The authors of the majority of the investigations consider[49-51,97,103,115,145-148] that pyrrole-2-aldehyde exists as the N,O-*cis*-conformer. Yet other results[83,98,103,115,145,149,150] indicate a definite contribution by the N,O-*trans*-form, though this can be explained[151] also by the possible existence of a non-planar conformer of 2-formylpyrrole. Stabilisation of the N,O-*cis*-conformers in this compound was originally explained[146] by a hydrogen bond of the type NH...O=C. Later, however, it appeared[98,152,153] that no significant increase† in the proportion of the N,O-*trans*-conformer occurs even in *N*-alkyl derivatives of this aldehyde. The N,O-*cis*-form is characteristic also of 2-formylindole[155].

Thus the factors causing stabilisation of the X,O-*cis*-conformers of the 2-formyl derivatives are common to all the five-membered heterocycles considered, and hence independent of the nature of the heteroatom X. A decisive role is played by Coulombic interaction of the charges of the cyclic heteroatom and the carbonyl oxygen atom. ππ-Conjugation of exo- and endo-cyclic parts of the molecules is not decisive (in the presence of Coulombic interactions), and can merely be superposed on the predominant Coulombic effect, either strengthening or weakening it. For these aldehydes both effects give the X,O-*cis*-forms[156-158].

2-Aldehydes of the azole series are characterised[159,160] mainly by conformationally rigid *cis*-structures (VIII)#. To understand the factors stabilising the *cis*-configuration of the 2-formylazole systems it must be borne in mind that molecules of aldehydes of the 1,3-diazole series (VIII) include fragments of the fundamental five-membered heterocycles (V) and six-membered nitrogenous heteroaromatic systems [azines, in particular pyridine (IX)]. Examination of the structure 2-formylpyridine[11,43,63,82,113,123,161-169] indicates almost complete formation§ of the rigidly fixed N,O-*trans*-isomer (X)

(VIII) (IX) (X)

¶ However, other studies[83,145] suggest that the X,O-*trans*-conformer predominates in the 2-aldehydes of furan and pyrrole.

† It must be emphasised, however, that the presence of significant steric hindrance (in *N*-aryl- and *N*-hetaryl-2-aldehydes)[154] leads to the O,N-*trans*-structure, in which Coulombic repulsion is minimal.

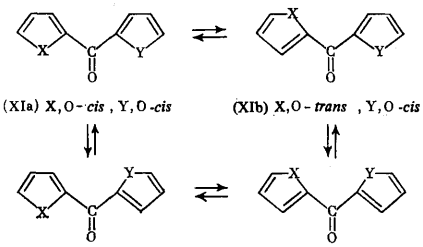
To avoid confusion we retain for the carbonylazole systems (VIII) the names of conformers analogous to the formyl derivatives of the fundamental five-membered heterocycles.

§ Yet other workers[82,165,170] regard pyridine-2-aldehyde as a stereochemically non-rigid system with up to 30% of the N,O-*cis*-form involved in the conformational equilibrium. This is well explained by both the above factors responsible for stabilising conformers in the *s-cis*–*trans*-equilibrium of formyl-containing heterocycles.

Indeed, both Coulombic interaction (repulsion of negatively charged nitrogen and oxygen atoms) and ππ-conjugation effects stabilise the planar N,O-*trans* form of pyridine-2-aldehyde (X). The above results suggest that both effects should tend to stabilise the X,O-*cis*(N,O-*trans*)-conformers (VIII) in the case of 2-formylazole systems, as has been confirmed experimentally[73,159,160] and by calculation[159].

In this connection the conclusion[72] that up to 50% of the X,O-*trans*-isomer of 2-formyl-*N*-methylimidazole is present in benzene solution appears unexpected, though it is difficult to deny the actual possibility that the X,O-*trans*-isomeric form may be involved in the conformational equilibrium of aldehydes of the azole series[73,160].

Ketones (R = Alk, Ar, Het). The attachment of aliphatic, aromatic, and heterocyclic substituents to the carbonyl group changes the barrier to rotation about the single bond



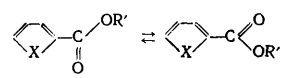
and in most cases leads to structural non-coplanarity of ketone derivatives of five-membered heterocycles[134,154,171]. Even the simplest alkyl substituent, methyl, yields two isomers, with the O,O-*trans*-form predominating in 2-acetylfuran[42,68,93,94,136,137,171-174]. Yet 2-acetylthiophen, 2-acetylselenophen, and 2-acetylpyrrole are characterised exclusively or predominantly by the planar X,O-*cis*-structure[69,92,103,124,140,152,175-178]. However, some data even for these compounds indicate both the establishment of a conformational equilibrium[59,68,94,152] and the presence of a substantially non-planar structure[152,178,179] with a dihedral angle $\phi \cong 30-55°$. Increase in the proportion of the *trans*-conformer (from 28% to 53%) is observed on passing from formyl to acetyl derivatives of tellurophen[59,99,144]. The inconsistency of all these results on the three-dimensional structure of the acetyls is due to the difficulty usually encountered in choosing unambiguously, on the basis of individual data, between non-planar rotamers and equilibrium systems containing planar *s-cis*- and *s-trans*-conformers.

A non-planar structure is characteristic of hetaryl phenyl and dihetaryl ketones[178,180,181]. That of furyl phenyl ketone is due solely to displacement of the phenyl group from the plane of the rest of the molecule[180], whereas the corresponding thienyl ketones exhibit simultaneous displacement of the hetaryl group from the plane of the carbonyl group[181]. This result is due to the greater gain in energy on conjugation of the carbonyl with the less aromatic[182] furan ring than with the thiophen ring, as is confirmed by quantum-chemical calculation[123].

Thus the conformational analysis of ketones, in contrast to that of aldehydes, must take into account not only *s-cis*(*trans*)-conformers but also the possibility of a non-planar molecular structure for the carbonyl-containing five-membered heteroaromatic systems[23,67,68,92,121,124,183-186]. Like the corresponding aldehydes, ketones of azoles usually have predominantly a structure with maximum separation of pyridine-type nitrogen atoms and carbonyl oxygen[187,188]. Addition of two heterocycles to a carbonyl group usually complicates the task of conformational analysis, since the possibility arises

of four planar conformers (XIa–d):

(XIa) X,O-*cis*, Y,O-*cis* (XIb) X,O-*trans*, Y,O-*cis*



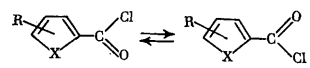
(XIc) X,O-*cis*, Y,O-*trans* (XId) X,O-*trans*, Y,O-*trans*

A non-planar structure is also possible for the ketones, as a consequence of electronic and steric effects of interaction between the heterocyclic rings and with the carbonyl group.

According to n.m.r. data difuryl ketone probably exists as a mixture of equal quantities of two forms, O,O-*cis*,O,O-*trans* and O,O-*trans*,O,O-*trans*[185]. Infrared[189] and n.m.r.[185] spectroscopy lead to fundamentally opposite conclusions on the structure of fur-2-yl fur-3-yl ketone. Whereas changes in dipole moments could not give an unambiguous indication of the spatial structure of dithienyl ketone[67], application of this method together with the Kerr effect has shown[68,181] a non-coplanar *cis,cis*-structure with the thienyl diverging from the carbonyl plane by 30–55°. Dielectric measurements and n.m.r. spectroscopy have demonstrated an unsymmetrical planar structure for a series of thioketones of pyrazole, thiophen, and several other heterocycles[190].

Carboxylic acids (R = OH). In contrast to aldehydes and ketones, *s-cis–trans*-isomerism in carboxylic acids of five-membered heterocycles has remained almost uninvestigated. X-Ray structural studies indicate that thiophen-, selenophen-, and tellurophen-carboxylic acids exist in the crystalline phase as planar X,O-*trans*-configurations, whereas furancarboxylic acid is characterised by the O,O-*cis*-form[119]. 1,3-Dimethylpyrazole-5-carboxylic acid has a planar N,O-*trans*-structure in the solid state[118].

Carboxylic esters (R = OR'). The esters have been investigated in greater detail. It can be accepted that the *s-cis–trans* equilibrium



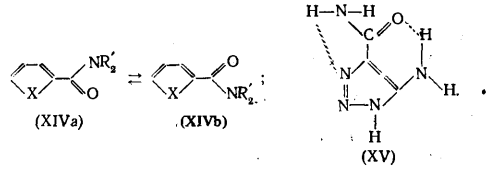
(XIIa) X, O_{carb}-*cis* (XIIb) X, O_{carb}-*trans*

is established in solution[47,59,65,106,191–193], but the clear dependence on the nature of the heterocycle characteristic of aldehydes is not observed[59]. Furancarboxylic esters (XII: X = O, R' = H) exist mainly as the X,O-*trans*-form (XIIb), which according to dipole moments[65] and n.m.r. spectra[106] constitutes 50–70%. Increase in the degree of branching of the group R' entails lowering of the barrier to rotation, which makes the identification of conformers difficult[106]. The content of the *cis*-conformer in conformational equilibrium is according to the dipole moments respectively 33%, 59%, and 42% in thiophen-, selenophen-, and tellurophen-carboxylic esters, in contrast to aldehydes and ketones.

These quantitative relations can hardly be regarded as sufficiently accurate, since it has been reported that conformational processes in thiophen- and furan-2-carboxylic acids have similar enthalpies, and also that furan- and tellurophen-carboxylic esters have equal contents of the two conformers[191].

In contrast to the above esters, methyl pyrrole-2-carboxylate exists in solution predominantly (73%) in the planar N,O_{CO}-*cis*-form: the rather higher content of the N,O-*trans*-isomer than in aldehydes and ketones is attributed to the ability of the imino-group to form a hydrogen bond not only with the carbonyl but also with the ethereal oxygen of the carboxyl group[194].

Acid halides (R = Hal). The barrier to rotation is higher in the chlorides of carboxylic acids of five-membered heterocycles than in the hetaryl methyl ketones, with a consequent conformational equilibrium between two planar conformations:



(XIIIa) (XIIIb)

Data on the conformations of acid halides are restricted to furan and thiophen derivatives[47,65,105,106,195,196].

