain polymers with the phosphorus in the side chain. Depending on the relative positions of the phosphorus atom and the double bond and also on the reactivity of the monomer, it is useful to divide all OPM into four types (typical examples are indicated below; X = OH, OAlk, OAr, NR_2, Alk, Ar, $CH_2=CH$, etc.).

A. OPM with the phosphorus atom linked directly to a vinyl or substituted vinyl group:

$$CH_2=CHP(O)X_2,\ CH_2=C(R)-P(O)X_2,\ CH_2=CHPX_2\ .$$

B. OPM with a diene group at the phosphorus atom:

$$CH_2=CH-CH=CHP(O)X_2,\ CH_2=CP(O)X_2-CH=CH_2\ ,$$
$$CH_2=CP(O)X_2-CP(O)X_2=CH_2\ .$$

C. OPM with the phosphorus atom linked by a double bond via oxygen, nitrogen, a methylene group, or their combination:

$$CH_2=CHOP(O)X_2,\ CH_2=CH-CH_2P(O)X_2,\ CH_2=CH-CH_2OP(O)X_2\ .$$

D. OPM with the phosphorus atom remote from the double bond:

$$CH_2=CHC(O)-OCH_2P(O)X_2,\ CH_2=CH-C_6H_4-P(O)X_2\ .$$

Not only the copolymerisation but also the homopolymerisation of OPM proceeds in very different ways depending on the type to which they belong. When the phosphorus atom is fairly remote from the C = C bond (type D), polymers with a high molecular weight are obtained; no significant differences associated with the influence of the phosphorus atom are observed, since we are virtually dealing only with the polymerisation of styrene, acrylate, etc. If the phosphorus atom is attached directly to the double bond or is separated from it by an oxygen atom (types A and C), polymers with a low molecular weight are obtained owing to specific chain transfer processes, for the explanation of which a number of schemes have been proposed[6,19-22]. When the allyl group is

present in the monomer (type C), the characteristics of allyl polymerisation become of primary importance, which also leads to oligomers. The polymerisation of 1,3-diene OPM (type B) yields polymers[23,24] or copolymers[22,25] with a high molecular weight, depending on their structure.

Organophosphorus monomers undergo copolymerisation virtually with all the usual vinyl monomers, but the yields and molecular weights of the copolymers in most cases decrease with increasing content of OPM units in the macrochain[6,22,37,38]. However, when comparatively small amounts of the phosphorus-containing monomer are used, it is possible to achieve high yields of copolymers with a sufficient phosphorus content to impart to them useful properties and to achieve a satisfactory molecular weight. The introduction of small amounts of phosphorus frequently imparts to polymers new valuable qualities without a significant impairment of their physicomechanical properties. The modification of the known polymers by small amounts of phosphorus is therefore at present of greater practical interest than the synthesis of new organophosphorus polymers.

The Alfrey–Price $Q-e$ scheme is most widely used to characterise the behaviour of monomers in radical copolymerisation reactions. In the present review the parameters Q and e for OPM have been recalculated using Greenley's recently published[26] average values of $\bar{Q}-\bar{e}$ for comonomers, which have been determined by the method of least squares taking into account the probable errors in the determination of the copolymerisation constants. In certain cases Greenley's values differ significantly from the "average" values found by Young[27] and usually employed. Furthermore, in many instances we corrected the values of Q and e for the OPM because sometimes[28-30] the authors of the original communications gave preference to chemically less reasonable values of e of the two possible ones in the solution of the quadratic Alfrey–Price equation. For those compounds where this was possible, we also calculated the average parameters Q and e from the Lüssi equation[31] using Greenley's[26] criterion (the subdivision of monomers into groups based on the degree of reliability, the use of at least three–four independent determinations of the constants r_1 and r_2 for copolymerisation with comonomers belonging to a group which is not below Greenley's group III). In addition we believe it is necessary to use data for not less than three comonomers and to exclude from consideration systems with acid components†, since all the OPM discussed in this review form strong hydrogen bonds with them[32]. In the Tables below Greenley's groups are denoted by Roman numerals, n is the number of independent determinations of r_1 and r_2 used for the calculation, and R is the correlation coefficient. We emphasize that in the case of OPM the use of the Lüssi equation is particularly convenient, since this equation does not include the copolymerisation constants r_1 referring to the phosphorus-containing macroradical, which are as a rule determined with a lower relative accuracy than the constants r_2 referring to the comonomer macroradical. Furthermore, systems with r_1, $r_2 > 1$ and $r_1 = 0$ can be used to calculate $\bar{Q}$ and $\bar{e}$ by the Lüssi–Greenley method.

The following abbreviations have been adopted in this review: (1) for the names of organic monomers: AA = acrylic acid, AN = acrylonitrile, VA = vinyl acetate, VDC = vinylidene chloride, VC = vinyl chloride, DMA = dodecyl methacrylate, MA = methyl acrylate, MAA = methacrylic acid, MAn = maleic anhydride, MVP = 2-methyl-5-vinylpyridine, MMA = methyl methacrylate, and St = styrene; (2) for the names of organophosphorus monomers (OPM): VP = vinylphosphonate(s), MPB = monophosphonobutadiene(s), DPB = diphosphonobutadiene(s), VPA = vinylphosphonic acid $CH_2=CHP(O)(OH)_2$, DMVP = dimethyl vinylphosphonate $CH_2=CHP(O)(OCH_3)_2$, DCVP = di-β-chloroethyl vinylphosphonate $CH_2=CHP(O)(OCH_2CH_2Cl)_2$, DEVP = diethyl vinylphosphate $CH_2=CHP(O)(OC_2H_5)_2$, DEIP = 1-diethylphosphono-2-methylbuta-1,3-diene $CH_2=CH-C(CH_3)=CHP(O)(OC_2H_5)_2$, DEMOP = diethyl α-methacryloyloxymethylphosphonate $CH_2=C(CH_3)C(O)-OCH_2P(O)(OC_2H_5)_2$, DEIPO = 1-(diethylphosphine oxide)-2-methylbuta-1,3-diene $1,3\text{-}CH_2=CH-C(CH_3)=CHP(O)(C_2H_5)_2$, DEPB = 2,3-bis(diethylphosphono)buta-1,3-diene $CH_2=C[P(O)(OC_2H_5)_2]-C[P(O)(OC_2H_5)_2]=CH_2$, TMDVP = tetramethyldiaminovinylphosphonate $CH_2=CHP(O).[N(CH_3)_2]_2$, TEDIP = 1-bisdiethylaminophosphono-2-methylbuta-1,3-diene $CH_2=CH-C(CH_3)=CHP(O)[N(C_2H_5)_2]_2$, and α-PVPA = α-phenylvinylphosphonic acid $CH_2=C(C_6H_5)-P(O)(OH)_2$.

II. MONOMERS WITH THE PHOSPHORUS ATOM AT A VINYL GROUP (TYPE A)

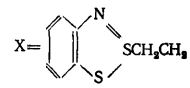
This class includes mainly derivatives of vinylphosphonic acid, vinylphosphines, and phosphine oxides (Table 1). The greatest amount of data has been obtained for the copolymerisation of vinylphosphonate esters.

The influence of the nature of the substituents at the phosphorus atom on the activity of VP can be traced in systems with St and VA. In relation to both polystyrene and poly(vinyl acetate) radicals, VP can be arranged in the following sequence in terms of their reactivities: DCVP > DMVP > DEVP, i.e. the reactivity of the OPM increases with the increasing electronegativity of the ester groups. The polymeric St and VP radicals add more readily to St and the poly-VA radical adds more readily to VP than to its own monomer: as a result, St is incorporated more effectively in the polymer chains than the OPM and VA and OPM have on the whole comparable reactivities in copolymerisation, but VP are nevertheless somewhat more reactive ($r_1 > r_2$).

Examination of the copolymerisation constants for the vinyl OPM together with the known copolymerisation constants for monomers without phosphorus[51] makes it possible to set up reactivity series for these monomers in relation to various macroradicals[38]. In relation to both polystyrene and poly(vinyl acetate) radicals, VP exhibit a reactivity which is intermediate between those for the conjugated (MA) and non-conjugated (VA) monomers with analogous structures. It is of interest that the reactivity of TMDVP does not differ from that of esters in relation to the polystyrene macroradical[38], which has also been noted for the addition of the phenyl radical[52].

The data in Table 1 make it possible to arrange monomers in the following sequence in terms of their reactivities with respect to the poly-DEVP radical ($1/r_1$): VA < AN < MAA < MA ≤ St < MMA. This series agrees on the whole with the series for the usual organic macroradicals[53], which shows that the behaviour of polymeric phosphorus-containing radicals in copolymerisation reactions is similar to that of ordinary macroradicals.

In addition, the copolymerisation constants together with the elementary chain propagation constants for OPM [7,8] and other monomers[53] make it possible to estimate the constants k_{21} for the addition of various radicals to the same OPM.[38] The reactivity of a phosphorus-containing macroradical may be comparable to that of the relatively inactive polystyrene



† The copolymerisation constants for the diethyl vinylphosphonate–acrylic acid system depend greatly on the nature of the solvent[33].

radical in the reaction involving addition to vinylphosphonates, while the large difference between the values of r_1 and r_2 in systems with St is almost exclusively caused by the high rate constants for the homoaddition of St and the low reactivity of VP as monomers. On the whole, some tendency towards a higher rate of addition of macroradicals to the dimethyl ester compared with the diethyl ester is observed[38].

Table 1. The copolymerisation constants for vinylphosphonic acid and its derivaties $CH_2=CHP(O)X_2$ (M_2) and the Alfrey–Price parameters.

Remarks: Solvents: [a]benzene, [b]dioxan, [c]ethyl methyl ketone, [d]water, and [e]DMF. Copolymerisation parameters and Greenley groups: $*\bar{e}_1=0.82$, $\bar{Q}_1=0.10$ (group IV, $n=5$, $R=0.92$); $**\bar{e}_1=0.92$, $\bar{Q}_1=0.074$ (group III, $n=6$, $R=0.99$); $***\bar{e}_1=1.59$, $\bar{Q}_1=0.07$ (group III, $n=7$, $R=0.91$); $****\bar{e}_1=0.62$, $\bar{Q}_1=0.03$ (group V, $n=3$, $R=0.28$); $*****\bar{e}_1=0.66$, $\bar{Q}_1=0.03$ (group V, $n=3$, $R=0.43$).

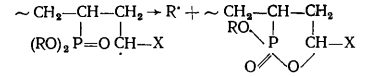
In all the systems (with the exception of AA and MAA) the parameters Q for the vinylphosphonate esters are similar and the electronegativity factors e (Table 1) vary within wide limits depending on the nature of the comonomer. For example, the shape of the curve representing the composition of the copolymers in the systems with St, MA, and MMA cannot therefore be predicted even qualitatively from the values of Q and e for the systems with VA, which is also characteristic of butyl vinylsulphonate[54], structurally similar to VP, and a number of other organoelemental monomers[55-57].

In contrast to the foregoing, when the values of $\bar{Q}$ and $\bar{e}$ obtained by the Lŭssi–Greenley method are used (Table 1), the copolymerisation constants calculated from them for VP and butyl vinylsulphonate agree qualitatively and frequently also quantitatively with the experimental values. The values of $\bar{e}$ for VP depend appreciably on the electron-accepting properties of the alkoxy-groups attached to phosphorus and there is a satisfactory linear correlation between the values of $\bar{e}$ and the Taft constants for these groups:

$$\bar{e}=1.75\sigma^*-2.05 \quad (n=5;\ R=0.986;\ s=0.07)\ .$$

This apparently provides an answer to the old question whether or not a relation exists between the capacity of VP for copolymerisation and the nature of the ester residue[37].

In terms of the resonance stabilisation factor Q, which varies from 0.03 to 0.10, VP occupy an intermediate position between typically non-conjugated monomers of the type of ethylene ($Q=0.012$ and VA($Q=0.031$), on the one hand, and conjugated monomers of the type of MA (0.44), AN (0.48), and St (1.0), on the other. For DMVP and DEVP, a linear correlation has been found between $\lg Q$ and the logarithms of the rate constants for the addition of the phenyl radical to the monomers[52]. For DEVP, a similar relation has also been observed between $\lg\bar{Q}$ and the enthalpies of activation for the thermal homolysis of azopropanes $(CH_3)_2C(X)-N=N-(X)C(CH_3)_2$, which are a measure of the energy of stabilisation of the radical by the adjacent substituent X, in the given instance $P(O)(OC_2H_5)_2$.[58] There exist also other similar correlations involving $\lg Q$ or e.[58,59]



Comparison of the copolymerisation parameters of the structurally related vinyl monomers is extremely instructive (Table 2). It is seen to what extent the data for the organoelemental monomers are similar to one another and differ from those for acrylate. The similarity extends also to the styrene and vinyl acetate systems. In both cases the systems not only belong to the same type ($r_1 < 1$ and $r_2 > 1$ for St; $r_1 < 1$ and $r_2 < 1$ for VA) but are also analogous in form (the values of r_1 and r_2); both monomers have similar reactivities in relation to the macroradicals M_2 ($1/r_2$) and in terms of the alternation parameter r_1r_2. For acrylate, these systems belong to other types ($r_1 < 1$, $r_2 < 1$ and $r_1 > 1$, $r_2 < 1$ respectively) and there are differences between the systems also as regards other parameters. The values of $\bar{Q}$ and $\bar{e}$ for both organoelemental monomers indicate a low degree of conjugation and a high electronegativity. The values of $\bar{Q}$ and $\bar{e}$ for DEVP are lower than for its sulphur analogue, as was to be expected for the transition from the phosphonate to the sulphonate structure, i.e. from a Group V element to a neighbouring Group VI element on the right. The greater electron-accepting capacity of phosphonate and sulphonate compared with acrylate (judging from the values of $\bar{e}$) reflects the greater electronegativity of the metalloids on moving to the right along the Periodic System. (This relation remains valid also for all the VP in Table 1 and for all the acrylates examined by Greenley[26], with the exception of the butyl homologue).

Table 2. Comparison of the copolymerisation parameters of vinyl derivatives of carbon, phosphorus, and sulphur of the type $CH_2=CH-X$ (M_1).

The rates of copolymerisation of VP with St, Ma, MMA, and VA decrease with increase of the content of the OPM in the system. On copolymerisation, quadratic termination of kinetic chains, usual for radical polymerisation, takes place[38]. An increase of the content of the OPM in the initial mixture and in the copolymer leads in all cases to a sharp decrease of the intrinsic viscosity and probably of the molecular weight, due to chain transfer to the OPM.[38] The determination of the constants for the chain transfer to the monomer led to the conclusion that the majority of the OPM investigated are chain transfer agents with a moderate activity. In terms of logarithmic coordinates, the constants for the chain transfer of the poly(vinyl acetate) radical to VP are satisfactorily correlated with the constants for the transfer of the same radical to the corresponding compounds of the type of POX_3 in which the vinyl group has been replaced by a third residue $X = OC_2H_5$, OC_3H_7-iso, or $N(CH_3)_2$.[60] However, the chain transfer constants themselves per group X (in the case of the monomers) are greater by 1.5–2 orders of magnitude than for POX_3.

If the chain transfer involves simply the homolytic abstraction of hydrogen, as is frequently stated in the literature[6,21] the above result can be accounted for solely by an increase of the reactivity of the hydrogen atoms in X when a single group X is replaced by a vinyl group, but we do not believe that it is possible to specify unambiguously the cause of such a radical change. Most probably the increased constants for chain transfer to the monomer are associated with the formation of relatively stable conformations of the growing ends of this chain with a greater proximity between the radical centre and the phosphoryl group of the penultimate unit, by analogy with the homopolymerisation of VP.[8,61]. In such a structure there is a possibility of intramolecular substitution leading to the abstraction of R$^\cdot$ which implies the termination of the old molecular chain and the generation of a new one without the termination of the kinetic chain (the so-called non-degradative chain transfer).

R$^\cdot$ + monomers → chain regeneration.

At any rate, there is no doubt about the significant role of the phosphoryl centre in the transfer mechanism.

The copolymerisation of VPA is of great practical interest, because it makes it possible to obtain linear, soluble, phosphorus-containing polyelectrolytes[34,35], despite the low reactivity of the monomer (Table 1).

The copolymerisation of α-PVPA has been studied in detail. In contrast to VPA,[34] this monomer does not undergo homopolymerisation[30], which was explained by the steric hindrance due to the two bulky geminal substituents. However, α-PVPA copolymerises more readily than VPA and its esters, which becomes particularly clear when the relative reactivities with respect to the polystyrene radical are compared (Table 3, the values of $1/r_2$). This is because the radical arising on addition to α-PVPA is stabilised by both substituents— the phenyl and phosphoryl groups. However, the degree of this stabilisation is greatly reduced compared with the monomer having the phenyl substituent alone, which follows directly from the copolymerisation parameters for the α-PVPA–St system[30].

β-Phenylvinylphosphonic acid, which is isomeric with α-phenylvinylphosphonic acid, and its derivatives, which are 1,2-disubstituted ethylenes, are scarcely capable of copolymerisation and do not form copolymers with MMA and PVA. Nevertheless the constants for the copolymerisation of *trans*-$C_6H_5-CH=CH-P(O)(OC_2H_5)_2$($M_1$) with St have been determined: $r_1 = 0$ and $r_2 = 34 \pm 2$.[69]

Apart from α-PVPA, a study has also been made of the copolymerisation of other α-substituted vinylphosphonates (Table 4). The isopropenyl derivative copolymerises less

effectively than the vinyl derivative. On the other hand, the behaviour of the remaining OPM of this type on the whole occupies an intermediate position between that of the unsubstituted vinylphosphonate and the corresponding acrylates, VA, or vinyl bromide. It is of interest to compare the constants for the copolymerisation of diethyl α-acetoxyvinylphosphonate with both "parent" monomers—DEVP and VA. For the same values of r_1, the constant r_2 is appreciably smaller for VA, which reflects primarily the increase of the resonance stabilisation factor following the introduction of the phosphono-group into VA. The increase of r_2 after the introduction of the phosphono-group into vinyl bromide can be explained analogously. The copolymerisation of α-alkoxycarbonylvinylphosphonates with MMA resembles much more the behaviour of unsubstituted phosphonates than acrylates. In this instance this is a consequence of the enhancement of the electron-accepting properties of the monomer as a result of the introduction of the phosphono-group, which affects both r_1 and r_2 despite the higher values of Q for the OPM considered compared with acrylates.

Remarks: Copolymerisation parameters and Greenley groups: *$\bar{e}_1=1.12$, $\bar{Q}_1=0.033$ (group V, $n=3$, $R=0.95$); **$\bar{e}_1=0.51$, $\bar{Q}_1=0.076$ (group IV, $n=4$, $R=0.86$).

Vinylphosphines, vinylphosphine oxides, and vinylphosphine sulphides belong to the same type of OPM with the phosphorus atom linked directly to the vinyl group (Table 5). The relative reactivity ($1/r_2$) of diphenylvinylphosphine oxide is greater by a factor of ~3 than that of dialkylvinylphosphine oxide in copolymerisation with both St and MMA and is comparable to the reactivity of the corresponding phosphine. The latter finding is extremely remarkable. It has an analogy in the behaviour of derivatives of tricoordinate and tetra-coordinate sulphur[54,55,71], which also do not differ greatly in reactivity in copolymerisation reactions. In contrast to copolymerisation with St and MMA, where the reactivity of phosphine oxides is much lower than that of the comonomers, in the copolymerisation with VA, as in the case of VP, the reactivity of the OPM is comparable and even somewhat greater than that of VA, which leads to the appearance in the system of products with azeotropic composition.

Divinylphosphinates $(CH_2=CH)_2P(O)(OC_2H_5)$ exhibit a low reactivity in copolymerisation with MMA and St.[72]

III. MONOMERS WITH THE PHOSPHORUS ATOM AT A DIENE GROUP (TYPE B)

This group of monomers includes derivatives of butadienyl- and isopropenylphosphonic acids, butadienylenediphosphonic acids, and the corresponding phosphine oxides.

Table 6 shows that, in relation to the polystyrene radical, the reactivity ($1/r_2$) of the dichloride and isopropenylphosphonic acid is higher than that of the esters and the reactivity of the latter is much higher than that of the corresponding vinylphosphonates (Table 1) and allylphosphonates (Table 10, see below). The reactivity of diene OPM is higher than that of the vinyl comonomers without phosphorus (St, MMA, and VDC). This makes it possible to obtain copolymers greatly enriched in the OPM. The sharp increase of the reactivity of the OPM of this type in copolymerisation processes is usually caused by the increase of the degree of

conjugation (Q) in the macroradicals formed following addition to the 1,4-dienes. In copolymerisation with isoprene, the products are copolymers with a rigorously alternating structure ($r_1 r_2 = 0.01$).

The study of the copolymerisation of MPB with different structures showed[77] that the reactivity of the OPM in relation to the poly-VDC radical ($1/r_2$) increases in the sequence ester < amide < oxide (Table 6). This is apparently caused by the increase of the values of e for the OPM in view of the electron-accepting nature of the VDC macroradical. An analogous behaviour has been observed also for the carboxy-radicals of the OPM.[78] The activity series established for the OPM varies in opposition to the series based on the rates of homopolymerisation of these monomers[49], i.e. in the given instance the principle of the ideal reactivity of the monomers is maintained[53].

In order to elucidate the relation between the structure and reactivity of phosphonobutadienes in radical copolymerisation with VDC, the correlation between the relative reactivity of the MPB and the electron density at the phosphorus nuclei has been examined[77]; the chemical shift ($\delta_{^{31}P}$) in the ^{31}P NMR spectra and the stretching vibration frequencies of the P=O group in the infrared spectra of the monomers investigated may serve as a measure of this reactivity within fairly narrow reaction series. Linear relations have been observed between these parameters:

$$\lg(1/r_2) = 0.34 - 0.02\,\delta_{^{31}P} \quad (R = 0.997;\ s = 0.028)$$
$$\lg(1/r_2) = 8.5 - 0.006\,\nu_{P=O} \quad (R = 0.999;\ s = 0.033).$$

As might have been expected on the basis of the values of e_1, the reactivity of MPB in relation to the electronegative poly-VDC radical increases with decrease of the stretching vibration frequencies of the phosphoryl group and as the ^{31}P NMR signals are displaced downfield, i.e. with increase of the positive charge on the phosphorus atom.

The determination of the microstructures of the polymers and copolymers by infrared and ^{31}P NMR spectroscopy showed[79] that MPB polymerise mainly in the 3,4-position, because the addition in the 1,4-position and even more so in the 1,2-position is sterically hindered owing to the presence of bulky phosphorus-containing groups. Other 1-substituted dienes with bulky silicon-, germanium-, and tin-containing groups also behave similarly in polymerisation reactions[80-82], while in the radical polymerisation of the less bulky carboxylic acid and ester analogues [$-C(O)OH$, $-C(O)OR$, and $-OC(O)CH_3$] polymers with the predominatly 1,4-structure are formed[78,83-86].

The copolymerisation of 1,3-dienes with two phosphorus atoms is of great interest from the standpoint of the modification of polymeric materials, because this process makes it possible to obtain copolymers with a higher phosphorus content but a lower fraction of OPM units and hence one can achieve the manifestation of the necessary specific properties without a significant alteration of other physicomechanical characteristics of the polymer. For this purpose, a detailed study has been made[49,77,87-89,95,132] of the radical copolymerisation of 2,3-bis[(dialkyl(aryl)]phosphonobutadienes with a whole series of vinyl and diene monomers (Table 7), which permitted a fairly complete estimate of the reactivity of these OPM in relation to different macroradicals.

For the majority of systems (with the exception of MMA, VA, and *N*-vinylpyrrolidinone), both copolymerisation constants are less than unity and $r_1 r_2 \ll 1$, i.e. the comonomers exhibit a considerable tendency towards the formation of copolymers with an alternating structure. The sequence in which the reactivity of the monomers relative to the DEPB radical ($1/r_1$) varies agrees, as for the copolymerisation of DEVP, with the analogous sequence for the majority of radicals free from phosphorus[53]: VA < AN < MMA < VDC < St < isoprene. The relative reactivity of diphosphonobutadienes with respect to the same polymeric radicals ($1/r_2$) is comparable to the reactivity of monophosphonobutadienes (Table 6) and is much higher than the reactivity of other unsaturated OPM. In particular, the reactivity of DEPB with respect to the polystyrene radical is ~20 times higher than the reactivity of DEVP (Table 1).

Table 7. Parameters of the copolymerisation of diphosphonobutadienes of the type $CH_2=C[P(O)(OR)_2]-C[P(O)(OR)_2]=CH_2$ (M_1) with 1-monosubstituted and 1,1-disubstituted ethylenes at 70 °C.

*$\bar{e}_1 = 1.20$, $\bar{Q}_1 = 0.97$ (group II, $n = 9$, $R = 0.78$).

The study of the copolymerisation of styrene with DPB[88], containing ester groups at the phosphorus atom with different electronegativities, showed that the relative reactivity of DPB with respect to the polystyrene radical is described satisfactorily by the Taft equation

$$\lg(1/r_2) = 0.32\,\sigma^* - 0.08 \quad (R = 0.988;\ s = 0.028).$$

This relation shows that the reactivity of DPB esters is largely determined by the polarity of the alkoxy-groups and is independent of steric effects. The positive sign of the constant ρ^* indicates an increase of the reactivity of the monomers with respect to an electron-donating radical with increase of the electron-accepting properties of the substituents.

The reactivity of DPB with respect to the polystyrene radical is also correlated with the chemical shifts of the signals of the *trans*- and *cis*-terminal protons (in relation to the phosphono-group) in the ^1H NMR spectra and also with the stretching vibration frequencies of the phosphoryl groups of the monomers:

$$\lg(1/r_2) = 1.01\delta_H^{trans} - 6.05\,(R = 0.998;\ s = 0.01)\ ;$$
$$\lg(1/r_2) = 0.76\delta_H^{cis} - 4.33\,(R = 0.982;\ s = 0.03)\ ;$$
$$\lg(1/r_2) = 0.01\,\nu_{P=O} - 12.03 \quad (R = 0.979;\ s = 0.04)\ .$$

The reactivity of DPB increases with increase of the chemical shifts of the protons, i.e. with decrease of the electron density in the diene system and with increase of the stretching vibration frequencies of the phosphoryl groups of the monomers. Using the relations obtained, it is possible to predict with a satisfactory accuracy the relative reactivities of phosphonobutadienes which have not yet been investigated.

Comparison of the behaviour of butadiene and DEPB in radical copolymerisation reactions with a common vinyl comonomer (Table 8) shows that the reactivity of DEPB is appreciably lower than that of butadiene (lower values of r_1). In all systems an inversion of the reactivities of the monomers can be observed, i.e. the diene becomes less reactive than the comonomer. The introduction of two phospheno-groups into the butadiene molecule reduces the reactivity of the diene system, which is caused, among other factors, by the steric hindrance due to the phosphonate groups. In terms of the relative reactivity ($1/r_2$) with respect to the macroradicals of the electron-donating type (St. MVP), DEPB is more reactive than butadiene, while with respect to electron-accepting radicals (MMA, VDC, AN), butadiene is actually more reactive than DEPB, which can be accounted for by the difference between the electronic natures of these diene monomers ($\bar{e}_{\text{butadiene}} = -1.36$; $\bar{e}_{\text{DEPB}} = 1.20$).

Table 8. Comparison of the copolymerisation constants of butadiene and DEPB.

M_2	DEPB (M_1) (Refs.88,132)		Butadiene (M_1) (Refs.51,90)	
	r_1	r_2	r_1	r_2
St	0.06	0.36	1.35	0.58
MMA	0.08	1.40	0.62	0.18
VDC	0.07	0.22	1.90	0.05
AN	0.09	0.43	0.33	0.25
MVP	0.10	0.32	1.32	0.72

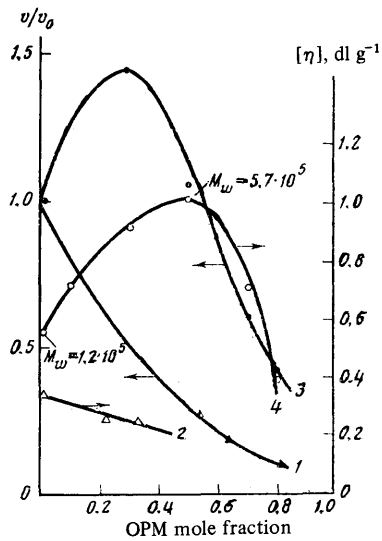
From the values of $\bar{e}$ and $\bar{Q}$, DPB must be regarded as electron-accepting highly conjugated monomers. The high specific reactivities of DPB can be accounted for by the presence of the conjugated 1,3-diene system in these compounds, which ensures the effective resonance stabilisation of the resulting radicals, while the high positive values of the polarity factors are due to the presence of two electronegative phosphonate groups in the monomers. Naturally the values of $\bar{e}$ and $\bar{Q}$ for DPB are much higher than the corresponding values for monovinyl OPM. The higher reactivity of diene derivatives in copolymerisation compared with the vinyl derivatives is due largely to the higher values of Q.

Analysis of the infrared and ^{31}P NMR spectra of the monomers and polymers has shown[77,79] that, in contrast to MPB, the polymerisation of DPB proceeds preferentially in the 1,4-position. The rate of copolymerisation of DPB is proportional to the concentration of the monomers and the square root of the initiator concentration, which indicates the bimolecular termination of the polymer chains and the absence of degradative chain transfer[87,91]. In this respect phosphonobutadienes do not differ from VP.[38]

Significant differences have been observed in the study of the dependence of the rate of polymerisation and the molecular weight of the copolymers on the composition of the initial monomer mixture[25,77,87-89,91]. In the copolymerisation of DPB with MMA, AN, VDC, and certain other monomers the rate of reaction diminishes with increase of the OPM content in the initial mixture (as for VP), which is apparently caused by the replacement of the active polymeric radical derived from the vinyl monomer by the less active phosphorus-containing radical of the allyl type stabilised by conjugation. The molecular weight (intrinsic viscosity) of the copolymer also diminishes under these conditions but less markedly than the yield of the copolymer, which nevertheless makes it possible to obain high-molecular-weight polymers with a fairly high phosphorus content.

The constants for chain transfer by the poly-MMA radical to DEPB, 2,3-bis(diphenylphosphono)buta-1,3-diene, and 2,5-dimethyl-3,4-bis(diethylphosphono)hexa-2,4-diene have been determined[88] from the Mayo equation[92]. Virtually identical chain transfer constants were obtained for all three DPB, amounting to $(2.9-3.3) \times 10^{-3}$, whence it follows that the chain transfer constants depend little or not at all on the nature of the alkoxy-groups. Consequently the chain transfer reaction is not associated with the abstraction of a hydrogen atom from these groups, as for vinyl OPM,[38] since otherwise the phenyl ester would have shown a much smaller reactivity than the ethyl ester. The methyl groups in 2,5-dimethyl-3,4-bis(diethylphosphono)-hexa-2,4-diene are also not significantly involved in the chain transfer reaction, since their presence in this diene does not increase the chain transfer constant[93]. In terms of the absolute values of the chain transfer constants in the polymerisation of MMA, DPB can be characterised as chain transfer agents of moderate activity, but they are much more active than the MMA comonomer [$(0.7-1.8) \times 10^{-5}$ at 60 °C].[94]

Other features are observed in the copolymerisation of DPB with isoprene, St, vinylpyridines, and MAn, i.e. with strong electron-donating and electron-accepting conjugated monomers. In this case the dependence of the yield and the molecular weight of the copolymers on the composition of the initial monomer mixture passes through an extremum. An extremum in the yield and moleclar weight of the copolymers is observed also in many instances for MPB, particularly in the copolymerisation of bis-2,4-dichlorophenyl 2-methylbuta-1,3-dienylphosphonate with isoprene[24].



Thus organophosphorus polymers with a higher molecular weight than the corresponding purely organic homopolymers can be obtained by the copolymerisation of diene OPM with many comonomers, which constitutes an important advantage of OPM over VP in the copolymerisation of which the rate of reaction and the molecular weight of the polymers are much lower, as mentioned above. The advantages of diene OPM are clearly illustrated in the Figure, which presents the dependence of the relative rates of the process and of the molecular weight (intrinsic viscosity) of the copolymers in the copolymerisation of DEPB and DEVP with St on the composition of the initial monomer mixtures.

The tendency of phosphonobutadienes to form copolymers with an alternating structure and the extrema in the dependence of the rates of copolymerisation and the molecular weights of the copolymers on the composition of the monomer mixture may indicate[95] the formation by these OPM of charge-transfer complexes (CTC) with the comonomer.

The formation of the 1:2 CTC in the DEPB–MAn system has been demonstrated by ^1H NMR and ultraviolet spectroscopy[96]. In the copolymerisation in this system a high degree of regularity in the alternation of monomer units in the copolymer and maxima in the rate and the molecular weight of the copolymers have been observed.

The copolymerisation of DEPB with MAn in the presence of any amount of acetone, tetrahydrofuran, and acetonitrile leads to the formation of a copolymer which does not differ in composition from the polymer obtained in the absence of

these additives; however, the introduction of dimethylformamide (DMF), dimethyl sulphoxide (DMSO), and particularly dimethylaniline into the system increases the reactivity of MAn. In terms of their influence on the reactivity of MAn, these compounds can be arranged in the sequence: DMF < DMSO ≪ dimethylaniline. This sequence is apparently caused by the decrease in the same series of the ionisation potentials of the compounds. The absence of an influence on the course of copolymerisation by other electron donors can evidently be accounted for by their inability to compete with DEPB in the donor–acceptor interaction with MAn.[96]

Dependence of the relative rates of copolymerisation v/v_0 (curves *1* and *3*) and the intrinsic viscosities of the copolymers [η] (curves *2* and *4*) on the composition of the monomer mixture in the copolymerisation of OPM with St; OPM: *1*) and *2*) DEVP; *3*) and *4*) DEPB.

With increase of the DMF concentration, r_2 increases sharply, while r_1 decreases[96,97], which indicates an appreciable increase of the reactivity of MAn in the presence of DMF. Thus the composition of the copolymers can be regulated within very wide limits by introducing electron-donating compounds into the system.

Data on the copolymerisation of DEPB with various imides of maleic acid have been published[98]. In these systems the reactivity of the monomers is independent of both the nature (DMF, dioxan) and the amount of the solvent employed. The relative reactivity of *N*-alkylmaleimides in relation to the DEPB macroradical ($1/r_1$) obeys the Taft equation:

$$\lg(1/r_1) = 0.80\,\sigma^* + 0.47 \quad (R = 0.999;\ s = 0.004)\ .$$

For *N*-arylmaleimides, a relation has been observed between the reactivity and the inductive constants σ_I of the substituents in the aryl residue:

$$\lg(1/r_1) = 0.46\,\sigma_I + 1.3 \quad (R = 0.990;\ s = 0.022)\ .$$

A study of the copolymerisation of allene OPM–diethyl and dibutyl 3-methylbuta-1,2-dienylphosphonates—with MA (M_2) established[99] that the allene derivatives of phosphorus are characterised by a low reactivity ($r_1 = 0$, $r_2 \gg 1$).[99] The replacement of the diene group by the allene group reduces sharply the copolymerisation capacity of the OPM, which was in fact to be expected in view of the absence of conjugation in the π-electron system of the allene group.

IV. MONOMERS WITH THE PHOSPHORUS ATOM IN THE β- OR γ-POSITION RELATIVE TO A VINYL GROUP (TYPE C)

Vinyl and allyl phosphates and vinyl- and allyl-phosphonates should be included in this group of monomers. It follows from Table 9 that vinyl phosphates copolymerise much more readily with structurally analogous vinyl esters than with St. The reactivity of vinyl phosphates in copolymerisation with St is very low and in practice only the St homopolymer is formed. The relative reactivity of vinyl phosphates in reactions with macroradicals is much lower, as was to be expected (by analogy with carboxy-analogues), than the reactivity of VP and is comparable to the reactivity of VA. The quantities Q and $\bar{Q}$ are on the whole lower than for VP, i.e. the introduction of oxygen between the vinyl group and phosphorus reduces the conjugation between the vinyl group and the phosphorus-containing residue which was in any case already low. This is also evident from the behaviour of diethylvinyl phosphate in relation to C_6H_5.[52] The copolymerisation with MAn likewise resembles the behaviour of VA and is characterised by a high degree of regularity in the alternation of units.

Table 9. Copolymerisation parameters of vinyl phosphates of the type $CH_2=CH-O-P(O)(OR)_2$ (M_1) at 60 °C.

There have been many communications on the copolymerisation of allyl derivatives of phosphorus[5,101], but the majority of the investigators restricted themselves to the determination of the phosphorus content in the copolymers and to estimating some of their properties. The available quantitative data on the compolymerisation of monoallyl derivatives of phosphorus are presented in Table 10. In terms of their ability to react with the poly-MAA radical, the monomers listed in Table 10 can be arranged in the sequence DEVP > diethyl allylphosphonate > 1,4-bis(diethylphosphono)-but-2-ene[102]. This sequence in the variation of the reactivities

is associated with the decrease of Q on passing from the vinyl to the allyl monomer (rupture of the conjugation chain) and with the transition from the mono- to the 1,2-disubstituted ethylene; the latter always causes a sharp reduction in the reactivity of monomers. Allyl derivatives of phosphorus exhibit a lower reactivity in copolymerisation with unsaturated polyesters[104,105].

A number of studies[103,106–109] have been devoted to the copolymerisation of diallyl OPM (Table 11), which copolymerise via both allyl groups with formation of cyclolinear polymers, which is indicated by the lower degree of unsaturation and the high solubility of the products. Table 11 shows that phosphonates are relatively inactive monomers. The relative reactivities of butyl- and phenyl-phosphonates are the same, i.e. the presence of acid groups does not influence the reactivity of the monomers which is apparently due to the remoteness of these groups from the double bond. On passing to the phosphates, the reactivity of the OPM increases somewhat. The reactivity of diallyl derivatives of phosphorus with respect to the polymeric methacrylate radicals is approximately the same regardless of their structure and somewhat higher than the reactivity of allyl OPM (Table 10). With increase of temperature, the reactivity of the OPM with respect to the poly-DMA radical increases. It is believed[109] that the negative values of r_1 are due to the influence of the penultimate unit but one cannot rule out the possibility that other factors also operated, since the experiments were performed at fairly high temperatures where there is a possibility of depolymerisation and of other processes.

The copolymerisation of diallyl methylphosphonate with ethylene[110], in contrast to the copolymerisation with MMA and St, involves one of the allyl bonds. Since the copolymerisation was carried out[110] at low OPM concentrations, only the constant r_2 can be determined with an adequate accuracy. It decreases with increasing pressure, while r_1 is stated by the author to lie in the range between 0 and 2.

V. MONOMERS WITH THE PHOSPHORUS ATOM REMOTE FROM A VINYL GROUP (TYPE D)

This class of OPM includes mainly substituted acrylates, methacrylates, and styrene derivatives. They copolymerise almost in the same way as the analogous monomers without phosphorus. Data on the copolymerisation of phosphonoacrylates with vinyl monomers are presented in Table 12, from which it follows that phosphonoacrylates enter into the composition of the copolymer with somewhat more difficulty than MA and MMA, while in the copolymerisation with St their reactivities are comparable, i.e. the copolymerisation resembles that in the MMA–St system. Naturally the ability of phosphonoacrylates to combine with macroradicals is much greater than that of VP, which makes it possible to obtain polymers with a high phosphorus content. The factors Q and e for phosphonoalkyl methacrylates are frequently close to the corresponding parameters for MMA.

Table 12. Copolymerisation parameters of methacryloyl derivatives of phosphorus $CH_2=C(CH_3)COOR$ (M_1).

*Acryloyl derivatives.

Examination of data for the copolymerisation of phosphonoalkyl methacrylates with St (Table 12) shows that the nature of the phosphorus-containing group nevertheless does exert some influence on the reactivity of these monomers, but the nature of this influence is not clear. We can only note that the higher electronegativity of the diphenyl phosphate group compared with the phosphite group also leads to a greater reactivity of methacryloyl phosphate also in relation to the polystyrene radical, compared with methacryloyl phosphite[111]. At the same time vinylphosphines and *p*-styrylphosphines have virtually the same copolymerisation constants as their oxides. This behaviour of the methacryloyl derivatives in cases where the influence of the environment of the phosphorus should be manifested to an even lesser extent requires further experimental confirmation particularly since methacryloyl phosphates are thermally unstable[112]

Styrenes with phosphorus-containing groups in the ring belong to monomers of the same type. The copolymerisation of the chloride and the dibutyl ester of *p*-styrylphosphonic acid with certain monomers has been investigated[121]. On the basis of the available data for the compositions of the copolymers and the initial mixtures, one may conclude that the ester is much more reactive than VA in copolymerisation while the acid chloride has a reactivity comparable to those of St and MMA.

The study of the copolymerisation of the styrenes listed in Table 13 [122,123] showed that these monomers are more reactive than St and MMA and that $r_1 > 1$ and $r_2 < 1$. This makes it possible to obtain copolymers greatly enriched in the OPM over the entire range of initial compositions. It is of interest that Q increases following the introduction of phosphorus-containing groups in St, evidently as a result of their inclusion in the conjugation chain. The quantity e also naturally increases as a result of the introduction of electronegative phosphorus-containing groups. It follows from Table 13 that the relative reactivities of both phosphine (P^{III}) and phosphine oxide and sulphide (P^{IV}) are virtually the same. The similar influence of groups with P^{III} and P^{IV} on the reactivity of the double bond in OPM of type A was noted above but, as already stated, the situation is different for methacrylates.

Table 13. Copolymerisation parameters of diphenyl-*p*-styrylphosphine, its oxide, and its sulphide of the type $CH_2=CH-C_6H_4-X$ (M_1). [123]

*According to the data of Braun et al. [122]

The data presented in Table 13 on the copolymerisation of styrenes substituted with phosphorus-containing groups in the *p*-position are described satisfactorily by the familiar[124,125] linear relation between the relative reactivity of the styrene monomers with respect to the polystyrene radical and the Hammett constants. The σ constants of the substituents taken from Tsvekov and coworkers[126,127] were used:

$$\lg(1/r_1) = 0.57\sigma + 0.14 \quad ,$$

i.e. phosphorus-containing styrenes obey the same relations as other *p*-substituted styrenes.

The styrene derivatives of arsenic, antimony, and bismuth with structures analogous to that of diphenyl-*p*-styrylphosphine exhibit the same reactivity as the phosphine in copolymerisation with St. [122]

VI. COPOLYMERISATION OF ORGANOPHOSPHORUS MONOMERS OF DIFFERENT TYPES

Direct comparison of the reactivities of different types of OPM in their copolymerisation with one another is of interest[49]. (see Tables 1, 6, and 12). Table 1 shows that acrylic and diene OPM have much higher reactivities than VP.

In the copolymerisation of diene OPM the ester of isoprenylphosphonic acid is more reactive than the amide (Table 6), as has been observed also for acrylic acid derivatives[128], and MPB are more reactive than DPB (Table 6). Phosphonoalkyl methacrylates have an activity comparable to that of monophosphonobutadienes, but higher than that of diphosphonobutadienes (Table 12). The reactivity of MPB with respect to the electronegative DCVP macroradical (Table 6) increases, like that with respect to the poly-VDC radical[77], with decrease of the stretching vibration frequencies of the phosphoryl group and with increase of the negative chemical shifts $\delta_{^{31}P}$:

$$\lg(1/r_2) = 0.59 - 0.02\,\delta_{^{31}P} \quad (R = 0.995;\ s = 0.028)$$

$$\lg(1/r_2) = 7.1 - 0.005\,\nu_{P=O} \quad (R = 0.993;\ s = 0.033).$$

The reactivity of phosphonoalkyl methacrylate with respect to the poly-DCVP radical ($1/r_2$) is comparable to that of isoprenylphosphonate but somewhat lower than the reactivity of butadienylenediphosphonate (Table 1), in agreement with data for the copolymerisation of these monomers with St[76,88,115].

Table 14. The relative reactivities ($1/r_2$) of organophosphorus monomers (M_1) with respect to the polystyrene radical.

VII. CONCLUSION

It is of interest to examine the reactivities of OPM of different types and with different structures in relation to the standard polystyrene radical (Table 14). Evidently the reactivity of OPM varies within very wide limits: the reactivities of the first and last OPM differ by more than two orders of magnitude. This reactivity series is apparently on the whole analogous to the series for other polymeric radicals, as can be seen from Table 15, which presents the reactivities of the most thoroughly investigated OPM with respect to various macroradicals. The behaviour of new OPM can be assessed and the most promising of these can be selected on the basis of similar series.

Table 15. The relative reactivities ($1/r_2$) of OPM (M_1) in reactions with various polymeric radicals

OPM	St [38, 76, 88, 115]	MMA [45, 88, 114]	VDC [77, 132]	VA [38, 132]	VC [47]
$CH_2=C[P(O)(OC_2H_5)_2]-C[P(O)(OC_2H_5)_2]=CH_2$	2.80	0.71	4.55	20.0	—

$CH_2=CHP(O)(OCH_2CH_2Cl)_2$	0.41	0.03	0.49	25.0	1.92

* $R = CH_3$. ** $R = C_2H_5$. *** $n = 2$. **** $n = 1$.

Tables 14 and 15 show that diene, methacrylate, and styrene derivatives of phosphorus are most suitable for the modification of polymers by the copolymerisation method. However, the synthesis of the last two types of monomers is extremely laborious, the latter being obtained in low yields and frequently with a low purity. Furthermore, the presence of bulky side groups in the chain at the phosphorus atom greatly reduces the thermal stability of copolymers based on them[129,130].

---oOo---

As can be seen from the foregoing, the method of the copolymerisation of unsaturated OPM can be used successfully to modify a wide variety of polymeric materials. By altering the nature and the structure of OPM, it is possible to vary widely both the rate of the process and the molecular weights of the products, on the one hand, and the composition of the copolymers and ultimately the properties of the polymers in the desired manner, on the other.

The Adsorption - Absorption Gas Chromatography on Silochromes with Layers of Liquid Crystals

Z.P.Vetrova, N.T.Karabanov, G.G.Maidachenko, and Ya.I.Yashin

The results of studies of the properties of liquid crystals in a version of gas adsorption-absorption chromatography are surveyed. A general property of liquid crystals deposited on active adsorbent carriers, consisting in the possibility of extending the temperature range of the existence of their mesomorphic state, is revealed.
The bibliography includes 94 references.

I. Introduction 879
II. The influence of various factors on the structural selectivity of thermotropic liquid crystals 880
III. The phase transitions in the mesomorphic state of a smectic liquid crystal 883
IV. Assessment of liquid crystal stationary phases on the basis of polarity factors 884

I. INTRODUCTION

Liquid crystals (LC) possess simultaneously the properties of liquids (fluidity, the ability to exist in the form of drops, etc.) and the properties of solid crystalline bodies (anisotropy, and electrical, optical, and other properties)[1]. Friedel[2] was the first to introduce the concept of the mesomorphic (liquid crystal) state and divided liquid crystals into two types: nematic and smectic. Certain liquid crystals belong to both types. In this case the smectic mesophase, in which molecules are not only arranged parallel to one another but are also fixed in layers, is formed initially; at higher temperatures there is a transition to the nematic mesophase, where this additional order is lost. A further increase of temperature leads to the formation of the isotropic liquid. The formation of a special kind of "twisted structure" is characteristic of the cholesteric mesophase, which is regarded as a variety of the nematic phase[1].

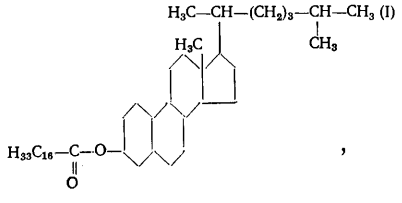
Liquid crystals can be formed not only on fusion of a solid (thermotropic liquid crystals) but also in the course of its dissolution (lyotropic liquid crystals). The chemical features, structure, and properties of low-molecular-weight liquid crystals have been described in reviews[3-5] and in a monograph[6].

The liquid crystal state is characteristic not only of many low-molecular-weight compounds but also of high-molecular-weight compounds. As early as 1941, Kargin and Slonimskii[7] and later Sanderman and Keller[8] drew attention to the possibility of the existence of the liquid crystal state in polymeric systems. However, theoretical and experimental studies only recently established that the phase transition of polymers to the mesomorphic state is just as feasible as for low-molecular-weight compounds.

The formation of liquid crystal polymers induced by the entropy effect as a result of the rigidity of the main chain has been described in a review[9]. Liquid crystal systems in which the ordering of the side groups is possible by virtue of the flexibility and not rigidity of the main chain have been examined, for example, in Refs.10–13. Plate et al.[14] proposed a new approach to the formation of liquid crystals of the thermotropic type from high-molecular-weight, which consists in synthesising mushroom-shaped polymers containing mesogenic groups at the ends of the side branches. The mesomorphic state of liquid crystals possesses a unique combination of properties, which is responsible for their wide scale employment in optics, holography, quantum electronics, visual observations of temperature changes by only 0.01–0.001 K, and the elucidation of molecular structures by NMR spectroscopy, as structural elements in living organisms, and finally as specific sorbents in the chromatographic separation of isomeric compounds. The applications of liquid crystals have been reviewed fairly completely[15].

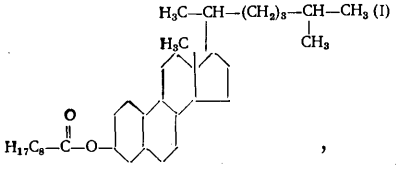
On the other hand, the first studies of the chromatographic characteristics of liquid crystals demonstrated their likely usefulness as sorbents for gas chromatography[16-19]. The ordered arrangement of molecules in the temperature range of the mesophase promotes the separation of aromatic *meta*- and *para*-isomers with similar boiling points. This effect, first observed[16-19] for azoxy-esters, proved to be characteristic of many liquid crystals: it arises because the more linear form of the *para*-substituted aromatic compounds enables them to penetrate more readily into the liquid crystal lattice and to interact more "intimately" than the *meta*- and *ortho*-substituted derivatives. This property has been noted in a number of studies[20-27] where it was shown that the maximum selectivity of the liquid crystals with respect to positional isomers is observed at the melting point and diminishes with increase of temperature, while the sorption capacity of the chromatographic column also increases sharply on passing from solid to the mesomorphic state of the liquid crystal.

Liquid crystals have found extensive applications in gas chromatography as highly selective stationary phases. Fairly numerous publications, including reviews, have been devoted to this problem[22,23,28-30]. The possible analytical applications of many known and also newly synthesised liquid crystals have been investigated by Soviet workers[28,31-42]. Difficult separations have been achieved on liquid crystals using not only packed but also micropacked[43] and capillary columns[44-47]. Chemical modification of the silica surface with cholesteric liquid crystals makes it possible to employ such sorbents for highly effective liquid chromatography[48].



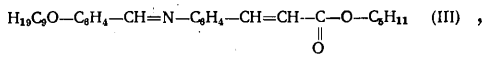
Liquid crystals have been used to separate the homologues of naphthalene[49], polynuclear aromatic hydrocarbons[50,51], steroids[52], polycyclic aromatic hydrocarbons up to C_{24}, [53] benzopyrene[54], herbicides[55], etc. A comparison has been made[56] of columns with bentonites and liquid crystals; it has been shown that the selectivity of liquid crystals with respect to *ortho*-, *meta*-, and *para*-isomers is in many instances greater. Theoretical problems concerning the selectivity of liquid crystals have been examined in a number of studies[36, 57-60].

One should note that accurate measurements, such as the determination of thermodynamic characteristics on liquid crystals[58,61-65], the determination of the orientational order in cholesteric[66] and nematic liquid crystals[67], the observation of a change in the selectivity and sorption capacity of the chromatographic column with liquid crystals following the application of an electric field[68-70], and the determination of the temperatures of transitions from one phase state of liquid crystals to another[58], can be carried out with the aid of chromatography.

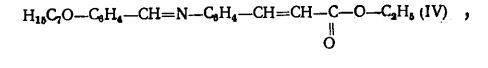


II. THE INFLUENCE OF VARIOUS FACTORS ON THE STRUCTURAL SELECTIVITY OF THERMOTROPIC LIQUID CRYSTALS

In all the studies quoted, except those of Zelenkova and coworkers[41,42], substances have been separated as a result of their dissolution in a film of liquid crystals deposited on an inert solid support, which hardly altered the properties of the liquid crystals and did not itself participate in the sorption of the components to be separated. We replaced the support with a low adsorption activity and a low specific surface ($s_{sp} \cong 1$ m^2 g^{-1}), usually employed, by a silica adsorbent support (silochrome) with $s_{sp} \cong 10$–150 m^2 g^{-1}.[71] It was assumed that, owing to the strong adsorption, there is a definite orientation of the polar molecules of the liquid crystal on the surface of the adsorbent support and that this rigidly fixed orientation persists over a wider temperature range due to the adsorption field of the adsorbent support. This made it possible, in its turn, to retain the selectivity of the liquid crystals with respect to isomers over a wide temperature range and for different amounts of liquid crystals.



For this purpose, we used the adsorption–absorption variant of gas chromatography (GAAC),[72] which is intermediate between the gas-adsorption and gas-liquid variants and presupposes retention, as a result of both adsorption and dissolution (absorption), of the specimen in a film of liquid phase deposited on the adsorbent support. Nematic and smectic liquid crystals as well as cholesteric forms of nematic liquid crystals were investigated: cholesteryl oleate



cholesteryl pelargonate

n-pentyl *p*-(n-nonyloxy)benzylidene-*p'*-aminocinnamate

ethyl *p*-(n-heptyloxy)benzylidene-*p'*-aminocinnamate

4,4'-diethoxyazoxybenzene

p-anisylideneaminoazobenzene

and *p,p'*-dibenzylidenebenzidine

The phase transition temperatures and the clarification temperatures t_{cl} of liquid crystals (I)–(VII) are listed below:

LC	(I)	(II)	(III)	(IV)	(V)	(VI)	(VII)
t, °C	19 (smc)	78 (smc)	80 (sosm)	120 (sosm)	135 (son)	147 (son)	234 (son)
t_{cl}, °C	33.5	91.5	135	156	165	183	260

(the following phase symbols are used for the specified phase transition temperatures: so = solid, sm = smectic, n = nematic, and c = cholesteric).

Specific macroporous adsorbent silochromes[73] with $s_{sp} = 120$, 150, 80, 50, 30, and 10 m^2 g^{-1}, a non-specific carbon adsorbent—PM-15 carbon black, and CaA molecular sieve ($s_{sp} \cong 800$ m^2 g^{-1}) were used as supports for the liquid crystals. The column size was 100×0.3 cm and the linear flow rate of nitrogen was 17 sm s^{-1}. For comparison, the liquid crystals were deposited also on the usual supports with a low activity: Chromaton ($s_{sp} = 1$ m^2 g^{-1}) and porous Teflon ($s_{sp} = 8$ m^2 g^{-1}).

Experimental measurements of the temperature variations to the retention volumes (V_g) on liquid crystals deposited on adsorbent supports confirmed the initial hypotheses. Fig. 1*a* presents the temperature variation of lg V_g of xylene isomers on cholesteryl pelargonate deposited on Chromaton ($s_{sp} \cong 1$ m^2 g^{-1}) in an amount of 6 wt.% (film thickness $\sigma \cong 60$ nm). Fig. 1*a* shows that the nature of these curves is consistent with the usual idea concerning the phase transition of liquid crystals when the temperature is varied, namely the plot shows clearly three regions of the phase states of cholesteryl pelargonate; solid, liquid crystal (mesophase), and liquid (isotropic region). The transition of cholesteryl pelargonate from the solid to the mesomorphic state is accompanied by a sharp increase of the V_g of the sorbates, i.e. at the melting point of 78 °C the retention times increase by a factor of ~5. In the region of the mesophase (78–91.5 °C) a further increase of temperature entails a decrease of V_g. In the transition of cholesteryl pelargonate to the isotropic liquid phase the retention parameters again increase but to a lesser extent. At the clarification point (91.5 °C) of the liquid crystal the selectivity of the separation (the factor α defined as the ratio of the corrected retention times of the *para*- and *meta*-isomers) diminishes. Whereas the values of V_g for the isomeric xylenes are similar in the region of the solid state of cholesteryl pelargonate and the isomers are not separated, in the region of the mesophase the V_g differ and the xylenes can be separated (Fig. 1*a*).

Thus the maximum selectivity of cholesteryl pelargonate with respect to the *meta*- and *para*-isomers is shown at the temperature where it undergoes a transition to the liquid crystal state and then decreases monotonically as the clarification point is approached. When the same amount of the liquid crystal (6 wt.%) is deposited on an active sorbent—Silochrome S-80 ($s_{sp} \cong 80$ m^2 g^{-1}) with a film thickness $\sigma \cong 0.7$, the nature of the phase transition curves changes markedly. Fig. 1*b* shows that in the region of temperatures corresponding to the transition of compound (II) to the mesophase no sharp and abrupt alteration of the retention parameters of the sorbates is observed. On the other hand, over the entire experimental range, an increase of temperature is seen to entail a decrease of the retention volumes. This

behaviour has also been observed[71] for monolayers of compounds (III) and (V) on Silochrome S-80.

The retention of a fairly high selectivity on such sorbents over the entire temperature range of the liquid crystal state of the given substance is of greatest interest. The initial adsorbent carrier does not separate xylene isomers and the selectivity in the separation is therefore due to the liquid crystal film. This unusual effect has been studied in detail in our investigations[71,74,75] for different ratios of the liquid crystal and the adsorbent carrier, i.e. a study was made of the influence of the thickness of the liquid crystal film on the effect of phase transitions; in addition the influence of the specific surface of the adsorbent carrier on this effect with retention of the chemical nature of the surface of the carrier was investigated in relation to both specific and non-specific adsorbents.

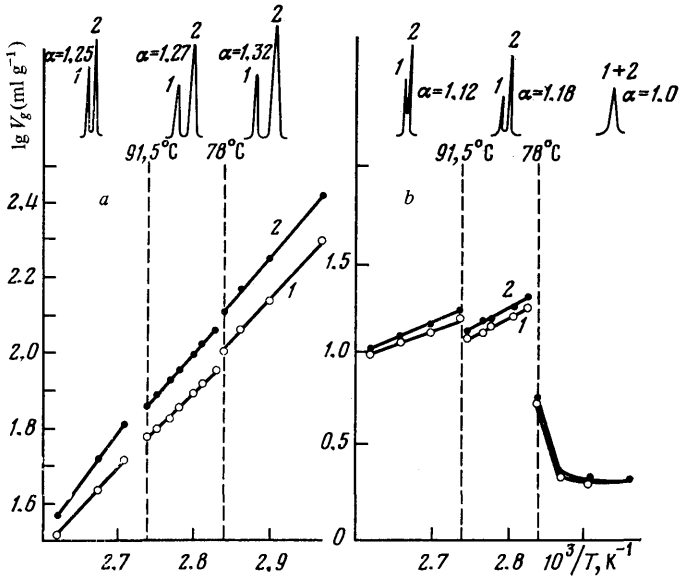


Figure 1. Temperature variation of the logarithms of the retention volumes (lg V_g) of xylene isomers on dehydroxylated Silochrome S-80 (*a*) and Chromaton (*b*) with 6 wt.% of cholesteryl pelargonate: 1) *m*-xylene; 2) *p*-xylene. The separation factors α for the pair of components at different temperatures are indicated[71].

It might have been supposed that the retention of a high selectivity obtains solely in the presence of small amounts of the liquid phase, i.e. for thin liquid crystal films, and that with increase of the film thickness on Silochrome S-80 a sharp increase of the retention parameters of the sorbates in the transition of compound (II) to the mesophase would be observed (as on a relatively inactive support—Chromaton). However, in the study of Silochrome S-80 specimens containing between 0.5 and 120 wt.% of compound (II) no breaks were observed in the relation between lg V_g and $1/T$. This can be explained by the fact that an increase of temperature does not lead to phase transitions, i.e. that the liquid crystal layers exist in the adsorbed state and that the adsorption energy exceeds the kinetic energy of the liquid crystal molecules corresponding to the given temperature.

At the liquid crystal clarification temperature there are also virtually no changes in the retention volumes.

Consequently the 6 wt.% of the liquid crystal on the surface of Silochrome S-80 has no phase transitions in the temperature range from 60° to 107 °C. The same behaviour of the liquid crystal has been observed also on Chromaton when a small amount of the liquid phase is deposited on its surface. For example, in the presence of 1 wt.% of the liquid crystal on Chromaton (Fig.2*a*) a virtually monotonic decrease of the retention characteristics with increasing column temperature is observed (by analogy with Silochrome). However, in this case the separation of xylene isomers is not observed even in the region of the mesophase.

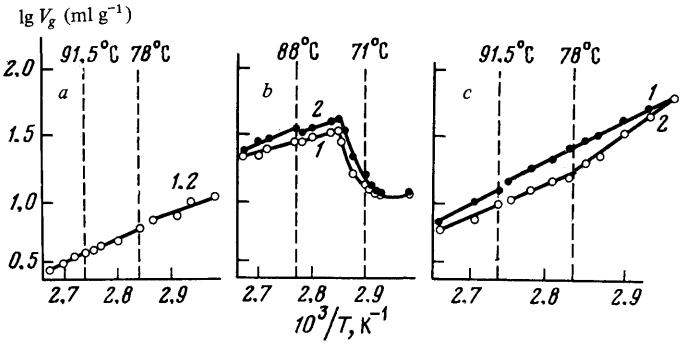

Figure 2. Temperature variation of lg V_g for xylene isomers on dehydroxylated Chromaton with 1 wt.% (*a*) and 12 wt.% (*b*) of cholesteryl pelargonate and on the same sorbent with 6 wt.% of aerosil dispersed in cholesteryl pelargonate (*c*):[74] 1) and 2) see Fig.1.

Similar relations have been observed by Gabitova and Vigdergauz[76] who noted a sharp decrease of the selectivity of the liquid crystal with respect to the *meta*- and *para*-isomers on reduction of the content of *p,p'*-ethoxymethoxyazoxybenzene on Chromosorb P to 1.2 wt.%. With increase of the content of compound (II) to 6 wt.% (Fig.1*a*) and to 12 wt.% (Fig.2*b*) on Chromaton, there is an abrupt increase of the retention characteristics on transition of the liquid crystal to the mesophase.

When the liquid crystal is deposited on Silochrome S-80 (an adsorbent with a high specific surface and a high adsorption potential), a definite orientation and ordering in the arrangement of the liquid crystal molecules on the surface of the adsorbent carrier apparently take place as a result of the adsorption field of the carrier. On further increase of the amount of liquid crystal on Silochrome, the molecules of the former are oriented relative to the liquid crystal molecules which have already been ordered. This orientation is probably close to the orientation of the molecules in the liquid crystal state and the selectivity of the separation is therefore high. As a result of the strong adsorption field of the surface of the adsorbent carrier, the ordered state persists over a wide temperature range (Fig.1*b*). Whereas the *meta*- and *para*-isomers of xylene are separated on Chromaton (Fig.1*a*) only at the melting point of compound (II), on Silochrome (Fig.1*b*) the xylenes are separated over the entire range of the specified temperatures.

Thus liquid crystals deposited in large amounts (in excess of 6 wt.%) on inert carriers with a low specific surface are selective only over a narrow temperature range, i.e. the temperature range of the anisotropic (mesomorphic) region is the only one where liquid crystals can be used. On the other hand, sorbents based on liquid crystals on an active adsorbent with a high specific surface are selective over a wide temperature range.

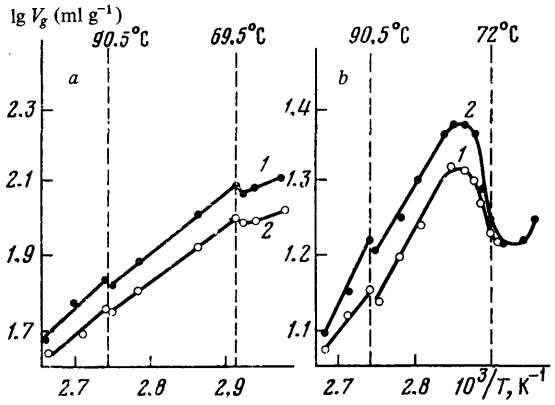

Figure 3. Temperature variation of lg V_g for xylene isomers on dehydroxylated Silochrome S-50 with 30 wt.% of cholesteryl pelargonate and on Silochrome S-10 with 6 wt.% of cholesteryl pelargonate[74]: 1) and 2) see Fig.1.

Apart from the high adsorption potential, the specific surface of the adsorbent support plays a major role in the attainment of a specific orientation and an ordered arrangement of the liquid crystal molecules. Fig.3 presents the temperature variation of lg V_g for xylene isomers on Silochrome with different values of s_{sp}. Thus, with decrease of s_{sp} of the Silochrome to 50 m^2 g^{-1} (Fig.3*a*) a large excess of the three-dimensional solid liquid crystal is already observed, which is indicated by the phase transition at 69.5 °C. There is also a phase transition at 90.5 °C, where the condensed film is transformed into a liquid. With decrease of s_{sp} of the Silochrome to 10 m^2 g^{-1} (Fig.3*b*), the nature of the curves representing the relation obeys the familiar hypothesis concerning the phase transitions of liquid crystals; however, the transition from the solid state to the mesophase is not so sharp as in the case of Chromaton (Fig.1*a*).

The temperature variation of the structural selectivity has been obtained[74] for liquid crystal (II) deposited on carriers with different values of s_{sp}; the maximum separation factor α is observed for compound (II) deposited on Silochrome S-150 ($s_{sp} = 153$ m^2 g^{-1}).

The influence of the chemical nature and geometrical structure of the adsorbent carrier surface on the mesomorphic state of a thermotropic liquid crystal has been investigated[74]. The temperature variation of the retention characteristics of xylene isomers was investigated on Silochromes—adsorbents of the same type but with different chemical surfaces (hydroxylated, dehydroxylated, and silanised Silochromes)—modified with cholesteryl pelargonate. On the silanised Silochrome S-180 with a liquid crystal monolayer (6 wt.%), it was observed that the xylene isomers are not separated over the entire specified temperature range (Fig.4*a*). This can be explained by the fact that the silanised (i.e. treated with hexamethyldisilazane) Silochrome is non-polar and that the adsorption of liquid crystal molecules on it is greatly reduced in contrast to the hydroxylated Silochrome; therefore, for a liquid crystal content of 6 wt.%, an ordered orientation of the liquid crystal molecules on the adsorbent surface does not take place and the xylene isomers are not separated. On the Silochrome hydroxylated to the maximum extent (continuous coverage by OH groups) with a monolayer of compound (II) (Fig.4*b*), the xylene isomers are separated just as completely as on the dehydroxylated Silochrome (OH groups removed from the surface by heat treatment at

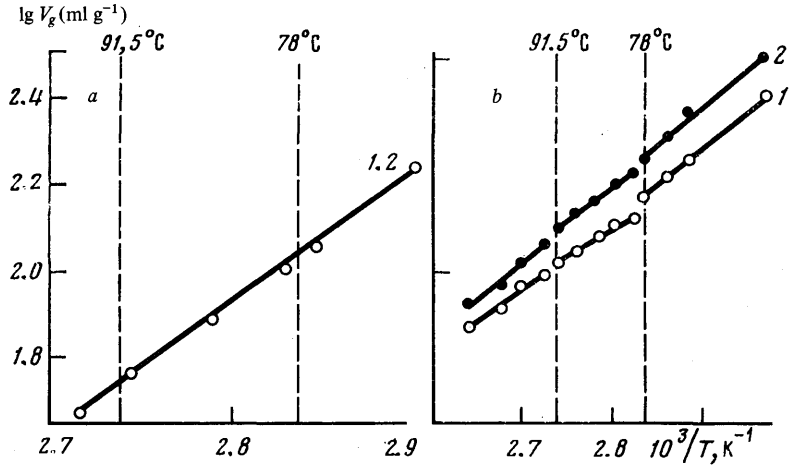

Figure 4. Temperature variation of lg V_g for xylene isomers on silanised (*a*) and hydroxylated (*b*) Silochrome S-80 with 6 wt.% (*a*) and 15 wt.% (*b*) of cholesteryl pelargonate[74]: 1) and 2) see Fig.1.

1000 °C) (Fig.1*b*). This finding confirms the hypothesis that, for the ordered parallel arrangement of the liquid crystal molecules, the nature of the surface, i.e. the nature of the adsorption forces of the adsorbent support, plays a major role.

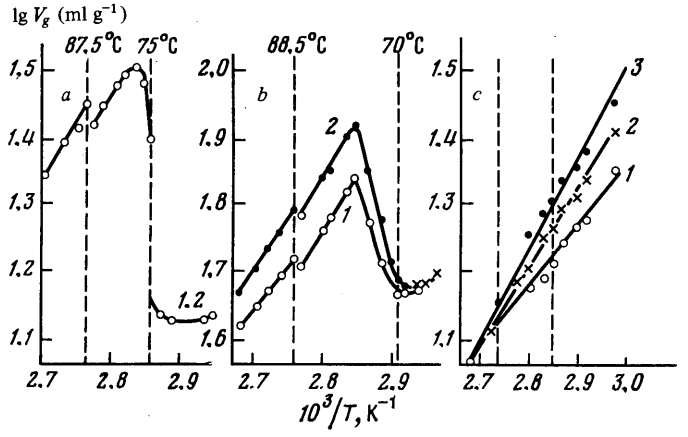

Figure 5. Temperature variation of lg V_g for xylene isomers on porous Teflon with 6 wt.% of cholesteryl pelargonate (*a*), PM-15 carbon black with 25 wt.% of cholesteryl pelargonate *b*), and CaA molecular sieve with 6 wt.% of cholesteryl pelargonate (*c*):[74] 1)–3) *m*-, *p*-, and *o*-xylenes respectively.

Fig.5 presents the temperature variation of lg V_g on carriers exhibiting marked chemical differences. Thus, on porous Teflon (a non-polar adsorbent with a weakly adsorbing surface) there is a distinct transition of the liquid crystal from the solid to the mesomorphic state, but the xylene isomers are not separated even in the region of the mesophase (Fig.5*a*). When the support is replaced by a non-specific carbon adsorbent—the PM-15 carbon black ($s_{sp} = 15$ m^2 g^{-1}), there is no sharp and abrupt change in the retention parameters (Fig.5*b*). In this case the fusion of the liquid crystal takes place gradually and not abruptly, the melting point of the liquid crystal being displaced towards lower temperatures. This can be explained by the fact that the liquid crystal film on the surface of the carbon adsorbent is acted upon by its adsorption field and the physical properties of the film therefore differ from those of the bulk-phase liquid[77]. When the CaA molecular sieve ($s_{sp} \approx 800$ m^2 g^{-1}) is used as the support for a thin film of compound (II), phase transitions at 78° and 91.5 °C are not observed and the liquid crystal exists in the form of a "condensed" film (Fig.5*c*). At 95 °C and above the liquid crystal does not exhibit selectivity with respect to the *meta*- and *para*-isomers, which apparently indicates the absence of an oriented arrangement of the liquid crystal molecules on the surface of the CaA molecular sieve. In the range 60–95 °C the selectivity of the liquid crystal decreases monotonically.

When silica (aerosil) was introduced into the liquid crystal in proportions of 1:1, i.e. on deposition of 6 wt.% of the liquid crystal and 6 wt.% of aerosil on Chromaton, appreciable phase transitions at 78° and 91.5 °C were not observed either (Fig.2*c*), and the behaviour was analogous to that observed on deposition of 30 wt.% on Silochrome S-80. However, the maximum selectivity occurs only at 78 °C (Fig.2*c*).

Thus the high structural selectivity with respect to positional isomers, the low viscosity in the region of the nematic and smectic mesomorphic states, and the high thermal stability of certain liquid crystals make it possible to recommend them for the separation of complex chemical compounds.

III. THE PHASE TRANSITIONS IN THE MESOMORPHIC STATE OF A SMECTIC LIQUID CRYSTAL

Several modifications of thermotropic smectic (soap-like) liquid crystals (SLC) can be distinguished[78]. The smectic mesophase A (S_A) consists of layers freely mobile relative to one another. The mesophase S_A is the highest-temperature phase and is least "organised" among the SLC. The smectic mesophase B (S_B) is more ordered than S_A. The smectic mesophase C (S_C) is analogous to the mesophase S_A but differs from it by the inclination of the molecular axes.

In addition to the physical methods for the investigation of liquid crystals, it is possible to employ the GAAC variant to study the phase transitions in SLC in the mesomorphic state. A study of the retention characteristics of xylene isomers on liquid crystal (III) deposited on Chromaton in an amount of 10 wt.% showed[79] that this SLC exhibits polymorphism (Fig.6*a*), namely in the region of the mesomorphic state (80–134 °C) the plot shows three breaks corresponding to the smectic states A, C, and S. As stated above, the phase states A, C, and S differ from one another by the different arrangements of the molecules in the smectic layers[78] and in this connection a triple increase of the retention parameters of the sorbate is observed.

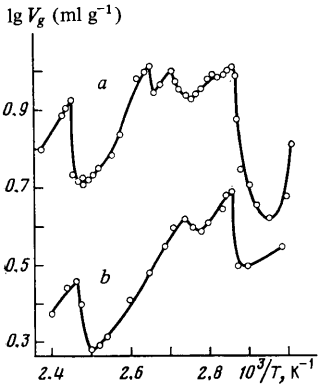

Figure 6. Temperature variation of lg V_g for *p*-xylene on dehydroxylated Chromaton with 10 wt.% (*a*) and 3 wt.% of n-pentyl *p*-(n-nonyloxy)benzylidene-*p*-aminocinnamate[79].

The polymorphism of the liquid crystal state of the test substance has been confirmed by microscopic and differential thermal (DTA) analyses. Fig.7 presents the heating and cooling thermograms for liquid crystal (III); the peak at 93 °C, corresponding to the transition from one liquid crystal modification to another, is clearly visible[79]. The peaks on the thermogram at 74° and 135 °C correspond to fusion and the transition to the isotropic liquid. It follows from the DTA that the substance has two modifications. However, microscopic analysis (Fig.8) demonstrated the presence of

three modifications. Yet another polymorphic transition occurs at 101 °C. According to Sackmann's classification[80], the test substance has smectic A, C, and S modifications which exist in the temperature ranges 135–101 °C, 101–93 °C, and 93–74 °C respectively (Fig.8). It may be that the S_A–S_C transition, which is not shown by the DTA curve of the second kind, or at any rate the thermal effect corresponding to this transition, is small.

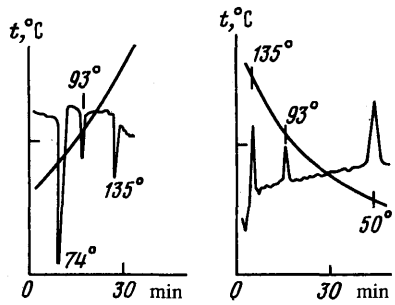

Figure 7. Heating and cooling thermograms for n-pentyl *p*-(n-nonyloxy)benzylidene-*p'*-aminocinnamate[79].

With decrease of the content of liquid crystal on Chromaton, i.e. in the case of a thin film (Fig.6*b*), the plot shows only two breaks. Fig.6*b* also shows that, with decrease of the amount of liquid crystal on the solid carrier, the phase transition temperature shifts towards lower values and the selectivity with respect to positional isomers falls. Similar features have been observed[76] in a study of the thermotropic liquid crystal *p*-methoxyethoxyazoxybenzene.

IV. ASSESSMENT OF LIQUID CRYSTAL STATIONARY PHASES ON THE BASIS OF POLARITY FACTORS

The existing methods for the estimation of the polarities of stationary phases have been examined in fair detail in a number of reviews[81–83]. Among all the known methods, the procedure proposed by Rohrschneider[84] and improved by McReynolds[85] has received the greatest recognition. It was of interest to assess the liquid crystals investigated in terms of selective properties as stationary phases (SP) with unique chromatographic properties.

We attempted[86] to classify such variable-selectivity sorbents by analogy with the methods used in gas–liquid chromatography. The possibility of using Brown's method[87] and the system of Rohrschneider's polarity factors[88] was tested on the basis of experimental results. According to Rohrschneider[88], the difference between the Kovats indices[89] on the test and standard stationary phase is a measure of the polarity of the stationary phase.

We determined the polarities of sorbents based on Silochromes and liquid crystals as the differences between the Kovats indices on squalane and the test sorbent:

$$\Delta I = I_{test} - I_{sq} \quad .$$

The overall quantity

$$\sum \Delta I = ax + by + cz + du + es \qquad (1)$$

characterises the polarity of the stationary phase and the components of the sum represent the degree of interaction of each reference substance (benzene, ethanol, ethyl methyl ketone, nitromethane, and pyridine) with the stationary phase. The polarity coefficients of the substances analysed (*a*, *b*, *c*, *d*, and *e*) must remain constant on different stationary phases[90]. In estimating the selectivity of stationary phases for the separation of positional isomers, Vigdergauz et al.[91] introduced and additional term into Eqn.(1), characterising the selectivity of the mesophase with respect to the *meta*- and *para*-isomers.

The polarity factors for different phase states of the following liquid crystals have been determined[86] by Eqn.(1): (II), (V), and (III). The results are in Table 1. For comparison, the table also includes the polarity factors for the adsorbent supports.

Figure 8. Textures of the liquid crystal state of n-pentyl *p*-(n-nonyloxy)benzylidene-*p'*-aminocinnamate[79].

As already mentioned, the nature of the curves for the temperature variation of V_g of several isomers of organic compounds is inconsistent with the classical concept of the phase transitions in liquid crystals as a function of temperature, namely that the retention characteristics diminish with increasing column temperature. Indeed, Table 1 shows that the polarity factors of Silochrome S-80 containing a monomolecular layer of cholesteryl pelargonate (0.754 mg m^{-2}) diminish with increasing column temperature.

Table 1. The polarity factors (x, y, z, u, and s) and the conventional chromatographic polarities (P) of sorbents based on silicas and liquid crystals (standard—squalane, t—column temperature).

LC	t, °C	x	y	z	u	s	P

(II) ***	63	0.26	4.14	3.03	2.79	—	27
(II) ***	78	0.34	4.70	3.83	3.86	—	29
(II) ***	91.5	0.31	3.40	4.07	3.32	—	15

*A hydroxylated adsorbent carrier was used, while in the remaining cases the carrier was dehydroxylated.

**$a_{LC} = 0.052$ mg m^{-2}.

***$a_{LC} = 0.009$ mg m^{-2}; in the remaining cases $a_{LC} = 0.754$ mg m^{-2}.

The system of Rohrschneider's coefficients constitutes a classification where, apart from the electron donor–electron acceptor activity, account is taken of the proton donor–proton acceptor activity of the phases in relation to the sorbates as well as the orientation interaction between them. Thus the polarity factors of the electron donor and acceptor characterising the retention of benzene (x) and nitromethane (u) diminish sharply on transition of compound (II) from the solid to the liquid crystal state and further to the isotropic liquid. The polarity factors of the proton donor characterising the retention of ethanol (y) change sharply on transition of this liquid crystal from the solid to the mesomorphic state.

The conventional chromatographic polarity of this sorbent (Table 1), which we estimated in relation to a specific pair of compounds (benzene–cyclohexane), also decreases with increase of column temperature. On the same liquid crystal deposited on the inert carrier Chromaton, higher polarity factors are observed at the point corresponding to the transition of the liquid crystal from the solid to the mesomorphic state (78 °C); the retention characteristics, particularly the retention times, then increase by a factor of ~5. At 78 °C the conventional chromatographic polarity is also a maximum.

Comparison of the polarity factors on hydroxylated and particularly on dehydroxylated Silochromes with those for the same Silochromes modified by liquid crystals shows that on the latter the polarity factors decrease markedly, especially the polarity factor z (for ethyl methyl ketone) characterising the orientational interaction. Among the initial Silochromes, a high capacity for orientational interaction has been observed for the hydroxylated Silochrome with an intact coating of hydroxy-groups on its surface, which is classified as a type II adsorbent in Kiselev's classification[92]. While the polarity factors s are exceptionally high, the constant a, characterising the dispersion interaction on the hydroxylated Silochrome, is low. A change in the chemical properties of the surface of hydroxylated Silochrome, namely its dehydroxylation (by heat treatment at 1000 °C) and modification with liquid crystals, leads to a sharp decrease of all the polarity constants.

Together with the Rohrschneider method, whereby one can take into account different intermolecular interactions, Brown's method[87] has been applied. Brown was the first to apply the triangular Gibbs–Roozeboom diagram to gas chromatography for a clear estimate of the properties of the stationary phases. This method provides for the use of a triangular graph along the axis of which one plots the retention fractions representing the ratios of the specific retention volume of one of the reference sorbates to the sum of the volumes of three reference sorbates. The following systems have been used for the latter: n-hexane–ethanol–ethyl methyl ketone or n-hexane–nitromethane–pyridine, i.e. nonpolar compound—electron donor–electron acceptor systems.

When the retention of all the elements is determined from a single chromatogram, the retention fraction can be calculated directly from the corrected retention times (t_r):[93]

$$F = t_r/(t_r' + t_r'' + t_r'''). \qquad (2)$$

For the initial and liquid crystal-modified silicas, the retention fraction of ethyl methyl ketone is greatest; consequently, the donor–acceptor interaction makes the main contribution to the retention. In addition, we demonstrated the possibility of using pyridine, a stronger electron donor, and nitromethane, a stronger electron acceptor, as reference sorbates together with n-hexane. For all the sorbent specimens, the retention fractions of pyridine are highest, which again demonstrates the dominant contribution of sorbate–sorbent donor–acceptor interactions to the retention.

Table 2. The polarity factors of certain stationary phases and sorbents based on Chromaton and SLC (V).

SP, sorbent	t, °C	x	y	z	u	s
OV-17	100	2.08	3.85	2.62	5.33	3.45
Sorbent	63	1.55	3.35	2.19	3.78	3.40
SKTF-100	100	1.57	4.96	2.05	3.13	2.17
Sorbent	120	1.51	2.96	2.13	3.53	2.67
OS-124	100	1.75	2.27	2.34	3.26	2.84
Sorbent	150	1.75	2.16	2.12	3.55	2.87

In order to estimate the possibility of the practical application of the polarity constants found for sorbents based on silicas and liquid crystals, it is necessary to compare the results with the literature data for known stationary phases. Such a comparison makes it possible to discover analogues of stationary phases and to illustrate the possibility of replacing the latter by sorbents based on silicas and liquid crystal systems. For comparision, use was made of data of

Subina[94], who characterises in terms of polarity the stationary phases most frequently used in gas chromatographic practice. As an illustration, Table 2 presents some of these data. It shows that the sorbent based on Chromaton and liquid crystal (IV) in a single chromatographic column at different temperatures and hence in different phase states can replace three sorbents: polyphenyl ester OS-124, SKFT-100, and OV-17.

Thus the use of liquid crystals as stationary phases makes it possible to reduce the number of stationary phases used in gas chromatography without diminishing the range in which selectivity can be regulated. Furthermore, the assessment of silica adsorbents and modified sorbents based on them, carried out on the basis of the retention characteristics of reference compounds, permits a well founded approach to the selection of a modified sorbent for the solution of a specific analytical problem.

Oxidation of Ketones by Molecular Oxygen

V.Karnojitzky

The results of fundamental studies on different methods of oxidising aldehydes and ketones by oxygen are presented; the purely thermal oxidation, the photochemical oxidation, as well as the low-temperature oxidation in alkaline media are considered. The general postulates of the reaction mechanisms are described and specific instances involving aliphatic, alicyclic, saturated, and aromatic ketones as well as the mechanisms of the decomposition of the hydroperoxides of α-ketones are surveyed.
The bibliography includes 101 references.

I. INTRODUCTION

The present author's two previous papers were devoted to various methods of oxidising alcohols[1] and phenols[2]; it is logical to examine also carbonyl compounds from this point of view. Indeed they are intermediates in the oxidation of hydrocarbons and are formed when animal or plant lipids are subjected to aerobic heat treatment. It is known that alcohols and carbonyl compounds (aldehydes or ketones depending on the structure of the hydrocarbons) are formed simultaneously in the oxidation of hydrocarbons via intermediate hydroperoxides; more carbonyl compounds are formed in the subsequent oxidation of the alcohols.

The mechanism of the formation of carbonyl compounds in the oxidation of hydrocarbons has been described in detail in reviews[1-3].

The main products of the oxidation of carbonyl compounds are carboxylic acids formed via chain dissociation or without such dissociation, depending on the initial compound—ketone or aldehyde. Different methods for the oxidation of carbonyl compounds are not only of theoretical but also of considerable practical interest for the synthesis of carboxylic acids and their derivatives by the oxidation of hydrocarbons, particularly for the synthesis of dibasic acids from alicyclic hydrocarbons.

The formation of mono- and poly-functional saturated and unsaturated carbonyl compounds from derivatives of oleic, linolenic, and linoleic acids has been described in detail in review articles[4-6]. Furthermore, numerous carbonyl compounds form part of the composition of natural products and are an important raw material for various branches of the manufacture of chemical products—solvents, pharmaceuticals, perfumes, dyes, and plastics.

It is noteworthy that methods for the oxidation of aldehydes in the liquid or vapour phase have now been described in fair detail (the latest review was published in 1976). Thus the liquid-phase oxidation of aldehydes has been described[7]; a review devoted to the mechanism and kinetics of the oxidation of aldehydes in the liquid and vapour phases has been published[8]. The photochemical oxidation of aldehydes in the liquid or vapour phase has been considered by Niclause and Lemaire[9], Maslov and Blyumberg[10] discussed in detail the liquid-phase oxidation of aldehydes and their joint oxidation with olefins. Elkik[11] described the mechanism of the oxidation of aldehydes in alkaline media.

Apart from the reviews listed above, the results of individual investigations during the last 26 years have been the subject of very detailed publications and in many instances noteworthy conclusions concerning the kinetics of the processes are presented.

Thus Combe et al.[12] published two papers on the oxidation of acetaldehyde and propionaldehyde in the vapour phase (certain considerations concerning the kinetics are presented and the experimental methods are described in detail). Lemaire[13] investigated the photochemical oxidation of C_7 aldehydes by infrared spectroscopy and Deglise[14] studied the photochemical oxidation of crotonaldehyde. The paper of Franck et al.[15], devoted to the liquid-phase oxidation of benzaldehyde, presents conclusions concerning the process kinetics and critical comments on previous studies. The autoxidation of furfural has been examined by Isacescu et al.[16], whose paper also contains an extensive historical review and a critical examination of early investigations.

Extensive review articles devoted to the oxidation of aldehydes of different types in volume VII of Grignard's collection[17-20] are noteworthy; they also deal with the oxidation reactions of aliphatic[17], alicyclic[18], aromatic[19], and unsaturated (mono- and poly-olefinic and acetylenic)[20] aldehydes.

Thus, since the methods for the oxidation of aldehydes have been described and discussed in a whole series of reviews (most of which were published in 1976) and original publications, the author believes that there is no need to consider them within the framework of the present survey.

The literature on the oxidation of ketones differs appreciably from that on aldehydes. As far as the present author is aware, there are only two reviews on the purely thermal[21] and vapour-phase[22] oxidations; the latter paper deals with various photochemical reactions in the vapour phase and with general postulates concerning the photochemical oxidation mechanism. However, the above reviews[21,22] do not deal either with the purely thermal liquid-phase oxidation of ketones in the presence of various catalysts or in their absence (there are only short sections in the general reviews on organic peroxides[23-25] with references up to 1960) or with their oxidation in an alkaline medium at a low temperature, which has been the subject of numerous detailed investigations in the last decade. The low-temperature oxidation in an alkaline medium proved to be highly effective, since it makes it possible not only to synthesise and isolate various

α-keto-t-hydroperoxides but also to investigate their properties, in particular their radical (in the liquid and vapour phases) and ionic decompositions catalysed by alkali.

It is noteworthy that individual ketones form part of the composition of many natural essential oils, sex hormones, and wood tar. It is known that methyl ketones CH_3COR (R represents an odd number of carbon atoms ranging from C_3 to C_{11}) are formed when saturated lipids become rancid and by the action of certain moulds on saturated aliphatic acids, their ammonium salts, and triglycerides, and also that ketones and aldehydes of various types are produced in the course of the thermal oxidation of lipids[4-6].

Data on the industrial applications of methyl ketones have been described by Miller[26].

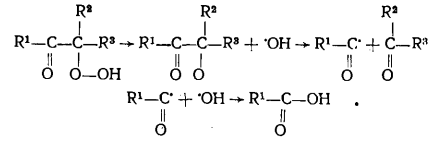
A review article[27] on ketones and an article in volume VII of Grignard's collection[28-31], which deals with the synthesis and reactions of saturated aliphatic[29], ethylenic[30], and acetylenic[31] ketones are noteworthy. Turro's paper[32] is devoted solely to cyclopropanone and its derivatives and that of Srinivasan[33] deals with the photochemistry of cyclic ketones.

Various chemical and physical aspects of the ketone oxidation reactions are fairly interesting, particularly the studies of the last decade; therefore, from our point of view, it is appropriate to survey the literature data on the methods of oxidising ketones in addition to the information about the reactions of these compounds already available.

II. GENERAL POSTULATES

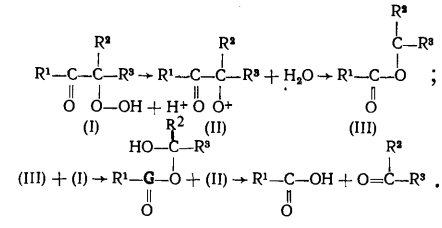
1. Thermal Oxidation under the Influence of O_2 in a Neutral Medium

Jenkins[34] claims that many ketones having the general formula $XC_6H_4-CH_2-COR$ acquire the smell of an aldehyde on simple storage at room temperature in the presence of atmospheric oxygen or in sunlight. He was unable to obtain *o*-chlorobenzoic acid and benzaldehyde from benzyl *o*-chlorophenyl ketone.