According to ^{1}H n.m.r. spectra[106] the equilibrium mixture of molecules of the chloride of furancarboxylic acid contains at low temperatures (~193 K) up to 90% of the O,O-*cis*-form (XIIIa). The same form (XIIIa) is predominant also in chlorides of thiophencarboxylic acids[195,197], although infrared spectra suggest[105] a significant contribution by the S,O-*trans*-form (XIIIb). The sequence is reversed on passing from chlorine to fluorine derivatives, and the proportion of the X,O-*cis*-form diminishes: under comparable conditions (solvent, temperature) the proportion of the O,O-*cis*-conformer of the fluoride of furancarboxylic acid is 75%, but in the corresponding thiophen derivative it has even dropped to 55%. This is obviously due to the strongly electronegative fluorine substituent, which is able to compete with the carbonyl oxygen in its ability to interact electrostatically with the endocyclic sulphur atom ($S^{\delta+}...F^{\delta-}$ and $S^{\delta+}...O^{\delta-}$), and this leads to approximate equivalence of the two forms in the thiophen derivative. In fluorides of furancarboxylic acids, on the other hand, the Coulombic repulsion between the terminal oxygen and the fluorine atom exceeds that between the two oxygen atoms, so that the proportion of the O,O-*cis*-form in them is higher[105] than in the corresponding aldehydes of the furan series.

Similar conclusions on the competitive electrostatic interaction of halogen and carbonyl oxygen with the cyclic heteroatom were reached in an investigation of conformational changes in series of chlorides of furan-2-carboxylic acids[196]. A detailed investigation showed, on the basis of infrared spectral data together with measurements of dipole moments and the Kerr effect, that such chlorides are present in solution as mixtures of two conformers, the proportion of the O,O-*trans*-form increasing with the acceptor properties of 5-substituents in the furan ring and with decrease in solvent polarity, whereas chlorides of thiophencarboxylic acids are characterised by a single O,S-*cis*-conformation (XIIIa).

Amides of carboxylic acids (R = NH_2, $NAlk_2$). In amides of carboxylic acids of five-membered heterocycles the barrier to rotation is much lower than in the aldehydes, which leads to predominance of a non-planar X,O-*trans*-structure (XIVb)[94,95,171]:

(XIVa) (XIVb) (XV)

Measurements of dipole moments indicate[59] that the 2-dimethylcarbamoyl derivatives contain in the equilibrium mixture respectively 89% (furan, tellurophen), 67% (selenophen), and 44% (thiophen) of the X,O-*trans*-isomers.

Whereas the non-planar structure of these compounds is apparently due to steric effects, formation of a predominantly X,O-*trans*-structure is a consequence of X...N and X...O electrostatic interactions[95]. Crystallographic examination[198] of 5-amino-1,2,3-triazole-4-carboxamide reveals in the solid state a structure of *trans*-type stabilised by fairly strong intramolecular hydrogen bonds. Furthermore, such an $N_{(3)}$,O-*trans*-conformation is consistent with the principle of maximum distance between a negatively charged oxygen atom and the pyridine nitrogen atom of the heterocycle.

The carbothioamides possess a considerably lower energy barrier (2.4–4.4 kcal mole^{-1})[199] than the 2-carboxamides of five-membered heterocycles and pyridine, but this hinders free rotation of the thiocarbamoyl group. Dielectric measurements show that furan-2-carbothioamide exists in benzene solution as a mixture of both planar conformers in the approximate proportions 2 : 1 (excess of the S,O-*trans*-form). On the other hand, the thiophen analogue is characterised by a fivefold excess of the S,S-*cis*-conformer. On the whole these results are consistent with what is known for the corresponding formyl and carbamoyl derivatives. However, the low energy barriers and the small difference in energy of the two forms (0.2 kcal mole^{-1}) facilitate appearance of the S,S-*trans*-form in thiophen-2-carbothioamide[199].

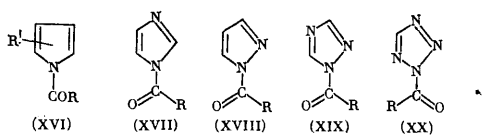
We note in conclusion that in none of the above carboxamide and carbothioamide derivatives could the coalescence point be reached (according to the ^{1}H n.m.r. spectra). This is due either to realisation of a single form (X,O-*trans*) or (more probably) to a low barrier to rotation (below 5–6 kcal mole^{-1}).[200]

Comparison of the structures of the various derivatives of carboxylic acids of five-membered heterocycles must take into account the great influence of the nature of the conformationally mobile group on the position of the conformational equilibrium. Compounds containing alkoxycarbonyl and dialkylcarbamoyl groups exhibit a shift in the equilibrium towards the X,O-*trans*-form. This is especially marked in carboxamides, with almost complete reversal of the equilibrium accompanied by a considerable lowering of the barrier to rotation and appearance of the ability to form non-planar structures. The situation is quite different with acid halides, where the state of the conformational equilibrium is determined by the halogen atom and its ability to compete with the carbonyl oxygen in attracting or repelling the heteroatom of the aromatic ring. This explains the marked difference in conformational equilibrium between acid chlorides and acid fluorides.

(b) Position of the Carbonyl Group in the Heterocycle

The remoteness of the carbonyl oxygen atom from the oppositely charged endocyclic atom X in 3-carbonyl derivatives facilitates the production of *s-trans*-conformations, which in individual cases may become the predominant or even sole form. This conclusion is confirmed theoretically for many 3-aldehydes[123,201]. Experimentally n.m.r. spectroscopy indicates[202–204] that the proportion of the *s-trans*-form in the 3-aldehydes of pyrrole, thiophen, and furan is respectively 78%, 82%, and 100%. Only introduction of a bulky (e.g. ester) substituent at position 2 in the heterocycle is able to change slightly the proportions of the conformers[203]. The structure of the latter has been confirmed by infrared spectroscopy[189] and by dielectric measurements[66,141,173,205].

The differences in the behaviour of 3-substituted furan and thiophen derivatives are explained[203] by the net effect of Coulombic (X...O_{ald}), dipole–dipole ($C_{(2)}$=$C_{(3)}$ and O=C), and resonance interactions. These three factors, acting in the same direction, lead to exclusive formation of the O,O-*trans*-modification in 3-formylfuran, but to both planar forms, with the S,O-*trans*-conformer predominating, in the thiophen analogue. Investigation of the conformations of the 3-formylselenophen gives more contradictory results. Thus the dipole moments indicate[143] that in benzene solution this aldehyde contains both conformers, in roughly equal quantities with the Se,O-*cis*-form in slight excess, whereas other dielectric measurements and proton n.m.r. spectroscopy suggest that the content of the Se,O-*cis*-form does not exceed 20%.[70,99]



In the case of pyrrole-3-aldehyde the planar N,O-*trans*-structure is the most highly populated[97,115,206,207] and apparently[147] the only form. Substituents and solvents are able merely to disturb the ratio of the conformers, but not to change the general tendency. Pyrazole-4-aldehyde, in which the formyl group is arranged approximately as in the previous compound, exists according to the ^{1}H n.m.r. spectra as an equilibrium mixture of N,O-*cis*- and N,O-*trans*-isomers[208]. The activation energy of isomerisation is smaller by 1.5 kcal mole^{-1} than for the corresponding pyrrole-3-aldehyde[208].

The content of the more stable X,O-*trans*-form in the 3-acetyl derivatives of five-membered heterocycles increases in the same sequence—from *N*-methylpyrrole through thiophen to furan—as for their formyl analogues[202]. However, the proportion of the conformers is less displaced towards this form than in the case of aldehydes: according to n.m.r. spectral results obtained by the use of shift reagents of the Overhauser nuclear effect[202] its content is on the average 52%, 56%, and 70% respectively (in the aldehydes 78%, 82%, and 97%). When the temperature is lowered to −100 °C coalescence of the signals cannot be observed in either 3-acetylfuran or 3-acetylthiophen, which indicates a low barrier to rotation in these compounds and less conjugation in 3- than in 2-substituted derivatives[185]. As in other five-membered heterocycles, the content of the X,O-*cis*-conformer in 3-acetylselenophen is double that in the 3-formyl analogue (30% and 15%).[99] 4-Acetylimidazole exists in the crystalline state solely in the $N_{(3)}$,O-*trans*-form[187].

Conformational equilibria in other 3-carbonyl derivatives of five-membered heterocycles (acids, esters, acid halides, and amides) remain almost uninvestigated.

2. *N*-Acyl Derivatives of Five-membered Heterocycles

In nitrogenous five-membered heterocycles derivatives are also possible in which a COR group is directly attached to the nitrogen atom—derivatives of pyrrole (XVI) and of azoles (XVII)–(XX)

(XVI) (XVII) (XVIII) (XIX) (XX)

The structure of *N*-acylazoles, though investigated by several workers[101–103,107,162,209–213], has not until recently received an unambiguous interpretation. Authors were one in accepting a planar structure[101,102,210–212,214], but attributed

to these compounds a *cis*-structure[101,102,107,212] or a *trans*-structure[215,216] on the basis of different methods of investigation, the contents of these forms varying within wide limits in papers by different authors[101-103,209,210].

In assessments of the conformations of *N*-acylazoles a detailed investigation was therefore made into their stereochemistry by measuring dipole moments, the Kerr effect[217], and n.m.r. spectra with the use of shift reagents[104]. Among the main conclusions[104,217] are that *N*-acetylimidazole (XVII) exists as a mixture of non-planar isomers (dihedral angle 21°) containing 75% of the $N_{(3)}$,O-*trans*-form and 25% of the N,O-*cis*-form, and that *N*-acetylpyrazole (XVIII) gives a mixture of almost planar conformers (10°) containing 90% of the $N_{(2)}$,O-*trans*-form (XVIII). A non-planar $N_{(2)}$,O-*trans*-form (dihedral angle $\phi = 30°$) is characteristic also of *N*-acetyl-1,2,4-triazole (XIX). In $N_{(1)}$-acetyl-1,2,3,5-tetrazole the $N_{(3)}$,O-*trans*-form (XX) is energetically advantageous.

Thus with all the *N*-acetylazoles studied the $N_{(2(3))}$,O-*trans*-form predominates significantly in solution. The energetic advantage of this form can be attributed to attainment of maximum distance between the negative charges of the acetyl oxygen atom and the nearest "pyridine" nitrogen atom of the azole ring. A nitrogen atom at position 2 in the azole ring leads to a greater content of the *trans*-form of *N*-acetylazole than when this atom is located at position 3. The apparent reason is strengthening of electrostatic repulsion as the acetyl oxygen atom approaches the cyclic nitrogen atom. The same factor leads to flattening of the $N_{(2)}$,O-*trans*-structure.

The influence on conformation of the cyclic nitrogen atom closest to the acetyl group is especially marked in *N*-acetyltriazole (XIX), since the $N_{(2)}$,O-*trans*-form observed for it is also a disadvantageous *cis*-form with respect to the $N_{(4)}$ atom.

These conclusions were confirmed by theoretical analysis of the stability of conformers of *N*-acetylazoles (energy of barrier to rotation, difference in energy of conformers, order of bonds in planar and orthogonal forms)[218]. In contrast to Otting's views[213] the results indicate that the rise in the frequency ν(CO) on passing from *N*-acetylpyrrole to *N*-acetylazoles is due not so much to a change in aromaticity of the heterocycles as to the non-planar structure of *N*-acetylazoles.

Among other *N*-carbonyl derivatives of pyrrole and azoles only the *N*-methoxycarbonyl derivative of the former and *N*-carboxamides of pyrazole and imidazole have been investigated[101].

3. Substituents in the Heterocycle

The chief effects of substituents on the state of conformational equilibrium in carbonyl derivatives of five-membered heterocycles can be divided into three types: (A) electronic effects of substituents are transmitted through the conjugated bond system of the heterocycle, with consequent changes in degree of conjugation of hetaryl with formyl group and in charges on heteroatoms and carbon atoms; (B) direct electrostatic or other specific interaction (e.g. hydrogen bonding of a substituent with a conformationally mobile group) tends to favour one of the forms; and (C) steric hindrance by a sufficiently bulky or closely adjacent substituent tends to prevent flattening of the system or causes a change in the state of conformational equilibrium. Separation of these factors is clearly a quite complicated task, which can be successfully accomplished only in isolated cases.

Type A

Interactions of the first type can be isolated only when the two cyclic substituents (conformationally mobile, e.g. formyl, and conformationally inert) are sufficiently far apart to exert no mutual influence. This occurs in 2-aldehydes of 4- and 5-substituted furans, thiophens, selenophens, and pyrroles.

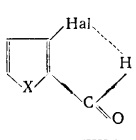
A change from electron-donor to electron-acceptor substituents produces a decrease in the proportion of the X,O-*cis*-form[42,67,219-221]. This is especially characteristic of conformationally mobile ring-substituted 2-furaldehydes. Thus for 5-substituted 2-furaldehydes the proportion of *cis*-conformer decreases from 90% to 30% in the sequence from dimethylamino through halogeno, methyl, and hydrogen to nitro[219,221]. Introduction of a 5-nitro-group leads to accumulation of the X,O-*trans*-form even in formyl derivatives of thiophen[80,135], selenophen[69,75,135], and pyrrole[23,97,147,194]. It changes the position of the conformational equilibrium in pyrrole-3-aldehyde from the pure O,O-*trans*-form to a mixture of equal quantities of the two conformers, brings their energies closer together, and lowers the barrier to rotation[97,206]. Introduction of an electron-accepting ester group has the same effect[97,206,207,211,222]. Nevertheless, in contrast to 2-furaldehyde, in the conformationally less mobile 2-aldehydes of thiophen[138,140,141,175,176], selenophen[75,80], and pyrrole[97,148,207] electron-donor substituents have little effect on the position of conformational equilibrium (in these cases almost 100% of the X,O-*cis*-form is present).

5-Substituted 2-acetylfurans, in contrast to the 2-aldehydes, exhibit no clear electronic effects of substituents on the position of conformational equilibrium: electron-donor and electron-acceptor substituents lower the relative content of the X,O-*cis*-form[223].

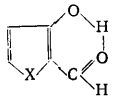
Substituents at positions 4 and 5 have hardly any effect on the conformations of 2-formyl- and 2-acetyl-thiophens: these derivatives exist in solution[67,92,124,140,176,177] and in the crystalline phase[92,175] in the single planar S,O-*cis*-form. The same situation is found with 4- and 5-substituted formylpyrroles[211].

Infrared spectra and dielectric measurements indicate[196] that 5-substituents have a significant influence on the position of conformational equilibrium in furancarboxylic acids and their chlorides: as in the case of the aldehydes, the content of the O,O-*cis*-form decreases from 100% to 41% on passing from 5-methyl to 5-nitro-derivatives.

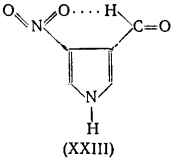
Annelation at positions 4 and 5 of the heterocycle should have had the same effect as the introduction of electron-accepting substituents[224]. However, fusion of a benzene ring usually has no significant influence on the conformational equilibrium[54,155]. Conformations similar to those considered above for formyl derivatives of five-membered heterocycles appear also in 2-aldehydes of 4,5-benzo-derivatives of thiophen[225], pyrrole[154,155], and imidazole[73,226].



Substitution in the aryl ring of *N*-methylbenzimidazole-2-aldehyde seems unable to change the state of conformational equilibrium[73], whereas ring substitution in pyrrole-2-aldehydes leads in many cases to appearance of a second conformer[159].



In contrast to *C*-carbonyl derivatives, in the corresponding *N*-derivatives benzannelation has a very substantial effect on the position of conformational equilibrium. Thus whereas in *N*-acetyl- and *N*-formyl-pyrroles the two conformations are equivalent ($\Delta H^{\neq} = 12-13$ kcal mole^{-1}),[212] two planar forms—$H_{(7)}$,O-*cis* and $H_{(7)}$,O-*trans*—can already be distinguished on passing to the corresponding indole and indazole derivatives. In this case the content of one of the conformers may vary within the range 10–90% depending on the nature of the mobile fragment and the substituent. Such



mobility of the position of conformational equilibrium in arene-annelated systems is due to steric effects and is clearly evident in derivatives of *N*-formylbenimidazole and *N*-formylindole[155]. (On further annelation—on passing to symmetrical *N*-carbonyl derivatives of carbazole—the two forms, of course, again become equivalent, as in the case of *N*-formylpyrrole[100].)

Type B

The second type of interaction of the conformationally mobile group (COR) with a substituent comprises direct (electrostatic or dipole–dipole) interaction or other specific effects of a substituent located *ortho* with respect to the COR group. In general steric and electronic effects of substituents may be superimposed on this interaction, but we can isolate quite reliably the specific effects of *ortho*-substituents.

(XXI)

(XXII)

(XXIII)

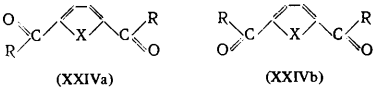
3-Alkylated and 3-halogenated (XXI) 2-aldehydes of the heterocyclic systems exist predominantly (75–100%) in the X,O-*cis*-form[44,97], but 3-hydroxy-derivatives (XXII) in the X,O-*trans*-conformation[219,227–229]. This is attributed to promotion of the X,O-*cis*-form in (XXI) by a hydrogen bond of type H...Hal, forces of repulsion $O_{carb}...Cl$,[97] and also steric effects of 3-substituents hindering formation of the X,O-*trans*-form. Similarly, a hydrogen bond of type H...O stabilises the *s*-*cis*-form of 4-nitropyrrole-3-aldehyde (XXIII)[97,194,206].

Replacement of the nitro-group by iodine leads to roughly equal contents of the two forms[194]. Such an intermediate position of the conformational equilibrium for 4-iodopyrrole-3-aldehyde is due to I...O repulsive interactions, which destabilise the N,O-*trans*-form, and to the absence of a stable intramolecular hydrogen bond between iodine and aldehydic hydrogen, sufficient to stabilise the *cis*-form[194,206].

The proportion of the O,O-*cis*-form in thiophen-3-aldehyde increases depending on the substituent, and on passing to the 4-bromo(iodo)-derivative reaches 100% owing to Br...H interaction[141,203], but in 4-hydroxythiophen-3-aldehyde falls to zero because of formation of the chelating hydrogen bond $C_{(4)}O–H...O=C$.[203] Similarly, 2-iodothiophen-3-aldehyde exists solely as the S,O-*cis*-form, as a consequence of the characteristics of I...H interaction[141].

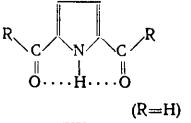
It is very significant that introduction of bromine at position 4 in selenophen-3-aldehyde also yields the Se,O-*cis*-form alone, in contrast to the unsubstituted aldehyde, which exists predominantly (80–100%) in the Se,O-*trans*-form[70].

Type C

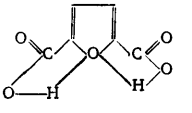


It is a complicated task to isolate in any pure form the steric influence of substituents adjacent to the aldehyde group on the ratio of the conformers, since this group is comparatively small to produce considerable steric hindrance. At the same time the bulky substituents investigated are usually extremely polar, so that their steric influence cannot be segregated from their electronic effects.

Steric effects on the position of conformational equilibrium can be traced more clearly for carbonyl derivatives of *N*-alkylated (*N*-arylated) five-membered heterocycles. The introduction of bulky substituents (e.g.t-butyl) at position 1 in pyrrole-2-aldehyde leads to accumulation of an N,O-*trans*-form or a non-planar conformer in the conformational mixture[152,153,230]. *N*-Aryl (*N*-hetaryl) substituents have a still stronger influence on the conformations of these compounds: *N*-phenyl derivatives of pyrrole[154] exist almost completely in the X,O-*trans*-form, which is not characteristic of the unsubstituted aldehydes.

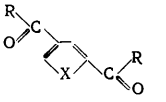


The above examples do not exhaust the whole variety of effects of substituents on conformational equilibrium in carbonyl derivatives of five-membered heteroaromatic systems.

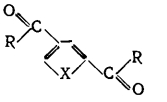


The conformations of dicarbonyl derivatives of five-membered heterocycles must also be discussed in terms of the above three effects. In fact, each carbonyl group, being an electron-accepting substituent, attracts to itself the electron density of the ring and diminishes the conjugation of the other carbonyl group with the heterosystem. Furthermore, adjacent carbonyl groups may promote formation of a particular conformer by electrostatic interaction, specific interactions (e.g. hydrogen bonding), and steric effects.

Introduction of a second carbonyl group into a heterocycle complicates the conformational problem: four conformers or three forms are formally possible in a molecule of symmetry C_2. Of the three conformers



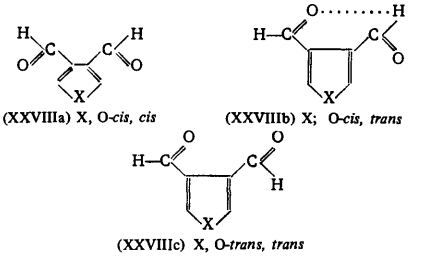
(XXIVa) (XXIVb) (XXIVc)



possible for 2,5-diformyl-thiophens[12,108,109,138,140,141,231,232] and -selenophens[70,143] two have been observed: the X,O-*cis*–*cis*-form (XXIVb) predominates or may even be present alone (when X = S)[231,232], and the content of the *s*-*cis*–*trans*-configuration (XXIVa) in the conformational mixture reaches 25%. A similar situation occurs[194,222] in the case of 2,5-diformylpyrrole, but the percentage of the *trans*–*trans*-form (XXIVc) is smaller[222]. It has been suggested[194] that this latter compound exists solely as the N,O-*cis*-form (XXV) stabilised by an intramolecular hydrogen bond.