Scharp et al.[35] isolated butyric acid and propionaldehyde in the thermal autoxidation of dipropyl ketone at 110–120 °C. Furthermore, the authors noted the formation of a peroxide, whose content increases (primarily as a function of reaction time), passes through a maximum, and then falls (as in the oxidation of hydrocarbons of various types and other organic compounds); this is not observed for the extent of conversion to aldehyde and acid, which increases continuously. The same workers[36] isolated acetone and isobutyric acid after the thermal autoxidation of di-isopropyl ketone at 100° and 110 °C. It is of interest to note that in the first instance (in the presence of a secondary carbon atom conjugated with C=O) a small amount of water is formed and part of the aldehyde is converted into the corresponding acid.

It has been shown[37] that in the thermal autoxidation of certain alicyclic ketones (cyclohexanone and α- and β-tetralinones) at temperatures from 75° to 100 °C peroxide is formed initially and then, as a consequence of ring rupture, the corresponding aldehydoacids.



The experimental results obtained for several aliphatic, benzyl, and alicyclic ketones have shown that molecular oxygen initially acts (at least to a large extent) on the carbon atom in the α-position relative to the C=O group, which leads to the formation of the ketohydroperoxide $R^1C(=O)C.[(OOH)(R^2)(R^3)]$, which then decomposes into an aldehyde and carboxylic acid with dissociation of the O–O and C–C bonds in the C–C=O group.

As in the general case of hydrocarbons of various types, the rate of oxidation and stability of the hydroperoxides increase on passing from a secondary to a tertiary carbon atom.

The decomposition of the hydroperoxide proceeds mainly via a radical mechanism:

and then via an ionic mechanism, the process being catalysed by the acid formed:

Indeed it has been shown[38] that in the case of cyclohexanone the rate of decomposition of the hydroperoxide formed greatly increases after the introduction of acetic acid. The formation of acid is then clearly autocatalytic, as for dipropyl ketone at 120 °C; the acid content is low during the first 5 h after the start of reaction and then it reaches 0.022 and 0.080 mole per mole of the ketone after 8 and 12 h respectively[39].

Table 1. The autoxidation of ketones.

Ketone	*t*, °C	Time, h	Content of oxidation products, moles per mole of initial ketone		τ*, h	Refs.
			peroxide	acid		
Di-isopropyl ketone	85	8	0.022	0.0148	—	[40]
Di-isopropyl ketone	100	36	0.05	0.05	6	[36]
Di-isopropyl ketone	110	16	0.040	0.040	0	[36]
Dipropyl ketone	110	24	0.005	0.05	8	[35]
Dipropyl ketone	120	6	0.01	0.02	—	[35]
Ethyl methyl ketone	120	10	0 003	0.003	—	[39]

*τ is the induction period in the formation of the acid.

Table 1 presents quantitative data for the formation of hydroperoxides and acids from three ketones at different temperatures.

The method of acid-catalysed ionic decomposition of hydroperoxides was first developed[40] in relation to the decomposition of decalinyl hydroperoxide in the presence of H_2SO_4; the decomposition of cumenyl-hydroperoxide to phenol and acetone proceeds via the same mechanism[41], which has been discussed in detail by Tobolsky and Mesrobian[42].

We may note that, apart from the main pathway involving the rupture of the bond in the α-position relative to the C=O group, there is also a possibility (to a much lesser extent) of the dissociation of the bond in the β-position, particularly if the group in the β-position relative to C=O is an H atom (the formation of H_2O) or $H_2CC_6H_4X$. Thus

although the action of O_2 on the carbon atom in the α-position relative to the C=O group constitutes the main pathway, it is not the only one: carbon atoms in other positions can also be acted upon by oxygen, as has been demonstrated for long-chain ketones.

Indeed Rif and coworkers showed in relation to the oxidation of 2-octanone[43] and 6-undecanone[44,45] that, apart from the compounds formed as a result of the dissociation of the chain in the α-position, several other substances are formed as a consequence of the dissociation of the chain in other positions.

2. The Effect of O_2 in the Presence of Ionising Radiation in a Neutral Medium

The photochemical oxidation of acetone and diethyl ketone under the influence of light at wavelengths in the range $267 < \lambda < 313$ nm at different temperatures has been the subject of numerous investigations which have been analysed by Bernard[21]. It has been shown that the primary reaction step consists in the formation of the radicals $R^2-\dot{C}=O$ (or $R^1-\dot{C}=O$ and $\dot{R}^2$), which are oxidised to the corresponding peroxy-radicals.

The final products are formed from the radicals $R^1O-\dot{O}$, $R^1-\dot{O}$, $R^2-C(=O)O\dot{O}$, and $R^2-(C=O)-O^{\cdot}$ and constitute a mixture of CO, CO_2, the acids R^1-COOH and R^2-COOH, as well as alcohols and aldehydes formed as a consequence of the disproportionation of the radicals $R^1O^{\cdot}$ and $R^2O^{\cdot}$.

3. The Effect of O_2 in an Alkaline Medium

Ketones can react with molecular oxygen also at a very low temperature in a highly alkaline medium in aprotic solvents with formation (as in a neutral medium) of an α-ketohydroperoxide as the primary product. The rate of reaction depends very markedly on the configuration of the carbon atom in the α-position relative to the C=O group. Thus it is very low for the primary carbon atom and very high for secondary and tertiary carbon atoms. However, in the former case the yield of hydroperoxides is low, since they rapidly decompose in an alkaline medium; in the case of a tertiary carbon atom it is possible to isolate hydroperoxides with a higher degree of purity and in a high yield.

The selection of temperature and reaction time is very important for the attainment of the maximum yield. (t-Hydroperoxides also decompose under the influence of alkali via the general mechanism $2ROOH \rightarrow 2ROH + O_2$ but at a much lower rate than secondary hydroperoxides[23].) It is noteworthy that in asymmetric ketones of the type $H_3C-(C=O).CH(CH_3)_2$ only the tertiary group is involved. We may note that the oxidation in a highly alkaline medium is possible not only for ketones but also for many other organic compounds with a tertiary α-carbon atom, for example, ethers, esters, nitriles, hydroxylamines, hydrazines, mercaptans, and phenols.

The influence of the solvent on the yield of hydroperoxide has been studied[46] in relation to isopropyl methyl ketone in the presence of the $(CH_3)_3COK/(CH_3)_3COH$ system at −8° for a reaction time between 4 and 10 min. It was shown that the yield of hydroperoxide decreases in the sequence dimethylformamide > dimethoxyethane > hexamethylphosphoramide > tetrahydrofuran > acetonitrile > toluene > acetic acid, the yields being in proportions of 87, 80, 72, 66, 56, 48, and 38% respectively.

Evidently in the first two solvents the reaction proceeds even in the presence of aqueous solutions of alkalies, while in others it is necessary to use stronger bases (such as alkoxides) and in aprotic solvents such as diglyme and hexamethylformamide the rate of reaction is much higher than in $(CH_3)_3COH$.

The first reaction stage is the ionisation of the initial compound (designated by RH) by the base $\ddot{B}$ with formation of the anion R^-, which then reacts with molecular oxygen:

$$RH + \ddot{B} \rightarrow R^- + BH \ ;$$

$$R^- + O_2 \rightarrow R^{\cdot} + {}^{-}O_2^{\cdot} \ ;$$

$$R^{\cdot} + O_2 \rightarrow RO-O^{\cdot} \xrightarrow{HR} RO-OH + R^{\cdot} \ .$$

Consequently this reaction involves the formation of the O_2^- radical-ion the properties and formation of which in the course of various chemical reactions have been described in a recent review[47].

The kinetic data and the mechanism of the oxidation in an alkaline medium, which is applicable to substances other than ketones, particularly to esters[48] and alkyl halides[49], have been discussed in detail in the literature.

III. OXIDATION OF SATURATED ALIPHATIC AND AROMATIC KETONES

The thermal oxidation of acetone has been the subject of numerous studies. Acetone contains only primary carbon atoms in the α-position relative to the C=O group; it is fairly resistant to the action of atmospheric oxygen and reacts with the latter (in the absence of any oxidation initiators) only above 250 °C, so that its thermal oxidation can be studied only in the vapour phase. Such oxidation has been the subject of two serious investigations[50,51] carried out using specially purified acetone in the temperature range 250–500 °C at acetone and oxygen pressures of 60 and 30 mmHg respectively. The reaction products were determined quantitatively and qualitatively at 284° and 498 °C. It was shown that at these temperatures considerable amounts of H_2O and CO are formed. On the other hand, the contents of CO_2 and HCHO are considerable at 284 °C and very low at 498 °C; furthermore, methane (in fairly large amounts) and ethyl methyl ketone (in much smaller amounts) are formed only at the latter temperature. At 284 °C there is an appreciable amount of methyl hydroperoxide (which was not detected at 498 °C) and also a very small amount of H_2O_2, H_2, CH_3OH, and OCH–CHO. These compounds are formed in accordance with the equations presented below, the first of which describes the reaction at 284 °C and the second at 498 °C:[50,51]

$$(CH_3)_2C=O+2.5O_2 \rightarrow 1.75H_2O+1.25CO+0.65CO_2+0.6CH_3\dot{O}OH + \\ + 0.5HCHO+0.1H_2 \ ;$$

$$(CH_3)_2C=O+O_2 \rightarrow 0.9H_2O+1.6CO+0.7CH_4 \\ + 0.3HCHO+0.07(C_2H_4+CO_2+H_2) \ .$$

The ratio of the contents of the same compounds (r) formed at 284° and 498 °C is 2 for H_2O, 0.8 for CO, and 9.3 for CO_2.

The results suggest the following reaction mechanism; in the first step, as in the liquid-phase autoxidation of ketones, at 498 °C hydrogen is abstracted from acetone with formation of a radical:

$$CH_3-\underset{\underset{O}{\|}}{C}-CH_3 + O_2 \rightarrow CH_3-\underset{\underset{O}{\|}}{C}-\dot{C}H_2 + {}^{\cdot}O-OH \ .$$

Its life is very short; it decomposes to keten and the radical $H_3C^{\cdot}$ before reacting with O_2:

$$CH_3-\overset{\overset{O}{\|}}{C}-CH_2^{\cdot} \rightarrow H_3C^{\cdot} + C\overset{\overset{O}{\|}}{=}CH_2 \ .$$

In the presence of O_2, keten decomposes almost exclusively to H_2O and CO with traces of CO_2 + C_2H_4, while $H_3CO-O^{\cdot}$ is formed from the radical $H_3C^{\cdot}$. The behaviour of this radical also depends on temperature: at an elevated temperature (498 °C) it decomposes mainly to H_2O and the $\dot{C}HO$ radical:

$$CH_3O-O^{\cdot} \rightarrow H_2O + H-\overset{\overset{O}{\|}}{C}^{\cdot} \ .$$

The latter can in its turn either recombine with formation of glyoxal or can react with O_2; in the latter case the products are CO and the radical $HOO^{\cdot}$:

$$H-\overset{\overset{O}{\|}}{C}^{\cdot} + O_2 \rightarrow CO + HO-O^{\cdot} \ .$$

The radical $HOO^{\cdot}$ can abstract hydrogen from acetone to form the radical $CH_3COCH_2^{\cdot}$ and H_2O_2.

At 284 °C the radical $H_3CCO^{\cdot}$ mainly abstracts hydrogen from acetone or HCHO to form CH_3CHO, partial decomposition of which yields HCHO and H_2O; the radical $CH_3COCH_2^{\cdot}$, whose lifetime at 284 °C is longer than at 498 °C, mainly reacts with CO_2 to form a radical which subsequently decomposes by the mechanism

$$CH_3-\overset{\overset{O}{\|}}{C}-CH_2O-O^{\cdot} \rightarrow CH_3^{\cdot} + CO_2 + HCHO \ .$$

The photochemical oxidation of acetone (particularly at λ = 313 nm) in the vapour phase in the range from room temperature to 250 °C and at different oxygen and acetone pressures has been described in extensive reviews[52-65] and the conclusions reached in them have been analysed in detail in Hoare's review[22]. The liquid-phase photochemical oxidation of acetone at 30 °C has also been studied[64].

In these investigations it has been shown that the principal compounds formed under different conditions are CO, CO_2, CH_3OH, AcOH, H_2O, and CH_3OOH with small amounts of HCOOH, CH_4, and C_2H_6.

It is noteworthy that compounds of the type RH are obtained only at low O_2 pressures (<1 mmHg) and, in order to suppress their formation, it is necessary to increase somewhat the oxygen pressure, raising simultaneously the temperature (for example, 0.0625 and 0.360 mmHg at 36° and 100 °C respectively).

Whereas the nature of the products formed is analogous to that of the compounds obtained in the thermal oxidation of acetone in the vapour phase at 280–320 °C, the relative compositions and kinetics of their formation are different and depend on the reaction time: in photochemical oxidation the amount of CH_3OH is much greater and OH is formed from the beginning of the reaction together with HCHO.

At a constant specified temperature the total amount of oxidation products increases with increase of the oxygen pressure (with the exception of CO, the amount of which decreases). It is of interest to note that more than 90% of the CO_2 is formed from the C=O group and CO is produced both from the CH_3 and C=O groups, the amount obtained from the latter group being smaller the higher the O_2 pressure; HCHO and CH_3OH are derived from CH_3 to an extent greater than 90%. Indeed, a study employing ^{14}C in the CH_3 group showed[61] that at 120 °C the amount of radioactive CO_2 is less than 10%. This result has been confirmed in studies[59,63] where the ^{18}O label was used over a wide temperature range, from 36° to 175 °C; the proportion of $^{16}O=C=^{18}O$ reached 92%. Furthermore, it has been shown[63] that proportion of $CH_3{}^{18}OH$ and $H_2C={}^{18}O$ is greater than 90%. In the first stage of the reaction acetone decomposes to methyl and acetyl radicals, this being followed by the partial decarbonylation of the latter, its extent increasing with increase of temperature and decreasing with increase of oxygen pressure:

$$H_3C-\overset{\overset{O}{\|}}{C}-CH_3 \rightarrow H_3C^{\cdot} + {}^{\cdot}\overset{\overset{O}{\|}}{C}-CH_3 \ ;$$

$${}^{\cdot}\overset{\overset{O}{\|}}{C}-CH_3 \rightarrow CO + {}^{\cdot}CH_3 \ .$$

In the absence of O_2, two $H_3C^{\cdot}$ radicals recombine and a disproportionation reaction takes place between the $H_3C^{\cdot}$ and $O=\dot{C}-CH_3$ radicals, which leads to the formation of C_2H_6, CH_4, and $O=C=CH_2$ respectively:

$$H_3C^{\cdot} + {}^{\cdot}CH_3 \rightarrow H_3C-CH_3 \ ;$$

$$H_3C^{\cdot} + HCH_2-\overset{\overset{O}{\|}}{C}^{\cdot} \rightarrow CH_4 + H_2C=C=O \ .$$

In the presence of O_2 the radical $H_3C-\dot{C}=O$ gives rise to CO_2 and the radical $H_3CO^{\cdot}$, i.e.

$$H_3C-\overset{\overset{O}{\|}}{C}^{\cdot} \xrightarrow{O_2} H_3C-\overset{\overset{O}{\|}}{C}-O-O^{\cdot} \rightarrow {}^{\cdot}\overset{\overset{O}{\|}}{C}-O-OCH_3 \rightarrow CO_2 + {}^{\cdot}OCH_3 \ ,$$

while HCHO and the radical $^{\cdot}OH$ are formed from the radical $H_3C^{\cdot}$, i.e.

$$H-\overset{\overset{H}{|}}{\underset{\underset{H}{|}}{C}}{}^{\cdot} \xrightarrow{O_2} H-\overset{\overset{H}{|}}{\underset{\underset{H}{|}}{C}}-O-O^{\cdot} \rightarrow {}^{\cdot}\overset{\overset{H}{|}}{\underset{\underset{H}{|}}{C}}-O-OH \rightarrow \overset{\overset{H}{|}}{\underset{\underset{H}{|}}{C}}=O + {}^{\cdot}OH$$

or H_2O and the radical $H-\dot{C}=O$ are produced:

$$\overset{\overset{H}{|}}{{}^{\cdot}\underset{\underset{H}{|}}{C}}-O-OH - H_2O + H-\overset{\overset{O}{\|}}{C}^{\cdot} \ .$$

The radicals $H_3C-C(=O)O^{\cdot}$ can be formed from the radicals $H_3C-\overset{\overset{O}{\|}}{C}-O-O^{\cdot}$:

$$H_3C-\overset{\overset{O}{\|}}{C}-O-O^{\cdot}$$

$$2H_3C-\overset{\overset{O}{\|}}{C}-O-O^{\cdot} \rightarrow 2H_3C-\overset{\overset{O}{\|}}{C}-O^{\cdot} + O_2 \ ,$$

while the radicals $H_3CO^{\cdot}$ can be formed from $H_3C-O-O^{\cdot}$:

$$2H_3CO-O^{\cdot} \rightarrow 2H_3CO^{\cdot} + O_2 \ .$$

The feasibility of the last reaction has been discussed in detail[66].

The products HCHO and H_3COH (the latter at least at the beginning of the reaction) are formed as a consequence of a disproportionation reaction between two methoxy-radicals:

$$H_3CO^{\cdot} + {}^{\cdot}OCH_3 \rightarrow H_3COH + HCHO \ .$$

This reaction has also been discussed[66].

Carbon monoxide can be formed via the two reactions presented below from the formyl radical obtained from the radical $H_2\dot{C}OOH$, the second reaction occurring at low oxygen pressures:

$$H-\overset{\overset{O}{\|}}{C}^{\cdot} + O_2 \rightarrow HO-O^{\cdot} + CO \ ;$$

$$H-\overset{\overset{O}{\|}}{C}^{\cdot} + H-\overset{\overset{O}{\|}}{C}^{\cdot} \rightarrow H-\overset{\overset{O}{\|}}{C}-H + CO \ .$$

The role of the reactions involving the abstraction of hydrogen by the radicals $H_3CO^{\cdot}$, $H_3CO-O^{\cdot}$, $H_3C-C(=O)-O^{\cdot}$, and $H_3C-C(=O)-O-O^{\cdot}$ increases with increasing temperature at least up to 200 °C. It is noteworthy that the abstraction of hydrogen from formaldehyde proceeds much more readily than from acetone. Indeed, depending on reaction time, the amount of HCHO passes through a maximum and the ratio $H_3COH/HCHO$ increases continuously; furthermore, when HCHO is introduced, the H_3COH content and the reaction rate increase. A new source of $H-\dot{C}=O$ radicals arises and hence the formation of CO is initiated.

At 250 °C the reactions involving the dehydrogenation of acetone by the above radicals become dominant and the rate of formation of all the compounds rapidly increases. The $H_3C-C(=O)CH_2$ radicals formed are oxidised to the corresponding peroxy-radicals, which become a new source of HCHO and the radicals $H_3C^{\cdot}$ as well as all their derivatives as a consequence of decomposition via the mechanism

$$H_3C-\underset{\underset{O}{\|}}{C}-CH_2O-O^{\cdot} \rightarrow HCHO + CO_2 + H_3C^{\cdot} \ .$$

The liquid-phase photochemical oxidation (λ = 313 nm) of acetone at 30 °C has been studied[64] and it has been shown that virtually the same reaction products are obtained as in the vapour phase at 284 °C. However, the amount of O_2 dissolved in acetone is insufficient for the complete suppression of the formation of CH_4 and C_2H_6, which suggests a greater ability of the $H_3C^{\cdot}$ radicals to abstract hydrogen and to dimerise in the liquid phase.

The photochemical oxidation of diethyl ketone at 25°, 100°, and 200 °C, diethyl ketone pressures of 35 or 12.5 mmHg, and oxygen pressures from 0 to 1.25 mmHg [67] and at 30°, 70°, 100°, and 150 °C, a diethyl ketone pressure of 35 mmHg, and oxygen pressures ranging from 0.55 to 1.85 mmHg [69] has been described[67-69]. These studies have been analysed in a review[22].

The principal reaction products include CO, CO_2, CH_3CHO, and C_2H_5COOH with small amounts of C_2H_4 and C_2H_6. Furthermore, it has been possible to establish by an isotope method that almost the entire amount of CO is formed from the carbonyl group (in contrast to acetone where the amount of CO derived from C=O does not exceed 20%) and that CO_2 at 30 °C is derived almost exclusively from C=O but at 100 °C only to the extent of 30%, while the remainder of the CO_2 arises from a group with a secondary carbon atom.

The above facts can be explained by the much easier decarbonylation of the radicals $C_2H_5\dot{C}=O$ than the radicals $H_3C\dot{C}=O$ and the much greater mobility of the hydrogen atom linked to a secondary carbon atom compared with a primary carbon atom (in the case of acetone). Consequently, for diethyl ketone all the hydrogen abstraction reactions are more important than in the oxidation of acetone. Hence it follows that the radicals $C_2H_5-\dot{C}=O$, $\dot{C}_2H_5$, and $C_2H_5-C(=O)-\dot{C}H-CH_3$ are formed even at room temperature in the initial stage of the reaction. The formation of different compounds can be represented by a sequence of steps:

$$C_2H_5-\underset{\underset{O}{\|}}{C}-C_2H_5 \xrightarrow{h\nu} C_2H_5-\underset{\underset{O}{\|}}{C}^{\cdot} + C_2H_5^{\cdot} \ ;$$

$$C_2H_5-\underset{\underset{O}{\|}}{C}^{\cdot} \rightarrow C_2H_5^{\cdot} + CO \ ;$$

$$C_2H_5^{\cdot} + C_2H_5-\underset{\underset{O}{\|}}{C}-CH_2-CH_3 \rightarrow C_2H_6 + C_2H_5-\underset{\underset{O}{\|}}{C}-\dot{C}H-CH_3 \ ;$$

$$C_2H_5-\underset{\underset{O}{\|}}{C}-\dot{C}H-CH_3 \rightarrow C_2H_5-\underset{\underset{O}{\|}}{C} + H_2C=CH_2 \ ;$$

$$C_2H_5-\underset{\underset{O}{\|}}{C}^{\cdot} \xrightarrow{O_2} C_2H_5-\underset{\underset{O}{\|}}{C}-O-O^{\cdot} \rightarrow CO_2 + {}^{\cdot}OC_2H_5 \ ;$$

$$H_3C-\underset{\underset{H}{|}}{\overset{\overset{H}{|}}{C}}-O-O^{\cdot} \rightarrow H_3C-\overset{\overset{H}{|}}{C}=O + {}^{\cdot}OH \ ;$$

$$C_2H_5-\underset{\underset{CH_3}{|}}{\overset{\overset{H}{|}}{C}}-\underset{\underset{O}{\|}}{C}^{\cdot} \xrightarrow{O_2} C_2H_5-\underset{\underset{CH_3}{|}}{\overset{\overset{H}{|}}{C}}-\underset{\underset{O}{\|}}{C}-O-O^{\cdot} \rightarrow \underset{\underset{CH_3}{|}}{\overset{\overset{H}{|}}{C}}-O-O + C-C_2H_5 \ ;$$

$$\underset{\underset{CH_3}{|}}{\overset{\overset{H}{|}}{C}}-O-\underset{\underset{O}{\|}}{C}-C_2H_5 \rightarrow \overset{\overset{H}{|}}{C}=O + {}^{\cdot}O-\underset{\underset{O}{\|}}{C}-C_2H_5 \ ;$$

$$C_2H_5-\underset{\underset{O}{\|}}{C}-O^{\cdot} + C_2H_5-\underset{\underset{O}{\|}}{C}-CH_2-CH_3 \rightarrow C_2H_5-\underset{\underset{O}{\|}}{C}-OH + C_2H_5-\underset{\underset{O}{\|}}{C}-{}^{\cdot}CH-CH_3 \ ;$$

$$H_3C-\underset{\underset{O}{\|}}{\overset{\overset{H}{|}}{C}} + R^{\cdot} \rightarrow H_3C-\underset{\underset{O}{\|}}{C}^{\cdot} + RH \quad (R = C_2H_5^{\cdot},\ C_2H_5-\underset{\underset{O}{\|}}{C}^{\cdot}) \ ;$$

$$H_3C-\underset{\underset{O}{\|}}{C}^{\cdot} \xrightarrow{O_2} H_3C-\underset{\underset{O}{\|}}{C}-O-O^{\cdot} \rightarrow CO_2 + {}^{\cdot}OCH_3 \ .$$

The reaction involving the abstraction of a hydrogen atom from H_3C-CHO is analogous to the abstraction of hydrogen from HCHO in the case of acetone. In the absence of oxygen, C_2H_6 and C_2H_4 are mainly formed[70].

The thermal oxidation of dipropyl ketone has been studied[35] and it has been shown that the maximum concentration of the hydroperoxide is 0.005 and 0.010 mole per mole of the initial substance at 110° and 120 °C respectively; these concentrations are reached after 24 and 5 h respectively. Under the same conditions, the concentrations of acids are 0.03 and 0.04 mol mol^{-1} and reach 0.05 and 0.08 mol mol^{-1} after 30 h at 100 °C and after 12 h at 120 °C.

The thermal oxidation of di-isopropyl ketone has been investigated[36] at 100° and 110 °C; the maximum content of the hydroperoxide reaches 0.05 and 0.04 mole per mole of the initial substance at 100° and 110 °C after 36 and 16 h respectively.

The oxidation of di-isopropyl ketone in a highly alkaline medium has been studied[46,49]. In the presence of $(CH_3)_3COK$ in a $(CH_3)_3COH$ + diglyme mixture the conversion of the ketone is complete after 45 h, the yield of the hydroperoxide amounting to 0.8 mol mol^{-1}.[49] The same alkoxide in solution in dimethyl formamide at −8 °C reacts completely after 4 min and the yield of the hydroperoxide is 0.87 mol mol^{-1}. Cubbon and Hewlett[46] studied the structure of the hydroperoxide

$$(CH_3)_2C(OOH)-CO-CH(CH_3)_2 \qquad \text{(IV)}$$

obtained by thermal oxidation at 100 °C as described by Scarp and Whitcome[36] or by base-catalysed oxidation at −8 °C as described by Gersmann and Bickel[48]. The absence of a cyclic structure of the type

$$(CH_3)_2\overset{\overset{OH}{|}}{C}(O-O)-CH(CH_3)_2$$

was demonstrated by the retention of specific properties of the O–OH and C=O groups. Indeed, in the presence of phenylhydrazine it is possible to obtain the hydroperoxide

$$(CH_3)_2C(OOH)-\underset{\underset{N-NHC_6H_5}{\|}}{C}H(CH_3)_2$$

and in the presence of $(C_6H_5)_3CCl$ the dialkyl peroxide

$$(CH_3)_2C(O-O-C(C_6H_5)_3)-COCH(CH_3)_2$$

can be synthesised.

The presence of a single hydroperoxy-group (with intramolecular and intermolecular hydrogen bonds) in the reaction product is fairly unexpected, because the simultaneous presence of two tertiary carbon atoms creates favourable conditions for attack at two positions simultaneously. The hydroperoxide decomposes via a radical mechanism (initiation of the polymerisation of vinyl monomers).

The oxidation of 2-octanone[42] at 130 °C and 15 atm in an alkaline medium in the presence of NaOH (from 0 to 4.25 *N*) has been studied[42] and it has been shown that, apart from the main attack on the 3-position (relative to the end of the chain), leading to the formation of C_2 and C_6 monobasic acids, there is attack on other positions albeit to a lesser extent. It is of interest to note that the direction of this attack varies with the alkalinity of the medium; with increase of alkalinity, the CH_2 group is involved to a lesser extent but the interaction with the CH_3 group in the α-position relative to C=O intensifies.

Thus in a neutral medium the overall yield of the C_2 and C_6 acids is 77% and the yield of α-oxoheptanoic acid is 2% of the overall yield of all the acids, while in an alkaline medium (NaOH, 6.25 *N*) the yields of the C_2 and C_6 acids are 63 and 18% respectively. On passing from a neutral to an alkaline medium, the yields of the C_3 and C_4 acids diminish somewhat, from 6.2 to 4.4% and from 8.4 to 6.5% respectively.

The thermal oxidation of γ-undecanone at 140 °C has been studied[43] under a pressure of 15 atm. As in the previous case, oxygen acts not only on the carbon atom in the 5-position relative to the end of the chain but also on all the carbon atoms although to a much smaller extent; this gives rise to the formation of both C_5 and C_6 acids, on the one hand, and of C_2, C_3, and C_4 acids, γ-oxovaleric acid, and β- and γ-oxocapric acids, on the other, as well as the formation of diketones (3,6- and 2,6-undecanediones) and methylethylbutyrolactone. The preferential attack on the 2-position (the α-position relative to the CH_3 group) is noteworthy. The amounts of the C_2, C_3, C_4, and C_5 acids formed relative to the C_6 acid are 0.17, 0.11, 0.10, and 0.66 respectively.

The amount of peroxides passes through a sharp maximum (8×10^{-2} mol mol^{-1}), which is attained after 20 min; after 2.5 h, the products contained 5×10^{-2} mol mol^{-1} of peroxides, 5×10^{-2} mol mol^{-1} of esters (after 3 h), and 1×10^{-2} mol mol^{-1} of lactones (after 3 h).

Esters can be formed partly as a result of the reaction with the initial ketone of the peroxide formed by the oxidation of the aldehydes formed. This is the classical Baeyer–Villiger reaction described by Hassall[71] and the present author[72].

The thermal oxidation of γ-undecanone has also been studied at 120° and 130 °C;[43] the maximum content of different compounds in the product is almost independent of temperature but is attained faster at higher temperatures. Thus the maximum amounts of products are formed after 180, 90, and 30 min for peroxides (8×10^{-2} mole), after 300, 180, and 90 min for acids (6×10^{-2} mole), and after 360, 180, and 150 min for esters (3×10^{-2} mole) at 120°, 130°, and 140 °C respectively.

It has been established[73] that benzyl mesityl ketone is converted at room temperatures into mesiteic acid and benzaldehyde on contact with even traces of atmospheric oxygen. The yield of the intermediate hydroperoxide $C_6H_5-CH(O-H)-COMes$ is 0.07–0.08 mol mol^{-1} and is reached after a period ranging from 15 days to 6 months. The hydroperoxide isolated in a pure form is a crystalline substance which melts with decomposition at 134–135 °C. After reduction by treatment with KI or Na_2SO_3 in acetic acid, the corresponding ketoalcohol is obtained, while heating up to 100–110 °C at a pressure of 1 mmHg results mainly in the formation of mesiteic acid, benzophenone, and a small amount of dibenzoyl and water.

IV. SYNTHESIS AND STUDY OF THE DECOMPOSITION OF α-KETOHYDROPEROXIDES

1. Synthesis

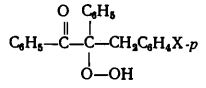
Hydroperoxides of different types, presented in Tables 2 and 3, have been obtained[74] by oxidising aldehydes or ketones ketones in an alkaline medium at −20 °C in the presence of $(CH_3)_3COK$ in $(CH_3)_3COH$ (method I) or C_2H_5ONa in C_2H_5OH + DMF (method II) with subsequent recrystallisation of the reaction products from an appropriate solvent.

Table 2. Hydroperoxides of the type $XC_6H_4-C(=O)-C(O-OH)(C_6H_5)-C_6H_5$.

X	Method	Solvent for recrystallisation	Purity, %	M.p., °C
H	I	petroleum ether	96	115—116
H_3CO-*p*	II	hexane + petroleum ether	85	118—119
H_3C-*p*	II	benzene + petroleum ether	77	112—114
Cl-*m*	II	benzene + petroleum ether	88	101—103
Cl-*m*	II	—	67	liquid

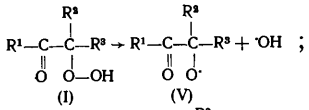
Table 3. Hydroperoxides of the type $C_6H_5-C(=O)-C(O-OH)(C_6H_5)-CH_2C_6H_4X$-*p* obtained by method II.

X	Solvent of recrystallisation	Purity, %	M.p., °C
CH_3O	benzene + petroleum ether	29	105—108
H_3C	—	50	liquid
Cl	—	60	liquid

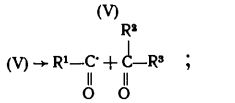


2. Various α-Ketohydroperoxide Decomposition Pathways

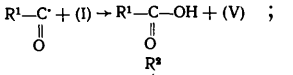
Various methods for the thermal[74] (at 250 °C in the vapour phase or at 130 °C in the liquid phase in chlorobenzene), photochemical[75], and alkali-catalysed[76] decomposition of α-ketohydroperoxides have been studied in very great detail. The papers indicated present the ratios of products in each individual instance and discuss the relevant mechanisms.



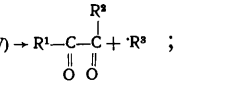
(a) The radical mechanism. The thermal decomposition of α-ketohydroperoxides in the vapour phase at 250 °C or in the liquid phase at 130° and 150 °C in C_6H_5Cl as well as their photochemical decomposition at room temperature give rise to the acid R^1COOH and the ketone R^2COR^3 as the main products



in yields of 0.75–0.80 and 0.75–1.00 mole per mole of the initial substance respectively. These products are formed as a result of the rupture of the bond between the carbon atom of the carbonyl group and the carbon atom linked to the hydroperoxy-group. Small amounts of R^1COCOR^2, the alcohol R^3OH, and the hydrocarbon R^3R^3 are also formed as a result of the dissociation of the C–C bond in the β-position relative to the C=O group. The ease of dissociation depends on the nature of R^3.



In the case of hydroperoxides

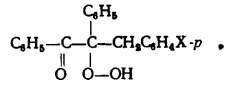


the yield of $C_6H_5-C(=O)-C(=O)-C_6H_5$ is 0.04, 0.054, and 0.08 mole per mole of the initial substance for X = Cl, H, and OCH_3 respectively. Consequently electron-accepting groups lower and electron-donating groups increase the rate of dissociation of the C–C bond in the β-position. The increased yield of the acid R^1COOH or the ketone R^2COR^3 as well as the fact that the rate of reaction in C_6H_5Cl is higher than in other solvents suggest that the thermal decomposition proceeds via a radical mechanism including a sequence of steps:

(1)

(2)

(3)

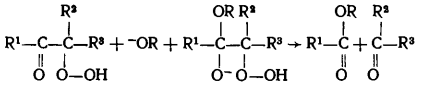


(4)

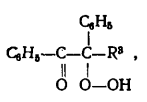
(5)

(6)

The first stage is the homolytic dissociation of the oxygen bridge in compound (I) with formation of radicals (V) and ·OH; this is followed by reactions (2)–(6). The main reactions are (2) and (3) and the side reactions are (4), (5), and (6). The contribution of the ionic mechanism under the experimental conditions given above (dilution to a low concentration in a non-polar solvent) is apparently insignificant. Furthermore, since the yields are analogous to those quoted in the previous instance (for the formation of the acid R^1COOH and the ketone R^2COR^3 in the photochemical decomposition of the above hydroperoxides at room temperature), presumably this process also involves a radical chain mechanism[75].

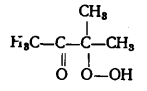


It is noteworthy that the oxidation-reduction reaction at 25 °C in aqueous 70% CH_3OH solution in the presence of $FeSO_4$ also proceeds via a radical mechanism analogous to that described by Sawaki and Ogata[74]. The hypothesis of the formation of the radicals $R^1\dot{C}O$ is also supported by the formation of the diketone R^1COCOR^1 in a yield of ~0.17–0.20 mol mol^{-1} for hydroperoxides of the type



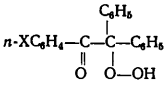
In contrast to cumenyl hydroperoxide, the α-ketohydroperoxide is not reduced to the corresponding alcohol. In the simultaneous presence of $FeSO_4$ and $FeCl_3$, R^1COOCH_3, $R^2R^3C=O$, and R^3Cl are formed in amounts of 0.4–0.6, 0.5–1.0 and 0.018–0.013 mole per mole of the initial substance respectively.

Kochi and Rust[77] discussed in detail the recombination of radicals in the presence of metal ions, while de la Mare and Kochi[78] published a similar discussion of the reduction and oxidation by metal salts.

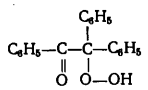


(b) Ionic decomposition catalysed by strong acids. This procedure has been studied in detail by Sawaki and Ogata[76]. It was shown that, in the presence of alkaline alkoxides ROM, where M = K or Na, in the corresponding alcohol or in an alcohol with added benzene at temperatures ranging from 0 °C to room temperature, the ester R^1COOR is formed almost exclusively with a small amount of the acid R^1COOH; however, the content of the latter increases with decrease of the ROM concentration and with increase of the amount of H_2O. Kinetic data suggest that the first reaction stage is the addition of the ^-OR anion to the carbonyl group followed by the heterolytic dissociation of the oxygen bridge and the C–C bond in the anion formed:

The rate of reaction evaluated from the amount of decomposed hydroperoxide varies very markedly with the structure of the hydroperoxide and also with the nature of the group linked to the C=O group compared with that linked to the COOH group. Thus for a hydroperoxide of the type

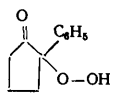


where R^3 = C_6H_5, CH_3, C_2H_5, or $C_6H_5CH_2$ (under the following identical conditions: temperature 0 °C, CH_3ONa concentration 0.10 M in a 1 : 1 mixture of CH_3OH and C_6H_6), the rates of decomposition (in relative units) are 308, 10.5, and 4.9 (the rate of decomposition of the hydroperoxide



was adopted as unity). The replacement of the C_6H_5 group by C_2H_5 lowers the rate of decomposition by a factor of 30 and the replacement by $C_6H_5-CH_2$ lowers it by a factor of 60; the yield of the ketone R^2COR^3 decreases in the same sequence: from 0.98 for R^3 = C_6H_5 to 0.77 mole per mole of the initial substance for R^3 = $C_6H_5CH_2$.

It is noteworthy that the relative rate of decomposition of the hydroperoxide $(CH_3)_2CH-\underset{\underset{O}{\|}}{C}-\underset{\underset{O-OH}{|}}{C}(CH_3)_2$ is 0.078, diminishing by a factor greater than 13 on replacement of the CH_3 group by $(CH_3)_2CH$.

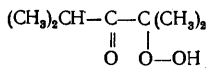


When the rate of decomposition for X = H is adopted as unity, the relative rates corresponding to X = CH_3O, CH_3, and Cl for hydroperoxides of the type

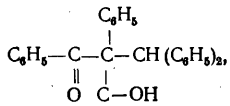
(the conditions were the same as above but CH_3ONa was replaced by C_2H_5ONa) are 0.11, 0.33, and 4.8, the rate diminishing by a factor of 14 following the replacement of the C_6H_5 group (linked to C=O) by CH_3 in

An especially high rate of decomposition of the hydroperoxide

has been noted. It is 7550 times greater than for the hydroperoxide

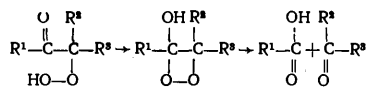


The above results depend mainly on the difference between the rates of addition of the anion ^-OR to the group C=O, caused by polar and particularly steric factors. Thus the rate of decomposition of the hydroperoxide



is extremely low due to steric hindrance. The rate of decomposition also varies with the RONa concentration: it increases by a factor of 4.5 for the $C_2H_5ONa/(CH_3COH + C_6H_6)$ system at 0 °C when the RONa concentration is raised by a factor of 20 (from 5×10^{-3} to 10^{-1} M) and increases by a factor of 25 with increase of temperature to 25 °C.

It is noteworthy that the ketone R^2COR^3 has been obtained in a yield of 0.8 mol mol^{-1} in a study[79] of the decomposition of the hydroperoxides



and

also in an alkaline medium but under other conditions (30 °C, $NaOH/CH_3OH + H_2O$ at a concentration of 0.1–0.5 M or CH_3ONa/CH_3OH at a concentration of 5×10^{-2}–5×10^{-1} M). Another compound formed was mainly the acid R^1COOH; the ester R^1COOCH_3 was obtained only in a yield of 0.13–0.16 mole per mole of the initial substance.

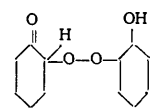
The results described suggest that the competitive addition of the groups RO^- and ^-OH to the carbonyl group leads to the formation of an ester and an acid. Furthermore, on the basis of kinetic data and luminescence phenomena, observed in the course of the decomposition of the hydroperoxides investigated, the authors[79] suggested that, as a consequence of the addition of the hydroperoxide hydrogen to the carbonyl group, a dioxetan is formed as an intermediate:

v. OXIDATION REACTIONS OF ALICYCLIC KETONES

1. Monocyclic Ketones

Three types of methods have been used to investigate monocyclic ketones, in particular cyclohexanone and its methyl derivatives:

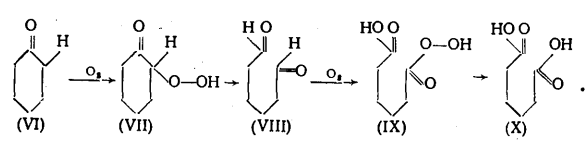
(a) oxidation in a neutral medium at 100 °C of a purely thermal type or in the presence of catalysts based on variable-valence metal salts;



(b) oxidation in an acid medium at 60–70 °C;

(c) oxidation in a highly alkaline medium below room temperature.

In the first two cases the reaction products consist mainly of dicarboxylic acids (or their derivatives) formed as a result of ring rupture; in the third case the products are α-diketones (without ring dissociation), which are obtained by the dehydration of the intermediate hydroperoxides or from the products of their subsequent condensation.



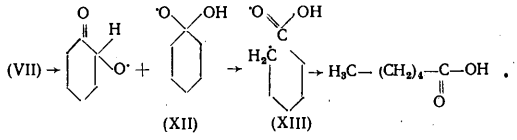
It has been shown[37] that the rate of oxidation of cyclohexanone in a neutral medium at 76 °C is low, becoming considerable at 100 °C. The kinetics of the formation of peroxides at 110°, 120°, and 130 °C have been determined by Denisov and Denisova[80]. Pritzkow[38] carried out the oxidation at 100 °C in the absence and presence of manganese laurate and determined the compounds obtained as well as the kinetics of the formation of peroxides and acids. It is noteworthy that in the presence of manganese laurate the maximum content of hydroperoxide is 9×10^{-3} mole per mole of the initial substance and is attained after only 2 h from the start of the reaction and the corresponding overall amount of the acids is 4.6×10^{-1} mole per mole of the initial substance, i.e. 7 times greater than in the absence of the catalyst.

By concentrating the crude oxidation product at a reduced pressure, it was possible[38] to obtain a product containing 10^{-1} mol mol^{-1} of peroxides. It decomposes 80 times faster in cyclohexanone than in cyclohexane, which suggests that cyclohexanone is involved in the formation of radical chains via the formation of the intermediate hydroperoxide

obtained as a consequence of the intermolecular addition of the hydroperoxide hydrogen to the carbonyl group[80]. The same phenomenon has been observed also in the general case where carbon compounds are treated with hydroperoxides[23].

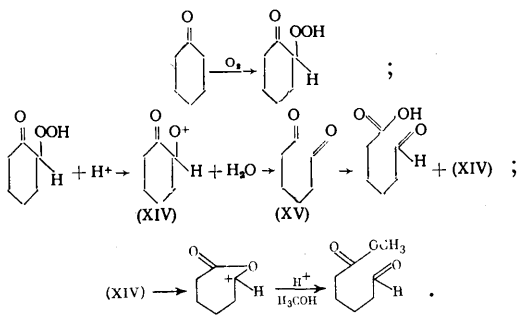
The compounds obtained consist mainly of C_4, C_5, and C_6 dicarboxylic acids, with adipic acid predominating, and of smaller amounts of C_5 and C_6 monobasic acids; ω-hydroxycaproic acid and the corresponding lactone are also formed. Adipic acid is formed via a radical mechanism (probably a chain mechanism), which can be represented by the following simplified scheme:

(VI) (VII) (VIII) (IX) (X)



The C_5 dicarboxylic acid is formed as a result of the decarboxylation of the peracid (IX) with formation of radicals (XI) and $^{\cdot}OH$, the former being oxidised to the corresponding

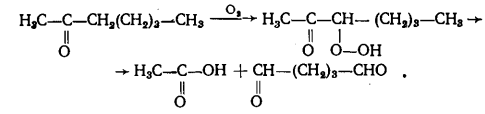
semialdehyde via the classical mechanism



$$(IX) \rightarrow CO_2 + {}^{\cdot}OH + HO{-}CO(CH_2)_3{-}CH_2^{\cdot};$$

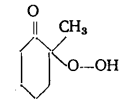
$$(XI) + O_2 \rightarrow HO{-}CO(CH_2)_3{-}CHO + {}^{\cdot}OH\ .$$

Monobasic acids may be formed from the hydroperoxide (VII) via the homolytic dissociation of the peroxy-bridge with subsequent dissociation of the carbon–carbon bond and the elimination of hydrogen:



The oxidation process in an acid medium has been investigated[81] at 60 °C in CH_3OH in the presence of 4% H_2SO_4 relative to the ketone. As for the oxidation in a neutral medium, the main products (0.70 mole per mole of the initial substance) are formed via the ring dissociation; they consist of derivatives of adipic semialdehyde (0.45 mole), its oxidation product—adipic acid (0.15 mole), and ω-hydroxycaproic acid (0.10 mole). The acid group is bound in the form of the methyl ester and the aldehyde group is bound in the form of the dimethyl acetal. These compounds are formed in the presence of acids via an ionic mechanism:

Oxidation in an alkaline medium has been investigated[82] in the $(H_3C)_3COK{-}(CH_3)_3COH{-}$diglyme system. It was shown that at −20 °C the degree of dissociation of the ring is low and that the main product (0.6 mol mol^{-1}) is α-cyclohexanedione, adipic acid being formed in the smallest amount (0.1 mol mol^{-1}). Only tarry products are obtained at room temperature in the presence of CH_3ONa/CH_3OH,[83] but in hexamethylphosphoramide (HMP) solution in the presence of NaOH or CH_3ONa adipic acid is formed in a yield of 0.80 mol mol^{-1} at 24° or 80 °C.[84]



The oxidation of 2-methylcyclohexanone has been investigated in a neutral medium[85] at 100 °C in the presence of $(1–5) \times 10^{-4}$ mol mol^{-1} of copper stearate. The main products are α-ketohydroperoxide, ε-methylcaprolactone, and oxoheptanoic, caproic, and acetic acids with a small amount of methyladipic, glutaric, succinic, methylsuccinic, and $C_3–C_6$ monocarboxylic acids. Compared with the non-catalytic oxidation, the catalyst apparently drives the reaction towards the formation of acids and the amount of the latter depends little on its concentration.

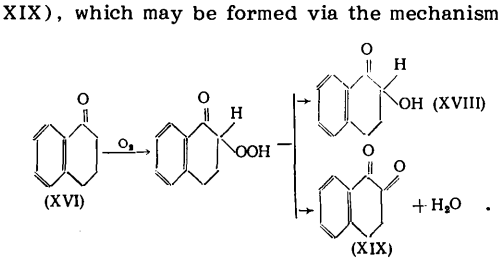
The nature of the compounds obtained suggests that the main attack is directed to the carbon atom in the α-position (with the CH_3 group); this results in the formation of a tertiary hydroperoxide, which then decomposes via a radical mechanism to 6-oxoheptanoic acid. Using the reoxidation method, the latter can be used as a source of monobasic acids, namely acetic acid:

However, the formation of α-methyladipic acid indicates the attack of O_2 on the α-position relative to the secondary carbon atom.

The oxidation of 2-methylcyclohexanone has been investigated[46] in the presence of NaOH or CH_3ONa in dimethylformamide as the solvent. At −50 °C the hydroperoxide

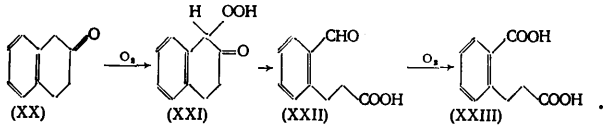
can be isolated in the form of a liquid; at −10 °C the main reaction product is oxoheptanoic acid.

The oxidation of 3-methylcyclohexanone in the presence of cobalt stearate at concentrations from 5×10^{-4} to 5×10^{-2} mol mol^{-1} has been studied by Serov et al.[86] The main products consist of α-methyladipic, δ-oxocaproic, and acetic acids; the secondary compounds are dicarboxylic acids; β-methyladipic, α-methylglutaric, and methylsuccinic acids. The results confirm the hypothesis that oxygen attacks the two secondary carbon atoms in the α- and α′-positions relative to the C=O group and the tertiary carbon atom. The quantitative composition of the products and hence the intensity of the attack on these positions are influenced by the temperature, the reaction time, and concentration.



The thermal oxidation of methylcyclohexanone isomers has been investigated in detail[87] in the presence of cobalt(II) and manganese(II) stearates and cobalt(III) and manganese(II) acetylacetonates as catalysts.

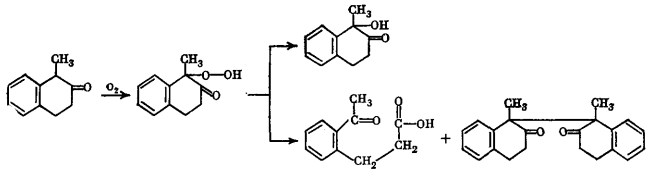
Rao et al.[82] described the oxidation of $C_5–C_8$ cyclanones in the highly alkaline $(CH_3)_3COK{-}(CH_3)_3COH{-}$diglyme medium at −20 °C. It was observed that 1,2-cyclopentanedione and glutaric acids are formed from cyclopentanone in yields of 0.36 and 0.19 mole per mole of the initial substance respectively, while α-diones are obtained from the C_7 and C_8 cyclanones and then undergo aldolisation with formation of spiran derivatives[82].



This difference in behaviour as a function of the type of ring can be due to the fact that the C_5 and C_6 diones almost always exist in the enolic form, which prevents the aldolisation reaction, while the C_7 and C_8 cyclanones exist in the keto-form and readily undergo this reaction[82].

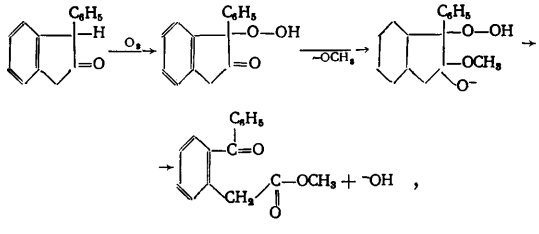
2. Cyclanones with Condensed Rings

The thermal oxidation of α- and β-tetralinones in a neutral medium has been studied[37]. The products obtained from the α-isomer (XVI) consist of peroxides [most probably largely of the hydroperoxide (XVII)], naphthoquinol (XVIII), and the diene (XIX), which may be formed via the mechanism



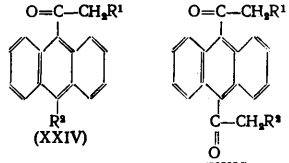
In the case of the β-isomer a single product was isolated—*o*-carboxyphenylpropionic acid (XXIII), which is apparently formed via an intermediate hydroperoxide (XXI):

(XX) (XXI) (XXII) (XXIII)



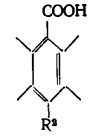
It is noteworthy that the rate of oxidation of the β-isomer is much higher than that of the α-isomer, because the carbon of the methylene group is located between the C=O and C_6H_5 groups.

The oxidation of α-methyl-β-tetralinone at room temperature has been studied by Naispuri et al.[88] The composition of the products formed via the mechanism



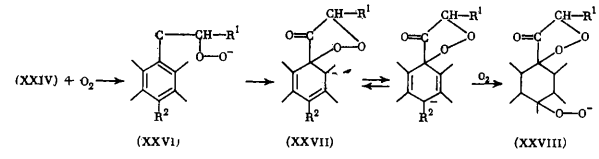
is as follows: 2-acetylphenylpropionic acid (main product, yield 0.3 mol mol^{-1}); 3,4-dihydro-1-hydroxynaphthalin-2(14)-one; 1,1-bis-3,4-dihydro-1-methylnaphthalin-2(14)-one. The latter is obtained as a result of the dimerisation of the initial keto-radical. It was not possible to isolate the hydroperoxide in a pure form.

The oxidation of 1-phenyl-2-indanone has been studied[89] in an alkaline medium (CH_3ONa/CH_3OH), and methyl *o*-benzoylphenylacetate, probably formed via the mechanism of Sawaki and Ogata[76], which in the given instance reduces to the mechanism



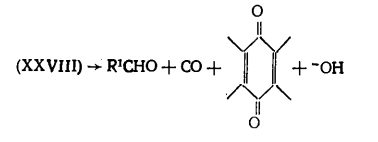
was obtained.

The oxidation (in an alkaline KOH/CH_3OH medium at room temperature) of α-monoketones and several anthracene α,α'-diketones having the general formula

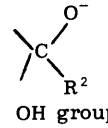


(XXIV) (XXV)

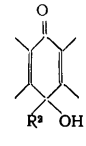
has been the subject of an interesting study by Rao et al.[90] In contrast to the classical mechanism, the products do not consist of the acid



and the aldehyde R^1CHO; their nature depends on the substituent R^2. Thus anthraquinone is formed for R^2 = H and hydroxyanthrone is formed for $R^2 = C_6H_5$; in addition CO is produced in both instances.

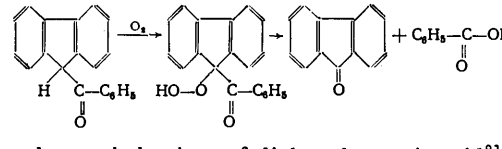


The formation of the above compounds can be accounted for by the following mechanism: the peroxide anion formed in the initial stage adds to the nearest carbon atom in the *meso*-position to form a five-membered ring, which causes the migration of the double bond and the appearance of a negative charge on another carbon atom in the *meso*-position, which is in its turn oxidised:



(XXVI) (XXVII) (XXVIII)

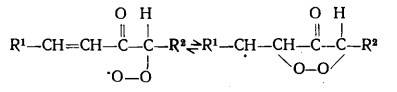
The course of the decomposition of compound (XXVIII) depends on the nature of R^2: the following reaction takes place when R^2 = H:



When $R^2 = C_6H_5$, the $>C-O-O-$ groups are reduced to  (probably by the initial ketone) with formation of the OH group, which is followed by the formation of hydroxyanthrone:

The oxidation of fluorenyl phenyl ketone in an alkaline medium has been described[91]. In a neutral or weakly alkaline medium ($NaHCO_3$) at pH 8.4 oxygen is not absorbed and at pH 12 the absorption is very slow; it is significantly accelerated in a highly alkaline medium, for example in $KOH-C_2H_5OH-H_2O$, and the yield of fluorenone becomes 0.85 mol mol^{-1}.

Fluorenone is formed by a general mechanism via the α-ketohydroperoxide:



The analogous behaviour of diphenylpyruvic acid[91]—oxidation with formation of oxalic acid and benzophenone—is noteworthy. The intermediate hydroperoxide could never be isolated because of its instability.

VI. OXIDATION OF α,β-UNSATURATED KETONES

The oxidation of ketones of this type has been studied mainly in an alkaline medium (KOH/CH_3OH) above room temperature. In all cases the main reaction is the formation of an epoxyketone, which is in equilibrium with the corresponding unsaturated ketol:

This can be followed by hydrolytic oxidative dissociation steps with formation of various compounds. Hydrogen peroxide, formed by the hydrolysis of the allyl hydroperoxide produced initially, can serve as the epoxidising agent. It is noteworthy that attack by oxygen is more likely to be directed to the carbon atom located in the α-position relative to the double bond than to the carbon atom in the α-position relative to the C=O group. Indeed the peroxy-radical arising in the second case should have been stabilised, by virtue of its resonance structure, by addition to a double bond with formation of a five-membered ring:

Incidentally, it is known that α,β-unsaturated aldehydes are oxidised with much greater difficulty than the corresponding saturated aldehydes[8,10].

The oxidation of mesityl oxide[24], pent-3-en-2-one,[92] pulegone[93], piperitone[94,95], carvenone[96], carvone[97], 1-methylcyclohex-1,2-en-3-one, 1,5-dimethylcyclohex-1-en-3-one, verbenone, carvotanacetone, isophorone, and eucarvone[98] has been investigated.

VII. INTERACTION OF STEROID KETONES WITH OXYGEN

The oxidation of various steroid ketones in an alkaline medium has been considered by comparison with certain simple ketones[99] and examples of compounds formed depending on the nature of the initial ketone, have been given.

The studies of Bailey et al.[100] and of Gardner et al.[101] were concerned with the hydroxylation of pregnan-20-ones to the corresponding hydroxy-compounds. In principle, the process consists in the oxidation of the ketone in an alkaline medium (CH_3ONa/CH_3OH + DMF) with reduction of the α-ketohydroperoxide *in situ* to the corresponding ketoalcohol. The reducing agent can be H_2 [100] or $P(CH_3O)_3$.[101] The latter reduction method is more effective, because the yield of the ketoalcohol reaches 65%. This reaction has been discussed in detail by Gardner et al.[101]

Chemical and Biological Kinetics

N.M.Emanuel'

Examples of the application of the methods and ideas of chemical kinetics in various branches of chemistry and biology are considered and the results of studies on the kinetics and mechanisms of atuoxidation and inhibited and catalysed oxidation of organic substances in the liquid phase are surveyed. Problems of the kinetics of the ageing of polymers and the principles of their stabilisation are discussed and certain trends in biological kinetics (kinetics of tumour growth, kinetic criteria of the effectiveness of chemotherapy, problems of gerontology, etc.) are considered.
The bibliography includes 281 references.

I. INTRODUCTION

Approximately half a century ago a new branch of natural science began to be formulated in various countries, namely chemical physics, which deals with the physical principles of chemistry and includes the physics of the structure of matter and of chemical reactions (chemical kinetics).

In 1931 Academician N.N.Semenov founded in the USSR the Institute of Chemical Physics of the USSR Academy of Sciences which has since celebrated its 50th anniversary. In this Institute, which has a long tradition in the field of kinetic research, general kinetics have been developed in many directions. At the time of the organisation of the Institute the studies of a group of scientists working under Semenov's supervision at the Physicotechnical Institute in Leningrad led to the discovery of branched chain reactions and laid the foundations of the theory of chain inflammation and thermal explosion. These scientific advances rapidly received high recognition in world science. They have occupied an important place as the foundation of Soviet chemical physics, which is distinguished by specific research into the kinetics and mechanisms of chemical reactions and combustion and explosive processes.

A quantitatively rigorous general theory of chemical chain reactions was created. This theory deals with the quantitative aspects of unbranched chain processes which have become the object of studies in chemical kinetics at the beginning of this century as a result of the outstanding research of Bodenstein and Nernst. The theory of chain termination on walls and within the space of the reaction vessel has been developed in the Institute of Chemical Physics of the USSR Academy of Sciences for unbranched chain reactions and the general case of chain termination in space and on the surface has been considered theoretically. Differential equations and their integral forms, whereby chain propagation can be described as a function of time, i.e. the

kinetics of chain reactions can be described, have been obtained. A theory of branched chain processes has been particularly thoroughly developed for the case of chain branching as a result of the multiplication of active centres (atoms and radicals) in the chemical interaction of active centres with molecules as well as a theory of energetic chain branching due to the excess energy of the reaction products (in the 1960's). Many new phenomena characteristic of branched chain processes have received a clear physical interpretation and a theoretical foundation. These are in the first place a theory of the lower and upper inflammation limits and the discovery of an unusual form of the regions of the chain inflammation of combustible gases in the form of "peninsulas" in terms of pressure–temperature variables.

A theory of degenerate branched chain reactions has been created. This theory made it possible to understand and describe quantitatively many instances of the slow development of a chain avalanche which does not lead to the inflammation of the combustible gas mixture. Subsequently many slow oxidation reactions of organic substances, initially in the gas phase and then in a condensed phase (in the liquid state and in solid polymers) were examined from the standpoint of this theory.

Much attention has been devoted to the study of the detailed chemical mechanisms of chain reactions, the identification of free atoms and radicals, the determination of their concentrations, and the study of elementary processes involving them.

The Institute of Chemical Physics has made a fundamental contribution to the theory of combustion and explosive processes, the thermal explosion of gases and condensed explosives, the propagation of flame in connection with the kinetics of chemical combustion reactions, and the detonation theory.

The mathematical apparatus of general kinetics consist of systems of differential kinetic equations including time as an independent variable.

A system of the type

$$\frac{dF_i}{dt} = f_i(F_1, F_2, \ldots F_n; t; a_1, a_2, \ldots a_m)$$

taking into account, when necessary, also heat and mass transfer, makes it possible to describe the kinetics of a wide variety of processes in chemistry, physics, biology, and geology. In this equation F_i are quantities varying with time and characterising the properties of the system, t is the time, and a_1, a_2, ..., a_m is a set of constant parameters. If the equations can be integrated in terms of quadratures, a set of formulae is obtained for the description of the kinetic curves for the process under consideration:

$$F_i(t) = \int_{t_0}^{t} \frac{dF_i}{dt} dt \quad .$$

The laws governing the development of gas-phase reactions represent the most complete field of general kinetics. Despite their enormous theoretical and practical importance, the kinetics of chemical reactions in condensed systems (liquid and solid) have been less thoroughly developed. The kinetics of biological processes have been still less developed.

This review is devoted to the kinetics of liquid-phase reactions in relation to the oxidation of organic substances, the chemical physics of the ageing and stabilisation of polymers, and the kinetics of certain biological processes.

II. KINETICS OF THE LIQUID-PHASE OXIDATION REACTIONS OF ORGANIC SUBSTANCES

During the last quarter of the century, considerable progress has been achieved in the kinetics and mechanisms of the oxidation processes of organic substances in the liquid phase.

1. Chemical Oxidation Mechanism

As a result of numerous studies throughout the world, the fundamental oxidation mechanism has been established. It includes elementary stages involving chain initiation (the formation of primary free radicals), chain propagation—the so-called "degenerate" branching, which lags behind the time of propagation of the main chain, the molecular decomposition of the peroxide with formation of a wide variety of oxidation products, and chain termination, which consists as a rule in the recombination of the radicals $R\dot{O}_2$.

The oxidation reaction does not always occur in an "unperturbed" form of this kind. In many instances the oxidation takes place in the presence of various inhibitors and catalysts, so that the overall oxidation mechanism is significantly complicated. In the general case account must be taken of the reactions of the active radicals $R\dot{O}_2$ and $\dot{R}$ as well as hydroperoxides with inhibitors and their reaction products, the set of elementary processes occurring in the presence of more than one inhibitor in the system, the complex formation reactions of homogeneous and heterogeneous catalysts with virtually all the starting materials, intermediates, and final products, and the reactions of the resulting complexes.

Thus the oxidation mechanism can be represented by the following set of elementary reactions in the most general form[1–4].

Autoxidation

$$2RH + O_2 \xrightarrow{k_0} 2\dot{R} + H_2O \ , \qquad (0)$$

$$RH + O_2 \xrightarrow{k_0'} \dot{R} + H\dot{O}_2 \ , \qquad (0')$$

$$\dot{R} + O_2 \xrightarrow{k_1} R\dot{O}_2 \ , \qquad (1)$$

$$\dot{R} \xrightarrow{k_{1'}} \dot{R}_1 + P_1 \ , \qquad (1')$$

$$R\dot{O}_2 + RH \xrightarrow{k_2} ROOH + \dot{R} \ , \qquad (2)$$

$$R\dot{O}_2 \xrightarrow{k_{2'}} R'COH + R''\dot{O} \ , \qquad (2')$$

$$R\dot{O}_2 + ROOH\ (ROH,\ R'COR'') \xrightarrow{k_{2''}} \dot{R}' + P_2 \ , \qquad (2'')$$

$$ROOH \rightarrow R\dot{O} + \dot{O}H \ , \qquad (3)$$

$$ROOH + RH\ (R_1COOH,\ R'COR'',\ \ldots) \xrightarrow{k_{3'}} 2\dot{R}'' + P_3 \ , \qquad (3')$$

$$ROOH + ROOH \xrightarrow{k_{3''}} R\dot{O} + R\dot{O}_2 + H_2O \ , \qquad (3'')$$

$$\dot{R}'\ (\dot{R}'',\ R\dot{O},\ \dot{O}H) + RH \rightarrow \dot{R}_4 + R'H\ (R''H,\ ROH,\ H_2O) \ , \qquad (4)$$

$$ROOH \rightarrow P_4 \ , \qquad (5)$$

$$R\dot{O}_2 + R\dot{O}_2 \rightarrow P_5 \ , \qquad (6)$$

$$R\dot{O}_2 \rightarrow \dot{\rho} \ . \qquad (6')$$

Inhibited oxidation

$$R\dot{O}_2 + InH \rightarrow In^{\cdot} + ROOH \ , \qquad (7)$$

$$\dot{R} + InH \rightarrow In^{\cdot} + RH \ , \qquad (7')$$

$$\dot{R} + Q \rightarrow P_6 \ , \qquad (7'')$$

$$ROOH + \rangle SH\ (\rangle PH) \rightarrow P_7 \ , \qquad (7''')$$

$$R\dot{O}_2 + In^{\cdot} \rightarrow InOOR \ . \qquad (8)$$

Catalysed oxidation

$$Cat + O_2 \rightleftharpoons Cat \ldots O_2 \xrightarrow{+RH} \dot{R} \ , \qquad (9)$$

$$Cat + RH \rightleftharpoons Cat \ldots RH \xrightarrow{+O_2} \dot{R} \ , \qquad (10)$$

$$Cat + R\dot{O}_2 \rightarrow Cat \ldots R\dot{O}_2 \begin{cases} \xrightarrow{+RH} P_8 + \dot{R} \ , & (11) \\ \rightarrow \text{chain termination.} & (12) \end{cases}$$

Here $\dot{p}$ is an inactive radical, InH a phenol or an amine, Q an inhibitor reacting with alkyl radicals, Cat a homogeneous or heterogeneous catalyst, $\rangle SH(\rangle PH)$ a sulphur-containing (or phosphorus-containing) inhibitor which reacts with hydroperoxides, and P_i are products.

For a long time, the detection and identification of the active centres of chain reactions (free radicals and atoms) were regarded as a kind of unique achievements. The wide-scale application of electron paramagnetic resonance (EPR) method altered the situation. The existence of free radicals has been detected by EPR in low-temperature oxidation reactions of various hydrocarbons. In many cases the spectra consist of a singlet with a g-factor of 2.015; the absorption line width depends on the structure of the peroxy-radicals and varies from 6 to 30 G (Fig.1, Table 1).[5-7]

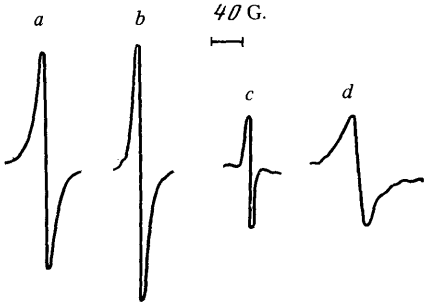

Figure 1. EPR spectra of peroxy-radicals in the oxidation of various substances: *a*) of cumene, catalysed by cobalt stearate, $[CoSt_2] = 1$ g litre^{-1}, 90 °C; *b*) of decalin, initiated by dicyclohexyl percarbonate, [PC] = 0.1 M, 85 °C; *c*) of 1,1′-diphenylethane, initiated by dicyclohexyl percarbonate, [PC] = 0.13 M, 69 °C; *d*) of iso-octane, initated by dicyclohexyl percarbonate, 78 °C.[5]

The formation of free radicals (chain initiation) in liquid-phase oxidation processes takes place as a rule in the bimolecular interaction of oxygen with the organic compound via reaction (0′).[3] A termolecular chain initiation reaction [reaction (0)] was discovered in the 1960's in relation to the oxidation of cyclohexanol and cyclohexanone[8-10]. The possibility of this reaction was subsequently confirmed in relation to the oxidation of n-decane[11], tetralin[9,12], and indan[12] (Table 1).

The termolecular mechanism of chain initiation can involve an intermediate stage in which a complex is formed in accordance with the scheme

$$RH + O_2 \rightleftarrows RH \ldots O_2 \ ,$$
$$RH \ldots O_2 + RH \rightarrow 2\dot{R} + H_2O_2 \ .$$

The formation of such complexes has been demonstrated spectrophotometrically[12].

In a fully developed oxidation process radicals are formed via degenerate chain branching. The rate of degenerate branching can be determined from the consumption of the inhibitor introduced into the reaction mixture at various stages of the oxidation process. It has been shown by this method, for example, in the study of Knorre et al.,[16] that in oxidation of n-decane the hydroperoxide is the only branching product. The chain branching rate constant $k_3 = 6 \times 10^8 \exp(-24\,800/RT)$ (s^{-1}).[16]

Table 1. The rate constants for chain initiation in the oxidation of various organic compounds.

Substance	A_0', litre mol^{-1} s^{-1}	E_0', kcal mol^{-1}	A_0, litre^2 mol^{-2} s^{-1}	E_0, kcal mol^{-1}	Refs.
	Bimolecular reaction (0′)		Termolecular reaction (0)		
Cyclohexane	$8.0 \cdot 10^{12}$	40.0			[15]
Isopropylbenzene	$3.5 \cdot 10^{9}$	27.4			[15]
o-Xylene	$2.0 \cdot 10^{8}$	31.0			[15]
Ethyl methyl ketone	$3.0 \cdot 10^{9}$	30.0			[13]
Ethanol	$6.0 \cdot 10^{7}$	30.0			[13]
Phenol	$7.0 \cdot 10^{12}$	35.0			[14]
p-Methoxyphenol	$7.5 \cdot 10^{9}$	27.0			[14]
p-Cresol	$3.0 \cdot 10^{11}$	32.0			[14]
α-Naphthol	$2.2 \cdot 10^{9}$	25.0			[14]
β-Naphthol	$4.5 \cdot 10^{10}$	29.0			[14]
α-Naphthylamine	$1.5 \cdot 10^{10}$	30.0			[14]
α-Naphthylphenylamine	$2.8 \cdot 10^{10}$	31.0			[14]
β-Naphthylphenylamine	$3.5 \cdot 10^{10}$	32.0			[14]
Tetralin			$4 \cdot 10^{3}$	20.7	[9]
Indan			$3.9 \cdot 10^{3}$	18.8	[12]
Cyclohexanol			8.3	16.0	[10]
Cyclohexanone			$2.1 \cdot 10^{2}$	17.5	[9]

Degenerate chain branching can occur not only as a result of the unimolecular decomposition of the hydroperoxide via reaction (3) but also via the bimolecular reaction (3′) with participation of the hydrocarbon. According to reaction (3′), the rate of branching decreases linearly with increasing hydrocarbon concentration[3].

With the decrease of the C–H bond strength in the hydrocarbon molecule in the sequence decane > 2,7-dimethyloctane > ethylbenzene > methyl oleate, the rate of decomposition of n-decyl hydroperoxide into radicals increases, which constitutes yet another piece of evidence for the occurrence of the bimolecular chain branching reaction (3′).[17]

At high hydroperoxide concentrations, which are particularly characteristic of the oxidation of α-olefins, the decomposition of the hydroperoxides and hence the degenerate chain branching take place via reaction (3″), the occurrence of which is promoted by the formation of hydrogen-bonded associated species:

$$ROOH + HOOR \rightleftharpoons [ROOH \ldots HOOR] \rightarrow R\dot{O} + R\dot{O}_2 + H_2O \ .$$

For high degrees of reaction, the products accumulating in the reaction mixture begin to participate in the chain branching. Organic acids, capable of forming a 2 : 1 complex with hydroperoxides, are important in this sense. Under the

influence of intermolecular hydrogen bonds, the dissociation of the O–O bond in the hydroperoxide molecule in such a complex is facilitated, which leads to the formation of free radicals[18,19]:

$$ROOH + 2RCOOH \overset{K}{\rightleftarrows} [ROOH \ldots 2RCOOH] \rightarrow R\dot{O} + \dot{O}H + 2RCOOH .$$

A study of the mechanism of chain propagation established that, as for gas-phase reactions, the liquid-phase oxidation reactions of organic compounds include in certain cases, together with the main chain propagation reaction

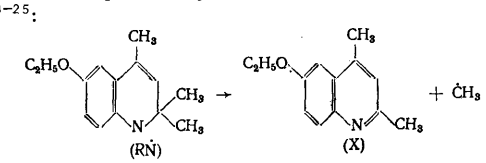
$$R\dot{O}_2 + RH \rightarrow ROOH + \dot{R} , \qquad (2)$$

also the isomerisation of peroxy-radicals accompanied by the decomposition of the radical with dissociation of the C–C bond and the formation of carbonyl compounds and radicals:

$$R\dot{O}_2 \rightarrow R'CHO + R''\dot{O} . \qquad (2')$$

The chain propagation in the oxidation of α-olefins constitutes two parallel reactions, in one of which the peroxy-radicals interact with the C–H bond [reaction (2)] with formation of hydroperoxides, while in the other peroxy-radicals add to the unsaturated bond [reaction (2‴)].[20] This reaction pathway leads to the formation of oxides, polyperoxides, and other products:

$$R\dot{O}_2 + \diagdown\!\!\diagup C\text{–}H\,(RH) \rightarrow ROOH + \dot{R} , \qquad (2)$$



$$R\dot{O}_2 + \diagdown C{=}C\diagup\,(RH) \rightarrow R\dot{O}_2\text{–}\underset{|}{C}\text{–}\dot{C}\diagup \rightarrow \text{products.} \qquad (2''')$$

The rates of reactions (2) and (2‴) have been determined from the accumulation of hydroperoxides and the consumption of double bonds[21,22] in the oxidation of cyclohexene and phenylcyclohexene.

The rate constants k_2 and $k_{2'''}$ were calculated from the parameters $k_2/k_6^{1/2}$ and $k_{2'''}/k_6^{1/2}$ and the rate constant k_6 for the recombination of peroxy-radicals (determined by the method of interrupted illumination). The corresponding rate constants have the following values (in litre mol^{-1} s^{-1}): $k_2 = 5.7 \times 10^4 \exp[(-6300 \pm 300)/RT]$, $k_{2'''} = 1.4 \times 10^9 \exp[(-14\,000 \pm 600)/RT]$, and $k_6 = 1.5 \times 10^6$ for cyclohexene[21,22] and $k_2 = 2.2 \times 10^5 \exp[(-5000 \pm 300)/RT]$, $k_{2'''} = 1.4 \times 10^8 \exp[(-8400 \pm 300)/RT]$, and $k_6 = 2.5 \times 10^8$ for phenylcyclohexene[21,22].

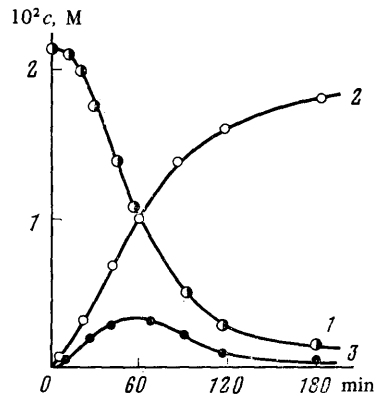
The conjugation of the C=C bond with the phenyl group increases the reactivity of the α-olefin, which is manifested by a considerable decrease of the activation energy for the addition of the peroxy-radicals to the unsaturated bond in phenylcyclohexene relative to cyclohexene. It is also striking that there is a considerable increase of k_6 following the introduction of the phenyl substituent into the cyclohexene molecule, whereas by analogy with the corresponding alkanes, a lower value of k_6 for phenylcyclohexene relative to cyclohexene should have been expected in view of the steric effect of the substituent (the values of k_6 for cyclohexane and phenylcyclohexane are respectively 1.6×10^6 and 1.6×10^5 litre mol^{-1} s^{-1}).

In the oxidation of 6-ethoxy-1,2-dihydro-2,2,4-trimethylquinoline (ethoxyquin) the rate-limiting stage in the chain propagation reaction is the decomposition of the primary free radical accompanied by the elimination of the methyl radical[23–25]:

(13)

The rate constant for this reaction is $k_{13} = 1.3 \times 10^{13} \exp(-20\,800/RT)$ (litre mol^{-1} s^{-1}).

At elevated temperatures this reaction leads to the formation of 6-ethoxy-2,6-dimethylquinoline (X) (Fig. 2) with a a selectivity up to 90% in chlorobenzene and more than 60% in n-decane, cumene, styrene, and phenylacetylene. At $t > 100$ °C the oxidation of ethoxyquin is a chain process.



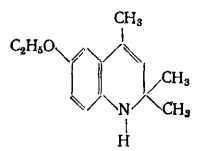


Figure 2. Kinetic curves for the consumption of ethoxyquin (curve *1*), the accumulation of the quinoline product (curve *2*), and the accumulation of methyl hydroperoxide (curve *3*) in the autoxidation of ethoxyquin in chlorobenzene (110 °C, oxygen flow rate 0.5 litre h^{-1}).[24]

The active centres for the chains are the free radicals RṄ, ĊH$_3$, and CH$_3$Ȯ$_2$ participating in the reactions

$$\dot{C}H_3 + O_2 \rightarrow CH_3\dot{O}_2 , \qquad (14)$$

$$+ CH_3\dot{O}_2\,(R\dot{O}_2,\ R\dot{O}) \rightarrow R\dot{N} + CH_3O_2H\,(RO_2H,\ ROH) , \qquad (15)$$

$$R\dot{N} + R\dot{N} \rightarrow RN\text{–}NR . \qquad (16)$$

The rate constant for the reaction of peroxy-radicals with the N–H bond of ethoxyquin is very high ($k_{15} \geq 10^6$ litre mol^{-1} s^{-1}) and does not limit the rate of oxidation. The rate constant for the recombination reaction (16), measured by flash photolysis, is $2k_6 = 9.8 \times 10^6$ litre mol^{-1} s^{-1} (20 °C, benzene).[26] Chain branching proceeds via a reaction of type (3′):

$$RNH + CH_3OOH\,(ROOH) \rightarrow R\dot{N} + CH_3\dot{O}(R\dot{O}) + H_2O .$$

In inert solvents this reaction proceeds with participation of methyl hydroperoxide.

At low temperatures, where the rate of decomposition of the radical RṄ via reaction (13) is low, ethoxyquin is one of the most effective antioxidants, since the rate constant for the interaction of peroxy-radicals with ethoxyquin [reaction (15)] is significantly greater than, for example, the corresponding constant for ionol ($k = 2 \times 10^4$ litre mol^{-1} s^{-1}, 60 °C [3]) and the RṄ radical formed is relatively inactive.

In hydrocarbons undergoing oxidation the RṄ radicals partly undergo a cross recombination reaction:

$$R\dot{N} + R\dot{O}_2 \rightarrow \text{products},$$

as a result of which the stoichiometric inhibition coefficient for ethoxyquin is greater than unity ($f \cong 1.3$ for the oxidation of phenylacetylene, styrene, ethylbenzene, and β-carotene; 50–60 °C).

Above 100 °C, the inhibiting efficiency of ethoxyquin falls in the oxidation of ethylbenzene, n-decane, and styrene, since the methylperoxy-radical formed in stage (15) is involved in the transfer of the hydrocarbon oxidation chain. The interaction of ethoxyquin with hydroperoxides plays a significant role in decreasing its efficiency as an inhibitor.

Ethoxyquin is an effective antioxidant for phenylacetylene even at a relatively high temperature. The inhibition is then due to the ethoxyquin reaction product—the corresponding quinoline.

The reactivity of the $R\dot{O}_2$ radicals with respect to the oxidation products [reaction (2″)] was determined by special kinetic procedures[27,28]; it was shown that, in the oxidation of n-decane, the ratios of the rate constant for reaction (2) (k_2) and the rate constants for the chain propagation as a result of the interaction of the radical $R\dot{O}_2$ with the alcohol ($k_{2''}$,ROH) and the hydroperoxide ($k_{2''}$,ROOH) are $k_2 : k_{2''},\mathrm{ROH} : k_{2''},\mathrm{ROOH} = 1 : 6 : 13$. The activation energies for the elementary stages[29,30] are $E_2 = 14.5$ kcal mol^{-1} and $E_{2''},\mathrm{ROH} = E_{2''},\mathrm{ROOH} = 10$ kcal mol^{-1}.

Thus the oxidation products are extremely reactive and have a significant influence on the oxidation mechanism.

The reactions of the $R\dot{O}_2$ radical with peroxides, alcohols, and ketones involve the interaction of two dipoles, which is significantly influenced by the dielectric constant of the medium.

The composition of the products of the oxidation of ethyl alcohol and ethyl methyl ketone at a pressure of 50 atm and a temperature of ~150 °C in a stainless steel reactor[32,33] is determined by the competition of two elementary chain propagation stages [reactions (2) and (2′)]. The principal oxidation products of ethyl methyl ketone are acetic acid, ethyl acetate, and diacetyl. In the oxidation of ethyl alcohol the products of the bimolecular reaction of the $R\dot{O}_2$ radical, namely acetic acid and ethyl acetate, constitute 80% of the total oxidation products. When ethyl methyl ketone and ethyl alcohol are diluted by a non-polar substance (benzene) the amount of the decomposition products of the $R\dot{O}_2$ radicals increases, because the addition of benzene diminishes the dielectric constant of the medium and the rate of reaction (2) falls.

The activation energy for reaction (2) in the oxidation of ethyl methyl ketone and ethyl alcohol increases with decrease of the dielectric constant of the medium[34]. The dipole moment of the activated complex $\mu_{\neq} = 8.4$ D, obtained from experimental data for the oxidation of ethyl methyl ketone, agrees well with the value calculated for one of the structures of the activated complex (8.1 D), i.e. in the case of ethyl methyl ketone the rate of reaction (2) is influenced solely by the dielectric constant of the medium. Not only the polarity of the medium but also the association of the alcohol via intermolecular hydrogen bonds plays an important role in the oxidation of the alcohol.

Chain termination in liquid-phase chain reactions takes place in the vast majority of cases via a quadratic recombination or disproportionation [reaction (6)] mechanism. The quadratic chain termination in the oxidation of hydrocarbons is apparently a complex process proceeding via a multistage mechanism[35–37]. According to Russell[38], the disproportionation of primary and secondary peroxy-radicals proceeds via an intermediate stage involving the formation of a cyclic complex, although it has been suggested that the process proceeds via a more complicated mechanism involving a zwitterion formation stage[37].

Tertiary peroxy-radicals probably interact via the mechanism

$$2R\dot{O}O \begin{cases} \rightarrow ROOR + O_2 , & (17a) \\ \rightarrow 2R\dot{O} + O_2 . & (17b) \end{cases}$$

The t-alkoxy radicals decompose with formation of a ketone and a low-molecular-weight primary radical, which is subsequently involved in disproportionation cross-reactions with the radicals $R\dot{O}O$.

For example, the radical $\dot{C}H_3$ is formed in the decomposition of the cumenyloxy-radical:

$$\begin{gathered} C_6H_5C(CH_3)_2\dot{O} \rightarrow C_6H_5(C{=}O)CH_3 + \dot{C}H_3 , \\ \dot{C}H_3 + O_2 \rightarrow CH_3\dot{O}_2 , \\ CH_3\dot{O}_2 + R\dot{O}_2 \rightarrow H_2CO + O_2 + ROH . \end{gathered} \qquad (18)$$

It is noteworthy that much attention has been devoted recently in the literature on the liquid-phase oxidation mechanism to the $R\dot{O}_2$ disproportionation reaction [reaction (17b)] as the chain propagation stage in the oxidation of hydrocarbons with tertiary[39] and secondary[40] C–H bonds.

A recent study[41] of the quadratic chain termination in the oxidation of cumene by the chemiluminescence method showed that the primary cumenylperoxy-radicals $C_6H_5CH(CH_3)CHO\dot{O}$, involved in the disproportionation cross-reactions

$$R\dot{O}O + C_6H_5CH(CH_3)CH_2O\dot{O} \rightarrow ROH + O_2 + C_6H_5CH(CH_3)CHO , \qquad (19)$$

play a major role in chain termination. Despite the low concentration of the primary peroxy-radicals, the contribution of reaction (19) to the overall rate of recombination is then comparable to the contribution of reaction (17) and greatly exceeds that of reaction (18) in the chain termination mechanism.

Various non-stationary methods are used to measure k_6, including rapid chemiluminescence (CL) methods[35,42]. A novel chemiluminescence method has been recently developed for the determination of the recombination and disproportionation constants of free peroxy-radicals in cases where the relevant processes are not accompanied by intense luminescence sufficient for its measurement under non-stationary conditions[43]. The method is based on the measurement of the non-stationary chemiluminescence in the coupled oxidation of the test substance RH with a small amount of an added "standard" compound R_1H characterised by fairly high chemiluminescence yields in chain termination processes. Non-stationary conditions are obtained as a result of the rapid introduction of an initiator into the system. The chemiluminescence arising in the coupled system is due to the reactions

$$\begin{gathered} R\dot{O}_2 + R_1\dot{O}_2 \rightarrow \text{products}, \\ R_1\dot{O}_2 + R_1\dot{O}_2 \rightarrow \text{products}. \end{gathered}$$

The ratio of the concentrations of the radicals $R\dot{O}_2$ and $R_1\dot{O}_2$ is determined by the rates of the chain propagation cross-reactions

$$R\dot{O}_2 + R_1H \rightarrow ROOH + \dot{R}_1 , \qquad (22)$$

$$R_1\dot{O}_2 + RH \rightarrow R_1OOH + \dot{R} . \qquad (23)$$

The effective rate constant for the recombination of radicals k_6^{eff} in mixtures of different composition is described by the formula

$$\ln \frac{1 + (I/I_\infty)^{1/2}}{1 - (I/I_\infty)^{1/2}} = 2(w_i k_6^{\mathrm{eff}})^{1/2} t$$

(I is the chemiluminescence intensity and I_∞ the limiting value of I for the given rate of chain initiation w_i), analogous to that used to decribe the non-stationary kinetics in the oxidation of pure hydrocarbons[42]. The constant k_6^{eff} varies

linearly with mixture composition and is given by an expression of the form

$$k_6^{\text{eff}} = k_6 + 2\frac{k_{22}}{k_{23}}(k_{20} - k_{21})\frac{[R_1H]}{[RH]},$$

which makes it possible to calculate the required constant k_6 from the dependence of k_6^{eff} on the ratio $[R_1H]/[RH]$. The method has been used[44] to determine k_6 for the oxidation of substituted 3-phenylindans.

In certain special cases there is apparently a possibility also of linear termination together with quadratic chain termination in liquid-phase oxidation reactions. A change of the chain termination reaction[45-47] from quadratic to linear with increase of temperature has been established in a study of the kinetics of the oxidation of unsaturated compounds: 4-(2,6,6-trimethyl-1-cyclohexenyl)but-3-en-1-one (β-ionone) and the acetoacetate ester of the corresponding alcohol (β-ionol acetate). At temperatures below 70 °C the rate of oxidation of these compounds w varies in proportion to $w_i^{1/2}$, which is a kinetic feature of quadratic chain termination; at 70–80 °C the variation of w is proportional to w_i, which indicates the predominance of linear termination in this case (Fig. 3). Kinetic analysis has shown that the linear chain termination is due to the isomerisation of the free peroxy- or alkyl-radicals involved in the chain propagation[45]:

$$RO_2^{\cdot}(R^{\cdot}) \rightarrow \dot{\rho}\,. \qquad (6')$$

The change in the chain termination mechanism is accompanied by a relative decrease of the rate of reaction.

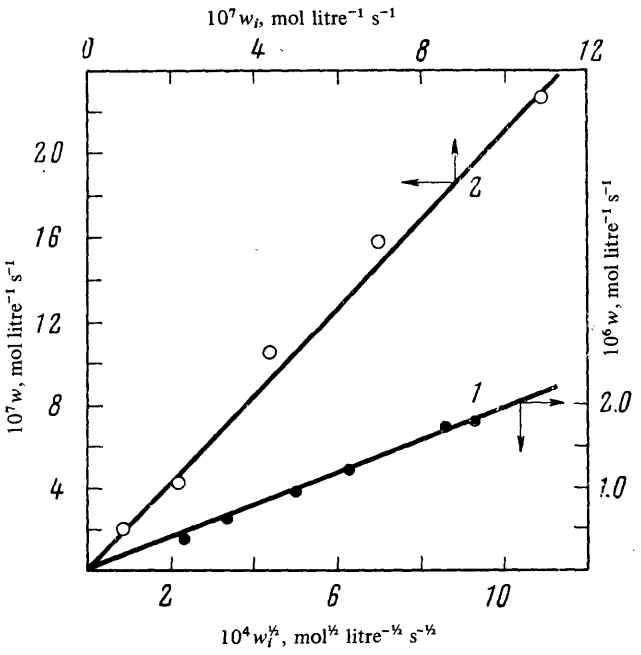

Figure 3. Dependence of the rate of absorption of oxygen in the initiated oxidation of β-ionone at 60 °C on $w_i^{1/2}$ (line 1) and at 85 °C on w_i (line 2); β-ionone concentration (M): 1) 0.09; 2) 0.1; initiators: 1) azobisisobutyronitrile; 2) benzoyl peroxide; solvent—chlorobenzene[46].