(R=H)
(XXV)

(XXVI)

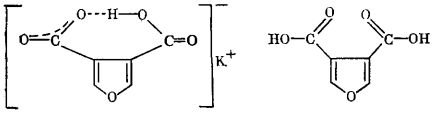


On passing from 2,5-diformyl to the corresponding diacetyl derivatives the proportion of the *s*-*cis*–*trans*-conformers (XXIVa) increases (for the thiophen derivative[140] to 55%). In 2,5-diacetylpyrrole only one carbonyl group forms the N,O-*cis*-structure, while the second is in the *trans*-position[49], which casts doubt on the possibility of a structure of type (XXV) in this case[49,222]. Diesters of 2,5-dicarboxylic acids of these heterocycles contain a mixture of roughly equal quantities of the two conformers[233] (for dimethyl tellurophen-2,5-dicarboxylate the proportion of the *cis*–*trans*-conformer[59] exceeds 50%). Furan-2,5-dicarboxylic acid itself, however, has the O,O-*trans*-structure (XXVI)[42,234].

(XXVIIa) X, O (2)-*cis*, X, O (4)-*cis*

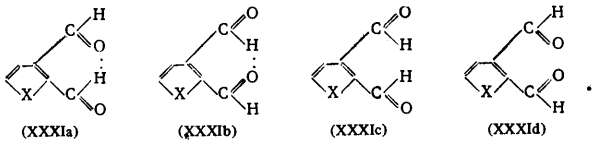
(XXVIIb) X, O (2)-*cis*, X, O (4)-*trans*

In the case of 2,4-dicarbonyl derivatives of the heterocycles only two (XXVIIa,b) of the four possible conformers are present in solution[70,97,138,143]. However, very contradictory values have appeared for their ratio[97,143,235]. Thus selenophen-2,4-dialdehyde has been regarded[143] as existing solely in the *cis*-form (XXVIIa), but has also been assigned[70] the *cis–trans*-configuration (XXVIIb). Similarly inconsistent results have been obtained for the conformations of pyrrole-2,4-dialdehydes: either the $N,O_{(2)}$-*cis*–$N,O_{(4)}$-*cis*-form[143,194] or the $N,O_{(2)}$-*cis*–$N,O_{(4)}$-*trans*-conformer (57%)[97] predominates.



The three planar structures

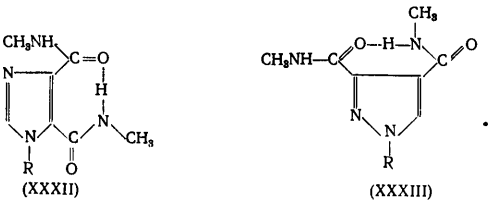
(XXVIIIa) X, O-*cis*, *cis* (XXVIIIb) X; O-*cis*, *trans*



(XXVIIIc) X, O-*trans*, *trans*

are possible in 3,4-diformylhetaryls. The structure (XXVIIIc) is energetically disadvantageous because of the strong Coulombic repulsion of the two carbonyl oxygen atoms. The more advantageous of the remaining two structures is (XXVIIIb), in which additional stabilisation by hydrogen bonding is possible. For this reason the structure (XXVIIIb) apparently predominates in thiophen-3,4-dialdehyde[138], and is the sole form in the selenophen analogue[70,143]. X-Ray results suggest that a similar structure is stabilised by a hydrogen bond also in the anion of potassium furan-3,4-dicarboxylate (XXIX)[117]. In this connection it seems strange that the O,O-*trans*–*trans*-structure (XXX) has been ascribed[236,237] to the acid itself in the crystalline phase.

(XXIX) (XXX)



Contradictory results have been obtained also on the conformers of 2,3-dicarbonyl derivatives of five-membered heterocycles. From electrostatic considerations, the most favourable conditions for intramolecular hydrogen bonding, and repulsive interactions, the conformers of 2,3-dicarbonyl derivatives should arrange themselves according to energetic stability in the sequence *cis–cis* (XXXIa) > *trans–trans* (XXXIb) > *cis–trans* (XXXIc) > *trans–cis* (XXXId)

(XXXIa) (XXXIb) (XXXIc) (XXXId)

This conclusion has been confirmed for thiophen-2,3-dialdehyde[70] and ethyl 3-formylpyrrole-2-carboxylate[194]. The view is also held that 2,3-diformyl derivatives of thiophen[138] and selenophen[143] exist predominantly in the *cis–trans*-form (XXXIc). Predominance (70%) of the *trans–cis*-configuration (XXXId) attributed[70] to furan-2,3-dialdehyde therefore appears extremely doubtful.

Results of ^1H n.m.r. infrared spectra, and also theoretical analysis have shown that bismethylamides of the imidazole (XXXII) and pyrazole (XXXIII) series have the structure[22]

(XXXII) (XXXIII)

In the *NN*-dimethylamide of thiazole-2-carboxylic acid only the S,O-*trans*-conformation is populated[200], which is surprising, as neither N,O-*cis*- nor S,O-*trans*-forms are normally characteristic of *o*-carbonyl derivatives. This can be explained both by the steric effect of the dimethylamino-group and by Coulombic attraction between this group and the sulphur atom preventing production of the traditional forms.

4. Influence of Cyclic Heteroatoms

Published information indicates that the nature of the cyclic heteroatom has a significant influence on the position of conformational equilibrium and the stereochemical rigidity of carbonyl-substituted five-membered heterocycles. Coulombic interactions between heteroatom and carbonyl oxygen have a decisive effect on the conformational rigidity of the system, since increase in the positive charge on the former in the sequence X = O, NH, S, Se is accompanied by increase in the $X...O_{CO}$ electrostatic attraction, and hence also stabilisation of the X,O-*cis*-conformer. It must be added that the negative charge on the β-carbon atoms of the heterocycle increases in the same sequence[238], which further stabilises the X,O-*cis*-form by $C_{(3)}...H_{ald}$ Coulombic interaction (in the case of formyl derivatives).

Since in butadiene derivatives the conformer with a *trans*-arrangement of the double bonds relative to the carbon–carbon single bond is thermodynamically the more stable, a similar phenomenon would be expected with carbonyl derivatives of five-membered heterocycles. Indeed, according to the Del Re criterion[243] the weakening of aromaticity in the series of heterocycles containing sulphur, selenium, imino, tellurium, and oxygen, caused by the nature of the heteroatom[71,120,239–242], should tend to increase the role of conjugation, and in the most "dienic" system (furan) lead to the highest content of the O,O-*cis*-conformer for furaldehyde. Experimentally, however, this is not observed: i.e. Coulombic X...O interaction has a greater influence than conjugation in stabilising the conformer.

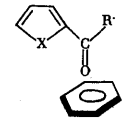
Quantum-chemical calculations[134] show some increase in energy difference between the two conformers, corresponding to stabilisation of the X,O-*cis*-form, in the series of carbonyl derivatives of furan, pyrrole, thiophen, and selenophen. Attempts to explain[162] stabilisation of certain conformers by dipole–dipole interaction between heterocycle and formyl group have not been confirmed for 2-aldehydes: thus according to theoretical calculation[134] the minimum energy of dipole–dipole interaction corresponds to the energetically less stable X,O-*trans*-conformer. Furthermore, the increases in the positive charge on and the size of the cyclic heteroatom diminish its ability to retain $p_\pi(pd_\pi)$-orbitals and simultaneously enlarge them, so that the contribution of overlap between the heteroatom orbitals and the lone pair of the carbonyl oxygen becomes somewhat greater with selenium than with sulphur; this also favours a more stable partial Se...O bond[244].

The role of the bridging heteroatom X in azole-containing systems has not been investigated separately, but on the basis of published results[73,159,160,218] conclusions can be

transferred from monoheteroatomic to azole rings. On passing from carbonyl derivatives of the fundamental five-membered heterocycles to the corresponding azoles, i.e. on replacing a cyclic methine group by a nitrogen atom, the energy difference between the conformers increases sharply[218]. In the establishment of conformations of *N*- and *C*-carbonyl derivatives of azoles both factors—Coulombic interaction of nitrogen atoms of pyridine type with carbonyl oxygen and minimisation of the energy of the system with the dipoles of the acyl group and of the ring directed antiparallel—play an important part and act together. However, electrostatic $N_{pyr}...O$ repulsion makes a decisive contribution, since on removal of the conformationally mobile group the energy difference diminishes (also the height of the barrier in the case of *N*-acetyl derivatives). In *N*-acetylazoles the "pyrazole" and "imidazole" nitrogen atoms have different roles in the establishment of certain conformers. This example reveals especially clearly the "Coulombic" nature of the stabilisation of rotational isomers. Thus, although the 3-nitrogen atom bears a considerably more negative charge than does the 2-nitrogen atom, the greater distance of the former than of the latter from the carbonyl oxygen leads to appearance of a greater proportion of the $N_{(3)}$,O-*cis*-form in *N*-acetylimidazole than in *N*-acetylpyrazole[104,217].

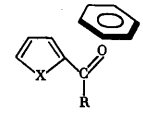
5. Influence of Nature of Solvent

The influence of the medium, mainly its polarity, on rotational isomerisation and conformational changes is well known. These results have been summarised and supported by numerous examples in an exhaustive review[6]. According to the reactive field model[6] the solvating effect of a solvent can be estimated on the basis of the Onsager theory by means of the formula



$$\Delta E_i^s = E_i^{vap} - E_i^{soln} = \frac{\mu_i^2}{a_i^3} \cdot \frac{\varepsilon_s - 1}{\varepsilon_s + 2}, \qquad (1)$$

where ΔE_i^S is the energy of solvation for the *i*th conformer of dipole moment μ_i and molecular radius a_i in a medium of dielectric constant ε_S. This equation shows that solvents of high dielectric constant have a greater solvating power and stabilise the more polar conformer. Taking into account the polarisability and the quadrupole moment of the solute molecules yields a more complete expression, regarded[6] as giving the best agreement between theoretical and observed solvation energies. A few other attempts have been made to improve the theory of solvation or to establish a new theory on the same premises[127,245-247].

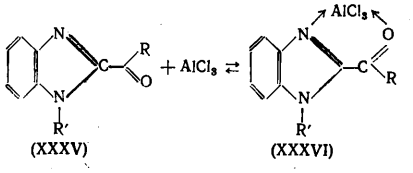


All these investigations involve several postulates restricting their application, but they support the well known rule that a polar isomer is stabilised by a polar solvent. When applied to 2-carbonyl derivatives of five-membered heterocycles, it explains the accumulation of the more polar X,O-*cis*-forms with increase in the dielectric constant of the solvent. Increase in the content of the O,O-*cis*-form with solvent polarity has been shown for 2-furaldehyde[6,202,219,248-251] and its derivatives[85,176,219], as well as for 2-acetylfuran[172] and the chloride and fluoride of furan-2-carboxylic acid[105,196,252].

Special attention should be paid to the work of Abraham[6,251], who has used his theoretical ideas to calculate energy differences between the two conformers of 2-furaldehyde and has compared the results with experimental values. On this basis he has explained the apparently contradictory results for the proportions of conformers in various media. It seems that the *s*-*trans*-form should be stabilised by polar solvents even in the case of carbonyl derivatives of thiophen, selenophen, and tellurophen, but relevant experimental results are lacking. In 2-carbonylpyrroles, on the other hand, the N,O-*trans*-conformer is more polar than the *cis*-isomer. This is why increase in solvent polarity leads in these compounds to stabilisation of the N,O-*trans*-form[97,103,123,147,206,222,253]. However, it must be borne in mind that a general solvation effect cannot explain stabilisation of the N,O-*trans*-form of 5-nitropyrrole-2-aldehyde[194,206] or the peculiar effect of benzene, which stabilises the X,O-*cis*-form of carbonyl derivatives of five-membered heteroaromatic systems more than would be expected from its dielectric constant[6,251] and several other factors[197,219,228].

All these phenomena can be explained by specific solvation effects. Thus the stabilising influence of benzene can be attributed[92] to its electron-accepting properties with respect to carbonyl oxygen. The steric accessibility of the latter is greater in the X,O-*cis*-form (XXXIVa) than in the X,O-*trans*-form (XXXIVb).

(XXXIVa)



(XXXIVb)

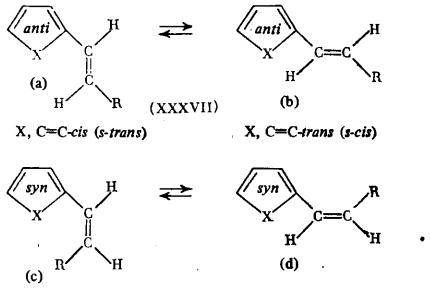
Another example of the specific effect of a solvent on the position of conformational equilibrium is its ability to form intermolecular hydrogen bonds with the solute. Thus dielectric measurements indicate that pyrrole-2-aldehyde contains less of the *s*-*cis*-conformer in dioxan than in benzene solution (73% and 86%). This is attributed[194] to the proton-accepting properties of dioxan, which tend to break the NH...OC type of intramolecular hydrogen bond that usually stabilises the N,O-*cis*-form. Indeed, the content of the *cis*-form of pyrrole-2-aldehyde in dioxan is close to that for *N*-methylpyrrole-2-aldehyde. Similarly, whereas the S,O-*trans*-form of 3-hydroxythiophen-2-aldehyde, stabilised by an intramolecular hydrogen bond, appears in inert solvents[219,228], in proton-accepting solvents the hydrogen bond is broken with formation of the S,O-*cis*-structure.

6. Complex Formation

Interaction with Lewis acids influences significantly the conformations of stereochemically non-rigid systems and in several cases leads to stabilisation of isomers that are uncharacteristic of the free molecules used as ligands. An attempt to relate theoretically the complex-forming power of conformationally mobile ligands with their three-dimensional structure has shown[254] that complex formation is accompanied by a change in conformation only when the sum of the free energies of complex formation and solvation of the complex exceeds in absolute magnitude the sum of the energies of desolvation of the metal ion and the ligand and of spatial reorientation of the latter. This general principle is valid also for carbonyl derivatives of five-membered heterocycles[159,255-258]. Thus the coordination of aluminium chloride yields well defined conformers of 2-formyl derivatives of furan[257] and thiophen[258,259] as well as 2-acetylthiophen[258]. In the case of 2-carbonylazole derivatives complex formation with aluminium chloride may convert the X,O-*cis*-form (XXXV) into

the *trans*-conformation (XXXVI):

(XXXV) (XXXVI)

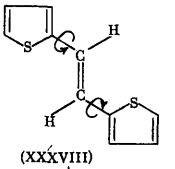


With 2-acetylbenzimidazole (XXXV: R′ = H, R = CH_3), in which the *cis*-form is stabilised by an intramolecular hydrogen bond of type NH...OC, however, this inversion of conformations is not observed. Similarly, conformations characteristic of uncoordinated carbonyl-azoles are preserved[159] even in their complexes with Lewis acids weaker than aluminium chloride—titanium tetrachloride and indium trichloride.

It must be emphasised that many shift reagents are also able to form complexes with carbonyl derivatives of heterocycles. Therefore conclusions concerning the conformations of the above stereochemically non-rigid systems, based on n.m.r. results obtained with the use of shift reagents, must be approached with great caution.

IV. CONFORMATIONAL PROCESSES IN SERIES OF STRUCTURAL ANALOGUES OF CARBONYL DERIVATIVES OF FIVE-MEMBERED HETARYLS

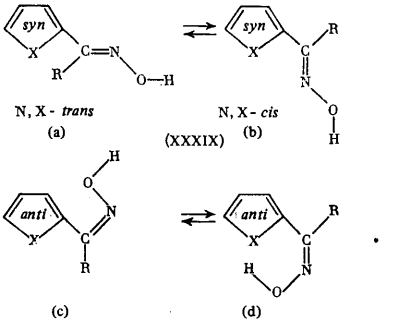
Among structural analogues of the above carbonyl compounds can be included heterocycles containing in the side-chain ethylenic, azomethine, oxime, or thiosemicarbazone groups directly attached to the ring by a single bond. The justification for such inclusion is not only that many of these compounds are obtained from carbonyl derivatives but mainly also that they resemble the latter in possessing multiple bonds capable of conjugation with the heterocycle, so that *s-cis–trans*-isomerism about the single bonds becomes possible.



Among representatives of these compounds are hetarylethylenes containing additional substituents attached to the ethylene group and therefore capable not only of *s-cis–trans*-conformational changes but also *syn–anti*-isomerism, e.g.

(XXXVII)

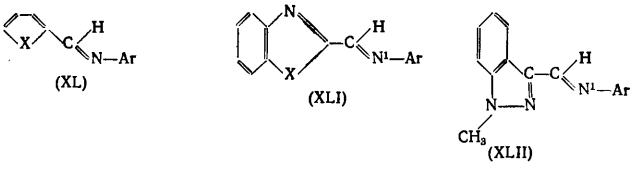
X, C=C-*cis* (*s-trans*) X, C=C-*trans* (*s-cis*)



2-Vinyl-furans and -thiophens exist in solution[260–262] solely or predominantly as the *anti*-X,C:C-*cis*-conformer (XXXVIIa), whereas their styryl analogues[235] are present almost completely as the planar X,C:C-*trans*-conformer (XXXVIIb). In the latter the hetaryl and phenyl groups are arranged *anti* with respect to the ethylenic group. If, however, they are located in *syn*-positions, the aryl rings diverge from the ethylene plane because of steric effects. A similar situation is observed with ethylenic derivatives of five-membered heterocycles, i.e. substituted 2-vinyl-furans, -thiophens, and -pyrroles[264–266]. *anti*-1,2-Dithien-2′-ylethylene

(XXXVIII)

exists in the crystalline state as the S,C:C-*cis*-form, with each of the thienyl groups diverging by ~32° from the ethylene plane[267].

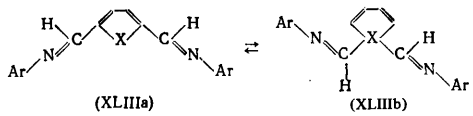


In the crystalline state 5-vinylimidazole exists as a mixture of both planar forms[268]. The thiophen analogues of chalcones exist exclusively in the S,O-*cis*–S,C:C-*cis*-form[269–272], except when a sufficiently bulky substituent is present at position 3 in the heterocycle[270]. Oximes of aldehydes of five-membered heterocycles are also able to exist in two stable isomeric forms—*syn* and *anti* (XXXIXa–d)—for each of which in turn two planar forms—N,X-*cis* and N,X-*trans*—are possible[126]:

N,X-*trans* (a) N,X-*cis* (b) (XXXIX)

(c) (d)

Investigations on oximes of furan (X = O, R = H) by n.m.r. and infrared spectroscopy together with quantum-chemical results have shown[126,273–275] that the N,O-*trans*-conformer is energetically advantageous for the *anti*-form ($\Delta H_{cis-trans}$ = 1.7 kcal mole^{-1} calculated by INDO), and is exclusively present in solution. In contrast, the *syn*-isomer is characterised by the simultaneous presence of two conformers with some predominance of the N,O-*cis*-form (59%), which is energetically more advantageous[276].



(XL) (XLI) (XLII)

All azomethines containing a five-membered heterocycle as the aldehydic moiety retain the X,N-*cis*-conformation (e.g. (XL)[277] and (XLI)[278,279]) characteristic of the corresponding formyl derivatives¶. Yet an *s-trans–trans*-conformation (XLII) has been very unexpectedly reported[280] for azomethines of 1-methylindazole-3-aldehyde. Equilibrium between the X,N-*cis–cis*-form (XLIIIa) and the X,N-*cis–trans*-form

¶ It must be stressed than anils of six-membered heteroaromatic systems are characterised by the N,N-*trans*-conformation[277].

(XLIIIb) has been found with dianils of thiophen-2,5-dialdehyde:

(XLIIIa) (XLIIIb)

In nitro-derivatives of these compounds the contents of the conformers vary within wide limits (100–40% of the *cis–cis*-form) depending on the position of the nitro-group in the aryl fragment[140]. Removal of the heteroatoms—the cyclic X and oxygen of the N → O group in aldonitrones (VII)

facilitates the appearance of X,O-*trans*-conformers in comparison with the corresponding aldehydes[281,282].

Investigation of the stereochemistry of 2-formylthiophen derivatives[283] suggests that thiosemicarbazones retain the same *cis*-structure as do 2-aldehydes of five-membered heteroaromatic systems.

V. CONCLUSION

Combination of all the above results, despite some inconsistency and in some cases inadequate experimental confirmation, enables several general conclusions to be drawn on the state of the conformational equilibrium in carbonyl derivatives of five-membered heterocycles.

Firstly, there is no doubt of the existence of two planar isomers (*s-cis* and *s-trans*) in the great majority of 2-carbonyl derivatives of furan in solution, with the exception of those cases in which, under the influence of substituents or external conditions, appearance of one of the conformers is energetically disadvantageous or sterically impossible. With few exceptions, but with the same reservations, the corresponding thiophen and selenophen derivatives exist solely in the X,O-*cis*-form. Carbonyl derivatives of tellurophen and pyrrole are conformationally more mobile than those of thiophen, but less mobile than the furan derivatives.