2. Oxidation Kinetics

In order to analyse the characteristics of the degenerate branched chain oxidation reactions of organic compounds occurring over a period of time, it is possible to examine a simplified mechanism reflecting the principal kinetic types of the elementary reactions of the initial compound (RH), the active centres—peroxy-radicals ($RO_2^{\cdot}$), and the intermediates (ROOH) involved in the formation of free radicals. In conformity with the detailed mechanism presented above, the following reactions are involved†:

$$\left.\begin{array}{l} RH + RO_2^{\cdot} \xrightarrow{k_2} RO_2^{\cdot} + ROOH, \\ \qquad\qquad \xrightarrow{k_2'''} RO_2^{\cdot} + \text{products}; \end{array}\right\} \text{(chain propagation)}$$

$$\left.\begin{array}{l} RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_6} P_6, \\ RO_2^{\cdot} \xrightarrow{k_{6'}} \rho\,; \end{array}\right\} \text{(chain termination)}$$

$$\left.\begin{array}{l} RH \xrightarrow{k_0} RO_2^{\cdot}, \\ ROOH \xrightarrow{k_3} RO_2^{\cdot}, \\ ROOH + ROOH \xrightarrow{k_{3''}} RO_2^{\cdot}. \end{array}\right\} \text{(chain initiation)}$$

The kinetic equations for the rate of a reaction proceeding via the above mechanism at quasi-stationary concentrations of free radicals are

$$w_i - k_6[RO_2^{\cdot}]^2 - k_{6'}[RO_2^{\cdot}] = 0\,, \qquad (24)$$

$$-\mathrm{d}[RH]/\mathrm{d}t = k_2[RO_2^{\cdot}][RH]\,, \qquad (25)$$

$$-\mathrm{d}[ROOH]/\mathrm{d}t = \alpha k_2[RO_2^{\cdot}][RH] - k_3[ROOH] - k_{3''}[ROOH]^2\,, \qquad (26)$$

$$w_i = k_0[RH] + \delta k_3[ROOH] + \delta k_{3''}[ROOH]\,, \qquad (27)$$

where δ is the number of free radicals per ROOH molecule decomposed and α is a parameter defining the fraction of ROOH in the sum of products formed in the chain propagation stages.

It follows from Eqns. (24) and (25) that in quadratic chain termination, where $k_6[RO_2^{\cdot}] \gg k_{6'}$, we have

$$[RO_2^{\cdot}] = (w_i/k_6)^{1/2},$$
$$-\mathrm{d}[RH]/\mathrm{d}t = k_2[RH](w_i/k_6)^{1/2}, \qquad (28)$$

while in linear termination, where $k_{6'} \gg k_6[RO_2^{\cdot}]$, we have

$$[RO_6^{\cdot}] = w_i/k_{6'},$$
$$-\mathrm{d}[RH]/\mathrm{d}t = k_2[RH](w_i/k_{6'}). \qquad (29)$$

The study of the kinetics of the oxidation of organic compounds of different classes led to the derivation of various functions $w_i = w_i\{[RH]\}$ and the corresponding overall kinetic equations. Up to a certain degree of conversion, particularly in the initial stages, the amount of compound consumed may be proportional to the ROOH concentration:

$$[ROOH] = \alpha([RH]_0 - [RH]). \qquad (30)$$

† The following assumptions have been made: all the radicals, including alkyl, alkoxy-, and hydroxy-radicals, are rapidly converted into peroxy-radicals: $\dot{R} + O_2 \rightarrow RO_2^{\cdot}$; $RO(OH)^{\cdot} + RH \rightarrow \dot{R}$ + products; the chain length is small, which makes it possible to neglect the consumption of RH associated with the formation of free radicals other than peroxy-radicals in the stage involving the decomposition of the intermediates (chain initiation). The product (ROOH) involved in chain branching is formed in one of the chain propagation reactions.

In this case Eqn.(27) can be put in the form

$$w_i = k_0[RH] + \alpha\delta k_3([RH]_0 - [RH]) + \alpha^2\delta k_{3''}([RH]_0 - [RH])^2 . \quad (31)$$

Eqn.(31) holds when the consumption of ROOH can be neglected in Eqn.(26) or when there are several compounds formed consecutively and decomposing into free radicals.

Integration of Eqn.(28) or (29) leads to different expressions, depending on the ratios of the rate constants for the chain initiation stages. We shall examine several cases.

1. The decomposition of ROOH is a first-order reaction and the chain termination is quadratic: $k_3 \gg k_{3''}[ROOH]$; $k_{6'} = 0$. In this case Eqn.(31) and the solution of Eqn.(28) are

$$w_i = k_0[RH] + \alpha\delta k_3([RH]_0 - [RH]) \quad (32)$$

$$\ln\frac{1 + (1 - [RH]/[RH]_0)^{1/2}}{1 - (1 - [RH]/[RH]_0)^{1/2}} = c_1 t, \quad (33)$$

where $c_1 = k_2\{\alpha\delta k_3[RH]_0/k_6\}^{1/2}$ is a parameter.

Eqn.(33) holds in the oxidation of β-carotene and phenylcyclohexene (at temperatures below 90 °C).[48,49] Eqn.(32) has been derived experimentally by determining w_i during the reaction by the method of inhibitors. In most cases Eqn.(32) holds in the initial stages of the reaction where its extent is low and one can assume that $[RH] \cong [RH]_0$; formula (33) can then be fitted by the equation of a parabola:

$$[ROOH] = c_1'' t^2 \quad (34)$$

where $c_1'' = 0.25\alpha^2 k_2^2[RH]_0^2\delta k_3/k_6$ is a parameter. Hydroperoxides accumulate in accordance with a parabolic law in the oxidation of aromatic alkyl-substituted hydrocarbons and paraffinic hydrocarbons in the initial stages of the reaction[50].

2. The decomposition of ROOH is a second-order reaction and the chain termination is quadratic: $k_{3''}[ROOH] \gg k_3$; $k_0 \ll k_{3''}[ROOH]$; $k_{6'} = 0$.

Function (31) and the solution of Eqn.(28) then become

$$w_i = \alpha^2\delta k_{3''}([RH]_0 - [RH])^2$$
$$\ln\frac{([RH]_0 - [RH])}{[RH]} = \frac{\alpha k_2(\delta k_{3''})^{1/2}[RH]_0}{k_6^{1/2}}t + \text{const} . \quad (35)$$

Using Eqn.(30), it is possible to obtain from Eqn.(35) an expression for the accumulation of the hydroperoxide:

$$\ln\frac{[ROOH]}{\alpha[RH]_0 - [ROOH]} = \frac{\alpha k_2(\delta k_{3''})^{1/2}[RH]_0}{k_6^{1/2}}t + \text{const} . \quad (36)$$

Eqns.(35) and (36) have been obtained for the consumption of cyclohexene and the accumulation of cyclohexenyl hydroperoxide in the autoxidation of cyclohexene[49] up to a degree of conversion of ~20% (Fig.4).

The main pathway in the consumption of cyclohexenyl hydroperoxide involves its oxidation via a chain mechanism with participation of the C–H bonds, as in the initial cyclohexene:

(37)

This process determines the maximum concentration of the intermediate and the rate of formation of free radicals. The main product of the reaction of a monohydroperoxide is the dihydroperoxide (Fig.4, curve 3).

Cyclohexenyl hydroperoxide is more reactive in reactions with peroxy-radicals than is cyclohexene. Thus, for a degree of reaction in excess of 20% (at 70 °C), the cyclohexene undergoing oxidation is a multicomponent system in which the initial compound is consumed under the conditions of its joint oxidation with the primary reaction product.

3. The product ROOH and the initial compound have similar reactivities in the formation of free radicals and the chain termination is linear: $\delta k_3 \cong k_0$; $k_6 = 0$.

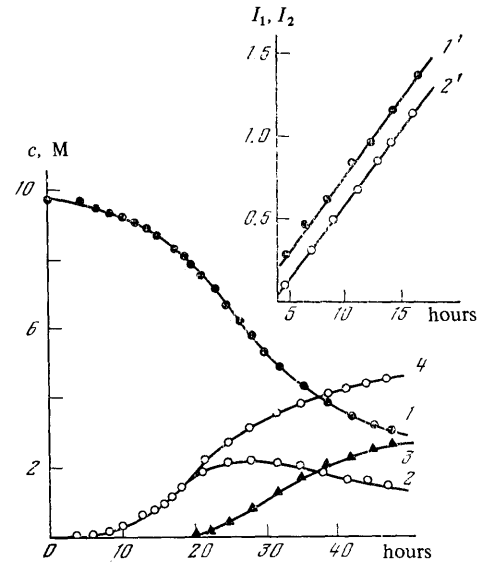

Figure 4. *a*) Kinetic curves for the consumption of cyclohexene (curve *1*), the accumulation of cyclohexenyl hydroperoxide (curve *2*), the accumulation of dihydroperoxide (curve *3*), and the sum of peroxides (curve *4*) in the oxidation of cyclohexene in a closed vessel under the conditions of the saturation of the liquid phase with oxygen; *b*) transformed kinetic curves for the consumption of cyclohexene (curve *1'*) and the accumulation of cyclohexenyl hydroperoxide (curve *2'*) in terms of the variables of Eqns.(35) and (36) up to a 20% degree of conversion of the hydrocarbon; 70 °C; $I_1 = 2 + \lg(\{[RH]_0 - [RH]\}/[RH])$; $I_2 = 2 + \lg([ROOH]/\{\alpha[RH]_0 - [ROOH]\})$ for $\alpha = 0.7$.[49]

In this case the decrease of w_0 as a consequence of the consumption of the compound is compensated by the increase of w_p and as a result the overall rate of formation of free radicals hardly changes in the course of the process. Eqn.(29) and the solution of Eqn.(28) have the form

$$w_i = k_3[RH]_0 , \quad (38)$$

$$[RH] = [RH]_0\exp(-c_3 t) . \quad (39)$$

where $c_3 = k_2\delta k_3[RH]_0/k_{6'}$ is an effective first-order rate constant.

Eqn.(38) and the first-order kinetic equation (39) have been obtained[45] for the oxidation of the unsaturated compound 4-(2,6,6-trimethyl-1-cyclohexenyl)but-3-en-2-yl acetate (β-ionol acetate) (Fig.5). In this case the first-order equation merely simulates a complex chain mechanism. This is indicated, for example, by the dependence of the effective rate constant c_3 on the initial concentration of the compound (Fig.5).

Phenylacetylene is apparently oxidised in accordance with a first-order equation with linear chain termination. This process constitutes oxidative polymerisation with a very small contribution by stages of the oxidative-degrative type[51].

In the oxidation of ethyl methyl ketone the rate of formation of free radicals w_i remains constant up to the complete decomposition of the compound with quadratic chain termination[52]:

$$w_i = c = \text{const}. \quad (40)$$

This feature of the chain initiation is associated with the thermal decomposition in the course of the reaction of two consecutively formed intermediates—a ketohydroperoxide and diacetyl.

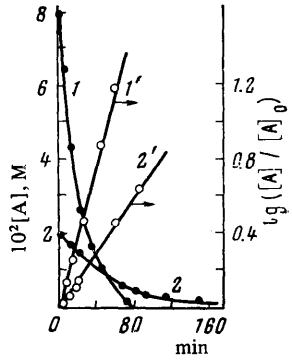

Figure 5. Kinetic curves for the consumption of β-ionol acetate (A) (curves *1* and *2*) and the semilogarithmic forms of the curves (curves *1'* and *2'*); solvent—chlorobenzene; 80 °C.[45]

Integration of Eqn.(28) leads to the expression

$$[RH] = [RH]_0 \exp(-c_3' t) \quad (41)$$

where $c_3' = k_2(w_i/k_6)^{1/2}$ is the effective rate constant. Thus we have a first-order equation, like Eqn.(39), but with another structure of the effective constant c_3'.

4. Free radicals are formed only with participation of the initial compound and the chain termination is quadratic: $k_0 \gg k_3$, $k_0 \gg k_{3''}[ROOH]$, $k_{6'} = 0$. According to Eqn.(31), the rate of chain initiation decreases in the course of the process:

$$w_0 = k_0[RH]\ . \quad (42)$$

Integration of Eqn.(28) leads to the expression

$$\frac{1}{[RH]_0^{1/2}} - \frac{1}{[RH]^{1/2}} = c_4 t\ , \quad (43)$$

where $c_4 = 0.5k^2(k_0/k_6)^{1/2}$ is a parameter.

Evidently Eqn.(43) is the kinetic equation of an unbranched chain reaction. Eqns.(42) and (43) have been obtained for the autoxidation of phenylcyclohexene above 90 °C.[49] For this cyclo-olefin, a change in the oxidation process conditions from degenerate branched (at t < 90 °C) to unbranched (at *t* > 90 °C) is observed due to the characteristics of the reactions of the intermediates.

The autocatalytic nature of the process at low temperatures is due to the formation in reaction (2) of unsaturated hydroperoxides, which readily decompose into free radicals. The main cause of the change in process conditions with increase of temperature is the oxidation of unsaturated hydroperoxides with participation of C=C bonds, leading to the formation of thermally stable compounds. At the same time the rate of reaction of phenylcyclohexene with oxygen (chain initiation) and the activity of the free radicals in chain propagation are sufficiently high for the reaction to develop at a high rate and without chain branching.

Thus the type of kinetic equation for the reaction is determined by the nature of the decomposition of the intermediates and the ratio of the reactivities of the initial compound and the intermediates in the formation of free radicals.

The overall kinetic equations contain the parameters c_1, c_2, etc., which can be determined from transformed kinetic curves. For autocatalytic reactions, the parameters of the equations contain the rate constants for chain propagation, termination, and degenerate branching: $c = k_2(\alpha\delta k_3/k_6)^{1/2}$. These parameters can serve as characteristics of the reactivity of organic compounds in oxidation processes.

3. Oxidation of Multicomponent Mixtures. Coupled Oxidation

In the coupled oxidation of binary mixtures of hydrocarbons R_1H and R_2H, two types of radicals, $R_1\dot{O}_2$ and $R_2\dot{O}_2$, which can interact with both hydrocarbons, are involved in chain propagation and termination[3]. As a result, together with the chain propagation and termination reactions occurring in the oxidation of the pure hydrocarbons R_1H and R_2H,[53–56] i.e.

$$\dot{R}_1 + O_2 \rightarrow R_1\dot{O}_2\ , \quad (1)$$

$$R_1\dot{O}_2 + R_1H \rightarrow R_1OOH + \dot{R}_1\ , \quad (2)$$

$$R_1\dot{O}_2 + R_1\dot{O}_2 \rightarrow \text{products}, \quad (6)$$

$$\dot{R}_2 + O_2 \rightarrow R_2\dot{O}_2\ , \quad (44)$$

$$R_2\dot{O}_2 + R_2H \rightarrow R_2OOH + \dot{R}_2\ , \quad (45)$$

$$R_2\dot{O}_2 + R_2\dot{O}_2 \rightarrow \text{products}, \quad (46)$$

chain propagation and termination cross-reactions also take place:

$$R_1\dot{O}_2 + R_2H \rightarrow R_1OOH + \dot{R}_2\ , \quad (47)$$

$$R_2\dot{O}_2 + R_1H \rightarrow R_2OOH + \dot{R}_1\ , \quad (48)$$

$$R_1\dot{O}_2 + R_2\dot{O}_2 \rightarrow \text{products}. \quad (49)$$

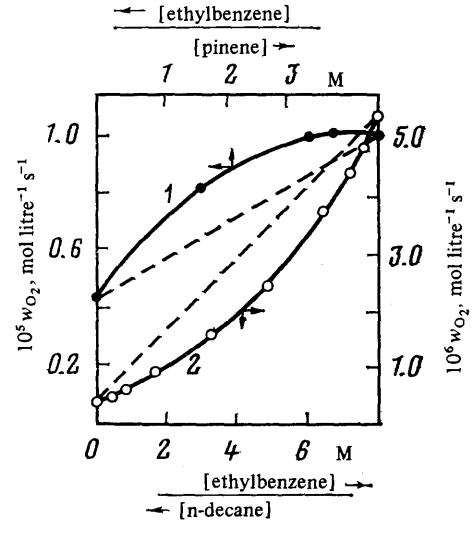

Figure 6. Dependence of the rate of oxidation on the composition of the mixtures of hydrocarbons: 1) pinene–ethylbenzene (70 °C); 2) n-decane–ethylbenzene (77 °C).

The occurrence of reactions (47)–(49) leads to the non-additive dependence of the rate of oxidation on the mixture composition (Fig.6).

Under the conditions of initiated oxidation, when the above joint oxidation mechanism is valid, the rate of absorption of oxygen is described by the formula

$$w_{O_2} = w_i^{1/2} \frac{r_1[R_1H]^2 + 2[R_1H][R_2H] + r_2[R_2H]^2}{((r_1^2/b_1^2)[R_1H]^2 + 2\Phi(r_1r_2/b_1b_2)[R_1H][R_2H] + (r_2^2/b_2^2)[R_2H]^2)^{1/2}}, \quad (50)$$

where $b_1 = k_2/k_6^{1/2}$, $b_2 = k_{45}/k_{46}^{1/2}$, $r_1 = k_2/k_{47}$, $r_2 = k_{45}/k_{48}$, and $\Phi = k_{49}/(k_6k_{46})^{1/2}$. This equation is used widely in the determination of the reactivity of peroxy-radicals with respect to a series of hydrocarbons (Table 2). Together with the chain propagation and termination "cross-reactions", reactions involving alkyl radicals can play a significant role in the oxidation of multicomponent mixtures[59–62]:

$$\dot{R}_1 + R_2H \rightarrow R_1H + \dot{R}_2, \quad (51)$$

$$\dot{R}_2 + R_1H \rightarrow R_2H + \dot{R}_1. \quad (52)$$

Table 2. The rate constants for the reactions $R_1\dot{O}_2 + R_2H \rightarrow R_1OOH + \dot{R}_2$ (75 °C).

*At 77 °C.
**At 60 °C.

If account is taken of the possibility of competition between reactions (1) and (51) and between (44) and (52) in initiated oxidation, then Eqn.(50) is transformed into[63]

$$w_{O_2} = w_i^{1/2} \frac{k_2[R_1H] + k_{47}[R_2H] + c(k_{48}[R_1H] + k_{45}[R_2H])}{(2k_6 + 2k_{49}c + 2k_{46}c^2)^{1/2}}, \quad (53)$$

where

$$c = \frac{(k_{51}[R_2H]/k_1[O_2])(k_2[R_1H] + k_{47}[R_2H]) + k_{47}[R_2H]}{(k_{52}[R_1H]/k_{44}[O_2])(k_{48}[R_1H] + k_{45}[R_2H]) + k_{48}[R_1H]}.$$

Analysis of Eqn.(53) shows that reaction (51) influences most strongly the kinetics of the oxidation of nearly equimolar mixtures. The overall rate of oxidation is sensitive to reaction (51) with $k_{51} \geq 10^3$ litre mol^{-1} s^{-1}.

As a result of the large difference between the activation energies for the reactions of free radicals $\dot{R}_1$ with O_2 and R_2H, reaction (51) occurs to a large extent at high temperatures.

Degenerate chain branching reactions also play an important role in the non-initiated oxidation of multicomponent systems at 100–140 °C. The rate of degenerate branching is then determined by the rates of unimolecular and bimolecular decomposition of the hydroperoxides R_1OOH and R_2OOH:

$$\left.\begin{aligned} R_1OOH &\rightarrow \dot{R}_1\dot{O} + \dot{O}H, \\ R_2OOH &\rightarrow R_2\dot{O} + \dot{O}H, \end{aligned}\right\} \quad (3)$$

$$\left.\begin{aligned} R_1OOH + R_1H &\rightarrow R_1\dot{O} + \dot{R}_1 + H_2O, \\ R_2OOH + R_2H &\rightarrow R_2\dot{O} + \dot{R}_2 + H_2O, \\ R_1OOH + R_2H &\rightarrow R_1\dot{O} + \dot{R}_2 + H_2O, \\ R_2OOH + R_1H &\rightarrow R_2\dot{O} + \dot{R}_1 + H_2O. \end{aligned}\right\} \quad (3')$$

The occurrence of the new chain transfer reaction (51) as well as the branching reactions results in a sharp difference between the characteristics of the oxidation of multicomponent mixtures under these conditions and those of initiated oxidation. Thus, in the degenerate branched chain oxidation reaction of mixtures of ethylbenzene with paraffins (n-decane, 2,7-dimethyloctane, 130 °C), one observes an acceleration of the oxidation of n-decane by small amounts of added ethylbenzene instead of its retardation (as in initiated oxidation) (Fig.7). On further increase of the content of ethylbenzene in the mixture to 7.5 vol.%, the consumption of n-decane begins to be inhibited strongly and virtually ceases in the presence of ~10 vol.% of ethylbenzene in the mixture[60]. Under these conditions, virtually only ethylbenzene is oxidised. The maximum rate of oxidation of ethylbenzene is observed in the range of ratios of mixture components in which the maximum rate of oxidation of n-decane is attained.

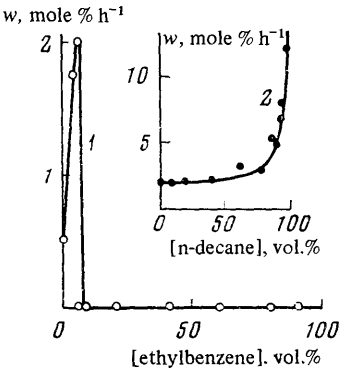

Figure 7. Dependence of the initial rate of oxidation of n-decane (curve *1*) and ethylbenzene (curve *2*) on the composition of the n-decane–ethylbenzene mixture; 130 °C.[60]

Mathematical analysis of the kinetic scheme of the coupled oxidation of two hydrocarbons (in relation to the oxidation of a mixture of n-decane and ethylbenzene at 130 °C), taking into account the chain transfer reaction (51) and the degenerate branching reactions (3)–(3'), showed[62] that the experimental dependence of the rates of oxidation of the mixture components on the mixture composition cannot be explained without taking into account reaction (51).

Thus, under the conditions of the high-temperature coupled oxidation of hydrocarbons, the set of elementary reactions making up the process mechanism greatly increases.

Reaction (51) must be taken into account particularly in the thermo-oxidative degradation of polymers, where the diffusion of O_2 into the polymer is difficult.

On the basis of coupled oxidation reactions, it is possible to devise technological processes in which the oxidising agents are highly reactive peroxy-radicals and not molecular oxygen. One of the substances being oxidised is then the source of peroxy-radicals, which interact with the second mixture component.

An example of such a reaction is the formation of epoxypropane and an organic acid by the joint (coupled) oxidation of aldehydes and olefins[64,65]. This process proceeds via the mechanism of a chain reaction and the main epoxidising agent is the acylperoxy-radical[66]:

$$RCOO\dot{O} + CH_2{=}CHCH_3 \rightarrow [RCOOO \cdot C_3H_6] \rightarrow -\overset{|}{C}-\overset{|}{C}- + R\dot{C}OO \ ,$$
$$\diagdown O \diagup$$

$$R\dot{C}OO + RH \rightarrow RCOOH + \dot{R} \ .$$

Together with the radical reaction, there is also a molecular pathway in the epoxidation of propene with peracetic acid (the Prilezhaev reaction[67]). However, the contribution of this reaction in the coupled acetaldehyde–propene process does not exceed 15 mole % of the overall rate of formation of epoxypropane. The concentration of dissolved oxygen has a significant influence on the rate of formation of epoxypropane[58].

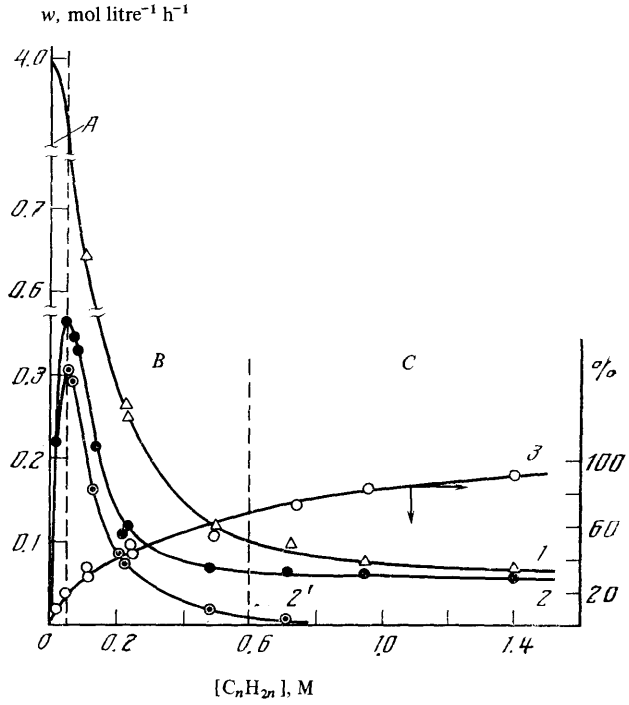

Figure 8. Dependence of the rate of consumption of benzaldehyde (curve *1*) and accumulation of epoxynonane (curve *2*) on the concentration of non-1-ene in chlorobenzene; *2'*) calculated curve for the rate of epoxidation of non-1-ene with perbenzoic acid; 3) variation of the yield of epoxynonane relative to the benzaldehyde which has reacted. Temperature 90 °C; rate of supply of oxygen 3 litres h^{-1}.[69]

The coupled oxidation of non-1-ene and benzaldehyde[69] is characterised by a nearly 100% selectivity in the formation of 1,2-epoxynonane relative to both initial reactants which have reacted—the olefin and the aldehyde. There is an extremum in the rate of formation of 1,2-epoxynonane as a function of the initial concentration of non-1-ene (Fig.8). The ratio of the rates in the two pathways leading to the formation of 1,2-epoxynonane (epoxidation by acylperoxy-radicals and the peracid) is determined by the composition of the initial mixture and the kinetic parameters of the system. At relatively low concentrations of the aldehyde the formation of epoxynonane has a radical mechanism, while at high values of [RCHO] the main epoxidising agent is the peracid.

In the coupled oxidation of olefins (C_nH_{2n}) and aldehydes (RCHO) an important role is played by the addition of acylperoxy-radicals to the double bond [reaction (60)], which is the main chain termination pathway, because the relatively inactive polyperoxy-radical $M\dot{O}_2$ formed under these conditions cannot enter into the exchange reaction (54) during the period of the propagation of the primary chain, i.e. the condition $1/k_{59}[C_nH_{2n}] < 1/k_{54}[RCHO]$ holds. The overall process mechanism can be formulated thus:

$$M\dot{O}_2 + RCHO \rightarrow RCOO\dot{O} + MOOH \ , \quad (54)$$

$$RCHO + O_2 \rightarrow R\dot{C}O + H\dot{O}_2 \ , \quad (55)$$

$$R\dot{C}O + O_2 \rightarrow RCOO\dot{O} \ , \quad (56)$$

$$RCOO\dot{O} + RCHO \rightarrow RCOOOH + R\dot{C}O \ , \quad (57)$$

$$RCOO\dot{O} + RCHO \rightarrow RCOOH + R\dot{C}O \ , \quad (58)$$

$$RCOO\dot{O} + C_nH_{2n} \rightarrow RCOO\dot{O} + \text{epoxide} \ , \quad (59)$$

$$RCOO\dot{O} + C_nH_{2n} \rightarrow M\dot{O}_2 \xrightarrow{k'_{60}} \dot{M} \xrightarrow{k''_{60}} M\dot{O}_2 \rightarrow \text{molecular products}, \quad (60)$$

$$RCOOOH + RCHO \rightarrow 2RCOOH \ , \quad (61)$$

$$RCOOOH + C_nH_{2n} \overset{K_{63}}{\rightleftarrows} RCOOOH \ldots C_nH_{2n} \rightarrow \text{epoxide} + RCOOH \ , \quad (62)$$

$$RCOOOH \ldots C_nH_{2n} \rightarrow RCOOH + {}^1/_2O_2 + C_nH_{2n} \ , \quad (63)$$

$$RCOO\dot{O} + RCOO\dot{O} \rightarrow \text{molecular products.} \quad (64)$$

When the proposed mechanism holds, the rate of formation of the epoxide (w_e) is described by the formula

$$w_e = \frac{k_{59}[C_nH_{2n}]w_i}{k + k_{60}[C_nH_{2n}]} + \frac{k_{57}k_{62}[RCHO]^2 w_i (1 + K_{63}[C_nH_{2n}])}{(k + k_{60}[C_nH_{2n}])\{k_{61}[RCHO] + (k_{62} + k_{63})K_{63}[C_nH_{2n}]\}} \quad (65)$$

where $k = k_{64}[RCOO\dot{O}]$. The first term in Eqn.(65) characterises the epoxidation of the olefin by the RCOOȮ radicals and the second characterises its epoxidation by the peracid (the Prilezhaev reaction).

The extremum in the relation between the rate of epoxidation and the olefin concentration is due to the molecular stage in the epoxidation of the olefin by the peracid, because in zone *B* (Fig.8) there is a sharp decrease of the steady-state concentration of the peracid in proportion to the square of the concentration of the olefin. The constancy of w_e as $[C_nH_{2n}]$ increases (zone *C*, Fig.8) is due to the radical component of the rate of oxidation; the role of the peracid becomes negligible. A 100% yield of 1,2-epoxynonane relative to the unconsumed benzaldehyde is characteristic of zone *C*. At low olefin concentrations (zones *A* and *B*, Fig.8) the incomplete utilisation of the active oxygen in epoxidation (Fig.8 curve *3*) is associated with reaction (61) and also with the molecular decomposition of the peracid induced by the olefin.

The rate constant for the epoxidation of the olefin by acylperoxy-radicals has been obtained for the joint oxidation of benzaldehyde and non-1-ene: $k_{54} = 1.8 \times 10^4$ litre mol^{-1} s^{-1}.

The mechanism of the coupled oxidation of olefins and aldehydes shows that the interaction of the RCOOȮ radical with an olefin leads to the formation of two new radicals—the active radicals RCȮ and the radicals $M\dot{O}_2$ which determine the

development of the polymerisation pathway in the system resulting in a decrease of the yield of the epoxide.

Analysis of the system showed that when the radicals $MO_2^{\cdot}$ are relatively inactive compared with RCO and do not participate in chain transfer to the aldehyde, the relative contributions of reactions (59) and (60) can be altered by a special procedure, which has come to be called selective inhibition[70] and thus the selectivity of the oxidation can be significantly increased by suppressing the undesirable reaction pathway as a result of the introduction of the appropriate inhibitor.

The selective inhibition method has been used to increase the yield of styrene oxide in the coupled oxidation of styrene and acetaldehyde[71] and to increase the yield of epichlorohydrin in the coupled oxidation of allyl chloride and acetaldehyde[72]. The inhibitor used was tanol (the 4-hydroxy-2,2,6,6-tetramethylpiperidin-1-yloxy-radical). In the presence of this inhibitor, which interacts with the radicals $\dot{M}$, the polymerisation reaction pathway [reaction (60)] is almost completely arrested (Fig. 9).

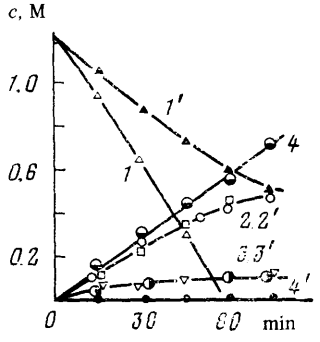

Figure 9. Kinetic curves for the consumption of styrene (curve *1*), the accumulation of benzaldehyde (curve *2*), styrene oxide (curve *3*), and the polymer (curve *4*) in the joint oxidation of styrene and acetaldehyde in benzene at 70 °C; the primed numerals denote the corresponding quantities in the presence of 2×10^{-5} M tanol. The end of the induction period was adopted as the starting point of the time readings[71].

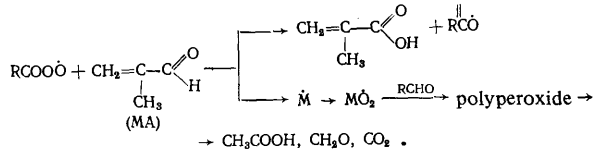
A necessary condition for selective inhibition is the ability of the inhibitor to interact preferentially with one of the radicals of the chain. This can be achieved both by selecting an inhibitor and with markedly different constants for interaction with different types of radicals and by maintaining an optimum inhibitor concentration in the system. The calculation of the optimum inhibitor concentration range, based on the coupled oxidation mechanism given above and supplemented by elementary stages with participation of tanol (Im), i.e.

$$\dot{RCO} + \dot{Im} \rightarrow RCOIm, \quad (66)$$

$$\dot{M} + \dot{Im} \rightarrow MIm, \quad (67)$$



$$MIm\ (RCOIm) + MO_2^{\cdot}\ (RCOO^{\cdot}) \begin{cases} \rightarrow MO_2M + \dot{Im}, \\ \rightarrow \text{molecular products}, \end{cases}$$

$$MO_2^{\cdot} + MO_2^{\cdot} \rightarrow \text{molecular products}, \quad (68)$$

leads to the following condition for selective inhibition in the system[70]:

$$\frac{k_{66}k_{60}[O_2]}{k_{66}(k_{59}+k_{60})} > \dot{Im} > \frac{k''_{60}(w_i k_{68})^{1/2}[O_2]}{k'_{60}k_{67}[C_nH_{2n}]}. \quad (69)$$

The selective inhibition method has also been used to develop a new procedure for the synthesis of methacrylic acid (MAA) [73] by the liquid-phase oxidation of methacroleine (MA), which can be regarded as a coupled reaction involving two reaction centres of the same molecule:

The use of tanol as the inhibitor and of a heterogeneous catalyst (TiB_2) made it possible to devise a process with a selectivity of 84 mole % (with respect to the aldehyde which has reacted) for a degree of conversion of 40 mole % (Table 3).

Table 3. The influence of tanol (T) on the composition and yields of methacroleine oxidation products (70 °C; air pressure 25 atm; solvent—benzene; TiB_2 catalyst).[73]

4. Kinetics of Oxidation Reactions in Open Systems

The study of the kinetics of chemical reactions in open systems as a theoretical basis for continuous processes in chemical engineering has made a definite contribution to the solution of problems of the optimisation of technological processes. The results of studies of the kinetics of liquid-phase oxidation reactions of hydrocarbons in open systems are considered below. The complex radical chain oxidation mechanism can be represented by the following sequence of transformations:

$$\underset{\text{hydrocarbon}}{RH} \xrightarrow{k_I} \underset{\text{hydroperoxide}}{ROOH} \xrightarrow{k_{II}} \underset{\text{ketone}}{R'COR''} \xrightarrow{k_{III}} \underset{\text{acid}}{R'COOH}. \quad (70)$$

Here k_I, k_{II}, and k_{III} are the overall reaction constants representing sets of rate constants for elementary stages.

In a continuous process the substance RH to be oxidised is introduced into the reactor at a constant rate and part of the reacting mixture is removed. The attainment of steady-state concentrations of products is characteristic of reactions in open systems. The steady-state concentration of the final product is then higher the lower the specific rate# of

The specific rate ν is the volume of the initial liquid component supplied per unit time per unit volume of the reactor and has the dimension of reciprocal time.

supply of the starting materials ν.[75] For intermediates, for example, the hydroperoxide[75], this relation has an extremum (Fig.10) and, in conformity with the simplified mechanism (70), can be formulated thus:

$$\frac{d[ROOH]}{d\nu} = \frac{k_I[RH]_0(\nu^2 - k_I k_{II})}{(k_I+\nu)^2(k_{II}+\nu)^2} .$$

The rate of accumulation of all the oxidation products also passes through a maximum as a function of ν and the maximum rate of accumulation of the more extensive oxidation product is attained at lower flow rates ν. The maximum rate of accumulation of the final reaction product is attained at the same flow rate as the maximum steady-state concentration of the precursor. This property of an open system suggested a method for determining the pathways leading to the formation of the final reaction products[75]. It consists in comparing the positions of the maxima in the relations between the rates of accumulation of the final products and the steady-state concentrations of intermediates, on the one hand, and the flow rate, on the other. When these maxima are attained for the same flow rate, one can assume that the intermediate is a direct precursor of the given final product.

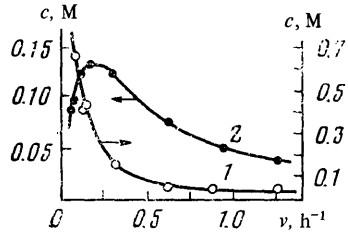

Figure 10. Dependence of the stationary concentrations of acids (curve *1*) and hydroperoxides (curve *2*) on the rate of supply of n-decane in the oxidation of the latter in an open system at 140 °C.[75]

A characteristic feature of reactions in open systems—the attainment of steady-state concentrations of the starting materials and reaction products—made it possible to develop a new kinetic method for the determination of the rate constants for the formation and consumption of intermediates in complex reactions involving free radicals. The method is based on the variation of the steady-state concentration of the intermediate, the rate of consumption of which is to be measured, keeping constant the steady-state concentration of free radicals. This is achieved by supplying into the reaction vessel initially the pure starting material and then its mixtures with the given product P at the same flow rate. Since ν remains constant, the steady-state concentrations of free radicals are the same in both cases. The effective rate constant $k_{2''}[RO_2]$ for the consumption of the product P can be calculated from the difference between the steady-state concentrations established when these solutions are introduced into the vessel, namely $[\bar{P}]$ and $[\bar{P}]_1$ respectively:

$$[P]_0/([\bar{P}]_1 - [\bar{P}]) = (1 + k_2'' [\dot{RO}_2]/\nu) ,$$

where $[P]_0$ is the concentration of P in the mixture entering the vessel.

This method has been used to determine the reactivity of products with respect to the radicals $\dot{RO}_2$ in the oxidation reactions of ethylbenzene and n-decane[28]. As an example, Fig.11 presents the steady-state concentrations of methylphenylmethanol and acetophenone for different contents of methylphenylmethanol in the ethylbenzene supplied to the vessel. The effective rate constant for the consumption of methylphenylmethanol ($k_{2''}$,ROH) was determined from the slope of the relation between $[\overline{ROH}]_1 - [\overline{ROH}]$ and $[ROH]_0$ (Fig.11, curve *4*). The reactivity of the $\dot{RO}_2$ radical with respect to the n-decane oxidation products was determined by the same method.

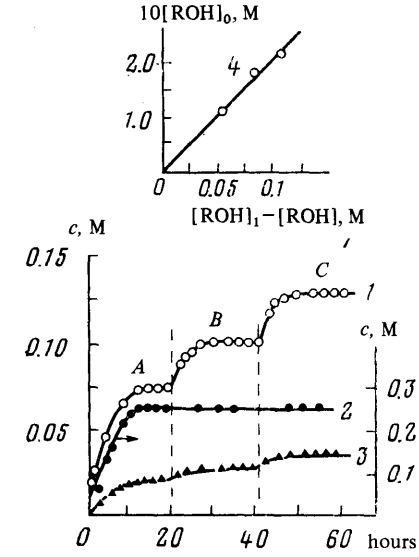

Figure 11. Kinetic curves for the accumulation of methylphenylmethanol (curve *1*), hydroperoxide (curve *2*), and acetophenone (curve *3*) in the oxidation of ethylbenzene in an open system with supply into the reaction vessel of ethylbenzene (*A*) and solutions of methylphenylmethanol in ethylbenzene containing 0.05 M (*B*) and 0.1 M (*C*) alcohol; ν = 0.215 h^{-1}; 4) dependence of the difference between the stationary concentrations of methylphenylmethanol on its concentration in ethylbenzene $[ROH]_0$; ν = 0.102 h^{-1}; 118 °C.[28]

If several isomers containing a functional group in different positions are formed in the reaction, the proposed method makes it possible to determine the rates of formation and consumption of each isomer separately without determining the concentrations of the individual isomers[77].

5. Catalysis of Oxidation

The most important method for increasing the rate and selectivity of oxidation involves the use of homogeneous and heterogeneous catalysts. Catalytic hydroperoxide oxidation and decomposition reactions as well as the problem of using catalysts to increase the selectivity of liquid-phase oxidation have been examined in detail recently in a number of reviews [78-81] and we shall therefore deal only very briefly with studies on catalysis.

The acceleration of liquid-phase oxidation processes by the addition of variable-valence metal compounds is associated with the participation of the catalysts in the chain branching

(radical decomposition of the hydroperoxide), chain initiation (activation of oxygen), and chain propagation stages. The decomposition of hydroperoxides, leading to the formation of free radicals, is the stage of the oxidation process involving the catalyst which has been studied in greatest detail. In most cases this reaction ensures the acceleration of the oxidation in the presence of both homogeneous[79] and heterogeneous[81] catalysts based on variable-valence metals.

The decomposition of hydroperoxides proceeds via an intermediate stage involving the formation of complexes between the catalyst and the hydroperoxide. To demonstrate this, a combination of kinetic and physicochemical (ultraviolet and infrared spectroscopy, NMR, EPR, etc.) methods for the quantitative investigation of catalyst–hydroperoxide systems under various conditions was used[82–84]. The simplest mechanism of the decomposition of a hydroperoxide, taking into account the formation of intermediate complexes between the catalyst and the hydroperoxide, is

$$n\,M^{n+} + m\,ROOH \rightleftarrows [n\,M^{n+} m\,ROOH] \rightarrow n\,M^{(n+1)+} + R\dot{O} + OH^- + (m-1)\,ROOH;$$

$$n_1 M^{(n+1)+} + m_1 ROOH \rightleftarrows [n_1 M^{(n+1)+} m_1 ROOH] \rightarrow$$

$$\rightarrow n_1 M^{n+} + R\dot{O}_2 + H^+ + (m_1 - 1)\,ROOH\ .$$

The quantities m, m_1, n, and n_1 depend on the nature of the catalyst and the hydroperoxide[83–85].

In the decomposition of the hydroperoxide in the presence of heterogeneous catalysts the process proceeds via a homogeneous-heterogeneous mechanism: the radicals formed in the decomposition of the hydroperoxide on the catalyst surface escape into space, where they can propagate the oxidation chain or recombine:

$$ROOH + S \begin{cases} \longrightarrow [ROOH \ldots S] \rightarrow R\dot{O} + [\dot{O}H \ldots S] \\ \longrightarrow [ROOH \ldots S] \rightarrow R\dot{O}_2 + [H \ldots S] \end{cases}.$$

This hydroperoxide decomposition mechanism has been demonstrated by the method of inhibitors[86] and by measuring the chemiluminescence of solutions[87] in the decomposition of cumenyl hydroperoxide in the presence of iron oxides.

The method proposed[89] for the investigation of the conductivities of transistor semiconducting structures has been used successfully to investigate complexes with partial charge transfer between the hydroperoxide and the heterogeneous catalyst. It makes it possible to identify the intermediate complexes and to determine their polarities and formation constants. The method is based on the change in the conductivity of the semiconducting triode structure of the type $p-n-p$ or $n-p-n$ following the adsorption of electron-donating and electron-accepting molecules. The adsorption of acceptors widens the base (the narrow middle band) in structures of the type $n-p-n$ and is accompanied by a decrease of conductivity. The adsorption of electron donors leads to an increase of n-type conductivity in the surface region of the base; for structures of the type $p-n-p$, donors and acceptors have the opposite effects.

The quantitative parameters of complex formation in the interaction of organic hydroperoxides with catalysts—copper and potassium hexacyanoferrates(III) and germanium oxide—have been obtained with the aid of this method[90]. The hexacyanoferrates(III) were deposited on the oxidised surface of a silicon structure of the $n-p-n$ type by adsorption from aqueous solutions. Fig.12 illustrates the variation of the conductivity $\Delta I/I_0$ of the structure with deposited hexacyanoferrates(III) (I_0 is the conductivity of the initial structure) under the influence of the adsorption of the hydroperoxide. It follows from the analysis of these curves that, in relation to both catalysts, α-phenylethyl hydroperoxide behaves as **an electron** donor. The limiting change in conductivity ΔI, observed when the catalyst surface is saturated with the hydroperoxide, is almost an order of magnitude higher for $Cu_3[Fe(CN)_6]_2$ than for $K_3[Fe(CN)_6]$. Thus the charge transferred from the hydroperoxide molecule to the first catalyst is much greater than for the second catalyst.

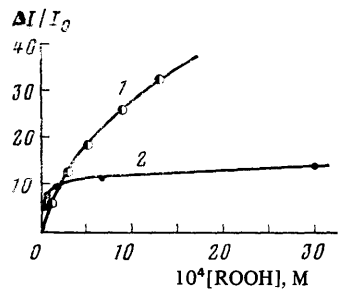

Figure 12. Variation of the conductivity of a transistor structure of the type $n-p-n$ with deposited metal hexacyanoferrates(III) as a function of the concentration of α-phenylethyl hydroperoxide in solution: 1) $Cu_3[Fe(CN)_6]_2$; 2) $K_3[Fe(CN)_6]$; solvent—heptane; 30 °C.[90]

The equilibrium constant for the formation of the complex of α-phenylethyl hydroperoxide with the catalyst, found from Fig.12 for $K_3[Fe(CN)_6]$, exceeds by a factor greater than 20 the equilibrium constant for $Cu_3[Fe(CN)_6]_2$ (Table 4).[90] It is significant that the equilibrium constant for the complex of the $Cu_3[Fe(CN)_6]_2$ catalyst with α-phenylethyl hydroperoxide, obtained by the method of transistor structures, virtually agrees with independent measurements of the same quantity by the kinetic method (5.5×10^2 litre mol^{-1}).[90] Table 4 also lists the parameters of the complex formation reactions of α-phenylethyl and t-butyl hydroperoxides with germanium oxide. In this case the activation of the hydroperoxide is associated with the transfer of an electron from the catalyst to the hydroperoxide.

Table 4. Physicochemical parameters of hydroperoxide–catalyst complexes (30 °C; solvent—heptane; gas phase—argon).[90]

Catalyst	α-Phenylethyl hydroperoxide		t-Butyl hydroperoxide		Cumenyl hydroperoxide	
	K, litre mol^{-1}	$\Delta I/I_0$	K, litre mol^{-1}	$\Delta I/I_0$	K, litre mol^{-1}	$\Delta I/I_0$
$Cu_3[Fe(CN)_6]_2$	$7.0 \cdot 10^2$	80.0	—	—	—	—
$K_3[Fe(CN)_6]$	$1.7 \cdot 10^4$	14.0	—	—	$1.4 \cdot 10^4$	3.0

*Gas phase—oxygen.

Comparison of the physicochemical characteristics of complexes of various hydroperoxides and heterogeneous catalysts with the activities of the catalysts in the hydroperoxide decomposition reaction shows that the highest rates of decomposition correspond to the formation of more polar and weaker reactant–catalyst bonds.

Together with the decomposition of the hydroperoxide, the formation of free radicals in the interaction of the catalyst with the starting materials—oxygen and the hydrocarbon (activation of oxygen and the hydrocarbon)—can play a major role in the presence of catalysts. The activation of oxygen apparently plays the main role in the initiation of the oxidation chain in the presence of catalysts. The possibility of the process via the mechanism

$$M^{n+} + O_2 \rightarrow M^{n+} \ldots O_2 ,$$
$$M^{n+} \ldots O_2 + RH \rightarrow M^{n+} + \dot{R} + H\dot{O}_2 ,$$

was first demonstrated by the method of inhibitors for the oxidation of ethylbenzene in the presence of nickel acetylacetonate[91] and was subsequently confirmed for a number of homogeneous and heterogeneous catalysts.

The activation of oxygen on the catalyst with subsequent increase of the rate of chain initiation apparently plays an important role in oxidation reactions in the presence of copper complexes of o-phenanthroline[92]. The study of the influence of oxygen on the rate of oxidation of cumene in the presence of copper complexes of o-phenanthroline at 30–40 °C demonstrated a strong dependence of the rate of oxidation on the oxygen pressure up to 760 mmHg [92] (Fig.13).

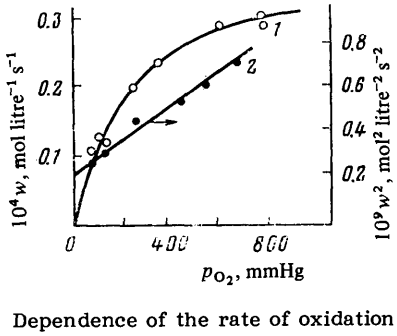

Figure 13. Dependence of the rate of oxidation of cumene in the presence of the complex $Cu(acac)_2$ with o-phenanthroline on the partial pressure of oxygen (curve *1*) and the transformed version of this relation (curve 2); 30 °C.[92]

The relation obtained can be readily explained by the involvement of the catalyst in the chain initiation reaction. Indeed the rate of oxidation of cumene should be described by the following equation in this case:

$$w = \frac{k_2}{k_6^{1/2}} [RH] \sqrt{w_0 + k' [O_2]} ,$$

which holds satisfactorily in the experiment (Fig.13). Furthermore, the rate of oxidation of cumene is in this case three times higher than the rate of oxidation calculated by the formula $w = (k_2^2/k_6)[RH]^2$, which takes into account the involvement of the catalyst only in chain branching.

The formation of charge-transfer complexes between $Rh(PPh_3)_3Cl$ and oxygen has been detected by EPR. In the presence of oxygen the diamagnetic catalyst species are converted into the complex $Rh(II).O_2^-$, in the EPR spectrum of which it is possible to identify groups of lines due to Rh(II) and O_2^- (Fig.14).[21] The role of these complexes in the oxidation process has been established by introducing into the systems certain specific additivies, which make it possible to increase the concentration of the oxygen complexes, the rate of oxidation increasing in the presence of such additives (Fig.14).

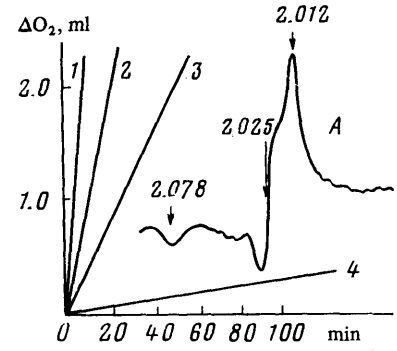

Figure 14. Kinetic curves for the absorption of O_2 in the oxidation of solutions of cyclohexene (line *1*), ethylbenzene (line *2*), and nonene (line *3*) in toluene in the presence of the modified complexes $Rh(PPh_3)_2COCl$ at 25 °C and kinetics of the absorption of O_2 by a solution of cyclohexane in the presence of the unmodified catalyst (line *4*). *A*) EPR spectrum of the modified catalyst at 77 K.

The activation of oxygen and the involvement of the catalyst in the chain initiation reaction are apparently largely responsible for the catalytic effect in the presence of variable valence metal oxides[93]. For a series of metal oxides, the initiating function in oxidation processes apparently reduces solely to their involvement in chain initiation. Thus the oxides ZnO, FeO, and NiO hardly decompose the hydroperoxide. In the presence of these catalysts virtually the only oxidation product is the hydroperoxide (Table 5).[93]

Table 5. The oxidation of cumene and the rate of decomposition of cumenyl hydroperoxide in the presence of metal oxides at 73 °C.[93]

Catalyst	Amount of catalyst, mg ml^{-1}	[ROOH], mole %	[DMPA], mole %	[AP], mole %	$10^2 w_{ROOH}$, mol litre^{-1} min^{-1}
MnO	0.10	54	17.0	2.0	100
Co_2O_3	2.50	52	16.0	1.6	55
Fe_2O_3	2.50	78	10.0	1.2	24

ZnO	20.0	96	2.0	0.1	0
Bi_2O_3	10.0	90	2.0	0.1	0

[It is not clear from the context what DMPA and AP are (Ed. of Translation)].

To increase the rate and selectivity of the liquid-phase oxidation of organic compounds in the presence of homogeneous and heterogeneous catalysts, the principle of the donor–acceptor modification of these catalysts is used[94]. Thus the selectivity of the oxidation of isopropylbenzene to the hydroperoxide can be increased from 82 to 92% (relative to the absorbed oxygen) with the aid of the preliminary

adsorption of carbon dioxide or dicyanomethylene-2,4,7-trinitrofluorenone [DTF] on the surface of the heterogeneous catalyst (AgO).[94] Electron-donating modifying agents (CO, NH_3) increase in this process the rate of oxidation and the rate of accumulation of the product (alcohol), while electron-accepting modifying agents (CO_2, DTF) decrease the rate of oxidation and ensure a high process selectivity with respect to the hydroperoxide.

An example of the modifying effect of solid additives is provided by the oxidation of ethylbenzene on silver catalysts containing 0.02 at.% of various metals (Ca, Mo, Cl, Bi, and Co).[95] The catalyst may be modified in the course of the oxidation process itself as a result of the accumulation of certain reaction products. Thus, in the liquid-phase oxidation of tetralin in the presence of the Ag_2O catalyst deposited on SiO_2 (Fig.15),[96] the composition of the products initially agrees with the composition of the products of the non-catalysed oxidation: the three main reaction products (tetralyl hydroperoxide, 1-tetralol, and 1-tetralone) accumulate at comparable rates. As the process develops, the accumulation of the ketone and alcohol stops completely and the only reaction product becomes the hydroperoxide, i.e. the catalyst is modified with participation of oxygen-containing products. The modified catalyst ensures the inhibition of the chain reaction and can activate molecular oxygen.

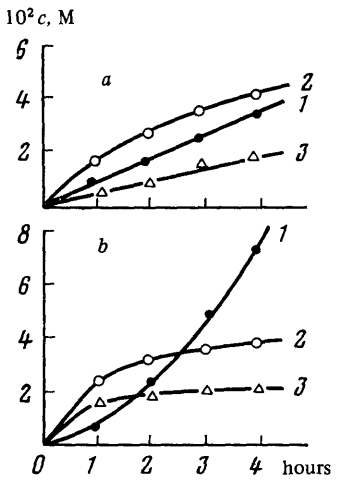

Figure 15. Kinetic curves for the accumulation of tetralyl hydroperoxide (curve *1*), 1-tetralone (curve *2*), and 1-tetralol (curve *3*) in the oxidation of tetralin: *a*) without catalyst; *b*) in the presence of 0.4 g litre^{-1} of deposited heterogeneous catalyst; 130 °C.[96]

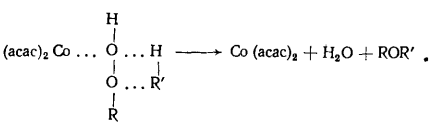

The efficiency of the donor–acceptor modification when homogeneous catalysts are used has been demonstrated in relation to the oxidation of ethylbenzene in the presence of nickel bis(acetylacetonate) [97] and the oxidation of cyclohexane catalysed by the rhodium complex $Rh(PPh_3)_3Cl$.[98]

The decomposition of the hydroperoxide without the formation of free radicals (molecular decomposition of the hydroperoxide) can play an important role in the mechanism of the catalytic oxidation of hydrocarbons and other organic compounds. Such decomposition can lead to the formation of new products uncharacteristic of the non-catalytic oxidation. On the other hand, the intense molecular decomposition of the hydroperoxide, which is an important source of free radicals, can lead to the inhibition of the oxidation process.

Direct evidence for the molecular pathway leading to the decomposition of the hydroperoxide in the presence of the catalyst has been obtained with the aid of the method of inhibitors in relation to the decomposition of n-decyl hydroperoxide in the presence of copper stearate[85]. The considerable (up to 90%) molecular decomposition of the hydroperoxide is characteristic of the decomposition of tetralinyl hydroperoxide in the presence of cobalt stearate[99].

The study of the dependence of the rate of decomposition of the hydroperoxide and of the consumption of the inhibitor (radical decomposition) on the catalyst and hydroperoxide concentrations established that both decomposition pathways proceed via the formation of the same complex[100,101]. The "cage effect" of the solvent plays an important role in the molecular mechanism of the decomposition of the hydroperoxide[102]. The radicals formed in the decomposition of the complex $M^{n+}.ROOH$ can either recombine in the solvent cage (molecular decomposition of the hydroperoxide) or can diffuse from the cage (radical decomposition). The ratio of the radical and molecular hydroperoxide decomposition pathways depends greatly on the viscosity of the medium (η): with increase of η, the contribution of the molecular decomposition of ROOH increases. The molecular decomposition of the hydroperoxide in the presence of heterogeneous catalysts takes place via an analogous mechanism[98].

In the non-catalytic decomposition of the hydroperoxide, the involvement of solvent molecules [reaction (3′)] in the process leads to an increase of the rate of formation of free radicals. In the presence of the catalyst the addition of organic solvents with a mobile C–H bond acclerates the molecular decomposition[98,102]. Thus, in the decomposition of cumenyl hydroperoxide in the presence of $Co(acac)_2$, the rate of decomposition of the hydroperoxide is almost independent of the concentration and nature of the solvent. The contribution by the molecular decomposition increases greatly with increase of the hydrocarbon concentration in the solvent and to a greater extent the smaller the C–H bond strength in the hydrocarbon[102], which is apparently associated with the interaction of RH with the hydroperoxide activated by the partial electron transfer to the catalyst–ROOH complex:

The decomposition of t-butyl hydroperoxide in the presence of oxide catalysts is significantly inhibited by the addition of hydrocarbons with a mobile C–H bond. A change in the composition of the reaction products is then observed—the accumulation of a new product, namely an asymmetric hydroperoxide containing the t-butyl group and the alkyl group forming part of the composition of the solvent. The hydroperoxide decomposes in this case without the release of free radicals into space and is apparently a "concerted" process (simultaneously dissociated of the bonds in the starting materials and the formation of new bonds in the hydroperoxides).

The catalytic oxidation of organic compounds in alkaline media by molecular oxygen is apparently a promising reaction[103–105]. Copper complexes of *o*-phenanthroline and bipyridyl can serve as catalysts in such systems. Alcohol and ketones capable of forming ions in alkaline media are oxidised. The rate of oxidation of these substances is

independent of the nature of the base and increases with increase of the pH of the medium in the pH range from 10 to 12 (Fig.16). At pH > 12 the rate of oxidation falls owing to the deactivation of the catalyst.

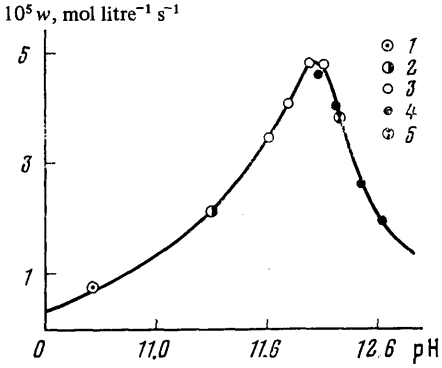

Figure 16. Dependence of the rate of oxidation of ethyl methyl ketone (EMK) on the pH of the medium in the presence of various bases: 1) $Mg(OH)_2$; 2) Na_2CO_3; 3) $(C_2H_5)_3N$; 4) NaOH; 5) $Ca(OH)_2$; 10 ml H_2O, 0.5 ml EMK; $[CuCl_2]_0 = 5 \times 10^{-3}$ M; $[o\text{-phen}]_0 = 1.5 \times 10^{-2}$ M; 50 °C.[92]

The alkali + $CuCl_2$ + *o*-phenanthroline catalytic system is capable of ensuring at pH > 9 rates of oxidation of alcohols and ketones up to 50–80 mole % per hour and more (at 30° to 50 °C), which are virtually unattainable in the catalytic oxidation of organic substrates in neutral media.

The main products of the oxidation of alcohols and ketones, i.e. acids, are the primary reaction products under the conditions of alkaline oxidation. The anions are the active form of the substrate. The strong influence of the medium on the electron-donating capacity of the anions makes it possible to alter the rate of the process and the selectivity of the oxidation by changing the solvent. Thus the rate of oxidation of a 40% solution of methanol in benzene is almost an order of magnitude higher than the rate of oxidation of methanol in bulk. The oxidation apparently develops via a non-chain mechanism without the release of free radicals into space and proceeds as a result of the interaction of O_2 with the anion A^- activated by its incorporation in the complex $Cat.A^-$ with the catalyst.

In the general form, the oxidation mechanism consists of a sequence of the following stages[106]:

$$Cu^{2+} + R'\overline{C}HC(O)R'' \rightleftarrows Cu^{2+} \cdot R'\overset{\ominus}{C}HC(O)R'',$$

$$Cu^{2+} \cdot R\overline{C}HC(O)R'' + O_2 \rightarrow Cu^{+} + R'C\begin{matrix}O\\ \diagdown\\ OH\end{matrix} + R''C\begin{matrix}O\\ \diagdown\\ OH\end{matrix},$$

$$Cu^{+} + R'\overline{C}HC(O)R'' \rightleftarrows Cu^{+} \cdot R'CHC(O)R''$$

$$Cu^{+} \cdot R'\overline{C}HC(O)R'' + O_2 \rightarrow Cu^{2+} + R'C\begin{matrix}O\\ \diagdown\\ OH\end{matrix} + R''C\begin{matrix}O\\ \diagdown\\ OH\end{matrix},$$

In the oxidation of ketones the interaction of the coordinated anion with O_2 proceeds at very high rates and does not limit the rate of oxidation. In the oxidation of alcohols oxygen participates in the rate-limiting stage of the process and in this case the rate of oxidation greatly depends on the oxygen pressure[104].

6. Metal Complex Inhibition

Approximately three decades ago, the phenomenon of the dual function[107] of variable-valence metal compounds in liquid-phase oxidation reactions was discovered. It consists in the fact that, with increase of the initial concentration of the metal complexes, there is a sharp (critical) change in the rate of reaction—a transition from the catalytic to inhibited oxidation conditions. Recently there has been a considerable growth of interest in the use of metal complexes as inhibitors of liquid-phase oxidation and in the study of the mechanism of the metal complex inhibition.

The inhibition of oxidation in the presence of metal compounds is due to two causes: the decomposition of the hydroperoxide into non-radical products and the interaction of free radicals with metal complexes. The latter type of inhibition is most common. The mechanisms of the reactions of $R\dot{O}_2$ radicals with metal compounds, leading to the termination of oxidation chains, are considered below.

The inhibition by the sulphur-containing metal complexes, namely bis(dialkyl phosphorodithioates) $[M(dtp)_n]$,[111–118] bis(*N*,*N*-dialkyldithiocarbamates) $[M(dtc)_2]$,[109–115] bis(8-mercaptoquinolinates) $[M(toq)_n]$,[119] and bis(α-thiopicolinanilides) $[M(tpa)_2]$ [108,109] takes place as a result of chain termination by the complexes. The stoichiometric inhibition coefficient *f* and the rate constant for the reaction of $R\dot{O}_2$ with the metal complexes depend greatly on the decomposition of the chelate unit, the nature of the metal, the coordinating atoms of the ligand, and the oxidation potential of the complex and its geometry (Table 6).

Table 6. Dependence of the effectiveness of inhibition (fk_7) by sulphur-containing complexes on the oxidation potentials ($E_{1/2}$) (oxidation of ethylbenzene; 75 °C; initiator—azobisisobutyronitrile; $w_i = 1 \times 10^{-6}$ mol litre^{-1} s^{-1}).[119]

Compound	$10^{-3}kf_7$, litre mol^{-1} s^{-1}	$+E_{1/2}$, V
	$M(toq)_n$	
$Zn(toq)_2$	2.3	1.10
$Ag(S\text{-}toq)$	1.3	0.93
$Co(S\text{-}toq)_3$	11	0.59
$Ni(S\text{-}toq)_2$	7.5	0.56
$Cu(toq)_2$	>60	0.48
	$M(dtc)_n$	
$Zn(dtc)_2$	1.6	1.01
$Bi(dtc)_3$	5.7	0.86
$Pb(dtc)_2$	6.3	0.80
$Ni(dtc)_2$	23	0.60
$Cu(dtc)_2$	60	0.43
	$M(tpa)_2$	
$Ni(tpa)_2$	2.6	0.88
$Cu(tpa)_2$	13	0.75

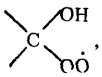

Table 6 shows that the inhibiting activity of the metal complexes is higher the greater the ease of oxidation of the complex[109,119]. An increase of the degree of covalence of the metal–ligand bond in the complex also promotes an increase of its inhibiting activity in the oxidation reaction[120]. The mechanism of the inhibition includes in this case the formation of a complex of $R\dot{O}_2$ with the chelate and subsequent electron transfer to the peroxy-radical[121]. The central metal ion plays the role of an agent transferring an electron to the peroxy-radical from the ligand, which is also split off in the

form of a radical incapable of participating in the chain propagation reaction. The degree of oxidation of the metal remains unchanged.

For $M(dtc)_2$, the reaction mechanism can be formulated as follows[109,110]:

$$M(dtc)_2 + R\dot{O}_2 \rightleftarrows \{M(dtc)_2 \ldots R\dot{O}_2\} \rightarrow \{[M(dtc)_2]^+ \ldots RO_2^-\},$$
$$\{[M(dtc)_2]^+ \ldots RO_2^-\} \rightarrow M(dtc)RO_2 + 2dt\dot{c},$$
$$2dt\dot{c} \rightarrow \text{disulphide}.$$

An analogous mechanism has been proposed for the inhibition of oxidation by the copper(I) complexes of triphenyl phosphite[122] as well as a number of phosphorodiothioates[115–118].

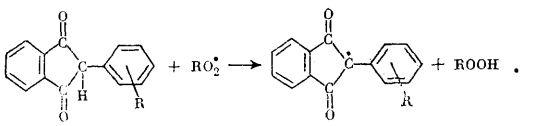
The electron transfer reaction between $R\dot{O}_2$ and the metal compounds can lead in some cases to a change in the oxidation state of the metal ion. Thus the oxidation of the Co^{2+} and Mn^{2+} ions has been observed in the interaction with radicals[123,124]. The phenomenon of repeated chain termination by metal ions has been observed in the oxidation of cyclohexanol and other secondary alcohols as well as amides in the presence of salts and certain complexes of copper, iron, cobalt, magnesium, and cerium[125]. This phenomenon is due to the fact that the hydroxyperoxy-radicals  , formed in the oxidation of secondary alcohols, can interact with metal ions in both valence states:

$$\rangle C(OH)O\dot{O} + Cu^{2+} \rightarrow H^+ + Cu^+ + O_2 + \rangle C{=}O,$$
$$\rangle C(OH)O\dot{O} + Cu^+ \rightarrow \rangle C(OH)OO^- + Cu^{2+}.$$

In this system the quantity f may increase to 10^3.

The oxidation-reduction potential of the metal ion is very important for the operation of the mechanism presented above. At high oxidation-reduction potentials the degree of involvement of the metal in the decomposition of the hydroperoxide increases; at low oxidation-reduction potentials the rate of reaction of M^{n+} with $R\dot{O}_2$ falls.

For certain types of metal complex inhibitors, the interaction with peroxy-radicals takes place via a mechanism involving the abstraction of a hydrogen atom from the ligand. The inhibition of the oxidation of cumene and cyclohexa-1,3-diene by cobalt(III) complexes [as well as iron(II), nickel(II), and copper(II) complexes] with dimethylglyoxime and other dioximes[126,127] and also by nickel bis(α-phenylanthranilate) apparently involves this mechanism[128].



A hydrogen atom is abstracted from the ligand in the complex much more readily than from the free ligand, which indicates the activation of the ligand in the complex. Thus $k_{12} = 9 \times 10^2$ litre mol^{-1} s^{-1} (at 90 °C) for *N*-phenylanthranilic acid in ethylbenzene, while $k_{12} = 4.5 \times 10^3$ litre mol^{-1} s^{-1} for the nickel complex of *N*-phenylanthranilic acid[128].

7. The Mechanism of the Inhibited Oxidation

The study of the mechanism of the action of inhibitors and the establishment of theoretical principles for the selection of effective antioxidant additives is an important task in chemical kinetics. New classes of antioxidants have been investigated, rapid methods for the estimation of their efficiency have been proposed, and the details of the elementary stages of the inhibition process have been determined in recent years. Many fundamental results have been obtained with the aid of modern physical research methods—the chemiluminescence method, EPR, NMR, flash photolysis, and chemically induced nuclear polarisation (CINP).

The oxidation process is usually inhibited by adding to the system inhibitors which interact with free radicals and terminate oxidation chains[129]. The most common inhibitors of this type are phenols and aromatic amines. They cause chain termination via reaction (7).

Together with amines and phenols, 2-arylindan-1,3-diones, which have a reactive C–H bond, also serve as inhibitors[130]:

The constants k_7 for these inhibitors depend on the substituent in the benzene ring and amount to 1×10^2–6×10^4 litre mol^{-1} s^{-1} (Table 7). The substituents in the *p*-position, both electron-donating and electron-accepting, increase k_7, while those in the *o*-position decrease it. The influence of *p*-substituents is described by the Hammett equation in the form[131]

$$\lg(k_7/k_{7,\,st}) = 0.28\sigma + 1.01E_R.$$

Table 7. The rate constants, activation energies, and stoichiometric coefficients (f) for the reactions of cumenylperoxy-radicals with 2-arylindan-1,3-diones at 60 °C.[131]

R*	$10^{-4}k_7$, litre mol^{-1} s^{-1}	f	E_{act}, kcal mol^{-1}
	1.95	1.0	7.3

*Substituent in the 2-diphenyl[2-phenyl?] ring.

The subscript st refers to the unsubstituted 2-phenylindan-1,3-dione and σ and E_R are the polar and resonance constants of the substituents.

Together with reaction (7), there is also a possibility of recombination inhibition mechanisms. A new example of an inhibitor of this type is 1,2-bis(*p*-dimethylaminophenyl-1,2-diphthaloylethane)(PP). The inhibiting activity of PP is due to the equilbirium

$$PP \underset{k(-)}{\overset{k(+)}{\rightleftarrows}} 2\dot{P} \qquad (71)$$

and the irreversible reaction

$$R\dot{O}_2 + \dot{P} \rightarrow \text{products}. \qquad (72)$$

The radical P has been detected by EPR. The equilibrium constant is $k_{71} = 6.16 \times 10^2 \exp(-17\,300/RT)$ mol litre^{-1}, the rate constant for the recombination of $\dot{P}$ radicals at 20 °C is $k_{(a)} = 2 \times 10^8$ litre mol^{-1} s^{-1} and $k_{72} \geq 10^8$ litre mol^{-1} s^{-1}.[133]

The question of reactivity with respect to alkyl radicals is important for the mechanism of the action of inhibitors:

$$InH + \dot{R} \rightarrow \dot{In} + RH, \qquad (7')$$

$$\dot{R} + \dot{R} \rightarrow \text{products}. \qquad (73)$$

Estimates of the parameter $k_7'/k_{73}^{1/2}$ for the interaction of 16 inhibitors (amines and phenols) with alkyl radicals derived from ethhlbenzene showed[137] that its maximum possible value is $(0.4–3.5) \times 10^{-1}$ litre$^{1/2}$ mol$^{-1/2}$ s$^{-1/2}$. For $k_{73} = 2.8 \times 10^8$ litre mol^{-1} s^{-1}, we have $k_7' < (1–6) \times 10^3$ litre mol^{-1} s^{-1}. For *N*-phenyl-β-naphthylamine, $k_7'/k_{73}^{1/2} = (3.2 \pm 0.2) \times 10^{-2}$ litre$^{1/2}$ mol$^{-1/2}$ s$^{-1/2}$ and $k_7' = 6.7 \times 10^2$ litre mol^{-1} s^{-1}.

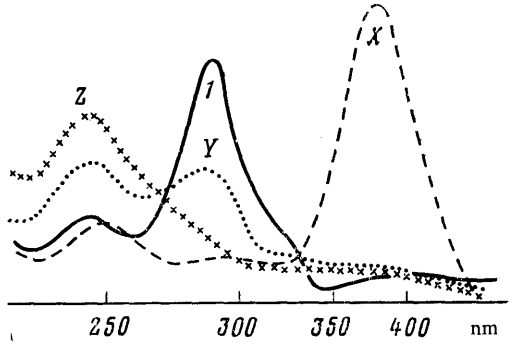
Thus phenols and aromatic amines interact with alkyl radicals much less vigorously than with peroxy-radicals, for which as a rule $k_7 \cong 10^4–10^5$ litre mol^{-1} s^{-1}.

The stable aliphatic nitroxy-radicals are effective acceptors of alkyl radicals[135]:

$$>\dot{N}O + \dot{R} \rightarrow NOR \quad . \qquad (74)$$

Aromatic nitroxy-radicals, which are capable of reacting with both the radicals $\dot{R}$ and $R\dot{O}_2$, act less selectively. Repeated chain termination in the oxidation of certain unsaturated hydrocarbons[137] and polypropylene[138] has been demonstrated for both types of nitroxy-radicals, apparently as a result of the regeneration of $>\dot{N}O$ when the ether derivatives of aliphatic nitroxy-radicals $>NOR$ interact with peroxy- and alkoxy-radicals and with oxygen[136]:

$$>NOR + R\dot{O}_2\ (R\dot{O},\ O_2) \rightarrow >N\dot{O} + \text{product}.$$



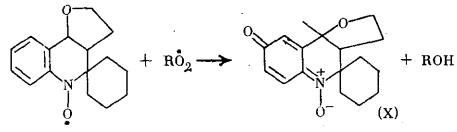


Figure 17. Ultraviolet absorption spectra of the 4-methyl-2-spiro-cyclohexyl-3,4,2',3'-tetrahydrofurano-1,2,3,4-tetraquinolin-1-yloxy-radical (curve *1*) and its reaction products (curves *X*, *Y*, and *Z*). Solvent—ethanol; [AIBN] = 4.9×10^{-2} M; $[N\dot{O}]_0 = 5.2 \times 10^{-4}$ M; 60 °C. Spectra *X* and *Z* were obtained in oxygen and spectrum *Y* was obtained in nitrogen[139].

Repeated chain termination in the inhibition by the aromatic 4-methyl-2-spirocyclohexyl-3,4,2',3'-tetrahydrofurano-1,2,3,4-tetrahydroquinolin-1-yloxy-radical of the oxidation of β-carotene[139] is due to a relay of radical reactions of the nitroxy-radical and its conversion products (Fig.17), which interact alternately with peroxy- and alkyl-radicals. The first stage involves the reaction of $>N\dot{O}$ with the radicals $R\dot{O}_2$:

The resulting quinone-nitrone (X) is an acceptor of the radicals $\dot{R}$:

$$X + 2\dot{R} \rightarrow Y; \quad Y + R\dot{O}_2 \rightarrow Z \quad .$$

The product Y then reacts with $R\dot{O}_2$.

As a result of the sequence of these reactions, five chains are terminated by the $>N\dot{O}$ fragment.

The radicals $\dot{In}$ formed in the interaction of InH with $R\dot{O}_2$ via reaction (7) interact with peroxy-radicals to form recombination products—quinolide peroxides (QP) [reaction (8)].

The values of k_8 for phenoxy-radicals depend little on the structure of $\dot{In}$ and $R\dot{O}_2$ and are in the range $(1.7–7.2) \times 10^8$ litre mol^{-1} s^{-1} (at 60 °C).[140–142] The probability α of the formation of QP depends on the concentration of the phenol, the rate of initiation, the rate constants k_7 and k_8, and the rate constant for the reaction

$$\dot{In} + \dot{In} \rightarrow \text{products}, \qquad (75)$$

and is defined by the equation[143]

$$\alpha^2(1+\alpha) - \frac{A}{k_9}(1-\alpha) = 0;$$

$$A = \frac{k_8^2 w_i}{k_7^2 [InH]^3} \quad .$$

Quinolide peroxides are formed with the highest probability ($\alpha = 1$) in inhibition by sterically hindered phenols whose phenoxy-radicals are stable and whose constants k_{75} are low. In the oxidation of low-molecular-weight hydrocarbons[144] in the presence of 2,4,6-tri-t-butylphenyl the yield of quinolide peroxide reaches 100%. Under the conditions of the inhibited oxidation, quinolide peroxides are capable of decomposing into radicals[143].

The initiating capacity of quinolide peroxides is comparable to that of azobisisobutyronitrile and benzoyl peroxide and is greatly superior to that of t-butyl hydroperoxide (Table 8).[143,144] The probability of the emergence of radicals from the cage in the decomposition of quinolide peroxides is close to unity. Their decomposition leads to a decrease of the antioxidant effectiveness of sterically hindered phenols in the autoxidation of hydrocarbons and polymers[143].

Table 8. Kinetic parameters of the thermal decomposition of quinolide peroxides (QP) [In = 2,4,6-tri-t-butylperoxy-radical, R = $C(CH_3)_3$] and certain initiators[143].

Compound	Decomposition rate constant, s^{-1}	$10^5 k$, s^{-1}
o-QP	$1.1 \cdot 10^{14} \exp[(-30500 \pm 1000)/RT]$	6.6
p-QP	$9.8 \cdot 10^{13} \exp[(-33000 \pm 2000)/RT]$	0.18
Azobisisobutyronitrile	$1.6 \cdot 10^{15} \exp(-30800/RT)$	57
Benzoyl peroxide	$3.0 \cdot 10^{14} \exp(-30800/RT)$	11
$(CH_3)_3COOH$	$3.6 \cdot 10^{12} \exp(-33000/RT)$	0.006

*At 93 °C.

Extensive information about the kinetics of reaction (75) for phenoxy-radicals has been obtained by flash photolysis[145–148]. The process mechanism can be represented by the following set of stages:

$$Ph\dot{O} + Ph\dot{O} \rightarrow D \quad , \qquad (76)$$

$$D \rightarrow Ph\dot{O} + Ph\dot{O} \quad , \qquad (77)$$

$$D \rightarrow \text{products}. \qquad (78)$$

The stage involving the irreversible transformation of the dimer [Eqn.(78)] is characteristic of radicals having at least one unoccupied *o*- or *p*-position. In this stage there is a possibility of the regeneration of the inhibitor. For the majority of phenoxy-radicals, $k_{76} \cong 10^9$–10^7 litre mol^{-1} s^{-1}.[148] The introduction of bulky substituents into the *p*-position relative to the O–H group causes a decrease of k_{76}. For example, the rate constant for the recombination of "galvinoxyl" radicals at 90 °C is 4.8×10^4 litre mol^{-1} s^{-1}.[149] The comparatively slow recombination of sterically hindered phenoxy-radicals is limited by molecular mobility. The cause of this effect consists in the low value of the steric factor for the interaction of these radicals[145].

The kinetic characteristics of the side processes involving inhibitors, i.e. the reactions of the inhibitor and its radicals with the hydrocarbon, the hydroperoxide, and oxygen, have been obtained. The kinetic parameters k_{79}/k_8, characterising the participation of the radical of *N*-phenyl-β-naphthylamine in the chain propagation reaction with a hydrocarbon (ethylbenzene), i.e.

$$\dot{\text{In}} + \text{RH} \rightarrow \text{InH} + \dot{\text{R}}, \qquad (79)$$

measured by the chemiluminescence method, is 3×10^{-9}.[150]

The rate constants for the reaction

$$\dot{\text{In}} + \text{ROOH} \rightarrow \text{InH} + \text{R}\dot{\text{O}}_2, \qquad (80)$$

involving t-butyl hydroperoxide and 2,6-di-t-butyl-4-R-phenols increase with increasing strength of the O–H bond in the phenol (the activation energy then falls). Thus, on passing from R = OCH_3 (D_{OH} = 73.9 kcal mol^{-1}) to R′ = CN (D_{OH} = 81.9 kcal mol^{-1}), the values of k_{80} at 60 °C increase from 0.07 to 170 litre mol^{-1} s^{-1} and the activation energy falls from 18 to 8.8 kcal mol^{-1}.

The formation of phenoxy-radicals in the reaction of a hydroperoxide with phenols[151],

$$\text{InH} + \text{ROOH} \begin{cases} \rightarrow \text{molecular products}, \\ \rightarrow \text{R}\dot{\text{O}} + \text{Ph}\dot{\text{O}} + \text{H}_2\text{O}, \end{cases} \qquad (81)$$

has been demonstrated by EPR for 2,4,6-tri-t-butylphenol. The constant k_{81} depends strongly on the structure of the phenol. For the interaction of cumenyl hydroperoxide with 2,6-dimethoxyphenol at 140, $k_{81} = 6.5 \times 10^{-3}$ litre mol^{-1} s^{-1} has been found, while the constant for the reaction with the sterically hindered 2,4,6-tri-t-butylphenol is $k_{81} = 7.5 \times 10^{-5}$ litre mol^{-1} s^{-1}.

It has been shown[152] that the reaction of aromatic amines, phenols, and naphthols with molecular oxygen,

$$\text{InH} + \text{O}_2 \rightarrow \dot{\text{In}} + \text{H}\dot{\text{O}}_2,$$

requires an activation energy of 25–35 kcal mol^{-1}. The contribution of this reaction to the initiation of the oxidation must be taken into account only above 180 °C and at high oxygen pressures.

For a long time, the question of the mechanism of the interaction of phosphites with a hydroperoxide [reaction (7‴)] remained controversial. The yield of radicals in this reaction is very low[154]. It was suggested that the reaction is either limited via a cryptoradical mechanism, with a low degree of liberation of radicals into space, or that two reactions take place in the system, involving radical and non-radical decomposition. Since the reaction products are the same in both cases, it was not possible to determine which of the two alternative mechanisms operates. It has been demonstrated unambiguously with the aid of CINP [153] that the reaction proceeds via two competing channels—radical and non-radical. The radical pathway, induced by the polarisation of the ^{31}P nuclei, makes an extremely small contribution (10^{-2} to 10^{-4} of the overall decomposition).

A special method using computers—an automatic system for testing inhibitors (ASTI), which takes into account the set of elementary stages in the action of inhibitors in the oxidation process—has been recently developed and introduced (Fig.18). Tests are performed simultaneously on four highly sensitive differential manometric sets of apparatus, with automatic recording of the rate of oxidation, located in the experimental section. The experimental data are transmitted to the intermediate memory of the computer—an autonomous accumulator on a magnetic drum (section B). Sections A and B are linked by a communication line. On command of the experimentor, the data are introduced into the computer for treatment; the results of the computation are transmitted to the laboratory and are reproduced in the form of tables and graphs with the aid of a graph plotting apparatus.

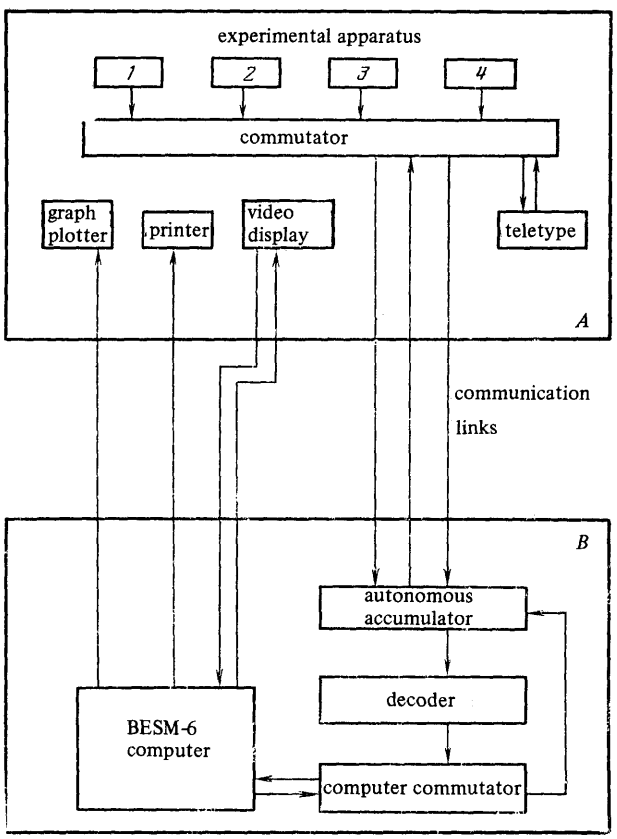

Figure 18. Schematic illustration of the automated system for testing the efficiency of stabilisers (ASTI): *A*) experimental section; *B*) section for the interpretation of data.

8. Synergism

The effects of synergism, which is manifested by the fact that the inhibiting effect of a mixture of two inhibitors exceeds the sum of the effects of each separately, is of practical importance. The mechanism of the synergism in the inhibition of oxidation by a mixture of inhibitors, each of which reacts with the radicals $\text{R}\dot{\text{O}}_2$, has been most thoroughly

investigated. The mechanism of the action of a mixture of inhibitors includes, together with the main elementary stages of the inhibited oxidation process [reactions (0), (2), (3), and (6)–(8)], also the following reactions[155–157]

$$In_1^{\cdot} + RH \rightarrow In_1H + \dot{R}\,(R\dot{O}_2)\,, \qquad (82)$$

$$In_1^{\cdot} + In_2H \rightarrow In_1H + In_2^{\cdot}\,, \qquad (83)$$

$$In_2^{\cdot} + In_1H \rightarrow In_2H + In_1^{\cdot}\,. \qquad (84)$$

The synergism is based on the phenomenon of the radical interaction of the inhibitors[155–158] consisting in the reduction of the more active inhibitor In_1H as a result of the transfer of a hydrogen atom to the radical $In_1^{\cdot}$ from the molecule of the less active inhibitor In_2H [reaction (83)]. The inhibitors In_1H can be primary and secondary aromatic amines, substituted pphenylenediamines, hydroxylamine ethers, and sterically unhindered alkylphenols[159]. The reducing inhibitors can be phenols and bisphenols containing bulky substituents in the 2,6-positions. The effective reduction of In_1H occurs only when the radical $In_2^{\cdot}$ formed is inactive and does not enter into the reversible reaction (84).

The influence of reaction (83) on inhibition by mixtures is enhanced due to the suppression, as a result of its occurrence, of reaction (79), which lowers the inhibiting activity of aromatic amines and unshielded phenols.

It has been shown by computer calculations that this mechanism describes satisfactorily the dependence of the synergistic effect on the overall concentration of inhibitors[160], the kinetic characteristics of the substrate being oxidised[156], the efficiency of the action of each inhibitor in the mixture[156,157], and the mixture composition[161]. For mixtures of the same inhibitor In_2H with inhibitors In_1H having the different antiradical activities, the synergistic effect increases with increase of the rate constant for the reaction of $R\dot{O}_2$ with In_1H and the maximum on the plot of the dependence of τ on the mixture composition shifts in the direction of mixtures containing a higher percentage of In_2H.[161]

A similar mechanism of the regeneration of the inhibitor explains in many instances the synergistic effect of a mixture of aromatic amines and sulphur-containing compounds, for example, mixtures of *N*-phenyl-β-naphthylamine and bis(2-hydroxy-5-methyl-3-t-butyl) sulphoxide[162]. The product of the thermal transformation of the sulphoxide (P) behaves as the reductant for the amine. The same mechanism is possible in inhibition by mixtures containing sulphides, where the product P can be obtained by the reaction of the sulphides with the hydroperoxide and subsequent decomposition of the resulting sulphoxide. The synergistic effect of a mixture of copper and nickel bis(*N*,*N*'-diethyldithiocarbamates) with thiuram disulphide—the product of the reaction of these complexes in liquid-phase oxidation—is due to the regeneration of the initial form of the metal-complex inhibitor $M(dtc)_2$.[163]

Together with the mechanism of the synergism discussed above, which is due to the regeneration of the active inhibitor, cases are possible where the synergism is due to the formation of a new active inhibitor in the system. This apparently happens in the inhibition of oxidation by mixtures of aromatic amines and copper compounds[164]. The formation of a new copper complex of the amine is responsible in this instant for the inhibiting effect[165]. The mechanism of the action of the synergistic mixture of an amine (AmH) with copper salts includes, together with the reactions known for each component, new stages[165] involving the complexes:

$$AmH + Cu(II) \rightleftarrows Cu(II)\cdot Am\dot{H}\,,$$

$$Cu(II)\cdot AmH + R\dot{O}_2 \rightarrow Cu(II)\cdot Am^{\cdot} + ROOH\,, \qquad (85)$$

$$Cu(II)\cdot Am^{\cdot} + R\dot{O}_2 \rightarrow Cu(II) + \text{product}, \qquad (86)$$

$$Cu(II)\cdot AmH + ROOH \rightarrow Cu(II)\cdot AmH + \text{product}. \qquad (87)$$

The mechanism describes quantitatively the characteristics of the initiated oxidation of ethylbenzene in the presence of a mixture of $CuSt_2$ and *p*-toluidine. An interesting feature of the action of such mixtures is the marked increase of their activity with increase of temperature[166]. The enhancement of the inhibition is caused by the formation of a new product of the thermal transformation of the primary complex, which has a higher inhibiting activity. It has been shown in recent years that the synergistic effect can be exhibited by mixtures of inhibitors reacting with the radicals $R\dot{O}_2$ (aromatic amines and phenols) and with acceptors of the radicals $\dot{R}$ (quinones and nitroxy-radicals),[167] as well as mixtures of u.v. absorbers and antioxidants[168]. As a consequence of the diffusion of the inhibitors from the bulk of the specimen to the surface layer, the synergistic effect greatly increases in the solid phase (diffusion synergism)[169].

9. Critical Phenomena in Liquid-Phase Oxidation

Analysis of kinetic equations for degenerate branched chain reactions with linear chain termination (for example, by an inhibitor) has demonstrated the possibility of the existence of limiting phenomena[170] of the kind observed in fully branched chain processes.

At a constant rate of initiation of the free radicals, the inhibitor is consumed linearly at a rate

$$-d[InH]/dt = w_i/f\,. \qquad (88)$$

In a degenerate branched chain reaction the inhibitor is consumed during the period of inhibition with self acceleration [in contrast to reaction (88)] as a consequence of the increase of the rate of initiation of chains during the reaction. For certain values and ratios of the rate constants for the elementary stages, there is a possibility of a progressive increase of the inhibition periods up to a sharp arrest of the reaction at a certain inhibitor concentration $[InH]_{cr}$.

For branched chain processes, the concentrations of the hydroperoxide and free radicals under the conditions of chain termination by the inhibitor are given by the equations

$$[R\dot{O}_2] = \frac{w_0 + \delta k_p [ROOH]}{f k_7 [InH]}\,, \qquad (89)$$

$$\frac{d[ROOH]}{dt} = \nu w_0 + \varphi [ROOH]\,, \qquad (90)$$

where $\nu = k_2[RH]/fk_7[InH]$ is the chain length, $w_i = w_0 + \delta k_p[ROOH]$ the rate of chain initiation, and $\phi = \delta k_p(\nu - 1/\delta)$ the reaction self-acceleration factor.

It follows from Eqn.(90) that, for $\phi > 0$, i.e. when $\nu > 1/\delta$, the hydroperoxide accumulates with self acceleration: $d[ROOH]/dt > 0$. For $\phi > 0$, i.e. when $\nu < 1/\delta$, conditions in which the hydroperoxide concentration may be assumed to be quasi-stationary, i.e. $d[ROOH]/dt = 0$, are established after a time interval. The change in conditions occurs at $\phi = 0$ ($\nu = 1/\delta$), which determines the critical inhibitor concentration:

$$[InH]_{cr} = \frac{\delta k_2 [RH]}{f k_7}\,. \qquad (91)$$

The limiting phenomena were first observed in the oxidation of n-decane catalysed by copper stearate[107].