Secondly, several carbonyl derivatives of five-membered heterocycles, in particular ketones, are characterised in most cases by a non-planar structure, with the phenyl group in hetaryl phenyl ketones usually diverging considerably from the trigonal carbonyl plane, while the heterocyclic group is less non-coplanar owing to Het–CO conjugation.

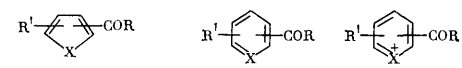
Thirdly, the predominant structure in all carbonyl derivatives of azoles is that in which the carbonyl oxygen atom and the pyridine type of cyclic nitrogen atom are as far apart as possible.

In all cases the predominant structure in carbonyl derivatives of five-membered heteroaromatic systems is governed by Coulombic interaction between the nearest heteroatoms and the carbonyl oxygen atom. Other factors—conjugation between carbonyl and heterocycle, compensation of dipole moments in one of the forms, etc.—can merely be superposed on the dominant Coulombic effect, which is either strengthened or weakened. Despite the many studies of the stereochemistry of carbonyl derivatives of heteroaromatic systems, they exhibit several defects.

1. Compounds have been chosen for investigation without sufficient regard to their relevance. With respect to thoroughness of study (apparently depending on synthetic difficulties) we have, for the same conformationally mobile groups (COR) but different heteroatoms X, the **sequence** O ≈ S ≫ NR > Azoles > Se > Te. The corresponding **sequence** for identical heterocycles but different COR groups is

$$CHO \gg COAlk > COAr > COOH > COHet > COHal > CONH_2 \gg COF.$$

Although the use of carbonyl derivatives of five-membered heterocycles in which X is an element from subgroup VI*b* can be accepted as satisfactory, heteroaromatic systems based on Group V are represented only by nitrogen (pyrrole, azoles).



2. Only isolated studies have been made of the influence of external factors (temperature, general and specific solvation, complex formation, state of aggregation) on the position of conformational equilibrium.

3. A weak point is the heterogeneous character of quantitative data on the stereodynamics of *s-cis–trans*-isomeric processes, with inadequate application of quantum-chemical calculations.

4. Too few conclusions on the position of conformational equilibrium have been reached on the basis of the aggregate results of diverse physicochemical and mathematical methods with the use of reliable schemes of theoretical calculation.

All the above defects constitute the main reason for inadequate conclusions concerning the stereochemistry of carbonyl derivatives of five-membered heteroaromatic systems.

In our opinion future research in this field should be concentrated on a more detailed study of the relation between the fine structure of the heterocyclic system and the conformations of carbonyl derivatives. For this purpose the range of compounds studied should include carbonyl derivatives of phosphole, arsenole, and antimonole (XLIV)[284,285].

X = PR^{11}, AsR^{11}, SbR^{11} (XLIV) X = N, P, As (XLV) X = O, S, Se (XLVI)

However, if we approach the more general problem—of studying the stereochemistry of carbonyl derivatives of heteroaromatic systems and their analogues—with use of the information in the present Review and without restriction to results for pyridine derivatives we must investigate the stereodynamics of carbonyl derivatives of six-membered heterocycles (XLV) and (XLVI) and also larger heterocycles[241, 286,287]. The remaining directions of research are clear: the defects formulated under (1)–(4) above must be eliminated (ways for achieving this are quite well known to chemists).

The present survey of *s-cis–trans*-isomerism in five-membered heterocycles shows convincingly that the fine structure of a stereochemically non-rigid system, and also intra- and inter-molecular interactions, are the main factors responsible for the conformations of *s-cis–trans*-isomeric systems. Detailed analysis and generalisation of published information in this field are necessary for the reliable establishment of stereochemically non-rigid structures for various classes of chemical compounds.

The Chemistry of Antitumour Platinum Complexes

A.I.Stetsenko, M.A.Presnov, and A.L.Konovalova

The antitumour activities of platinum complexes have been characterised in connection with their composition, structure, and properties. A relation has been established between the antiblastoma properties of platinum complexes and the charge and nature of neutral and acido-ligands, the geometrical configuration, and the degree of oxidation of the central atom. Hypotheses are put forward concerning the mechanism of the antitumour activity of platinum complexes. The prospects for the application of platinum and other platinum metal complexes in tumour chemotherapy are assessed.
The bibliography includes 131 references.

I. INTRODUCTION

In many biologically active substances such as haemoglobin, chlorophyll, vitamin B_{12}, and certain enzymes the coordinating atom and active centre is a metal (iron, magnesium, cobalt, copper, zinc, etc.). The need for a comprehensive investigation of the biological activities of complexes, particularly their antitumour properties, is therefore fully justified. The possibility of a wide-scale expansion of such research is supported by the present vast accumulation, in coordination chemistry, of experience on the synthesis of complexes of different metals differing in structure and complexity.

After the publication in 1912 of the communication of Neuberg et al.[1], numerous studies have been carried out in many countries on the search for antitumour substances among metal-containing compounds. In the Soviet Union much work has been done in this field by investigation at the Kiev School of experimental Oncologists, in particular by Magat and coworkers[2], who studied the antitumour properties of the iron tartrate complex. Unfortunately active agents could not be discovered and interest in this branch of the chemotherapy of malignant tumours began to flag. However, in their reviews Larionov and Vermel'[3,4] emphasised that this field should not be forgotten and they believed it useful to investigate metal coordination compounds as potential antitumour agents.

In recent years considerable advances in the search for antitumour preparations were made in the study of organic compounds—alkylating agents, antimetabolities, antibiotics, and plants alkaloids[5,6]. The search for new antitumour prepations has therefore been carried on mainly among these compounds: thus among the 150 000 substances tested at the National Cancer Institute of the USA up to 1970, only 20 were inorganic[7].

The discovery in 1969 by Rosenberg et al.[8] of powerful antitumour properties in *cis*-dichlorodiammineplatinum(II) (henceforth it will be abbreviated to DDP), which is an inorganic substance known since the past century, aroused fresh interest among chemotherapists in metal complexes, particularly platinum complexes. The DDP complex exhibited a pronounced effect on a number of animal and human tumours[9,10].

Since then an intensive search for new antitumour substances has begun in many laboratories of various countries among platinum complexes and studies on the mechanism of their action have been expanded. At the National Cancer Institute of the USA alone approximately 500 different platinum complexes have been investigated towards 1977 [11] and oncological clinical tests have been carried out on five compounds. With each year, the intensity and scale of research into this field of cancer chemotherapy has consistently increased, new laboratories continuously joining in the search. Three International Congresses have been held and more than 1000 communications dealing with various aspects of the antitumour activity of platinum complexes (and certain other metal complexes) under experimental and clinical conditions have been published. Rational ways of synthesising active preparations incorporating coordination compounds are being sought.

On the basis of the authors' own research and literature sources, this review deals with certain problems of the chemistry of platinum complexes with antitumour properties. Particular attention has been devoted to the interrelation between the structure and activity of the compounds, which is one of the most important problems in chemotherapy. The review uses surveys, reports, and symposium and conference proceedings published in recent years[7-10,12-17].

II. CHARACTERISTICS OF THE ANTITUMOUR ACTIVITIES OF PLATINUM COMPLEXES IN RELATION TO THEIR CHEMICAL STRUCTURE AND PROPERTIES

1. Discovery of the Antitumour Activity of Platinum Complexes

The first systematic studies on the antitumour activities of platinum and certain other metal complexes were begun in the USA and the USSR. Using as ligands active antitumour antimetabilities which have already been tested—6-mercaptopurine (Hmp) and butylthiopurine (Butp), Kirschner et al.[18] observed in 1966 the effectiveness of the complexes $Na_2[Pt.(Hmp)_2Cl_4].2H_2O$ and $[Pd(Butp)_3Cl]Cl$ against two strains of mouse tumours. At the same time in 1965–1966 the activity of a number of compounds, particularly platinum and palladium complexes of 6-mercaptopurine and 5-fluorouracil as well as the gold complex of 6-mercaptopurine, was studied at the Institute of Experimental and Clinical Oncology on the Academy of Medical Sciences of the USSR (which has since become the All-Union Oncological Scientific Centre of the

Academy of Medical Sciences of the USSR).[19,20] The palladium and gold complexes of 6-mercaptopurine showed the greatest therapeutic effect:

$[Pd(Hmp)_2]SO_4$—80–92% inhibition of adenocarcinoma AK-755, 50–60% inhibition of Sarcoma 180.
$[Au(Hmp)_3]Cl$—90–95% inhibition of AK-755.

Unfortunately in the above studies[18,20] no advantages were discovered in the activities of the complexes compared with the free antimetabolities and these studies are therefore of merely theoretical interest.

The discovery by Rosenberg of the antiblastoma activity of DDP [8] attracted the attention of investigators to this field and stimulated further search for antitumour agents among metal complexes. By studying the effect of the electric field on a culture of *E.coli*, the authors observed in 1965 the cessation of cell division and the occurrence of unbalanced growth, which was reflected in the lengthening of the microorganisms by a factor up to 300 (the formation of the so-called filamental forms of the bacteria)[21]. The electrolysis was carried out with the aid of platinum electrodes and the nutrient medium contained NH_4Cl, Na_2HPO_4, KH_2PO_4, NaCl, $MgCl_2$, Na_2SO_4, and other ingredients. The study showed that during electrolysis platinum dissolves with formation of a non-electrolytic platinum(IV) complex with a *cis*-structure, which is subsequently reduced in the light to *cis*-$[Pt(NH_3)_2.Cl_2]$ and the latter compound showed a biological activity.

The result of the above investigation[21] was confirmed in a study of the direct effect of *cis*-$[Pt(NH_3)_2Cl_2]$ on tumours[8]. The complex *cis*-$[Pt(NH_3)_2Cl_2]$ (in physiological solution) was administered intra-abdominally on a specific day after transplantation of the tumour; after a time, the mice were killed and the tumour was cut out. The efficiency of the preparation was estimated by comparing the average weight T of the tumours cut out from a batch of mice subjected to chemotherapy and the average weight K of the tumours in mice of a control group; the smaller the ratio T/K, the greater the inhibiting effect of the complex. The following data were obtained in experiments with Sarcoma 180:

Complex	$[Pt(NH_3Cl)_2]$	$[PtEnCl_2]$
Maximum tolerance dose (MTD), mg kg^{-1}	8	16
T/K, %	1	27

Here En is ethylenediamine. The best result was produced by the complex $[Pt(NH_3Cl)_2]$, for which T/K = 1%, which corresponds to 99% inhibition of the growth of the tumour. A considerable proportion of the animals were completely cured. As a result of the primary selection, Rosenberg concluded that non-electrolytic platinum(II) complexes with a *cis*-structure, containing two molecules of a neutral inert ligand (NH_3, amine) and two anions of moderate lability (preferentially Cl^- ions), are biologically active. After a comprehensive experimental investigation of the therapeutic activity and side effects, DDP was subjected to clinical tests and has found extensive applications in the treatment of a number of human tumours, particularly in combination with other antitumour agents[10,22–24].

2. Geometrical Configuration of Non-Electrolytic Platinum(II) Complexes and their Antitumour Activity

Table 1 presents data for the antitumour activities and selectivities of the action of isomeric diacidodiamineplatinum-(II) complexes in relation to two strains of transplantable mouse tumours[7]. The antitumour activity of the complexes administered intra-abdominally single in the maximum tolerance dose (MTD), on Sarcoma 180, was determined 10 days after the injection and was expressed as a percentage inhibition of the growth of the neoplasm. The selectivity of the action of the substances was investigated on mice with plasmacytoma ADJ/PC6 using the same schematic arrangement of the experiments and was expressed by the therapeutic index $TI = LD_{50}/ED_{90}$, where ED_{90} is the effective dose resulting in 90% inhibition of the growth of tumours on the tenth day after injection. The higher the TI, the greater the antitumour activity and the smaller the toxic effect of the substance on the organism.

The data presented in Table 1 in relation to isomeric complexes with different amines and acido-ligands fully confirmed the conclusion that, when the complex exhibits antiblastoma activity, the latter is characteristic only of the *cis*-isomer; the *trans*-isomers have no antitumour properties (TI = 1).

Since this conclusion is general, the search for new antitumour platinum preparations attention was concentrated on the synthesis of non-electrolytic compounds with the *cis*-structure (Table 2). Such complexes are obtained particularly readily when potassium or sodium chloroplatinites are treated with bidentate amines which combine with platinum like ethylenediamine. Among them, complexes with 1,2-diaminocyclohexane proved to be the most promising.

Table 1. The influence of the geometrical isomerism of non-electrolytic platinum(II) complexes on their antitumour activities[7,17].

Complex	Medium	Dose range, mg kg^{-1}	Toxic limit, mg kg^{-1}	T/K, %	Dose, mg kg^{-1}
cis-$[Pt(NH_3Cl)_2]$	*S*	0.5—20	8	1	8
trans-$[Pt(NH_3)_2Cl_2]$	*S*	2.5—40	40	85	2.5—40
cis-$[Pt(CH_3NH_2Cl)_2]$	*S*	10—30	12—20	25	15
trans-$[Pt(CH_3NH_2)_2Cl_2]$	*S*	5—100	25	100	5—20
cis-$[Pt(C_2H_5NH_2Cl)_2]$	*S*	5—50	45	14	40
trans-$[Pt(C_2H_5NH_2)_2Cl_2]$	*S*	5—20	20	105	5—20
cis-$[Pt(NH_3Br)_2]$	*B*	5—20	15	30	14
trans-$[Pt(NH_3)_2Br_2]$	*B*	10—40	40	110	10—40

ADJ/PC_6 plasmacytoma

Complex	Medium	Dose range, mg kg^{-1}	LD_{50}, mg kg^{-1}	ED_{90}, mg kg^{-1}	TI
cis-$[Pt(NH_3Cl)_2]$	*A*	0.1—40	13.0	1.6	8.1
trans-$[Pt(NH_3)_2Cl_2]$	*A*	0.1—40	27.0	>27.0	<1.0
cis-[Pt( $NHCl)_2$]	*A*	2.5—160	56.5	2.6	21.7
trans-[Pt( $NH)_2Cl_2$]	*A*	2.5—160	18.0	>18.0	<1.0
cis-[Pt( $NHCl)_2$]	*A*	3—200	140	10.8	13.1
trans-[Pt( $NH)_2Cl_2$]	*A*	3—200	72	>72	<1.0

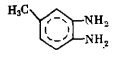
Notation: *S* = 0.13 M NaCl; *B* = 0.04 M NaBr; *A* = suspension in groundnut oil.

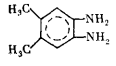
It is seen from the data in Table 2 that, despite their *cis*-configuration†, some of the complexes show little activity in relation to the plasmacytoma (TI ≅ 2).

† We shall either indicate the geometrical configuration of the isomers (*cis*- or *trans*-) or shall employ the coordination formulae, for example *cis*-$[Pt(NH_3Cl)_2]$ and *trans*-$[Pt(NH_3)_2.Cl_2]$.

3. The Nature of the Acido-Ligand in the *cis*-Isomers

Among the complex *cis*-non-electrolytes with monodentate acido-ligands, the chloride ligands exhibit a high activity. Thus, in relation to sarcoma 180, the activity varies in the following sequences[7]:





$$[Pt(NH_3X)_2]$$

X:	$Cl^- > Br^- > SCN^- > NO_2^- > I^-$				
T/K:	1	30	70	99	110

$$[PtEnX_2]$$

X:	$Cl^- > Br^- > NO_2^- > I^- \cong SCN^-$				
T/K:	4	31	71	82	83

Table 2. The activities of certain new complexes of the type $[PtLCl_2]$ with bidentate ligands against plasmacytoma ADJ/PC6.[25–27]

Ligand L	LD_{50}, mg kg^{-1}	ED_{90}, mg kg^{-1}	TI
	14.1	2.1	6.9
	48	2.4	20
	22.5	3.7	5.3
	283	2,5	113
	180	90	2

The Pt–X bond strength increases from Cl^- to I^-, which can be seen from the decrease of the overall instability constant and the decrease of the positive standard free energy:

	$[PtCl_4]^{2-}$	$[PtBr_4]^{2-}$	$[PtI_4]^{2-}$	References
K_{inst}	$2.5 \cdot 10^{-17}$	$4 \cdot 10^{-21}$	$2.5 \cdot 10^{-30}$	[28,29]
ΔG°, kcal mol^{-1}	+ 34.40	+ 31.80	+ 18.40	[30]

Note. The numbers in square brackets denote references (Ed.of Translation).

These data indicate the opposite variation of the Pt–X bond strength and the activity of the complex. Complexes with carboxylate ions bound as bidentate species, of the type $[Pt(NH_3)_2X$ and $[PtEnX]$, exhibit an appreciable activity, malonate and substituted malonate complexes (T/K = 7–12%) being more active than the oxalate complexes (T/K = 25–26%).[7] It was found unexpectedly that, in contrast to $[Pt(NH_3)_2 \cdot (C_2O_4)]$, the complex $[PtEn(C_2O_4)]$ exhibits a curare-like activity, like the aquo-cationic complexes. Under the usual conditions, $[PtEn(C_2O_4)]$ is not hydrolysed; the complex apparently undergoes enzymatic hydrolysis in the organism. The compounds $[Pt(NH_3)_2(N_2O_2)]$ and $[PtEn(N_2O_2)]$ were the first complexes with a cyclic acido-ligand, namely the hyponitrite ion $N_2O_2^{2-}$, to be isolated[31].

The antitumour activities of these compounds were studied in relation to three strains of transplantable mouse tumours: adenocarcinoma 755, the Lewis lung cancer (LLC), and leukaemia L-1210. The complexes were dissolved in a physiological solution and were administered to mice intra-abdominally in the maximum tolerance doses. The activity of both hyponitrite complexes was tested on adenocarcinoma 755 (73–80% inhibition of the growth of tumour in relation to the control). In constrast to $[PtEn(C_2O_4)]$, the complex $[PtEn \cdot (N_2O_2)]$ does not exhibit neurotoxicity[32].

The influence of the nature of the acido-ligand on the antitumour activities on a series of non-electrolytic *cis*-complexes of platinum(II) with 1,2-diaminocyclohexane have been studied in detail[33,34] in relation to 15 acido-ligands (Table 3). The activity M was estimated from the formula

$$M = \frac{LD_{50} \times ILT_{opt}}{ID_{99.9} \times 100},$$

where $ID_{99.9}$ is the dose killing 99.9% of the tumour cells and ILT_{opt} is the optimum increase of lifetime (expressed as a percentage). The greater the value of M, the higher the activity of the complex.

Table 3. The activities of non-electrolytic *cis*-complexes of platinum(II) with 1,2-diaminocyclohexane and various acido-ligands against lympholeukaemia L-1210.[33,34]

Ligand	SO_4^{2-}	OH^-	$B_4O_7^{2-}$	$C_2H_5SO_4^-$	$NH_2SO_3^-$	NO_3^-	Cl^-
M, %	100	80	70	50	30	22	18
Ligand	HPO_4^{2-}	SO_3^{2-}	BrO_3^-	SeO_4^{2-}	SiF_6^{2-}	NO_2^-	CNO^-
M, %	14	14	32	7	3	1	0

The sulphide complex is the most active (M = 100%). In this case complexes with less strongly bound acido-ligands also proved to be more active; the activity decreases in the sequence $SO_4^{2-} > B_4O_7^{2-} > C_2H_5SO_4^- > NO_3^- > Cl^-$. The change in the nature of the acido-ligand is reflected not only in the bond strength but also in the solubility of the complex, which influences in its turn its antitumour properties. The complexes of this series are in most cases more soluble and more active.

4. The Nature of the Amine in the *cis*-Isomers

The replacement of NH_3 by amines of different structure greatly alters the activity of the complex; an idea about this can be obtained from Table 1. Thus, in relation to sarcoma 180, the aliphatic amines CH_3NH_2 and $C_2H_5NH_2$ lower the activity of the complex. Aniline and pyridine have little effect on the activity.

The plasmacytoma ADJ/PC6 proved to be extremely sensitive to the nature of the amine in *cis*-$[Pt(ACl)_2]$. Table 4 presents data for the activities of complexes of this type containing NH_3, methyleneamine, heterocyclic bases (aziridine and pyrrolidine), and a number of alicyclic amines (the complexes with amines are sparingly soluble in water and were administered to mice intra-abdominally in the form of a suspension in grount-nut oil). The replacement of NH_3 by heterocyclic bases improved the result by a factor of 2–3. The activity increases particularly markedly following the introduction of alicyclic amines: TI increases up to 200 (cyclopentylamine) or 267 (cyclohexylamine). The increase

of TI is caused by the sharp reduction of the toxicity of the complexes: LD_{50} is 3200 mg kg^{-1} for cyclohexylamine and 13 mg kg^{-1} for NH_3, but the inhibiting activity (ED_{90}) changes only slightly.