The characteristic features of the critical phenomena for metal complexes can be seen in relation to the kinetics of the oxidation of n-decane in the presence of bis{3-hydroxo-2-benzo[*b*]thenylideneanilinato}copper (CuL_2) (Fig.19). At low concentrations the copper chelate greatly accelerates the reaction. At high concentrations inhibition periods appear and increase sharply at a critical concentration $[CuL_2]_{cr}$.[172]

However, at the end of the inhibition periods the process takes place under catalytic conditions, owing to the consumption of the chelate down to low concentrations[172]. Since the rate constants for chain termination by metal complex inhibitors depend on the structure of the chelate unit, the critical inhibitor concentration depends on the nature of the chelate [according to Eqn.(91)].

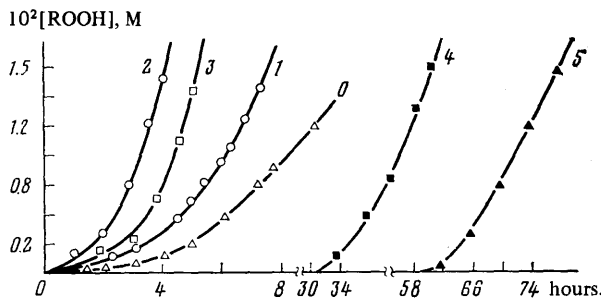

Figure 19. Kinetic curves for the accumulation of hydroperoxides in the oxidation of n-decane (120 °C) without a catalyst (0) and in the presence of bis{3-hydroxy-2-benzo[*b*]-thenylideneanilinato}copper(II) at different concentrations (M): 1) 1.5×10^{-6}; 2) 9.0×10^{-5}; 3) 1.1×10^{-4}; 4) 1.2×10^{-4}; 5) 1.5×10^{-4}.[171]

The existence of critical concentrations of transition metals has been established for simple and complex compounds of manganese, cobalt, and other metals[170]. Critical phenomena are also observed for phenols and aromatic amines[1,173].

Limiting phenomena occur in the oxidation of n-butane under pressure when the hydrocarbon is diluted with benzene. The reaction proceeds at a high rate only when the mole fraction of butane is ≥0.28, the process undergoing a sharp arrest when butane is consumed to give this dilution[174]. By taking into account the limiting phenomena, it is possible to explain the arrest of the oxidation of n-decane in the presence of potassium permanganate[175].

Limiting phenomena should be observed for a fairly high rate constant for the decomposition of hydroperoxides into free radicals and a low chain initiation rate constant[171]. In this case there are short inhibition periods τ in the region of inhibitor concentrations below the critical value and there is a sharp increase of τ following the attainment of limiting conditions where the rate of the process is determined mainly by the rate of chain initiation. The critical phenomena for organic inhibitors and metal complexes are therefore observed in most cases when the hydroperoxides decompose with participation of metal-containing catalysts.

Distinct limiting phenomena are observed in the continuous inhibited oxidation of hydrocarbons (open systems).[176] The critical inhibitor concentration is in this case given by[177]

$$[\mathrm{InH}]_{cr} = i_{cr} = \left(\sqrt{i_{\varphi=0}} + \sqrt{w_0/fv}\right)^2,$$

where $i_{\phi=0}$ is the inhibitor concentration defined by Eqn.(91) and w_0 is the rate of chain initiation.

Fig. 20 illustrates the accumulation of hydroperoxides in the oxidation of n-decane under conditions where the hydrocarbon with different concentrations of α-naphthol is continuously supplied into the reaction vessel and the oxidised product is removed from it, also continuously, at the same rate. Evidently a sharp change in the process conditions occurs for a slight alteration of the InH concentration in the entering solution—from 9.0×10^{-6} to 9.05×10^{-6} M.[176]

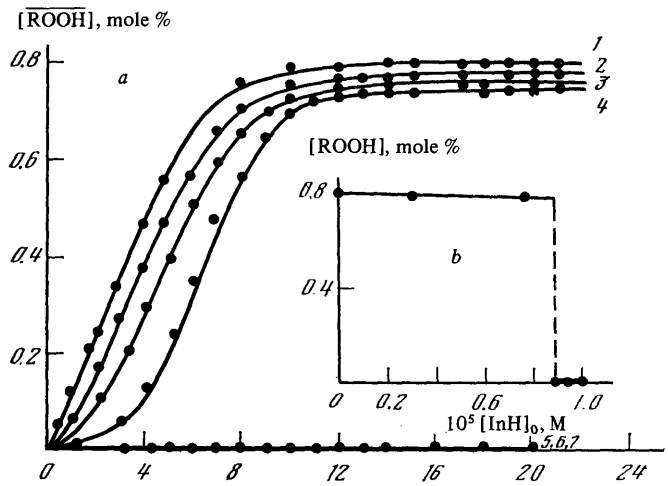

Figure 20. *a*) Kinetic curves for the accumulation of the hydroperoxide in the oxidation of n-decane in an open system in the presence of α-naphthol. Inhibitor concentration in the solution entering the vessel (M): 1) 0.0; 2) 3×10^{-6}; 3) 7.5×10^{-6}; 4) 9.0×10^{-6}; 5) 9.05×10^{-6}; 6) 1.2×10^{-5}; 7) 1.4×10^{-5}; *b*) dependence of the stationary concentration of the hydroperoxide on the inhibitor concentration[176].

III. KINETICS OF THE AGEING OF POLYMERS AND THEIR STABILISATION

Much attention has been devoted to the chemical kinetics of the ageing of polymers and to problems of their stabilisation as one of the branches of the modern science of macromolecular compounds. The knowledge of the kinetics and principal parameters of ageing makes it possible to predict the useful life and the optimum utilisation of polymeric materials. The results of kinetic studies of the ageing of polymers also make it possible to put forward the fundamental principles of the selection of effective stabilisers, increasing the quality of polymeric materials and their useful life.

During two decades, this field has greatly developed. It has become a special branch of the chemistry of the solid state in which studies are made of complex coupled radical-chain, ionic, and molecular reactions under the conditions of solid polymeric matrices with participation in the chemical process of the polymeric molecules of the matrix[178,179].

Specific types of the ageing of polymeric materials—thermal and thermo-oxidative ageing, ageing under the influence of light, penetrating radiation, and mechanical degradation, ageing under the influence of corrosive chemicals, biochemical and microbiological ageing, etc.—have been examined in a large number of monographs[180–190]. The experimental results obtained in recent years at the Institute of Chemical Physics of the USSR Academy of Sciences have been published recently[178,179]. In the present section we shall therefore briefly summarise the principal ideas of the chemical

physics of the ageing of polymers and the principles and problems of the stabilisation of polymers and polymeric materials.

1. The Ageing of Polymers as a Multifactorial Problem

The ageing of polymers can be defined as a set of chemical and physical transformations occurring in the polymer during its use, processing, or storage and leading to its losing a set of useful properties. Here one must bear in mind that the polymer is acted upon by numerous factors: heat, light, penetrating radiation, oxygen moisture, corrosive chemical compounds, and mechanical loads; therefore the ageing of the polymers must be considered as a multifactorial problem.

From the point of view, a system of equations for a multidimensional space can be proposed for the description of the time variation of the properties Y_i of a polymeric material under conditions X_i:[178]

$$Y=f(X, t)\ . \qquad (92)$$

The material is suitable for use in the course of a certain period τ, after which, under conditions X, the point Y leaves the region of operational suitability ε_0 in this space (Fig. 21). The solution of Eqns. (92) would make it possible to determine the useful life of the polymer τ. In principle, this problem is susceptible to solution in a general form by modern computer techniques. The following processes are usually considered: thermal degradation, photodegradation, mechanodegradation, oxidation, hydrolytic degradation, etc.—these are limiting cases of the ageing process in which the changes in the properties of the material are determined by one factor only.

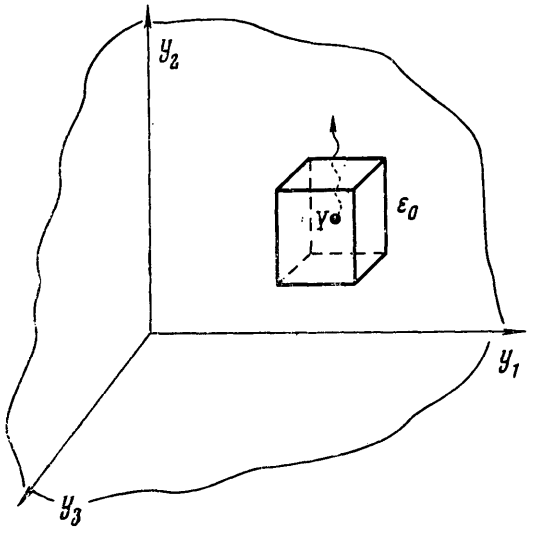

Figure 21. A qualitative picture of the time variation of the set of properties of a polymer Y (special case—point in a three-dimensional space); ε_0—the region of the operational suitability of the polymer[178].

In the general case ageing involves three stages: initiation—the stage in which active ageing centres are formed; development of ageing—the principal stage determining the changes in the properties of the polymeric material; the stage in which the active ageing centres are destroyed.

The physicochemical nature of the initiation of ageing can be various. For example, in photoageing this involves the formation of free radicals or ions under the influence of light, the appearance of ions, electrons, and radicals under the influence of radiation, and in mechanodegradation the initiation consists in the dissociation of molecules by mechanical forces with formation of free radicals.

External factors determine in the first place the initiation stage. Certain influences act also on the development of ageing. For example, the presence of oxygen converts the entire process into an oxidative reaction (thermal degradation becomes thermal oxidation, photolysis becomes photooxidation, and mechanodegradation becomes oxidation in the field of mechanical forces). Temperature influences all the elementary stages with the exception of processes whose activation energy is close to zero.

2. The Nature of the Active Centres

One of the principal problems of the chemical physics of ageing and the stabilisation of polymeric materials is the determination of the nature of the active centres responsible for the ageing of polymers and the mechanisms of their migration. It can now be regarded as to a large extent solved: the principal types and chemical nature of the active centres and their electronic structure have been determined, methods have been developed for the identification and measurement of the number of active centres, and the principal reactions and in many instances also their quantitative characteristics (rate constants on activation energies) are known[191,192].

The chemical reactions in the ageing of polymers proceed in most instances with participation of three types of active species: free radicals, excited species, and, to a lesser extent, ions. It has been shown in many studies that free radicals play the main role in the ageing of polymeric materials, which is due to the fact that reactions involving either the homolytic dissociation of the main molecular chain or the homolytic abstraction of atoms or radicals from side groups are characteristic of the majority of polymers. The structure and properties of the free radicals participating in the ageing of polymers and polymeric materials have been thoroughly investigated by EPR.[193] The central and terminal macroradicals and polymer radical-ions have been identified, the formation of low-molecular-weight radicals in the decomposition of macroradicals and the formation of radicals from stabiliser molecules have been demonstrated, and the formation of radical pairs has been observed.

Ions are formed in polymers usually only at the stage involving the initiation of the radiation processes associated with the degradation of polymers in corrosive media. Unfortunately, owing to the lack of special methods resembling EPR, it is much more difficult to identify the active centres in degradation by an ionic mechanism. In this field there have been virtually no systematic studies, with the exception of those concerning the degradation of certain natural polymers in solution[189].

Electronically excited molecules in the lowest excited singlet or lowest triplet states can play the most important role in the photochemical ageing of polymers. Two-quantum photochemical processes with participation of the highest triplet states as well as certain labile species in an excited state, for example, "hot" free radicals, are important[186,187].

3. Kinetics of the Polymer Ageing Processes

The thermal oxidation and photo-oxidation of polymers have been most thoroughly investigated, apparently because these processes are very close to the liquid-phase oxidation reactions of organic substances, which have been thoroughly studied.

The rate constants for the elementary reactions in polymers have been usually measured by modifications of methods developed previously for liquid-phase processes[178]. The rate of initiation w_i has been measured by the method of inhibitors in various versions and also by determining the induction period of the inhibited oxidation. The chain termination rate constant has been determined from the equation $k_t = w_i/[R\dot{O}_2]^2_{st}$, if the stationary concentration of peroxy-radicals is known, or by a non-stationary method based on the kinetics of the destruction of the radicals $R\dot{O}_2$ formed in the polymer, for example, after brief exposure to ultraviolet light. The parameter $k_p/k_t^{1/2}$, characterising the susceptibility of the polymer to oxidation, has been determined from the rates of the initiated chain oxidation (w_i = const.).

The kinetic parameters obtained showed that, compared with the liquid phase, the absolute values of the rate constants for the elementary processes in the solid polymer are usually smaller and the activation energies are higher. In addition, the differences between the relative reactivities of substances of different chemical types involved in isotypical chemical processes diminish ("level off"), which is due to the difficulty of the transport of reactants and the stability of the walls of the cage surrounding the reaction centres, which are characteristic of the solid phase[178].

The kinetics of the thermo-oxidative and photo-oxidative ageing processes for polymers in a highly elastic state and many semicrystalline polymers above their glass points qualitatively differ little from the kinetics of the oxidation of melts and low-molecular-weight organic substances. As an example, one may quote the oxidation of a polypropylene powder at low temperatures using a highly sensitive manometric apparatus which permits the measurement of the amount of absorbed oxygen from the very earliest oxidation stages (Fig. 22).[194]

The oxidation of films of isotactic polypropylene at 130 °C, investigated up to more advanced reaction stages, proceeds similarly (Fig. 22b). The process takes place with self-acceleration: its rate increases from the very beginning and at a degree of oxidation of ~15% reaches a maximum, after which it gradually falls. The variation of the rate of oxidation parallels the accumulation of hydroperoxides (Fig. 22b, curve 3), which indicates the decisive role of hydroperoxides in the propagation of polymer oxidation processes[195].

Thus the oxidative ageing of polymers is a degenerate branched chain reaction. It has been shown at a quantitative level that the photo-oxidation of polyolefins (PH) is described by the following kinetic scheme[196]:

$$PH \rightarrow P\dot{O}_2,$$

$$P\dot{O}_2 + PH \xrightarrow{O_2,\, k_p} POOH + P\dot{O}_2 \text{ (propagation)},$$

$$POOH \xrightarrow{h\nu} P\dot{O} + \dot{O}H \rightarrow 2P\dot{O}_2 + S \text{ (branching)},$$

$$[C{=}O] \xrightarrow{h\nu} P\dot{O}_2 + S,$$

$$P\dot{O}_2 + P\dot{O}_2 \xrightarrow{k_t} [C{=}O] \text{ (termination)},$$

where [C=O] are carbonyl compounds and S represents the step involving the dissociation of macromolecules. The rate constants for all the elementary reactions in the above scheme, which are required for the description of the kinetics of the accumulation of products, were determined by independent methods. The agreement between calculations and experiment confirmed the reliability of the proposed scheme.

In the course of their ageing, processes characteristic only of high-molecular-weight compounds take place in the polymers: degradation and cross-linking, the formation of cross-linked three-dimensional structures, and the propagation of reactions along the polymer chain.

The specific features of the structure of macromolecules are manifested, for example, in the kinetics of thermal degradation. The presence of two macroscopic thermal degradation stages is characteristic of the majority of polymers[197]. In the initial stage the process proceeds at a relatively high rate and with a low activation energy. At advanced stages the

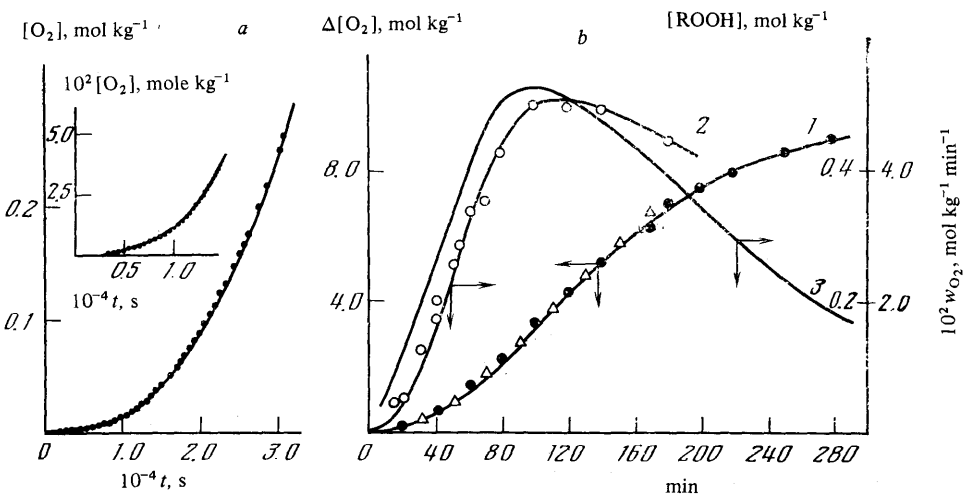

Figure 22. a) Kinetic curves for the absorption of oxygen in the autoxidation of polypropylene powder at 92 °C (the inset shows the initial stages of the process)[194]; b) kinetic curves for the autoxidation of polypropylene films at 130 °C: 1) absorption of O_2; 2) variation of the rate of oxidation; 3) accumulation of hydroperoxides[195].

rate of degradation falls and the activation energy increases. The fraction of the substance decomposing in the first stage depends on the method of synthesis of the polymer (Fig. 23).

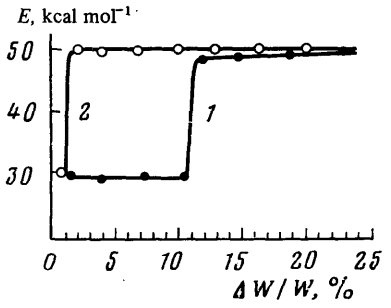

Figure 23. Dependence of the activation energy for the thermal degradation of polyvinyltoluene obtained by radical (curve *1*) and anionic (curve *2*) polymerisation on the degree of conversion (weight loss) $\Delta W/W$.[197]

The low activation energy for the initial stage is evidently associated with the fact that at this stage weak bonds or defective sites in macromolecules are ruptured. Only after they have been used up does the degradation of the normal strong bonds in the polymer begin. The artificial creation of defects in the polymer by its photolysis or preliminary oxidation can lead to the complete disappearance of the second, slower stage of the process. On the other hand, the formation of a defect-free structure makes the concentration of weak bonds insignificant, which has been achieved in polycaproamide.

4. Characteristics of the Chemical Reaction in the Polymer Matrix

The non-equivalence of the local properties of the environment of the reactive centres and correspondingly their spatially different chemical reactivities are characteristics of polymers as structurally inhomogeneous systems. Chemical reactions therefore occur in the first place in those regions where the conditions are most favourable. As a result, at a certain degree of conversion, the reactions are strongly retarded—the so-called "kinetic arrest of the reaction" is observed. A change of conditions, for example of temperature, leads to the renewal of the reaction. As an example, Fig. 24 illustrates the kinetics of the destruction of macroradicals in polymethacrylic acid under the conditions of a stepwise variation of temperature. The phenomenon of the "kinetic arrest" of the reaction has been observed in a wide variety of processes in solid polymers[178]. Methods have now been developed for the description of processes of this kind with the aid of the so-called polychromatic kinetics[198,199,200]. The variation of the macroscopic concentrations of the reactants is described by an integro-differential equation, which assumes the following form in the case of the simplest unimolecular reaction:

$$\frac{d[A]}{dt} = -\int_0^\infty kA(k)\,dk\,, \qquad (93)$$

where $A(k)$ is the density of the distribution of the concentration of substance A with respect to its reactivity, characterised by the chemical reaction rate constant k. The distribution $A(k)$ varies with time both due to the chemical transformation of substance A, described by Eqn. (93), and due to relaxation and diffusion processes, which alter the local properties of the medium around the reaction centre.

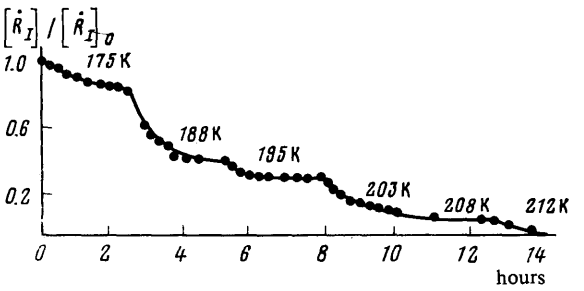

Figure 24. Kinetic curves for the thermal decomposition of central macroradicals in polymethacrylic acid in the temperature range 175–212 K.[221]

At temperatures considerably below the glass point of the polymer the process proceeds, as it were, in microreactors with unaltered local properties. Solution (93) then has the form of an integral Fredholm equation of the first kind:

$$[A] = \int_0^\infty e^{-kt}A(k)\,dk\,. \qquad (94)$$

Thus the kinetic curve for the variation of the concentration of A is a representation (in the sense of a Laplace transformation) of the initial distribution function $A(k)$. The form of the function $A(k)$ can be obtained from the kinetic curve $[A](t)$ by the reverse Laplace transformation.

The principles of polychromatic kinetics made it possible to calculate the distributions of species with respect to rate constants, activation energy, and activation entropy and to establish the fundamental mechanisms of the averaging out of the kinetic non-equivalence of the species and the conditions for the transition from polychromatic to monochromatic kinetics[191].

The kinetics and direction of chemical reactions in solid polymers are influenced significantly by the molecular dynamics and physical structure of the polymer, which occurs as a consequence of a change in the translational diffusion coefficients of the low-molecular-weight reactants or a change in the frequencies and amplitues of the segmental movements of the macromolecules and macroradicals, which influence directly the chemical reaction step itself.

It is well known that mobility influences the kinetics of the destruction of macroradicals in solid polymers—the rate of destruction decreases on transition from the amorphous to the crystalline phase, the rate constant for the destruction in oriented specimens is lower than in non-oriented specimens, the stability of macroradicals increases when the polymer is cross-linked, the rate of destruction of macroradicals in three-dimensional polymers increases with increase in the length of the oligomeric block, etc.

The molecular mobility has been varied[201,202] by altering the external pressure and by introducing into the polymer chemically inert solvents, which induced plasticisation. Under

these conditions, the rate constants for the recombination of radicals in amorphous polymers decreased with increase of pressure at temperatures above T_g. The destruction of peroxy-radicals in polystyrene[203] and polypropylene[204] was accelerated by the addition of small amounts of benzene.

The influence of molecular mobility on the rates of reaction of phenoxy-radicals with polyolefin hydroperoxides[205,206] and of nitroxy-radicals with phenols[207] in solid polyolefins has also been studied. It was found that the rates of these reactions are independent of the nature of the polymer and increase following the addition of aromatic solvents, whose role reduces to increasing molecular mobility. The increase of the rate constants for the above reactions is correlated with the increase of the frequency of rotation of the paramagnetic probe[205,207].

In mechanodegradation the change in the lifetime of the polymers cannot be described by taking into account only the changes in the rate constant for the elementary chemical processes in accordance with the Zhurkov equation

$$k = k_0 e^{-\frac{E-\gamma\sigma}{RT}}, \qquad (95)$$

where E is the activation energy, σ the mechanical stress, and γ a proportionality coefficient. A radical chain mechanism agrees only qualitatively with the experimental results. It has been shown[208,209] (Fig. 25) that mechanical stresses do not exert an appreciable influence on the rate of formation of radicals in chemical or radiation-chemical initiation and hence on the rate of degradation of macromolecules initiated by these radicals. At the same time the lifetime of polymers

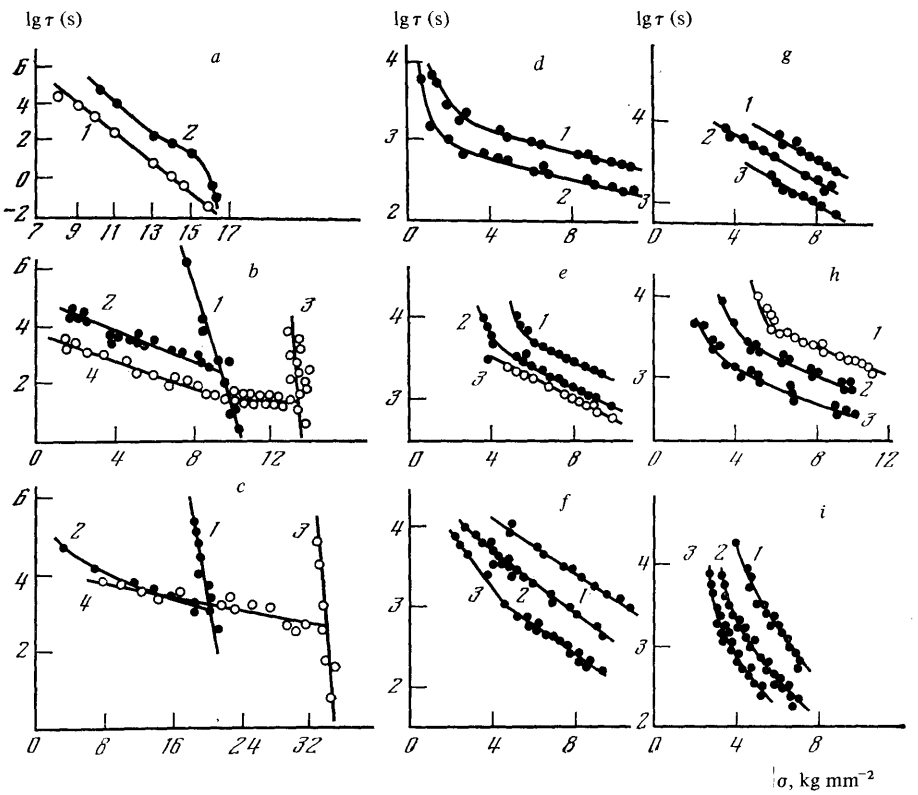

Figure 25. Variation of the lifespan of the polymer (τ) under a mechanical stress (σ) due to the introduction of an inhibitor (*a*) [222] and initiators (*b*–*i*) [209] of radical reactions: *a*: 1) pure nitrocellulose; 2) nitrocellulose with added 0.3% of the 4-ethyl-4-hydroxy-2,2,6,6-tetramethylpiperdin-1-yloxy-radical; *b*) 1,2-polycarbonate and 3,4[sic]-triacetylcellulose containing added $FeCl_3$, without (curves *1* and *3*) and with (curve *2*) photolysis of the additive; *c*) 1,2-poly(ethylene terephthalate) and 3,4-polycaproamide containing added $FeCl_3$, without (curves *1* and *2*) and with (curve *3*) photolysis of the additive; *d*) photodecomposition of triacetylcellulose without additives [1) 314 K; 2) 360 K; unfiltered light of DRSh-500 lamp; $I = 1.6 \times 10^{21}$ m^{-2} s^{-1}]; *e*) photodecomposition of triacetylcellulose with 0.6 wt.% of naphthalene [1) 286 K; 2) 301 K; 3) 323 K; nitrogen; $I = 2.6 \times 10^{21}$ m^{-2} s^{-1}; $\lambda > 300$ nm]; *f*) photodecomposition of triacetylcellulose with 9.1 wt.% of benzoyl peroxide [1) 303 K; 2) 325 K; 3) 348 K; air; $I = 0.4 \times 10^{21}$ m^{-2} s^{-1}; $\lambda > 300$ nm]; *g*) photodecomposition of triacetylcellulose with 0.16 wt.% of $HFeCl_4$ [1) 293 K, air depleted in oxygen; 2) 293 K; 3) 308 K; air; $I = 0.6 \times 10^{20}$ m^{-2} s^{-1}; $\lambda > 340$ nm]; *h*) photodecomposition of triacetylcellulose with 1.1 wt.% of naphthalene [1) 304 K; 2) 329 K; 3) 360 K; air; $I = 1.6 \times 10^{21}$ m^{-2} s^{-1}; $\lambda > 300$ nm]; *i*) thermal decomposition of triacetylcellulose with 9.1 wt.% of benzoyl peroxide [1) 378 K; 2) 388 K; 3) 393 K; air].

diminishes with increasing stress, i.e. a smaller number of breaks in macromolecules becomes sufficient for their decomposition. The breakdown of the specimen is not therefore related to the occurrence of a critical number of breaks, as suggested previously. The decomposition of the polymer is determined not only by the kinetics of its chemical degradation but also by the kinetics of the physical relaxation processes as a result of which the structure of the polymer changes after the breaks in the molecules.

5. Relation Between Practically Important Properties of the Polymers and the Kinetics of Ageing

Knowledge of the kinetics of the changes in their physicomechanical characteristics, for example, the relative elongation on rupture, the ultimate tensile strength, etc., is important in the practical utilisation of polymeric materials. The determination of the detailed ageing mechanism made it possible to relate the changes in these properties under various operating conditions for the polymers to the kinetic characteristics of their ageing. In particular, this relation has been established for the photo-oxidation of polypropylene[210].

Fig. 26 presents kinetic curves for the variation of the relative elongation in the photo-oxidation of various specimens of polypropylene (PP) under the influence of light of different intensity and spectral composition. Despite the fact that the curves have different shapes, they can be made to coincide when the number of breaks in the macromolecular chain Ω during the process time is plotted along the abscissa axis.

The number of breaks is defined as the sum of steps involving the photodecomposition of branching products—hydroperoxides and carbonyl compounds:

$$\Omega = \int_0^t (\alpha [\text{ПООН}] + \alpha' [\text{C=O}])\, dt \ . \qquad (96)$$

Thus the dynamics of the variation of the physicomechanical properties of the polymer is related to the kinetics of the chemical ageing process and calculations can be made on the latter using measurements of its kinetic characteristics.

6. Fundamental Principles of the Stabilisation of Polymeric Materials

The known methods of stabilising polymeric materials can be classified in terms of the stage of the ageing process on which they act. A large group of stabilisers comprises substances which decrease the probability of the formation of active centres at the initiation stage. They include agents quenching excited states ("quenchers")—substances which react with admixtures catalysing the decomposition of polymers. Stabilisers which deactivate chemically active reaction products, for example, substances which decompose hydroperoxides, are particularly important.

The stabiliser influencing the propagation stage of the ageing process, for example, the oxidation chain propagation stage, include substances which prevent the penetration of oxygen into the polymeric material or lower its concentration in the material.

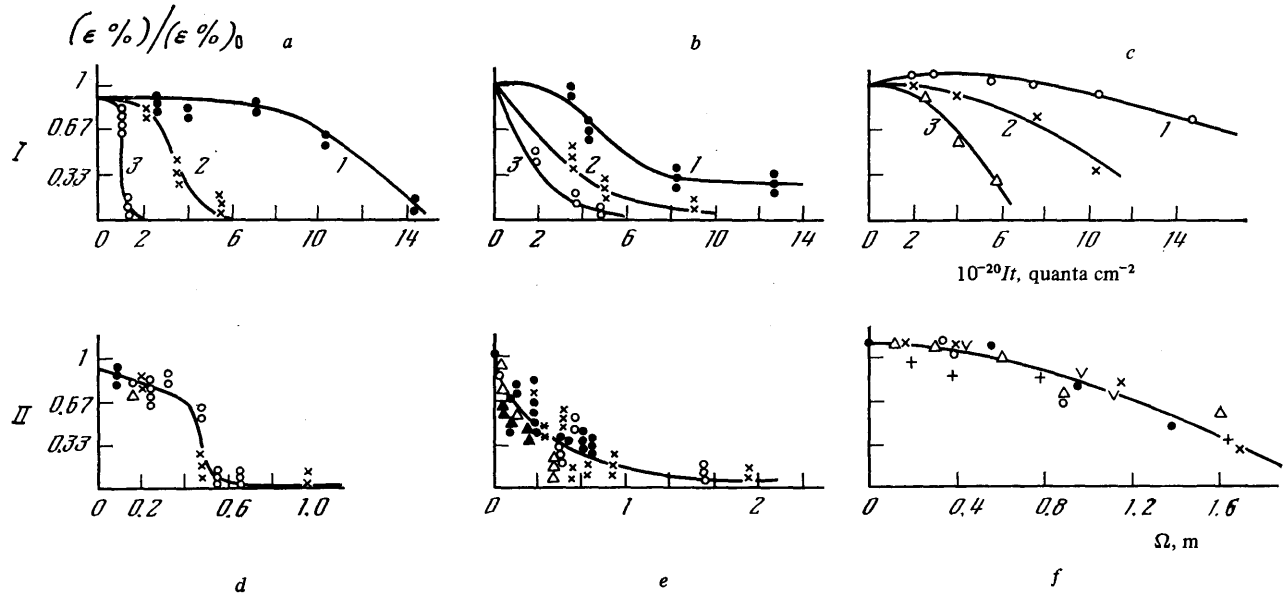

Figure 26. Variation of the relative elongation on rupture in the course of the photo-oxidation of polypropylene: *a*)–*c*) dependence on the amount of light with λ = 254 nm incident on the specimen [light intensity (10^{-15} *I*, quanta cm^{-2} s^{-1}): 1) 4; 2) 0.7; 3) 0.24]; *d*)–*f*) dependence on the number of breaks in the macromolecules of the specimen in a given time; *a*) and *d*) isotropic specimen; *b*) and *e*) oriented annealed specimen; *c*) and *f*) oriented specimen (950%).[178]

The class of stabilisers accelerating the stage involving the destruction of active centres, for example, the acceptors of free radicals or the inhibitors of free radical processes InH, is most widely used in practice and has been most thoroughly investigated. The mechanism of the action of such substances and the criteria used to estimate their efficiency were examined in detail above (Section II, 7). As in the liquid-phase oxidation of hydrocarbons, critical inhibitor concentrations have been observed in the oxidation of polymers, above which the inhibition period of the oxidative degradation increases sharply. A synergistic effect, arising when various stabilising compositions are used, has also been observed[211-213].

The kinetic characteristics are usually determined at comparatively low stabiliser concentrations. The region of extensive inhibition of autoxidation at sufficiently high concentrations (much higher than the critical concentration), usually employed under technological conditions, is of practical interest. Kinetic analysis is significantly simplified under these conditions by the fact that the quasi-stationary principle becomes applicable not only to free radicals but also to the branching product—the hydroperoxide. For example, the mechanism of the inhibited oxidation by sterically hindered phenols can be described as follows[214]:

$$\text{initiation} \xrightarrow{+O_2,\ w_0} R\dot{O}_2\ ,$$
$$R\dot{O}_2 + RH \xrightarrow{+O_2;\ k_2} ROOH + \dot{R}\ ,$$
$$ROOH \xrightarrow{+O_2;\ k_3} 2f R\dot{O}_2 + \text{product},$$
$$R\dot{O}_2 + PhOH \xrightarrow{k_7} ROOH + Ph\dot{O}\ ,$$
$$R\dot{O}_2 + Ph\dot{O} \xrightarrow{k_8} QP\ (\text{quinolide peroxides}),$$
$$Ph\dot{O} + Ph\dot{O} \xrightarrow{k_9} PhOH + \text{products},$$
$$QP \xrightarrow{+O_2,\ k_{11}} 2\delta R\dot{O}_2 + \text{products}.$$

In the presence of the effective antioxidant used in practice, the contribution of the remaining reactions is usually small.

Table 9 presents analytical expressions for the induction period τ, the critical concentration $[PhOH]_{cr}$, and the rate of consumption w_{PhOH} of the inhibitors—phenols of two types: (I) k_9 is small and the radicals $Ph\dot{O}$ are destroyed only via reaction (8); (II) k_9 is large and the radicals $Ph\dot{O}$ are destroyed only via reaction (9). Evidently the characteristics of the antioxidant activity (τ and w_{PhOH}) under the conditions used depend little on the antiradical activity of the inhibitors (on the constant k_7) and are largely determined by the constant for the interaction of the inhibitor radicals k_9 and the probability of the emergence of radicals from the cage in the decomposition of hydroperoxides (f) and quinolide peroxides (δ). In solid polymers f and δ are relatively low, which is consistent with the high antioxidant activity of the inhibitor. On passing to a melt, the antioxidant activity diminishes owing to the increase of f and δ, which is sometimes formally interpreted as a result of the additional formation of free radicals by inhibitor molecules.

In practice it is important to obtain from standard tests on stabilisers information necessary for predicting their effectiveness under the operating conditions. As mentioned above, on passing from the liquid phase to a solid polymer, the reactivity of stabilisers levels off. The relative reactivities of the species in the solid polymer (k_S) and in the liquid phase (k_L) are linked by the relation[215]

$$\frac{(k_1)_S}{(k_2)_S} = \left[\frac{(k_1)_L}{(k_2)_L}\right]^{1/2}. \qquad (97)$$

Eqn.(97) makes it possible to select stabilisers for polymeric materials (antioxidants, quenchers) on the basis of much less laborious experiments, carried out in model liquid-phase systems.

The influence of molecular physics on the chemical reactions in polymers leads to the discovery of new physical principles of the stabilisation of polymeric materials by specific structural-physical modification of the material (deformation, stress, orientation, isotropic compression, regulation of the supermolecular structure and morphology, etc.). For example, the rate of formation of the branching product (the hydroperoxide) diminishes in oriented polyolefins, which leads to an increase of the thermal stability of the oriented filaments compared with isotropic films[216]. There are many factors governing the stabilisation and the increase of the strength and lifetime of polymeric materials as a result of their structural-physical modification[191].

Table 9. Characteristics of the antioxidant activity of stabilisers under the conditions of extensive inhibition of oxidation[214]*.

Parameter	Type of phenol	
	I	II
$[PhOH]_{cr}$	$\frac{fk_2[RH]}{(1-f-\delta)k_7}$	$\frac{2fk_2[RH]}{(1-2f)k_7}$
τ	$\frac{2(1-f-\delta)(\gamma-1)^2[PhOH]}{\gamma^2 w_0}$	$\frac{2(1-2f)(\gamma-1)^2[PhOH]}{\gamma^{*2} w_0}$
w_{PhOH}	$\frac{w_0}{2(1-bf-\delta)}$	$\frac{w_0}{2(1-2bf)}$

*Here $b = 1 + \frac{k_2[RH]}{k_7[PhOH]}$; $\gamma = [PhOH]/[PhOH]_{cr}$.

7. Special Procedures for the Stabilisation of Polymers

Many stabilisers cannot be used at sufficiently high concentrations for a variety of reasons. In particular, some of them impart an undesirable colour to the polymeric material. Thermal stabilisers can be effective photosensitisers. The free radicals formed from stabiliser molecules in some cases enter into reactions promoting the decomposition of the polymer. Furthermore, the stabiliser can be consumed in useless side processes.

It is therefore desirable to produce stabilising compositions in such a way that the effective inhibitor acts in accordance with the *in statu nascendi* principle, i.e. in such a way that its main bulk is in a bound state, in a kind of "depot", and the active form of the stabiliser is released by it gradually or when necessary.

A quantitative criterion of the efficiency of the action of the inhibitor is *in statu nascendi* can be formed by analysing a simplified kinetic mechanism of the action of such an inhibitor on an initiated chain process.

$\xrightarrow{w_i} \dot{r}$—initiation of the formation of the active radical;

$Z \xrightarrow{k} \dot{R}$—the formation from the "depot" of the active form of the inhibitor $\dot{R}$, which behaves as a stabiliser (for simplicity, the stabiliser in a radical form is considered);

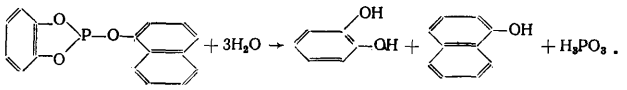
$\dot{R} + \dot{r} \xrightarrow{k_7}$—inhibition reaction;

$\dot{R} \xrightarrow{k_{10}} \dot{r}$—the generation of the active centre by a reaction involving the inhibitor.

The effectiveness of the stabilisation is characterised by the ratio of the rate of initiation to the rate of consumption of the active form of the inhibitor (for $k_{10} \gg k$):

$$\Psi = \frac{w_i}{\mathrm{d}[\dot{R}]/\mathrm{d}t} \cong \frac{w_i}{k[Z]} . \quad (98)$$

If the inhibitor is introduced into the system at the initial instant at a concentration $[Z]_0$, the efficiency of its action is determined by the expression



$$\Psi_0 = \frac{w_i}{w_i + 2k_{10}[Z]_0} . \quad (99)$$

Since $k_{10} \gg k$ by hypothesis, it follows that $\Psi > \Psi_0$. The ratio $\Psi/\Psi_0 = Q$ can serve as a criterion of the efficiency of the action of the inhibitor *in statu nascendi*:

$$Q = \frac{\Psi}{\Psi_0} = \frac{w_i + 2k_{10}[Z]_0}{k[Z]_0} \simeq \frac{2k_{10}}{k} . \quad (100)$$

Sterically hindered piperidines protect polymers from the action of light by the "depot" mechanism[217]. The mechanism of the light stabilisation of polymers by sterically hindered piperidines is more complex than that considered above. The piperidines themselves are not stabilisers but are converted under the influence of radiation into a mixture of nitroxy-radicals and other compounds which act as inhibitors.

Phosphorus acid esters, whose hydrolysis gives rise to the corresponding phenols or catechols, also function as a "depot":[218]

Clathrate compounds, from which the stabiliser is liberated on thermal decomposition and photodecomposition, can apparently also act via the "depot" mechanism.

Not only compounds from which the stabiliser is synthesised in the course of ageing but also the diffusion of the stabiliser to the degradation zone from another, undecomposed part of the polymer can be used as a stabiliser "depot". The diffusion phenomenon has been recently observed in the study of the photo-oxidation of polybutadiene films[219,220]. In the presence of an ultraviolet absorber light does not penetrate into the bulk of the polymer specimen. Photo-oxidation takes place only in the surface layer, which results in the consumption of the antioxidant (A). A concentration gradient of A is produced and the antioxidant diffuses from the bulk of the polymer to the surface layer. Since the deep layers serve as a source of inhibitor, thick specimens are oxidised more slowly than thin ones. It has recently been shown that this phenomenon is the main cause of the synergism observed in the stabilisation of polymers by mixtures of u.v. absorbers (UVA) and antioxidants, which interact with free radicals[219] or decompose hydroperoxides[220].

In the diffusion mechanism the synergistic effect depends on the ratio of the rates of reaction (w_r) and diffusion (w_d). For $w_r \gg w_d$, there is insufficient time for the diffusion of antioxidants to affect the process and synergism is not observed. The maximum effect can be obtained for the opposite condition: $w_d \gg w_r$. Here the entire oxidant is consumed in the inhibition of the photo-oxidation process in the photoreaction zone and the oxidation induction period is $\tau = \tau_0(L/l)$, where τ_0 is the induction period for $w_r \gg w_d$ and l and L are the thicknesses of the photoreaction zone and of the polymer films respectively.

The ideas developed concerning the mechanism of the synergism have created a scientific basis for the selection of effective synergistic mixtures which protect polymers from light-induced ageing, taking into account the properties of the polymer and the stabilisers, as well as the operating conditions. Within the framework of the mechanism examined, the requirements for the thickness of the specimens and for conditions under which accelerated tests of the light stability of polymers stabilised by synergistic mixtures must be performed also become understandable.

IV. KINETICS OF THE BIOLOGICAL PROCESSES

The living organisn is regarded as the most complex system of coupled chemical reactions under the influence and with participation of a multiplicity of chemical and physical factors, which initiate, catalyse, inhibit, and regulate these processes. This is responsible for the possibility of employing in biological and medical research methods and ideas characteristic of chemistry, physics, and mathematics.

Kinetic studies in biology permit quantitative estimates of the rate of propagation of the most important biological processes and of the influence on the latter by various factors as well as the establishment of quantitative criteria for the estimation of the efficiency of such influences. The mathematical description of the kinetics then involves a series of parameters which can be used to model the processes investigated and to analyse them using modern computer techniques.

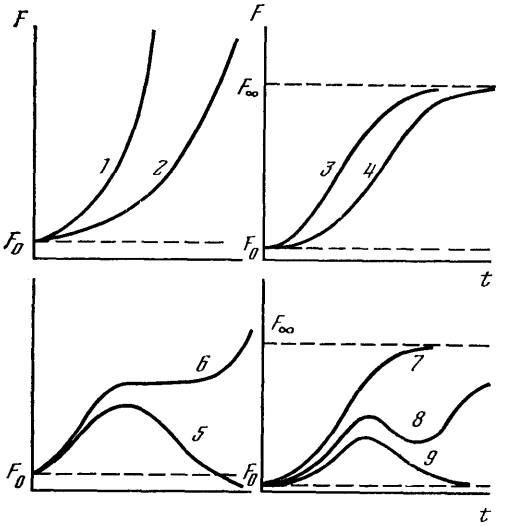


Figure 27. Plots of the functions used to described the kinetics of tumour growth. The analytical forms of the curves are presented in Table 10.[226]

Extensive kinetic studies on many pathological processes and phenomena—carcinogenesis, malignant growth, radiation damage, as well as the ageing of the living organisms—are being prosecuted at the present time[223–226]. The broad principles of the kinetic approach to the study of biological objects can be examined in relation to experimental tumour processes[226].

1. Kinetics of Tumour Growth

The differential equation for the growth of a tumour can be formulated as follows:

$$\frac{1}{F}\frac{dF}{dt} = \varphi(t) \quad , \qquad (101)$$

where $\phi(t) = \phi_1(t) - \phi_2(t)$ and F is the volume, diameter, or weight of the tumour, the number of tumour cells, or any other quantity characterising the growth of the tumour. The quantity $(1/F)(dF/dt)$ is the specific rate of growth, $\phi_1(t) \geq 0$ characterises the overall rate of multiplication of the cells, and $\phi_2(t) \geq 0$ characterises the overall rate of their destruction. The function $\phi(t)$ can be both positive and negative.

The overall form of the solution of the differential equation (101) is given by the expression

$$F = F_0 e^{\int \varphi(t)dt} \quad . \qquad (102)$$

Different deterministic models of the growth of a tumour can be reduced to the selection of the corresponding functions $\phi(t)$. Fig. 27 illustrates schematically the types of kinetic curves corresponding to the model functions frequently employed. Table 10 presents the corresponding kinetic equations. After the selection of the most suitable functions approximating the experimental data, regression analysis is carried out by standard methods. A linearising transformation is usually performed for the function F, which simplifies the calculation of the kinetic parameters.

Table 10. Functions used to describe the kinetics of tumour growth.

Name of function	Type of $\varphi(t)$	Differential equation*	No. of curve in Fig. 27
Exponential	$\varphi = \text{const}$	$F = F_0 e^{\varphi t}$	1
Exponential with a constant term	$\varphi = \frac{1}{1/a + c \cdot e^{-at}}$	$F = F_0 e^{at} + F_1$	—
Power	$\varphi = \frac{b}{t+a}$	$F = F_0 \left(1 + \frac{t}{a}\right)^b$	2
" "	$\varphi = \frac{b}{t+a} - c$	$F = F_0 \left(1 - \frac{t}{a}\right)^b e^{-ct}$	—
Gompertz function	$\varphi = ae^{-bt}$	$F = F_\infty \exp\left\{-\frac{a}{b} e^{-bt}\right\}$	3
Logistic function	$\varphi = \frac{b}{1 + e^{bt/a}}$	$F = \frac{F_\infty}{1 + ae^{-bt}}$	4
Bertalanphi function	$\varphi = \frac{be^{-bt}}{1/a - e^{-bt}}$	$F = F_\infty (1 - ae^{-bt})$	—
Polynomial function	$\varphi = \varphi_0 + \varphi_1 t + \cdots + \varphi_s t^s$	$F = F_0 \exp\left\{\varphi_0 t + \frac{1}{2}\varphi_1 t_2 + \cdots + \frac{1}{s+1}\varphi_s t^{s+1}\right\}$	5, 6
Asymmetric polynomial exponential function	$\varphi = (a_0 + a_1 t + \cdots + a_s t^s) e^{-bt}$	$F = a \exp\{[c_0 + c_1 t + \cdots + c_s t^s] e^{-bt}\}$	7, 8, 9

*Here a, b, and c are constants.

Extensive experimental data on the kinetics of the growth of tumours have now accumulated [226]. More than 60 experimental strains of solid and ascites transplantable and spontaneous animal tumours and leukaemias have been investigated. The equations presented above are used for a formal kinetic description of the development of these malignant processes.

An exponential relation is fairly frequently used both in experimental studies and for the analysis of the growth of human tumours. Fig. 28*A* presents generalised kinetic curves for exponentially growing animal tumours in terms of the dimensionless coordinates $\eta = e^{\theta}$, where $\eta = F/F_0$ and $\theta = \phi t$.

In principle, the most general type of kinetic curve is an S-shaped curve, because it is natural to expect that F tends to a limiting value in the course of the growth of the tumour by virtue of the characteristics of the development of tumours in the organism. In those cases where a logistic function of the type $F = F_\infty/(1 + ae^{-bt})$ is applicable to the description of the kinetics of the growth of such tumours, it is possible to construct a generalised plot in terms of the variables of the equation $\eta = 1/(1 + e^{\theta})$, where $\eta = F/F_\infty$ and $\theta = \ln a = bt$ (Fig. 28*B*).

For a comparative analysis of the rates of growth of different experimental tumours, one can use the maximum specific rate of growth ϕ_{max}. [226] For tumours growing exponentially, $\phi_{max} = \phi$.

Analysis of the distribution of 62 experimental tumours with respect to ϕ_{max} showed that the cumulan of the distribution in the range from $\phi_{max} = 0$ to 0.7 day^{-1} is linear, i.e. that the distribution of ϕ_{max} in this range is virtually uniform. From this it follows that tumours can apparently exist with arbitrarily small specific rates of growth. Approximately 80% of the tumours examined in terms of their values of ϕ_{max} fall within this linear range. There are many fewer tumours for which $\phi_{max} > 0.8$ day^{-1}.

2. Kinetic Criteria for the Estimation of the Effictiveness of Antitumour Preparations

The study of the kinetics of the development of tumour processes has made it possible to develop a series of criteria of the effectiveness of a particular therapeutic agent. For this purpose, it is necessary to compare control and experimental kinetic curves.

In the simplest case where tumour growth takes place exponentially both in the control,

$$F_c = F_0 e^{\varphi_c t} \qquad (103)$$

and in the experiment,

$$F_e = F_0 e^{\varphi_e t} \quad , \qquad (104)$$

the ratio

$$\varkappa = \varphi_e/\varphi_c \quad , \qquad (105)$$

showing by what factor the rate of development of the experimental process is reduced compared with the control, can be used as a measure of the effectiveness. For exponentially growing tumours, this criterion was introduced in 1962 [227] and was subsequently used in many investigations.

A series of criteria, used independently of the type of kinetic curves for the tumour growth in the control and in the experiment, have also been proposed [226]. In particular the criterion

$$\varkappa_9' = 1 - (\bar{F}_{te}/\bar{F}_{tc})\,100 \quad , \qquad (106)$$

which is called the percentage inhibition, is frequently used in the USSR. Here $\bar{F}_{te}$ is the average experimental value of F and $\bar{F}_{tc}$ is the value for the control.

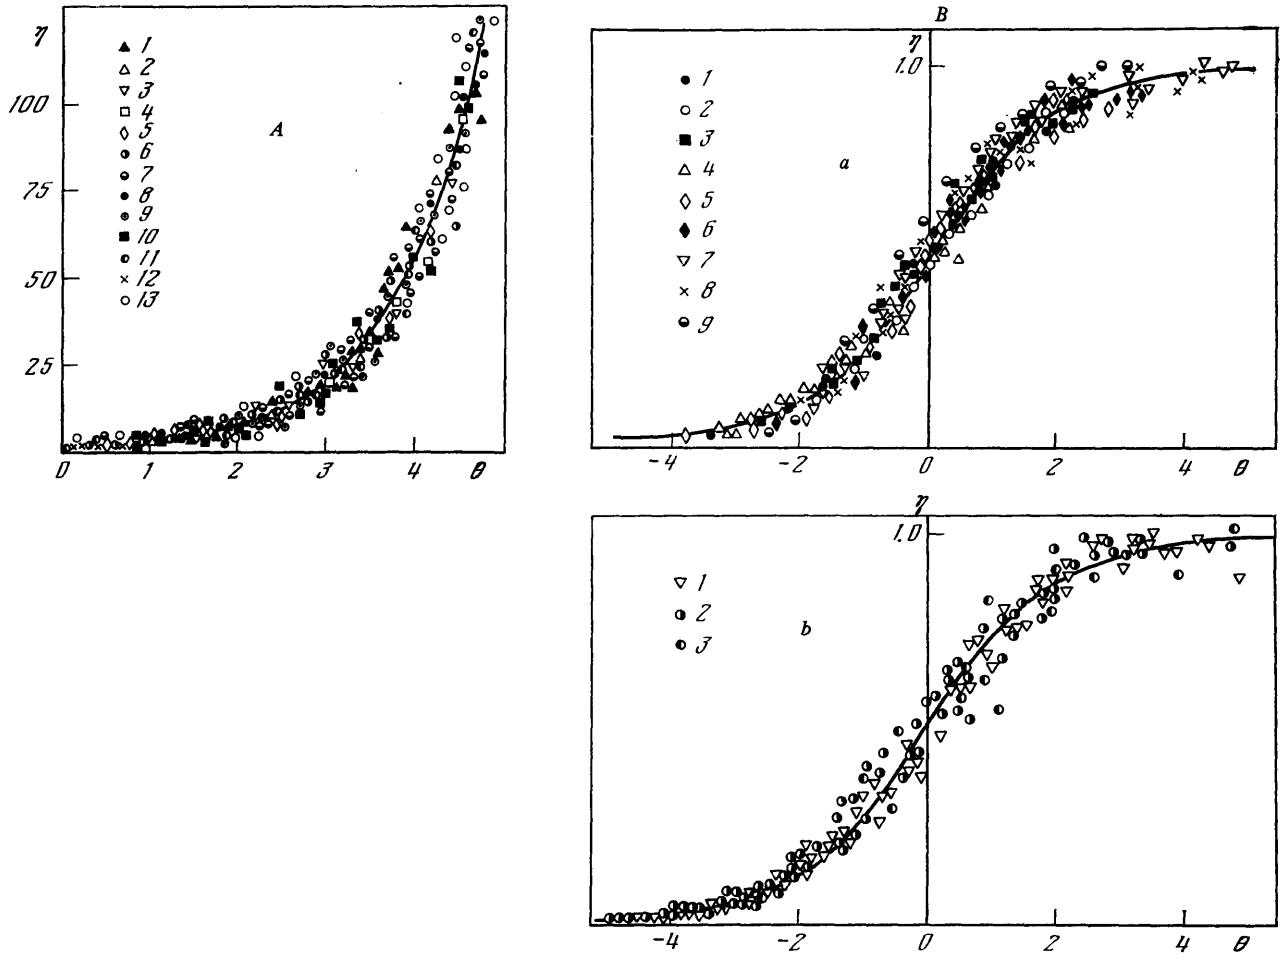

Figure 28. *A*) Generalised kinetic curve for the exponential growth of tumours $\eta = e^{\theta}$ for various types of transplanted tumour processes: 1) tumours in rat skin induced by radiation; 2) adenocarcinoma 755; 3) sarcoma 180; 4) sarcoma CCK; 5) haepatomas; 6) Ehrlich ascites carcinoma; 7) Svec erythromyelosis; 8) Waler carcinosarcoma; 9) reticulosarcomatosis; 10) leukaemia La; 11) leukaemia L-1210; 12) spontaneous leukaemia in mice of AKR strain; 13) leukaemia La; B) generalised S-shaped kinetic curves for the growth of solid (*a*) and ascites (*b*) experimental tumours; *a*: 1) Walker carcinosarcoma; 2) Geren carcinoma; 3) sarcoma 45; 4) adenocarcinoma 755; 5) haepatomas; 6) melanomas; 7) sarcoma 180; 8) other models (osteogenic Ridgeway sarcoma, sarcoma T241, adenocarcinoma EO-771, and carcinoma C1025); 9) Svec erythromyelosis; *b*): 1) sarcoma 180; 2) Ehrlich ascites carcinoma; 3) leukaemia L-1210.[226]

It should be noted that the kinetic criterion κ [Eqn.(105)] for exponentially growing tumours characterises the tumour process much more satisfactorily than the percentage inhibition criterion κ'_9, since κ is the independent of the time of completion of the experiment. The relation between κ and κ'_9 is given by§

$$\kappa_0' = \{1 - \exp[(1-\kappa)\varphi e^{t}]\}1^{0} \quad . \qquad (107)$$

The advantage of the kinetic criterion consists in its high "sensitivity" in the assessment of the most effective preparations. The criterion κ therefore makes it possible to solve one of the main problems of experimental chemotherapy—to establish a relation between the chemical structure and the antitumour activity of the most effective preparations.

§ The numbering of the criteria is based on that in a monograph[226].

Other kinetic criteria, based on the estimation of the average specific rates of tumour growth $\bar{\phi}(t)$, can also be proposed for the estimation of the effectiveness of the antitumour treatment. The average specific rate of growth in the time interval (t_1, t_2) is

$$\bar{\varphi}(t_1, t_2) = \frac{1}{t_2 - t_1}\int_{t_1}^{t_2} \frac{d(\ln F)}{dt}\, dt = \frac{\ln F(t_2) - \ln F(t_1)}{t_2 - t_1} \qquad (108)$$

and, as can be seen from the above equation, depends only on the values of F at the ends of the interval. Thus the quantity $\bar{\phi}(t_1, t_2)$ is equal to the exponent of the "equivalent exponential function", which passes through the ends of the kinetic curve $F(t)$ in the time interval considered.

The ratio of the average specific rates of tumour growth in the control and in the experiment can be adopted as a measure of the effect:

$$\bar{\kappa} = \frac{\bar{\varphi}_c(t_{1c}, t_{2c})}{\bar{\varphi}_e(t_{1e}, t_{2e})} = \frac{t_{2e} - t_{1e}}{t_{2c} - t_{1c}} \cdot \frac{\ln F_c(t_{2c}) - \ln F_c(t_{1c})}{\ln F_e(t_{2e}) - \ln F_e(t_{1e})} \; . \qquad (109)$$

It is natural to adopt the instant t_1 when the therapeutic action begins as the common starting point for reckoning the time intervals (t_{1c}, t_{2c}) and (t_{1e}, t_{2e}) for the averaging. The ends of the time intervals can be chosen in different ways: (a) the ends of the average kinetic curves for tumour growth t_f are adopted as the ends of the time intervals for the averaging, whereupon

$$\bar{\varkappa}_{10} = \frac{\bar{\varphi}_c(t_1, t_{fc})}{\bar{\varphi}_e(t_1, t_{fe})} = \frac{t_{fe} - t_1}{t_{fc} - t_1} \cdot \frac{\ln F_c(t_{fc}) - \ln F_c(t_1)}{\ln F_e(t_{fe}) - \ln F_e(t_1)}\ ; \qquad (110)$$

(b) any instant t_2 at which both kinetic curves to be compared exist can be selected as the common end of the time intervals for the averaging. In this case

$$\bar{\varkappa}_{11} = \frac{\bar{\varphi}_c(t_1, t_2)}{\bar{\varphi}_e(t_1, t_2)} = \frac{\ln F_c(t_2) - \ln F_c(t_1)}{\ln F_e(t_2) - \ln F_e(t_1)}\ . \qquad (111)$$

If the development of the tumour processes in the experiment and in the control proceeds in accordance with exponential laws, then

$$\bar{\varphi}_c(t_1, t_{2c}) = \varphi_c;\ \bar{\varphi}_e(t_1, t_{2e}) = \varphi_e \text{ and}$$
$$\bar{\varkappa}_{10} = \bar{\varkappa}_{11} = \frac{\varphi_c}{\varphi_e} = \varkappa,$$

i.e. the criterion derived previously is obtained.

The fact that the quantities κ_{10} and κ_{11} become infinite following the complete inhibition of tumour growth (at $\bar{\phi} = 0$) constitutes a definite disadvantage (Fig. 29*a*). It is therefore more convenient to employ modified criteria κ^*_{10} and κ^*_{11} which are free from this disadvantage:

$$\varkappa^*_{10} = 1 - \frac{1}{\varkappa_{10}}, \qquad (112)$$

$$\varkappa^*_{11} = 1 - \frac{1}{\varkappa_{11}}\ . \qquad (113)$$

Since both modified criteria are linear functions of the average specific rate of tumour growth in the experiment, i.e.

$$\varkappa^*_{10(11)} = 1 - \frac{1}{\varphi_c}\varphi_e, \qquad (114)$$

the value $\kappa_{10} = \kappa_{11} = 0$ corresponds to the absence of an effect, positive values of κ_{10} and κ_{11} correspond to effective treatment (inhibition of tumour growth), and negative values correspond to treatment stimulating tumour growth (Fig. 29*b*).

The kinetic criterion κ proposed at the Institute of Chemical Physics of the USSR Academy of Sciences in 1962 has been used to investigate the antitumour effectiveness of a large number of chemical compounds of different classes, which made it possible to discover four new highly active preparations: 2,6-di-t-butyl-4-methylphenol (ionol or dibunol), nitrosomethylurea (NMU),[230,231] 1,2-bisdiazoacetylethane (diazan),[232] and PAT-1, a paramagnetic analogue of Thio TEPA.[233] Fig. 30 illustrates the antitumour effectiveness of a series of preparations in relation to the experimental leukaemia La in mice. Under the same "dibunol", ionol is nowadays used in clinical practice in the treatment of the cancer of the bladder and radiation cystitis in man[234] and NMU is used in the treatment of the undifferentiated cancer of the lung, lymphogranulomatosis, and melanoma[231–235].

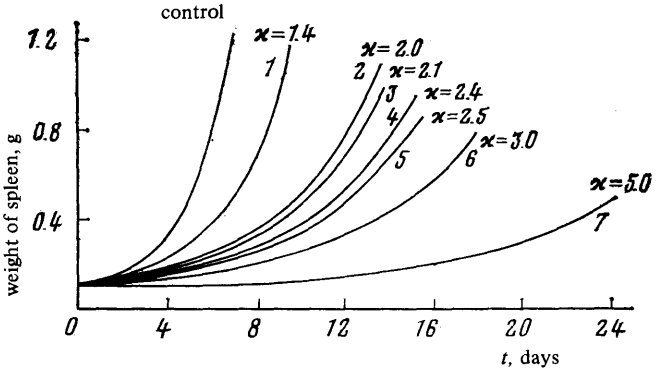

Figure 30. Inhibition of the growth of leukaemia La in mice under the influence of various chemotherapeutic preparations: 1) thiophosphamide, carminomicin; 6) mercapturopurine; 2) sarcolysine; rubomycin; 3) HMM; 4) dibunol, cyclophosphane; 6) PCNU [1-(2-chloroethyl)-3-(2,6-dioxo-3-piperidinyl)-1-nitrosylurea]; 7) diazan.

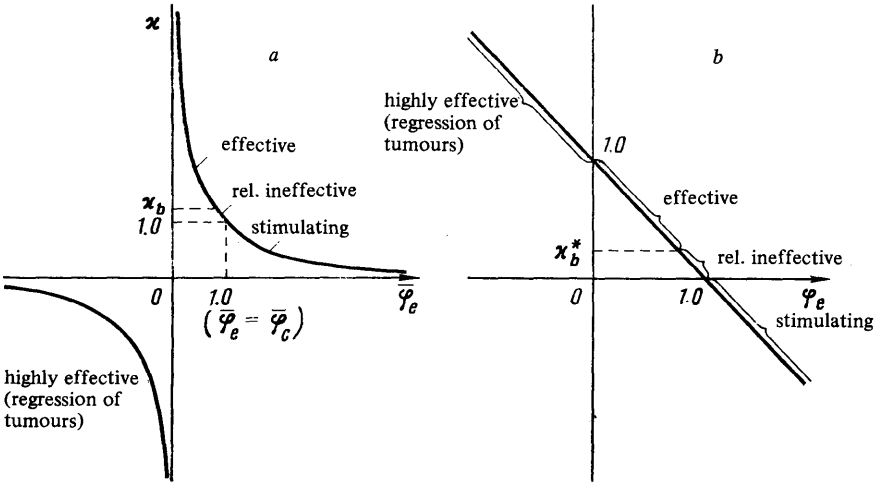

Figure 29. The regions in which therapeutic treatments are effective; $\kappa_b = 1.25$ and $\kappa^*_b = 0.2$ are conventional quantities separating relatively ineffective and effective treatments[226].

The development of kinetic approaches to the description of tumour growth processes in chemotherapeutic treatment is closely related to the problem of the pharmacokinetics of antitumour agents. The parameters of the pharmacokinetic equations are quantitative characteristics of processes involving the entry, distribution, transformation in the organism, and secretion of substances and their estimation makes it possible to relate the intensity of the therapeutic effects to the active concentration of the active forms of the preparation and not to the dose. This permits rational planning of chemotherapeutic regimes[236,237].

3. Kinetics of the Survival of Patients and the Effectiveness of Chemotherapy

The most important and most evident index of the effectiveness of the treatment of malignant tumours is the survival time of the patients. The survival time is a random quantity the statistical characteristics of which are determined by the type and stage of the development of the tumour, the theropeutic regime, and other factors.

Survival can be regarded as the kinetics of the change in the number of living patients determined by the distribution of the survival time in the initial group. The view that survival is a kinetic process makes it possible to apply to it standard mathematical methods adopted in kinetic studies and to obtain a complete quantitative description of survival with the aid of a small number of parameters having a definite physical significance. This is an advantage of the kinetic method over the traditional statistical method in which the percentage survival of patients is estimated solely in relation to a single specific time (for example, the five year survival)[238].

As a result of systematic studies on the kinetics of the survival of patients subjected to radical operations and untreated patients with malignant tumours in different locations, based on observations on several tens of thousands of patients, it has been established that the entire wide variety of forms of kinetic survival curves can be satisfactorily fitted by a small number of simple analytical relations.

If the factual data permit a detailed analysis of the survival curve, it is found that it is as a rule S-shaped. This is due to the unimodality of the corresponding distribution density $f(x)$ of the survival time, since the kinetics of the change in the fraction of surviving patients $P(t)$ are determined by integrating this density:

$$P(t) = \int_t^\infty f(x)\,dt \quad . \tag{115}$$

It has been shown that in many cases this distribution is of the lognormal type[238]:

$$f(x) = \frac{1}{x\sigma\sqrt{2\pi}} \exp\left[-\frac{(\ln x - m)^2}{2\sigma}\right], \quad x > 0 \quad , \tag{116}$$

so that the survival function is

$$P(t) = \frac{1}{\sqrt{2\pi}} \int_{\frac{1}{\sigma}\ln\frac{t}{T}}^{\infty} e^{-x^2/2}\,dx \quad , \tag{117}$$

where T is the median of the survival and σ^2 is the variance. The survival of patients suffering from cancer of the stomach, the mammary gland, the neck of the uterus, the lung, the mouth and the pharynx, and the tongue, as well as bone tumours can be described in terms of this relation.

In cases where clinical data are insufficiently detailed, it is useful to use a simpler one-parameter family of functions. Families of exponential and hyperbolic functions have been used for this purpose. In the first case the survival function is of the form $P(t) = e^{-kt}$ and describes, for example, the survival of patients with cancer of the stomach. In the second case the survival function is of the form $P(t) = 1/(a + kt)$; this case refers to cancer of the lung, the mammary gland, the rectum, the kidney, and the bladder.

It was shown that each location of the tumour is characterised by its own type of kinetic survival curve, which is the same for different hospitals and different times and is determined solely by the type of tumour[238]. This makes it possible to compare the effectiveness of different methods of treatment by comparing the different kinetic parameters.

Analysis of the influence of various clinical-morphological factors on the parameters of kinetic survival curves established that, for each type of tumour, the spread (stage) of the tumour process at the instant of diagnosis or the beginning of treatment plays the main role. The remaining factors such as sex, age, histological structure of the tumour, etc. are secondary.

The parameters of the functional relations for survival can be estimated along a comparatively short section of the kinetic curve, for example from data for the first 2–3 years of observation on patients subjected to a radical treatment or the first 3–6 months for non-operable patients. Knowing these survival constants, it is possible in its turn to extrapolate the kinetic curve to longer times and thus obtain a prognosis of survival at any time. Such prognosis is extremely important for practical medicine, since it makes it possible to accelerate the assessment of the effectiveness of new methods of treatment of malignant tumours. The observed 5–10 year survival of patients subjected to radical operations for cancer of the stomach, the lung, the mammary gland, the rectum and the large intestine, the kidney, and the bladder hardly differs from the calculated values obtained from data for 2–3 year survival.

The availability of stable kinetics relations for each type of tumour makes it possible to apply standard statistical procedures and to obtain estimates of the parameters for the general set of survival data for patients with tumours of a particular type. The analytical relations used to describe the factual data can be linearised in terms of appropriate coordinates and their parameters can be estimated by the method of linear regression. Such estimates have been obtained for patients who have undergone a radical operation for cancer of the stomach, the lung, the mammary gland, the bladder, and the rectum and for non-operable patients with cancer of the stomach and the lung[238].

These results have served as a theoretical and methodological basis for the development of a kinetic method for comparative estimates of the effectiveness of treatment in which the enormous amount of information accumulated in various clinics in the world is used as the "historical" control. The method makes it possible to abandon the simultaneous establishment of special control groups of patients and significantly accelerates the study of new medicinal compounds and the practical application of the most effective preparations.

As an example of the practical application of this method, Fig. 31 presents survival data from 33 clinics, generalised with the aid of the kinetic method, for patients with inoperable cancer of the lung who had not been subjected to a special treatment ("historical control") and survival data for 168 similar patients receiving chemotherapy. Fig. 31 shows that data for the 3 and 6 months survival of patients for whom a direct improvement was observed after chemotherapy (the majority of the patients were treated with nitrosomethyl-

urea) lie outside the 95% confidence zone of the "control". On the other hand, the survival of patients in which there was no improvement after treatment did not differ from the control. Thus kinetic analysis made it possible to observe that the use of prepations leading to a direct improvement of patients with cancer of the lung reliably increases their survival time, but the improvement is so far restricted to only 6 months.

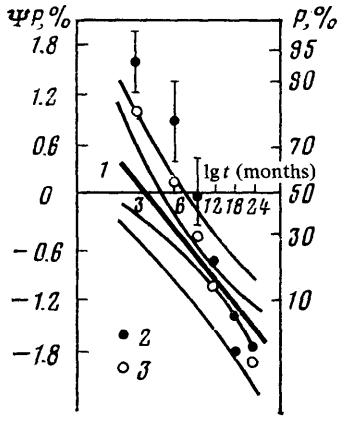

Figure 31. 1) Generalised survival curve for patients with inoperable lung cancer who have not been receiving chemotherapy, calculated from data from 33 clinics by the method of linear equation and transformed into a plot in terms of logarithmic statistical coordinates. The circles denote data for patients receiving chemotherapy: 2) cases involving improvement; 3) remaining cases[240].

The survival of patients is evidently closely related to the nature of the growth of the corresponding type of tumour, so that the study of this relation makes it possible to estimate from survival data parameters of tumour growth which cannot be derived by direct measurements[239].

A mathematical model relating to the survival of patients to the rate of growth of the mass of the tumour has been developed. The following expression has been obtained for the survival time:

$$t_m = \tau\gamma(V_0, V_m) \ , \qquad (118)$$

where τ is the time required for the doubling of the volume of the tumour and γ the coefficient of growth which depends on the nature of the growth of the tumour and on the rate of the initial (V_0) and final (V_m) masses.

The model makes it possible to estimate the mass of the tumour in the organism for different extents of the tumour process. It has been shown, for example, that the organisms of patients subjected to radical operations for cancer of the stomach without regional metastases, who subsequently died from the tumour, contained after the operation on average 10^7–10^8 residual tumour cells, while in non-operable patients there are 10^{11} tumour cells, etc. Such data can probably be used in the planning of the therapy of patients with different extents of the process.

Subject to the condition that the increase in survival as a result of treatment of the tumour (irradiation or chemotherapy) is due to the destruction of a specific proportion of tumour cells, the model makes it possible to estimate this fraction from survival data, i.e. to estimate the factor by which the treatment reduces the mass of the tumour. As an example, Fig. 32 presents kinetic curves for the survival of patients subjected to radical operations for cancer of the lung. For some patients, the treatment was confined to the operation, while others were given an additional chemotherapy with cyclophosphane [data from the Gertsen Moscow Institute of Oncology (MNIOI)]. Evidently the combined treatment led to an improvement of survival.

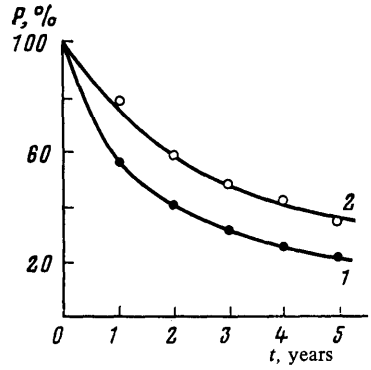

Figure 32. Kinetic survival curves for patients after radical operations for lung cancer; 1) surgical treatment alone; 2) chemotherapeutic treatment after operation [240].

According to the model, the decrease of the mass of the tumour as a result of the additional treatment is defined by the expression

$$\ln\frac{V'}{V} = \gamma\left(1 - \frac{T'}{T}\right) , \qquad (119)$$

where V and V' are the average masses of the tumours in patients belonging to the groups being compared and T and T' are the medians of the survival times of the patients in these groups.

The calculations showed that in the example presented in Fig. 32, the increase of survival was a result of the decrease of the mass of the tumour by a factor of 400 (the average for the group considered). This can be regarded as a quantitative index of the effectiveness of cyclophosphane in the combined treatment of cancer of the lung.

Similar parameters can be used also for comparative estimates of the effectiveness of different preparations.

4. Application of Factorial Analysis in the Quantitative Estimation of the Joint Action of Combined Preparations

The greatest effect in the chemotherapy of cancer is usually attained when two and more antitumour preparations are used. In practice optimum chemotherapeutic regimes are chosen empirically at the present time. The number of possible combinations is then extremely large and it is difficult to count on finding the objectively optimum regime. The possibility of a rigorous determination of the mutual influence of the preparations as a basis for the optimisation of combined chemotherapy then becomes particularly important.

The method of factorial analysis was used for the first time to assess quantitatively the joint action of diazan and cyclophosphamide in the treatment of leukaemia R-388.[232] This made it possible to determine the contribution of each preparation (factor) to the overall final result of the therapy and also to find a quantity characterising the interaction of the factors (λ).

The effectiveness and interaction of the factors can be expressed in an analytical form by the equation

$$\lambda_{k_1 k_2} = \sum_{l=1}^{m} \left\{ (-1)^q \sum_{i=1}^{m} \tau_{ij} \right\}, \qquad (120)$$

where $k_1 = 1, 2, \ldots, l$, $k_2 = 1, 2, \ldots, l$, $q = 1$ or 2, and τ_{ij} is the lifetime of the animal.

The application of factorial analysis led to the discovery of different degrees of therapeutic synergism for identical activity indices of the preparation. In Fig. 33 the experimental results are presented in the form of equieffective curves. A point in the plane represents the results of the combined action of two preparations taken in specific doses. The numerals in the graph represent the activity coefficients. By interpolating the values of the effectiveness on the basis of the experimental points, it is possible to calculate the values for other points and then to plot curves on which each point corresponds to the same effectiveness. Fig. 33 presents equieffective curves of κ ranging from 2 to 6.

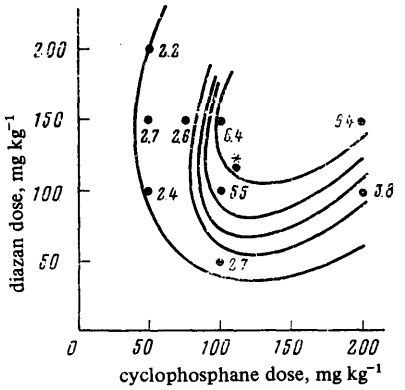

Figure 33. Equieffective curves for the combined treatment with diazan and cyclophosphane calculated for κ ranging from 2 to 6.[240]

The equieffective curves make it possible to determine the region of the maximum effectivness and to estimate the optimum treatment, i.e. to determine the minimum doses of the preparation sufficient to achieve the maximum effect. Evidently the point (represented by an asterisk) at which the diazan dose is 120 mg kg^{-1} and the cyclophosphane dose is 110 mg kg^{-1} corresponds to these conditions. Indeed subsequent experiments showed that the maximum effectiveness of the treatment is then observed.

This approach to the analysis of the results of polychemotherapy leads to the possibility of rigorously justified clinical recommendations and permits the solution of the problem of optimising combined therapy.

5. Classification of Antitumour Preparations in Terms of the Principle of Chemical Reactivity

The synthesis of substances with antitumour properties specified beforehand constitutes an insignificant fraction of the enormous amount of research throughout the world into the synthesis of new chemical compounds. To some extent, this is a consequence of traditional self-limitations, as a result of which the search for new effective antitumour preparations is usually prosecuted within the limits of a few empirically discovered classes of chemical compounds such as alkylating agents, antimetabolites, antibiotics, and hormonal preparations.

In terms of the mechanism of their action, these substances can be divided into two main groups—compounds characteristic of the metabolic processes in normal or tumour cells or derivatives similar to such compounds (biochemically functionally active compounds) and substances for which a purely chemical interaction with the cell molecules plays the main role (chemically functionally active substances).

A condition for the most effective application of the antitumour preparations of both groups is in most cases a natural or artificially created enhanced sensitivity of tumour cells to the action of preparations relative to normal cells.

Biochemically functionally active preparations. Enzymes (L-aspartase and ribonuclease), hormones (cortisone, prednisolone, testosterone, and diethylstilboestrol), certain metabolites from a series of membrane-active regulators of metabolic processes and structural analogues of metabolites—the antimetabolites of nucleic acid exchange (mercaptopurine, thioguanine, 5-fluorouracil, ftorafur, 5-azacytidine, etc.), and antimetabolites of folic acid metabolism (methotrexate and aminopterin) should be included among biochemically functionally active antitumour compounds.

It is possible to discover new effective preparations among biochemically functionally active substances. This is indicated particularly by the unexpectedly successful application in tumour chemotherapy of synthetic analogues of bioantioxidants—ionol, ambunol, etc.

Chemically functionally active compounds. It is known that the total number of specific substances with which chemists have dealt for one reason or another is almost ten million in the field of organic chemistry alone and there are no fundamental difficulties in multiplying this number by a large factor.

The classification of antitumour preparations generally adopted at the present time is based on several different principles: the mechanism of biological action (antimetabolites and hormones), the source (antiobiotics, alkaloids, and enzymes), and chemical properties (alkylating agents). Synthetic preparations the mechanism of whose action has not yet been established constitute a large group, which is not in fact included in the above classification. Such classification of the antitumour preparations is inadequate as a basis for the rational planning of the synthesis of new preparations or for the selection of potential antitumour agents from the enormous number of chemical compounds known at the present time. Furthermore, from a purely chemical standpoint, it is possible to put forward a more systematic classification based on the types of structures and the types of chemical reactivities of these compounds[240]. Indeed they can all be divided into five main groups in terms of their characteristic reactions:

(1) electrophilic reactions;
(2) free-radical reactions;
(3) complex formation reactions;

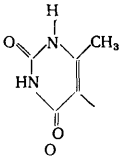
(4) nucleophilic reaction;
(5) cycloaddition.

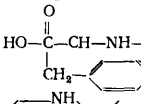
In this section the chemical structures and mechanisms of the action of antitumour agents will be considered from the standpoint of the classification based on this principle.

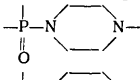
(1) Electrophilic reactions. In the modern arsenal of effective antitumour agents the greatest proportion consists of chemical compounds reacting via the mechanism of electrophilic interactions, which include the formation of electrophilic species (carbonium ions which alkylate or acylate the nucleophilic centres of principal chemical components of the cell).

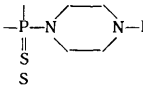
β-Chloroethylamines, β-chloroethyl sulphides, epoxides, aziridines, sulphonate and phosphate esters, halogenomethyl ketones, chloromethyl ethers, ammonium and sulphonium compounds, β-lactones, diazoketones, and nitrosocarbamides behave as alkylating agents *in vivo*.

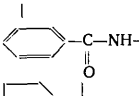
Table 11. Alkylating agents.

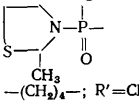


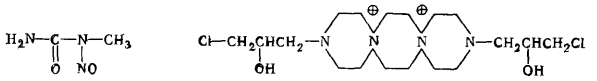


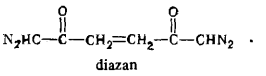












Overall formula	Carbonium ions	Name of preparation	R
$R-N(CH_2CH_2Cl)_2 \rightarrow [R-N(CH_2\overset{\oplus}{C}H_2)(CH_2CH_2Cl)]$		embichin	CH_3-
		chlorobutin	$HO-C(=O)-(CH_2)_3-C_6H_4-$
		sarcolysine	$HO-C(=O)-CH(NH_2)-CH_2-C_6H_4-$
		dopan	
		lofenal	$HO-C(=O)-CH(CH_2-)-NH-C(=O)-CH_2-C_6H_4-$
		cyclophosphane	
		dipin	
		thiodipin	
$R-N(CH_2)_2 \rightarrow [R-NH-CH_2\overset{\oplus}{C}H_2]$		thiophosphamide	$-P(=S)-$
		benzotef	
		imiphos	
$R-S(=O)_2-OCH_2R' \rightarrow [R'-\overset{\oplus}{C}H_2]$		myelosan	$-(CH_2)_4-$; $R'=CH_3$
$R-C(=O)-CHN_2 \rightarrow [R-C(=O)-\overset{\oplus}{C}H_2]$		azaserine	$HOOC-CH(NH_2)-CH_2-O-$
		DON	$HOOC-CH(NH_2)-CH_2-CH_2-$
		diazan	$-CH_2-CH_2-$
		nitroso-methylurea	$-CH_3$
$R'HN-C(=O)-N(NO)-R \rightarrow [R^{\oplus}]$		CCNU	$-CH_2CH_2Cl$; $R' =$ 
		BCNU	$-CH_2CH_2Cl$; $R' = -CH_2CH_2Cl$

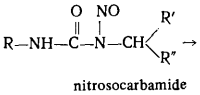


Table 11 presents the structures of the compounds encountered most frequently in practice and of the carbonium ions formed from them. Further progress in the synthesis of antitumour preparations with an alkylating activity is associated with the finding of new types of cytotoxic groups and also with the modification of transport fragments ensuring the selectivity of the action of the preparations. New effective antitumour preparations have been synthesised recently: nitrosomethylurea containing the functionally active nitrosocarbamide group[231], prospidin in which a spiro-heterocycle with quaternary nitrogen atoms serves as the carrier of the bis-β-chloroalkylamino-group[241], and 1,2-bisdiazoacetylethane (diazan) containing two diazoacetyl fragments[226]:

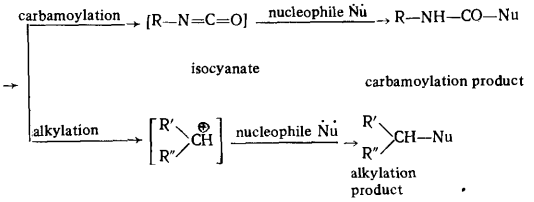
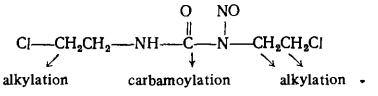


nitrosomethylurea

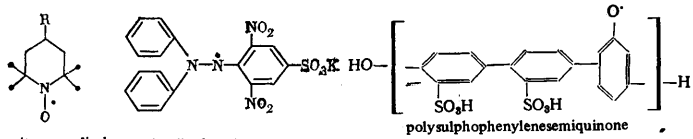
prospidin



diazan

Nitrosomethylurea, proposed in 1964 as an antitumour preparation, and its homologues and analogues exhibit a dual electrophilic reactivity, in contrast to other alkylating agents, involving not only an alkylating activity but also a carbamoylating activity, which is responsible for the characteristics of the mechanism of the biological activity of compounds of this class:

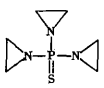
nitrosocarbamide

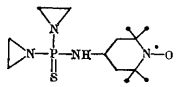


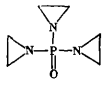
Chloroethylamino-derivatives of nitrosocarbamides contain several reaction centres, in particular the familiar preparation BCNU has a single carbamoylating centre and three different alkylating centres:

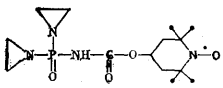
Prospidin also contains two types of alkylating centres—the ammonium and chloroalkyl groups. The ionic centres of spiro-heterocycles ensure the specific binding of the preparation to the chemical components of the cell. Prospidin is used in the treatment of cancer of the larynx, retinoblastomas, papillomatesis of the upper respiratory tract, and Kaposi's angiosarcoma[242].

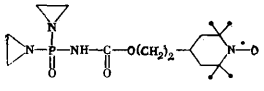
(2) Free-radical reactions. Free-radical reactions constitute an appreciable proportion of the chemical processes occurring in living systems. It is therefore to be expected that compounds capable of being involved in these processes—stable radicals and antiradical agents (inhibitors)—should exhibit a physiological activity.











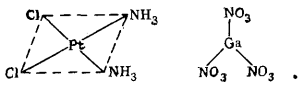
The antitumour effect of stable free radicals was first observed by ourselves in 1964 for nitroxy-radicals and triarylhydrazyls[243] and then for polysulphophenylenesemiquinone[244]:

The radiosensitising effect of nitroxy-radicals has also been demonstrated[225].

The use of stable radicals for the structural modification of certain known antitumour preparations is extremely promising. The paramagnetic derivatives of thiophosphamide, phosphamide, and triethylenemelamine synthesised and investigated at the present time are characterised by a toxicity lower by more than an order of magnitude than that of the initial compounds, while retaining the same or even higher antitumour activity (Table 12).

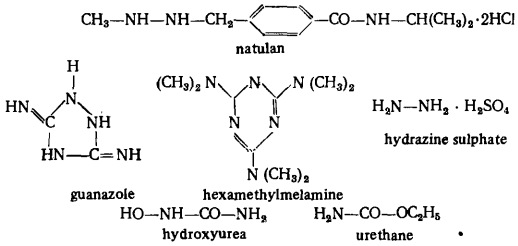
Table 12. The antitumour activities of paramagnetic analogues of antitumour agents[240].

Formula	LD_{50}^{a}, mg kg^{-1}	Δ^{b}, % (leukaemia La)	x^{c} (leukaemia La)	Inhibition of tumour growth^{b}, %			
				WCS	SEM	EAC	S-180
 Thiophosphamide	18	20	0.3	100	100	45	—
	187	80	0.5	100	100	70	50
 Phosphamide	15	—	—	65	—	50	—
	150	170	1.0	100% inhibition of tumour growth			
	280	80	0.4	100% inhibition of tumour growth			



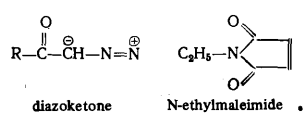
Notation: *a*) dose of the preparation for which 50% of the animals die due to its toxicity; *b*) increase of the average lifespan of the animals; *c*) WCS = Walker carcinosarcoma 256; SEM = Svec erythromyelosis; EAC = Ehrlich ascites carcinoma; S-180 = sarcoma 180.

The synthesis of chemically polyfunctional antitumour preparations, incorporating a stable nitroxy-radical as the carrier of the alkylating group, leads to a fundamentally new type of preparations with a combined mechanism of action, which combine the properties of substances with electrophilic reactivity and substances undergoing free-radical reactions.



(3) Complex formation. Complex-forming agents capable of donor–acceptor interactions of various types (the formation of charge-transfer complexes, hydrogen bonding, hydrophobic interactions, and the formation of metal complexes) constitute a large and structurally varied group of antitumour preparations. Many antibiotics, which combine with the nitrogen-containing DNA bases as intercalating agents (antibiotics of the anthracycline [anthramycin? (Ed.of Translation)] series—adriamycin, rubomycin and carminomicin, antibiotics belonging to the aureolic acid group—olivomycin and mithramicin, as well as actinomycins) should be assigned to this group. The intercalation mechanism can be proposed for many polycyclic compounds and ionic forms of polyheterocycles (phenothiazines, phenoxazines, and acridines).

Metal salts and complexes (gallium nitrate and platinum group metal complexes) constitute a special group of antitumour preparations. The mechanism of their biological action is due to their ability to combine with information biomacromolecules. This field of tumour chemotherapy has in essence only begun to develop.



In the future one may expect the synthesis of new antitumour preparations consisting of a series of mononuclear and dinuclear complexes of various metals:

(4) Nucleophilic reactions. Nucleophilic reactions have not been considered at all in the literature as reactions of importance from the standpoint of the antitumour effect. Nevertheless the electrophilic centres of metalloenzymes (carbonyl and azomethine groups) can serve as targets for preparations with nucleophilic reactivity. Indeed, among antitumour preparations classified as substances with different (or even unelucidated) mechanisms of action, it is possible to distinguish derivatives of hydrazine, carbamide, and nitrogen-containing bases which are strong nucleophiles:

(5) Cycloaddition. Direct data indicating the possibility of cycloaddition reactions in the organism involving antitumour preparations are not at present available. However, the presence of activated double bonds in many metabolites does not rule out the Huisgen or Diels–Alder reactions. *N*-Ethylmaleimide and diazoketones can be included among antitumour agents capable of participating in these reactions:

The new classification of preparations in terms of types of reactivity, which the present author proposed, is more general than the traditional classification, permits a more

detailed treatment of the chemical and biochemical mechanisms of the action of antitumour preparations, and provides a basis for the rational planning of their synthesis. Preparations with hybrid structures and correspondingly with hybrid reactivities fit satisfactorily within the framework of this classification.

6. Correlation between the Chemical Structure and the Antitumour Activity of Compounds

Quantum-chemical calculations can be used to predict the biological activity and to select the optimum structures of antitumour preparations. Among the many methods for the determination of quantitative relations between the structures of compounds and their biological activities, those of Free and Wilson[245] and Hansch and Deutsch[246] are most widely used. The Hansch equation makes it possible to establish a correlation between the biological activity A and the physicochemical characteristics of the substance:

$$\lg A = \rho\sigma + \alpha\pi + \gamma E_s + B \,, \qquad (121)$$

where σ characterises the polar effects in the molecule (in particular it can be Hammett constants or quantum-chemical characteristics of the electronic structure), E_S are steric factors (for example Taft constants), and π represents the distribution of the preparation in the lipid–water system ($\pi = \lg P$, where P is the partition coefficient in the 1-octanol–water system). The polar factors σ depend on the distribution of electron density in the molecule and on the free valence indices of the reactive atoms, which determines in its turn the chemical reactivity of the molecule as a whole.

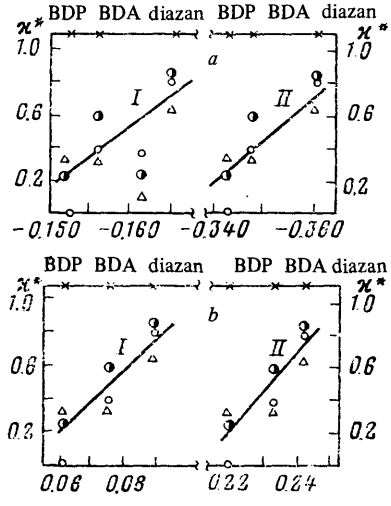


Figure 34. Correlation between the negative charges (*a*) and free valence indices (*b*) of the oxygen atoms (I) and carbon of the methine group (II) and the antitumour activity κ^* in a series of bisdiazoketones; BDD = bisdiazoacetyl; BDP = bisdiazoacetylpropane; ○—Ehrlich ascites carcinoma; ◑—leukaemia La; △—sarcoma 180.[240]

Quantum-chemical calculations of the structure of bisdiazoketones by the semiempirical CNDO/2 method[247] showed that a change in the electron-donating properties of the substituents influences significantly the distribution of electron density in the diazoketone fragment. It was found that the antitumour effect is correlated with the charges on the C and O atoms and the Wiberg indices and also with the Hammett constants σ and the energies of the highest occupied molecular orbitals E_{HOMO} and the lowest unoccupied molecular orbitals [E_{LUMO} (Fig.34)].

7. Free Radicals and Tumour Growth. Inhibitor-antioxidants as Anticarcinogenic and Antitumour Preparations

A little more than two decades ago, the author put forward ideas concerning the possibility of biophysical shifts associated with changes in the content of free radicals in tissues in various pathological states (malignant growth, radiation damage, and the effect of toxic substances).

Paramagnetic centres—free radicals (FR) and transition metal complexes (Mn, Fe, Mo, etc. complexes)—have now been detected in many tissues of animal and plant organisms functioning normally and their nature has been determined. Fig.35 illustrates the characteristic EPR spectrum of liver cells. The narrow EPR singlet with a g-factor of 2.003¶ corresponds to free radicals of the semiquinone type, observed in many other organs and tissues. Mainly flavins in the semioxidised state and the semiquinone form of ubiquinones, functioning as electron transferring agents in the respiratory and energy chains of mitochondria, are responsible for this signal.

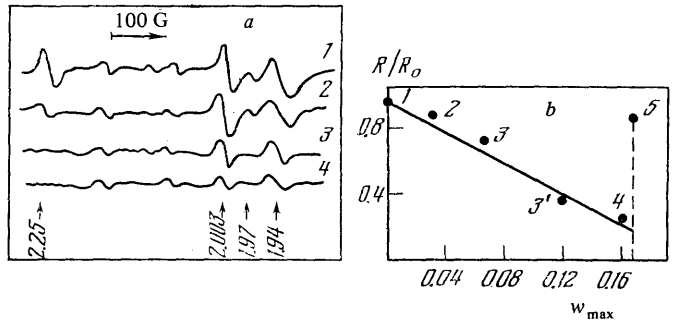

Figure 35. Paramagnetic centres in tissues of normal liver and in transplanted haepatomas: *a*) EPR spectra of frozen specimens of normal liver tissue (*1*), haepatoma 46 showing a minimal deviation (*2*), rapidly growing haepatomas 60 and 22a (*3* and *4*); *b*) relative content of free radicals in normal ($R/R_0 = 1.0$) and regenerating livers (*5*) and also in haepatomas with different rates of growth[226].

The EPR signal of flavin radicals in tissues has a half-width of 14–15 G,[248,249] and for ubiquinone radicals $\Delta H = 10$–11 G.[250] Depending on the ratio of the amounts of flavin, ubiquinone, and other free radicals, the EPR signal half-width for the tissue can vary from 10 to 16 G.

The signal with $g = 1.94$ is due to iron sulphur complexes in mitochondria. The haem iron of cytochrome P-450 in microsomes in a low-spin state gives rise to an anisotropic signal with $g = 1.91$, 2.25, and 2.42; the component with

¶ In certain studies a different value of the g-factor of the free radical signal has been reported (up to 2.005).

g = 2.25 is most intense. A signal with g = 1.97, due to molybdenum compounds of xanthine oxidase and sulphate redutase, can also be observed.

It is natural to expect that, in the development of pathological processes in the organism, the content of free radicals and other paramagnetic centres can differ from the norm and that EPR signals not characteristic of the organism under normal conditions may appear. Indeed, in many pathological processes such as radiation damage, cancer, virus diseases, and various stresses on the organism (hypoxia, hyperoxia, etc.), the content of free radicals (g = 2.003) and other paramagnetic centres in the tissues changes and new signals appear, for example, a signal with g = 2.03 [251–253] and a triplet signal with the centre at g = 2.007.[254,255]

A quantitative relation has been observed between the intensities of individual signals in the EPR spectra and the level of metabolic activity of the tissues[256]. This served as a basis for the study of the kinetics of the change in the paramagnetic properties of organs and tissues in carcinogenesis and tumour growth. The change in the content of paramagnetic centres in the tumour is one of the physicochemical characteristics of tumour growth.

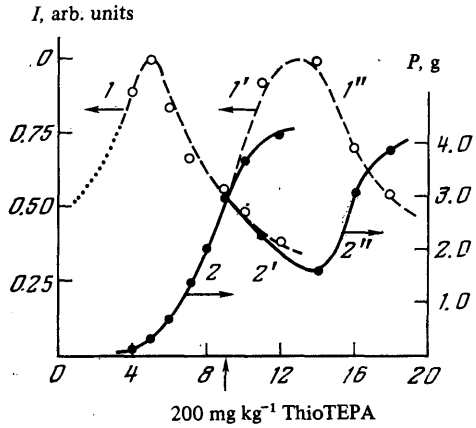

Figure 36. Variation of the content of free radicals (curves *1*, *1'*, and *1''*) in tumour tissue and of the weight of the tumour (curves *2*, *2'*, and *2''*) in the course of growth (curves *1* and *2*), regression (curves *1'* and *2'*), on treatment with ThioTEPA (200 mg kg^{-1}), and relapse (curves *1''* and *2''*) of adenocarcinoma 755 in mice. The arrow indicates the instant of administration of ThioTEPA (I = amplitude of signal with g = 2.00 in EPR spectrum).

In all cases (approximately 25 experimental tumours) the kinetic curves for the variation of the content of free radicals in the tumour passed through a maximum near the point of the maximum tumour growth[257]. As an example, one may consider curve *1* in Fig.36, which reflects the characteristics of the variation of the number of radicals in an experimental tumour (adenocarcinoma 755) on the 4th–12th day of its development (the EPR spectra were measured at 77 K). Taking into account the concentration of radicals in the tumour tissue on the 9th day, when the tumour was transplanted, one may postulate that in the first three days after transplantation the content of free radicals increases (shown by circles) up to the maximum values observed on the 4th–5th day. Evidently the maximum in the kinetic curves for the variation of the content of radicals is determined by consistent biophysical changes in malignant growth. The content of free radicals in developing tumours is appreciably below the norm (sometimes by a factor of 2–3).

The process of the development and growth of a malignant tumours induces specific biochemical changes in various organs and tissues of the animal tumour carrier. In particular, the decrease of the functional activity of the liver in the course of the growth of transplanted tumours is reflected in a decrease of the concentration of paramagnetic metal complex and free radical centres relative to the norm. It has been shown for six types of experimental transplanted leukaemias that the content of radicals in the livers of mice remains at the normal level in the course of the latent period of the development of the leukaemic process and then falls[258].

In the chemotherapy of tumours the EPR spectra of tumour cells and the organs of tumour carriers shown an increase of the intensity of EPR signals corresponding to the magnitude of the antitumour effect. Such data have been obtained, for example, when leukaemia La was treated with diazan, haepatoma 46 was treated with dibutyryl-cAMP, and melanoma B-16 was treated with thiophenosphamide. The observed increase of signal intensity in the EPR spectra under these conditions is probably associated with the growth of the metabolic activity of the tissues.

In the chemotherapy of adenocarcinoma 755 with cyclophosphane an increase of intensity (by 30–40%) and of the half-width of the free radical signal (from ΔH = 10 G to ΔH = 12–13 G) was observed in the tumour regression stage, while in the subsequent recovery of the tumour the opposite effect was noted (see Fig.36). This can be accounted for by changes in the ratio of the paramagnetic forms of flavin and ubiquinone and their different contributions to the measured EPR signal of the tumour tissue[259]. An analogous result was obtained also under clinical conditions: in the therapy of cancer of the rectum the decrease in the size of the tumour was accompanied by an increase of the intensity of the EPR signal of the free radicals in the specimens.

Thus the study of the kinetics of the changes in the paramagnetic properties of tissues can be used to investigate the development of tumours and to assess the effectiveness of the therapy.

Free-radical shifts have also been observed in kinetic studies of the paramagnetic properties of animal tissues in the course of chemical carcinogenesis. Fig.37 shows that complex multistage changes in the content of free radicals take place in rat livers in the course of the malignant degeneracy under the influence of diethylnitrosamine (DENA).[251] Analogous curves have been obtained in the carcinogenesis under the influence of other carcinogens: dimethylaminoazobenzene (DAB),[260] 3,4-benzopyrene[261], and Teflon[262].

The study of the kinetics of the variation of the concentration of radicals in tissues and cells in the course of viral, chemical, and spontaneous carcinogenesis made it possible to observe many common features, despite the different nature of the agents inducing this process, and to put forward hypotheses concerning the nature of these shifts. The most characteristic feature is a maximum on the curves for the content of free radicals in tissues in the initial period of carcinogenesis regardless of the species, sex, and age of the animals, the type of cells undergoing malignant degeneracy, and the experimental conditions.

An analogous maximum in the content of radicals in liver tissues has been observed when animals were treated with non-carcinogenic toxic substances—benzene, DDT, and oxidised sunflower oil (Fig.37*b*). Evidently the observed maximum is associated with a non-specific response of the organism to the introduction of the toxic compound.

The free-radical shifts observed in animal livers and also brains under the influence of toxic substances can serve as a measure of the influence on the organism of particular agents in the environment.

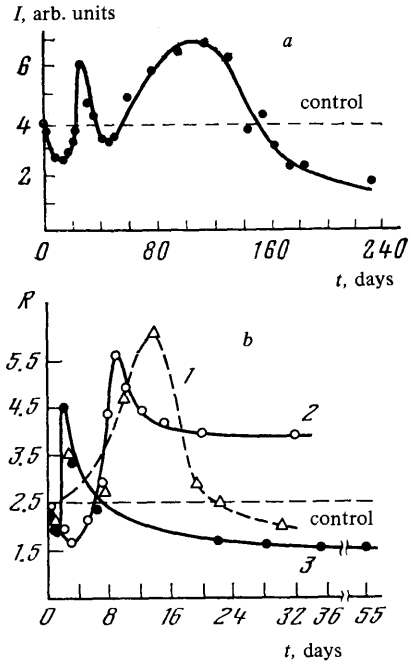

Figure 37. Variation of the content of free radicals (g = 2.003) in rat liver in carcinogenesis induced by diethylnitrosamine (a) and under the influence of toxic agents (b):[226] 1) oxidised sunflower oil; 2) benzene; 3) DDT.

The ideal of a significant role of free-radical shifts in tumour growth and carcinogenesis served as a basis for the hypothesis that inhibitors with a low toxicity which suppress the development of radical processes can prove to be effective anticarcinogenic agents. Numerous experiments have shown that the familiar inhibitor of radical processes and antitumour preparation 2,6-di-t-butyl-4-methylphenol (dibunol) does indeed exhibit an effective anticarcinogenic activity. Rat liver tumours have been induced by including dimethylaminobenzene (DAB) in the diet[263]. Under the influence of DAB, tumours arose in 90% of the animals after 90 days. When 0.3 wt.% of ionol was added to the food together with the carcinogen, tumours did not develop even after treatment with DAB for 150 days. Pre-tumour changes in the animal livers were completely absent.

The anticarcinogenic activity of radical process inhibitors which we established was confirmed by other workers[264,265].

We have investigated the molecular aspects of this extremely important problem[260]. We observed that the introduction of ionol together with the carcinogen prevents an increase of the concentration of free radicals in the initial stage of the action of the carcinogen, maintaining it at a level close to that in the normal liver tissue (Fig.38). Tumours did not arise in the course of twelve months of observation in animals receiving 2,6-di-t-butyl-4-methylphenol.

The experimental data obtained give rise to the problem of the development of methods for the prophylaxis of malignant diseases.

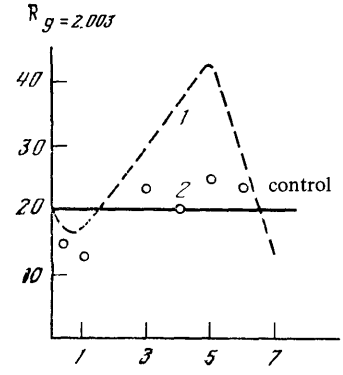

Figure 38. Variation of the concentration of free radicals in rat liver under the influence of DAB (*1*) and under the joint influence of DAB and ionol (*2*).[226]

8. The Antioxidant Activity of Lipids in Normal and Tumour Tissues and Chemotherapy

Approximately two decades ago, the concept of the antioxidant activity (AOA) of tissue lipids, characterising the involvement of bioantioxidants in metabolic processes, was introduced into biochemistry[266].

The value of AOA (in ml h g^{-1}) is determined from the ability of lipid fractions to inhibit the oxidation of a standard substrate, for example, methyl oleate, which is oxidised at a rate suitable for measurement even at physiological temperatures:

$$(\mathrm{AOA}) = \frac{\tau - \tau_{\mathrm{stand}}}{P} \quad , \qquad (122)$$

where τ and τ_{stand} is the time of attainment of the same degree of oxidation of the substrate with the lipid fraction and of a standard substrate and P is a sample of the lipid fraction. The quantity AOA is extremely sensitive to various normal physiological and pathological states of the organism and also to the action of physical and chemical factors.

The growth of transplanted tumours is accompanied by a change in the AOA of the lipid fractions of the tissues and organs of animal tumour carriers and in the tumour tissues formed compared with the norm (for organs) and with the initial value of AOA for the transplanted material[267,268]. This change passes through an extremum as a function of the time of development of the tumour process. In successful chemotherapy the retardation of tumour growth is accompanied also by the retardation of the increase of AOA. This can be used for monitoring the course of the therapy.

The study of the changes in AOA in animal tissues under the influence of chemical and physical factors leads to important conclusions. All the effective antitumour preparations reduce AOA compared with the normal level after administration to healthy animals[269] (Fig.39).

This effect is observed for all alkylating compounds and synthetic antioxidants when they are administered in doses ensuring the antitumour activity of hormones and antimetabolites. In the case of hormones the suppression of AOA after a certain time is replaced by an increase of AOA to which corresponds an acceleration of tumour growth in chemotherapeutic experiments. However, repeated administration of these preparations, ensuring the maintenance of the AOA level below the norm, results in the retention of the antitumour activity. These observations are fully consistent with clinical data concerning the application of hormones and antimetabolites as antitumour agents. Non-specific influences such as irradiation with X-rays and stress also cause a decrease of AOA and the corresponding antitumour effect.

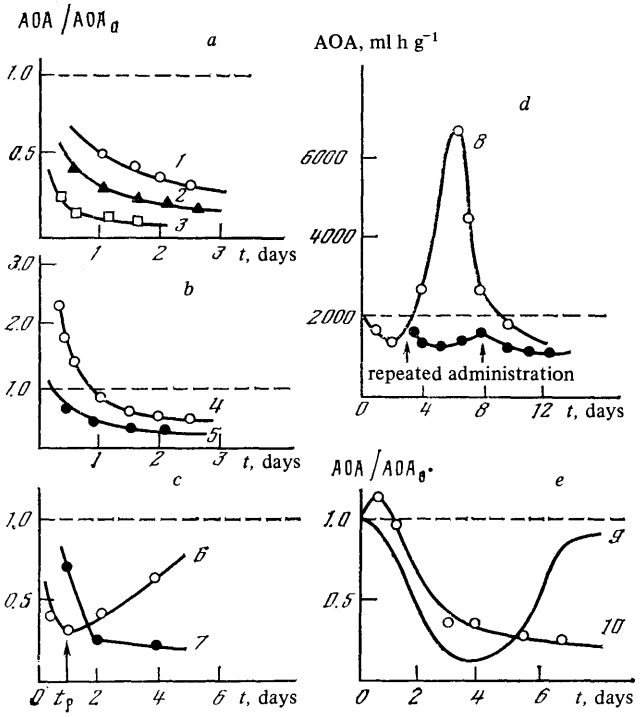

Figure 39. The influence of various preparations [*a*) alkylating agents; *c*) antimetabolites; *d*) hormones; *e*) physical factors] on the AOA of the lipids in the livers of healthy animals: 1) ThioTEPA; 2) phenylacetic acid; 3) myelosan, sarcolysine, spirazidine; 4) antioxidant; 5) nitrosomethylurea; 6) 6-mercaptopurine; 7) 5-fluorouracil; 8) adrenaline; 9) irradiation with a dose of 450 r; 10) cold; the horizontal dashed line indicates the normal value of AOA; t_r = the recommended instant for repeated administration[240].

An inverse correlation between antitumour activity and $(AOA)_{min}$—the minimum value of AOA which can be attained by a given antitumour treatment (Fig.40)—has been established for the model of the transplantable leukaemia La. On the basis of this correlation, it is possible to develop a new principle of the screening of antitumour preparations in which healthy animals are used to determine their effectiveness.

The study of the antioxidant properties of tissues can be used also for a rational selection of preparations with anticarcinogenic properties. The changes in the AOA of tissues in carcinogenesis correspond to the morphological stages of the latter (Fig.41).[271] It has been shown that, in the stage involving a decrease of AOA, anticarcinogenic activity is shown by preparations which increase AOA to values close to the norm; at later stages of carcinogenesis it is necessary to decrease AOA.[271,272] Thus at a given stage of carcinogenesis the AOA test makes it possible to establish the dose in which the antioxidant will exhibit an effect retarding carcinogenesis.

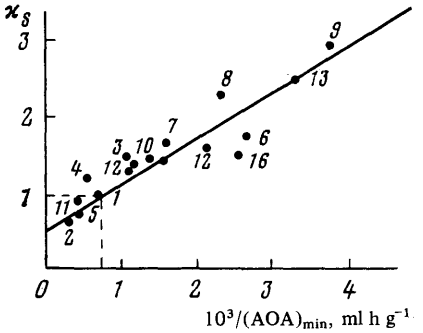

Figure 40. Dependence of the inhibition coefficient $\varkappa_S$ for transplanted leukaemia La on the reciprocal of the minimum AOA of lipids under the influence of antitumour preparations and other types of treatment[268].

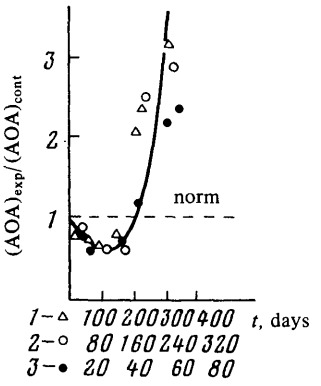

Figure 41. Variation of the AOA of mouse liver lipids in carcinogenesis; 1) o-aminoazotoluene; 2) γ-radiation; 3) 3,4-benzpyrene.[268]

9. Kinetic Aspects of the Ageing of Living Organisms. Physicochemical Principles of Increasing the Life Span

The ageing of man is one of the most dramatic laws of nature. A wide variety of processes in the living organism take place in open heterophase chemical systems under the influence of numerous chemical and physical factors. Many of the undesirable and "harmful" phenomena in chemistry are

also referred to as ageing processes. These are, for example, the ageing processes in polymers and articles made from them, examined above, the spoiling of food products and medicinal preparations, etc. Many processes with analogous elementary process mechanisms (molecular, ionic, and free-radical) take place both in the ageing of "non-living" chemical systems and in the ageing of living organisms. The entire experience concerning the control of chemical reactions gained in the study of chemical kinetics should be reasonably employed for the inhibition and suppression of ageing processes in living organisms.

There is as yet no single accepted method for the measurement of the rates of ageing of individual organisms in gerontology, although various procedures have been proposed for the determination of "biological age". Instead, statistical ageing indices, referring to a group of similar individuals, are usually employed. The main effect of ageing is that the probability of death in the forthcoming period of time (year, month, etc.) increases with age. The principal statistical ageing indices are therefore derivable from the survival curve. The survival curve $P(t)$ represents a function describing the dependence of the fraction of surviving organisms P on their age t. The principal mortality indices such as the mortality rate dP/dt and the quantity $R_m = (1/P) \cdot (dP/dt)$, which has come to be referred to as the strength, intensity, or index of mortality, can be derived from the survival curve. In the absence of ageing $R_m = \text{const.}$, i.e. is independent of the age; ageing processes are manifested by the fact that R_m increases with age. The survival curve also yields other indices, such as the average and maximum lifespans, the average remaining lifespan, etc.[239]

Survival curves have the usual complex S-shape. For humans and certain laboratory animals, they can be fitted, for example, by the empirical Gompertz–Makeham formula:

$$R_m = A + R_0 e^{\alpha t}, \qquad (123)$$

where A, R_0, and α are constant parameters. Other empirical formulae are also used for laboratory animals.

The application of the probit method[273] in the treatment of these data makes it possible to represent the survival curve by a straight line making an intercept on the time axis equal to the age of the animals corresponding to 50% mortality ("median"); the average rate of mortality as a percentage can be determined from the slope of the straight line[274]. This method of representing data is particularly clear in those cases where the rate of the ageing process is altered by means of some kind of influence in the course of the experiment, as will be shown below (see also Fig.43).

In the case of effective influences leading to an increase of the lifespan of animals and to a change of particular parameters, the survival curves for the experimental group can differ in shape from the curves from the control group. The group of animals used to determine the survival curve can be divided to a first approximation into two subgroups: "short-lived" and "long-lived". Geroprotectors can have different effects on these subgroups and the nature of the changes in the overall survival curves is accordingly also different[275].

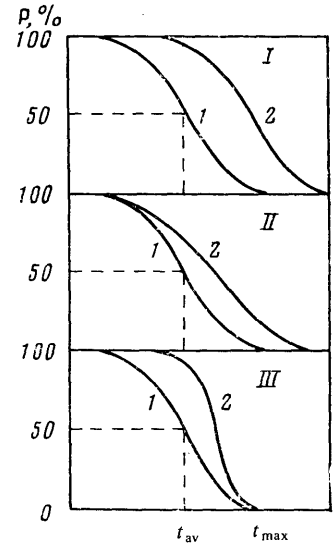
I. If the lifespan of all the members of the group increases by the same amount, the average and maximum lifespans also increase and the survival curve shifts to the right parallel to itself (Fig.42*a*). The mortality rate may not then change.

II. The influence may decrease the mortality rate in the group of "long-lived individuals". In this case the average and maximum lifespans also increase and the survival curve has the form shown in Fig.42*b*.

III. If the lifespan of the subgroup of short-lived individuals increases and the maximum lifespan remains unaltered, the curves have the form shown in Fig.42*c*. The mortality rate then increases but the average lifespan nevertheless also increases.

The proposed subdivision of the experimental group into two subgroups can serve as a basis for the classification of effective influences increasing the lifespan of animals.

Numerous data indicating the involvement of free radicals in ageing processes suggested that inhibitor-antioxidants should exhibit a prophylactic and therapeutic effect and should increase the lifespan of organisms. By preventing the development of different kinds of pathological processes, antioxidants can reduce the amount of damage in organisms and hence can prevent ageing.



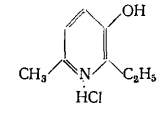


Figure 42. Various types of changes in the survival curve observed experimentally when the organism is treated with agents decreasing the rate of ageing: 1) control; 2) treatment with geroprotector[275].

Harman[276] observed that the addition to food of ionol (2,6-di-t-butyl-4-methylphenol), a well known radical process inhibitor, increases the lifespans of mice on average by 40%. 2-Mercaptoethanolamine, butylhydroxyanisole, and cysteine cause a somewhat smaller increase, the result depending on the breed of the animals. It has been shown[277] that the introduction of the antioxidant santoquin into food also increases the lifespan of mice. The lifespan of animals does not then exceed the maximum known for mice of the given strain under optimum conditions.

The lifespan of laboratory animals is also increased by the relatively non-toxic water-soluble antioxidant 2-ethyl-3-hydroxy-6-methylpyridine hydrochloride, a structural analogue of vitamin B_6:[278–280]

SHK and C3HA mice were given the geroprotector starting from the age of two months. In experiments with two month old SHK animals (Fig.43*a*) an increase of the latent period on the survival curve (the time of attainment of 10% mortality)

and an increase of the maximum lifespan from 25.4 months in the control to 29 months under the influence of the geroprotector were observed. The entire survival curve then underwent a parallel shift to the right. The average lifespan increased to 17.8 ± 6 months compared with 13.7 ± 0.5 months in the control. As a result of the probit transformation for the control and experimental groups, parallel straight lines were obtained. The mortality rate determined from them was 6.2% month^{-1}.

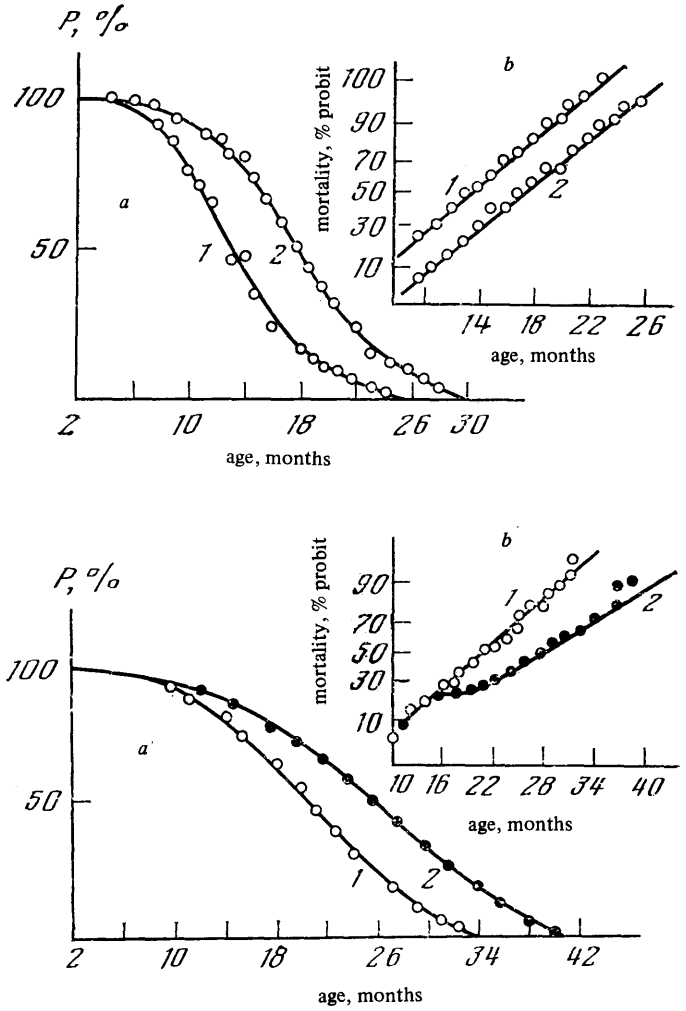

Figure 43. The influence of 2-ethyl-8-hydroxy-6-methylpyridine on the lifespan of SHK (*A*) and C3HA (*B*) mice. Treatment begun at the age of 2 months: *a*) survival curves; *b*) probit transformation; 1) and 2) control and experimental groups respectively[279,280].

Other results were obtained for two month old mice of the C3HA strain (Fig.43*b*). The average experimental lifespan reaches 27.05 ± 0.80 months and the maximum lifespan is 41.2 months compared with 21.90 ± 0.75 and 32 months respectively in the control. Line 2, observed by the probit transformation, has a break in the region of 16 months. The mortality rate decreases to 3.7% month^{-1} compared with 4.7% month^{-1} for the control group.

Comparison of the experimental data with the above analysis of the form of survival curves (Fig.42) shows that the nature of the action of 2-ethyl-3-hydroxy-6-methylpyridine hydrochloride depends on the strain of the animals. The effect of the geroprotector in experiments with two month old SHK mice can be assigned to type 1, since it exerts the same influence on all members of the population. In the case of 2 month old mice of the C3HA strain an effect of type 2 is observed, whereupon the mortality rate of the long-lived section of the population diminishes.

The influence of 2-ethyl-3-hydroxy-6-methylpyridine hydrochloride on the ageing of the Drosophila fly has also been observed reliably. The effectiveness of the geroprotector depends on its concentration, the stage of development of the Drosophila, and the age of the flies at the beginning of the experiment[281].

Experiments on the application of the geroprotector in the larval stage only are of particular interest. It was found that an increase of the lifespan of the adult fly is then observed. It has been suggested that defects leading subsequently to ageing accumulate in the tissues of the larva from which the organs of the adult fly are produced (the nervous tissue and the imaginal buds). The rate of ageing of adult individuals can be retarded by decreasing with the aid of the geroprotector the rate of accumulation of these defects during the larval period. It may be that the DNA molecules retain a "memory" of the geroprotecting effect.

The data obtained show that the kinetic approaches to the study of ageing are promising and that wide possibilities arise in gerontology from the application of antioxidants as geroprotectors.

---o0o---

This review has dealt with only a few examples of successful application of the methods and ideas of chemical kinetics to various branches of chemistry and biology. There is no doubt that chemical kinetics will make an increasing contribution to the solution of theoretical and practical problems of modern chemistry, chemical engineering, biology, and medicine.

Transformations of Condensed Substances under Shock-wave Compression in Controlled Thermodynamic Conditions

G.A.Adadurov and V.I.Gol'danskii

The development of dynamic methods of acting on matter is reviewed, with special emphasis on isentropic shock-wave compression methods, which minimise the thermal contribution to the pressure. The effect of pressure, temperature, micro- and macro-plastic deformations, and of pressure relief waves is discussed. Problems arising in studies of the low-temperature compression of condensed gases under dynamic conditions and of chemical synthesis by shock-wave compression of solid-gas systems are examined. 53 references.

I. INTRODUCTION

The aim of this paper is to examine the possibility of exploiting various regions of the p,T phase diagram of substances (where p is the pressure and T is temperature) and of obtaining high levels of compression under different heating regimes in dynamic experiments. Dynamic interactions include various types of compressive load: from compression by a single or a multiple shock wave (SW) to dynamic isentropic (or, more exactly, nearly isentropic) compression (DIC). Shock waves are generated in condensed substances under dynamic conditions by the detonation of an explosive substance (ES) in contact with the sample, or by impact from a body accelerated to a high velocity by the products of an explosion.

The dynamic approach to the physics and chemistry of high pressures includes: a) studies of the state of substances during shock-wave compression (measurement of the compressibility and construction of the equations of state, study of the visco-elastic characteristics and of the optical and electrical properties, study of the low-temperature plasma generated by the pressure relief following a shock wave in a porous substance), and b) studies of the physicochemical transformations of substances contained in strong vessels (sample preservation bulbs) after shock-wave compression. The latter approach has attracted a great deal of interest during the past two decades because of the possibility of its direct practical application in synthetic work under SW conditions.

Some aspects of high-pressure physics and chemistry are related to the physics of high energy densities.

A generalised p,T diagram (Fig.1*a*) shows (as cross-hatched areas) the regions of high static or dynamic pressure which have so far been exploited. In order to simplify the diagram the regions of ~10^3 GPa and 10^4–10^5 K (explored in compression experiments[1]) and of a few hundred GPa at 10^3–10^4 K (in experiments with preservation of the sample[2]), mainly involving an axially symmetrical loading geometry, have not been included.

The static method has one undeniable advantage: it allows the sample to be exposed to high pressures and temperatures for long times, and therefore the two parameters can be varied in the desired sequence (Fig.1*b*). The initial substance is usually first compressed, then heated, and at the end of the experiment the temperature is lowered before the pressure. This allows metastable states to be preserved under normal conditions. A general review of the thermodynamics and kinetics of reactions under static compression conditions is given in Ref.3.

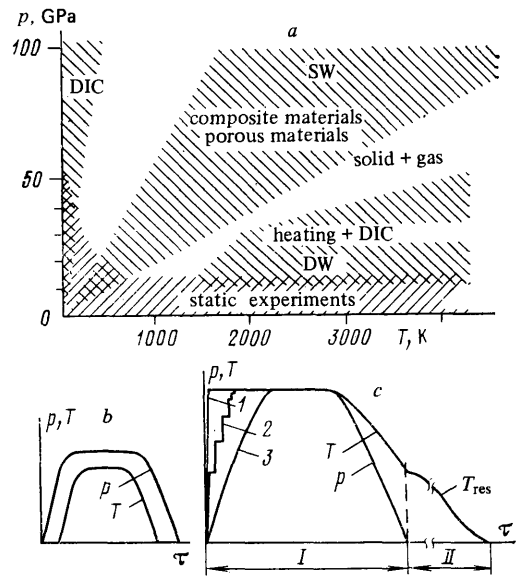

Figure 1. Generalised p,T diagram showing the regions of high static or dynamic pressure application (*a*), and idealised plots of p and T against time under static (*b*) and under dynamic conditions (*c*); DIC is the dynamic isentropic compression region, SW is the region of shock-wave compression of composite or porous solid materials, and of gas–solid systems, DW is the region of high p and T values generated in a detonation wave; *1*), *2*), and *3*) are the wave fronts for single and for multiple shock compression, and for DIC, respectively. Cooling rate ~10^8 K s^{-1}; the durations of processes I and II are ~10^{-5} s and ~1 s respectively.

Shock compression does not offer these advantages. Both the pressure and the temperature rise in a narrow zone (the SW front) in times of 10^{-12}–10^{-9} s, after which the pressure relaxes in ~10^{-6} s through isentropic pressure relief waves, while the temperature falls to some intermediate value (T_{res}, see Fig.1c) owing to the irreversibility of the shock compression. The whole process is completed in ~10^{-5} s: the final cooling of the depressurised sample follows the normal heat conduction laws. Obviously, high-pressure phases can be eliminated by high residual temperatures unless special precautions are taken (e.g., the back-graphitisation of the diamond formed by shock-wave compression).

Nevertheless, the shock interaction method has a number of specific features and advantages, including the ease with which ultra-high pressures and temperatures can be achieved, the generation of extremely high shear strains on the SW front (which give anomalously high rates of physicochemical reactions in the solid state), extremely fast cooling rates, strict control of the development of pressure, etc. All these advantages have been exploited in studies of physical and chemical changes in experiments with preservation of the sample, and shock compression has been shown to lead to defect formation, complex chemical reactions, polymorphism, etc.

This review will deal with the basic problems in the development of the SW method, and with the results obtained in diagnostic experiments on the factors (temperature, pressure, microscopic or macroscopic plastic deformation, pressure relief waves) responsible for various processes. The problem of achieving low-temperature compression under dynamic conditions will be examined in detail.

II. THE SHOCK-WAVE COMPRESSION REGION

Most of the work on the dynamic aspects of high-pressure physics and chemistry so far reported refers to the SW region (Fig.1a). Studies of the properties of matter under the influence of shock compression have been discussed in many monographs and reviews (see, for example, Refs.4–12). Studies of the properties retained after compression have shown[13–16] that the very short duration of the shock compression process is not a serious obstacle to the widespread use of the method. The products can be preserved after relief of the pressure if the residual temperature is not too high (a condition easily satisfied by the enormous cooling rates (~10^8 K s^{-1}) accompanying the decrease in pressure). However, many processes can take place as a post-effect, i.e. after relief of the pressure, if the residual temperature of the material activated by the SW front is relatively high. This unique situation is never encountered except in SW systems.

1. Planar Loading Scheme

SW application from one side only in the planar variant (Fig.2a) allows the development of pressure to be calculated with high precision. Macro-plastic deformation of samples in bulbs, mainly during pressure relief, is usually less than 10% at moderately high pressures. Low-density substances can easily be compressed to 50 GPa by repeated SW, reflected from the denser metallic walls of the bulb. By using a flat bulb design the samples can be pre-cooled to 4.2 K: a very important facility for studies of thermally unstable states[17]. The retention of these states is assisted by fast heat transfer from the experimental region towards the bulb walls at the end of the shock compression process. Even more marked effects are obtained by rapidly cooling the bulb at the end of the experiment (for example, to 77 K [17]).

Systematic comparative studies of organic reactions initiated by SW (in particular, the shock polymerisation of acrylamide[18]) have revealed a strong dependence of the final state of the sample on the initial temperature (T_0). At T_0 = 77 K the reaction products are found (by ESR) to include a fairly high concentration of paramagnetic active centres (AC): 10^{20}–10^{21} kg^{-1}. Furthermore, the presence of these centres gives rise to post-polymerisation even within the thermal explosion period, but no post-polymerisation is observed for T_0 = 293 K.

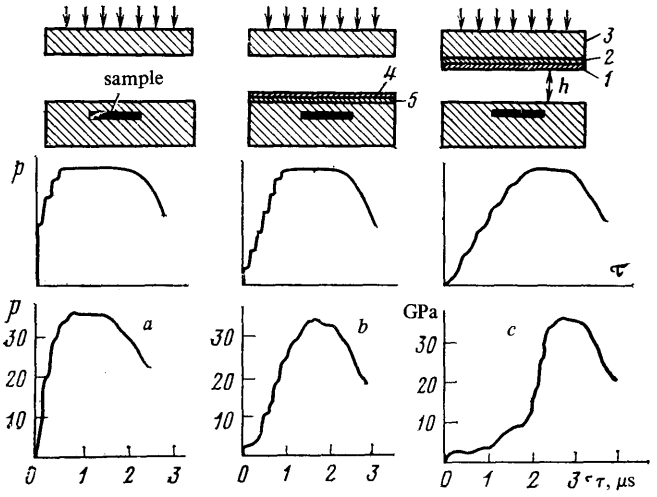

Figure 2. Schematic diagrams of the generation of multiple shock compression (*a*) and of dynamic isentropic compression (*b* and *c*), with idealised and experimental compression wave profiles: *1*), *2*), and *3*) are Perspex, aluminium, and copper plates; 4) and 5) are copper and Perspex plates.

Gamma-irradiation of many monomers at low temperatures is known to lead to the formation of stabilised ACs, which cause polymerisation if the temperature is raised. The combined effect of γ-radiation and SW on acrylamide samples has been studied[19] at 77 K. After pre-irradiation with 5–6 Mrad doses, shock compression was found to increase the yield of polymer to a level higher than the sum of the contributions from the separate agencies. This observation can be ascribed to the transition of the polymerisation process to the thermal explosion regime owing to the high rate of heat evolution produced by the simultaneous radiation-chemical and mechanical initiation of ACs.

We should note that studies of defects in materials exposed to shock compression have shown that the changes in the sample are not equivalent to simple thermal dissociation, and that the final product is often similar to the product of radiation-induced decomposition[14].

A comparative study of the thermal decomposition of ammonium perchlorate samples previously exposed to γ-radiation (1 Mrad dose) or to shock compression (1.5–20 GPa) has been reported[20]. Differential thermal analysis of these samples has shown a substantial decrease in thermal stability in both cases: decomposition begins at 490–500 K, whereas the initial sample of ammonium perchlorate begins to decompose at 563 K. The extent of decomposition in the low-temperature stage of the process increased more than three-fold.

Increasing the amplitude of the SW to 20 GPa causes 96% decomposition of the sample in a single step at 490 K. Thus, irradiation and SW treatment of ammonium perchlorate give very similar results.

We should stress that samples exposed to shock treatment develop defects similar to those found in irradiated samples[14]. In particular, Lisin points out[21] that irradiation of solids by powerful beams can give rise to localised SW, but this hypothesis needs to be confirmed experimentally.

2. Cylindrical Loading Scheme

Bulbs having a cylindrical geometry are most often used in experiments with preservation of the sample after shock compression. The creation of a three-impact configuration in a sample contained in a cylindrical bulb by a glancing detonation wave allowed the pressures to be calculated[2] and thus greatly advanced the development of the physics and chemistry of high dynamic pressures. The proof[2] that the detonation velocity of the explosive surrounding the bulb is equal to the rate of propagation of the three-impact configuration justifies the calculation of pressure in the sample without special direct measurements (if the shock-wave adiabatic curve of the sample is known).

Under these conditions pressures of several hundred GPa can easily be obtained. Thus, by using explosives having detonation velocities of $\sim 8 \times 10^3$ m s^{-1}, pressures of ~500 GPa have been obtained in monolithic tungsten samples, and ~60 GPa in sodium chloride[2]. The pressure in the salt can be raised to 100 GPa or higher simply by mixing the salt with tungsten powder. By using a low salt content, and by making the sample denser by repeated SW compression, pressures as high as 500 GPa can be obtained, accompanied by very high temperatures (10^3–10^4 K). The compression conditions generated in the cylindrical loading scheme are convenient for chemical syntheses (which are also favoured by the very strong macro-plastic deformations).

3. Shock Compression of the Solid–Gas System

The simplest system of this type is a low-density substance with pores filled with water at atmospheric pressure. If the solid particles are small, shock compression in these systems can be assumed to cause pressure equalisation, but not thermal equilibrium. Because of the small mass of the air its contribution to the temperature is insignificant, and the average temperature of the mixture will not differ substantially from that of the solid component, in spite of the much stronger heating of the air in the micro-pores in the initial stage of compression.

Under powerful shock compression a porous medium experiences a strong deformation than a continuous medium, and as a result its entropy increases by a greater amount than that of the continuous medium compressed to the same final pressure[7] (Fig. 1*a*). Shock compression under vacuum can produce temperatures of tens of thousands of degrees, and convert part of the sample into the plasma state[23]: this can give rise to thermionic electron emission[24].

Shock compression of porous substances does not cause special difficulties in the preservation of the compression products. Complications arise only if the sample decomposes, or reacts with the large volume of gas evolved, or if the pores are previously filled with gases compressed to high pressures or condensed. Under these conditions the bulbs usually burst as a result of the high internal pressures developed. A special bulb design is needed to prevent bursting. Obviously, partial (or complete) reaction of the evolved gas to form a solid helps the preservation of the sample.

We have recently carried out a systematic study of the design of sample preservation bulbs of the planar and of the cylindrical type for the shock compression of solid–gas mixtures in various chemical investigations[25,26], and we have developed a bulb for the planar loading (up to 40 GPa) of porous substances mixed with gases for initial temperatures of $T_0 \cong 300$ and 77 K.[25] The gas (for example, hydrogen) is admitted under pressure to the working volume of the bulb through a thin connecting tube from a standard or a special gas storage cylinder. These bulbs are not fractured by the shock compression of their contents, and the solid products of the transformation can be examined. On the other hand the excess of gas is lost through the open vent provided.

Cylindrical bulbs offer an extended pressure range and substantial macroplastic deformations, with their associated heating effects, which assist chemical reactions. This feature allows the required gas to be produced during the experiment by compression of a "donor" of this gas (for example, a source of oxygen) either mixed with the sample or separately located[26]. As in the planar variant, the design of these bulbs allows the addition of gases from cylinders as well as cooling of the sample to 77 K. With a solid sample having a high dynamic stiffness the pressure in the mixture can reach 100 GPa or more. Unlike the planar variant, however, this variant allows the bulb to remain sealed during the compression, giving a product at some intermediate (residual) pressure.

We have used these bulbs to study the interaction of various substances with nitrogen, solid carbon dioxide, oxygen, and hydrogen. In particular, we have demonstrated the formation of niobium nitride and carbide by shock-wave compression of a mixture of niobium powder and liquid nitrogen or carbon dioxide[25]. In an attempt to prepare solid CO_2 under normal conditions we have studied[26] the oxidation of SiC under shock compression of a bulb containing a mixture of powdered SiC and gaseous or liquid oxygen. The products were examined by X-ray diffraction and i.r. spectroscopy, and oxidation of the SiC with formation of a non-molecular lattice structure was detected. Heating the oxidised SiC to 800–1300 K produces oxides of carbon.

The interaction of various metals with hydrogen yielded hydrogen compounds of titanium, manganese, and other substances. Saturated hydrocarbons, or water, can be used as hydrogen sources in these reactions.

III. METHODS OF CONTROLLING THE THERMODYNAMIC PARAMETERS DURING DYNAMIC COMPRESSION

Because pressure and temperature in the SW front are closely interrelated, the scope for achieving high pressures without a correspondingly high level of heating is very limited (DIC region in Fig. 1*a*). The possibility in principle of minimising the self-heating of the sample during shock compression by a stepped application of the pressure has been exploited, for example, in measurements of the compressibility as well as in experiments with preservation of the sample. Various experimental schemes for sample preservation under industrial conditions can be used to apply either single or multiple shock loading with variable final pressures, initial temperatures, etc.

By using multiple shock compression the entropy can be decreased very substantially (as compared with one-step compression to the same final pressure). However, in the multiple SW compression of very compressible condensed substances the amplitude of the first SW has to be very high in order to reach a high pressure, and its contribution to the

final temperature rise is predominant. For example, in the multiple shock compression of Perspex to pressures of 50 and 100 GPa the amplitude of the first SW must be ~10 and 20 GPa respectively, corresponding to maximum temperatures of 770 and 1570 K and residual temperatures of 520 and 860 K respectively[9].

Obviously, in order to achieve low-temperature dynamic compression we must lower the amplitude of the first SW and increase the number of compressions. In our work these requirements were met by using layer systems[27]. Clearly, a "smooth" dynamic compression could be achieved also by other methods: some of these are described in Refs. 28–30. However, magnetic accumulation generators[30] seem hardly likely to be compatible with experiments requiring preservation of the sample.

1. Layer Systems

The simplest experimental schemes for the planar leading variant (though they are applicable in principle to axially symmetrical loading) are shown in Fig. 2 for: (*a*) multiple shock compression, (*b*) compression by a SW transmitted through a system of screens having different dynamic stiffnesses, and (*c*) compression by successive impacts from an assembly of striker plates made from high dynamic stiffness materials moving towards the target at different times. By using the layer system in scheme (*b*) it has been possible[31] to lower the amplitude of the first SW to 3 GPa while achieving multiple shock compression to 50 GPa of organic substances having densities of ~10^3 kg m^{-3}.

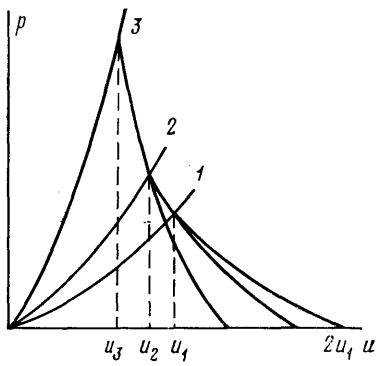

Figure 3. Shock compression adiabatic curves for Perspex (*1*), aluminium (*2*), and copper (*3*), and pressure relief adiabatic curves for the same materials plotted as pressure against mass velocity.

Loading by scheme (*c*) produces a complicated compression pattern, due to the possibility of interaction between the strikers after reflection from the target, spallation phenomena, etc.[32] Therefore it is advisable to plot the true loading profiles produced by the compression waves (using Manganin pressure sensors[27]). The principle of operation of scheme (*c*) is illustrated in Fig. 3. The planar detonation of the explosive charge sends a shock wave through the system of striker plates (e.g. copper, aluminium, and Perspex) whose shock-wave adiabatic curves are shown in the Figure in *p*,*u* coordinates (where *u* is the mass velocity of the material behind the SW front). When the shock wave reaches the free surface the Perspex plate is accelerated to a velocity approximately double the mass velocity of Perspex (since the velocity upon removal of the load is equal to the mass velocity); the aluminium (and especially the copper) striker will have lower speeds. Load is applied to the target containing the sample by successive impacts from the striker plates, the final pressure being determined by the impact of the copper plate (of thickness greater than the combined thicknesses of the aluminium and the Perspex plate).

A qualitative analysis of this method suggests that by varying the relative dynamic stiffness of the plate materials, their thickness, and the distance from the layered striker to the target (*h*), it should be possible to produce compression waves with different profiles: from a pressure increasing monotonically with time to a "saw-tooth" profile with gradually increasing pressure plates. The method allows the time of application of the pressure to be increased to 10 μs or more in large-scale applications. If the damping law which applies to the collision of the first (thin) striker in the target is known, the geometry of the experiment can be designed so as to make the amplitude of the SW reaching the sample during the first compression step negligibly small.

Because of their low thermal stability, organic substances can be used as "thermal indicators" in the search for suitable low-temperature compression conditions. Large differences in the final state of the sample were noted in comparative experiments on the dynamic compression of organic compounds with sample preservation by the schemes of Fig. 2*a*, *b*, and *c* with constant (50 GPa) final pressure and initial (room) temperature. Whereas conventional multiple SW compression of acrylamide caused full thermal degradation of the sample, compression by schemes (*b*) and (*c*) did not degrade the material, nor was degradation observed during the structural transformation in polypropylene. On the other hand compression by scheme (*a*) to 20 GPa or above converts any propylene structure into a microspherulitic phase, because the polymer activated by the SW front is exposed to a relatively high residual temperature.

These results suggest the possibility of achieving a substantially isentropic condition in dynamic experiments.

2. Dynamic Isentropic Compression of Condensed Substances at Low Initial Temperatures

The solution of many problems such as metallisation of dielectrics (including compressed gases) requires high degrees of compression, as well as low temperatures in the case of compressed gases. For a given compression, the temperature on the isentrope is proportional to the initial temperature of the samples. Hence, in order to achieve the lowest possible temperatures in dynamic experiments the interaction with isentropic compression waves is carried out after pre-cooling the sample to temperatures as low as 4.2 K.

We shall discuss below the results obtained for multiple shock compression and DIC of acrylamide samples in copper bulbs at pressures up to 40 GPa and initial temperatures of 10, 77, and 293 K.[17] After the experiments the bulbs were cooled back to 77 K in order to determine the relative amount of products formed.

The compression conditions of samples loaded in different ways can be determined, and their temperatures estimated, by using data on the compressibility of Perspex, whose density is similar to that of acrylamide and which has been fully investigated at high pressures. Under the multiple collision compression conditions used in Ref. 17 most of the

heat is generated by the first SW, which has an amplitude of ~8 GPa, and the subsequent compression waves (up to 40 GPa) can be treated as isentropic. The Grüneisen coefficient was assumed to depend on volume only, and the specific heat on temperature[33]. The calculated results (Table 1) show that the heating effect under DIC conditions is much weaker (especially for $T_0 = 10$ K) than under shock compression. It is also clear that under shock compression the residual temperature effect is substantially lowered for $T_0 < 77$ K, and the residual temperature of the bulb wall can be made even lower with $T_0 = 10$ K.

Table 1. Sample temperatures (K) calculated for different compression conditions ($p = 40$ GPa).

T_0	T_{DIC}	T_{SW}	T_{res}	T^*_{res}
10	24	545	320	30
77	124	565	330	90
293	480	765	445	310

*Residual temperature of the bulb.

These experiments revealed large differences in the yield of polymer from acrylamide and in the rate of the polymerisation process. Shock compression at $T_0 = 10$ K gives 10% of acrylamide polymer during the compression or within a few seconds. The concentration of growing polymer chains is high, and thawing the sample to 293 K results in strong polymerisation with a final yield of 40%. Evidently, the rapid removal of heat from the sample towards the bulb wall (Table 1) helps to retain the ACs. At 77 K the yield of polymer is 30%, and post-polymerisation does not take place on thawing the sample because the ACs are lost by annealing at the relatively high residual temperatures. Shock compression of acrylamide at $T_0 = 293$ K causes only thermal decomposition of the sample.

Under DIC conditions and $T_0 = 10$ or 77 K the yield of polymer does not exceed 2–3%, and no polymerisation takes place on thawing the sample, because of the small number of ACs resulting from the relatively modest pressure gradients at the SW front; DIC at $T_0 = 293$ K gives a higher yield of polymer (20%), but no thermal degradation is observed. From the above comparison of SW compression and DIC we may conclude that polymerisation under shock compression is initiated by the SW front.

Studies of the low-temperature compression of gases and of gas systems were stimulated by the growing interest in the transition of hydrogen to the metallic state. Clearly, the only suitable experimental region in this case was the DIC region (Fig. 1*a*). As we have already pointed out, the procedure used in our experiments for realising these conditions in practice relied on the use of conventional explosives. Most of the work was carried out with gases and gas systems frozen at 77 K. Special bulbs were designed to preserve the samples after dynamic compression to 50 GPa. Immediately after the experiment the bulb with its charge were cooled back to 77 K, opened at that temperature, and the physicochemical properties of the products were studied at and above 77 K.

Carbon dioxide, chlorine, water, a mixture of water and carbon dioxide, and a mixture of n-heptane and chlorine were also investigated. Changes in state of these substances at low temperatures were monitored by the radiothermoluminescence (RTL) method[34]. Compression was found to affect the RTL spectra of many substances. For example, new peaks appear in the glow-curve of CO_2 after compression. After DIC, a mixture of C_7H_{16} and Cl_2 can no longer react rapidly at 153 K, unlike the initial mixture. Other similar results were also reported.

The most important outcome of this type of experiment so far has been the demonstration of the possibility of working with condensed gases under dynamic compression with preservation of the products and direct observation of their properties.

3. Dynamic Isentropic Compression of Condensed Substances at High Initial Temperatures

The main difference between shock compression and DIC lies in the leading edge of the compression wave (Fig. 4*a* and 4*b*). In the case of DIC the microscopic shear deformations and the excess temperatures at the front are smaller even than in multiple shock compression. On the other hand the time of exposure to high pressures, the rate at which the pressure relaxes, and the amount of macroscopic plastic deformation of the bulb and sample after relief of the pressure are practically the same for shock compression and for DIC.

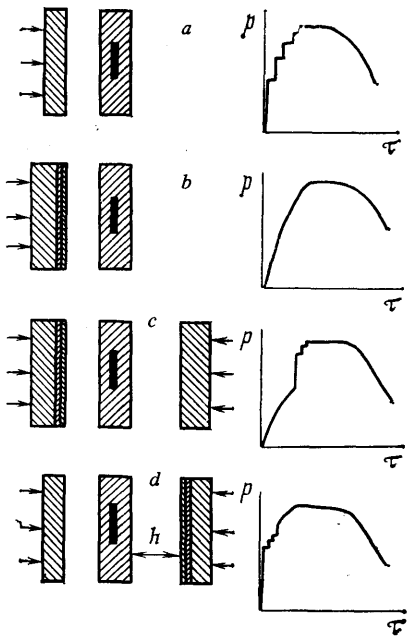

Figure 4. Main loading schemes and idealised profiles of the compression wave: (*a*) multiple shock compression, (*b*) dynamic isentropic compression, (*c*) combination of DIC and shock compression, (*d*) combination of shock compression and DIC.

As has already been stated, DIC of acrylamide samples at $T_0 = 293$ K does not cause thermal degradation: the concentration of ACs is small, and no post-polymerisation is observed. These observations suggest that the SW front is

responsible for the initiation and development of polymerisation during shock compression. However, the DIC experiment alone cannot distinguish the relative roles of micro-shear deformation and of the temperature factor, since any decrease in the effect of the former is invariably accompanied by a decrease in the temperature of the substance at the compression front. Preliminary heating of the sample under DIC conditions should yield p,T conditions identical to those of the conventional multiple shock compression arrangement, but without substantial micro-shear deformations, thus revealing the effect of the SW front in a "pure" form.

With that aim, we have studied the effect of pre-heating in conjunction with DIC on two quite different processes under shock compression: the chemical polymerisation and the structural transformation of graphitic boron nitride (g-BN) into the dense, wurtzite-like modification (w-BN).[35]

The main experimental arrangements and the corresponding idealised pressure profiles are shown in Fig.4*a* and 4*b*. Planar multiple shock compression at pressures up to 20 GPa of samples 2×10^{-3} m thick contained in a bulb was applied by impact from a copper plate 7×10^{-3} m thick; DIC to approximately the same pressure (Fig.4*b*) was achieved by layered Perspex, aluminium, and copper strikers 1×10^{-3}, 2×10^{-3}, and 7×10^{-3} m thick respectively. A more detailed description of the experimental arrangements is given in Ref.35.

Table 2. Yield of polymer (W), concentration of polymer chains (N), and increase in the final and in the residual temperature (ΔT (K) $= T - T_0$) under shock compression and DIC conditions for high initial temperatures.

T_0, K	W, %	$10^{-20}N$, kg^{-1}	ΔT_{fin}	ΔT_{res}
293	30	SW 4.7	220	120
293	2	DIC 1.7	75	0
323	7.5	1.7	135	0
348	13	1.7	170	0

Polymerisation of acrylamide. The polymerisation process requires both the presence of ACs and heating, since activation energy must be supplied to allow the chains to grow. Under shock compression the SW front satisfies both these requirements. As Table 2 shows, shock compression of acrylamide at 293 K gives the polymer in 30% yield. The concentration of polymer chains under these conditions is 4.7×10^{20} kg^{-1}. The yield of polymer under DIC conditions at 293 K is an order of magnitude less, with a concentration of polymer chains three times smaller and unaffected by an increase in the initial temperature almost to the melting point of the monomer. The increase in the yield of polymer (to 13%) is due to the higher residual temperature.

Since the pressure and the residual temperature for shock compression at $T_0 = 293$ K and for DIC at $T_0 = 323$ K are not very different (according to calculations of the residual temperature similar to those used in Table 1), the formation of a greater number of polymer chains under shock compression conditions suggests that the SW front plays a dominant role in the generation of ACs and in bringing about the polymerisation reaction during shock compression. In the present example the concentration of Acs was 10^{20} kg^{-1}, and their time of formation was 10^{-6} s or less, corresponding to the strikingly high rate of generation of 10^{26} kg^{-1} s^{-1}.

g-BN–w-BN *transformation.* Shock compression of graphitic boron nitride to pressures higher than 12 GPa is known to cause irreversible transformation into a dense wurtzite-like modification. Two explanations have been put forward to account for the high speed of this transformation[36,37]: 1) strong shear deformations and 2) a martensitic type of transformation, proceeding athermally and under the influence of pressure alone.

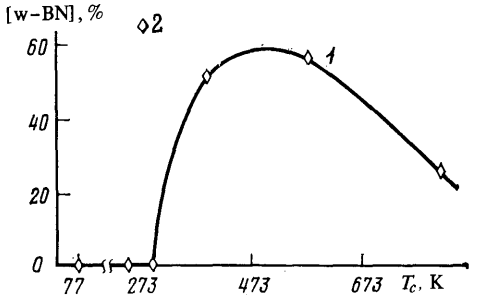

Figure 5. Yield of dense boron nitride phase against initial temperature: *1*) dynamic isentropic compression, *2*) shock compression.

By exploiting the application of almost isentropic compression in dynamic experiments at different initial temperatures we can distinguish between these alternative explanations. The results show (Fig.5) that if multiple shock compression is replaced by DIC at low or at normal temperatures the phase transformation in boron nitride is inhibited. However, a preliminary heating of the sample is sufficient to restore the transformation, even under conditions close to isentropic compression. Stronger pre-heating of the sample causes partial annealing of the dense boron nitride phase after removal of the pressure.

These results suggest[35] that a simple increase in pressure is insufficient to cause the g-BN–w-BN transformation in times of $\sim 10^{-5}$–10^{-6} s. An increase of temperature is also required in order to overcome the substantial activational barrier.

About 20 years ago, when structural transformations by shock compression were first reported[52,53], the possibility of SW generation in the deeper layers of the Earth by the sudden movement of rock formations was considered in relation to the generation of dense phases and to the initiation of earthquakes. Of course, these conditions are possible, but the generation and more sustained existence of strong and smooth pressure waves seems more likely (for example, after the passage of a SW). Because of the uneven temperature distribution in the Earth's core (varying by hundreds of degrees over distances of 100 km), and noting the above experimental results, we can expect transformations over large volumes in the depth of the Earth not only in regions which can support shock waves but also at greater depths, where the SW is transformed into a smooth compression wave.

Bridgman[38] recently suggested that SW pressure could be applied to a sample already under static compression. Our simple method of generating almost isentropic compression in dynamic experiments can be used to produce conditions in which a sample which has been compressed "smoothly" and with negligible heating (especially at low initial temperatures)

is subsequently subjected to shock compression (Fig. 4*c*). The opposite situation can also be arranged: isentropic compression of a shock-compressed sample (Fig. 4*d*).

Modern explosive handling techniques allow very precise synchronisation of the detonation of the charges used for launching the strikers. The required distance from the striker to the target (shown as *h* in Fig. 4*d*) and the corresponding pressure can be calculated from the *p*,*u* diagram if the shock-wave adiabatic curves of the materials and the striker velocities are known. For small sample thicknesses the pressure due to the reflected SW is equal to the pressure in the bulb material.

Frontal collision of compression waves has been used so far only in studies of compressibility and electrical conductivity by shock compression[39,49]. The above discussion shows that both shock waves and isentropic compression waves can be used (in their various combinations) to generate frontal collisions. In other words, we can now apply different types of controlled dynamic loading to a sample, and we can monitor changes in the state of the sample both during its compression and by direct analysis of the preserved sample.

IV. EFFECT OF PRESSURE RELIEF WAVES ON THE PHYSICOCHEMICAL TRANSFORMATIONS OF CONDENSED SUBSTANCES

After shock-wave compression the sample invariably experiences pressure relief waves which have the effect of removing both the pressure and the excess temperature in times of $\sim 10^{-5}$ s. Let us examine the planar loading scheme, which offers a simpler variant of sample compression. In the experiments with sample preservation the sample is located outside the disruptive load region formed by the interaction of opposing pressure relief waves. Therefore the sample is exposed to the pressure relief waves, and its pressure can fall to atmospheric (in most cases). With very short SW, generated by the impact of a thin (2–3 mm thick) plate, the pressure in the sample is relieved by overtaking relief waves from the direction of the free surface of the striker. The extent of macro-plastic deformation for moderate pressures is not very great in this case (1–2%). When the SW is generated by impact from a thick plate, or by the contact detonation of an explosive charge, the residual deformation of the bulb and sample can be as high as 10%.

There are no estimates so far in the published literature of the temperatures produced by deformation, nor is there any evidence on the formation of defects or on structural transformations by the pressure relief waves during the fall of the pressure to atmospheric levels. We shall attempt to answer these questions by using the results of comparative studies of substances subjected to shock-wave and to dynamic isentropic compression respectively, given in sub-section 3 of the previous Section.

Comparison of the two sets of results for acrylamide at 293 K (Table 2) shows that the combined effect of micro-plastic deformations and high temperatures, characteristic of shock compression, increases the yield of polymer by a factor of 10 and the number of ACs (assuming the concentration of polymer chains to be proportional to the concentration of ACs) approximately 3-fold. Hence we may conclude that the number of ACs formed by pressure relief waves and by macro-plastic deformations during shock compression is one-third of the total. The relative proportions of ACs formed by pressure relief and by deformation respectively cannot be estimated at present. Since the character of the pressure relief and the extent of macro-plastic deformation are very similar in SW compression and in DIC it would appear that the contribution of the pressure relief waves to the initiation of polymerisation is negligible in comparison with the contribution of the SW front.

Let us examine a different type of transformation: the formation of dense phases by shock compression. Multiple shock compression of g-BN samples to 20 GPa gives the dense w-BN phase in ~70% yield (Fig. 5). If DIC is used at initial temperatures in the range 77–293 K the dense phase is not formed, in spite of the increased macroplastic deformation produced by the "discharge" of material into the free volume of the bulb.

The conversion of g-BN into the dense phase under shock compression occurs at 12–20 GPa pressures in the presence of high temperatures. If the temperature rise produced by the presssure relief waves and by the resulting macro-plastic deformations in this pressure range were sufficient to bring about the transformation, a dense phase would be detected in the boron nitride samples preserved after DIC. The absence of w-BN is evidence that the macro-plastic deformations have failed to raise the temperature of the g-BN sufficiently. The results obtained for DIC with high initial temperatures (Fig. 5) show that the temperature rise of the sample under these conditions is not very marked.

A third example can be taken from Ref. 41, which describes a metallographic study of copper single crystals and of nickel and brass polycrystals exposed to DIC conditions (changing to shock compression within the sample). The DIC was produced by multiple reflection of SW in an intermediate layer (between the striker plate and the target, see Fig. 2*b*) consisting of a low-density material: liquid hydrogen, which also acted as a coolant. The density of deformations and the micro-hardness were found to be lower in the region affected by the DIC than in the shock compression region.

These examples show that the effect of the pressure relief waves on the formation of defects in the sample is very small. When a planar loading scheme and moderately high pressures are used the macro-plastic deformations generated during pressure relief make a negligible contribution to the final residual temperature rise.

We should also mention a report[42] of phase transformations induced by shock compression and giving less dense structures: these are most probably caused by the expansion stresses arising during load removal. However, the exact stage during pressure relief corresponding to these changes is still not clear: they could take place during the decrease of pressure to atmospheric values, or they could require negative (disjoining) pressures. The results[42] are a good illustration of the wide scope of scientific and practical applications of shock waves.

V. DIRECT APPLICATION OF THE HIGH PRESSURES AND TEMPERATURES DEVELOPED DURING THE DETONATION OF EXPLOSIVES

Detonation is the propagation (at supersonic speed) of an exothermic chemical reaction front through a substance capable of sustaining the reaction without the participation of the surrounding medium. The hydrodynamic theory of detonation treats the detonation wave as a shock front followed by a zone of chemical reaction and a zone in which the reaction products are ejected. The detonation wave is propagated at a constant speed because any loss in energy of the SW is immediately replaced by the energy evolved by the chemical reaction in new regions of the sample. The passage of a detonation wave converts solid or liquid compounds into a mixture of gaseous products (CO_2, CO, H_2O, H_2, N_2, etc.) whose density at the end of the reaction zone is $\sim 2 \times 10^3$ kg m^{-3}.

The size of the stationary zone (a) and the duration of the chemical reaction (τ) in the explosive substance depend on a number of factors, such as the power of the explosive and the density of the charge. For example, if the density of TNT is changed from 1.0×10^3 to 1.6×10^3 kg m^{-3} the parameter a changes from 1.6×10^{-3} to 1.0×10^{-3} m, and τ from 0.5 to 0.2 μs. The pressure at the end of the chemical reaction zone changes from 6.5 to 18 GPa. For Hexogen a change in density from 1.0×10^3 to 1.72×10^3 kg m^{-3} changes the a value from 1.4×10^{-3} to 0.7×10^{-3} m, the τ value from 0.4 to 0.1 μs, and the pressure from 9.5 to 30 GPa. These results were obtained[43] by an electromagnetic method. The temperature of the detonation in condensed explosives is 2000–5000 K (Fig.1, DW region).

Several recent publications have described the direct application of the high pressures and temperatures and of the products of the detonation in physicochemical studies of a sample mixed with the explosive. The products were preserved by carrying out the experiments in strong, sealed containers, able to withstand the pressure of the detonation products.

One of these publications[44] describes the synthesis of silicate crystals from a mixture of oxides; others discuss the interaction of the nitrogen formed during the detonation with metal powders to give aluminium, beryllium, boron, magnesium, and zirconium nitrides[45], and the preparation of boron oxide, nitride, and carbide by the reaction of boron with detonation products[46]. The possibility of inducing structural changes under these conditions has been demonstrated[47]: the density dependence of the detonation velocity of a mixture of TNT and quartz was found to include a break, which was interpreted as a phase formation in the quartz.

In the light of these results it is interesting to examine the state of additives affected by a detonation wave. There have been various attempts at describing the establishment of equilibrium between the particles of an inert additive and the detonation products during the chemical reaction period, i.e. during the equilibration of pressure and temperature[48]. Similar problems were considered in a study[47] of the effect of added aluminium on the parameters of the detonation of TNT, and in a calculation[49] of the parameters of detonation waves in mixtures of explosives and inert substances. The detonation of water-filled explosives has attracted much attention, and the addition of water has been shown to enhance the detonation parameters[50]. The water acts as an internal envelope, and it prevents the dispersal of the detonation products, thus increasing the time available for chemical reactions and leading to a more complete evolution of energy. This effect is observed only in explosives with a negative oxygen balance[51].

Let us examine the state of particles of inorganic additives having a density of $\sim 2 \times 10^3$ kg m^{-3}, i.e. close to that of the detonation products, in terms of published results[48–51] and of known features of the shock compression of condensed substances. Because the densities are so similar, the additive in the front will experience a single shock compression, and it will be heated by the SW compression and by the hot detonation products. Clearly, the state of a mixture of inert particles and dense gases in a detonation wave is determined by the reaction time, and by the physical properties (and size) of the particles. We shall take the average size of the chemical reaction zone to be $a \cong 0.5 \times 10^{-3}$ m, and $\tau \cong 10^{-7}$ s. In this case the size of the inorganic particles which are heated, $l \cong (\lambda\tau)^{1/2}$, is ≤ 0.5 μm (where λ is the thermal diffusivity of the material). Pressure equalisation between the detonation products and the particles of the additive will occur in time $\tau_1 \cong l/D$, where D is the velocity of propagation of the shock wave in the additive ($\sim 5 \times 10^3$ m s^{-1} at 20 GPa). In our case the pressure will be equalised for $\tau_1 < \tau$, i.e. for $l < 0.5$ μm. Thus, if the particle size of the additive is <0.5 μm we can expect temperature and pressure equalisation in a heterogeneous detonation zone.

The presence of high temperatures and pressures, and of chemically active products, in the reaction zone of the detonation should stimulate physicochemical changes in the additives. It is important to note that the cooling rate of the detonation products[43] and of the additive particles (or of the resulting compounds) is as high as during pressure relief after shock compression ($\sim 10^8$ K s^{-1}). The only difference is that after shock compression the sample in a preservation bulb remains in a densified state, whereas in the detonation products the particles fly apart: this helps to quench them and to preserve the compounds or the structural changes produced by the detonation.

We should also note that in a detonation wave the high pressures and temperatures can exist for times significantly longer than in the shock compression process. Some reactions probably occur when the detonation products are being ejected but while their temperature and pressure are still high.

In conclusion we should stress that the detonation parameter region (high temperatures and moderate pressures) is not easily accessible in SW experiments. These parameters can be achieved by DIC of previously heated samples (Fig.1*a*), but this approach does not offer the quenching conditions associated with the ejection of detonation products.

VI. CONCLUSIONS

We have shown that the wide range of methods recently developed for generating dynamic pressures can be applied to substances in the pressure range 10–100 GPa (or more) and the temperature range 4.2–10^4 K, and that the state of the sample after this treatment can be studied. The development of nearly isentropic dynamic compression methods is important, because it has allowed high levels of compression to be achieved by lowering the thermal contribution to the pressure generated by shock compression. By using DIC in conjunction with low initial temperatures it has been possible to work with compressed gases and to preserve the products thus obtained. Colliding pressure waves have been shown to create conditions in which an isentropically compressed sample can be additionally subjected to shock compression.

Comparison of the results obtained by shock compression and by DIC at high initial temperatures has established (by a direct experimental method) the role of the SW front in various processes. The conversion of boron nitride into a dense modification has been shown not to involve the strong microshear deformations generated at the SW front, and to be a thermally activated process. A chemical polymerisation reaction has been studied, and shown to be produced by the SW front.

By comparing shock compression and DIC results for moderately high pressures (using planar loading) we have shown that the pressure relief waves in the region of pressure falling to atmospheric levels do not contribute significantly to the creation of defects or to the final (residual) temperature rise of the sample associated with the macroplastic deformations.

Some very revealing experiments on the shock compression of systems including gaseous components have allowed new chemical syntheses to be performed. It appears that high residual temperatures convert a large proportion of the products (and possibly also some other unstable compounds) into the initial compounds. However, the resulting phases can be quenched by pre-cooling the sample. In principle it should be possible to establish conditions similar to those of

static experiments during the final stages of the shock compression (i.e. to cool the sample under high residual pressure). This requires a strong bulb, which will remain gastight after removal of the pressure. Our calculations suggest that samples can be retained under residual pressures of 1 GPa or more. This problem requires further study, and becomes even more complex when the compression products include gases.

We have shown that the region in the p,T diagram of a condensed substance which is not easily accessible in SW experiments (high temperatures at relatively low pressures) can easily be reached by applying dynamic isentropic compression to a pre-heated sample or by exploiting the high pressures and temperatures developed in a detonation wave.

Kinetics of the Thermal Decomposition of *N*-Nitro-compounds

F.I.Dubovitskii and B.L.Korsunskii

Results primarily on nitramines are summarised. Analysis of modern views indicates that a non-chain radical mechanism with rupture of the N-NO_2 bond in the rate-determining stage is the most soundly based. Kinetic parameters of the thermal decomposition of *N*-nitro-compounds are systematised. The kinetic role of phase constitution is discussed, and prospects for future research are considered. A list of 108 references is included.

I. INTRODUCTION

The problem of the thermal stability of nitro-compounds is closely connected with those of the explosives industry. Their molecules contain relatively unstable chemical bonds, which are responsible for their great reactivity (and consequent danger involved in handling them under storage conditions and in technical operations).

For a long time estimates of the thermal stability of nitro-compounds were usually empirical in character, although attempts at a kinetic investigation of their thermal decomposition were made as early as the 1920s.[1,2] However, systematic kinetic studies began only with the founding of the Institute of Chemical Physics of the USSR Academy of Sciences in 1931, and these isolated the problem of the thermal decomposition of nitro-compounds as a separate branch of science having immense practical application. A considerable role in establishing this line of research was played by Roginskii, Apin, and Andreev[3-5]. Results obtained during the first few years were surveyed in Semenov's monograph[6].

The present Review is devoted to the kinetics of the thermal decomposition of *N*-nitro-compounds, which include such well known explosives as hexogen, octogen, tetryl, and dina. Reviews on this topic have not been published hitherto.

II. DECOMPOSITION IN THE GAS PHASE

The thermal decomposition of nitro-compounds comprises very many steps, and for the large majority the detailed mechanism remains obscure. Investigators have hitherto concentrated their efforts on elucidating and describing kinetically the primary rate-determining stages, especially as these mainly govern the thermal stability. The extraordinary complexity of the mechanism of pyrolysis led to early studies being made under relatively simple conditions—in the gas phase—uncomplicated by the surrounding medium, with any contribution by secondary reactions reduced to a minimum. The first attempt at such an investigation was made by Flournoy[7] on dimethylnitramine, after which other dialkylnitramines were examined. The main results can be summarised as follows.

Dialkylnitramines decompose in the gas phase with slight autocatalysis. In this respect they differ from most nitro-compounds of other classes—nitro-ethers, aliphatic and aromatic nitro-compounds—which decompose unimolecularly in the gas phase: i.e. the rate of the process is controlled by a single stage. Homolytic rupture of the N–NO_2 bond must be regarded as the first step in the breakdown of nitramines, since the energy of dissociation of this bond was found to coincide, within the limits of experimental error, with the activation energy of the reaction[8-11]. An important point in connection with the mechanism of the gas-phase thermolysis of nitramines is that analysis of the products from dimethylnitramine showed[7] a high yield (80 mole %) of dimethylnitrosamine. The general mechanism of the gas-phase decomposition of dialkylnitramines can be represented by the equations (for dimethylnitramine as example)

$$(CH_3)_2NNO_2 \rightleftarrows (CH_3)_2N + \dot{N}O_2$$
$$(CH_3)_2NNO_2 + NO_2 \rightarrow NO + \text{Oxidation products}$$
$$(CH_3)_2\dot{N} + NO \rightarrow (CH_3)_2NNO$$
$$(CH_3)_2NNO + NO_2 \rightarrow \text{Oxidation products}$$

A noteworthy feature is the reversibility of the first step, which was proved by the introduction of additives capable of reacting rapidly with nitrogen dioxide (to form inactive products) and thereby removing it from the sphere of reaction. Such additives (e.g. formaldehyde) were found[9,12] to accelerate decomposition, but only to a certain limit: on attainment of a certain concentration of additive (corresponding to complete removal of nitrogen dioxide) the kinetics were unaffected by further addition.

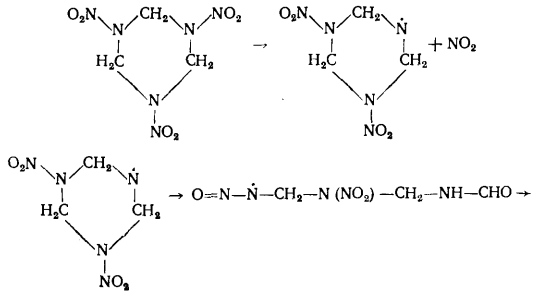
Two important conclusions follow from the reversibility of the first stage in the decomposition of nitramines. Firstly, the relatively low chemical activity of dialkylamino-radicals is confirmed. Secondly, the use as inhibitors of substances capable of reacting readily with oxides of nitrogen, a method widely applied to stabilise nitro-compounds, may produce directly contrary effects on nitramines.

An interesting feature of the above mechanism is the tendency to undergo oxidation by nitrogen dioxide, which is characteristic of nitramines in general. Since other classes of nitro-compounds did not in most cases react so readily with nitrogen dioxide, it may be supposed (although the reactions of nitramines with this compound have never been studied) that the reaction centre in the nitramine molecule is the amino-nitrogen atom, which is attacked by an oxygen atom of the nitrogen dioxide.

Table 1 gives activation parameters for the first stage (rupture of the N–NO_2 bond) in the thermal decomposition of dialkylnitramines. The paucity of experimental results does not permit correlation analysis of the kinetic data. However, Table 1 reveals closely similar activation parameters for the

decomposition of all the compounds. Since the activation energy is equal, within the limits of experimental error, to the energy of dissociation of the $N-NO_2$ bond, it is easy to calculate enthalpies of formation of dialkylamino-radicals from those of the corresponding *N*-nitro-compounds. This gave a value 19.8 kcal mole^{-1} for the enthalpy of formation of the diethylamino-radical[12].

Table 1. Activation parameters for thermal decomposition of dialkylnitramines in the gas phase†.



Nitramine	ΔT, °C	E_a, kcal mole^{-1}	A, s^{-1}	Ref.
Dimethylnitramine	180—240	38.9	$10^{13.7}$	[9]
Diethylnitramine	180—240	41.6	$10^{15.1}$	[12]
N-Nitropiperidine	200—240	42.1	$10^{14.8}$	[12]
N-Nitromorpholine	210—245	38.9	$10^{13.6}$	[12]

† ΔT = temperature range of measurements; E_a = activation energy; A = pre-exponential factor.

Several studies have been made of the gas-phase decomposition of the relatively non-volatile cyclic nitramines—hexogen (RDX) (1,3,5-trinitro-1,3,5-triazacyclohexane) and octogen (HMX) (1,3,5,7-tetranitro-1,3,5,7-tetra-azacyclooctane)—whose vapour pressures at temperatures convenient for kinetic measurements are extremely low. Nevertheless, a portion does evaporate when these compounds undergo decomposition in a condensed phase (liquid or solid), and special experiments have shown[13-17] that the gas-phase process may make a contribution, sometimes very substantial, to the total rate of decomposition.

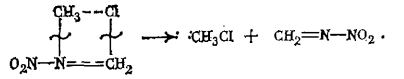
An extremely important discovery for understanding the mechanism of the gas-phase decomposition of cyclic nitramines has been the intermediate formation of nitrogen dioxide[14,16,18], which can reasonably be interpreted in terms of the above mechanism for dialkylnitramines, with rupture of the $N-NO_2$ bond as the first stage[14,17]. Among the decomposition products of hexogen have been detected not only nitrogen dioxide but also nitrogen, nitrous and nitric oxides, carbon monoxide and dioxide, water, formaldehyde, hydrogen cyanide, ammonia, formic acid, hydroxymethylformamide, 1,2-dihydro-1,3,5-triazine, trimethylamine nitrate, and a polymer $(CH_2N-CHO)_n$.[13,14,16,18]. Mass-spectrometric detection of still other compounds has been reported[18], but they could not be identified unambiguously (in all the above studies decomposition took place in both gaseous and condensed phases).

A scheme suggested[17] for the gas-phase decomposition of hexogen

$$\rightarrow O_2N-\dot{N}-CH_2-NH-CHO + N_2 + CH_2O,$$
$$O_2N-\dot{N}-CH_2-NH-CHO \rightarrow N_2O + \dot{C}HOH-NH-CHO,$$
$$\dot{C}HOH-NH-CHO \rightarrow CH_2OH-NH-CHO,$$
$$CH_2O + NO_2 \rightarrow CO + CO_2 + NO + H_2O,$$
$$CH_2OH-NH-CHO \rightarrow \text{Polymerisation products},$$
$$CH_2OH-NH-CHO \rightarrow CH_2(NH-CHO)_2 + H_2O + CH_2O,$$
$$CH_2OH-NH-CHO + CH_2O \rightarrow (CH_2)_3N + CO_2 + H_2O,$$

shows good agreement with the composition of the pyrolysis products, but cannot be regarded as strictly proved. In particular, ring fission may occur in the first stage[18] giving formaldehyde, but this suggestion was not accompanied by a detailed scheme, and no clear distinction was made between processes taking place in gaseous and condensed phases.

If nevertheless we take the mechanism with rupture of the $N-NO_2$ bond as the most probable for gas-phase pyrolysis, we must expect that the activation parameters for the decomposition of hexogen will be closely similar to those for the above dialkylnitramines (Table 1). However, the activation energy and the pre-exponential factor has been given respectively as[15] 34.1 kcal mole^{-1} and 3.14×10^{13} s^{-1}, and also[19,20] as 30.0 and $10^{11.7}$. It is difficult to explain the discrepancy in these values and their appreciable departure from those for the pyrolysis of dialkylnitramines. Only two comments must be made: papers on the gas-phase pyrolysis of hexogen do not indicate whether any heterogeneous contribution to the kinetics (wall effect) is excluded; furthermore, the technique[15] of differential scanning calorimetry measured the kinetics in the later stages, after 96.5% conversion, i.e. in the presence of a large quantity of decomposition products, the influence of which on hexogen has not been specially studied.



Clarity is introduced into this problem by a study[21] in which the activation energy and the pre-exponential factor for the gas-phase decomposition of hexogen have been found to be 35.0 kcal mole^{-1} and $10^{13.5}$ s^{-1}, almost the same as in Ref. 15. However, this work shows[21] that the reaction is inhibited by nitric oxide, from which it may be suggested that the above activation parameters represent not simply the primary decomposition step but a totality including secondary reactions. For the inhibited decomposition of hexogen the activation energy is 40.4 kcal mole^{-1} and the pre-exponential factor $10^{15.58}$ s^{-1},[21] values in excellent agreement with those in Table 1. They can be regarded as a strong argument in support of a mechanism of the gas-phase pyrolysis of hexogen involving rupture of an $N-NO_2$ bond as primary step.

From a detailed analysis of possible schemes for the decomposition of octogen based on published information it has been concluded[22] that the primary step is most probably homolytic rupture of an $N-NO_2$ bond, for which the activation energy and the pre-exponential factor were estimated as 46.2 kcal mole^{-1} and $10^{16.2}$ s^{-1}. The Reviewers regard these values merely as tentative, for implausible postulates had to be used[22] in their estimation. Thus the energy of dissociation of an $N-NO_2$ bond in octogen was determined from data for dimethylnitramine, but the pre-exponential factor was calculated from data for nitromethane and dinitrogen tetroxide. Other workers[19,20] give completely different parameters—32.0 kcal mole^{-1} and $10^{13.4}$ s^{-1}—for the gas-phase pyrolysis of octogen. As with hexogen, we find it difficult to explain such a marked scatter in values obtained by different workers.

In conclusion it is relevant to mention a short paper[23] expressing the interesting idea that the kinetics of the thermal decomposition of nitramines should depend on the geometrical configuration of the nitramino-group. Inspection of the experimental results shows that, if this group is

planar (dialkylnitramines, etc.), the activation parameters should be 40.9 kcal mole^{-1} and $10^{14.1}$ s^{-1}; but if it is pyramidal (hexogen, etc.) 37.8 kcal mole^{-1} and $10^{14.1}$ s^{-1}. This aspect merits further study and in particular quantum-chemical calculations.

We have been considering the thermal decomposition of compounds containing no reactive functional group other than nitramino. An investigation[24] of the pyrolysis of methylchloromethylnitramine $CH_3N(NO_2)CH_2Cl$ has shown that introduction of the chlorine atom has lowered significantly the thermal stability of dimethylnitramine and appreciably changed the kinetics of thermolysis, which is now definitely autocatalytic. The reaction is influenced appreciably by the addition of nitric oxide and inert gases (nitrogen, neon), which suggests[24] the presence of chain processes. It is significant that chloromethane and hydrogen chloride were detected among the decomposition products, and special experiments showed that the latter was the autocatalyst. Chloromethane may be formed in a unimolecular primary stage involving production of a cyclic activated complex:

This hypothesis is supported by the low pre-exponential factor $10^{10.5}$ s^{-1} of the first stage, whose activation energy is 30.7 kcal mole^{-1}.

III. DECOMPOSITION IN THE LIQUID PHASE

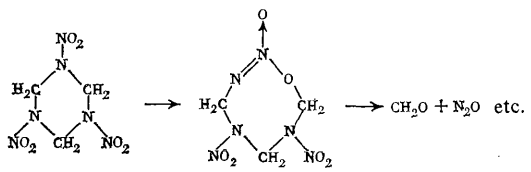
At the present time we are still far from having a general kinetic picture of the liquid-phase decomposition of nitramines. Moreover, there is no single nitramine whose mechanism of liquid-phase decomposition could be regarded as reliably established, although dozens of papers have appeared on this topic. It therefore appears advisable to discuss published results for each compound separately.

1. Hexogen

The thermal decomposition of hexogen (1,3,5-trinitro-1,3,5-triazacyclohexane, m.p. 205 °C) has been studied especially intensively during recent years, although Robertson's pioneering work was undertaken as early as the 1940s.[25,26] Essentially two main lines of attack—analysis of decomposition products and measurement of kinetic parameters—have been adopted in all investigations aimed at elucidating the mechanism and measuring the thermal stability of hexogen (this applies to all nitro-compounds). Unfortunately, neither of these approaches, despite their undoubted usefulness, provides an unambiguous interpretation of the reaction mechanism, mainly because kinetic investigations provide information only on the rate-determining steps—and then for not very complicated molecules—whereas the final products are mostly formed as a result of diverse secondary reactions. It is therefore to be expected that future progress in this field will involve the use of modern methods for identifying and studying intermediate reactive species (electron spin resonance, chemical polarisation of nuclei, spin traps).

The above work[25,26] detected the formation of nitric and nitrous oxides, nitrogen, hydrogen, carbon monoxide and dioxide, water, and formaldehyde. Table 2 gives as example the quantitative composition of the decomposition products. These are formed in somewhat different proportions when decomposition is conducted in solution in dicyclohexyl phthalate and trinitrotoluene.

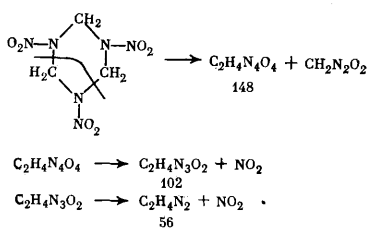
The paper[14] first reporting the detection of nitrogen dioxide is extremely important: unlike the substances in Table 2, this may be a primary reaction product. Subsequently other products have been detected—hydrogen cyanide[14], hydroxymethylformaldehyde[16], formic acid, ammonia, trimethylamine nitrate[17], 1,2-dihydro-1,3,5-triazine, vinylnitramine (the peak in the mass spectrum having $m/e = 88$, which has been attributed to the structures $(CH_2)_2NNO_2$, $CH_2:CHNHNO_2$, and $CH_3CH:NNO_2$),[18] and also several other compounds, for which the empirical formulae



$$C_2H_4N, \quad C_2H_4N_2, \quad CH_2N_2O_2, \quad C_3N_3H_4, \quad C_3N_3H_5, \quad C_2H_4N_3O_2,$$
$$CH_2N_3O_4, \quad C_3H_4N_4O_2, \quad C_2H_4N_4O_3, \quad C_2H_4N_4O_4$$

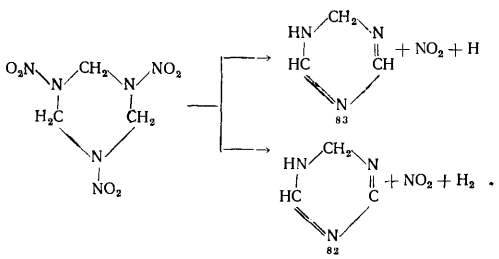
have been proposed[27] on the basis of the mass spectra (we must repeat here that in most cases the decomposition was studied under two-phase conditions, with simultaneous occurrence of gas-phase and liquid-phase reactions).

Table 2. Products of the liquid-phase decomposition of hexogen (moles mole^{-1} hexogen).[26]



Temp.	NO	N_2O	N_2	H_2	CO	CO_2
225° C	0.54	0.98	1.16	0.09	0.40	0.48
267° C	0.75	0.76	1.03	0.06	0.29	0.44

The first ideas on the mechanism of the liquid-phase decomposition of hexogen were expressed by Robertson[26,14]:



This scheme provides a reasonable explanation of the appearance of formaldehyde and nitrous oxide, but excludes the possibility of rupture of an N–NO_2 bond in the first stage, since nitrogen dioxide was not found. Although this product has since been detected[14,18,27], its kinetic behaviour with variation in the volume of the reaction vessel and in the weight of starting material differs from that of nitrous oxide and carbon dioxide[14]. From this it was concluded[14] that these products are formed under different conditions—nitrogen dioxide in gas-phase decomposition, but nitrous oxide and carbon dioxide in the liquid-phase reaction.

One of the possible mechanisms based on mass-spectrometric analysis of the decomposition products[27] involves cleavage of the ring (the numerals below the formulae indicate the masses of the ions detected in the mass spectrum):

However, these workers[27] assume a mechanism with separation of nitrogen dioxide without ring fission:

A similar mechanism was based by other workers[18] on the detection of 1,2-dihydro-1,3,5-triazine, although they examined the decomposition of hexogen only in gaseous and solid phases.

Before considering the mechanism of the liquid-phase decomposition of hexogen we note that the thermal stability was assessed qualitatively by differential thermal analysis[28]. The first kinetic investigation, showing a first-order reaction, was made by Robertson[26], who determined the kinetic parameters. However, later workers have obtained different results: thus over the range of degrees of conversion 10–80% the order appears[29] to be 1.36. A still more complicated picture has been observed[15], with an order of reaction 0.84 at degrees of conversion of 20.7–77%, followed by a sharp decrease, and then an increase to 0.94 at 96.5% conversion. Such complicated behaviour can be partly explained by the above two-phase character of the process, but the most important factor is most probably the complexity of the reaction itself, so that changes in experimental conditions lead to appreciable differences in kinetic behaviour. We may also mention the view[30] that the thermal decomposition of hexogen is autocatalytic.

Table 3. Activation parameters for the thermal decomposition of hexogen in the melt.

Method*	ΔT, °C	E_a, kcal mole^{-1}	A, s^{-1}	Ref.

**Depending on choice of formula for calculation.

Table 3 shows quite good agreement among values obtained by different workers for the activation parameters of the liquid-phase decomposition of hexogen. With regard to the divergence shown by Ref.31, it may be noted that values given in this paper for other substances also differ appreciably from general published values. Furthermore, the temperature range of the measurements is not indicated[31], so that it is not very clear whether a hexogen melt was actually studied (this applies also to measurements under non-isothermal conditions in Ref.34).

The thermal decomposition of liquid hexogen is obviously complicated, and is accompanied by the formation of reactive intermediate species responsible for diverse secondary processes. It therefore appears quite natural to investigate the decomposition in solution, when bi- and ter-molecular secondary reactions are slowed down in comparison with the unimolecular decomposition of the initial compound.

Table 4. Activation parameters for the thermal decomposition of hexogen in solution.

Solvent	c*, %	ΔT, °C	E_a, kcal mole^{-1}	A, s^{-1}	Ref.

*c = concentration of solution.
**Polyphenyl ether.

Appreciable autocatalysis is observed in dilute solution[26,35], in contrast to the melt. The induction period becomes shorter with rise in temperature, and completely disappears above 250 °C. The reaction is slower in solution than in the melt. Activation parameters in solution, determined from the initial portions of the kinetic curves on the assumption that a first-order equation is obeyed here, show good agreement among various workers (Table 4) with the exception of Ref.31. Another worker[36] did not observe autocatalysis in the thermal decomposition of hexogen: a first-order equation was satisfied throughout. The probable reason is that the experiments were conducted in relatively concentrated solutions, as first order is observed in the melt. It must therefore be expected that the induction period will become shorter with increase in concentration. This worker[36] noted also that products of the decomposition of hexogen are able to decompose trinitrotoluene. In this respect the latter is not the optimum solvent, although Table 4 shows that this does not affect the overall kinetic results.

The autocatalytic character of the thermal decomposition of hexogen in solution is most simply explained as above for the gas-phase breakdown of dimethylnitramine: on the hypothesis of a series of consecutive reactions. With rise in temperature the induction period may gradually diminish, and then completely disappear, as was observed by Robertson above 250 °C.[26]

An appreciable similarity in kinetic behaviour is evident between hexogen in solution and dimethylnitramine—the simplest secondary nitramine—in the gas phase, with slight acceleration and similar activation parameters (we have already noted a difference of 3 kcal mole^{-1} in the activation energies for the decomposition of these two compounds[23], attributed to a difference in the geometrical configuration of the nitamino-groups; however, this difference has little significance for our discussion, as the determination of activation energy in such experiments usually involves an error of 1–2 kcal mole^{-1}). Since the main features of the

mechanism of the decomposition of dimethylnitramine—primarily rupture of the $N-NO_2$ bond as the rate-determining stage—have been quite reliably established, the mechanism of the pyrolysis of hexogen in the liquid phase can reasonably be interpreted on the same basis, especially as such a hypothesis is supported by analysis of the decomposition products[18,27]. The increase in the rate of decomposition with solution concentration, passing to the melt in the limit, can reasonably be explained by an increasing contribution to the overall kinetics by bi- and ter-molecular secondary reactions, as noted above. The kinetic parameters (in particular those in Table 3) must then be regarded as overall values, not representing any particular elementary stage, which incidentally is supported by the high pre-exponential factors uncharacteristic of truly unimolecular reactions.

Robertson[26] suggested a chain mechanism for the thermal decomposition of hexogen in the melt. However, his experimental results[26] indicate that the length of the chain would be 1.31 and 2.96 at 205 and 273 °C respectively. Therefore we can hardly regard this as a chain process, and it is simpler to apply the concept of successive stages, which are eliminated with dilution of the solution.

As already stated, ideas on alternative mechanisms for the decomposition of hexogen assume in effect ring cleavage either following[26] or in the absence of[27] rearrangement. In the Reviewers' opinion, however, the composition of the products can provide only an indirect argument in support of these mechanisms, for they may be entirely formed in secondary stages, perhaps after rupture of an $N-NO_2$ bond. Furthermore, ring fission in primary stages will be expected to have activation parameters differing substantially from those for a mechanism with rupture of this bond. Nevertheless, as already stated, the decomposition of hexogen in solution is kinetically similar to that of dimethylnitramine in the gas phase.

Thus, of the two possibilities for the liquid-phase decomposition of hexogen, we prefer the radical mechanism with rupture of an $N-NO_2$ bond. In our view it is consistent with all the available experimental facts, whereas mechanisms involving ring fission show poor agreement with kinetic data for decomposition in solution. On the other hand, the choice between different mechanisms cannot be regarded as finally settled, since there is no direct evidence to prove or disprove a particular mechanism. In particular, the increase in reaction velocity on passing to the melt can be explained by a change in mechanism, with the possibility of bimolecular interaction between hexogen molecules in the melt. This aspect has been considered by Stals[37] in terms of quantum chemistry (applied to the decomposition of solid hexogen).

2. Octogen

Octogen (1,3,5,7-tetranitro-1,3,5,7-tetra-azacyclo-octane) resembles hexogen, so that it is not surprising that it behaves similarly on thermal decomposition, although quantitatively it is more thermostable: according to differential thermal analysis[28] octogen and hexogen undergo intense decomposition at 260 and 215 °C respectively. The decomposition of octogen has been studied also by differential scanning calorimetry[29]: this paper gave degrees of decomposition corresponding to the maximum on the scanning curve as a function of rate of heating, but the kinetic parameters had not been calculated.

The first detailed kinetic investigation of the thermal decomposition of octogen was reported by Robertson in the paper already mentioned[26]: he found a first-order reaction, and traced an analogy between hexogen and octogen. Table 5 collects existing data on the liquid-phase decomposition of the latter. Another study[15] by differential scanning calorimetry indicated an order of 0.6 at degrees of decomposition of 15.5–97.7%, but the experimental method was such that reaction took place in both gas and liquid phases. In Table 5 such large activation energies as 228 kcal mole^{-1} [31] are improbable and uncharacteristic not only of nitramines but also of nitro-compounds in general. The remaining very few values show quite good mutual agreement.

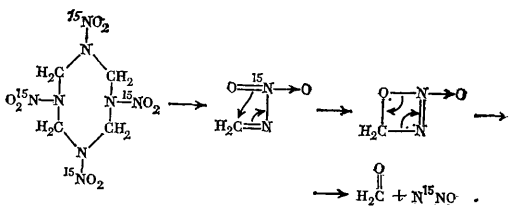

Table 5. Activation parameters for the thermal decomposition of octogen in the melt.

*Unpublished results of Johnston, quoted in Ref.31.
**Unpublished results of Lind, quoted in Ref.31.
***Depending on method of calculation.

As with hexogen, useful information can be obtained from decomposition in solution. In Convalex-10 (a polyphenyl ether) the activation energy was 50.3 kcal mole^{-1}.[31] A more detailed investigation[35] in *m*-dinitrobenzene solution established the slightly autocatalytic character of decomposition (as with hexogen in solution and dimethylnitramine in the gas phase). The activation energy and the pre-exponential factor were respectively 44.9 kcal mole^{-1} and 10^{16} s^{-1}.

The composition of the gaseous decomposition products from octogen was about the same as from hexogen[26]. The isotopic composition of the gaseous products from octogen labelled with nitrogen-15 in the nitro-group was the same ($^{14}N^{15}NO$, ^{15}NO, $^{14}N^{15}N$, $HC^{14}N$) below and above the melting point (over the range 230–285 °C).[39] It has thus been reliably established that nitric oxide is formed only from a nitro-group, nitrogen and nitrous oxide from a nitro-group and a nitrogen atom of the ring, and hydrogen cyanide only from a cyclic nitrogen atom. From these results it was concluded[39] that the decomposition of octogen does not involve rupture of $N-NO_2$ bonds and perhaps involves the stages

Although this scheme appears reasonable from our point of view and supports a reaction mechanism involving ring cleavage in the rate-determining stage, we nevertheless consider that it does not disprove, and moreover does not even contradict, a radical mechanism with $N-NO_2$ bond rupture in the first step. Indeed, nitrogen dioxide may attack another octogen molecule at an amino-nitrogen atom (a similar scheme has been given above for dimethylnitramine), and nitrous oxide and nitrogen having the observed isotopic composition could be formed by a series of secondary processes. Oxidation by nitrogen dioxide of formaldehyde resulting from the decomposition of octogen yields not nitrous oxide[39] but nitric oxide[40], which would of course have the isotopic composition ^{15}NO.

As with hexogen, an unambiguous interpretation of the mechanism of the liquid-phase decomposition of octogen is at present impossible. However, in view of the close analogy between these nitramines (similar structure, behaviour on thermal decomposition both in the melt and in solution, and composition of reaction products), we are inclined to support a radical mechanism with rupture of an $N-NO_2$ bond in the first stage, especially as it is indicated also by a thorough analysis[22] of possible decomposition schemes (though this was undertaken for gas-phase pyrolysis). The greater activation energy of decomposition of octogen than of hexogen can be explained (in terms of the ideas in Ref. 23) by differences in stability of $N-NO_2$ bonds depending on the geometrical configuration of the nitramino-group (planar, pyramidal, etc.).

3. Dinitropiperazine and Dinitroimidazolidine

Information on the thermal decomposition of other cyclic nitramines has appeared quite recently[40,41]. The kinetics of the decomposition of *NN'*-dinitropiperazine and *NN'*-dinitroimidazolidine (1,3-dinitro-1,3-diazacyclopentane) are fairly complicated: in the melt slight autocatalysis was observed by one group of investigators[40], but not by the other group[41], who worked at higher temperatures. On the other hand, the latter observed[41] that the ratio of the initial weight taken to the volume of the reaction vessel m/V influenced the kinetics, as also in solution did the concentration or at constant concentration this ratio. Thus, although as with other compounds data obtained in dilute solution are most convenient to interpret, there is no certainty that the rate constants obtained represent solely the primary step in decomposition.

Table 6. Activation parameters for the thermal decomposition of *NN'*-dinitropiperazine and *NN'*-dinitroimidazolidine in the liquid phase[40,41].

Nitramine	State	ΔT, °C	E_a, kcal mole^{-1}	A, s^{-1}
NN'-Dinitropiperazine	melt	216—250	47.4	$10^{17.3}$
NN'-Dinitropiperazine	soln.	130—245	45.8	$5.68 \cdot 10^{15}$
NN'-Dinitroimidazolidine	melt	135—200	37.1	$8 \cdot 10^{13}$
NN'-Dinitroimidazolidine	soln.	120—210	37.9	$9.53 \cdot 10^{13}$

Activation parameters determined by the two groups over different temperature ranges sometimes differed appreciably, but quite satisfactory agreement was obtained when both sets of results[40,41] were included in a single Arrhenius plot (Table 6). Furthermore, varying the solvent (*m*-dinitrobenzene, 1,3,5-trinitrobenzene, 2,4,6-trinitrotoluene) has no appreciable influence on the kinetics. Both groups interpret the results, as with hexogen and octogen, in terms of a radical mechanism involving rupture of an $N-NO_2$ bond in the first step. Comparison of the results in Table 6 for reactions in solution shows that activation parameters for the thermolysis of dinitropiperazine and dinitroimidazolidine are identical, within the limits of experimental error, with those for octogen and hexogen respectively.

Several general conclusions can be drawn from all these results on the influence of certain factors on the thermal stability of cyclic nitramines. Change in size of ring or number of nitro-groups apparently does not affect thermal stability directly. Indeed, octogen and dinitropiperazine are respectively eight- and six-membered rings containing four and two nitro-groups: and the less thermostable pair hexogen and dinitroimidazolidine are six- and five-membered rings with three and two nitro-groups. Nor does the distance between the nitramino-groups play an appreciable part: in octogen and dinitropiperazine they are separated by one and two methylene groups respectively, but the difference in activation energy in solution does not exceed 1 kcal mole^{-1}. With respect to thermal stability it is obviously most significant that change in molecular structure (ring size or number of nitramino-groups) entails a change in strength of the $N-NO_2$ bond perhaps owing to the above change in geometrical configuration of the nitramino-group[23].

The most interesting result of an analysis[40] of the gaseous products of the thermal decomposition of dinitropiperazine and dinitroimidazolidine is that nitrous oxide is not produced from the former in solution. Thus it is not necessarily a product of the thermal decomposition of cyclic nitramines.

4. Tetryl and its Analogues

Tetryl (*N*-methyl-*N*,2,4,6-tetranitroaniline), together with trotyl and nitroglycerin, was for many years a kind of model substance, from which the principal laws governing the thermal decomposition of explosives were elucidated. Thus Knowles[42], who was apparently the first to regard thermal decomposition as a method for assessing the chemical stability of explosives, worked with tetryl.

Investigation of the thermal decomposition of tetryl by differential thermal analysis showed[28] that it is less thermostable than many other explosives, including those considered above. Together with thermogravimetry these results indicate a two-stage reaction: at 162 °C the heat curve shows a sharp exothermic peak, which is followed at about 200 °C by a less marked second peak. Other workers[43] have observed exothermic peaks at 160 and 230 °C. Under somewhat different experimental conditions the same peaks have been observed[44] at 197 and 293 °C. Qualitative results have been published for the thermal decomposition of a mixture of 30% of tetryl and 70% of trotyl[45,46].

The first kinetic investigations of the thermal decomposition of tetryl have now become classics[1,2]. The reaction exhibits clearly developed autocatalysis, effected by picric acid formed in the reaction. It has since been established[47] that the rate of the liquid-phase decomposition comprises the rate of the first-order non-catalytic decomposition and that of a second-order autocatalytic reaction (first order with respect to tetryl and to the catalyst). This paper noted that calculation of catalytic rate constants must take into account the decrease in volume of the condensed compound during the reaction, as

such decrease causes an additional increase in catalyst (picric acid) concentration.

Table 7 compares results obtained for the thermal decomposition of tetryl by various workers, some of whom did not separate the stages and found gross values for the activation parameters (Table 8). All the results show good agreement: activation energies for the non-catalytic reaction lie in the range $E_a = 37.5 \pm 2.5$ kcal mole^{-1}, and the pre-exponential factors $A = 10^{14.5 \pm 1.5}$ s^{-1}; for the catalytic reaction $E_a = 37 \pm 1.5$ kcal mole^{-1} and $A = 10^{15 \pm 0.5}$ s^{-1}. Some values in Table 8 are exceptions: apart from the absence of separation of catalytic from non-catalytic stages, Roginskii's miscalculations[3,54] were based on extremely limited experimental results[1,2]; we have already noted that values in Ref. 31 show poor agreement with those obtained by other authors; and the results in Ref. 33 were obtained over a temperature range of only 4 deg.

The above mean activation parameters for the liquid-phase decomposition of tetryl agree in general with those for the other nitramines discussed, although tetryl decomposes more rapidly and has a lower activation energy, which may have several causes. Tetryl is an aromatic nitramine, and the trinitrophenyl group may influence the electronic structure of the nitramino-group, enhancing its reactivity. Furthermore, the rate of the non-catalytic stage increases with the m/V ratio[50], which implies that the reaction is catalysed not only by the condensed product (picric acid) but also by gaseous products. The activation parameters also depend on this ratio: with increase in m/V from 0.80 to 35.35 mg cm^{-3} the activation energy of the non-catalytic stage increases from 35.2 to 42.2 kcal mole^{-1}, and the pre-exponential factor from $10^{13.5}$ to $10^{17.5}$ s^{-1}.[50] Thus this rate constant is not a true but an effective value, which includes a contribution by reactions involving gaseous products. Hence the activation parameters in Table 7 (and in general those of the other nitramines considered) represent only to a first approximation the primary stage of decomposition (the data from Ref. 50 in Table 7 apply to $m/V = 0.80$ mg cm^{-3}).

Several analyses have been made of the gaseous products of the thermal decomposition of tetryl[50,51,43]. Some workers detected nitrogen dioxide, nitric oxide, and carbon dioxide and monoxide[48,49]; others found methane together with nitrogen dioxide, nitric oxide, and nitrogen[43]; methyl nitrite and nitrate are also formed[53]. During decomposition the concentrations of nitrogen dioxide and nitric oxide pass through a maximum[50]. Together with the above tendency of nitramines to be oxidised by nitrogen dioxide, this suggests that such oxidation is responsible for the dependence of the rate of the non-catalytic stage on the m/V ratio.

Gaseous decomposition products are mostly formed in secondary stages, so that their analysis gives little information on the mechanism of the initial stages. In this respect condensed decomposition products have the greatest interest. One of them (picric acid) has been known for a long time[1,2]. Other condensed products—2,4,6-trinitroanisole and *N*-methyl-2,4,6-trinitroaniline—have also been found[51]. These conclusions have since been confirmed[55,56], together with the detection of small quantities of 2,4,6-trinitroaniline, 1,3,5-trinitrobenzene, *N*-methyl-*N*,2,4-trinitroaniline, and perhaps *N*,2,4,6-tetranitroaniline.

Table 9. Kinetics of the thermal decomposition of 2,6-$(NO_2)_2$-4-$R^1C_6H_2N(NO_2)R^2$ in dinitrobenzene solution[52,53].

R^1	R^2	ΔT, °C	10^5k, s^{-1} (at 160 °C)	E_a, kcal mole^{-1}	A, s^{-1}
OCH_3	CH_3	145—165	$1.78 \cdot 10$	32.1	$10^{12.44}$
CH_3	CH_3	150—170	$1.5 \cdot 10$	34.2	$10^{13.42}$
Cl	CH_3	145—165	9.6	33.7	$10^{13.11}$
Br	CH_3	155—175	9.2	33.8	$10^{13.41}$
NO_2	CH_3	150—175	5.5	35.9	$10^{13.50}$
NO_2	C_2H_5	144—165	$3.7 \cdot 10$	33.3	$10^{13.90}$
NO_2	n-C_3H_7	135—155	$6.6 \cdot 10$	32.7	$10^{13.30}$
NO_2	iso-C_4H_9	130—150	$1.75 \cdot 10^2$	33.5	$10^{14.16}$

The above close similarity between the activation parameters of the thermal decomposition of tetryl and other nitramines suggests identity of the first stage in their decomposition—rupture of an N—NO_2 bond—which is consistent with the formation of *N*-methyl-2,4,6-trinitroaniline among the decomposition products. This compound may be formed by detachment of a hydrogen atom from an adjacent molecule by an *N*-methyl-2,4-6-trinitrophenylamino-radical produced in the first stage. Additional evidence supporting rupture of an N—NO_2 bond in the first stage of decomposition was obtained by Stepanov et al.[52,53], who made a kinetic investigation of tetryl and several of its analogues of general formula 2,6-$(NO_2)_2$-4-$R^1C_6H_2N(NO_2)R^2$. With variation of R^1 the results (first five lines in Table 9) conform well to the correlation

$$\lg k = -(0.488 \pm 0.026)\sigma - (3.898 \pm 0.011)$$
$$(r = 0.996,\ S_y = 0.016,\ n = 5).$$

A different relation is satisfied with variation of R^2 (last four lines):

$$\lg k = -(7.825\pm0.240)\sigma^* - (0.556\pm0.032)E_s - (4.259\pm0.017)\ (r=0.999,\ r_1=0.961,\ r_2=0.849,\ S_y=0.025,\ n=4).$$

Thus increase in electron density on the amino-nitrogen atom of the nitramino-group increases the rate of thermal decomposition. Examination of possible decomposition schemes also led to the conclusion[52,53] that a radical scheme is most consistent with the kinetic data and the correlation analysis. From this and the published composition of the products the following mechanism was proposed[52] for the decomposition of tetryl [Ar = 2,4,6-$(NO_2)_3C_6H_2$]:

$$\begin{aligned}
&ArN(CH_3)NO_2 \rightarrow Ar\dot{N}CH_3 + NO_2\ ,\\
&Ar\dot{N}CH_3 + NO_2 \rightarrow ArN(CH_3)\dot{O} + NO\ ,\\
&Ar\dot{N}CH_3 + NO \rightarrow ArN(CH_3)NO\ ,\\
&ArN(CH_3)NO \rightarrow ArON{=}NCH_3\ ,\\
&ArON{=}NCH_3 \rightarrow ArOCH_3 + N_2\ ,\\
&ArN(CH_3)\dot{O} \rightarrow Ar\dot{N}H + CH_2O\ ,\\
&Ar\dot{N}H + NO \rightarrow ArNHNO\ ,\\
&ArNHNO \rightarrow ArN{=}NOH\ ,\\
&ArN{=}NOH \rightarrow ArOH + N_2\ ,\\
&CH_2O + NO_2 \rightarrow CO + CO_2 + H_2O + NO\ ,\\
&ArOCH_3 \xrightarrow{\text{hydrolysis}} ArOH\ .
\end{aligned}$$

Here we may refer again to the possible formation of $ArNHCH_3$ from $ArN(CH_3)\cdot$ by acceptance of a hydrogen atom from some molecule. Similarly $ArN(H)\cdot$ can accept hydrogen to form $ArNH_2$. Picric acid can be obtained by the hydrolysis not only of trinitroanisole but also of tetryl itself[42].

The nature of the autocatalysis has remained largely obscure. Decomposition of tetryl is accelerated not only by picric acid but also by sulphuric acid[1], whereas nitric and acetic acids have no catalytic effect, apparently because of their volatility. It was suggested[2] that picric acid acts as a protic catalyst; other workers[51] assumed that protonation occurs at the amino-nitrogen atom, but gave no evidence of the mechanism of catalysis. Moreover, it remains obscure why the thermal decomposition of tetryl but not of other nitramines is so strongly autocatalytic.

5. Substituted Dialkylnitramines

The present subsection examines the liquid-phase decomposition of compounds of general formula $R^1N(NO_2)R^2$, where R^1 and R^2 are substituted alkyl groups.

The kinetics of the thermal decomposition of bis-2,2-dinitropropylnitramine in 5% solution in *m*-dinitrobenzene at 145–196.2 °C is similar[57] to that of the gas-phase pyrolysis of dimethylnitramine, with slight autocatalysis and activation parameters characteristic of the nitramines already discussed: the activation energy is 39.7 ± 1.4 kcal $mole^{-1}$, and the pre-exponential factor $10^{15.7\pm0.7}$ s^{-1}. Hence it may be supposed that decomposition of this compound resembles that of the other nitramines, having a radical mechanism with primary rupture of an $N-NO_2$ bond.

Similar results have been obtained[58] for the thermal decomposition of *N*-nitro-γ-azavaleric acid at 180–220 °C. Appreciable autocatalysis was observed; for the initial stage the activation energy and the pre-exponential factor were respectively 42.08 kcal $mole^{-1}$ and $10^{14.72}$ s^{-1}. The decomposition products included acrylic acid, nitrosomethane, *N*-methylmethyleneimine, carbon monoxide and dioxide, water, nitrogen, and nitric and nitrous oxides. The kinetic parameters again indicate rupture of an $N-NO_2$ bond in the first stage, and the scheme

$$\begin{aligned}
&CH_3N(NO_2)CH_2CH_2COOH \rightarrow CH_3\dot{N}CH_2CH_2COOH + NO_2\ ,\\
&CH_3\dot{N}CH_2CH_2COOH \rightarrow CH_3\dot{N}H + CH_2{=}CHCOOH\ ,\\
&CH_3\dot{N}CH_2CH_2COOH \rightarrow CH_2{=}NCH_3 + \dot{C}H_2COOH\ ,\\
&CH_3N(NO_2)CH_2CH_2COOH + A \rightarrow CH_3N(NO_2)CH_2\dot{C}HCOOH\ ,\\
&CH_3N(NO_2)CH_2\dot{C}HCOOH \rightarrow CH_3\dot{N}NO_2 + CH_2{=}CHCOOH\ ,
\end{aligned}$$

was suggested to explain the composition of the products, where A is a hydrogen acceptor, e.g. NO_2. The remaining gaseous decomposition products may be formed by the oxidation of $CH_3N(H)\cdot$ and $\cdot CH_2COOH$ with nitrogen dioxide and by the breakdown of $CH_3N(NO_2)\cdot$.

The decomposition of many nitramino-carboxylic acids and their salts has been studied[59] by differential thermal analysis, thermal stability being assessed from the temperature corresponding to an exothermic peak. Although kinetic parameters were not determined, qualitative relations could be established between thermal stability and molecular structure. It was found in particular that the stability increases with the length of the aliphatic chain and with the p*K* of the acid. Thermal stability is influenced also by the position of the nitramino-group in the molecule.

Table 10. Kinetics of the thermal decomposition of $R^1N(NO_2)R^2$ in dibutyl phthalate solution[53].

R^1	R^2	Δ*T*, °C	10^5k, s^{-1} (at 210 °C)	E_a, kcal $mole^{-1}$	*A*, s^{-1}
CH_3	$(CH_2)_2COOCH_3$	200–230	2.89	40.4	$10^{13.77}$
CH_3	$(CH_2)_2CN$	190–230	2.57	41.9	$10^{14.43}$
CH_3	CH_2OCH_3	190–230	2.34	40.9	$10^{13.89}$
$(CH_2)_2COOCH_3$	$(CH_2)_2COOCH_3$	210–250	1.78	40.7	$10^{13.76}$
$(CH_2)_2CN$	$(CH_2)_2CN$	210–250	1.46	41.3	$10^{13.92}$
CH_3	$(CH_2)_2COOH$	200–230	3.40	40.8	$10^{14.03}$
$(CH_2)_2COOH$	$(CH_2)_2COOH$	200–240	4.05	40.8	$10^{14.07}$

A systematic investigation of the decomposition of several substituted dialkylnitramines in 5% solution in dibutyl phthalate has shown[53] that variation in the substituents has very little effect on the kinetics (Table 10), which is characteristic of the thermal decomposition of nitramines in general. Nevertheless, a correlation was obtained between structure and reactivity (except for the last two examples whose decomposition kinetics were apparently influenced by ionisation of the carboxyls):

$$\lg k = -(0.495\pm0.02)\ (\sigma^*_{R^1}+\sigma^*_{R^2}) - (4.34\pm0.01)\ (r=0.982,\ S_y=0.028,\ n=6).$$

As in the tetryl series the values of the activation parameters and the sign of the constant ρ* again support rupture of an $N-NO_2$ bond in the first stage.

Manometric and derivatographic methods have been used[60] for a kinetic study of the thermal decomposition of ferrocenylmethylnitramines $FcCH_2N(NO_2)R$ (where Fc = ferrocenyl and $R = CNCH_2CH_2$, $CH_3C(NO_2)_2CH_2CH_2$, $FcCH_2$) in 2% solution in dibutyl phthalate. The second of these compounds follows a first-order law up to 50% decomposition, but the other two show slight autocatalysis. Table 11 lists the kinetic parameters of the initial stages calculated on the assumption that they are described by a first-order equation. The activation parameters for decomposition of the latter two compounds are closely similar to those for other nitramines,

from which it was concluded[60] that they decompose with rupture of an N–NO_2 bond in the first stage. The cyanoethyl compound decomposes appreciably more rapidly, which is attributed[60] to a different mechanism: the first stage involves rupture not of an N–N but of a C–N bond.

Table 11. Kinetics of the thermal decomposition of $FcCH_2N(NO_2)R$.[60]

R	ΔT, °C	10^4k, s^{-1} (at 170 °C)	E_a, kcal mole^{-1}	A, s^{-1}
CH_2CH_2CN	160–180	1.29	42.9	$10^{17.26}$
$CH_2CH_2C(NO_2)_2CH_3$	180–200	$6.30\cdot10^{-2}$	36.8	$10^{12.96}$
$FcCH_2$	190–200	$3.16\cdot10^{-2}$	38.5	$10^{13.49}$

In the Reviewers' opinion, however, there are insufficient grounds for such a conclusion, and it is more reasonable to suppose that the cyanoethyl derivative, like the other nitramines, breaks down with rupture of the N–NO_2 bond as the rate-determining stage. This view can be supported by the absence of obvious differences between cyanoethyl and the other two substituents that could cause such a sharp change in reaction mechanism. The cyanoethyl derivative decomposes with slight autocatalysis, so that the observed rate constant evidently does not characterise solely the first step. In view of the narrow temperature range of the measurements, the observed activation parameters may therefore differ markedly from those representing the primary step. Furthermore, the value $E_a = 42.9$ kcal mole^{-1} in Table 11 is closely similar to those given above for other nitramines.

Derivatographic investigation of ferrocenylmethylnitramines[60] revealed several exothermic peaks, indicating that decomposition involved a series of consecutive reactions, but their nature was not studied.

Study of the decomposition of 2,4,6-trinitro-2,4,6-triazaheptamethylene diacetate by differential scanning calorimetry[33] gave the activation energy 53 ± 5 kcal mole^{-1}. The fewness of the experimental results makes any interpretation of this value difficult.

6. Dina

Dina (nitraminodiethyl dinitrate) contains different reactive functional groups—nitrimino and two nitrato—each of which can influence the kinetics of thermal decomposition in its own way.

Kinetic study by manometric, gravimetric, and calorimetric methods with small quantities in the reaction vessel (in the manometric experiments $m/V = 10^{-4}$ g cm^{-3}) at 150 to 170 °C showed[61] a first-order reaction with $E_a = 45.0$ kcal mole^{-1} and $A = (3.8–4.8) \times 10^{18}$ s^{-1} (depending on the mode of measurement). These kinetic parameters were used[62] to calculate those of thermal explosion. Good agreement was found between calculation and experiment.

However, later research showed[63] that the decomposition of dina has more complicated kinetics: with sufficiently high m/V ratios at sufficiently low temperatures the reaction is autocatalytic, the more strongly so the higher the ratio and the lower the temperature. With decrease in the ratio and rise in temperature, however, autocatalysis becomes increasingly weaker, and finally disappears altogether. Thus with $m/V = (5–10) \times 10^{-4}$ g cm^{-3} at 160 °C the rate of decomposition falls monotonically during the reaction, but more slowly and not in conformity with a first-order law: in other words, if the process is described formally by a first-order equation, the observed rate constant increases during the reaction. The first order reported in Ref.61 was apparently due precisely to the use of low m/V ratios (10^{-4} g cm^{-3}) at high temperatures (150–170 °C).

The dependence of the rate of decomposition of dina on the m/V ratio indicates the participation of a gaseous product in the rate-determining stage. This is most probably nitrogen dioxide, which, as we have noted, tends to oxidise the nitramino-group. Indeed, with increase in the ratio and fall in temperature (i.e. on passing to conditions of appreciable autocatalysis) the content of this gas among the reaction products diminishes[63], which can be attributed to an increasing role of redox processes involving it under conditions ensuring autocatalysis.

Detailed experiments with additions of water revealed[63] that the autocatalysis is probably largely due to acid hydrolysis of dina, which becomes more intense with accumulation of water, nitrogen dioxide, and nitric acid. In this respect dina resembles many other nitric esters, in particular nitroglycerin. However, there is no complete analogy with the latter, since the above redox processes play an important part in the decomposition of dina, which also contains a nitramino-group readily oxidised by nitrogen dioxide and perhaps nitric acid.

The complicated character of the thermal decomposition of dina probably prevents determination of the kinetic parameters of the first step even from the initial rates; the rate constants of the initial stage of decomposition themselves are obviously effective values, and depend on the experimental conditions. It is therefore not surprising that the activation parameters obtained[63] (on the assumption of a first-order equation) differed somewhat from those in Ref.61: with $m/V = (5–20) \times 10^{-4}$ g cm^{-3} at 100–170 °C, the activation energy and the pre-exponential factor were respectively 42.0 kcal mole^{-1} and 10^{17} s^{-1}; with $m/V = (6–12) \times 10^{-2}$ g cm^{-3} at 70–90 °C the corresponding values were 41.5 and 10^{16}.

Subsequent research has confirmed and developed the earlier results[61,63]. The kinetics of the decomposition of dina has been studied[64] calorimetrically with very high m/V ratios (with the reaction vessel almost completely filled): the reaction velocity exceeds some hundredfold the value when $m/V = 10^{-4}$ g cm^{-3}, which is fully consistent with the accelerating role of gaseous reaction products. Kinetic curves for the evolution of heat under isothermal conditions between 103 and 111 °C are complicated with two maxima, which indicates the occurrence of two processes separated in time and responsible for the acceleration of decomposition; they have activation energies of 34 and 32 kcal mole^{-1}. The observed activation energy diminishes non-uniformly with the degree of decomposition over the range $\eta = 0.1–0.45$, after which it remains unchanged at 32 kcal mole^{-1}. The conclusion[64] that two processes accelerate the thermal decomposition of dina is consistent with a contribution[63] by acid hydrolysis and redox stages to this reaction.

The kinetics of decomposition has also been investigated[65] calorimetrically over the pressure range 0.05–5 atm. A rise in pressure favours dissolution of gaseous products in liquid dina, and according to the above discussion should accelerate the reaction. This is indeed observed, with the activation energy and pre-exponential factor (45.0 kcal mole^{-1} and 3×10^{18} s^{-1}), obtained at 0.05 atm on the assumption of a first-order reaction, showing good agreement with the above values[61]. Rise in pressure to 1 atm is accompanied by

gradual increase in the contribution by gaseous products to the overall reaction, with a consequent fall in the activation energy to 35 kcal mole^{-1} and in the pre-exponential factor to 2.5×10^{13} s^{-1}. Further rise in pressure to 5 atm does not affect the activation energy, but the rate constant continues to increase somewhat (owing to the pre-exponential factor). The kinetic parameters for 1 atm were used[65] to calculate parameters of thermal explosion in good agreement with experimental values.

Thermographic investigation of the decomposition of dina gave heating curves[66] with two exothermic peaks, indicating as before[64] two time-separated reactions accelerating the decomposition. A computer simulation was based on the simplified formal scheme

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \quad (1)$$

$$A + B \xrightarrow{k_3} 2B + C \quad (2)$$

Stage (1) represents a series of consecutive reactions (perhaps B = NO_2) and stage (2) an autocatalytic process (perhaps acid hydrolysis). Activation energies E_1–E_3 corresponding to the rate constants k_1–k_3 were obtained of 43.8, 28.6, and 28.7 kcal mole^{-1}, with corresponding pre-exponential factors A_1–A_3 of 1.1×10^{18}, 4.3×10^9, and 4.3×10^{11} s^{-1}. The kinetic parameters corresponding to the stage A → B are closely similar to values observed previously[61,63], and those corresponding to the other two stages to values observed at high m/V ratios[64] and under high pressures[65].

The macrokinetic characteristics of the thermal decomposition of dina have been studied[67] also by impulse calorimetry.

It was suggested[63] that the primary stage in the thermal decomposition of dina, as of other nitric esters, involves rupture of the O–NO_2 bond. However, it must be recalled that in the gas phase simple nitric esters and nitramines have closely similar activation parameters: i.e. nitrato- and nitramino-groups are similar in reactivity. Furthermore, the above activation parameters for dina[61,63], though not fully representing the primary step, are nevertheless closely similar to corresponding values for other nitramines. Thus the nature of the first stage in the thermal decomposition of dina remains an open question.

7. Nitramides and *N*-Nitrocarbamates

In 1955 White showed[68] that heating *N*-n-butyl-*N*-nitroacetamide in tetrachloromethane solution at 77 °C for 15 h gives n-butyl acetate (in 75% yield) with acetic acid and but-1-ene (each in 23% yield) as well as nitrous oxide. This reaction was subsequently[69,70] extended to a wide range of nitramides $R^1N(NO_2)CO.R^2$ and *N*-nitrocarbamates $R^1N(NO_2)COOR^2$ (where R^1 = Alk and R^2 = Alk, Ar). By analogy with nitrosamides, which by that time had been studied in detail (for reference see Refs.68–70), a reaction mechanism with intermediate formation of a diazoxy-ester was suggested:

$$R^1N(NO_2)C(O)R^2 \rightarrow [R^1N{=}N^+(O^-)OCR^2] \cdot$$

This intermediate is unstable, and can decompose in two ways:

$$[R^1N{=}N^+(O^-)OCR^2] \rightarrow R^1OC(O)R^2 + N_2O$$

$$[R^1N{=}N^+(O^-)OCR^2] \rightarrow R^2COOH + N_2O + \text{Alkene},$$

where the alkene corresponds to detachment of a hydrogen atom from R^1. Thermal decomposition is accompanied by isomerisation. For example[70] *N*-isobutyl-3,5-dinitrobenzonitramide in tetrachloromethane solution at 76 °C gives not only isobutyl 3,5-dinitrobenzoate but also the corresponding s-butyl and t-butyl esters in respective yields of 16% and 1–3% relative to the isobutyl compound. A weighty argument in support of the suggested mechanism was that the diazoxy-ester was obtained *in situ* by an independent method, and on decomposition gave the same products as did the corresponding nitramide.

Table 12. Rate constants for the thermal decomposition of nitramides, nitrosamides, and nitrocarbamates[71].

N-Nitro-compound	Solvent	Temp., °C	k, s^{-1}

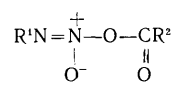
A detailed kinetic investigation[71] of the thermal decomposition of several nitramides and nitrocarbamates was directed mainly at the influence of structure on reactivity. Decomposition followed a first-order equation, the rate presumably[71] determined by the first stage, i.e. formation of the diazoxy-ester. Tables 12 and 13 include for comparison data on related *N*-nitro-compounds. It is evident that reactivity is indeed very strongly dependent on structure. Qualitative explanations were based[71] on the view that the greater thermal stability of nitrocarbamates than of nitramides[70] was due to enhancement of the resonance stabilisation of the former by the alkoxy-group:

$$R^1{-}N(NO_2){-}C(O){-}O{-}R^2 \longleftrightarrow R^1{-}N(NO_2){-}C^+(O^-){-}O{-}R^2 \longleftrightarrow R^1{-}N(NO_2){-}C(=O^+){-}O^-{-}R^2 \cdot$$

The resonance form indicated on the extreme right is absent from nitramides:



Since the transition state involves little or no resonance interaction of the alkoxy-group, the lower energy of the ground state of nitrocarbamates than of nitramides leads to a lower activation energy of decomposition of the latter.

Thermal decomposition of nitrocarbamates becomes significantly more rapid with increase in size of the substituent R^1, which may be due to non-bonding interactions of R^1 with nitro and alkoxycarbonyl groups. To a first approximation the energy of the transition state is independent of the size of R^1 (owing in particular to the near perpendicularity of the alkoxycarbonyl group to the plane of the molecule); yet as a consequence of the above non-bonding interactions the energy of the ground state is proportional to the size of R^1. As a result, increase in size lowers the activation energy of the reaction and causes "steric acceleration".

Nitramides and *N*-nitrocarbamates are thermally more stable than the corresponding *N*-nitroso-compounds. This may be partly due to greater nucleophilicity of the nitroso- than of a nitro-oxygen atom. Another explanation may be the possibility of non-bonding interaction between R^1 and a nitro-oxygen atom in the transition state. All the above factors are energetic in character, and do not affect the entropy of activation.

The above results show that nitramides and *N*-nitrocarbamates differ significantly in thermal stability, mechanism of decomposition, and dependence of reactivity on structure from the nitramines discussed previously. Since the first step in breakdown of the first two groups—formation of a diazoxy-ester—involves rupture of an $NO_2.N-CO$ bond, it must be supposed that this bond has been weakened by the carbonyl or carboxyl group. Similar weakening is absent from nitramines, so that they decompose by a different mechanism, although it must be borne in mind that Robertson's mechanism[14,26] for the decomposition of hexogen with cleavage of the ring (subsection 1) resembles the mechanism of the decomposition of nitramides and nitrocarbamates.

The mechanism of decomposition of the diazoxy-ester

is unknown. It may consist in elimination of nitrous oxide with formation of R^1 and R^2COO radicals, which then interact in the solvent cage.

8. *N*-Fluoronitramines

Graff et al.[72-74] made a series of kinetic investigations on the thermal decomposition of the isomeric *N*-fluorobutylnitramines. The first study already showed[72] that *N*-fluoro-n- and -s-butylnitramines have about the same reactivity, whereas the t-butyl compound decomposes more rapidly by a factor of 20.

A detailed kinetic investigation[73] indicated a first-order equation with parameters listed in Table 14. The course of decomposition is appreciably influenced by the nature of the solvent. Thus in ethylcyclohexane, tetrachloromethane, and a mixture of the latter with ethanol (2.5 : 1) the rate constants at 61.7 °C are (in 10^{-4} s^{-1}) respectively 14.62, 8.41, and 5.64. Table 14 shows that the activation parameters are still more strongly influenced by the nature of the solvent.

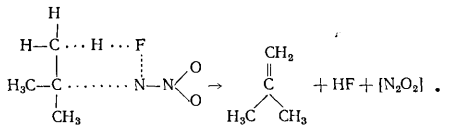
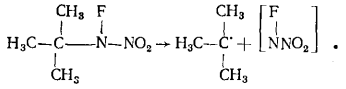
2-Methyl-1-nitropropene	5.6
2-Methyl-1-nitropropan-2-ol	24.2



*s = relative area of chromatographic peak.

Table 15 gives the composition of the thermal decomposition products of *N*-fluoro-t-butylnitramine found chromatographically. The relative area of a chromatographic peak can be regarded to a first approximation as the proportion of the given product in the mixture. Besides the compounds listed in Table 15 hydrogen fluoride, and α-substituted isobutyraldehyde, and ammonium hexafluorosilicate were detected among the decomposition products. Nitrogen is not formed in the reaction. In special experiments on the decomposition of this nitramine labelled with nitrogen-15 in the nitro-group (5.64%) the isotope was detected in nitrous oxide (3.2%), ammonium hexafluorosilicate (4.02%), 2-fluoro-2-methyl-1-nitropropane (4.07%), and 2-methyl-1-nitropropan-2-ol (4.01%).

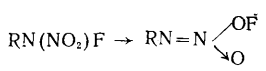
The complicated composition of the decomposition products led to the suggestion[73] that two mechanisms—molecular, involving a five-membered activated complex, and radical—might operate simultaneously. On the reasonable assumption that the former mechanism is characterised by a negative and



the latter by a positive entropy of activation, it may be concluded that the contributions by these mechanisms to the overall process should depend on the nature of the solvent. According to the results in Table 14 a radical mechanism predominates in ethylcyclohexane, and a molecular mechanism in tetrachloromethane.

The molecular mechanism can be represented by the scheme

It readily explains the formation of methylpropene and hydrogen fluoride, but encounters several objections. Firstly, little methylpropene is formed (Table 15), although a molecular mechanism can be expected to predominate particularly in tetrachloromethane solution. Secondly, this mechanism does not explain the formation of other decomposition products, in particular 2-methyl-2-nitropropane. Thirdly and finally, formation of nitric oxide—not nitrous oxide—must be expected from the above scheme.



The radical mechanism was written[73]

Several special experiments were undertaken[73] to substantiate a radical mechanism. It was shown in particular that acrylonitrile readily polymerises in the presence of the isomeric *N*-fluorobutylnitramines. However, formation of the t-butyl radical could not be proved: it was not captured by the stable galvinoxyl radical; and 2,2,3,3-tetramethylbutane, which usually appears in the presence of t-butyl radicals, was not detected among the decomposition products. Finally, decomposition of the isomeric *N*-fluorobutylnitramines in toluene solution is not accompanied by formation of bibenzyl.

In the Reviewers' opinion the chief objection to a radical mechanism of decomposition lies in the low activation energies (Table 14), which do not correspond to the bond strengths in *N*-fluoronitramines: in fact the energy of dissociation of the N–F bond is close to 70 kcal mole^{-1},[72] the stability of the N–NO_2 bond has been much discussed in the preceding sections, and the C–N bond is in any case stronger than the N–N bond.

Thus the mechanism of the thermal decomposition of *N*-fluoronitramines remains in considerable measure obscure. As working hypothesis for future research it may be supposed that the mechanism is identical with that discussed in the preceding subsection for the decomposition of nitramides and nitrocarbamates. Furthermore, it would have been interesting to examine the possibility of a mechanism involving a rearrangement analogous to formation of the *aci*-form of nitro-compounds:

followed by elimination of nitrous oxide.

Analysis of the products of the thermal decomposition of *N*-fluoro-t-butylnitramine was extended to the n- and s-butyl derivatives (Tables 16 and 17).[74] Several unidentified compounds are also found in all three cases. Comparison of Tables 15–17 indicates that the n-butyl isomer on decomposition gives only n-butyl derivatives, whereas the s- and t-butyl isomers give both mono- and di-substituted butane derivatives. From this it was concluded[74] that the decomposition of the s- and t-butyl isomers, but not that of the n-butyl compound, may involve the above molecular mechanism.

9. Primary Nitramines

Primary nitramines differ from secondary nitramines in the presence of a hydrogen atom attached to the amino-nitrogen atom: i.e. they have the general formula $RNHNO_2$. They are less thermostable than the secondary compounds, as is evident in the activation parameters of their decomposition.

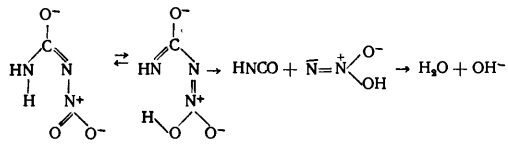
The thermolysis of methylenedinitramine (medina) over the range 110–130 °C follows a first-order equation with activation energy 35.4 kcal mole^{-1} and pre-exponential factor $10^{15.6}$ s^{-1}.[75] Ethylenedinitramine (edna) also decomposes according to a first-order law, with corresponding parameters 30.5 kcal mole^{-1} and $10^{12.8}$ s^{-1} at 184–254 °C.[48]

The lower thermal stability of primary than of secondary nitramines suggests a difference in the mechanism of decomposition, most probably due to the mobile hydrogen atom of the primary nitramino-group.

Products of the thermal decomposition of medina and edna are similar in composition, consisting mainly of nitrous oxide and the corresponding aldehyde, respectively formaldehyde and acetaldehyde. Thus the thermal decomposition of edna follows essentially the stoichiometric equation[48]

$$C_2H_8N_4O_4 \rightarrow 2N_2O + CH_3CHO + H_2O.$$

It is interesting that the decomposition of primary nitramines in aqueous solution follows the same stoichiometric equation: for medina[76]



$$CH_2(NHNO_2)_2 \rightarrow 2N_2O + CH_2O + H_2O,$$

and for *N*-nitrourea[77]

$$H_2NCONHNO_2 \rightarrow HNCO + N_2O + H_2O.$$

However, ethylene glycol has also been detected[78] in the decomposition of edna in aqueous solution and in the solid phase (this paper[78] mentions that it was first detected in decomposition in aqueous solution by Franchimont and Klobbie as early as 1887).

Primary nitramines are weak acids[79], and the reactive form undergoing decomposition may correspond to the anion RN^-NO_2. Thus for nitrourea the thermolysis mechanism

was suggested[77], with an activation energy of 27.5 kcal mole^{-1} and an activation entropy of 7.7 e.u. (pH 10). Since this compound is a nitramide, the typical mechanism (subsection 7)

$$H_2NC(O)NHNO_2 \rightarrow H_2NC(O)ON(\rightarrow O)=NH \rightarrow N_2O + H_2NCOOH \rightarrow HNCO + H_2O$$

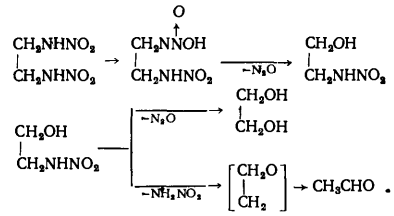
is also possible. However, it is not altogether consistent with the kinetic results: Table 13 shows that the thermal decomposition of nitramides has negative activation entropies. Nevertheless, this mechanism cannot finally be rejected.

For the decomposition of medina in aqueous solution a mechanism has been suggested[76] analogous to the first of the above mechanisms for urea:

Subsequent processes may yield the final products:

$$CH_2=NNO_2 \rightarrow CH_2O + N_2O;\ \bar{N}HNO_2 \rightarrow N_2O + OH^-.$$

A similar scheme is in principle possible for edna:



$$O_2N\bar{N}CH_2CH_2NHNO_2 \rightarrow \bar{N}HNO_2 + CH_2=CHNHNO_2;$$
$$CH_2=CHNHNO_2 \rightarrow N_2O + CH_2=CHOH;\ CH_2=CHOH \rightarrow CH_3CHO\ .$$

As primary nitramines give the same products of decomposition in the melt and in solution, identical mechanisms can be assumed. In the melt, however, the degree of ionisation is smaller and the concentration of the anionic form lower, which should tend to slow down decomposition. Primary nitramines do in fact decompose in the melt with measurable velocities at significantly higher temperatures than in aqueous solution.

In a medium of low polarity ionisation is almost completely suppressed, and a different mechanism of decomposition should operate. This apparently occurs when ring-substituted *N*-nitroanilines decompose in octan-2-ol solution[80]. Reaction takes place at a very high temperature (120 °C), nitrous oxide is not formed, and the products are nitrogen, water, the corresponding aromatic hydrocarbon, and octan-2-one. A mechanism involving intermediate formation of the *aci*-form of the nitramine and aryl radicals was suggested (RH = solvent, nitramine, or product molecule):

$$ArNHNO_2 \rightleftarrows ArN=N(\rightarrow O)OH\ ,$$
$$ArN=N(\rightarrow O)OH \rightarrow \dot{O}H + Ar\dot{N}=NO \longleftrightarrow ArN=N\dot{O}\ ,$$
$$ArN=N\dot{O} + RH \rightarrow ArN=NOH + \dot{R}\ ,$$
$$ArN=NOH \rightarrow \text{Products of ionic cleavage}\ ,$$
$$2ArN=NOH \rightarrow ArN=NON=NAr + H_2O\ ,$$
$$ArN=NON=NAr \rightarrow \dot{A}r + N_2 + ArN=N\dot{O}\ .$$

A similar mechanism, also involving formation of the *aci*-form, was suggested[78] for the thermal decomposition of edna, in order to explain the formation of both acetaldehyde and ethylene glycol:

In neutral aqueous solution edna decomposes according to a first-order equation with activation energy 32.5 kcal mole^{-1} and pre-exponential factor 10^{13} s^{-1}; increasing the acidity of the medium accelerates the reaction[76].

Kinetic study[60] of the thermal decomposition of ferrocenylmethylnitramine $FcCH_2NHNO_2$ in 2% solution at 110–130 °C shows a first-order reaction with activation energy 33.2 kcal mole^{-1} and pre-exponential factor $10^{14.98}$ s^{-1}. Decomposition of this compound thus has the same activation parameters as that of other primary nitramines, and apparently the same mechanism.

IV. DECOMPOSITION BELOW THE MELTING POINT

An important feature of the decomposition of organic explosives and in particular of nitramines at temperatures below the melting point is the formation during the reaction either of liquid products in which the initial substance dissolves or of a eutectic mixture of this compound with the products. As a consequence the process has already acquired a two-phase character soon after the start: reaction takes place in both solid and liquid phases. The quantity of liquid products increases during decomposition, and with a consequent gradual increase in the role of the liquid-phase process and decrease in that of the solid-phase process. On the other hand, the great practical experience that has now accumulated indicates that a given compound decomposes considerably more rapidly in the liquid than in the solid phase (see below). Therefore the increasing role of the liquid-phase process during decomposition should inevitably lead to autocatalysis. And indeed the autocatalytic character of decomposition below the melting point is a general feature of organic explosives, including nitramines. A formal kinetic description has been given[81,82] for such processes.

1. Tetryl

Historically tetryl was the first nitramine whose decomposition below the melting point was investigated in detail. The fact that the solid decomposes considerably more slowly than the liquid was noted as early as the 1920s.[1,2] On the basis of Lewis's ideas Hinshelwood suggested that the difference in behaviour was due merely to a difference in activation energy, in turn equal to the latent heat of fusion[2]. Simple calculation then indicates that liquid tetryl should decompose more rapidly than the solid by a factor of at least 1300, but in fact the ratio of the reaction velocities is considerably smaller at 50–100. From this Hinshelwood made the important deduction that the initial solid tetryl contained impurities (and possibly catalysts) already causing partial

occurrence of the liquid-phase reaction in the very first stages of decomposition.

Hinshelwood's calculation was based on assumptions, of course, that nowadays might be regarded as oversimplified (if only because the topochemical character of solid-phase decomposition was completely ignored). Nevertheless, his main conclusion concerning the possible role of impurities in inducing liquid-phase decomposition below the melting point seems valid. Moreover, this conclusion applies not only to tetryl but also to other solid organic compounds. Therefore the possibility of partial occurrence of the reaction in the liquid phase must always be taken into account in the investigation of decomposition below the melting point. Such possibility creates considerable difficulties in research on the decomposition of solids, for methods of monitoring small quantities of impurities and removing them from solid organic compounds have been inadequately developed.

In the above work[2] the decomposition of tetryl was studied at low degrees of conversion (when the contribution of autocatalysis by picric acid was small), in conformity with Farmer's view[1] that autocatalysis in decomposition below the melting point may be due to appearance of a eutectic mixture of tetryl with its decomposition products. Experimental results showed good agreement with calculation, despite an error in the latter[2] that has since been corrected[82].

Table 18. Activation parameters for the thermal decomposition of tetryl below the melting point.

E_a, kcal mole^{-1}	A, s^{-1}	Ref.
52.0	$10^{22.5}$	[3.53]*
36.6	$10^{12.7}$	[81]**
54.9	—	[31]

*Calculated from experimental results in Ref.1.

**In Ref.81 unpublished results are quoted that had been calculated by Wiseman from experimental data in Ref.1.

On the assumption of first order in the initial stage several calculations were made, from the initial segments of the kinetic curves, of the activation parameters of the thermal decomposition of tetryl. Table 18 shows marked discrepancies between results obtained by different authors, which may have several explanations. One lies in the above possibility of an indefinite contribution by liquid-phase decomposition to the overall process. Furthermore, as is evident from the footnotes to Table 18, in several cases the estimates were based on the few results obtained by Farmer[1], moreover within a narrow temperature range. It must also be borne in mind that the measured kinetic parameters may be influenced by the experimental conditions, in particular the extent to which the reaction vessel is filled[83,84]. As a last reason, perhaps the most important, Hall[33] found, on processing experimental results obtained by various workers on thermal decomposition both above and below the melting point, that the Arrhenius law breaks down near this temperature (more precisely for a few degrees below it): whereas at temperatures substantially below the melting point the slope of the Arrhenius relation does not greatly differ from the slope for decomposition above the melting point, so that differences in rates above and below this point are determined mainly by the pre-exponential factor, the slope increases abruptly in the immediate vicinity of the melting point, and hence the observed activation energy and pre-exponential factor increase markedly. Thus the observed activation parameters for the thermal decomposition of tetryl depend on the temperatures (relative to the melting point) at which the measurements were made. In fact breakdown of the Arrhenius law in the vicinity of the melting point is evident not only with tetryl: it is very general in character, and has been observed in the decomposition of several solids[85]. This interesting phenomenon has not yet found a rigorous explanation.

It follows from the above discussion that kinetic results for the thermal decomposition of tetryl below the melting point do not admit of a simple physical interpretation. The main details of the mechanism of the solid-phase decomposition of tetryl also remain obscure.

2. Hexogen

Decomposition at temperatures below the melting point (and also above this temperature) has been studied in greater detail for hexogen than for other nitramines. The early work on the decomposition of solid hexogen[81,35,36] already established that the kinetics follows the sigmoid law characteristic of solid-phase processes. The results that have now accumulated show that the decomposition of hexogen is extremely complicated, being subject to the influence of various factors, which of course makes interpretation of the kinetic results difficult.

The influence on decomposition of the geometry of the specimen, more precisely of the accessibility of its surface to the surrounding atmosphere, has been studied[86] in experiments with hexogen either scattered on the surface of the reaction vessel or placed in special tubes whose number was varied from one experiment to another, although the total quantity of hexogen was the same in every experiment. The construction of the tubes was modified in certain experiments, by making the outlet smaller or dividing the tube into two connecting chambers, containing the compound in its usual compact state and in an almost disperse state respectively. Change in the geometry of the specimen was found to have different effects on individual stages of the process. In any case, enhancing the accessibility of the specimen surface to the surrounding atmosphere shortens appreciably the induction period and accelerates decomposition.

It can thus be regarded as reliably established that gaseous reaction products influence the kinetics of the decomposition of hexogen. Detailed analysis of this effect led to the conclusion[86] that the gas phase contains substances that both catalyse and retard decomposition. Such compounds have been listed[35]: nitrogen dioxide in small quantities shortens the induction period, but in large quantities increases the initial rate of decomposition; nitric oxide in small quantities shortens the induction period but in large quantities lowers the initial rate; and oxygen appreciably lengthens the induction period.

Results were also obtained[35] indicating the role of reactions involving gaseous products: the process became slower as the reaction vessel was filled. The explanation was that reaction in the condensed phase was accompanied by gas-phase decomposition of partly vaporised hexogen, the role of the latter process being smaller the greater the m/V ratio. Estimates showed that, in order to explain the results, it was necessary to suppose that hexogen breaks down in the gas phase more rapidly than in the liquid by a factor of 100. This value agrees quite well with results[21] showing that the

decomposition of hexogen in the gas phase inhibited by nitric oxide takes place 10 times as rapidly as in solution; the uninhibited gas-phase reaction occurs more rapidly than in solution by factors of 30–40.

However, the arguments in Ref.35 encountered the objection[86] that with large portions of hexogen giving high m/V ratios it takes a long time to heat up the reaction vessel, and an appreciable proportion of the reaction takes place under non-isothermal conditions, which casts doubt on the correctness of the kinetic results. Thus the nature of the influence of the m/V ratio on the kinetics of the decomposition of hexogen cannot be regarded as finally elucidated. Incidentally, the above difference between rates of decomposition of hexogen in gas and liquid phases may be due to a cage effect.

Other work on the influence of gases and in particular gaseous decomposition products on the kinetics of the decomposition of hexogen[87] showed that nitrogen, carbon monoxide and dioxide, and nitrous oxide have some retarding effect; water slows down the reaction more strongly; nitric oxide, formaldehyde, and methanol accelerate the reaction; oxygen and nitrogen dioxide are inhibitors; and propene and toluene have no appreciable influence on the kinetics. A detailed study has been made of the accelerating effect of formaldehyde[88]. Yet other workers have obtained similar results[17]: nitrogen, carbon monoxide and dioxide, nitrous oxide, and water retard the reaction; nitric oxide also diminishes the rate of decomposition, but to a less extent, and formaldehyde accelerate the process.

The explanation given for the influence of nitrogen, carbon monoxide and dioxide, and nitrous oxide was that these gases prevented the vaporisation of hexogen and diminished the contribution by its gas-phase decomposition. However, when decomposition occurs in a vacuum[86], a part of the hexogen evaporates and settles on the walls of the reaction vessel: i.e. what was termed[86] a change in specimen geometry takes place. The role of this geometry was interpreted[86] as facilitation of the removal of reactive gaseous products from the surface of the specimen with increase in contact between the latter and the surrounding medium. Without objecting to this concept, we note nevertheless that a possible alternative explanation is that the role of heterogeneous reactions of gaseous products with the hexogen surface becomes greater (not smaller) with increase in such contact. It should be noted that with restricted contact between specimen and surrounding atmosphere (e.g. when the hexogen is enclosed in a narrow tube) a gaseous product formed within the specimen must first pass through it, before escaping into the atmosphere. However, the time required for such escape is brief, in any case considerably shorter than the characteristic time of the overall process of thermal decomposition.

The discrepancy in the results for the influence of nitrogen dioxide on the kinetics of the decomposition of hexogen can apparently be attributed to measurement of respectively the quantity of gas evolved[35] and the degree of conversion[87]. Since the quantity of gas evolved on the decomposition of hexogen increases in the presence of nitrogen dioxide[87], a greater quantity of gas evolved may correspond to a lower degree of conversion. Thus nitrogen dioxide apparently inhibits the decomposition of hexogen. The reasons for this phenomenon are not very clear. A possible cause is that nitrogen dioxide may be involved in two opposite processes—oxidation of the initial compound (accelerating effect) and recombination with amino-radicals arising in the primary step (inhibition)—as already discussed in connection with the gas-phase pyrolysis of nitramines[9]. The role of the latter effect on decomposition in a condensed phase may be enhanced by the cage effect. Another explanation of the inhibiting action of nitrogen dioxide is that condensed decomposition products accelerate the reaction[87], not only physically (by liquefaction) but also chemically. It is possible that nitrogen dioxide may react with the above condensed products and lower their catalytic activity. This deduction might in principle be tested by studying the influence on the thermal decomposition of hexogen exerted by condensed decomposition products previously treated with nitrogen dioxide, but such experiments have not been undertaken as far as the Reviewers are aware.

The accelerating influence of formaldehyde[86–88] may be at least partly due to its ready reduction of nitrogen dioxide to nitric oxide[89]. It is also possible that formaldehyde is able to react with hexogen itself, attacking it at a nitro-group[87].

The acceleration of the decomposition of hexogen under the influence of methanol may be closely connected with the above reactions. Methanol is able to reduce nitrogen dioxide, being oxidised to formaldehyde; furthermore, methanol may inhibit the oxidation of formaldehyde by nitrogen dioxide[87].

Nitric oxide like other gases somewhat retards decomposition by impeding evaporation[17], but it also has a chemical effect, being involved in secondary reactions and accelerating decomposition. The nature of these reactions is unknown. The view was expressed[35] that nitric oxide may yield the nitroso-analogue of hexogen, but in the absence of additional experiments this suggestion may be regarded as purely hypothetical.

An objection has appeared[86] to the above view[13–17] that hexogen undergoes slight vaporisation below the melting point with partial decomposition in the gas phase, the contribution of which to the overall process may be very considerable. All the observations could be explained[86] by the above influence (both accelerating and retarding) of gaseous decomposition products of hexogen on the kinetics of its decomposition. It was also concluded[86] that liquefaction during decomposition of solid hexogen also is unconnected with a purely gas-phase process.

Without going into the essence of the controversy, we note that there appears to be no direct disproof of either view. Moreover, we feel that these concepts are not mutually contradictory, and both gas-phase decomposition of vaporised hexogen and the influence of active gaseous products on decomposition of the solid must be accepted as possible. Greater clarity can be introduced into this question only by detailed kinetic investigation of the decomposition of hexogen solely in the gas phase and solely in the solid phase.

Several studies have been made on the important kinetic influence of crystal size on the solid-phase decomposition of hexogen. Grinding crystals of size 1–2 mm to 0.1 mm had no kinetic effect[35], and another worker[90] also found no kinetic effect of crystal size. Working with finer crystals[21] showed that at 170 °C the ground hexogen had grown to 0.003–0.01 mm after 10–20 min. Nevertheless, the ground material decomposed considerably more rapidly than a specimen with larger crystals. This can be explained both by enhanced reactivity of surface molecules of the crystal and by the above[86] influence of specimen geometry on decomposition kinetics. Thus the influence of crystal size on the kinetics of the decomposition of hexogen remains in considerable measure obscure: further research is required to clear up this problem.

Occluded solvents and gases are evolved before decomposition of hexogen begins, and therefore do not influence its course[90]. Preparation of the crystals in different ways, and also terminating the reaction by cooling the system, likewise

have no effect on the kinetics. Somewhat different results have shown[21] that acetone (the solvent from which hexogen had been recrystallised) could not be removed by drying, and its escape from the crystals during decomposition increased the observed rate of gas evolution. However, purification by sublimation combined with preliminary degasification enabled the effect of impurities of the kinetics to be eliminated. The difference between these sets of results[21,90] may be due to the different conditions—temperature, sample size, volume of reaction vessel—under which the kinetic measurements were made. The decomposition of hexogen is influenced[90] by solid additives (copper sulphate, carbazole) and also by ultraviolet irradiation.

Table 19. Activation parameters for the thermal decomposition of hexogen below the melting point.

**Depending on the geometry of the specimen and the segment of the kinetic curve.

***In the presence of formaldehyde.

****Depending on the experimental conditions.

Because of the complicated character of the thermal decomposition of hexogen the activation parameters (Table 19) have been calculated from the initial portions of the kinetic curves on the assumption that at low degrees of conversion reaction occurs mainly in the solid phase and is described by a first-order equation. Calorimetric data have also been published[94], but without kinetic parameters. The complexity of the process and the influence of numerous factors are especially evident in the results from Refs.88 and 91 (Table 19), according to which the activation parameters are strongly influenced by gaseous decomposition products. There is therefore every reason to suppose that the majority of the activation parameters in Table 19 are effective values characterising not a single but a whole set of reactions. The contribution by each reaction to the observed rate constant depends in general on the experimental conditions, so that the considerable scatter between the results obtained by different workers is not surprising.

Especially noteworthy are results[20,21] showing a departure from the Arrhenius law in the vicinity of the melting point, as has already been discussed in connection with tetryl. Breakdown of this law may be one reason for the high activation parameters in Table 19. Those from Refs.19—21 had been obtained over a temperature range within which the Arrhenius law applies, and if they in particular are assumed to represent the solid-phase process, it is at once evident how close are the activation energies of reactions in gas phase, solution, and solid state. This naturally suggests a common reaction mechanism, in particular that the rate-determining step in the solid phase is rupture of an $N-NO_2$ bond. The diminished pre-exponential factor from Ref.20 may be due to a cage effect or to the topochemistry of the reaction, in particular its localisation at non-equilibrium lattice defects.

Nevertheless, kinetic data alone are insufficient to prove a common mechanism of decomposition under different phase conditions, so that the alternative view of different mechanisms in gas and condensed phases[17,18] cannot be regarded as incorrect. In this connection especial attention should be paid to the concept of a definite mutual orientation of hexogen molecules in the crystal lattice, making possible bimolecular interaction between two hexogen molecules in the first stage of decomposition[37,87].

Physical aspects—the influence of crystal structure on molecular reactivity—are no less important than the above chemical aspects. As little work has been done on this problem applied to the decomposition of molecular crystals, we can welcome the use of X-ray diffraction and electron microscopy[20,95] to study physical phenomena (plastic deformation, elastic stresses) in the thermal decomposition of hexogen.

In concluding this subsection we note that research on decomposition under the influence of various physical factors—impact[96,97], electric field[98,99], vibration[100,93]—may assist understanding of the solid-phase process. Thus an electron spin resonance signal arises when hexogen is subjected to impact, which indicates the formation of free radicals during decomposition, although their nature was not revealed[96]. It was also concluded[96] that rupture of an $N-NO_2$ bond occurs in the rate-determining step. This was confirmed by later results[97], though they were based on the doubtful assumption that in hexogen a nitrogen–nitrogen bond is more stable than a carbon–nitrogen bond. The model adopted in this work[97] assumes the transfer of lattice phonons to vibrational degrees of freedom of the hexogen molecule during impact compression. Such a model provides an explanation for several observed features, in particular the slowing down of the thermal decomposition of hexogen with increase in hydrostatic pressure. It would have been interesting to develop this model to apply to the purely thermal (not impact) decomposition of nitramines.

3. Octogen

As octogen is an analogue of hexogen, its thermal decomposition exhibits similar features. This compound can exist in various polymorphic modifications[101], each with its own thermal stability, as will be shown below.

Like other solid explosives octogen decomposes autocatalytically[35,36]. The initial rate diminishes with increase in the m/V ratio[35]. As with hexogen, this effect can be attributed either to the involvement of active gaseous decomposition products or to a contribution by gas-phase pyrolysis of partly vaporised octogen to the overall reaction. The latter explanation is less probable in the case of octogen (at least in the absence of additional experiments), since it is less volatile than hexogen.

The gaseous decomposition products—nitrogen and oxides of nitrogen and carbon (Table 20)—have the usual composition for nitramines. The temperature dependence of the composition apparently indicates that these products are formed by secondary reactions. Each product is characterised by its own activation parameters, and its contribution to the overall rate depends on the temperature. Data on the isotopic composition of the decomposition products were given

in a paper[39] already mentioned in connection with liquid-phase decomposition.

Several studies have been made on the kinetic influence of crystal size. According to Maksimov[35] grinding crystals of size 1–2 mm down to 0.1 mm does not affect the initial rate of decomposition, but at the later stage of acceleration the fine crystals decompose more slowly. Visual observation showed that large crystals had retained their shape and transparency of being heated at 176 °C for 2–3 h: they began to become cloudy after 20–30 h, after the evolution of 0.5–1% of gases; but cracking began after 100–200 h (5% of gases).

Table 20. Composition of gaseous products of thermal decomposition of the β-modification of octogen (moles mole^{-1} octogen).[101]

Temp., °C	N_2O	N_2	NO	CO	CO_2	HCN	CH_2O

*Depending on method of measurement.
**Crystal size 160–315 μm.
***Crystal size <50 μm.
****Depending on the temperature.

Different results have been obtained[102] by workers using finer crystal. Derivatographic investigation showed that octogen of mean crystal size 160–315 μm under non-isothermal conditions at 185–280 °C decomposes in a single stage. If, however, the octogen is ground to below 50 μm, the reaction occurs in two stages, the first of which has already begun at 160 °C. This was explained[102] in topochemical terms, by the effect of grinding in producing surface defects and dislocations possessing excess energy and hence enhanced reactivity. However, an alternative explanation is the involvement of active gaseous products, i.e. what has been termed the specimen geometry effect (subsection 2).

Table 21 shows a considerable scatter among the kinetic data obtained by different workers for the decomposition of octogen. The above complicating factors—role of gaseous decomposition products, appearance of a liquid phase during decomposition, breakdown of the Arrhenius law in the vicinity of the melting point—are partly responsible. Yet the aggregate of results reliably indicates the kinetic influence of the crystalline modification. This is supported also by the dependence of the thermal stability of octogen on its mode of recrystallisation[105] (though in this case the possible role of occluded solvent is not clear) and by vigorous decomposition of the δ-modification of octogen even at 150 °C.[106]

Despite the considerable scatter the results of several studies[19,20,34,35,102,104] show quite good mutual agreement, with activation energy ~40 kcal mole^{-1} and pre-exponential factor 10^{13} s^{-1}, values characteristic of the pyrolysis of nitramines in gas and liquid phases, which involves rupture of an N–NO_2 bond in the rate-determining stage. However, this hypothesis cannot be accepted as strictly based, and the possibility of a different mechanism for solid-phase decomposition is not excluded. In particular, the rate-determining stage in the solid-phase decomposition of octogen may be electron transfer in the crystal lattice[103,107].

The enhanced thermal stability of solid octogen in comparison with hexogen[19,20] has been explained by the greater energy of interaction between its molecules in the crystal.

In conclusion we may mention another study[94] of the thermal decomposition of octogen, but without determination of the kinetic parameters.

4. Primary Nitramines

Study of the thermal decomposition of methylenedinitramine (medina) at 70–100 °C reveals[75] a more complicated course than the sigmoid law followed by the preceding nitramines: the kinetic curve has two points of inflexion. Initially the rate of decomposition diminishes with time, after which a period of autocatalysis ensues, which is followed by fresh retardation of the reaction. At 80 °C the rate is described by the equation (t = time)

$$w = 5.5(1-e^{-0.16t}) + 0.00192t^{1.76}.$$

The results were interpreted in terms of a topochemical model[75], according to which the reaction develops on surface nuclei, whose number remains unchanged. At each centre the compound decomposes according to a first-order law until a definite quantity has changed, after which decomposition follows a power law (e.g. a second-order equation) with a significantly smaller rate constant than for the preceding first-order reaction. Analysis of this model yields an equation identical with that given above. Moreover, the model indicates that the duration of the induction period (from the start of reaction to the first point of inflexion on the kinetic curve) should depend on temperature according to the Arrhenius law, as is observed in fact with an activation energy of 27.8 kcal mole^{-1}. It was shown also that picric acid coating the crystal surface inhibits reaction, diminishing the degree of conversion during the induction period.

The chemical mechanism of the solid-phase decomposition of medina was not discussed[75], and available data are insufficient for definite conclusions to be drawn.

An undoubted merit of this work[75] is its development of a topochemical model with a complete description of the kinetic curve, which has not been done for other nitramines. However, it must be borne in mind that agreement between calculated and experimental values is not sufficient proof of the correctness of the model, since an alternative model might also agree with available experimental results. Furthermore, we do not know how far the induction period is due to impurity processes, which are extremely widespread in solid-phase decomposition.

Data on the solid-phase decomposition of ethylenedinitramine (edna) are also very sparse. As would be expected, reaction in the solid is considerably slower than in the liquid phase[48,78]. The kinetic curve resembles that for medina, with two points of inflexion; impurities and gaseous decomposition products accelerate the reaction[78]. The activation energy and the pre-exponential factor determined at 100–120 °C are respectively 36 kcal mole^{-1} and $10^{12.5}$–10^{13} s^{-1}.[78] However, this paper[78] gives results of unpublished work, according to which the activation energy depends on the temperature range, its value in a vacuum being respectively 37.0, 41.5, and 51.5 kcal mole^{-1} at 100–120, 120–135, and 135–145 °C; for atmospheric pressure the values at 120–135 and 135–145 °C were 43.5 and 59.5 kcal mole^{-1}. The pre-exponential factor remained almost unchanged over these temperature ranges at 10^{12}–10^{13} s^{-1}.

Without any grounds it is stated[78] that the decomposition of edna in a vacuum has a chain mechanism in its initial stages (2–3% conversion).

Kinetic data on the thermal decomposition of edna agree well with a first-order equation[49,30] in the initial stage (5% conversion). Between 5% and 10% a period of "autostabilisation" ensues: i.e. the observed first-order rate constant diminishes. After 10% conversion the reaction again accelerates, the rate constant increases, and a first-order equation is satisfied. The activation energy and the pre-exponential factor for the initial stage are 30.8 ± 2.0 kcal mole^{-1} and $10^{11.1 \pm 1.0}$ s^{-1}, the corresponding values in the region of "autostabilisation" being 71.7 ± 1.6 and $10^{31.6 \pm 0.8}$.[49] In view of the experimental error the values in Refs.78 and 49 show quite good agreement, and are close to those given above for the liquid-phase decomposition of primary nitramines. As in preceding cases this suggests identical reaction mechanisms in liquid and solid phases, although direct evidence for such a hypothesis is lacking.

5. Other Nitramines

Information has been published on the thermal decomposition of several other nitramines, for which kinetic parameters have not been determined. Differential thermal analysis was used to study the decomposition of nitroguanidine[28,108] and of nitramino-carboxylic acids and their salts[59]. Those of the latter that decompose below the melting point possess greater thermal stability than compounds that decompose in the liquid state. The thermal decomposition of 1,5-*endo*-methylene-3,7-dinitro-1,3,5,7-tetra-azacyclo-octane has been examined[33] by differential scanning calorimetry, and the activation energy roughly estimated as 100–300 kcal mole^{-1}.

V. CONCLUSION

It can be concluded from the above survey that considerable progress has now been made in understanding the main features of the thermal decomposition of *N*-nitro-compounds. Nevertheless, it is worth considering the unsolved problems and indicating possible routes to their solution.

In the kinetics of the gas-phase decomposition of *N*-nitro-compounds the most detailed attention has been paid to the nature of the first, rate-determining stage, although even here complete unanimity is absent, as discussed above in connection with hexogen and octogen. For the hypothesis of a radical mechanism of breakdown to be confirmed or refuted systematic investigations of the dissociation energies of bonds are necessary; these can be achieved by spectroscopic methods, thermodynamic estimates of the enthalpies of formation of nitro-compounds and free radicals, and quantum-mechanical calculations. At the same time estimation of pre-exponential factors with the help of the modern theory of unimolecular reactions will be extremely useful.

The time has arrived to pass from the first stage to a detailed analysis of the complete mechanism of the decomposition of *N*-nitro-compounds. Strange as it may seem, not even a first step has been taken in this direction: no complete quantitative analysis of the products at different stages of decomposition has been made, although standard methods of mass spectrometry and chromatography can be used for this purpose. In order to elucidate the mechanism of these reactions it is extremely important to make a kinetic study of the reactions of oxides of nitrogen, primarily of nitrogen dioxide, both with the nitramines themselves and with their decomposition products. Further, considerable interest attaches to the interaction of nitrogen dioxide with amino-radicals, mainly because this is the reverse reaction to the presumed first stage of decomposition of nitramines—rupture of an N–NO_2 bond—and its examination might reveal to what extent this first stage is reversible. Useful information on the mechanism of the thermal decomposition of *N*-nitro-compounds might be obtained from experiments on non-thermal decomposition, e.g. flash photolysis.

At the outset of research on the thermal decomposition of nitro-compounds Roginskii and Semenov put forward the hypothesis of a chain mechanism[6], but this idea was not developed. It is now considered that the decomposition is not a chain reaction, since oxides of nitrogen are formed, and these are effective inhibitors of chain processes. Clearly, however, this is not a decisive argument, and the involvement of a chain mechanism in the decomposition of nitro-compounds, including nitramines, remains an open question. Correlation analysis, enabling quantitative relations to be established between structure and reactivity, is at present widely used in organic chemistry. Unfortunately, this approach has not yet been duly applied to the pyrolysis of nitro-compounds, despite its obvious relevance. This gap must undoubtedly be bridged, for which purpose it is extremely desirable that the measurement of true rate constants of primary steps should be started and a larger number of compounds investigated to ensure statistical reliability of the results.

The problems formulated above for gas-phase pyrolysis are in urgent need of solution also for processes in the liquid phase, where moreover the use of powerful physico-chemical methods (electron spin resonance, chemical polarisation of nuclei, spin traps), permitting the study of reactive intermediates, becomes especially effective. Unfortunately, such methods, which have proved their value in the most diverse fields of chemistry, have not yet been applied to the decomposition of nitro-compounds. Incidentally, chemical polarisation of nuclei may perhaps help to reveal and study the cage effect, which has not yet been detected in the decomposition of nitro-compounds although widespread in radical liquid-phase reactions. Further investigation of the nature of catalysis and autocatalysis in the breakdown of nitro-compounds is of great practical interest, since solution of this problem is closely connected with the stabilisation of explosives. An example is tetryl, for which autocatalysis by picric acid has been reliably established, but the nature of the catalytic action is unknown.

The most urgent aspect of the solid-phase decomposition of *N*-nitro-compounds is to ascertain its topochemistry, which involves a wide range of unsolved problems: there is no proper topochemical model of the reaction (as stated above, such a model has been suggested only for medina, and then

its adequacy has not been rigorously proved); the kinetic influence of crystal size and polymorphic modification has not been ascertained; and only the first steps have been taken in studying the physical processes occurring in the crystals during decomposition (the above work by Klimenko et al.). An interesting problem in the kinetics of solid-phase decomposition is to establish the nature of the breakdown in the Arrhenius law near the melting point. The nature of the reaction centres involved in the thermal decomposition of *N*-nitro-compounds still remains unknown.

Future progress in research on the kinetics and the mechanism of the thermal decomposition of *N*-nitro-compounds will probably depend in considerable measure on the application of modern methods of investigation—field-ionisation mass spectrometry, optical spectroscopy, electron microscopy, X-ray diffraction, nuclear magnetic resonance, chemiluminescence, etc.—besides those mentioned above. The use of quantum-chemical calculations to analyse the reactivity of *N*-nitro-compounds is also promising.

It may be hoped that solution of the above problems will assist further development of the chemistry of *N*-nitro-compounds, extension of the possibilities for their practical application, and penetration of methods of chemical kinetics into the physics of combustion and explosion.

Photonics of Organometallic Semiconductors—Copper Organoacetylides

S.Myl'nikov

Processes associated with the interaction of photons with organometallic photosemiconductors are examined. Attention is concentrated on the nature of the photoelectric and optical properties of copper organoacetylides and also on the elucidation of their structures by methods using electromagnetic radiation. It is shown that the organometallic compounds can be regarded as a new class of semiconducting materials, because they have a number of properties typical for inorganic and organic semiconductors.

I. INTRODUCTION

The history of photoconductivity, which runs to a little more than 100 years[1], has demonstrated convincingly that each significant step forward in the study and applications of this phenomenon was associated with the appearance of new photosensitive materials with specific physicochemical properties. This was initiated by studies of elements such as germanium and silicon and subsequently inorganic compounds of the type A^3B^5, A^2B^6, and $A^2B^4C_2^5$, and vitreous, organic, and other semiconductors began to be included in the range of photosemiconducting materials. Thus the ways in which the chemical and energetic structures of newly discovered semiconducting compounds have increased in complexity can be clearly traced.

The present review deals with a new type of photosemiconductors—organometallic compounds (OMC). The wide variety of types of bonds ensured by the selection of appropriate organic ligands and metals suggests that such systems have extremely interesting physical and in particular semiconducting properties. The results of studies of the electronic processes in organometallic compounds can be used to determine the structure and energetic parameters of organometallic solids, to elucidate the mechanism of the migration of energy in them in order to find ways of achieving superconductivity in OMC at high temperatures, to model biophysical processes involving microelements in complex macromolecular systems, and to study the mechanisms of catalytic reactions proceeding via intermediate OMC. These studies are of interest also in connection with the likely usefulness of organometallic materials in various kinds of semiconductor devices in optoelectronics, in microelectronics, in the preparation of electrophotographic emulsions, for printing schemes, diapositives, microfilms, etc.

Approximately 100 organometallic compounds are now known in which an internal photoeffect has been observed and investigated. These are copper organoacetylides (COA), silver organoacetylides of the type $(M-C\equiv C-R)_x$[2-45], ferrocene[46,47], and polyconjugated polymers with double and triple bonds in the macromolecule, containing silicon, germanium, tin, and lead atoms in the conjugation chain[48]. The electronic properties and structures of these compounds are usually examined from the standpoint of ligand field theory which is understood as the set of theoretical ideas ranging from the electrostatic crystal field theory to the molecular orbital method[49-54].

Copper organoacetylides whose properties are the subject of the present review are at present the most thoroughly investigated organometallic photoconductors from the standpoint of optical and photoelectric properties. We shall consider initially the structure of copper organoacetylides on the basis of data obtained by methods involving the use of electromagnetic radiation. In considering the optical and photoelectric properties particular attention will be devoted to the relation between these two properties in the structure of copper organoacetylides, the mechanisms of the primary steps in the formation of carriers and their drift, and methods for the chemical and spectral sensitisation of the internal photoeffect in order to increase the integral photosensitivity and expand the spectral photosensitivity of copper organoacetylides. Data are presented concerning the possibility of the practical application of such compounds.

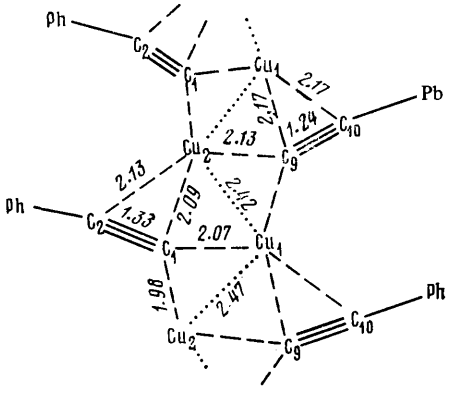
II. THE STRUCTURE OF THE COMPOUNDS

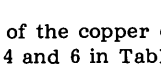
Copper organoacetylides are complex coordination polymers. The structural formulae of the monomeric units of certain copper organoacetylides, investigated in a number of studies[2-45], are presented in Table 1, which includes also the principal energetic parameters of such organoacetylides determined from the absorption and photoconductivity spectra which will be considered in this review.

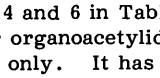
The principal information about the synthesis and chemical properties of copper organoacetylides can be found in a series of communications[45,54-56]. These compounds are finely dispersed infusible and insoluble crystalline powders of different colours (from yellow to red) with resistivities

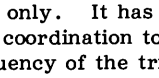
of 10^8–10^{11} Ω cm.[3,6,41] On the basis of the insolubility of the copper organoacetylides and the fact that the characteristic frequency of the triple bond in infrared spectra is reduced on average by 250 cm^{-1}, it has been suggested that copper organoacetylides are coordination polymers[57,58].

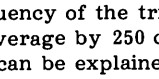
The structure of copper phenylacetylide (CPA), based on X-ray diffraction data, has been published in a monograph[49] (Fig. 1). It has the form of an infinite rectangular tube made up of copper atoms separated by specific metal–metal bond lengths and are linked to the phenylethynyl groups arranged outside the tube. Each phenylethynyl group is apparently linked by a σ-bond to one copper atom, by a symmetrical π-bond to a second copper atom, and by an asymmetric π-bond to a third copper atom. For simplicity, Fig. 1 illustrates only half of the rectangular tube. Subsequent study of the infrared spectra of a series of copper organoacetylides showed[8,16,19] that the characteristic frequency of the triple bond has been reduced to 1930–1970 cm^{-1} and depends little on the nature of the substituent in the ethynyl group of the ligand.

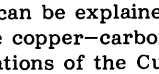


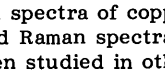


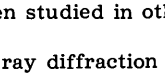












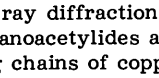


Figure 1. The structure of copper phenylacetylide $(CuC{\equiv}CPh)_x$.[49]

It follows from the infrared spectra of the copper derivatives of diacetylenic compounds (Nos. 4 and 6 in Table 1) that the copper atoms in these copper organoacetylides are coordinated to the terminal C≡C bond only. It has been suggested[16,19,20] that, apart from the coordination to the metal atoms, the decrease of the frequency of the triple bond in copper organoacetylides on average by 250 cm^{-1} compared with free organoacetylenes can be explained by the promotion of an electron along the copper–carbon bond $Cu^{\pm}C{=}C{-}R$, which leads to the vibrations of the Cu=C=C skeleton[59].

A broad asymmetric band at 130–180 cm^{-1}, which apparently reflects the presence of the copper–copper bond, has been observed in the far infrared spectra of copper organoacetylides[21]. The infrared and Raman spectra of copper organoacetylides have also been studied in other investigations[60,61].

Thus infrared spectroscopic and X-ray diffraction data make it possible to regard copper organoacetylides as coordination polymers consisting of zigzag chains of copper atoms coordinated to ethynyl groups. This structure and the quasi-allenic nature of the copper–carbon bond is confirmed by X-ray photoelectron spectroscopic data for copper organoacetylides (Table 2)[23]. The considerable shift of the $2p_{3/2}$ level of the copper atom towards higher bond energies compared with the metal indicates an effective charge transfer from the copper atom to carbon atoms of the ligands and the involvement of the *d* orbitals in the hybridisation of the Cu–C bond. The degree of charge transfer from copper atoms increases in the sequence of the compounds in Table 2. On average, the effective charge of the copper atoms in the polymers is only 0.17e when it is calculated using the Pauling electronegativities and assuming that the multiplicity of the copper–carbon bond is two. If it is assumed that the chemical shift due to the change in the effective charge by unity is 5 eV,[62] then the results indicate the transfer of an average charge of 0.4e from the copper atom. The broadening (on average by 0.5 eV) of the electronic lines in the spectra of copper organoacetylides relative to the metal apparently confirms the presence of non-equivalent copper atoms in the molecule (Fig. 1). The chemical shift ΔE_b suggests that the oxidation state of copper is close to 1.5. The shift of the 1s electronic lines of the carbon atoms in the organic ligands is, as for the level of the copper atom, in the direction of increasing binding energy compared with the free hydrocarbons but is smaller by a factor of 2. This finding indicates the conjugation of the acetylenic bonds with both copper atoms and with substituting organic groups as well as the withdrawal of electrons from these groups towards the acetylenic bond.

Table 1. The position of the long-wavelength maximum (λ) and of the optical absorption edge (*E*) and the optical activation energy for photoconduction (Δ*E*) in copper organoacetylides[34].

In the electron spectra of the 1s level of carbon a fine structure corresponding to different states of the carbon atoms in the ligands was not observed, although the lines are far broader than in the hydrocarbons. The observed lines are apparently due to substituents in the acetylenic groups of the ligands; otherwise one would have to expect the presence of at least two lines of identical intensity in the spectrum of copper vinylacetylide or a significant broadening of the carbon line due to chemical shifts in the different directions. It has been suggested[23] that the electron density is concentrated near the carbon atom nearest to the copper atom and that this atom in fact ensures the coordination polymeric structure of these compounds. An increase of electron density of the carbon atom nearest the metal leads to a decrease of the binding energies for all the levels of the atom, including the valence levels.

Table 2. The binding energies E_b, the electronic line half-widths $\Delta E_{1/2}$, and the chemical shifts ΔE_b (all expressed in eV) of copper organoacetylides[31].

Compound	Cu $2p_{3/2}$			C 1s		S 2p	
	E_b	$\Delta E_{1/2}$	ΔE_b	E_b	$\Delta E_{1/2}$	ΔE_b	E_b

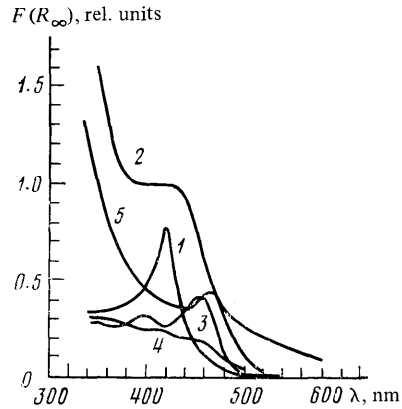
CuC≡C—CH=CH_2	934.4	2.2	2.2	286.7	3.1	1.7	—
CuO	935.1	2.3	2.9	—	—	—	—
C in hydrocarbons	—	—	—	285.0	3.0	0	—
S	—	—	—	—	—	—	164.4

The valence levels of the carbon atom nearest the copper atom apparently form a sub-band at the top of the valence band. This is also confirmed by the results of the study of the external photoeffect[31]. The photoelectric work functions for compounds with different ligands are very similar and are in the range 5.0–5.4 eV, which shows that the highest occupied state of the copper organoacetylide is determined by the structural unit Cu–C≡C. The weak but regular dependence of the photoelectric work function on the electron-donating properties of the substituent is in good qualitative agreement with the changes in the ionisation potentials of the free molecules containing the ethynyl group[63] due to the positive inductive effect of the substituents.

III. OPTICAL PROPERTIES

The optical absorption spectra of copper organoacetylides have been studied[6,8,17,20,22,33] by the diffuse reflection method[64]. The data obtained are presented in Table 1. Fig. 2 illustrates the spectra of copper organoacetylides having the general formula $(RC{\equiv}CCu)_x$. The overall characteristics obtained in the analysis of the electronic absorption spectra reduce to the following.

With increase of the conjugation chain length along the monomer unit, a bathochromic shift of the long-wave length maximum is observed. The introduction of aromatic rings leads to the appearance in the spectra of a structure due to the vibrational states. The characteristic frequencies in the absorption, photoconductivity, and photo-e.m.f. spectra can be attributed to the effect of ethynyl bonds (2100–2200 cm^{-1}), the out-of-plane deformation vibrations of the benzene ring, and the stretching vibrations of the ≡C–H group (~3200 cm^{-1}) (Table 3)[20]. The absence from the electronic absorption spectra of the 1930 cm^{-1} frequency, normally observed in the infrared spectra, suggests that in the excited state there is an alteration of the electronic configuration of the molecule, leading to an increase of the multiplicity of the ethynyl bond linked directly to the copper atom.



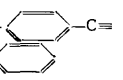


Figure 2. Optical absorption spectra of copper organoacetylides $(RC{\equiv}CCu)_x$ with different R: 1) n-Bu; 2) CH=CH_2; 3) Ph; 4) PhC≡C; 5) 1,4-C_6H_4≡CPh; $F(R_\infty)$ = Kubelka–Munk function taken from Myl'nikov[20].

Table 3. The manifestation of the vibrational structure in the absorption and photoconductivity spectra of copper organoacetylides[20].

Structural formula of monomeric unit	Positions of maxima				Frequency difference in spectra $\Delta\nu$, cm^{-1}	
	absorption spectra		photoconductivity spectra		absorption	photoconductivity
	λ, nm	ν, cm^{-1}	λ, nm	ν, cm^{-1}		
CuC≡C– 	455,395	22000, 25300	500,430	20000, 23220	3300	3220
CuC≡C–C≡C– 	455,415	2200, 24100	500,480, 450	20000, 20850, 22200	2100	850,1350 (2200)
CuC≡C–  –C≡ ≡C–	465	21500	510,490, 440	19620, 20450, 22750		830,2300 (3180)

From the standpoint of the donor–acceptor interaction, one can assume that the bands observed in the visible region are due to the resonance interaction between the *d* electrons of the copper atoms and the π electrons of the corresponding ligands[20]. Indeed acetylenic compounds of the type HC≡CR absorb in the ultraviolet, like copper(I) compounds[65]. The bathochromic shift of the absorption edge observed when the

substituent in the ethynyl group of the ligand is altered and the high absorption coefficient ($>10^4$ cm^{-1}) also confirm that the bands are due to charge transfer between the *d* orbitals of copper and the antibonding π orbitals of the ligands. Considering copper as a substituent in the main chromophore, it can be assumed that the $d-\pi$ conjugation is manifested in the spectra from the standpoint of the theory of conjugated systems and the theory of colour[20].

Analysis of the edge of the absorption band in the spectra of copper organoacetylides made it possible to determine the energies of the forward transitions[20]. For the compounds considered (the numbering is the same as in Table 1), these energies have the following values (eV): 2.75 (1) 2.53 (2) 2.48 (4), 2.50 (5), and 2.46 (6). It has also been shown that the Urbach rule holds for the edge of the absorption spectrum[20].

By altering the chemical structure, it is possible to achieve a fine control of the energetics and nature of the transitions in the COA.[17,22,33] For example, the introduction of the CH_2 group between the benzene ring and the triple bond [see compounds (3) and (5) in Table 1] interrupts the interaction with the π electrons of the benzene ring with the π electrons of the triple bond, which shifts the absorption maximum from 465 to 415 nm. Introduction of the ethynyl group instead of CH_2 [compound (4)] restores this conjugation. An increase in the number of aromatic rings in the ligand [compounds (5) and (7)–(10)] leads to a bathochromic shift of the spectra. Analysis of the spectra indicates a strong non-additive interaction of the electrons of the aromatic substituents with the intrinsic copper acetylide structural unit, which is common to all the molecules. It is known[66] that in the initial series of acenes the frequencies of the singlet–singlet transitions decrease on average by 6000 cm^{-1} following the addition of each benzene ring[66]. In the spectra of the COA with biphenylyl and naphthyl groups the long-wavelength maxima differ by only 200 cm^{-1} from the spectrum of the compound with the phenyl group, while the maximum in the spectrum of the anthracene derivative differs by 2800 cm^{-1}. The mode of addition of a further aromatic ring [compounds (7)–(9)] has little influence on the position of the long-wavelength maximum. After the introduction of substituents into the benzene ring, the bathochromic shift in the spectra increases in the following sequence: $Cl < I < OCH_3 < NO_2$.[66] The inclusion of sulphur or oxygen atoms with an unshared electron pair in the molecule increases the delocalisation of electrons along the chain. This is shown particularly strikingly when the spectra of compounds (5) and (11) are compared: evidently the introduction of an oxygen atom gives rise to a bathochromic shift of approximately 20 nm.[33]

For COA having the general formula $(R_2PC{\equiv}CCu)_x$ [compounds (20) and (21)], the nature of the absorption curves is independent of R. This fact as well as comparison of the absorption spectra of copper acetylides containing phosphino-groups with the corresponding absorption spectra of copper organoacetylides shows that the introduction of a phosphorus atom interrupts the conjugation along the monomeric unit. In contrast to phosphorus, the introduction of an arsenic atom does not affect the conjugation. Bearing in mind that the phosphorus and arsenic atoms in the tervalent state have a free electron pair which can be involved in the formation of $p-d$ donor–acceptor bonds, presumably in compounds containing such ligands there is an appreciable weakening of the $\pi-d$ bonds compared with the usual copper acetylides. The polymeric structure of these compounds is apparently due to both types of bonds.

It was noted above that the transitions in the visible region of the spectrum are due to charge transfer between the *d* orbitals of copper and the antibonding π orbitals of the ligands. At the same time an increase of absorption on passing to the short-wavelength region is a striking feature of almost all the COA. One should also bear in mind that the power relation between the absorption coefficient and the photon energy above the optical absorption edge has been obtained[20] with a power exponent of 1/2, which is characteristic of forward dipole-allowed transitions; all these features suggest that the charge transfer bands in the long-wavelength region of the absorption spectra are superimposed on transitions of the band–band type. The absorption of light is determined by transitions of the band–band type and by charge transfer between the copper atoms and the ligands.

IV. PHOTOELECTRIC PROPERTIES

The photoelectric properties of the COA have been studied in fair detail[3–10,12–19,22,24,25,27–34,39–45] by the photoconductimetric and photo-e.m.f. methods. The resistance of the specimens decreases from 10^7–10^{11} Ω to 10^5–10^7 Ω under the influence of monochromatic light with an intensity of 10^{13} photons cm^{-2} s^{-1}. The maximum photocurrents reach 10^{-5} A.[6]

The dependence of the photocurrent i_{ph} on the degree of illumination *L* is expressed by the formula $i_{ph}=\alpha L^n$, where $0.5<n<1$.[3,6,32,33,41] It has been shown that the COA exhibit a predominantly *p*-type conductivity[3,6,40]. Ohm's law holds for the dark photocurrent only for electric field strengths up to 10^2 V cm^{-1}, after which the current increases faster than the potential, which is apparently associated with space charge. The study of the relaxation of photoconductivity has shown[6,33] that a steady photocurrent is established as a rule after 1–2 min. For the majority of compounds, the descent of the kinetic curves obeys a hyperbolic relation. Specimens with an extremely high degree of inertia, in which the relaxation phenomena take place over a period of several hours, are also encountered [compounds (7) and (22), Table 1].[33]

Prolonged relaxation processes in COA, apparently due to the large number of inhomogeneities and in some cases also photochemical phenomena, are in essence analogues of the memory effects widely investigated in inorganic photosemiconductors[67]. The most reasonable explanation of the prolonged relaxations of photoconductivity in semiconductors is provided by the barrier model[67], which postulates the presence in the specimen of collective (microscopic) potential barriers.

There exist extensive experimental data on the photoconductivity and photo-e.m.f. spectra of copper organoacetylides with various substituents in the ethynyl group of the ligand[3,6,9,14,17,19,22,33,40,41]. The photoconductivity spectra of compounds of the type $(RC{\equiv}CCu)_x$ are presented in Fig. 3[19]. Analysis of the photoconductivity spectra of the COA shows that they exhibit the principal features typical of the absorption spectra of the COA, namely (1) there is a bathochromic shift with increase in the number of electrons in the substituent of the ethynyl group and there is a simultaneous decrease of the optical activation energy for photoconduction (Table 1), (2) the structure of the spectra is determined by the vibrational states, and (3) the bands are due to charge transfer between the Cu atoms and the C≡C bond with manifestation of $d-\pi$ conjugation.

In most compounds photoconductivity is accompanied by a photo-e.m.f.[3,6,8,16,19,22,23,33]. The most common result is a hypsochromic shift of the photo-e.m.f. spectra relative to

the photoconductivity spectra (Fig. 4); the maxima of the photoconductivity spectra then coincide with the minima of the photo-e.m.f. spectra. The optical activation energies for photosensitivity, determined from the photoconductivity and photo-e.m.f. spectra, agree with one another and with the energy of the edge in the optical absorption spectra. Analysis of the photoconductivity and photo-e.m.f. spectra from the standpoint of the influence of the chemical structure of the molecule has been carried out for COA with aliphatic and aromatic substituents[3,6,8,16,17,22,41] and with heteroatoms[15,17,33] in the ligand. Mixed acetylides [compounds (17) and (18) in Table 1] have been investigated together with individual acetylides[16,19].

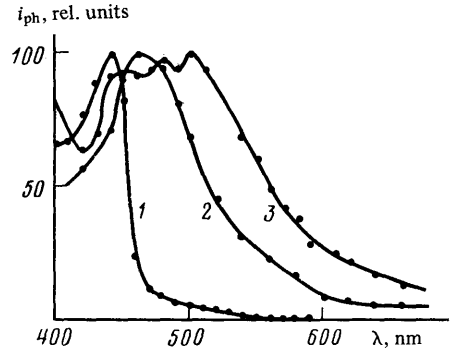

Figure 3. Photoconductivity spectra of the compounds $(RC{\equiv}CCu)_x$ with different R: 1) n-Bu; 2) $CH{=}CH_2$; 3) $PhC{\equiv}C$.[19]

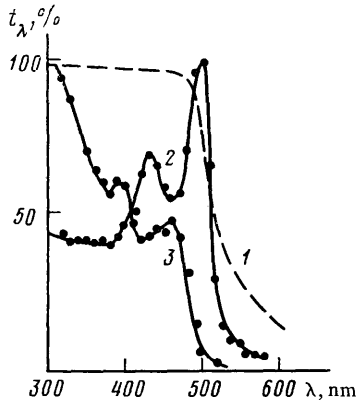

Figure 4. Absorption (curve *1*), photoconductivity (curve *2*), and photo-e.m.f. (curve *3*) spectra of copper phenylacetylide[3]; t_λ = transmittance.

A study has been made[32] of the photoconductivities of certain COA which occur under the influence of powerful laser radiation. The lux–ampere characteristic of the impurity photoconductivities is close to the characteristic obtained under illumination in the region of the fundamental absorption. This shows that the laser pulse probes the local levels directly. The optical stability of the COA decreases monotonically with decrease of the energy of the optical absorption edge.

V. RELATION BETWEEN THE OPTICAL AND PHOTOELECTRIC PROPERTIES

In order to understand the nature of the photoelectric processes, it is of interest to compare the photoconductivity and absorption spectra[3,6,17,20,22,33]. Such a comparison has been carried out in Figs. 5, 6, and 7 for COA with different substituents in the ligand. It was shown above (Table 1) that there is a fairly satisfactory correspondence between the optical activation energy for the photoeffect and the energy of the optical absorption edge.

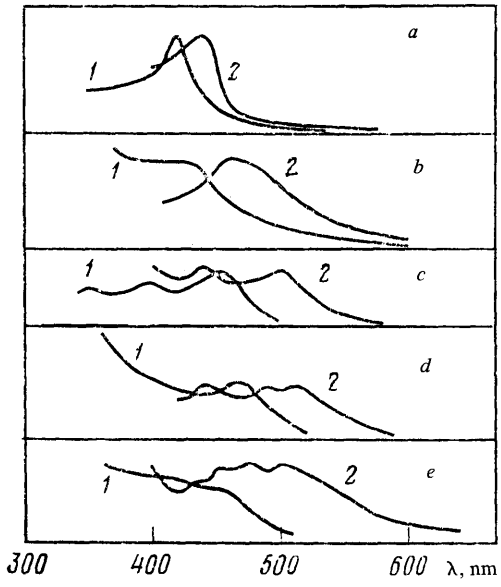

Figure 5. Absorption (curves *1*) and photoconductivity (curves *2*) spectra of copper organoacetylides[19,20]: *a*) $(CuC{\equiv}C{-}C_4H_9)_x$; *b*) $(CuC{\equiv}C{-}CH{-}CH_2)_x$; *c*) $(CuC{\equiv}CPh)_x$; *d*) $(CuC{\equiv}C{-}Ph{-}C{\equiv}C{-}Ph)_x$; *e*) $(CuC{\equiv}C{-}C{\equiv}C{-}Ph)_x$.

The principal photoconductivity maximum is as a rule located on the descending branch of the fundamental absorption. This relation between the absorption and photoconductivity spectra is as a rule fairly general in photosemiconductors and can be accounted for by the decrease in the life-time of the photocurrent carriers in the region of strong absorption due to the increased rate of surface recombination[68,69]. It is noteworthy that the low photosensitivity ("tail") in the majority of compounds investigated persists up to 1000 nm. This phenomenon is probably related to the lack of order and different sizes of the coordination blocks.

It was noted above that the absorption and photoeffect spectral bands, due to charge transfer between the ligand and the metal, are apparently superimposed on transitions of the band–band type. Bearing in mind the complex

structure of the spectra, it is difficult to determine unambiguously which types of transition are most effective in the formation of free carriers. The molecular nature (vibronic structure) of the photoconductivity, photo-e.m.f., absorption, and luminescence spectra is one of the indications that, as for organic semiconductors, a molecular excited state of the type of the Frenkel' exciton is involved in the primary step of the internal photoeffect in COA, migrating in the macromolecule until it encounters a defect or another exciton, which results in the formation of free charge carriers. On the other hand, it has been shown[42,43] that the temperature dependence of the photoconductivity of copper phenylacetylide at a frequency of 10^{10} Hz is insignificant, which can indicate either that the exciton decomposition energy is low or that band–band transitions are involved in the generation of carriers.

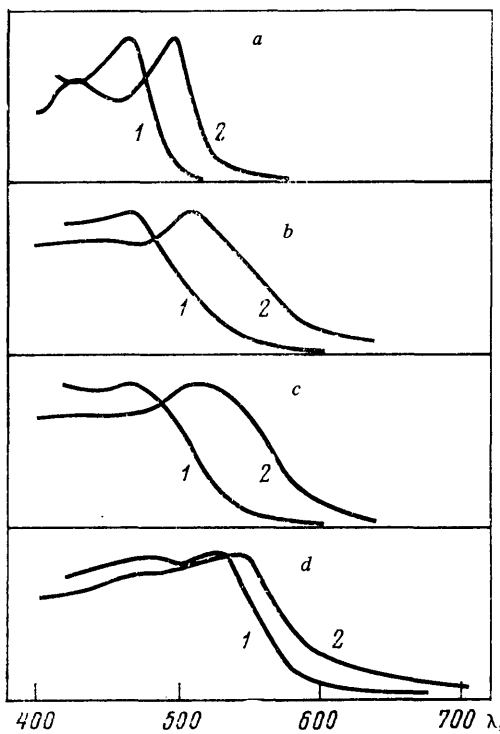

Figure 6. Absorption (curves *1*) and photoconductivity (curves *2*) spectra of copper organoacetylides with organic substituents in the ligand[22]: *a*) $(CuC{\equiv}C{-}Ph)_x$; *b*) $\left(CuC{\equiv}C{-}\text{C}_{10}\text{H}_7\right)_x$; *c*) $\left(CuC{\equiv}C{-}\text{C}_{14}\text{H}_9\right)_x$; *d*) $\left(CuC{\equiv}C{-}\text{C}_{14}\text{H}_9\right)_x$.

A direct determination of mobility in copper phenylacetylide yielded 0.10–0.05 $cm^2\ V^{-1}\ s^{-1}$ for holes and 0.18–0.05 $cm^2\ V^{-1}\ s^{-1}$ for electrons. Such mobilities show that the solid state bands in COA are extremely narrow and one must consider a jump mechanism of the movement of carriers in COA. It has been shown[70] that the mobility in copper phenylacetylide depends on temperature with an activation energy of 0.2 eV and that five adhesion levels are located in the valence band in the range of energies 0.07–0.1 eV and are combined into a narrow band with a width of 3×10^{-1} eV. The above facts suggest that the mechanism of conduction in COA reduces to a series of consecutive thermally activated jumps involving adhesion levels.

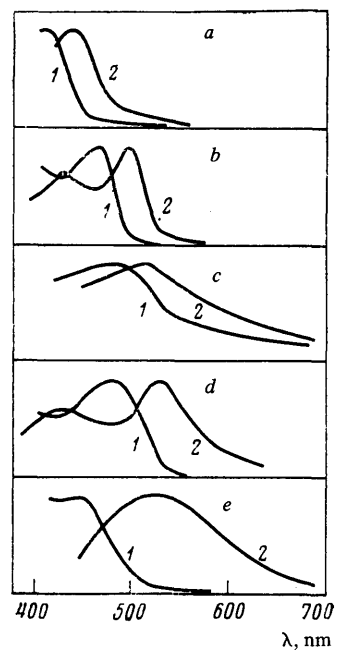

Figure 7. Absorption (curves *1*) and photoconductivity (curves *2*) spectra of organoelemental copper acetylides[33]: *a*) $\left(CuC{\equiv}C{-}CH_2{-}\text{C}_6\text{H}_5\right)_x$; *b*) $\left(CuC{\equiv}C{-}\text{C}_6\text{H}_5\right)_x$; *c*) $\left(CuC{\equiv}C{-}O{-}\text{C}_6\text{H}_5\right)_x$; *d*) $(CuC{\equiv}C{-}S{-}C_2H_5)_x$; *e*) $\left(CuC{\equiv}C{-}S{-}\text{C}_6\text{H}_5\right)_x$.

Spectroscopic studies make it possible to discover the influence of molecular structure on optical and photoelectric properties. It has been shown[2,13] that COA exhibit a much greater photoelectric sensitivity than polymers with triple bonds but without metal atoms. This shows that the coordinating copper atoms and the ethynyl groups play an important role in ensuring photosensitivity. Together with these, steric factors, which are determined by the size of the ligands as well as the size of the main chain, are decisive for charge transfer. Thus photosensitivity diminishes in the series of copper phenyl-, naphthyl-, and anthryl-acetylides [compounds (5), (8), (9) and (10) in Table 1][22,41]. The same type of relation has been established for compounds with heterocyclic substituents in the ligand[17,33]. Thus, despite the increase of the number of π electrons and of the degree of their delocalisation, the photosensitivity falls. Since the efficiency of light absorption and hence of the

formation of carriers apparently varies little, one must suppose that the decrease of photosensitivity is caused mainly by the fact that drift is difficult owing to the bulky nature of the substituents.

For aromatic substituents, the size of the ligands is fairly large but the latter ensure close packing, probably due to their planar structure, which facilitates charge transfer. In this case one may expect that, in compounds with non-planar bulky substituents, the photosensitivity should be a minimum. This has been confirmed by the finding that no photosensitivity has been observed in $(RC{\equiv}CCu)_x$ with R = t-butyl, ferrocenyl, and *o*-carboranyl[33].

Summarising, one may conclude that the decisive factor for charge transfer in COA is not the length of the conjugation system but intramolecular and intermolecular configuration interactions (short-range order in the terminology of the orthodox semiconductor physics), which lower the potential barriers at the boundaries between the macromolecules.

Apart from copper acetylides, we are aware of only one organometallic compound (ferrocene) whose photoconductivity spectrum has been measured[47]. The photocurrent increased monotonically in the range from 270 to 230 nm and no photoconductivity was observed in the regions with a low oscillator strength (320 and 440 nm). According to Hoestery and Letson[47], the latter can be explained either by the inadequacy of the energies of two excitons for the formation of carriers or by the fact that the life time of excitons is too short and the rate of their migration is too low to ensure a high probability of their annihilation. Bearing in mind the narrowness of the section of the spectrum in which the photocurrent was measured, one should apparently exercise extreme caution in stating that the photoconductivity spectrum is identical with the absorption spectrum in the region of the $\pi-\pi^*$ transitions. We may note that the mobility of holes in a ferrocene single crystal was determined in the same investigation as 2.2×10^{-2} cm^2 V^{-1} s^{-1} at 300 K and a number of considerations concerning the conduction mechanism were put forward.

VI. THE PHOTOEFFECT AND LUMINESCENCE

The absorption of light leads to the excitation of the macromolecule. Radiationless degradation of energy, luminescence, and the formation of free carriers are the possible ways in which the excited states are deactivated. We shall therefore consider studies[6,8,9] in which the luminescence and photoelectric properties of copper phenylacetylide (CPA) were investigated simultaneously. Fig.8 presents the absorption, photo-e.m.f., and luminescence spectra of CPA. The luminescence yield varies linearly with the excitation intensity in the range 313–436 nm, is insensitive to the presence or absence of air, and has two maxima, at 516 and 583 nm. Preliminary irradiation of CPA with ultraviolet light decreases the integral luminescence yield and simultaneously increases the integral photoeffect[8]. This is manifested spectroscopically (Fig.9) by a redistribution of the maxima in the action spectra, which is most strikingly manifested in the luminescence spectra. Preliminary irradiation *in vacuo* is accompanied by more complex changes in the photo-e.m.f. spectrum[4]. The luminescence is determined by the decay of excitons.

The changes in the spectra on irradiation with ultraviolet light are probably caused by the photolysis of the coordinate bonds in the polymer, which results in a change of the ratio of the polymer-homologues of the substance. When bonds are broken, the decomposition of excitons by defects is facilitated, which increases the photoeffect and diminishes the luminescence yield.

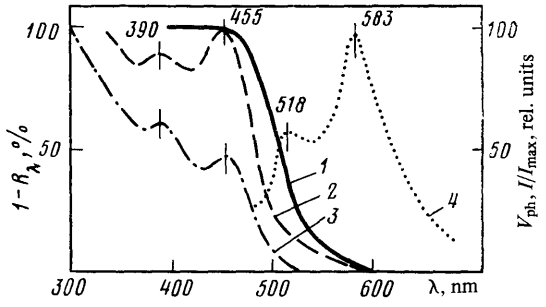

Figure 8. Spectroscopic data for copper phenylacetylide; 1) distribution of reflections ($1-R_\lambda$) from CPA in powder form; 2) distribution of reflections ($1-R_\lambda$) from CPA "diluted" with magnesium oxide (1:100); 3) photo-e.m.f.; 4) luminescence at $T = 293$ K.[8]

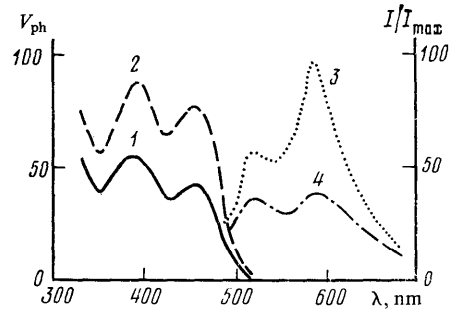

Figure 9. Variation of the luminescence intensity and photo-e.m.f. on irradiation of copper phenylacetylide with ultraviolet light: 1) photo-e.m.f. of the initial specimen; 2) ditto after 10 min irradiation with the light from an SVD-120 lamp using a water filter; 3) luminescence of the initial specimen; 4) ditto after 10 min irradiation with the light from an SVD-120 lamp using a water filter according to the data of Lashkov and Myl'nikov[8].

The proposed mechanism has been confirmed by low-temperature luminescence experiments[8] in which it was shown by spectroscopic studies that the degradation of CPA by ultraviolet light takes place as far as the formation of individual diphenylbutadiyne molecules implanted in the polymer structure. It is of interest that the phosphorescence of the diphenylbutadiyne molecules adsorbed on CPA (their absorption band is located at wavelengths below 340 nm) is excited by light at a wavelength of 365 nm. One can therefore postulate energy transfer from the semiconductor support to the diphenylbutadiyne molecules adsorbed on it. The low-temperature experiment showed that the luminescence of CPA is associated with radiative transitions on the surface. It was found that the state of the surface has a significant influence also on the photoelectric properties of organometallic photosemiconductors.

VII. THE INFLUENCE OF VAPOURS AND GASES ON THE SEMICONDUCTING PROPERTIES OF COA

The influence of oxygen, water vapour, mercury vapour, and electron-accepting molecules on the electrical conductivity, photoconductivity, and photo-e.m.f. of copper phenylacetylide has been studied in a number of investigations[4-9,14,41]. The nature of the change in the electrical conductivity and photoconductivity of CPA under the influence of oxygen is illustrated in Fig.10. The absence of a photochemical interaction of CPA with oxygen was demonstrated, since the spectral characteristics of the photosensitivity hardly changed.

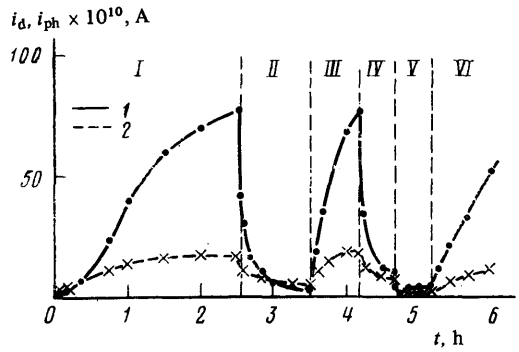

Figure 10. The influence of oxygen on the electrical conductivity (curve *1*) and photoconductivity (curve *2*) of CPA: I) evacuation of air to 5×10^{-5} mmHg; II) admission of oxygen; III) evacuation; IV) admission of oxygen; V) discharge in oxygen; VI) evacuation[4].

It is known that the adsorption of gases on the surface of the semiconductor can lead to the formation of a double layer due to adsorbed molecules or of new recombination or adhesion centres. For a *p*-type semiconductor, it has come to be assumed that the adsorption of molecules with an electron affinity should increase the photoconductivity owing to the capture of an electron by the adsorbed molecule. CPA, a *p*-type semiconductor, shows the opposite behaviour. Oxygen apparently generates new effective recombination centres, which decrease the lifetime of the majority carriers (holes); this has been demonstrated particularly by the present author[4]. On the basis of the analysis of the effect of oxygen, water vapour, and preliminary ultraviolet irradiation on the photo-e.m.f. and photoconductivity spectra, it was postulated in the same study that *in vacuo* oxygen undergoes effective photodesorption from the CPA surface. The suppression of the electrical conductivity and photoconductivity of eleven copper organoacetylides *in vacuo* compared with dry air has been demonstrated[41].

It has been shown[6,7] that water vapour suppresses reversibly the electrical conductivity and photoconductivity and increases the photo-e.m.f. of CPA, which is caused by the formation of an electrical double layer owing to surface states which capture the majority carriers. The change in the semiconducting properties of polymers under the influence of electron-accepting (quinone, chloranil) molecules is associated with the capture of conductivity electrons by these molecules. The set of results obtained concerning the influence of vapours and gases on the semiconducting properties confirms the significant role of the surface for the understanding of the photoelectric processes in organometallic compounds.

In this connection we may note that CPA proved to be a catalyst[11] of the oxidation of the leuco-form of thionine by atmospheric oxygen. The reaction is of interest, since many catalytic reactions on metals proceed via the formation of intermediate organometallic compounds.

VIII. THE SENSITISATION OF THE INTERNAL PHOTOEFFECT

The results considered above suggest that COA constitute a new class of substances with photoelectric properties. However, in many instances the photoelectric sensitivity of these materials is low or is observed at shorter wavelengths in the spectrum than are required for practical applications. All these factors give rise to the question of ways of expanding the spectral sensitivity and of increasing the integral photosensitivity of these compounds.

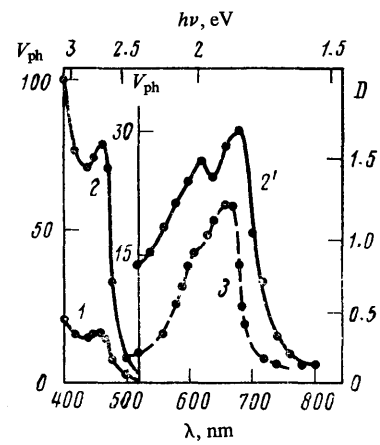

Figure 11. Spectral distribution of the photo-e.m.f. of copper phenylacetylide: 1) before dyeing; 2) and 2') after dyeing in solution of Methylene Blue; 3) absorption spectrum of 10^{-3} M solution of Methylene Blue in ethanol (D = optical density)[25].

A powerful means of increasing the photoelectric sensitivity of inorganic semiconductors is known to be chemical and spectral sensitisation[71]. Chemical sensitisation can be usefully defined as different kinds of treatment of the semiconductor leading to an increase of the photoelectric sensitivity without an alteration of the spectral characteristics of the material. The effect of spectral sensitisation consists in the manifestation of photoelectric sensitivity in the absorption band of molecules adsorbed on the surface of the semiconductor or injected into the latter. For COA, the spectral sensitisation of the internal photoeffect was first observed in studies[24,25] of the adsorption of dyes on the surface of CPA. Subsequently a number of studies of the principal characteristics of the spectral sensitisation of

copper organoacetylides were carried out[24-30,34]. The sensitisation of the photoconductivity and the photo-e.m.f. has been observed in the visible and near infrared regions of the spectrum using dyes of different classes: cationic (pinacyanol, Methylene Blue, carbocyanines, and pentacyanines), anionic (erythrosine), and non-ionic (chlorophyll, phthalocyanine, and haematin). Typical results for the sensitisation of the photo-e.m.f. and the photoconductivity of CPA are presented in Fig.11 in relation to Methylene Blue.

Analysis of the above studies[24-30,34] has led to the following findings. The sensitised photosensitivity spectrum is close to the absorption spectrum of the dye in solution. The increase in the intensity of the bands in the regions corresponding to dimeric and more highly aggregated forms of the dye in the photosensitivity spectra compared with the absorption spectra of the solutions of the dyes leads to the conclusion that, apart from the molecularly dispersed form of the dye, its more highly aggregated forms are involved in the sensitisation step.

The study of the efficiency of sensitisation as a function of the dye concentration showed that the sensitised photosensitivity reaches 30–40% of the intrinsic sensitivity. A dye concentration in solution of 10^{-3} M proved to be the most effective for spectral sensitisation. With increase of the dye concentration from 10^{-6} to 10^{-2} M, an increase in the intensity of the bands due to the dimeric and more highly aggregated forms has been observed in the sensitisation spectra. The sign of the carriers (positive) in the region of intrinsic photosensitivity of the polymeric photosemiconductor and in the region of sensitisation is as a rule the same. Instances of a change in the polarity of the sensitised photo-e.m.f. relative to the polarity of the intrinsic photo-e.m.f. have also been observed. The nature of such changes in sign as a function of time apparently reflects the kinetics of the adsorption of the dye on the COA surface[25].

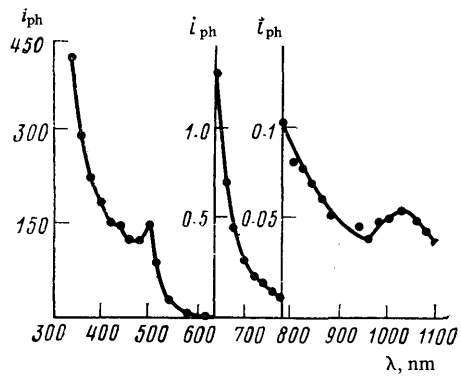

Figure 12. The photoconductivity spectrum of copper phenylacetylide dyed with pentacarbocyanine[26].

Systems based on organic semiconductors with photosensitivity in the near infrared are of considerable interest for technical purposes. The sensitisation of the COA photoeffect by pentacarbocyanine (Fig.12), allocyanine, and xenocyanine, which ensure photosensitivity up to 1300 nm, has been observed[26,28,29]. The principal features of the infrared sensitisers are analogous to those observed in sensitisation in the visible region of the spectrum.

It is noteworthy that, apart from the appearance of sensitised photosensitivity, the adsorption of dyes alters the absolute magnitude of the photoeffect in the region of the intrinsic absorption of the COA. For example, the adsorption of erythrosine increases the intrinsic photo-e.m.f. of CPA by a factor of 30.[24] The effect is apparently due to the type of traps generated by the adsorbate. This has been confirmed particularly by the increase of the inertia of the photoconductivity of coloured compounds relative to non-coloured compounds[28,29].

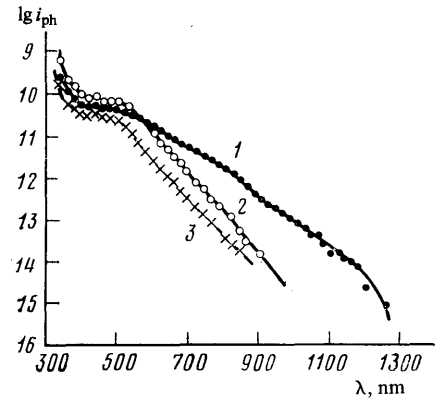

Figure 13. The photoconductivity spectrum of copper phenylacetylide dyed with polyoxyphenylene in solutions at different concentrations (g cm^{-3}): 1) 10^{-1}; 2) 10^{-2}; 3) 10^{-3}.[30]

As already stated, the use of organic dyes as sensitisers leads to the appearance of photosensitivity, whose spectral characteristics are determined by the absorption spectrum of the dye in solution. The majority of dyes have fairly narrow absorption bands, which makes it impossible to obtain panchromatic sensitivity in wide spectral ranges. In 1968 it was suggested for the first time[72] that organic polymers with conjugated bonds, characterised by diffuse structureless absorption spectra, be used as high-resistance photosemiconductors. Together with panchromatic sensitivity within wide spectral ranges, such polymer sensitisers also exhibit a high thermal stability. In addition, in selecting the appropriate polymer sensitiser, one can in principle do without non-photoactive polymeric binders in preparing electrophotographic layers.

Polyphenylenes and polyoxyphenylenes have been used[27,29,30] as sensitisers of COA. Typical curves for the polyoxyphenylene-sensitised photoconductivity of CPA at different sensitiser concentrations are presented in Fig.13. The principal characteristics of the sensitisation by polymers proved to be the same as those for dyes. In particular, the optimum sensitisation was observed for polymer concentrations in the range 10^{-1}–10^{-2} g cm^{-3} and the intrinsic photosensitivity of the adsorbent also changed following the adsorption of the polymer sensitisers.

It is noteworthy that a significant difference in the spectral distribution of the sensitiser efficiency has not been observed for polymers with different numbers of monomeric units in the sensitiser macromolecule. This may be associated with the fact that polyconjugation does not extend over the entire length of the polymer chain[30]. There is no doubt that the use of organic polymers as sensitisers will make it possible to increase significantly the integral sensitivity and to expand the spectral sensitivity of photosemiconductor devices (in particular electrophotographic layers) based on high-resistance photosemiconductors. It is to be expected that the use of polymers as sensitisers of photographic emulsions will also prove to be extremely effective.

In considering problems associated with the sensitisation of the photo-effect by organic polymers, one should note that the organometallic compounds themselves can behave as sensitisers when they are introduced into polymer matrices. It has been suggested[18] that CPA introduced into polyvinylcarbazole at the *N*-vinylcarbazole polymerisation stage acts as a sensitiser.

The above study[18] was carried out because the system comprising polyvinylcarbazole and CPA proved to be effective as electrophotographic layers[35,36,48]. In particular, it was shown that such layers exhibit a photosensitivity comparable to the sensitivity of the electrophotographic layers based on zinc oxide and selenium[40]. It was suggested that a complex involving charge transfer between the components is then formed. However, the photoconductivity spectrum of the system virtually coincides with that of CPA, while the sensitivity of the system in the visible region is higher than that of the pure CPA. Thus one can assume that a charge-transfer complex is not formed in such a system or is too weak to be manifested spectroscopically. Apparently, when light is absorbed, the formation of intrinsic carriers in CPA is accompanied by the effective transfer of part of the light energy to polyvinylcarbazole, which generates electron–hole pairs. Presumably the drift of the carriers (holes) in such a system takes place via jump photoconduction[18].

The main problem of the mechanism of spectral sensitisation is known to consist in the fact that, under the influence of a photon whose energy is significantly smaller than the width of the forbidden gap of the semiconductor, the charge carrier appears in the conductivity band. The majority of modern theories deal with alternative mechanisms of the transfer of energy of an electron from an adsorbed sensitiser to a semiconductor[71]. It is noteworthy that the problem of the mechanism of spectral sensitisation has not been finally solved even for inorganic semiconductors.

Analysis of studies[24–30,34] on the sensitisation of the COA photoeffect has shown that its principal features are the same as those observed for inorganic photosemiconductors (zinc oxide, silver halides). This suggests that the sensitisation has identical mechanisms in the two instances.

A critical examination of the existing views suggests that the preferred mechanism of spectral sensitisation involves energy transfer from the adsorbate to the adsorbent. The most significant evidence in support of this is the relative positions of the energy levels of the COA and the sensitiser dyes[34]. It is seen from the example presented in Fig. 14 that the levels of the sensitiser dyes can be located both above (pinacyanol, chlorophyll, and cryptocyanine) and below (erythrosine and Methylene Blue) the ground state of CPA. Furthermore, for the transfer of a hole to a *p*-type semiconductor it is necessary that the singlet ground level of the dye should be located below the top of the filled semiconductor band. For infrared sensitisers, even a correction for the adsorbed state cannot ensure an arrangement of levels necessary for the transfer of a hole. The relative positions of the energy levels of the COA and the sensitiser are thus not decisive for the sensitisation effect.

In previous sections it was stated that water and mercury vapours, the addition of electron-accepting oxygen compounds, as well as the adsorption of dyes and organic polymers on the surfaces of the COA lead to an alteration of the intrinsic photoelectric sensitivity of the latter. All these phenomena can be regarded as the manifestation of the chemical sensitisation of the internal photoeffect in organometallic semiconductors.

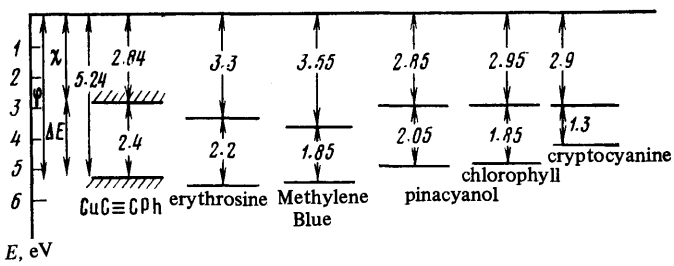

Figure 14. Schematic illustration of the energy levels of copper phenylacetylide and sensitiser dyes; ϕ = photoelectric work function; ΔE = energy of the optical absorption edge; χ = electron affinity[34].

We may also note a study[12] in which it was shown that the photoconductivity, the photo-e.m.f., and the electrical conductivity of CPA increase by 2–3 orders of magnitude when the specimen is treated with deoxyribonucleic (DNA) and ribonucleic (RNA) acids. The nature of the photosensitivity spectra does not then change significantly. The use of pyrimidine (thymine, cytosine, and uracil) and purine (adenine and guanine) bases, which form part of the composition of the acids, shows that the same effects are observed only for adenine and are somewhat smaller in the case of thymine. It is remarkable that these bases are paired in DNA. The observed effects have been explained[12] in terms of a model where the increase of the photosensitivity of the CPA is considered to be a consequence of the introduction into the latter of new recombination centres involving adenine, which increase the lifetime of the majority carriers, this being confirmed particularly by kinetic measurements. Such a model has been considered, for example, in the sensitisation of the photoeffect in cadmium sulphide[73].

We may note that the method of investigating the chemical sensitisation by biologically active molecules in specially sensitised model systems is apparently promising for the understanding of specific properties of such molecules.

IX. THE APPLICATIONS OF ORGANOMETALLIC PHOTOSEMICONDUCTORS

The discovery and study of the photoelectric sensitivity in organometallic compounds leads to the possibility of using them in many technical devices where the main photosensitive element is made of these materials. In this connection we may point out that COA and polyacetylenes containing germanium, silicon, tin, and lead atoms in the conjugation chain have been suggested as electrophotographic layers[10, 35–40,45,48]. The photosensitivity under electrophotographic conditions, determined from the decrease of the potential by

a factor of two, amounts to 300 lux s for CPA in polyvinylbutyral and 70 lux s in polyvinylcarbazole. Thus layers with COA have an integral sensitivity comparable to those of layers made of amorphous selenium and paper containing zinc oxide[10,39,40].

We may note that studies under electrophotographic conditions[10,40] confirmed the nature of the spectral distribution of the internal photoeffect, the sign of the charge carrier, and the activation of the photosensitivity of COA by preliminary ultraviolet irradiation, which was demonstrated by the photoconductimetric and photo-e.m.f. methods[3-6]. At the same time electrophotographic methods made it possible to obtain a series of new data concerning the mechanism of photoconduction in organometallic compounds.

The procedure for the preparation of transparent electrophotographic layers for diapositives is of great interest[38]. The monomer of the binder (vinylcarbazole) is then polymerised in the presence of finely dispersed COA. This results in the formation of fairly homogeneous systems of the type of "solid solutions", which are suitable for the preparation of electrophotographic layers[37,38]. Copper organoacetylides have proved suitable for printing schemes involving the electrophotographic method, which ensure highly technological and economical set ups[40].

The first steps in the application of organometallic compounds in technology have shown that there are definite prospects and possibilities, the realisation of which depends to a considerable extent on how widely and deeply the electronic phenomena in this new class of semiconducting compounds will be investigated. Apart from the solution of technical problems, the study of the properties of organometallic solids may prove useful in relation to a wide range of problems associated with biocatalysis and carcinogenic activity[74].

---o0o---

The data considered in this review show that organometallic compounds constitute a large and interesting class of new semiconducting compounds many of which effectively manifest a fundamental property such as the internal photoeffect. The possibility of a wide variation of the types of bonds by selecting the appropriate metals and ligands permits the reliable prediction that in the future the range of organometallic compounds with semiconducting properties will be greatly extended and that the study of the electronic phenomena in them will be vigorously continued.

The Physics and Chemistry of the Reactions of Positrons and Positronium in Polymers

A.Z.Varisov, Yu.N.Kuznetsov, E.P.Prokop'ev, and A.I.Filip'ev

The problems of the annihilation of positrons in polymers are discussed and the reactions of positrons and positronium, the effect of external electric and magnetic fields, and the influence of various kinds of radiation, temperature, pressure, phase transitions, etc. are examined. The practical value of the positron method for the investigation of polymers is demonstrated.
The bibliography includes 180 references.

I. INTRODUCTION

During the last 10–15 years, there has been an appreciable growth of interest in the study of the reactions of positrons and positronium. The improvement of the experimental technique and methods and the increase of the resolving power of the apparatus, which have become possible as a result of advances in electronics, permitted fairly detailed observations of the reactions of positrons and positronium in matter. At the same time the observed high sensitivity of the characteristics of the electron–positron annihilation to the electronic structure, composition, and defects in the crystal structure of matter, temperature, pressure, phase transitions irradiation, and the effects of external electric and magnetic fields gave rise to the question of a new and in many instances unique method in the physics and chemistry of matter—the positron method.

The aim of the review is to give a systematic account and analyse the experimental and theoretical data, to discuss the main trends in research on the possibilities of the positron method in the physics and chemistry of polymers, and also to attract the attention of specialists in polymer science to the positron method. Without dwelling on the characteristics of the annihilation of positrons in various substances and on the description of the experimental technique and methods (see the relevant reviews, monographs, and corrections[1-15]), we shall proceed to the analysis of the reactions of positrons and positronium in polymers.

II. THE ANNIHILATION OF QUASI-FREE POSITRONS IN POLYMERS

1. The Characteristics of the Electron–Positron Annihilation

It has come to be believed that, as a result of various kinds of energy losses, the fast positrons which arise in the β^+-decomposition of the nuclei of radiative isotopes (^{22}Na, ^{64}Cu, and others) and pass into matter and are slowed down to thermal velocities (thermalisation) long before annihilation. During the retardation process, a proportion of the positrons form positronium. The fraction of positrons annihilated "in flight" is insignificant[2]. The average depth of penetration of positrons (^{64}Cu) is 370.4 ± 20.6 μm in polyethylene (PE) and 156.2 ± 6.1 μm in Teflon (PTFE)†.[15] If the spins of the particles are antiparallel (the singlet state of the e^+e^- pair), the 2γ-annihilation is most probable. On the other hand, for the parallel orientation of the spins of the particles (the triplet state of the e^+e^- pair), the minimum number of annihilation γ-quanta is three (3γ-annihilation). In the 2γ-annihilation the angle of dispersion of γ-quanta differs from π by an amount θ if the e^+e^- pair possesses momentum; the movement of the pair also leads to a Doppler shift ΔE_γ of the energy of the γ-quanta. The probability of the 2γ-annihilation of free particles per unit time in the non-relativistic approximation is, according to Dirac[17], $\lambda = \tau^{-1} = \pi r_0^2 cn$, where $r_0 = 2.818 \times 10^{-15}$ m is the classical radius of the electron, c the velocity of light, and n the number of electrons per unit volume.

The characteristics of the electron–positron annihilation (θ, ΔE_γ, and τ) correspond to the existing experimental methods based on the following measurements: (a) the angular distribution of γ-quanta in 2γ-annihilation (AD); (b) the distribution of γ-quanta in 2γ-annihilation in terms of the Doppler shift; (c) the time distribution of the annihilation radiation (TD); (d) TD corresponding to different angles θ (combined AD–TD method).

In the general case the TD spectrum consists of several components:

$$p(t) = \sum_i I_i \lambda_i e^{-\lambda_i t}, \quad (1)$$

where λ_i are decomposition constants ($\tau_i = \lambda_i^{-1}$ are the experimental average lifetimes of the positrons) and I_i are the

† Here and henceforth the following notation has been adopted: PE = polyethylene, PTFE = Teflon; PS = polystyrene; PVC = poly(vinyl chloride).

intensities of the components. The probability of the annihilation of the positron in a state i in a many-electron system per unit time with emission of two γ-quanta with an overall momentum p is given by the following expression in the one-particle approximation[18]: $\gamma_i(p) = \pi r_0^2 c \rho_i(p)$, where

$$\rho_i(\mathbf{p}) = \sum_j \left| \left(\frac{1}{2\pi\hbar}\right)^{3/2} \int \psi_i^+(\mathbf{r}) \psi_j \exp\left(-\frac{i}{\hbar}\mathbf{pr}\right) d\mathbf{r} \right|^2 \qquad (2)$$

is the function of the distribution density of the e^+e^- pairs being annihilated in terms of momenta, $\psi_i^+(\mathbf{r})$ is the wave function of the positron, and $\psi_j(\mathbf{r})$ are the one-electron wave functions of the atom (ion, molecule). The summation in Eqn.(2) is carried out over all the electrons in the system. The decomposition rate constant $\gamma_i = \sum_p \gamma_i(p)$ is given by

$$\gamma_i = \pi r_0^2 c n_i^*; \; n_i^* = \sum_j \int |\psi_i^+ \psi_j|^2 d\mathbf{r}, \qquad (3)$$

where n_i^* has the significance of the effective number of electrons for annihilation per unit volume of the substance. In the general case $\gamma_i \neq \lambda_i$.

The theoretical AD curves in the case of the isotropic distribution of the e^+e^- pairs in terms of momenta in the Steward approximation[19] can be calculated from the formula

$$I_i(\theta) = 2\pi \int_{p_z}^{\infty} \gamma_i(p) p \, dp; \; \theta = p_z/m_0 c,$$

where m_0 is the mass of the electron. The overall distribution is $I(\theta) = \sum_i I_i(\theta)$. The function of the distribution density of the pairs in terms of the momenta $\rho(p)$ and the momentum distribution of the pairs# $N(p)$ can be reproduced from the results of the measurement of the AD:

$$\rho(p) \propto -\theta^{-1} dI/d\theta, \quad N(p) = 4\pi p^2 \rho(p) \propto -\theta dI/d\theta.$$

We may also note that the decomposition constant γ_i is equal to the area under the theoretical $I_i(\theta)$ curve:

$$\gamma_i = m_0 c \int_{-\infty}^{+\infty} I_i(\theta) d\theta.$$

2. The Annihilation of Quasi-Free Positrons in Polymers

According to Gol'danskii[2], in the general case one can imagine three fundamental mechanisms of the annihilation of positrons in matter: (a) the annihilation of positrons in quasi-free collisions with the electrons of the surrounding medium; (b) the annihilation of positrons in different bound states of the non-positronium type arising on capture of thermalised positrons by ions, atoms, molecules, atom-molecule complexes, and defects; (c) the annihilation of positrons bound in positronium atoms.

In the annihilation of positrons in quasi-free collisions with (valence) electrons, one can infer the distribution densities of the valence electrons in space and with respect to momenta from the results of measurements of their TD and AD parameters. The rate of annihilation of slow quasi-free positrons in a molecular substance can be formulated as follows according to Eqn.(3):

$$\gamma_f = \frac{1}{\tau_f} = \pi r_0^2 c \frac{\rho}{M} N_A \sum_k \nu_k n_k^*, \qquad (4)$$

More precisely the distribution of the pairs with respect to momenta, but in the physics of slow positrons the term "momentum distribution of pairs" is used more often.

where ρ is the density, M the molecular weight, N_A the Avogrado number, ν_k the number of atoms (ions) of the kth kind in the molecule, and n_k^* the number of electrons in an atom (ion) of the kth kind which is effective for annihilation. For liquids and solids, $\gamma_f \cong 10^9$ s^{-1} according to Eqn.(4) and is proportional to the density of the substance. As an example, Table 1 presents the results of measurements[20,21] of the TD parameters (τ_i and I_i) for certain polymers.

Table 1. The average lifetimes of positrons (and the intensities of the TD components) relative to annihilation in certain polymers[20].

Substance	$10^{10}\tau_0$, s	$10^{10}\tau_1$, s	$10^{10}\tau_2$, s	I_0, %	I_1, %	I_2, %
Polystyrene	4.10±0.20	12.2±0.6	21.0±0.6	49±3	4.3±0.5	29.0±1.5
Polyethylene	3.20±0.12	7.7±0.3	27.4±0.8	61±4	15±1	22.8±1.2
Polyvinyltoluene	3.58±0.13	10.5±0.6	21.0±0.6	50±3	6.9±0.6	31.8±1.6
Polypropylene	3.46±0.10	9.9±0.5	23.5±0.7	74±4	7.5±0.7	14.6±0.8
Cellulose acetate	3.71±0.11	9.5±0.5	22.0±0.7	67±4	6.1±0.6	16.3±0.9
Lucite	3.20±0.10	8.2±0.4	19.6±0.6	63±4	11±1	22.0±1.1
Teflon (Ref.21)	3.3±0.1	9.7±0.5	40.9±0.3	64±4	15.0±1.9	21.0±0.4

Remarks: For polystyrene, polyvinyltoluene, and cellulose acetate, there is a component with $\tau_0' = 1.2 \times 10^{-10}$ and intensities of 18 ± 3, 14 ± 2, and 5.5 ± 0.7% respectively. In order to unify the notation, τ_0, τ_1, τ_2, and τ_3 have been replaced by τ_0', τ_0, τ_1, and τ_2 respectively.

Table 2. The number of electrons n_k^* effective for the annihilation of quasi-free positrons and the number of electrons z in the outer shell of the atom[20].

Atom	n_k^*	z	Atom	n_k^*	z
H	2.36±0.15	1	Si	11.2±0.3	4
B	4.5±0.2	3	S	11.7±0.4	6
C	5.08±0.22	4	Cl	11.4±0.3	7
N	6.6±1.4	5	Br	14.4±0.3	7
O	5.21±0.30	6	I	17.8±0.4	7

Cova and Zappa[20] suggested that $\tau_f = \tau_0 = 1/\lambda_0$ (or $\gamma_f = \gamma_0$) (we replaced the symbol τ_1 used by the above workers[20] for a short lifetime by τ_0). To test this hypothesis, we determined the number n_k^* for H, C, and O atoms from Eqn.(4) putting in the latter $\tau_f = \tau_0$ and substituting the experimental values of τ_0 for molecular liquids[22]. The values of n_k^* were then substituted in Eqn.(4) and the lifetimes τ_f in the polymers were calculated (these are listed in Table 1). It was found that $\tau_f = \tau_0$ to within 5%. The numbers of annihilation electrons calculated[20,22] from the lifetimes of positrons τ_0 in various substances are presented for a series of atoms in Table 2. Theoretically γ_f can be calculated in principle from Eqn.(3).

In the free positron approximation, we have

$$\psi^+(\mathbf{r}) = V^{-1/2} \exp(i\,\mathbf{kr}),$$

where V is the normalised volume and k the wave vector of the positron. For thermalised positrons, $\mathbf{k} \cong 0$ and the momentum distribution of the e^+e^- pairs

$$N(p) = \int_0^{2\pi} d\varphi \int_0^{\pi} \rho(p) p^2 \sin\vartheta \, d\vartheta$$

represents the momentum distribution of the electrons (in practice only valence electrons, in view of the inaccessibility of the inner regions of atoms to positrons).

The function $N(p)$ was calculated (by the method of Coulson and Duncanson[23-26]) by various workers[15,27-34] for low-molecular-weight substances (methane, benzene, hexane, etc.) in accordance with the scheme

$$N(p) = \sum_k \alpha_k N_k(p),$$

where α_k is the relative number of bonds of the kth type in the molecule, $N_k(p)$ is the momentum distribution of electrons in a bond of the kth type. The use of the Hartree–Fock wave functions for the 2s and 2p atomic orbitals of carbon instead of the Slater orbitals leads under these conditions to a much better agreement with experiment[28]. There is a discrepancy only in the region of momenta $p \cong (9-10) \times 10^{-3} m_0 c$. If account is taken of the distortion of the planar wave by the field generated by the atoms, in particular by the nuclei, it is possible to obtain a satisfactory agreement with experiment also in the region of large momenta[30-35]. [Fig.1; the appearance of a low-momentum component in $N(p)$ for liquid methane is associated with formation of positronium; see below]. The momentum distribution of the electrons of covalent bonds is insensitive to the fusion of the substance, as was to be expected (Fig.1).

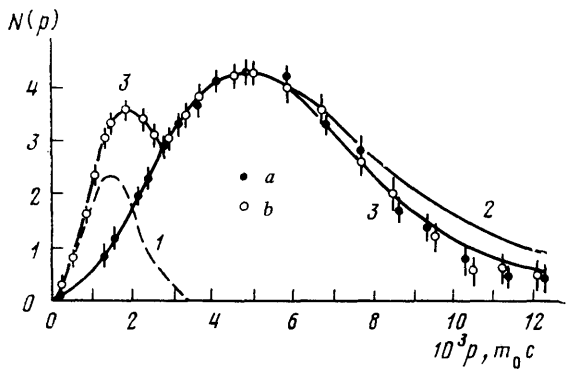

Figure 1. The momentum distribution $N(p)$ for e^+e^- pairs in methane according to AD measurements[30]: *a*) and *b*) experimental points for solid and liquid methane respectively; *1*) momentum distribution of parapositronium atoms; *2*) and *3*) $N(p)$ curves calculated in terms of the approximations of free positrons (curve *2*) and positrons interacting with atoms (curve *3*).

An analogous method can be applied in principle to the calculation of $N(p)$ and hence of the AD curve for high-molecular-weight substances. $N(p)$ for PE can be calculated comparatively simply if the bonds are assumed to be tetrahedral and the ratio of the number of electrons in the C–H and C–C bonds of the $[CH_2]_n$ molecule is assumed to be two in constructing the hybrid orbitals of the carbon atom. The results of the calculation of $N(p)$ and $I(\theta)$ for PE (with Hartree–Fock wave functions) are illustrated in Fig.2.

III. POSITRONIUM IN POLYMERS

1. The formation of Positronium

The properties of the positronium (Ps), i.e. a bound system consisting of an electron and a positron, *in vacuo* are well known (see sub-section 2). The Ps atom is a hydrogen-like atom with a reduced mass equal to $m_0/2$; its ionisation potential is $E_{Ps} \cong 6.77$ eV and its Bohr radius is $a_{Ps} = 2a_0 \cong 0.106$ nm (a_0 is the Bohr radius in the ground state of hydrogen). Parapositronium (*p*-Ps) undergoes spontaneous 2γ-annihilation at a rate $\lambda_s^0 = 8 \times 10^9$ s^{-1} (lifetime $\tau_s^0 = 1/\lambda_s^0 = 1.25 \times 10^{-10}$ s). Orthopositronium (*o*-Ps) is annihilated with emission of three γ-quanta at a rate $\lambda_t^0 = 7.14 \times 10^6$ s^{-1} (lifetime $\tau_t^0 = 1/\lambda_t^0 = 1.4 \times 10^{-7}$ s). As a consequence of the mixing of the substates $^1S_0$ and $^3S_1$ ($m = 0$), in a magnetic field the lifetime of orthopositronium is shortened (magnetic quenching of positronium). The "hydrogen-like" nature, the short lifetime, magnetic quenching, and the possibility of detecting even only one Ps atom [the real density of Ps atoms in matter in the course of the experiment is approximately 10^6 m^{-3} (!)] on the basis of the annihilation γ-quanta make positronium one of the unique research instruments in the physics and chemistry of matter.

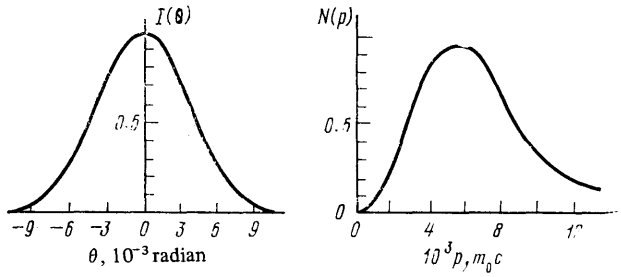

Figure 2. Theoretical AD curves $I(\theta)$ and the momentum distribution curves $N(p)$ for e^+e^- pairs in polyethylene.

The probability of the formation of positronium by retarded positrons in matter is "regulated" by energetic conditions. For a condensed phase, the so-called Ore gap or energy gap, within the limits of which the formation of positronium is most probable, is determined by the following inequality according to Ferrell[2,12,15]: $\mathcal{I} - E_{Ps} - Q_{Ps} < E_+ < E^* - Q_*$, i.e. the energetic condition for the formation and dynamic stability of positronium is represented by the inequality

$$Q_- + Q_+ < E_{Ps} + Q_{Ps},$$

where $\mathcal{I}$ is the ionisation potential and E^* the energy of the electronic excitation of the substance, E_+ the kinetic energy of the positron, and Q_-, Q_+, and Q_{Ps} are the affinities of the substance for the electron, the positron, and the Ps atom.

Even if there is no energetic prohibition of the formation of positronium, not all the positrons form positronium. Some of the positrons are annihilated within the limits of the Ore gap, are captured in non-positronium states ("adhere" to molecules, fall into traps, etc.), are retarded

to an energy $<E_+$ by non-elastic interactions, with individual molecules, etc. All these processes, which have been combined under the name of positronium inhibition processes, depend on the chemical composition, the intermolecular interaction, the structural defects, and other factors.

The so-called spur model of the formation of positronium, proposed[35] to account for the formation of positronium in liquids, has been widely discussed in recent years. It is assumed in this model that positronium is formed when a positron is bound to one of the electrons arising in the trace (spur) of the retarded positron as a result of the ionisation of molecules and accompanying ("escorting") the positron. For liquids (and solutions), it is possible to set up a quantitative theory of the reactions of positrons and positronium taking into account their interaction with the species in the trace of the positron (with electrons, ions, and radicals) and the surrounding medium (see, for example, Refs.15 and 35–41). Attempts have been made to apply the spur model to molecular crystals[36,42], but the problem of its applicability to molecular crystals and polymers has not been finally resolved[36].

2. The Quenching of Positronium

The interaction of positronium with the surrounding medium in matter leads to a significant alteration of its properties compared with a vacuum. Processes such as (a) pick-off annihilation, i.e. annihilation of the positron in the Ps atom by a "foreign" electron, (b) the ortho-para conversion ($^3S_1 \; ^1S_0$) in the interaction of Ps atoms with paramagnetic species M as a consequence (in the simplest case) of the direct spin exchange

$$M(\downarrow) + {}^3S_1(\uparrow\downarrow) \rightleftarrows M(\uparrow) + {}^1S_0(\uparrow\downarrow),$$

and (c) different kinds of chemical reactions of positronium with the molecules of the given substance (addition, substitution, and oxidation) alter the lifetime of positronium compared with τ_s^0 and τ_t^0. For orthopositronium, all the above processes, which open the channel to 2γ-annihilation, shorten the lifetime (compared with τ_t^0) and are therefore combined under the term "quenching" of positronium[2]. If we introduce the quenching rate constant λ_q, then usually $\lambda_t^0 \ll \lambda_q \ll \lambda_s^0$. Parapositronium is therefore relatively insensitive to the above processes. In the general case pick-off annihilation, which shortens the lifetimes of orthopositronium to $\lesssim 10^{-9}$ s, is most significant for polymers.

We shall consider the kinetics of the pick-off annihilation process. Suppose that the probability of the formation of positronium is P. Then at the initial instant $t = 0$ the probability of detecting the positron in a quasi-free state is $P_f(0) = 1-P$ and the probabilities of detecting positronium are $P_S(0) = \frac{1}{4}P$ in the singlet state and $P_t(0) = \frac{3}{4}P$ in the triplet state. The populations of the above states vary with time in accordance with the law

$$P_f(t) = (1-P)\,e^{-\lambda_f t}, \quad P_s(t) = \frac{1}{4}P\,e^{-\lambda_s t},$$
$$P_t(t) = \frac{3}{4}P\,e^{-\lambda_t t},$$

where $\lambda_s = \lambda_s^0 + \lambda_p$, $\lambda_t = \lambda_t^0 + \lambda_p$, λ_f is the rate of annihilation of quasi-free positrons, and λ_p is the rate of pick-off annihilation. The TD spectrum consists of three components with the average durations $\tau_0 = \lambda_s^{-1}$, $\tau_1 = \lambda_f^{-1}$, and $\tau_2 = \lambda_t^{-1}$ and with the intensities $I_0 = \frac{1}{4}P$, $I_1 = 1-P$, and $I_2 = \frac{3}{4}P$. If the TD components with the decomposition constants λ_s and λ_f cannot be resolved, the experimental (average) short lifetime is

$$\tau_1 = \frac{1}{I_1}\left(\frac{I_f}{\lambda_f} + \frac{I_s}{\lambda_s}\right),$$

and $I_1 = I_f + I_S$.

Since the momentum of the p-Ps atom retarded to thermal velocity is comparatively small, the self-annihilation of parapositronium contributes to the AD curve in the region of small angles, while a comparatively narrow peak appears on the AD curve—a narrow $N(\theta)$ component and a low-momentum component on the $N(p)$ curve (see Figs.3 and 4 and also Fig.1). The intensity $I_N = \lambda_S^0 \int_0^\infty P_S(t)dt$ of the narrow AD component is

$$I_N = \frac{1}{4}P\,\frac{\lambda_s^0}{\lambda_s^0 + \lambda_p} \approx \frac{1}{3}I_2, \qquad (5)$$

since usually $\lambda_p \ll \lambda_S^0$. The annihilation of free positrons and the pick-off annihilation of positronium give rise to the broad AD component.

The relative probabilities of the 3γ-annihilation of quasi-free positrons and orthopositronium are $P_{3\gamma}^0 = 1/372$ (Gol'danskii[2]) and $P_{3\gamma}^t = \lambda_t^0 \int_0^\infty P_t(t)dt$ respectively and the overall probability of 3γ-annihilation is therefore

$$P_{3\gamma} = I_2\frac{\tau_2}{\tau_t^0} + \frac{1}{372}\left(1 - \frac{4}{3}I_2\right).$$

The inequality $P_{3\gamma} > P_{3\gamma}^0$ is an "indicator" of the formation of positronium in matter. In polymers $P_{3\gamma} > P_{3\gamma}^0$ (see, for example, Refs.7 and 45–47). Thus we have $P_{3\gamma}/P_{3\gamma}^0 \cong 2.60$ for PTFE and $P_{3\gamma}/P_{3\gamma}^0 = 3-4$ for rubbers[7].

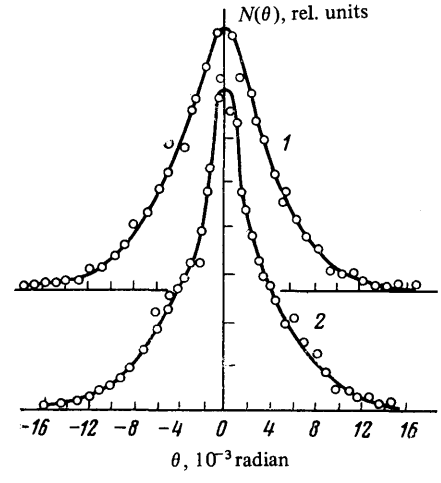

Figure 3. AD curves for Teflon recorded at 77 K (curve *1*) and 525 K (curve *2*).[43]

The positronium formed in the given substance is thus manifested experimentally by the appearance of a long-lived component in the TD and a narrow component in the AD and also by the higher probability of 3γ-annihilation $P_{3\gamma}$ compared with $P_{3\gamma}^0 \cong 0.27\%$. At the same time the relevant measurements make it possible to follow the reactions

of positronium in the substance and its properties on the basis of the TD and AD parameters and $P_{3\gamma}$.

If parapositronium is thermalised and exists in a free state, then its momentum distribution is Maxwellian:

$$N(p) \sim p^2 \exp(-p^2/4m_0k_0T),$$

while the narrow component of AD has a Gaussian form:

$$N(\theta) \sim \exp(-m_0c^2\theta^2/4k_0T).$$

The width of the $N(\theta)$ distribution profile at half its height at the maximum (the half-width of the narrow component) is $\Gamma_N \cong 4.33 \times 10^{-2} T^{1/2}$ mrad. At 295 K we have $\Gamma_N \cong 0.74$ mrad, so that the distribution $N(\theta)$ should be indeed manifested in the given instance by a very narrow peak in the AD. However, in polymers such a narrow distribution is usually not observed.

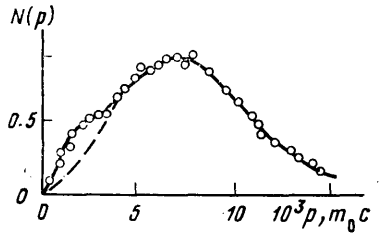

Figure 4. The momentum distribution of e^+e^- pairs in Teflon at room temperature[44] [dashed curve—theoretical calculation of the $N(p)$ function in the region of low values of p].

3. The States of Positronium in Molecular Substances. The "Positronium Capture Model"

There is reason to believe[10,48-51] that positronium can exist in a condensed phase in two states: the quasi-free or delocalised state and the localised state. The localised state arises in the "capture" of a Ps atom by a trap, whose role may be assumed by a macrocavity, a region of reduced density, etc. Bearing in mind that $\lambda_t^0 \ll \lambda_s^0$ and assuming that $\lambda_f \cong \lambda_p$, $\lambda_{pv} \ll \lambda_s^0$, $\lambda_t^0 \ll \lambda_{pv}$, and $\lambda_t^0 \ll \lambda_p + k$, where λ_p and λ_{pv} are respectively the rates of the pick-off annihilation of the quasi-free and localised positronium and k is the rate constant for the capture of positronium by traps, Bartenev and coworkers[49,50] interpreted the observed TD components (when the spectrum was resolved, as usual, into three components) as follows. The long-lived component τ_2 corresponds to the annihilation of o-Ps atoms in a trap, the intermediate component τ_1 corresponds to the annihilation of free positrons, and the short-lived component τ_0 corresponds to the annihilation of o-Ps atoms in a free state and of the p-Ps atoms in free and localised states. The parameters of the experimental TD spectrum are related to the parameters of the model as follows[49,50]:

$$\tau_0 = \frac{1}{4 - 3k/\Lambda_p}\left[\frac{k}{\Lambda_p}\left(\frac{1}{\lambda_{so}} - \frac{1}{\lambda_s} - \frac{3}{\lambda_t}\right) + \frac{1}{\lambda_s} + \frac{3}{\lambda_t}\right],$$

$$\tau_1 = 1/\lambda_f, \quad \tau_2 = 1/(\lambda_t^0 + \lambda_{po}) \approx 1/\lambda_{po},$$

$$I_0 = 1 - I_1 - I_2, \quad I_1 = 1 - P, \quad I_2 = 3/4Pk/\Lambda_p,$$

where $\Lambda_p = \lambda_p + k - \lambda_{pv}$, $\lambda_{sv} = \lambda_s^0 + \lambda_{pv} \cong \lambda_s^0$, $\lambda_s = \lambda_s^0 + \lambda_p + k$, and $\lambda_t = \lambda_t^0 + \lambda_p + k \cong \lambda_p + k$. The form of the narrow AD component is defined by the expression

$$N(\theta) = (\lambda_{so}/\lambda_s) N_f(\theta) + (k/\lambda_s) N_v(\theta),$$

where the $N_f(\theta)$ and $N_v(\theta)$ components are due to the self-annihilation of the quasi-free and localised parapositronium. The intensity of the narrow component is $I_N \cong \frac{1}{4}P[1-(k/\lambda_s^0)]$.

If the τ_1 component is attributed to the annihilation of free positrons, as suggested by Bartenev and coworkers[49,50], then it is difficult to explain the reason for the long lifetime (for example 1.22 ns in PS; see Table 1) of this fraction of positrons. Furthermore, it follows from the calculations of Cova and Zappa[20] (see above) that $\lambda_f^{-1} \cong \tau_0$. Judging from the value of τ_1, the τ_1 component can be due to the faster, than in the case of the τ_2 component, pick-off annihilation of orthopositronium. There is then a possibility of several versions. For example, traps in the crystalline and amorphous regions of the polymer have different constants λ_{pv} and k (we shall denote them respectively by λ'_{pv}, k, and λ_{pv}, k) and $\lambda_{pv} < \lambda'_{pv}$. Positronium is formed and annihilated, remaining in its own region—crystalline or amorphous. Then $\tau_1 \cong (\lambda'_{pv})^{-1}$, $\tau_2 \cong \lambda_p^{-1}$, $I_1 = 3\chi Pk'/4\Lambda'_p$, and $I_2 = 3(1-\chi) \cdot Pk/4\Lambda_p$, where $\Lambda'_p = \lambda'_p + k' - \lambda'_{pv}$ and $\Lambda_p = \lambda_p + k - \lambda_{pv}$, while χ is the degree of crystallinity of the polymer. In the more general case account may be taken of the "escape" of the Ps atoms from the traps and their diffusion from one region of the polymer to another[52-56]. We shall return to the problem of the nature of the τ_1 component in discussing experimental data.

IV. THE INFLUENCE OF TEMPERATURE, PHASE TRANSITIONS, AND PRESSURE ON THE PROPERTIES OF POSITRONIUM IN POLYMERS. THE "FREE VOLUME" MODEL

1. The Effect of Density in the Quenching of Positronium in Polymers. The "Free Volume" Model

The shortening of the lifetime of the long-lived component (τ_2) of TD with decrease of temperature[57] (for example, $\tau_2 = 3.5$, 2.5, and 1.6 ns for PTFE at 20°, −78°, and −196 °C), the enhancement of the narrow AD component on heating polymers[43,58] (see, for example, Fig. 3), and finally a decrease of the intensity of the narrow component (for PTFE[58]) and at the same time of τ_2(lucite, PTFE, and PE at pressures up to 1.01 GPa)[59] were originally observed in earlier investigations. The decrease of τ_2 both with decrease of temperature and following the compression of the test substance is interpreted as a density effect, i.e. as a consequence of the increase of the density and hence of the decrease of the "free volume" (i.e. of the interstitial volume, the volume of microcavities, the volume of regions with a reduced density, etc.) in which the Ps atom is "located".

The dependence of τ_2 on the "free volume" can be accounted for on the basis of a simple model of the interaction of a Ps atom in a trap with the surrounding medium—as a species with a mass $2m_0$ in the potential well[58,60]. The probability $\mathscr{P}$ of the Ps atom being outside the well, i.e. in the given substance, is determined by the shape, size, and depth of the well. The overlap of the wave function $\psi(\mathbf{R})$, describing the movement of the centre of inertia of the Ps atom, with the wave functions of the surrounding molecules, and therefore the rate of pick-off annihilation of positronium increase with decrease of the size of the well, i.e. of the "free volume", and τ_2 correspondingly decreases. The rate of pick-off annihilation in the "free volume" model can be

formulated thus:

$$\gamma_p = \mathcal{P}\gamma_0;\ \mathcal{P} = 1 - \int_{v_f} |\psi(\mathbf{R})|^2 d\mathbf{R}, \qquad (7)$$

where $\gamma_0 = \pi r^2 c n^*$, v_f is the "free volume" (the volume of the trap), and n^* is the electron density in the given substance effective for the pick-off annihilation of positronium. $n^* = 3.8 \times 10^{29}$ m^{-3}, which corresponds to the electron density in the region where the positron is present in the P$\bar{s}$ ion ($\tau^0 = \gamma_0^{-1} = 0.35$ ns), is frequently chosen for estimates. Calculations of $\mathcal{P}$ have been carried out[61-71] for various geometries of the free volume: spherical (Figs.5*a* and 5*b*), cylindrical (Figs.5c), and planar (Fig.5d).

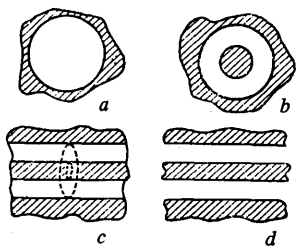

Figure 5. Different geometries of the free volume: *a*) and *b*) spherical geometry; *c*) cylindrical geometry; *d*) planar geometry.

2. Brandt's Free Volume Model

According to Brandt et al.[61,63,64],

$$\mathcal{P} = \frac{1 + G\{\exp[2\xi^2(S, v^*)\langle u^2(T)\rangle/R_0^2] - 1\}}{1 + F(S, v^*)}, \qquad (8)$$

where $S = (4m_0/\hbar^2)U_0R_0^2$ is a dimensionless parameter proportional to the height of a rectangular potential U_0 and the square of the radius R_0 of the core of the cell (i.e. the "excluded" volume v_0) and $v^* = v_1/v_0$ is the reduced "free volume", while v is the volume of the entire cell with a radius R_1 (in the range $R_0 \leq R \leq R_1$ we have $U_0 = 0$ and $n^* = 0$ and the cell constitutes the intrinsic "free volume" $v_f = v_1 - v_0$); the factor G varies from 1/2 to 1 and is approximately given by

$$G \simeq 1 - \frac{1}{2}\, t\hbar\, \frac{\mu - 1}{\xi(S, v^*)},$$

where u = 1, 2, or 3 for the planar, cylindrical (chain), and spherical geometries of the cell respectively. The temperature variation of the reduced mean-square amplitude $\langle\mu^2\rangle/R_0^2$ of the vibrations of the core in the region $\Theta_D \leq T \leq T_m$ is given by the expression

$$\langle u^2\rangle/R_0^2 = v^{*2/\mu}\gamma_m T/T_m,$$

where γ_m is the critical value of $\langle u^2\rangle/R_0^2 v^{*2/\mu}$ attainable on fusion and Θ_D and T_m are respectively the Debye temperature and the melting point. For a melt (T/T_m),

$$\langle u^2\rangle/R_0^2 \simeq v^{*2/\mu}\gamma_m.$$

If $T < \Theta_D$, then $\langle u^2\rangle \cong$ const. and $\mathcal{P}$ depends only on the model parameters S and v^*: $\mathcal{P}[1 + F(S, v^*)]^{-1}$.[71] The functions $\xi(S, v^*)$ and $F(S, v^*)$ have been expressed[64] in analytical and graphical forms. Interpolation formulae for ξ and F are[64]

$$\xi^2(S, v^*) = S[1 - (1+F)^{-2/3}],$$

$$F(S, v^*) = \frac{4}{\pi^3}\{[1 + S^{1/2}(v^{*1/\mu} - 1)]^3 - 1\}.$$

The half-width of the narrow AD component in the free volume model can differ appreciably (is greater) from Γ_N for free thermalised positronium. (The experimentally observed broadening of the narrow component relative to Γ_N for thermalised positronium has served as a basis for the authors' hypothesis[58] concerning the possible localisation of Ps atoms). In Brandt's "free volume" model the half-width of the component (in mrad) is[71]

$$\Gamma_N \simeq 0{,}25 g_\mu^{1/3} \frac{S^{1/2}}{R_0}\left(\frac{\gamma_p}{\gamma_0}\right)^{1/3}, \qquad (9)$$

where $g_\mu = \frac{1}{2}\mu$ for $\mu = 1$ and 2 and $g_\mu = 1/\mu$ for $\mu = 3$; R_0 is measured in nanometers. Thus a relation has been established between Γ_N and γ_p.

3. The "Empty Free Volume" Model (The "Trap" Model).

In the region where the Ps atom is localised is regarded as spherical without a "core" (Fig.5*a*) and the interaction of the Ps atom with the surrounding medium is modelled by a rectangular spherically symmetrical potential well with a radius a and a depth U_0, then $\mathcal{P} = k^2/\alpha(\alpha + aP_0 + k^2/\alpha)$, where $k = (2/\hbar)(m_0E)^{1/2}$, $\alpha = (2/\hbar)[m_0(U_0 - E)]^{1/2}$, $P_0 = (4/\hbar)m_0U_0$, and E is the energy of the Ps atom in the well[65]. Bearing in mind that $\mathcal{P} = \gamma_p/\gamma_0$ and assuming that $E \cong \frac{1}{16}m_0c^2\Gamma_N$, in this model the parameters of the well (or the trap of the Ps atom if the terminology of the "positronium capture" model is used) can be estimated from the experimental values of γ_p and Γ_N as $a \cong 0.77\chi/\Gamma_N$ nm and $U_0 \cong 3.2 \times 10^{-2}(\Gamma_N/y)^2$ eV, where Γ_N is expressed in milliradians and x and y constitute the solution of the equations

$$y = \sin x, \quad \gamma_p/\gamma_0 = y^3/[y + x(1 - y^2)^{1/2}]$$

for $\cot x < 0$. In a more rigorous solution of the problem, one calculates in the first place the narrow AD component and then its half-width is determined. For an infinitely deep spherically symmetrical rectangular potential well, the wave function of the Ps atom is

$$\psi(\mathbf{R}) \sim \sin kR/R,$$

and the angular distribution of the annihilation γ-quanta assumes the form

$$N(\theta) \sim \int_\beta^\infty \left(\frac{\sin z}{\pi^2 - z^2}\right)^2 \frac{dz}{z};\ \beta = \frac{m_0 c a}{\hbar}\theta.$$

Numerical calculation of the width of the $N(\theta)$ distribution profile at the level of half its height at the maximum yields[72] $\Gamma_N \cong 1.660\, a^{-1}$ mrad, where a is expressed in nanometers. The $N(\theta)$ distribution for a spherical well with a finite depth[72] and also for a rectangular potential box[73] has also been discussed. The parameters of the well can be determined also from the form of the $N(p)$ momentum distribution[15,67].

4. Dependence of the "Positronium Parameters" of AD and TD on Temperature and Pressure in Polymers and the "Free Volume" Model

Studies on the temperature and pressure dependence of the AD and TD parameters, associated with the reactions of positronium, in various polymers have on the whole confirmed

the conclusions derived from the "free volume" model[1,2,57-63,66,74-87].

In a study[62] of the dependence of the parameters τ_2 and I_2 of the long-lived TD component (the TD component decomposed into two components) on temperature (up to 200 °C) and pressure (up to 6.06 GPa), a relation of the following type was established for a number of substances:

$$\tau_2 \simeq \tau_2^0(T)(1-\eta\Delta V/V_0).$$

Here $\Delta V = V_0 - V$ is the volume change under the influence of pressure. The values of τ_2^0 (30 °C) and η, determined from the experimental data, are as follows:

Polymer	Lucite	PTFE	PS
τ_2^0 (30° C), ns	1.7 ± 0.2	3.2 ± 0.2	2.2 ± 0.2
η	4.3 ± 0.9	5.0 ± 0.8	4.3 ± 0.7

Having formulated $\tau_2^{-1} \cong \mathcal{P}\gamma_0$ [see Eqn.(7)] and having defined as the probability that the Ps atom is located outside the limits of a three-dimensional rectangular potential well with a volume v ($\mathcal{P} \propto v^{-0.87}$), so that $\tau_2 \propto v^{0.87}$, the authors[62] based their treatment in essence to the "empty free volume" model. Hence, if one assumes on the basis of compressibility data for polymers that the fraction of vacancies in non-compressed polymers is 20%, it follows that[62]

$$\tau_2 = \tau_2^0(1-5\Delta V/V_0)^{0.87},$$

which corresponds to $\eta = 4.35$ in the empirical $\tau_2(V)$ relation. The calculated and experimental values of η agree within the limits of the error of the measurements.

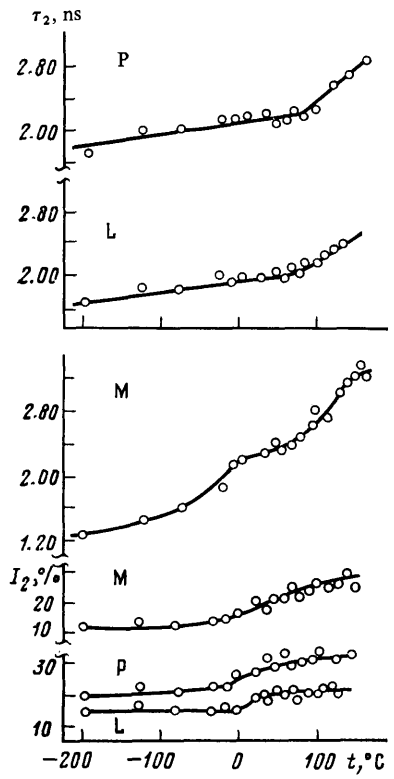

Figure 6. Dependence of the parameters of the long-lived TD component (the lifetime τ_2 and the intensity I_2) in polystyrene (P), lucite (L), and Marlex-50 polyethylene (M).[76]

The ratio I_2/I_2^0 for polymers decreases as the substance is compressed, which, however, is not obligatorily related to the decrease of the probability of the formation of positronium and may be caused, according to the "positronium capture model" [see Eqn.(6)] by the corresponding change in the parameters k, λ_p, and λ_{pv} ($k \propto n$, where n is the number of traps per unit volume of the polymer and λ_p and λ_{pv} are determined respectively by the density of the polymer and the volume of the traps). The decrease of τ_2 in polymers with decrease of temperature and the breaks in the $\tau_2(T)$, $I_N(T)$, and I_2 curves in the region of phase and relaxation transitions[1,2,15,66,76,79,82-86] (Figs. 6 and 7) are also qualitatively consistent with the "free volume" model. The glass points determined from the positronium data are somewhat lower than those found by other methods, which indicates a higher sensitivity of the positronium method to changes in the structure of the polymer[84,86]. In the region of vitrification I_2 is almost independent of temperature[1,75,84,86], i.e. the increase of the size of the microcavities is not accompanied by an appreciable change in their number.

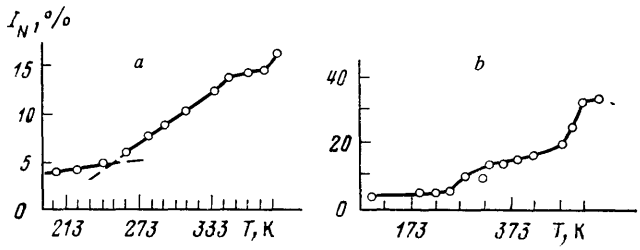

Figure 7. Temperature dependence of the intensity of the narrow AD component in high-pressure polyethylene (*a*) and in Teflon with a degree of crystallinity of 64% (*b*).

One of the causes of the appearance of breaks in the $\tau_2(T)$ curves is "vibrational" movement of atoms (and molecules) and the fluctuations in the density of the substance caused thereby, which lead to the "smearing" of the electron density and hence to an increase of the rate of pick-off annihilation of orthopositronium in contrast to the "free volume" effect, due in this instance to thermal expansion. These effects have been analysed quantitatively[63,70] (they are "inherent" in Brandt's "free volume" model—see above). In polymers the smearing of electron density and hence the associated acceleration of the pick-off annihilation of positronium can arise when the mobilities of particular kinetic units are "switched on" in the temperature range of the relaxation transitions on heating the polymer[51,85].

The TD spectra in polymers contain up to three (or even up to four) components[24,63,87-89] (Table 1). Having measured the temperature dependence of the TD parameters in PE and PTFE (and also in glycerol), Brandt and Spirn[63] concluded that the component τ_2 is due to the pick-off annihilation of the *o*-Ps atoms in the disordered regions of the polymer, while the component τ_1 is due to the annihilation of free positrons; the *p*-Ps atoms located in the disordered regions and the *o*-Ps and *p*-Ps atoms in the ordered regions contribute to the component τ_0. We may note that an analogous interpretation of the TD spectrum has been adopted by the authors of the "positronium capture" model (see Section III).

Fig. 8 presents the experimental values of τ_2 for PE and PTFE and the calculated $\tau_2(\nu^*) = 1/\gamma_p(\nu^*)$ curves based on Eqns. (7) and (8) for $\mu = 2$, $S = 25$, and $\gamma_m = 1/16$ and 1/12 respectively. Extrapolation of the data in Fig. 8 to close packing conditions yields values of τ_2 close to τ_0, which, as it were, confirms the validity of the hypothesis concerning the relation between τ_0 and the pick-off annihilation of positronium in the ordered domains of the polymer. In a subsequent study[71] dealing with the TD spectrum in paraffins, including PE, the above interpretation was wholly retained. At the same time it is assumed that the component τ_1 of TD involves the contribution of the positrons located in the disordered domains in the form of A_+ centres[90] (see also Refs. 6, 9, 10, and 12); on the other hand, the annihilation of free positrons contributes to the component τ_0. According to Brandt[71], the half-width of the narrow AD component in paraffins [see Eqn. (9)] is $\Gamma_N \approx 3.5$ mrad. Measurement of Γ_N for PE yields the same value[82].

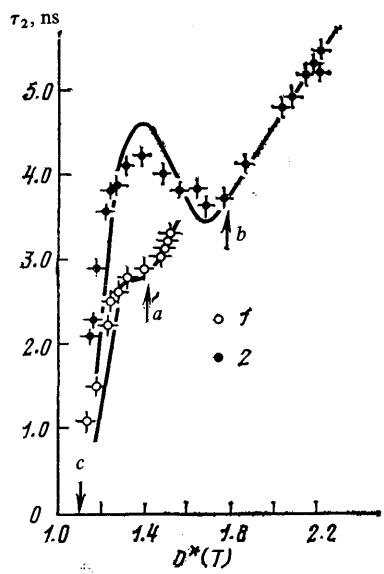

Figure 8. Dependence of the lifetime of positronium τ_2 on the reduced free volume $\nu^*(T)$ in polyethylene (*1*) and Teflon (*2*);[63] symbols—experimental data; curves—calculation; *a*) and *b*) $\nu^*(T_m)$, where T_m = melting point; *c*) close packing.

Thus the dependence of the TD (and also AD) parameters on the reduced "free volume" in molecular substances, including polymers, has been given the same treatment in studies by Brandt and coworkers[63,71]. Nevertheless one must bear in mind that there are discrepancies in the experimental data of different workers (cf. for example, the data in Refs. 63 and 75, on the one hand, and Ref. 77 on the other). The definition of τ_0 as the average lifetime of free positrons or positrons bound in A_+ centres, adopted by Brandt and coworkers[63,71] (see above), is also open to objection. Whereas according to Brandt and coworkers[63,71] the value of τ_0 in PE and PTFE is independent of temperature and that in PE is independent of the degree of crystallinity (Table 3), according to, for example, the data of other workers for PTFE [89] and PE [1,15,91] this is not the case.

Finally, one must bear in mind the approximate nature of the "free volume" model itself, associated with the choice of the form of the potential of the interaction of the Ps atom with the surrounding medium, with the uncertainty of the electron density n^* effective for pick-off annihilation [see Eqn. (7)], with neglect of the details of the formation and reactions of positronium preceding its localisation (such as the probability of the formation of positronium in the crystalline and amorphous region of the polymer, the nature of the population of the "free volumes" by Ps atoms—gas-kinetic or diffusional, etc.), and other factors.

Table 3. Dependence of the TD parameters for polyethylene on the degree of crystallinity χ of the specimens[71] (ρ = density; ν^* = reduced "free volume").

χ, %	$10^{-3}\rho$, kg m^{-3}	ν^*	τ_0, ns	I_0, %	τ_1, ns	I_1, %	τ_2, ns	I_2, %
46	0.917	1.298	0.31	63	0.65	10	2.61	27

V. DEPENDENCE OF THE PROPERTIES OF POSITRONIUM ON THE STRUCTURE AND DEGREE OF CRYSTALLINITY OF POLYMERS

In the "free volume" model it is in essence assumed that the overall probability of the formation of positronium in molecular substances is independent of temperature, state, and structure. However, numerous experiments (see, for example, Refs. 2, 6, 8, 42, and 92–96), involving observation of the formation of positronium in molecular substances (and in ionic compounds) indicate the opposite behaviour in crystal–liquid and crystal–glass transitions when the conditions and nature of the preliminary treatment are altered. The same applies also to polymers[1,2,15,77,78,80,82–84,91,97–101].

In PTFE with a lower degree of crystallinity (~44%) and density (2.14×10^3 kg m^{-3}), obtained by the rapid cooling of specimens heated to 350 °C, the intensity of the long-lived component $I_2 \approx 23.8\%$ and the sum $I_1 + I_2 \approx 33.1\%$ proved to be appreciably higher than in PTFE with a higher degree of crystallinity (~76%) and density (2.26×10^3 kg m^{-3}), obtained by slow cooling: $I_2 \approx 6.9\%$ and $I_1 + I_2 \approx 21.9\%$.[89] The conversion of PTFE into an amorphous form entails an increase by 6.3% of the fraction of the narrow component in AD.[97]

Later measurements of TD and AD in polymers (PE, PTFE, PS, nylon, and lucite) confirmed the sensitivity of the TD and AD components, bound to positronium, to the degree of crystallinity (Table 3) and to the configuration and conformation of the molecular chains of polymers[1]. In particular, it has been observed[100] that, on passing to a PE "single crystal", the narrow component in AD virtually disappears. Studies on polymeric systems based on epoxy-resins[15,84,86] demonstrated a high sensitivity of the TD parameters to the microstructure of the free volume. According to Grinev et al.[84], the positron method is at present apparently most promising for the study of the microstructure of the free volume of polymers.

In order to elucidate the nature of the long-lived components in molecular substances, attempts have been made[102–105] to employ the combined AD–TD method. Thus McGervey and

Valters[105], who studied PTFE by this method, concluded that the component τ_1 is due to the annihilation of free positrons (the hypothesis of Brandt and Spirn[63]) or the positrons linked to the PTFE molecules. According to Kerr's measurements[44], $I_N \cong I_2/3$ for PTFE and PE. Hence the author concludes [see Eqn.(5)] that only the τ_2 component of TD is due to orthopositronium. On the other hand, other investigators[89,97,99] attribute the component τ_2 to the pick-off annihilation of the *o*-Ps atoms in the amorphous regions and τ_1 to the pick-off annihilation in the crystalline domains of the polymer, i.e. they believe that the ratio $I_1/(I_1+I_2)$ can serve as a measure of the crystallinity of the polymer. The same view is maintained by other investigators[15,86,91]. However, one cannot rule out the possibility that both views on the nature of τ_1 are to some extent valid if it is assumed that a positron–many-electron system, capable of being positronium-like to some extent, can be formed in the polymer. In the simplest case such a system can consist of a positron–exciton complex (see also Section III, sub-section 1).

Chandra and coworkers[106–109] drew attention to a correlation between I_2 and τ_2: a lower intensity corresponds to a longer lifetime and the points on the $I_2-\tau_2$ diagram are arranged in groups, one of which corresponds to liquids, another to polymers, and a third to crystals (Fig.9). According to the "free volume" and "positronium capture" models, the above correlation is due to the fact that γ_p (and hence also τ_2) are determined by the elementary free volume v_f and $I_2 \propto V_f/v_f$, where V_f is the overall free volume. As a result, it is possible to obtain a relation of the type[107,108]

$$I_2 = a'(1+\ln(\tau_2/\tau_c))/[b+\ln(\tau_2/\tau_c)],$$

where a', b, and τ_c are the parameters of the model and $a' \propto v_f$. The theoretical curves in Fig.9 were calculated for $\tau_c = 0.7$ ns, $b = 0.01$, and $a' = 3.375$ (crystals), 12 (polymers), 17 (liquids), and 25 (amorphous bodies).

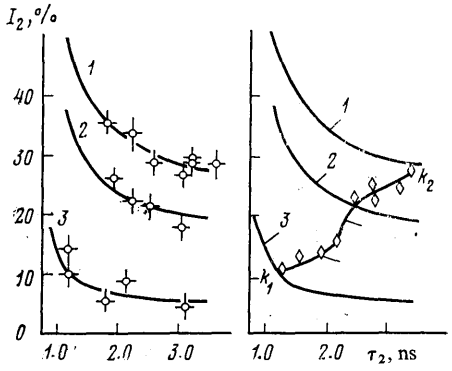

Figure 9. $I_2-\tau_2$ diagrams for simple unassociated liquids and amorphous substances including polystyrene and fused quartz (*1*), partially crystalline substances—poly(vinyl chloride), polyethylene, lucite, and Teflon (*2*), and molecular crystals (*3*); circles—experimental data; lines–calculated data; (*4*) the values of I_2 and τ_2 for Marlex-50 in the range from −196 °C (point k_1) to 142 °C (point k_2).

We shall now quote certain results obtained[49,50] with the aid of the "positronium capture" model. The solution of Eqn.(6) with experimental TD parameters for PTFE with different degrees of crystallinity χ [89] yields $k_1 = (0,32 \pm 0.05) \times 10^9$ s^{-1} and $\lambda_{p1} = (2.5 \pm 0.4) \times 10^9$ s^{-1} for $\chi_1 = 76\%$ and $k_2 = (0.67 \pm 0.10) \times 10^9$ s^{-1} and $\lambda_{p2} = (1.7 \pm 0.3) \times 10^9$ s^{-1} for $\chi_2 = 44\%$. The expected difference $\Delta I_N = I_N(\chi_2) - I_N(\chi_1) = 6 \pm 1\%$ between the intensities of the narrow components, calculated using these constants, agrees with the measured value[97]: $\Delta I_N = 6.3 \pm 0.4\%$. If we put $k = \sigma\bar{v}n$, where σ is the capture cross-section and $\bar{v}$ the average velocity of the thermal movement of the Ps atoms, then, under conditions such that $n \cong (1-\chi)n_a$, where n_a is the bulk density of traps in the amorphous region of the polymer, we have (provided that n_a is independent of χ) $k_1/k_2 = (1-\chi_1)/(1-\chi_2)$, which is confirmed by the above data: $k_1/k_2 \cong 0.48$ and $(1-\chi_1)/(1-\chi_2) \cong 0.43$. If the equilibrium concentration of traps n in the polymer obeys the Arrhenius law, i.e. $n \propto \exp(-E_a/k_0T)$, where E_a is the activation energy for the formation of traps, then the temperature variation of the rate of capture is largely determined by the factor n (Fig.10). The change in the slopes of the $\ln k - 1/T$ linear plots in phase transitions is apparently associated with the change in the activation energy E_a.

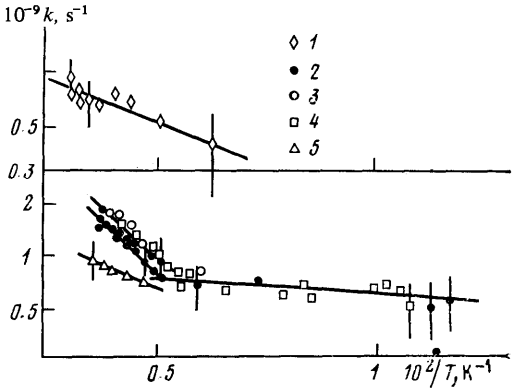

Figure 10. Dependence of the rate constant k for the capture of positronium on the reciprocal of temperature (on the semilogarithmic scale) in Teflon (*1*), polyethylene (*2–4*), and glycerol (*5*) plotted[49] on the basis of data from a series of investigations[49,63,76].

Using the results of TD and AD measurements and the "empty free volume" model (see Section IV, subsection 3) and the "positronium capture model" (see Section IV, subsection 4), Bartenev et al.[50] estimated the radius of the traps, the capture rate constant k, and the bulk density of traps n in high-pressure PE of two types—PEA (autoclave reactor) and PET (tubular reactor). The relation $\sigma = \pi a^2$ was used to estimate n from the measured values of k: $a = 0.45 \pm 0.05$ nm, $k = 1 \times 10^9$ s^{-1} (±30%), and $n = 0.15 \times 10^{22}$ m^{-3} for PEA, and $a = 0.34 \pm 0.05$ nm, $k = 4 \times 10^9$ s^{-1} (±30%), and $n = 1.1 \times 10^{22}$ m^{-3} for PET.

The temperature effects of the annihilation of positrons in polymers do not reduce solely to those discussed above. The TD (I_2 and τ_2)[1,84,110,111] and AD (I_N) [51] parameters are influenced significantly by the thermal degradation of the polymer, since the free radicals arising in this process cause additional quenching of orthopositronium (see below). In the solution

of the problems considered here (and in the previous Section), general approaches have so far been outlined; there is still a need for much tedious theoretical and experimental work in order to achieve an unambiguous quantitative utilisation of the results of measurements of TD and AD parameters in the physics and chemistry of polymers. The results of studies of the reactions of positronium in molecular[42,112–115] and liquid crystals[116–120], haemoglobin[121], aminoacids[122], optical isomers[122,123], etc. may prove to be not without interest from this point of view. In molecular crystals the reactions of positronium are influenced significantly by phase transitions, structural defects, impurities, and the form of the free volume. In liquid crystals the TD parameters (I_2 and τ_2) undergo considerable sudden changes at the phase transition points, and in the isotropic liquid → liquid crystal phase → crystal transitions τ_2 increases abruptly for liquid crystals with negative dielectric anisotropy ($\varepsilon_a < 0$) and conversely decreases for liquid crystals with $\varepsilon_a > 0$. In aminoacids a difference has been observed between the values of I_2 and τ_2 for D- and L- isomers, the sign of the differences ΔI_2 and $\Delta\tau_2$ being positive for some aminoacids and negative for others.

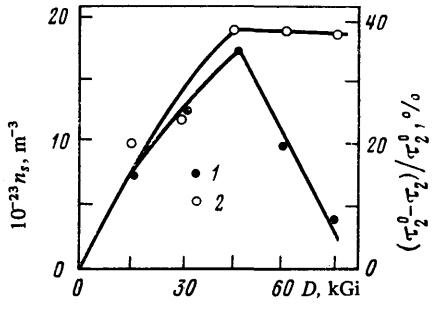

Figure 11. The relative decrease of τ_2(*1*) and the change in the concentration of free radicals (*2*) in Teflon with increase of the dose of irradiation with ^{60}Co γ-rays (for the non-irradiated specimen, $\tau_2^0 = 3.5 \pm 0.2$ ns).[124]

VI. THE FATE OF POSITRONIUM IN IRRADIATED POLYMERS

1. Teflon

The lifetime of orthopositronium τ_2 in PTFE irradiated with ^{60}Co γ-rays is not determined[124] unambiguously by the concentration of free radicals n_s (Fig.11). The rupture of the C–F and C–C bonds leads to the formation, together with free radicals, of vacancies at the sites of fluorine atoms or in the slit arising in the main polymer chain as a consequence of some compression of its two sections after the dissociation of the C–C bond[124]. The positronium located in these vacancies (type A) can be rapidly "quenched" by the neighbouring unpaired electron (lifetime $\tau_2' < \tau_2^0$). Saturation with respect to the yield of radicals is due to their recombination, but the slits at the sites of dissociation of the C–C bonds are retained under these conditions. Such slits again serve as the locations (type B) of Ps atoms, but here positronium is annihilated after a time $\tau_2'' \cong \tau_2^0$. The authors[124] expressed the observed lifetime of orthopositronium by the formula

$$\frac{1}{\tau_2} = \frac{N_0 + N_B}{N_0 + N_A + N_B}\frac{1}{\tau_2^0} + \frac{N_A}{N_0 + N_A + N_B}\frac{1}{\tau_2'}, \qquad (10)$$

where N_0 is the number of vacancies in the non-irradiated polymer and N_A and N_B are the numbers of vacancies of types A and B. The quantities N_A and N_B are related to the dose D, the radiation intensity I, and the radiation yield in the formation of radicals q by the expressions[2]

$$N_A = N_S\frac{\exp(2N_S ID) - 1}{\exp(2N_S ID) + 1}, \quad N_B = qD - N_A,$$

where $N_S = qI/k_r$, k_r being the rate constant for the recombination of radicals. The limiting value is $N_A = N_S$. The maximum value of τ_2 is attained when $N_0 + qD = \frac{1}{2}N_S\exp(2N_S ID)$. On the other hand, if $D \to 0$ or $D \to \infty$, then $\tau_2 \to \tau_2^0$, which is observed experimentally. It should be noted that Eqn.(10) is inconsistent with the "positronium capture model". In essence, it is assumed in Eqn.(10) that the *o*-Ps atom can undergo pick-off annihilation with a probability $1/\tau_2^0$ and quenching by radicals with a probability $1/\tau_2'$.

When the TD spectrum was resolved into three components, and not two as in the study of Chandra et al.[124], Green and Tao[125] observed a decrease of the "longest time" τ_2 and an increase of the ratio $I_1/(I_1 + I_2)$ with increase of the γ-irradiation dose in PTFE. Green and Tao[125] explained the decrease of τ_2, like Chandra et al.[124], by the quenching of positronium by radicals and the increase of the ratio $I_1(I_1 + I_2)$ by the increase of the degree of crystallinity of PTFE (in conformity with the hypothesis of the same workers[89], mentioned above). Later measurements[21,126–128] confirmed on the whole the results of the above studies[124,125] and at the same time revealed the influence of air on the dependence of τ_2 and I_2 on the irradiation dose, but the results were contradictory (cf. for example, the data of Hsu and Hadly[21] and Khan et al.[126]). Furthermore, according to the measurements of Hsu and Hadley[21], the intensity I_1 of the intermediate component is independent of the irradiation dose (in contrast to the data of Green and Tao[125]). If this is so, it would follow, according to Hsu and Hadley[21], that the component τ_1 of TD is not related to the pick-off annihilation of orthopositronium and the problem of its nature arises again (see above).

The influence of γ-irradiation on TD in PTFE has been studied[129,130] in the region of small doses (up to 30 kGr). Together with TD spectra, measurements were made of the EPR and NMR spectra, the density, and the dielectric constant. It was shown that the dependence of the degree of conversion of positronium in irradiated PTFE on the irradiation dose is influenced by factors such as the change in free volume, free radicals, and crystallinity.

2. Polyethylene

In contrast to PTFE, when PE is subjected to γ-irradiation[131], radiation-induced cross-linking of the chains takes place and not their degradation at C–C bonds. For rapid cross-linking, an EPR signal is not observed. According to X-ray diffraction data[131], the irradiation of PE leads to a decrease of the number and size of the polymer microcrystals with a corresponding increase of the fraction of amorphous low-density regions. Therefore, from the standpoint of the "free volume" model, one may expect an increase of the lifetime τ_2 on irradiation of PE, which has indeed been observed (see Fig.12). (The TD spectrum was resolved into two components[131]). Data concerning I_2 were not presented[131].

Ito and Tabata[132] measured TD in PE obtained from ethylene at high pressure by radiation polymerisation. The polymer was irradiated with γ-rays and the TD was measured at −78 °C *in vacuo*. As a result, it was possible to "reveal" the influence of free radicals on the quenching of orthopositronium in PE; there is a linear relation between the increase of the rate of annihilation of orthopositronium λ_2 under irradiation and the increase of the spin concentration n_S, namely $\Delta\lambda_2 = \lambda_2 - \lambda_2^0 = k_r n_S$, where $k_r \cong 0.22 \times 10^{-17}$ m^3 spin^{-1} s^{-1}. With the increase of the irradiation dose, τ_2 decreases linearly, while I_2 remains almost unchanged (approximately 30%). The decrease of τ_2 in γ-irradiated PE (at low temperatures) was explained[132] by the "quenching" of orthopositronium as a result of the reaction of *o*-Ps atoms with free radicals R: $Ps + R \rightarrow PsR \rightarrow 2\gamma$. The rate of this reaction is an order of magnitude lower than the rate of reaction of *o*-Ps atoms with acceptors in solutions. Assuming that the mobility of the *o*-Ps atoms is determined by diffusion, Ito and Tabata estimated the diffusion coefficient of *o*-Ps atoms: $D_p = (0.58-1.75) \times 10^{-9}$ m^{-2} s^{-1}. The value of D_p obtained is higher than for the reaction of *o*-Ps atoms with DPPH in solid pyridine at −78 °C but lower than, for example, for the diffusion of *o*-Ps atoms in metal oxides.

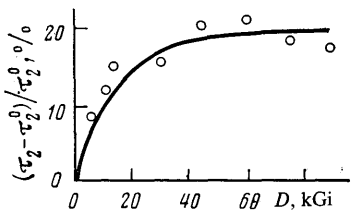

Figure 12. The relative increase of τ_2 in polyethylene with increase of the dose of irradiation by ^{60}Co γ-rays ($\tau_2^0 = 2.0 \pm 0.2$ ns).[131]

3. Polystyrene

Thosar et al.[133] did not observe an influence by γ-radiation (doses up to 250 kGr) on PS—either on τ_2 or on I_2. However, the results of Hsu and Hadley[134] led to the opposite finding. They investigated very dense PS specimens with a low crystallinity, obtained from the monomer by annealing *in vacuo* at 70 °C. The PS specimens were irradiated with ^{137}Cs γ-rays (dose rate 10^3 Gr h^{-1}). The irradiation and the measurement of TD were carried out at room temperature *in vacuo* and in air.

Vacuum irradiation (dose 80 kGr) leads to a decrease of I_2 from approximately 33.8% to approximately 29.3% when TD is measured *in vacuo*; after annealing the irradiated specimens at 70 °C for 24 h and measurement of TD under the same conditions, the previous value of I_2 is found to be restored (approximately 33.5%); on the other hand, measurement in air yields $I_2 \cong 30.4\%$. In air I_2 decreases with increasing irradiation dose from approximately 34.1% to approximately 28.2% for a dose of 150 kGr; τ_2 also diminishes somewhat under these conditions (from 2.33 ± 0.02 to 2.25 ± 0.02 ns). After annealing, the previous value of I_2 is restored, while τ_2 remains unchanged (or decreases slightly: $\tau_2 = 2.23 \pm 0.02$ ns). The changes in I_2 are apparently due to the inhibition of the formation of positronium in γ-irradiated PS by free radicals and also by stable oxygen-containing groups (C=O and OH)—the products of the conversion of free radicals in the presence of atmospheric oxygen[134]. The insensitivity of τ_2 to γ-irradiation is explained by the absence of appreciable changes in the supermolecular structure (i.e. in the "free volume").

Irradiation of PS with neutrons in the thermal column of a nuclear reactor causes a marked decrease of I_2 (by approximately 40% for a dose of approximately 2.4×10^7 kGr), leaving $\tau_2 = 2.2 \pm 0.2$ ns unchanged[133]. Neutron irradiation of PS leads to the breakdown of the benzene rings (according to NMR data) and to the accumulation of free radicals (according to EPR data). Since the formation of positronium in PS is probably associated mainly with benzene rings[133], the breakdown of the latter under neutron irradiation leads to a decrease of I_2. Hence, if Ps atoms are annihilated preferentially in the benzene rings, the quenching influence of the free radicals produced under irradiation outside the benzene rings will be negligible compared with the quenching of the Ps atoms as a consequence of pick-off annihilation by interaction with the electrons of the aromatic rings.

The results of the study of the influence of irradiation on the formation and destruction of positronium in polymers (as in other molecular substances[2] and even in substances such as quartz[10,92]) confirm qualitatively the "free volume" model and the role of order. At the same time it has been observed that in molecular solids (apart from the studies quoted above, see also, for example, Refs. 1, 15, 110, 111, and 135–139), the quenching of positronium by free radicals can play a significant role together with pick-off annihilation. The same conclusion follows also from the analysis of the measurements of the TD and AD parameters in polymers subjected to thermal degradation, which was already mentioned above. One should note that an estimate[111] of the rate of quenching of positronium by radicals in PVC yielded a value greater by 3–4 orders of magnitude than that observed in PE (see above): $k_r \cong 8.4 \times 10^{-12}$ kg spin^{-1} s^{-1}. Free radicals (as well as their reaction products) can apparently function not only as quenching agents but also as inhibitors of the formation of positronium.

4. The Quenching of Positronium by Radicals

The mechanisms of the quenching of positronium by free radicals (or stable groups—the products of the reactions of radicals) can be various: *ortho–para* conversion, addition and oxidation reactions, etc. Analysis of the kinetics of the reactions of positronium taking into account the above quenching mechanisms shows that the increase of the rate of quenching of orthopositronium is

$$\Delta\lambda_2 = \lambda_2 - \lambda_2^0 = k = k_r n_s, \qquad (11)$$

where $\lambda_2^0 = \lambda_t^0 + \lambda_p$ and k is the rate constant of *ortho–para* conversion, the addition reaction, the oxidation reaction, etc. In the case of *ortho–para* conversion Eqn. (11) is valid provided that $k \ll \lambda_S^0$ and $\lambda_p \ll \lambda_S^0$. In terms of the approximation indicated, *ortho–para* conversion leaves unaltered the intensity of the long-lived TD component ($I_2 \cong \frac{3}{4}P$) and intensifies the narrow AD component:

$$I_N \simeq \frac{1}{4} P \left(1 + \frac{3k}{\lambda_2^0 + k}\right).$$

As already mentioned, in γ-irradiated PE the intensity I_2 remains almost unchanged as λ_2 increases [in conformity with Eqn. (11)] in the course of the accumulation of free radicals[132].

The addition reaction $Ps + R \rightarrow PsR$ weakens both the long-lived TD component, i.e.

$$I_2 = \frac{3}{4}P\left(1 - \frac{k}{\lambda_p + k + \lambda_{pr}}\right),$$

where λ_{pr} is the rate of pick-off annihilation in the PsR system, and the narrow TD component:

$$I_N \simeq \frac{1}{4}P\left(1 - \frac{k}{\lambda_s^0}\right) \text{ (for } \lambda_p, \lambda_{pr}, k \ll \lambda_s^0).$$

One cannot rule out the possibility that the simultaneous decrease of τ_2 and I_2 (in terms of our notation!) on γ-irradiation of PS is due to the addition reaction[134].

In the oxidation reaction $Ps + R \rightarrow Re^- + e^+$ the I_2 and I_N components are also simultaneously weakened [for example, $I_N \cong \frac{1}{4}P(1-\frac{\lambda_p + k}{\lambda_s^0})$], but, in contrast to the addition reaction, other TD parameters behave differently.

Each version of the quenching of positronium by radicals thus has its specific distinctive features, which make it possible to identify them from experimental data. Other mechanisms of the quenching of positronium by radicals examined above behave analogously. It is easy to see also the possible ways of devising general models taking into account the "free volume" and "positronium capture" models. In order to construct general models taking into account the possibility of the limitation of the rates of reaction by the rate of diffusion of Ps atoms and radicals (as well as traps), one can use the formal treatment developed by Brandt, Seeger, and coworkers[52-56].

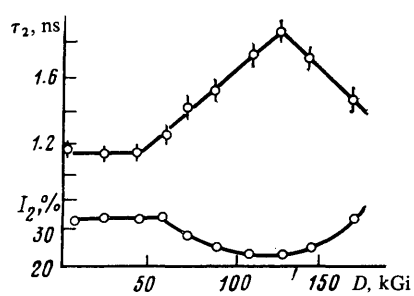

Figure 13. Dependence of τ_2 and I_2 on the irradiation dose for the crystalline monomer *N*-vinylcarbazole (rate of irradiation 7.2×10^{-2} Gi h^{-1}).[136]

VII. THE EFFECTS OF THE MOLECULAR WEIGHT AND COMPOSITION

1. The Effects of the Molecular Weight

In the radical polymerisation of *N*-vinylcarbazole ($C_{15}H_{14}N$), a crystalline monomer, the TD parameters (τ_2 and I_2) associated with orthopositronium depend in a complex manner on the degree of polymerisation[136] (Fig.13). The maximum in τ_2 corresponds to the polymerisation saturation point; further irradiation leads to the accumulation of positronium quenching radicals, which is the reason, according to the authors[136], for the decrease of τ_2 in the region of doses ≥130 kGr. Analogous studies were carried out also for other monomers[1,140-143], but their results showed that the parameters of the TD spectrum are sensitive to the degree of polymerisation and are correlated with EPR data.

Khan[111] studied in detail the influence of temperature on τ_2 (and also on I_2) in PVC, which differs from the polymers studied in most of the investigations quoted above by being thermally unstable. Measurements were made of the long lifetime τ_2, of the intensity of the EPR signal (concentration of free radicals), and of the decrease of the molecular weight as a function of the time *t* during which specimens of pure and plasticised PVC with different initial molecular weights were heated at a constant temperature (at 150 °C and also, for comparison, at 170 °C). Findings such as the exponential decrease of τ_2 with increase of the duration of heat treatment (the ratio $\tau_2/\tau_2^0 \cong 0.2$ for $t = 7$ days) together with the exponential increase of the concentration of free radicals and decrease of the molecular weight, and the dependence of the rates of the above changes on the molecular weight, temperature, etc. show that the quenching of positronium is due to the free radicals arising in the thermal degradation of PVC.

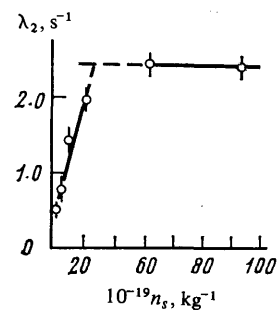

Figure 14. Dependence of $\lambda_2 = \tau_2^{-1}$ on the concentration of free radicals n_S produced by thermal degradation at 150 °C in pure poly(vinyl chloride) powder with $M = 200000$.[111]

Khan believes that positronium is more likely to be quenched by the capture of Ps atoms by free radicals (addition) or the capture of the unpaired electron of the free radical by a Ps atom with formation of the Ps^- ion (formally this mechanism can be regarded as an addition reaction—Section VI) and not via the *ortho–para* conversion mechanism. Evidence in support of the formation of the ion comes from the finding that τ_2 in PVC reaches a minimum value (0.37 ± 0.05 ns) at a spin concentration $n_S \cong 25 \times 10^{19}$ spins kg^{-1} and remains unchanged as n_S increases further (Fig.14). The minimum value of τ_2 is almost equal to the lifetime of the ion Ps in relation to annihilation (0.35 ns).

The dependence of the lifetime of positrons on the average molecular weight M_w has been observed directly[144,145] for polypropylene. The following approximate relation holds for the TD components:

$$\tau_i = \tau_i^0 - \delta_i \bar{M}_w,$$

where τ_i^0 and δi are constants. For polypropylene, $\tau_0(\text{ns}) = 0.30 - 0.080 \times 10^{-6}\,\bar{M}w$ and $\tau_2(\text{ns}) = 0.48 \times 10^{-6}\,Mw$. Chuang and

Tao[145] attempted to justify this relation in terms of the "free volume" model.

2. Elastomers

Interesting results have been obtained[7,146-148] from measurements of the parameters τ_2, I_2 and $P_{3\gamma}$, characterising the probability of the formation and quenching of positronium in elastomers. On passing from raw rubber to isoprene and then to cured rubber (3% of sulphur), a decrease is observed in $P_{3\gamma}$ (the ratio $P_{3\gamma}/P^0_{3\gamma} = 3.8$, 2.08, and 2.2 respectively) and I_2 (50, 13, and 26% respectively), while $\tau_2 \cong 2.2$ ns remains almost unchanged. On passing to ebonite (32% of sulphur) and to sulphur, τ_2 falls to approximately 0.5–0.6 ns. A more detailed study of the AD and TD parameters (I_N, I_2, and τ_2) for raw rubber and its vulcanised forms with different sulphur contents (up to 10%) and corresponding to different vulcanisation times confirmed the decrease of I_2 [under these conditions, $\Delta I_2 \cong 3\Delta I_N$; see Eqn.(5)] with increase of the sulphur content, I_2 being proportional to the degree of unsaturation. With increase of the vulcanisation time, ΔI_2 increases in parallel with the increase of the relative amount of bound sulphur.

A correlation between the network density and the change in I_2 (at $t = 40$ min, I_2 diminishes by a factor of approximately 2) has been observed[15,84] for sulphur-vulcanised ternary ethylene–propene rubber with increase of the vulcanisation time.

The observed decrease of I_2 from 28% for raw rubber to 8% for raw rubber +10% S, to which corresponds a weakening of the narrow component in AD ($\Delta I_2 \cong 3\Delta I_N$) with a virtually unchanged τ_2 has been attributed[146] to the inhibition of the formation of positronium with decrease of the degree of unsaturation, i.e. of the fraction of double bonds in the rubber (it varies from 95 to 74% respectively). On the other hand, the relation $\Delta I_2 \cong 3\Delta I_N$ indicates the absence of chemical interactions between the Ps atoms and the surrounding molecules and groups and of *ortho–para* conversion (see Section VI, subsection 4). It is suggested that positronium is formed in raw rubber at the sites of double bonds as a result of the capture of π-electrons by positrons. The formation of positronium is apparently inhibited as a result of the annihilation of the volumes in which it can be formed and exist (by analogy with the influence of the neutron irradiation of PS on I_2—see above). The inhibiting effect of the non-static (microheterogeneous) distribution of vulcanisation cross-links on the formation of positronium in raw rubber relative to the static (homogeneous) distribution has been observed[148].

Having applied the "positronium capture" model (see Section III, subsection 3), Arifov et al.[148] estimated from TD parameters the probability P of the formation of positronium and the rate constant k for its capture by traps in elastomers based on the butadiene–styrene rubber: $P \cong 0.6$–0.7 and $k \cong (0.6\text{–}0.7) \times 10^9$ s^{-1}. The extent of the region (trap) in which the Ps atom is localised in the rubber amounts to approximately 0.86 nm, which corresponds to the distance between the groups of neighbouring chains[51,146].

3. Mixtures

Studies have been made[1] on mechanical mixtures of PVC and PE homopolymers and graphite–polyethylene and graphite–4-vinylpyridine copolymers. In the case of macromixtures (grain size more than 10 nm) the annihilation characteristics of the mixture constitute a linear superposition of the annihilation characteristics of the initial polymers; in micromixtures there is no such superposition. It is assumed that in macromixtures positronium is localised in the component where it was formed, while in micromixtures, it is able to diffuse into the other mixture component. The influence of the micromixture on the reactions of positrons and positronium in filled polymers (PE + Al_2O_3 + perlite, polybutadiene + carbon black, etc.) has been investigated[15,86,91,149]. In the case of filled PE it proved possible to elucidate[15,91] the cause of the strengthening of the material (maximum degree of crystallinity) for a specific content of the filler (35%) and also the role of pressure and temperature in the treatment of the material.

Here we shall also point to studies[150-152] in which measurements were made of TD (and AD) in mixed organic crystals and to an investigation[81] in which it was noted that, according to the TD measurements, the vitrification of dry nylon occurs at 50 °C, while in the presence of 0.5% of water it takes place at 30 °C, which indicates yet again a fairly considerable sensitivity of the positron method. There is no theory of the formation and reactions of the positrons and positronium in polymers of complex composition, in elastomers, and in mixtures and compositions.

VIII. THE INFLUENCE OF THE ELECTRIC AND MAGNETIC FIELDS ON THE REACTIONS OF POSITRONS AND POSITRONIUM IN POLYMERS

1. The Effects of the Electric Field

The formation of positronium in matter in the presence of an electric field has been studied theoretically[71,153-155]. On the one hand, the field displaces positrons outside the limits of the Ore gap (see Section III), which leads to a decrease of the probability of the formation of positronium, and, on the other hand, the heating of "slow positrons" increases the yield of positronium. The relative contributions of the two processes are determined by the ratios of the cross-sections for the positronium processes, the loss of energy by positrons, and the annihilation of positrons. In weak fields the first of the above effects of the electric field may predominate the inhibition of the formation of positronium may therefore be observed (see also the considerations put forward by Mogensen[156]). The effect involving the "heating" of positrons by the field, i.e. the increase of the yield of positronium, predominates in strong fields. Experiments with gases on the whole confirmed this picture[2,154,155].

On passing to polymers, we note in the first place that in polymers the probability of the formation of positronium as well as the rate of its quenching depend appreciably on the dipole moment of the molecules: I_2, τ_2, and $P_{3\gamma}$ decrease with increase of the molecular dipole moment of the polymer (see, for example, Refs.7, 89, and 157). For example, the above quantities have the following values for PE and PVC with almost identical valence-electron densities and ionisation potentials but markedly different molecular dipole moments (0 for PE and 6.7×10^{-3} C m for PVC):[7] $P_{3\gamma} = (2.14 \pm 0.3) P^0_{3\gamma}$, $I_2 = 22 \pm 2\%$, and $\tau_2 = 2.1 \pm 0.2$ ns for PE; $P_{3\gamma} = (1.23 \pm 0.15) P^0_{3\gamma}$, $I_2 = 13 \pm 2\%$, and $\tau_2 = 1.23 \pm 0.1$ ns for PVC.

Thus in polymers and, incidentally, in liquids[2] the probability of the formation of positronium diminishes with enhancement of the polarity, i.e. with increase of the molecular dipole moment, while the rate of pick-off annihilation actually increases. The effect of polarity is shown clearly on passing from raw rubbers (non-polar compounds) to isoprene (in which the C–CH_3 bond leads to a dipole moment

of 1.7×10^{-30} C m), cured rubber, and ebonite (32% of sulphur) (polar dielectrics)[7] and from butadiene–styrene rubber with a static (homogeneous) distribution of vulcanisation cross-links to a rubber with a non-statistical (heterogeneous) distribution of such links[140].

The electric field of the dipoles can apparently influence not only the probability of the formation of positronium but also the spatial distribution of positrons and positronium in matter, directing them (positrons and Ps atoms) to specific atomic groups (into the region of enhanced electron density), so that their annihilation is accelerated. Furthermore, the rate of self-annihilation and the half-width of the momentum distribution of Ps atoms can change significantly in the electric field of the dipoles[158].

Static fields up to $E = 12$ MV m^{-1} decrease significantly the lifetime of the long-lived component in PTFE and PE: $\tau_2 = \tau_2^0(1-\alpha E)$, where $\alpha = (9.3\pm1.3)\times10^{-3}$ m MV^{-1}, while in polar polymers (lucite, nylon, and PVC) this type of influence of the field has not been observed[74]. The absence of an effect by the electric field on τ_2 in polar polymers is apparently associated with the fact that in the vicinity of the electric dipoles generated by them the field greatly exceeds the external field.

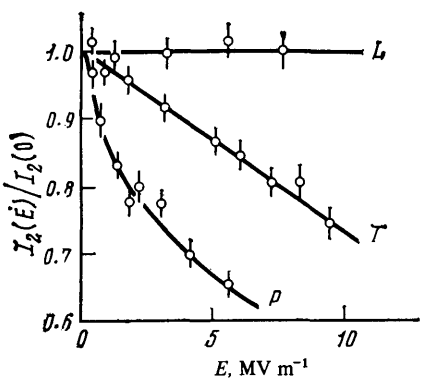

Figure 15. The influence of the electric field on the intensity of the long-lived TD component (τ_2) in lucite (L), Teflon (T), and polyethylene (P).[159]

In typically non-polar polymers like PS and PTFE the probability of the formation of positronium greatly diminishes with increase of the electric field (by 33 and 13% respectively for $E = 5$ MV m^{-1}). On the other hand, in polar polymers (lucite, nylon, and PVC) the electric field does not affect the probability of the formation of positronium (Fig.15)[159] (this may be due to the cause indicated above in the discussion of τ_2). Analogous conclusions were also reached on the basis of the analysis of the results of measurement of $P_{3\gamma}$ in polymers with application of a static electric field: $P_{3\gamma}(E) = P_{3\gamma}(0)(1-\beta E)$ for non-polar polymers, where $\beta \approx 0.80$ m MV^{-1} for PS and $\beta \approx 0.022$ m MV^{-1} for PTFE.[7] The influence of the electric field for PTFE and PE has also been investigated in other studies[71,160-166]. We may note that the results quoted by Patterson and Stewart[160] conflict with the previous ones: no effect of the field (on AD) is not observed up to 11 MV m^{-1}. The absence of a field effect in polar polymers has been confirmed[71].

Bertolaccini et al.[164] (see also Refs.162 and 163) observed a time effect in the influence of the electric field on the probability of the formation of positronium in PE. Immediately after the application of the field, $P(E)$ decreases sharply relative to $P(0)$ and then, when some time has elapsed, the ratio $P(E)/P(0)$ begins to increase and reaches a plateau (Fig.16). On the other hand, in the initial instant the probability of the formation of positronium in PE decreases with increasing field, in conformity with the results of previous measurements. When the field has been switched off, the ratio $P(E)/P(0)$ does not immediately reach unity (Fig.17). It has been suggested[164] that the time dependence of the probability of the formation of positronium in PE, observed when the field is applied and removed, is a consequence of the relaxation of the effective electric field $E(t)$, which in fact acts upon the PS atom in the given substance. The data in Figs.16 and 17 agree with the $E(t)$ relation of the type $E(t) = E(\infty) + [E(0)-E(\infty)]\exp(-t/\tau)$. Thus a whole series of effects of the electric field have been observed in polymers: the effect of the polarity of the polymers, the quenching and inhibition of the formation of positronium, and relaxation effects in the inhibition of the formation of positronium by the electric field.

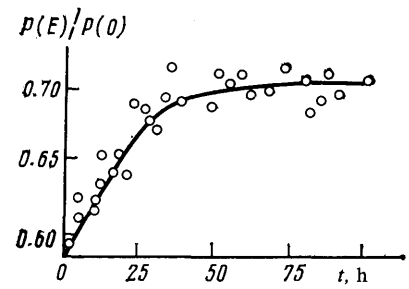

Figure 16. Dependence of the probability of the formation of positronium in polyethylene on the time elapsed from the instant of the application of the electric field $E = 10$ MV m^{-1}.[164]

2. Magnetic Quenching of Positronium in Polymers

The magnetic field (B) is one of the most reliable indicators for the determination of the amount of positronium formed in a given substance. The observed quenching of positronium by the magnetic field constitutes an additional source of information about the properties of positronium in the given substance and hence about the properties of the substance itself.

In the simplest case where the interaction of positronium with the surrounding medium reduces to pick-off annihilation (see Section III), the factors characterising the changes in $P_{3\gamma}$, I_N, and I_2 in a magnetic field as a consequence of the magnetic quenching of positronium are given by the following expressions (see, for example, Refs.2, 12, 33,47, and 167–170) in terms of the approximation $y^2 \ll 1$ [$y = [(1+x_2)^{1/2}-1]/x$, where $x = 4\mu_B B/\Delta E$, μ_B = Bohr magneton, and ΔE is the amount by which the energy of the triplet substate of the Ps atoms exceeds the energy of the singlet substate; *in vacuo* $\Delta E = 8.4\times10^{-4}$ eV], which is valid for

$\lambda_p \ll \lambda_s^0$ and fields up to $B = 2$ Tl:

$$w_{s\gamma} = P_{s\gamma}(B)/P_{s\gamma}(0) = 2/3 + 1/3(1-Q)^{-1}, \quad (12)$$

$$\varepsilon(B) = [I_N(B) - I_N(0)]/I_N(0) = Q/(1+Q), \quad (13)$$

$$R(B) = \left[\int_{\tau_2}^{\infty} p(t)\,dt\right]_B \Big/ \left[\int_{\tau_2}^{\infty} p(t)\,dt\right]_0 = \frac{1}{3}(2 + e^{-Q}), \quad (14)$$

where $Q = y^2\tau_2/\tau_s^0$ is the parameter of the magnetic quenching of positronium. In still weaker fields, where $x^2 \ll 1$ ($x = 0.275$ V if B is expressed in Tl), one can put $Q \approx 0.151\,B^2\tau_2$ (B expressed in Tl and τ_2 expressed in ns).

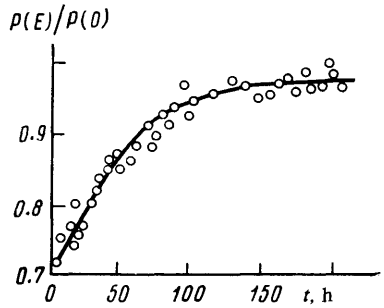

Figure 17. The relaxation of the formation of positronium in polyethylene after switching on the electric field $E = 10$ MV m^{-1}.[164]

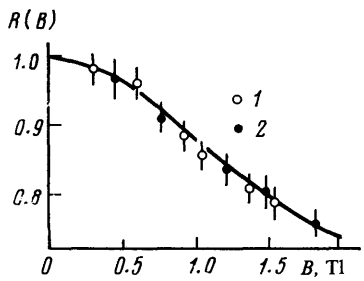

Figure 18. Suppression of the long-lived TD component by the magnetic field in Teflon (*1*) and lucite (*2*); circles—experimental data; lines—calculated data[167].

The nature of the influence of the magnetic field on the experimental characteristics of the annihilation of positronium in matter can be seen directly from Eqns.(12)–(14): in the presence of a magnetic field the probability of 3γ-annihilation [Eqn.(12)] diminishes, the narrow AD component intensifies [Eqn.(13)], and the long-lived component τ_2 of the TD spectrum is suppressed [Eqn.(14)]. The results of the observation of the magnetic quenching of positronium in polymers[2,33,47,167,169,171–177] confirmed the theoretical conclusions (Fig.18). The magnetic quenching of positronium has been investigated[178] within the framework of the "positronium capture" model.

Having analysed the results of the measurements of the factor $R(B)$ in PTFE, PE, PS, PVC, and nylon, Bertolaccini et al.[177] concluded that the Ps atom is "deformed" in polymers (as in ionic crystals[12]). The deformation of the Ps atom in matter can be characterised by the relation $\alpha_m = |\psi(0)|m^2/|\psi(0)|_0^2$, where $|\psi(0)|m^2$ and $|\psi(0)|_0^2$ is the electron density at the "zero" point in the Ps atom in matter and *in vacuo*. In polymers $\alpha_m \leq 1$ (Table 4), i.e. the Ps atom exhibits a tendency to "swell"[177]. Within the framework of the phenomenological model of the interaction of positronium with the surrounding medium, proposed by Urbanovich[179], the energy of the interaction of the atom with the molecules surrounding it in a given substance can be estimated, provided that the parameter α_m is known: $U(\text{eV}) = -13.6(1-\alpha_m^{1/3})^2$. As was to be expected, in polar polymers (PVC and nylon) the interaction of the Ps atom with molecules is stronger than in non-polar polymers (Table 4).

Table 4. The "deformation" parameters (α_m) and the energies U of the interaction of the Ps atom with the surrounding medium in polymers.

Substance	α_m (Ref.162)	$-U$, eV
Teflon	1.00±0.09	0
Polyethylene	0.71±0.04	0.16
Polystyrene	0.80±0.06	0.07
Poly(vinyl chloride)	0.060±0.08	0.35
Nylon	0.56±0.4	0.44

The influence of the magnetic field on the intermediate TD component τ_1 in different polymers is manifested unequally[177]: in PTFE no effect of the field is observed, in PE, PS, and nylon the effect is very weak, and in PVC the magnetic quenching of the component τ_1 is clearly observed. It can therefore be suggested (see Section V) that the component τ_1 is due to the positron state which is to some extent positronium-like. One should note that there are still comparatively few data concerning the influence of fields on the AD and TD parameters and $P_{3\gamma}$ and the available data are frequently fragmentary. Such data are necessary to refine our ideas concerning the mechanisms of the reactions of positrons and positronium in polymers and, as already mentioned, to convert "qualitative" information, provided by the method indicated, into quantitative information.

---oOo---

Fairly extensive experimental data have now accumulated on the properties of positrons and positronium in polymers and we are able to account for the results of the measurements at least qualitatively if not quantitatively. The available data make it possible to claim confidently that positrons effectively "sense" polymers and therefore the positron method can indeed become a valuable supplement to the already existing methods in the physics and chemistry of polymers. Naturally much is still obscure and even contradictory in both experimental results and in their interpretation. There are virtually no data obtained simultaneously by all methods for the observation of the annihilation of positrons (AD, TD, AD-TD, $P_{3\gamma}$, etc.) in the same specimens with

a well known history. There is no rigorous quantitative theory of many of the observed phenomena. Nevertheless studies are being performed along a widening front, the number of investigators is increasing, the experimental technique and methods are being improved, and theoretical studies are being prosecuted; it may be hoped that the positron method will permit the solution of many problems in the physics and chemistry of polymers and other substances[180].

Catalytic Properties of Zeolites Towards Oxidation Reactions

D.B.Tagiev and Kh.M.Minachev

We shall review experimental data on the catalytic properties of zeolites towards the oxidation and oxidative dehydrogenation of aliphatic, naphthene, and alkylaromatic hydrocarbons, and of inorganic or organic molecules containing hetero-atoms. The influence of the zeolite structure, of the nature and concentration of the exchangeable cations, and of the valency state of the transition metals on the activity and selectivity of the catalysts will be discussed, together with the effect of these factors on the course of the hydrocarbon oxidation reactions. Specific aspects of the interaction of molecular oxygen and of oxidisable compounds with various zeolites will be examined in the light of ESR, i.r. spectroscopy, and thermal desorption data. We shall show that variations in the structure and composition of the zeolite can lead to different types of reaction, yielding valuable products, and thus confirming the importance of zeolites among oxidation catalysts. 188 references.

I. INTRODUCTION

Zeolites are salts of solid alumino-silicic acids, characterised by a well defined crystal lattice structure and classified as catalysts of the acidic type. Since the earliest reports of the high catalytic activity of zeolites[1-3] a great deal of work has been done on the acidic properties of zeolites and on their catalytic activity towards reactions of the acid–base type (cracking, isomerisation, alkylation, etc.). Efficient bifunctional catalysts have been developed from zeolites containing Group VIII metals.

One of the least characterised of the zeolite-catalysed reactions of hydrocarbons is their oxidative transformation. The problem is inadequately discussed in the reviews and monographs on zeolites which have been published so far[4-22], and therefore the present review will attempt to deal with various problems in the oxidation of aliphatic, naphthene, and alkylaromatic hydrocarbons, and of H_2, CO, NH_3, H_2S, and alcohols in the presence of zeolites of different composition and structure.

II. OXIDATION OF ALIPHATIC HYDROCARBONS

Though the oxidation of ethylene[23] and of H_2S [24] on zeolites was first reported in 1961, detailed studies of these reactions began only more recently. The deep oxidation†

†This term is used throughout the paper to denote total oxidation to CO_2 and H_2O.

of methane on type X zeolites containing various transition metal cations has been investigated[25,26], and the reaction on iridium-, rhodium-, and palladium-containing zeolites has been shown to be kinetically of first order with respect to methane and of zero order with respect to oxygen[25]. On a Pt-containing X-type zeolite the reaction has a negative order with respect to oxygen, suggesting competitive adsorption of methane and oxygen. The correlation between the activity of the zeolite and the coordination number of the transition metal cation has been stressed[26]. The activation energy of the reaction on Pd-containing type X zeolites prepared by steeping and by ion exchange methods is 50 and 88 kcal $mole^{-1}$ respectively, indicating a large difference in the catalytic properties towards the deep oxidation of methane between metallic palladium and the palladium cations in a zeolite lattice.

The oxidation of ethylene on type Y zeolite containing transition metal cations is discussed in Refs. 27 and 28. Deep oxidation of ethylene, with formation of CO_2 and H_2O, was observed on all the samples. The most active catalysts are Cu(II)Y and Cr(III)Y, and the least active are Ni(II)Y and Mn(II)Y, the latter being almost indistinguishable from the initial NaY zeolite in catalytic activity. The possibility of participation in the reaction by the oxygen atoms of the catalysts themselves was tested by first treating the zeolites with oxygen and then admitting the ethylene as a series of separate pulses. The presence of active oxygen in the zeolite is inferred from the appearance of peaks of reaction products in the chromatograms. The amount of reaction oxygen stored in the sample depends on the nature of the ion-exchange cation. With the least active [Ni(II)Y and Mn(II)Y] samples the amount of oxidation products detected in the chromatograms is very small, whereas on Cu(II)Y zeolite the amount of active oxygen increases steeply with the oxygen pre-treatment temperature.

The catalytic activity of type Y zeolite and the amount of reactive oxygen held by the catalyst have been shown[29] to vary non-linearly with the degree of exchange of sodium by copper cations, suggesting non-equivalence of the copper localisation sites in the zeolite lattice. Activated adsorption of ethylene in the pre-catalytic region has been demonstrated. At lower temperatures physisorption takes place, and the degree of exchange of sodium by copper ions has no effect on the heat of adsorption of ethylene. After removal of the active oxygen from CuY zeolites the adsorption of ethylene is markedly enhanced, possibly as a result of a strong direct bond between ethylene and the copper ion. Substantial adsorption of ethylene on Cu(I)Y and Ag(I)Y zeolites with formation of π-complexes has been detected[30] by i.r. spectroscopy. With the Cu(II)Y, Zn(II)Y, and CaY zeolites the main contribution to the interaction with ethylene is from van der Waals forces. The heat of adsorption of ethylene on Cu(I)Y is 15.9 kcal $mole^{-1}$, but only 9.5 kcal $mole^{-1}$ on Cu(II)Y.

An oxidation reaction of ethylene of great practical importance is the preparation of ethylene oxide. A method of producing ethylene oxide by using zeolite catalysts was patented[23] in 1961, but a detailed study of this reaction on type A and X zeolites in the presence of ionic silver was only recently reported[31]. Samples prepared by ion exchange were shown to have a low selectivity towards ethylene oxide at 200–300 °C, whereas the catalysts prepared by steeping the initial zeolite offer both a high activity and a high selectivity in this reaction. The most selective catalyst is Ag–CaA, the yield of ethylene oxide and the selectivity of the reaction increasing in proportion to the amount of silver and reaching levels of 25 and 70% respectively on a 30% Ag–CaA catalyst at 250 °C.

The oxidation of ethylene on type Y zeolite containing both copper and palladium cations has been shown[32–35] to give acetaldehyde in the presence of water vapour. In isolation, neither Pd(II)Y nor Cu(II)Y is an active catalyst; the activity of a sample prepared by adding first 4 wt.% of Cu and then 1 wt.% of Pd is twice as high as that of a catalyst containing the same amounts of Cu and Pd but added in the reverse order[32].

The activity of PdCu catalysts towards the oxidation of ethylene and propylene is markedly dependent on the crystal structure of the zeolite[33]. In particular, the X and Y zeolites with large pores are more active towards the formation of acetaldehyde than type A and mordenite type zeolites. It appears that the reaction takes place mainly in the zeolite lattice holes, and the contribution to the total activity from centres located on the outer surface of the crystal is small. It is stressed[33] that samples prepared by steeping are often superior to ion-exchanged forms of zeolite in both activity and selectivity.

The highest activity towards the oxidation of ethylene to acetaldehyde is found[34,35] in type Y zeolite containing 6 wt.% of copper and 1.5 wt.% of palladium. The optimum oxidative regeneration temperature of these samples was found to be 300°.

Several workers[36–42] have studied the oxidation of propylene on zeolites containing exchangeable transition metal cations. In the presence of type Y zeolite in which the sodium cations have been replaced by copper the main reaction at 350° is deep oxidation of propylene[36]. Small amounts of formaldehyde, acrolein, and acetaldehyde are also formed. A comparison of the activity of Cu(II)Y with that of CuO supported on SiO_2 has shown that the rate of oxidation of propylene on the zeolite can be an order of magnitude greater than on CuO/SiO_2: according to Mochida and coworkers[36] this is due to a specific state of the copper ions on the surface of crystalline aluminosilicates. The activity of Cu(II)Y towards the oxidation of propylene was found to be greater than towards the oxidation of ethylene.

The oxidation of propylene in the presence of water vapour at 300° gives a high yield of acrolein [up to ~7% on Cu(II)Y zeolite if the reaction mixture contains 30–50 vol.% of water vapour[37]]. On Ag(I)Y zeolite under otherwise similar conditions the yield of acrolein is less than 3%, and on Ni(II)Y no acrolein can be detected in general. At 200° isopropanol formation is detected, in keeping with the acidic function of the zeolite.

Increasing the $C_3H_6:O_2:H_2O$ molar ratio in the reaction mixture to 1:1:20 gives acetaldehyde at 250° and acetone at temperatures above 500°.[38] It is pointed out[39] that in order to obtain equal concentrations of acrolein and carbon dioxide in the reaction products the $C_3H_6:O_2$ ratio must be increased to 1:7, and the temperature must be raised to 350°.

In the liquid phase propylene dissolved in benzene is converted into propylene oxide with a selectivity of 70% in the presence of NaX zeolite steeped in ammonium molybdate and of oxygen (150 °C, 45 atm).[40] In a study[41] of the oxidation of propylene on type X zeolites containing Pd, Cu, Co, Ni, Zn, Mn, Cr, Fe, and NH_4 cations the main reaction products were found to be CO_2 and H_2O, with small amounts of acrolein, formaldehyde, and acetaldehyde. The activity of the samples increased with their acidity, but the addition of pyridine to the reaction mixture lowered the activity of the catalysts. From these results the authors concluded[41] that the reaction mechanism is

$$CH_3{-}CH{=}CH_2 + H^+ \rightarrow CH_3{-}C^+H{-}CH_3$$
$$CH_3{-}C^+H{-}CH_3 + (Cu\ldots O_2)^+ \rightarrow CH_3{-}C^+H{-}CHO + H_2O + Cu^+$$
$$CH_3{-}C^+H{-}CHO \rightarrow CH_2{=}CH{-}CHO + H^+ .$$

The intermediate products are further oxidised with formation of CO_2 and H_2O.

Iron-containing zeolites of types A, X, and Y also are active exclusively towards the deep oxidation of propylene[42]. The addition of Fe(III) to X and Y zeolites increases their activity slightly, but in type A zeolite the effect is not detected.

The oxidation of propylene on VONaY zeolite, prepared by ion exchange between NaY zeolite and an aqueous solution of vanadyl sulphate, gives mainly CO_2, acetone, and acetaldehyde[43]. Supported catalysts (V_2O_3/SiO_2) are less active than VONaY towards the oxidation of propylene. It is suggested[43] that this reaction gives only partial oxidation, whose products undergo polymerisation or carbonisation and remain in the internal cavities of the zeolite structure.

The addition of ammonia to the reaction mixture used in the oxidation of propylene leads to oxidative ammonolysis, with formation of acrylonitrile. The activity of the catalysts depends on the structure of the zeolite and on the coordination of the transition metal ions in the zeolite matrix. A study[44] of the activity of Fe(III)-containing zeolites towards this reaction has shown that the yield of acrylonitrile decreases in the sequence FeNaX > FeNaY > FeNaA. The low activity of type A zeolite as compared with the faujasites obviously stems from special features of this type of zeolite skeleton. The most selective catalysts with respect to the formation of acrylonitrile are FeNaX, FeCaX, and FeCaA, whereas FeNaY is the most active towards the formation of CO_2.

The oxidative ammonolysis of propylene has been studied[45] on Fe(II)Y and Fe(II)-mordenite zeolites. At 450° the conversion of propylene on Fe(II)Y was only 17% (10% CO_2, 7% acrolein, acrylonitrile not detected), but in the presence of the Fe(II)-mordenite catalyst the yield of acrylonitrile is as high as 40% for a total conversion of 43%. These results illustrate the important effect of the zeolite structure on the activity and selectivity of the catalyst. Using γ-resonance spectroscopy data Garter and coworkers[45] ascribe this difference between the Fe forms of type Y and mordenite zeolites to the oxidation state and to the location of the iron ions in the two materials.

In the oxidative ammonolysis of propylene and of the butylenes the Mn form of type X zeolite shows a selectivity higher than those of MnY and Mn-erionite zeolites[46], which are more effective as cracking catalysts. It has been pointed out[47] that on NaX zeolite containing 10% Ag_2O the yield of acrylonitrile is 35.5%, whereas gumbrin containing the same amount of silver is more active and selective towards the formation of acrolein.

The interaction of butenes adsorbed on CaA and NaX zeolites with oxygen at 25–90° has been studied[48]. The resulting complex mixture of products can be separated from the zeolites only by extraction with moist ether. This very strong interaction between the zeolites and organic molecules is due to the similarity between the pore size and the molecular diameters. The effect is most clearly seen when the products are more polar than the initial hydrocarbons. After analysing the reaction products the authors[48] conclude that catalytic oxidation on zeolites causes preferential breaking of the double bond.

The Pt–NaA zeolite was found[49,50] to have a high activity towards the oxidation of CO. When a mixture of air and CO (2 mole %) is passed through the catalyst at 427–540° the degree of conversion of CO is 86–100%. Under the same conditions the conversion of n-butane is only 2.4–5.5%.[49] The Pt–CaA zeolite containing 0.3 wt.% Pt has a high selectivity towards the oxidation of n-paraffins and n-olefins mixed with iso-paraffins and iso-olefins. Thus, 97% of the n-butane and only 0.1% of the isobutane are oxidised to CO_2 and H_2O from a 6:4 mixture of the two compounds at 315°. On the same catalyst propylene and but-2-ene are oxidised fully and selectively in the presence of isobutane. Thus, these systems show the molecular sieve effect.

One of the earliest studies of the deep oxidation of hydrocarbons was on zeolites not containing transition metals[51]. The activities of NaX, CaX, and MnX zeolites towards the oxidation of hexane isomers were compared, and MnX (i.e. a zeolite containing cations of a typical transition metal) was found to be inferior to NaX zeolite in its activity towards deep oxidation. The catalysts were placed in the following series with respect to the extent of carbon formation: CaX > MnX > NaX. The authors[51] point out that the zeolite reaction does not correspond to the typical oxidation–reduction mechanism of transition metal oxides, since NaX is more active than MnX. Gradual replacement of the sodium by bivalent cations suppresses the oxidative activity, and the cracking reaction becomes predominant.

Recent scientific papers and patent applications highlight the high activity of zeolites towards the oxidation of various substances. Thus, Doronina and coworkers[52] studied the catalytic behaviour of the zeolites NaA, NaX, NaY, PdY, NiY, CoY, Pd-mordenite, and Tseokar-2 towards the deep oxidation of chlorinated organic compounds. At 400–450° over 90% oxidation was obtained on NaY, PdY, CoY, and Pd-mordenite. Selective oxidation of hexafluoropropylene takes place on catalysts consisting of NaY zeolite in which the Na atoms have been replaced by Cr, Mn, Fe, Ni, Pd, or Ce ions to an extent greater than 50 equiv.%.[53] A substantial level of activity towards this reaction was obtained also with samples prepared by steeping NaY zeolite and amorphous alumina–silica in an aqueous solution of copper nitrate[53,54]: the extent of conversion was 15.0 to 29.1% at 250–300°, with a selectivity of 45.1–47.7%. A high activity towards the deep oxidation of carbon compounds at relatively low temperatures (<150°) has been observed with synthetic zeolites steeped in a solution of $H_2PtCl_6 \cdot 6H_2O$ in an organic solvent[55] and with ZSM-5 zeolite containing copper cations[56]. The increasing number of publications on the deep oxidation of various compounds in the presence of zeolite catalysts shows the importance of this topic.

We may conclude from published results that low-molecular-weight hydrocarbons on the whole undergo deep oxidation on zeolites, those containing transition-metal cations usually being the most active. As the molecular weight of the hydrocarbon increases, oxidative dehydrogenation may occur in parallel with the deep oxidation, but this phenomenon has not been studied extensively so far. Thus, Al'tshuler and Tsitovskaya[57] suggested the following method of preparing catalysts for the oxidative dehydrogenation of paraffins in the presence of halogens: a sample of Na-mordenite zeolite is steeped in an aqueous solution of H_2PtCl_6, dried at 140°, baked in air at 380°, and reduced in hydrogen at the same temperature. The sodium cations are then exchanged by caesium cations. In the presence of this catalyst the conversion of n-butane is 37.1%, with a selectivity of 79.2% towards butylenes and divinyl, for a mixture of reactants in the molar ratio n-butane : O_2 : Br_2 = 1:2:0.7.

In a study of the oxidative dehydrogenation of isopentane on zeolite catalysts[58,59] the conversion of isopentane on CaA, CaX, and CaY at 540° and a molar ratio iso-C_5H_{12} : O_2 = 1:1.8 was found to increase with the pore size of the zeolite, but the selectivity of the process was low[58]. In the case of type A zeolite containing Fe(III), Cr(III), Co(III), or

Zn(II) cations a direct relationship is observed between the extent of conversion of isopentane and the ionic radius of cations with the same charge[59]. The selectivity of the reaction towards isopentylenes and isoprene is not greater than 26%.

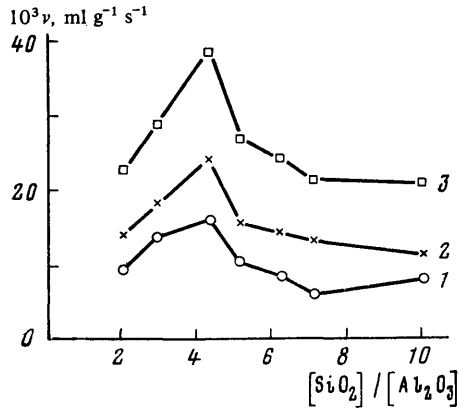

Figure 1. Rate of oxidative dehydrogenation of 2-methylbut-2-ene against the $[SiO_2]/[Al_2O_3]$ ratio in zeolite at: *1*) 400, *2*) 425, and *3*) 450 °C (Ref.60).

A study[60] of the effect of the composition and structure of the zeolites on the oxidative hydrogenation of 2-methylbut-2-ene showed that, in addition to oxidative dehydrogenation, zeolite catalysts can induce deep oxidation, isomerisation of the double bond, and cracking reactions. The yield of isoprene and the selectivity of the process are particularly sensitive to the zeolite structure. A comparison of the activities of the Na forms of A, X, and Y synthetic zeolites, chabazite, erionite L, and mordenite showed that the reaction rate goes through a maximum (corresponding to type Y zeolite) as the ratio of silicon to aluminium oxides is varied (see Fig.1). The apparent activation energy for Na-faujasite is ~15 kcal $mole^{-1}$, increasing to 18–20 kcal $mole^{-1}$ for type A zeolites, chabazite, erionite, and mordenite. The faujasites are superior to the narrow-pore zeolites in the yield of isoprene and in the selectivity of the process, but the latter are more active towards deep oxidation. In other words, X and Y zeolites behave differently from zeolites with narrow pores towards the oxidative dehydrogenation of 2-methylbut-2-ene.

The interaction of 2-methylbut-2-ene with different zeolites has been studied also by programmed thermo-desorption[61]. The thermo-desorption spectra of X, Y, and L zeolites were found to include three peaks (at 75–80, 130–170, and 200–300° respectively), though the adsorption capacity of faujasites for this compound is much greater than that of type L zeolites. With chabazite and erionite only one desorption peak is observed (t_{max} = 125–150°), and with type A zeolite two peaks with t_{max} at 150–160 and 300–350° respectively (Fig.2). This difference in the interaction of 2-methylbut-2-ene with different Na-zeolites accounts for the difference in activity and selectivity between faujasites and narrow-pore zeolites.

The effect of the nature of the exchangeable cation in type Y zeolite on the oxidative dehydrogenation of 2-methylbut-2-ene has also been studied[60]: as the ionic radius increases in the sequence Li < Na < K < Rb the yield of isoprene and the selectivity of the reaction decrease, and the yield of carbon oxides increases. At 400–450° a linear decrease of the reaction rate with increase of the ionic radius of the alkali metal cation is observed. It may be due to variations in the electrostatic field within the zeolite holes, or alternatively it may be due to the blocking effect of the larger cations on the "windows" leading to the large zeolite holes, which could hinder the diffusion of hydrocarbon molecules.

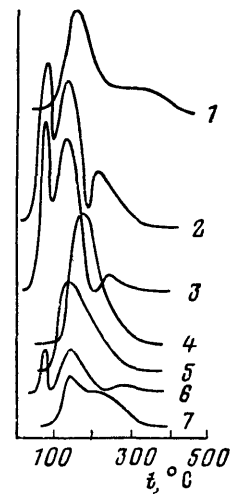

Figure 2. Thermo-desorption spectra of 2-methylbut-2-ene on zeolites: *1*) NaA, *2*) NaX, *3*) NaY, *4*) Na-chabazite, *5*) Na-erionite, *6*) NaL, *7*) Na-mordenite (Ref.61).

III. OXIDATIVE TRANSFORMATIONS OF NAPHTHENES

The oxidation of cyclohexane on zeolite catalysts has been studied in detail in the Soviet Union and in Japan. Using type Y zeolites containing copper cations the main products were found[62] to be benzene, CO_2, and H_2O. Cu(II)Y zeolite is more active than the conventional catalyst for this reaction (CuO on silica gel). For conversions up to 10% the selectivity of the reaction with respect to benzene can be as high as 80%. In addition to the Cu(II) form, type Y zeolites containing Pd(II), Ag(I), Zn(II), Ni(II), and Cr(III) were also investigated. Cu(II)Y was found to be the most active in the formation of benzene, and Pd(II)Y in the deep oxidation reaction. The authors point out[62] that the most active catalysts have the highest activation energies and frequency factors. The dependence of the initial rates of formation of benzene and of carbon dioxide on the standard heat of formation of the metal oxide is described by curves with two peaks[63]. Similar relationships are observed for the dehydrogenation of cyclohexane to benzene on oxide catalysts[64,65], but in this case the activity maximum corresponds to the catalyst Cr_2O_3.

NaY zeolite was found[66,67] to be active only towards the deep oxidation of cyclohexane (which sets in at temperatures as low as 150–160°). In contrast to the reaction on NaY, the oxidation of cyclohexane on the Cu(II) and Fe(III) forms of type Y zeolite begins at 240–260°, and proceeds

in two directions: deep oxidation, and oxidative dehydrogenation to benzene. As the degree of exchange of the sodium cations by transition metal cations is increased, the yield of benzene increases, but the specific activity of the catalyst [expressed for one Cu(II) or Fe(III) ion] decreases. The selectivity of the reaction towards benzene and the concentration of mobile oxygen in the zeolite increase with the exchange of sodium cations by transition metal cations. Mobile oxygen atoms are absent in Mn(II)Y, Co(III)Y, and Zn(II)Y zeolites: these materials behave like NaY zeolite, giving only deep oxidation products. On the other hand the zeolites containing Cu(II), Fe(III), Cr(III), and Ni(II) cations (active towards the oxidative dehydrogenation of cyclohexane) contain "active" oxygen. It has been pointed out[66,67] that the selectivity of the benzene formation reaction is higher in crystalline alumina–silicas containing transition metal ions than in the amorphous catalysts containing the same transition metals.

Spectral studies by the pulse method[68] have demonstrated the strong adsorption of cyclohexane on NaY zeolite in the pre-catalytic temperature region. After exposure to a $C_6H_{12} + O_2$ mixture, even at 60–80°, NaY zeolite shows characteristic absorption bands at 1720, 1780, and 1820 cm^{-2} (corresponding to carbonyl and peroxide compounds). After partial replacement of the sodium ions by Cu(II) these compounds are no longer observed (up to 180°).

An interesting feature of the deep oxidation of cyclohexane on NaX and NaY zeolites in the development of an oscillatory (autocatalytic) oxidation regime, ascribed[68,69] to periodic increases in the concentration of peroxide compounds on the zeolite surface. By studying the effect of temperature on this process it was shown that the oxidation of cyclohexane on Na faujasites has a mixed (homogeneous–heterogeneous) mechanism[68–70]. The penetration of the reaction into the gas phase occurs at 120° in the case of NaY, and at 220° in the case of zeolites containing transition metals. According to Elinek and coworkers[70] the relative extent of the homogeneous reaction exceeds 60% when the reaction mixture contains 0.3–0.6 vol.% of cyclohexane.

By applying thermo-desorption and calorimetry methods to the cyclohexane–NaX system it was shown[71] that cyclohexane is adsorbed in one form only, with an activation energy for desorption of 18 kcal $mole^{-1}$ in a stream of helium and 13 kcal $mole^{-1}$ in air. In both cases the adsorption is reversible, and almost the whole of the adsorbed cyclohexane is evolved during the desorption. This excludes any mechanism which explains the oscillatory regime (i.e. periodic changes in extent of conversion and in temperature) by postulating several forms of adsorbed cyclohexane. The heat of adsorption of the cyclohexane is independent of the surface coverage of the catalyst, showing that the surface is energetically uniform towards cyclohexane, and allowing the dependence of the activation energy of one of the steps on the coverage of the surface by the reactant to be rejected as an explanation of the oscillations occurring during the oxidation of cyclohexane. On the basis of these results the authors suggest[71] that when cyclohexane and oxygen are added sequentially peroxide compounds are formed by the reaction of cyclohexane with the free radical forms of adsorbed oxygen, further oxidation involving oxygen from the gas phase. The marked dependence of the reaction rate on the concentration of oxygen in the reaction mixture is interpreted[72] as evidence for the participation of oxygen in the chain propagation reactions.

The kinetics of the oxidative dehydrogenation of cyclohexane on Cu(II)Y zeolite were studied by Elinek and coworkers[73]. The rates of oxidative dehydrogenation and of deep oxidation of cyclohexane were found to depend on the partial pressures of the reactants according to the equations

$$v(\text{benzene}) = k \cdot p_{O_2}$$

$$v(CO_2) = k' \cdot p_{O_2}^{0.5} .$$

Thus the rates of both reactions are practically independent of the partial pressure of cyclohexane.

By studying the adsorption of oxygen and cyclohexane on the catalysts by the chromatographic pulse method, with the reactants introduced in different orders, the adsorption of oxygen was found to be rate-determining in the oxidative dehydrogenation of cyclohexane to give benzene. The high yields of benzene in the presence of Cu(II)Y are due to the high adsorption capacity of this zeolite towards oxygen. The rates of deep oxidation and of oxidative dehydrogenation of cyclohexane at 290° are given in Table 1, together with the adsorption capacities of various cationic forms of type Y zeolite towards cyclohexane and oxygen[73]. For low degrees of exchange of sodium by copper cations the reaction products contain only a small amount of cyclohexane (<1%), and on the samples with a high Cu(II) content no cyclohexane can be detected. According to these results the authors[73] propose the following scheme for the transformations of cyclohexane on zeolites:

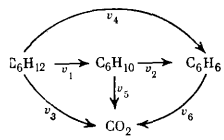

Table 1. Catalytic activity (α) and adsorption capacity (γ) of the cationic forms of type Y zeolite[73].

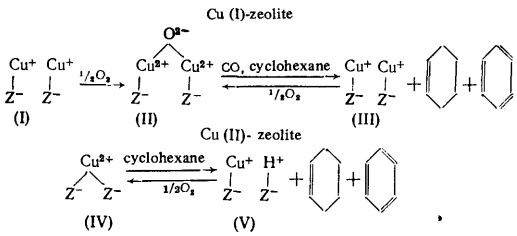
Catalysts	$10^2 \alpha$*, ml g^{-1} min^{-1}		γ**	
	$v(C_6H_6)$	$v(CO_2)$	C_6H_{12}	O_2
Cu (II) Y	52.0	22.0	100	100
Pd (II) Y	4.4	7250.0	200	<1***
Cr (III) Y	2.3	9.6	<1	<1
Zn (II) Y	0.4	3.2	<1	<1
Ni (II) Y	1.4	7.3	<1	<1
Ag (I) Y	0.2	2.5	<1	<1

*Rate of the reaction at 290°.



**The adsorption capacity of Cu(II)Y zeolite is arbitrarily taken as 100.

***On Pd(II)Y benzene is formed by dehydrogenation of cyclohexane without involving oxygen.

The oxidation of cyclohexane, ethylene, and CO on type Y zeolites containing Fe(III), Fe(II), Cu(II), and Cu(I) cations has been studied[74], and the Cu(I)Y and Fe(II)Y zeolites were found to be catalytically more active towards the oxidation of CO than Cu(II)Y and Fe(III)Y zeolites. This is explained in terms of the amount of oxygen chemisorbed on the catalyst [negligibly small in the case of catalysts containing Cu(II) and Fe(III) ions]. A further increase in the valency of these ions is energetically very difficult, whereas oxygen chemisorption on zeolites containing Cu(I) and Fe(II) can readily take place, to give a 0.44–0.5 ratio of the numbers of oxygen atoms and metal ions. The authors[74] point out that Cu(II) zeolite has a small but measurable

activity although oxygen adsorption on this material is undetectable, and they explain this observation by postulating activation of the oxygen in the zeolite structure by the added copper.

In contrast to the oxidation of CO, in the oxidative dehydrogenation of cyclohexane no difference was found between the catalytic activities of Cu(II)Y and Cu(I)Y [or Fe(III)Y and Fe(II)Y]. The behaviour of the system is explained[74] by postulating the following reaction schemes for Cu(I) and Cu(II) zeolites:

In these equations Z^- is the anionic form of the zeolite. In the oxidation of CO, which requires the presence of active O^{2-}, the preferred structure is (II). However, in the dehydrogenation of cyclohexane structures (II) and (IV) have equal activities. An analogous mechanism can be written for Fe(II) and Fe(III) zeolites.

The selectivity of the formation of benzene by the oxidative dehydrogenation of cyclohexane on Cu(I)Y, Cu(II)Y, Cu(II)-mordenite, and CuO/SiO_2 catalysts was found[75] to be 83, 76, 0.44, and 33% respectively, with activation energies of 27, 18, 38, and 20 kcal $mole^{-1}$. The kinetic order of the reaction with respect to oxygen was 1 on Cu(II)Y zeolite and 0.5 on Cu(I)Y. Cyclopentane on these catalysts undergoes mainly deep oxidation: whereas in the presence of Cu(I)Y the rate of oxidation of cyclohexane is almost an order of magnitude greater than that of cyclopentane, in the presence of Cu(II)Y the two rates are almost equal. Furthermore, the activity of Cu(I) towards the oxidation of cyclopentane rapidly decays with time, whereas the activity of Cu(II)Y is relatively stable. These differences between the catalytic properties of copper-containing zeolites are explained[75] by postulating the participation of O_2 in the oxidation on Cu(II)Y and of dissociatively adsorbed oxygen in the oxidation on Cu(I)Y.

The dehydrogenation of cyclohexane on various cationic forms of type X zeolite has been studied[76-78] both in the presence and in the absence of oxygen. Na-, Ca-, and decationated forms were found to be practically inactive towards the formation of benzene, but the introduction of nickel cations creates dehydrogenation activity which increases with the amount of nickel added to the sample. In the presence of oxygen the Ni-containing zeolites are active also in the oxidative dehydrogenation with formation of benzene, whereas the activity of NaX is high only towards deep oxidation. As the amount of sodium in the zeolite decreases the extent of the deep oxidation reaction also decreases very markedly. The most active and selective catalyst for the formation of benzene is a sample in which 25% of the sodium has been exchanged by nickel cations and 33% by hydrogen ions.

An interesting feature of the Fe(II) form of type Y zeolite has been pointed out[79]: the production of cyclohexene by the oxidative degradation of cyclohexane. In a pulsed regime at 180° the conversion of cyclohexane is 2.5%, with 58% selectivity for cyclohexene. The Co(II)Y, Cu(II)Y, and Cr(III)Y zeolites show a lower activity and selectivity for the formation of cyclohexene. Increasing the partial pressure of oxygen in the reaction mixture and the contact time increases the conversion, but it lowers the selectivity for cyclohexene. On Fe(II)X zeolite, and in the presence of water vapour, the conversion of cyclohexane at 260° is 14%, and the selectivity for cyclohexene is 30%.[80] The Fe-mordenite catalyst shows no activity towards the formation of cyclohexene up to 430°. Thus, the activity of iron-containing zeolites towards the formation of cyclohexene decreases in the sequence FeX > FeY > Fe-mordenite. Kubo and coworkers[80] suggested, in the light of published results[81-83], that dissociatively adsorbed oxygen [detected by γ-resonance spectroscopy on Fe(II) zeolites] plays an important role in this reaction on low-valency cationic forms of faujasite.

Later work on the oxidation of cyclohexane on crystalline aluminosilicates showed that the direction of the reaction is also strongly influenced by the structure of the zeolite. Thus, whereas faujasites catalyse the reaction (depending on the nature of the exchanged cation) towards deep oxidation of the cyclohexane or towards oxidative dehydrogenation with formation of benzene, in the case of the alkali metal forms of synthetic type A zeolites and of sodalite, chabazite, erionite, and mordenite the oxidative dehydrogenation of cyclohexane stops at the cyclohexene stage[84-91]. On the more active catalysts the yield of cyclohexene is greater than 20%, which is almost 5–10 times greater than the activity of Fe(II)-containing faujasites. Table 2 shows some results on the activity and selectivity of zeolite catalysts towards the oxidative dehydrogenation of cyclohexane to cyclohexene[85-88]. The tabulated values show that the introduction of transition metal cations (Pd, Cu, Fe) into the zeolite composition lowers the selectivity for this reaction (in comparison to the alkali metal cation forms). Thus, in contrast to the Na faujasites (which are active only towards deep oxidation), the Na forms of narrow-pore zeolites cannot accommodate the cyclohexane molecules in the internal zeolite holes, and on these catalysts the oxidative dehydrogenation stops at the stage of cyclohexene formation.

Table 2. Oxidative dehydrogenation of cyclohexane on zeolites (molar ratio $C_6H_{12}:O_2 = 1:1.5$; $V = 1\ h^{-1}$)*.[88]

Zeolite	$[SiO_2]/[Al_2O_3]$	t, °C	Conversion, %	$W_{C_6H_{10}}$, %	S, %

*Symbols: V is the volume velocity for cyclohexane, $W_{C_6H_{10}}$ is the yield of cyclohexene, S is the selectivity of the reaction.

**Molar ratio $C_6H_{12}:O_2 = 1:1$, $V = 0.5\ h^{-1}$.

A study of the interaction of cyclohexane with various zeolites by the thermo-desorption method[89] has shown that cyclohexane is adsorbed only on type X and Y zeolites, and to a smaller extent on type L zeolite. Hence it was suggested that the strong adsorption on faujasites is responsible for the deep oxidation of cyclohexane on zeolites.

But although L type zeolite adsorbs cyclohexane, its adsorption capacity is very low. This may be the reason for the low yield of cyclohexene (as compared with other narrow-pore zeolites) of this catalyst, which occupies a position intermediate between the narrow-pore catalysts and the faujasites.

The t_{max} value of the cyclohexane desorption peak on different cationic forms of zeolite Y is displaced towards lower temperatures as the initial NaY zeolite is converted into the working form: in other words, the strength of the adsorbate–adsorbent bond is lowered, and the effective diffusion coefficient increases almost by two orders of magnitude[89]. These changes affect the catalytic properties of the samples. Unlike NaY, which catalyses only the deep oxidation of cyclohexane, NdY catalyses the oxidative dehydrogenation of this compound to give benzene. On the other hand, with narrow-pore zeolites (which do not, in general, adsorb cyclohexane) the main product is cyclohexene.

The kinetics of the oxidative dehydrogenation of cyclohexane in the presence of Na, K-erionite have been studied in our laboratory[88]. The reaction is first-order in oxygen, and has a fractional order with respect to cyclohexane. The apparent activation energy is only 5.5 kcal mole^{-1}. The rate-limiting step is assumed to be the surface reaction between cyclohexane and the weakly adsorbed molecular oxygen. The experimental results are satisfactorily described by the equation

$$v = \frac{k \cdot p_{O_2} p_{C_6H_{12}}}{1 + a_{C_6H_{12}} p_{C_6H_{12}}},$$

where $a_{C_6H_{12}}$ is the adsorption coefficient of cyclohexane.

Table 3. Oxidative dehydrogenation of cyclohexene on zeolites (450 °C, $C_6H_{10}:O_2 = 1:1$, $V = 1\ h^{-1}$).[88]

Zeolite	Conversion, %	W, %		S, %	
		C_6H_8	C_6H_6	C_6H_8	C_6H_6

0.08Pd-mordenite	10.0	2.3	5.5	23	50

Since the oxidative dehydrogenation of cyclohexane on narrow-pore zeolites stops at the cyclohexene formation stage, we examined[88] the possibility of preparing cyclohexadiene by the oxidative dehydrogenation of cyclohexene. The results (Table 3) show that (except in the case of Na, K-chabazite sample) the yield of cyclohexadiene is 3.4% or less, and the selectivity of the reaction varies between 7 and 48%. An increase in temperature or in the oxygen to cyclohexene concentration ratio favours the yield of benzene and thus lowers the selectivity for cyclohexadiene. The introduction of transition-metal cations into the zeolite also results in a lower selectivity.

We have also studied[90] the oxidative dehydrogenation of cyclohexane on natural zeolites (thomsonite, stilbite, natrolite, analcite, lomontite, mordenite, heulandite, and clinoptilolite). On all these samples the reaction was found to yield mainly cyclohexene: the highest activity was observed with a zeolite sample of the thomsonite type, which gave a 20.8% yield of cyclohexene at 450° with a selectivity of 80%. The zeolite structure has a marked effect on the temperature dependence of the yield of cyclohexene (Fig.3). In some cases the yield goes through a maximum at 400° (clinoptilolite and heulandite), whereas with thomsonite the yield continues to increase with temperature up to 450°. However, at still higher temperatures the selectivity decreases in every case.

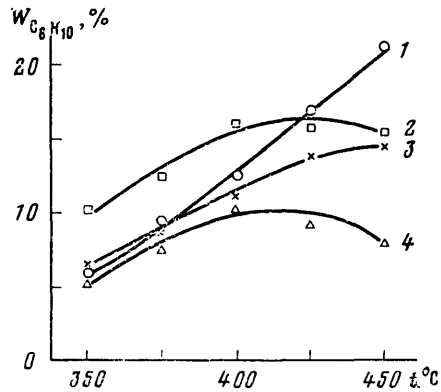

Figure 3. Yield of cyclohexene against temperature for natural zeolite types: *1*) thomsonite, *2*) clinoptilolite, *3*) stilbite, *4*) heulandite[90].

Table 4. Oxidative dehydrogenation of methylcyclohexane on zeolites (450°, $CH_3C_6H_{11}:O_2 = 1:1.3$, volume velocity for methylcyclohexane $1\ h^{-1}$).[97]

Zeolite	Composition of product, %				W_{CO_2}, %
	C_6H_{12}	$CH_3C_6H_{11}$	$CH_3C_6H_8$	$CH_3C_6H_5$

Na-mordenite	0.5	62.1	8.3	28.7	4.0

The influence of the structure and composition of the zeolite on the course of the reaction is even more marked in the oxidation of methylcyclohexane. The main product of the dehydrogenation of methylcyclohexane on metallic or oxide catalysts is toluene. There are published reports that only toluene is formed by the dehydrogenation of methylcyclohexane on 0.5% PtNaY zeolite[92], and that the partial dehydrogenation products which are formed in small quantities are converted into carbon. By studying the kinetics of the reaction and the carbonisation of the catalyst the authors concluded[92] that an intermediate dehydrogenation step is involved.

A recent patent[93] discloses that the reaction of methylcyclohexane on PtCaY zeolite at 505° yields toluent (55.2%), benzene (12.3%), and xylenes (17.0%). The bifunctional PtCaY catalyst apparently catalyses the dehydrogenation (on the platinum) of methylcyclohexane to toluene, which then undergoes disproportionation of the methyl group (on the acidic centres) to give benzene and xylenes. The dehydrogenation of alkylcyclanes to the corresponding aromatic hydrocarbons in the presence of Pt-zeolite catalysts has also been reported[94].

The oxidative dehydrogenation of methylcyclohexane on zeolite catalysts is discussed in detail in Refs.91 and 95–97, and it is shown that the direction of the reaction, the yields of the various products, and the selectivities of the process are a function of the composition and structure of the zeolite. Thus, on Na-faujasite the main reactions of methylcyclohexane are deep oxidation and oxidative dehydrogenation with formation of toluene[95]. The alkali cationic forms of chabazite and erionite are more active and selective towards the formation of methylcyclohexenes[97], but the type A and L zeolites (and mordenite) have a lower selectivity towards methylcyclohexenes than chabazite and erionite, though they yield methylcyclohexenes as well as toluene (Table 4). The low selectivity of the faujasites with respect to methylcyclohexenes can be explained, as in the cyclohexane reaction, by the strong adsorption of methylcyclohexane on these zeolites, which favours the more disruptive transformations within the internal cavities on the zeolite. On the other hand, on the narrow-pore zeolites the reaction takes place on the outer crystal surfaces, and the resulting cyclo-olefin intermediates can be desorbed into the gas phase and escape further dehydrogenation to toluene.

Table 5. Conversion of methylcyclohexane on cationic forms of type Y zeolite (450°, volume velocity 1 h^{-1}).[96]

Zeolite	Carrier gas	Conversion, %	Composition of product, %					W_{CO_2}, %
			C_6H_6	$CH_3C_6H_5$	$C_2H_5C_6H_5$	$(CH_3)_2C_6H_4$	$(CH_3)_3C_6H_3$	
0.48 HY	air	85.4	3.2	38.7	—	22.3	—	4.0
0.48 HY	helium	64.4	—	16.1	—	9.1	—	—
0.86 CaY	air	96.2	2.0	43.2	0.9	35.6	3.5	3.7
0.86 CaY	helium	48.0	1.3	8.7	0.2	8.3	1.6	—
0.60 MgY	air	85.9	1.5	31.5	—	9.2	—	3.6
0.60 MgY	helium	48.4	—	8.5	—	1.4	—	—
0.93 NdY	air	95.5	2.9	45.9	0.9	34.8	—	3.3

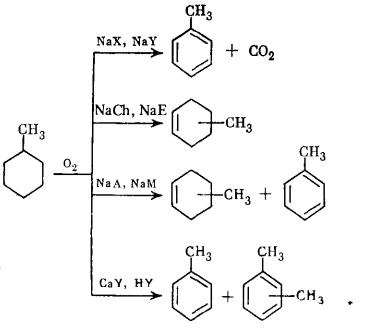
0.50 CoY	helium	10.3	—	2.5	—	—	—	—

*At 350 °C.



We note from Table 4 that the insertion of copper and iron cations into erionite increases the yields of toluene and carbon dioxide and thus lowers the selectivity of the reaction towards methylcyclohexenes[95]: in other words, zeolites containing transition metal cations tend to favour the more radical transformations of methylcyclohexane.

It has been shown[91,96] that in the presence of oxygen methylcyclohexane (unlike cyclohexane) reacts on decationated and on alkaline-earth cationic forms of type Y zeolite to give various aromatic hydrocarbons including toluene and xylenes (Table 5). In other words, the Ca, Mg, and NH_4 forms of type Y zeolite behave as typical bifunctional catalysts towards the oxidative transformation of methylcyclohexane into xylenes, even though their composition does not include Group VIII metals or transition-metal oxides. We may assume that the xylenes are formed by the oxidative dehydrogenation of methylcyclohexane to toluene, followed by disproportionation into benzene and xylenes. However, it appears from the distribution of products that benzene is always present in smaller amounts than the xylenes. Furthermore, under otherwise identical conditions the yield of xylenes from the disproportionation of toluene is smaller than from the reaction of methylcyclohexane, and therefore an alternative mechanism for the formation of xylenes from methylcyclohexane (by-passing the toluene formation step) cannot be excluded.

In a study[96] of the effect of the degree of decationation of type Y zeolite on the reaction of methylcyclohexane it was found that the yield of xylenes becomes progressively less sensitive to the presence of oxygen in the reaction mixture as the degree of decationation of the zeolite is increased. It has also been reported[98] that on decationated zeolite Y containing 3% Rh methylcyclohexane at 300° and 30 atm pressure undergoes isomerisation and hydrogenolysis reactions, giving various five-membered cyclic and aliphatic hydrocarbons.

The lack of activity of the alkali cationic forms of various zeolites and of amorphous alumina–silicas and aluminium oxide towards the oxidative conversion of methylcyclohexane into xylenes suggests that both acidic properties and a specific crystal structure are required to give an active catalyst[96]. Thus, decationated mordenite has a negligibly small activity for this reaction, and CaX zeolite gives a much smaller yield of xylenes than CaY.

The following reaction scheme reflects the main directions of the oxidative dehydrogenation of methylcyclohexane on zeolite catalysts (NaCh, NaE, and NaM are Na-chabazite, Na-erionite, and Na-mordenite respectively):

By varying the structure and composition of the zeolites over a wide range we can control the direction of the transformation of methylcyclohexane, and thus obtain desirable end-products. This flexible and selective application suggests that crystalline alumina–silicas will be used increasingly as practical oxidation catalysts.

IV. OXIDATIVE DEHYDROGENATION OF ALKYLAROMATIC HYDROCARBONS

The oxidative dehydrogenation of ethylbenzene on type Y zeolite containing transition metals was first reported by Venuto and Landies[5]. On MnY zeolite the yield of styrene was not higher than 8.7%. This low activity did not justify a detailed study of the oxidative dehydrogenation of alkylaromatic hydrocarbons on other types of zeolite.