Table 4. The influence of the nature of the amine on the antitumour activities of non-electrolytic *cis*-complexes of platinum(II) against plasmacytoma ADJ/PC6.[7,26]

Amine	LD_{50}, mg kg^{-1}	ED_{90}, mg kg^{-1}	TI
The complexes $[Pt(ACl)_2]$			
NH_3	13.0	1.6	8.1
CH_3NH_2	18.5	18.5	1.0
	56.5	2.6	21.7
	140	10.8	13.1
	56.5	2.8	24.6
	67	6	11
	480	2.4	200
	3200	12	267
	625	1.8	35
	660	230	2.9
The complexes $[PtACl_2]$			
	14.1	2.1	6.9
	48.0	2.4	20.4
	283	2.5	113

Such high therapeutic indices are not enountered among other antitumour preparations. The result is hopeful, since, by altering the composition of the complex, it is possible to obtain fairly effective and relatively non-toxic preparations. The disadvantages of the complexes with alicyclic ligands are their low solubility, which hinders their clinical use and a narrower therapeutic spectrum than for DDP; thus their activity in relation to Sarcoma 180 and L-1210 is low. The complex with cyclopentylamine exhibits the most comprehensive activity. The complexes with alicyclic diamines (1,2-diaminocyclohexane) are also active in relation to L-1210. At the same time, one should note that in many instances it is difficult to reach unambiguous conclusions concerning the influence of the nature of the amine or the substituent on the activity of the complex, the effect depends on the tumour strain. For example, $[Pt(PyCl)_2]$ [35] is active towards Ehrlich ascites carcinoma but its activity towards Sarcoma 180 is low. The activity of the complex is also sensitive to the structure of the ligand: the complex $[PtLCl_2]$ containing *trans*-1,2-diaminocyclohexane is more active than the complex with *cis*-1,2-diaminocyclohexane, the activity being a maximum for the complex with the laevorotatory *l-trans*-isomer[36].

In coordination chemistry the reactivity of complexes is usually attributed to the electronic structure of the ligands—their σ-donor and π-acceptor properties. It is difficult to make a comparison of this kind for the antitumour activity, since the latter is determimed not only by chemical and physicochemical characteristics but also by other factors—the lyophilic and lyophobic properties of the complexes, the permeability of cell membranes to them, and pharmacokinetic parameters.

5. The Solubility of the *cis*-Non-Electrolytes

The majority of dichlorodiamineplatinum(II) complexes are sparingly soluble in water and yet a fairly high solubility of complexes is necessary for intravenous injections. The efforts of investigators have therefore been directed to the synthesis of soluble active complexes (Table 5).

Table 5. The influence of the acido-ligand and substituents on the solubilities of the complexes in water at room temperature (L = 1,2-diaminocyclohexane).[7,26,30]

Complex	Solubility, g/100 ml H_2O	Complex	Solubility, g/100 ml H_2O
$[PtEnCl_2]$	0.08	$[Pt(NH_3Cl)_2]$	0.22
[PtEnmal]	1.00	$[Pt(NH_3)_2mal]$	0.04
$[PtEn(C_2H_5\text{-mal})]$	0.10	$[Pt(NH_3)_2(CH_3\text{-mal})]$	0.25
$[PtLCl_2]$	0.10	$[Pt(NH_3)_2(C_2H_5\text{-mal})]$	0.59
[PtLmal]	0.5	$[Pt(\text{iso-}PrNH_2)_2Cl_2]$	0.10
[PtL(OH-mal)]	1.5	$[Pt(\text{iso-}PrNH_2)_2mal]$	3.50

Table 6. Comparison of the solubilities of complexes of the types $[PtL'X_2]$ and $[PtL''X_2]$ (L' = 1,2-diaminocyclohexane and L'' = *o*-phenylenediamine) and their antitumour activities (against L-1210).[37,38]

X in complex $[PtL'X_2]$	Solubility at 25 °C, mg ml^{-1}	M, %	X in complex $[PtL''X_2]$	Solubility at 25 °C, mg ml^{-1}	ILT, %
$BrCH_2COO^-$	1	200	$1/2\ SO_4^{2-}$	5	100
$1/2\ SO_4^{2-}$	3	100	NO_3^-	5	48
$1/2\ mal^{2-}$	0.5	23	$BrCH_2COO^-$	5	43
Cl^-	0.1	18	$1/2\ mal^{2-}$	0,25	23

An increase of the solubility in water can be achieved in the following way: (1) by replacing Cl^- ions by cyclic carboxylate ions, for example malonate and its derivatives; (2) by introducing hydrophilic groups into the ligand; (3) by employing less strongly bound acido-ligands; (4) by using platinum(IV) complexes (but not in all cases). The replacement of $2Cl^-$ by mal^{2-} in the complexes where L = 1,2-diaminocyclohexane or other diamines increases the solubility by a factor of 5–10 (Table 6). This has also been observed to a lesser extent for ammines (with the exception of the replacement of $2Cl^-$ by mal^{2-}). The reason is apparently that in the case of a cyclic acido-ligand the intermolecular bonds are weakened and the lattice energy is lower.

The introduction of an organic substituent (C_2H_5) lowers the solubility of the complex and the introduction of the lyophilic OH group increases it. The increase of the hydrolysability of the complex in the case of less strongly bound ligands (SO_4^{2-} and NO_3^-) also promotes an increase of the solubility of the complexes with 1,2-diaminocyclohexane [33,34,37,38] (Table 6).

The activities of the complexes $[PtL'X_2]$ increases in the following sequence of L': $\frac{1}{2}SO_4^{2-} > OH^- > \frac{1}{2}B_4O_7^{2-}$; their solubilities in water at 40 °C decrease in the same sequence[33]. Hence one can conclude that the more soluble complexes are more active. However, this is not always so; in a series of complexes with branched aliphatic amines and alicyclic amines the less soluble complex is less toxic and therefore has a higher therapeutic index TI.[27]

The antitumour activities have been compared with non-aqueous, lipid solubilities, since the latter are related to the permeability of the membranes to the complexes. For this purpose, the solubilities of the complexes are determined in 1-octanol or chloroform by extremely sensitive methods—the atomic absorption and fluorescence methods[27]. In the series with alicyclic amines complexes with cyclopentyl- and cyclohexyl-amines, whose solubilities in water and chloroform are comparable—the partition coefficients K_{CHCl_3/H_2O} are 0.88 and 0.84—have the best TI. Unfortunately there are many discrepancies, particularly for DDP, where TI = 8 and $K_{CHCl_3/H_2O} = 0.008$. Therefore it is at present difficult to make any predictions about the activity of the complexes on the basis of their partition coefficients between non-aqueous and aqueous phases. One thing is certain, namely that intravenous injections in clinical tests require complexes which are fairly soluble in water.

6. The Nature of the Donor Atom in the Neutral Ligand

The relacement of amines by phosphorus- or sulphur-containing ligands [$P(C_6H_5)_3$, DMSO, $S(C_2H_5)_2$, etc.] in the *cis*-isomers $[Pt(ACl)_2]$ leads to the disappearance of activity: the percentage inhibition of the growth of Sarcoma 180 is in the range 40–20.[7] These ligands exhibit a powerful *trans*-influence. It may be that this entails a marked increase of the mobility of the Cl^- ion in the *trans*-position with respect to the ligand and an increase of the capacity of the complex for non-specific reactions, as in the case of *trans*-$[Pt(NH_3)_2.Cl_2]$. The complex with the cyclically bound glycimate ion, i.e. $[Pt(NH_2CH_2COO)_2]$, is also inactive.

7. The Antitumour Activities of Charged Platinum(II) Complexes

It was mentioned above that antitumour activity is characteristic of non-electrolytic platinum(II) complexes which permeate most effectively through the cell membrane. In 1975 Davidson, Rosenberg, and coworkers[39] observed an antitumour activity in complexes differing in structure from the non-electrolytic complexes—the so-called "platinum pyrimidine blues". These substances are obtained by keeping a solution of $[Pt(NH_3H_2O)_2](NO_3)_2$ at 37 °C in contact with 2,4-dihydroxypyrimidines—uracil, thymine, and their derivatives (Table 7). Amorphous blue or green precipitates are isolated from the resulting blue solution by adding alcohol and cooling. The chemistry of "pyrimidine blues" has not been investigated; only their overall composition is known. The majority of the analyses correspond to the ratios Pt : NH_3 : pyrimidine : OH = 1 : 2 : 1 : 1. It has been observed by electrophoretic and chromatographic methods that platinum pyrimidine blues contain platinum in the form of a cation and have the structure $[Pt(NH_3)_2(pyrimidine)]X_n$, where X = NH_3^-, CH_3COO^-, $\frac{1}{2}SO_4^{2-}$, Cl^-, etc.[40] They form blue precipitates with a number of anions [for example, $B(C_6H_5)_4^-$, PF_6^-, or $P_2O_7^{4-}$]. Thus these compounds belong to the class of the few active cationic complexes.

The "blues" are mixtures of polymeric species whose molecular weight is in the range 1000–3000. Bridging hydroxo- and olate groups and base anions are involved in the polymerisation.

According to X-ray electron spectroscopic data, the "blues" contain platinum(II) (ionisation energy $E_{Pt\ 4f}$ = 74 eV). At the same time the paramagnetic properties of these compounds are attributed to the presence of platinum-(III), the content of which can reach 25%, which corresponds to an average degree of oxidation of platinum of 2.25.[40,41] Approximately 70 complexes of the "blues" type have been studied in relation to several strains of mouse tumours. Among them 14 complexes showed a higher therapeutic effect against Sarcoma 180 than DDP (see Table 7).

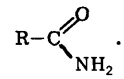


Table 7. The antitumour activities of platinum pyridimine "blues" (against ascites Sarcoma 180).[39,42]

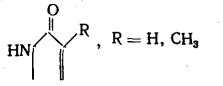
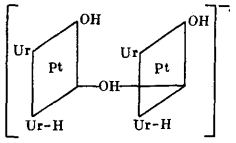


Complex	Toxic dose, mg k^{-1}	ILT, %	Single dose, mg kg^{-1}	Number of cured mice/number of experimental mice
cis-$[Pt(NH_3Cl)_2]$	10	49	7	1/12
Platinum pyridine "blues"				
Uracil	400	91	200	5/6
5,6-Dihydrouracil	400	92	200	4/6
6-Methyluracil	800	87	600	3/6
5,6-Dimethyluracil	400	100	400	5/6
5-Fluorouracil	100	90	100	4/6
Free 5-flurouracil		8	60	0
5-Chlorouracil	200	67	50	3/6
Thymine	450	72	300	2/6

The advantages of the "blues" include high solubility in water (5% against 0.1% for DDP) and a lower toxicity than that of DDP (LD_{50} = 200–500 mg kg^{-1}, the corresponding value for DDP being 12–14 mg kg^{-1}). The activity of the platinum(II) complex of 5-fluorouracil is much higher than that of the free ligand[39]. Biochemical and electron-microscope studies have shown that the "blues" hardly interact with proteins but are strongly bound by nuclear DNA; with their aid, it is possible to "label" DNA and to follow the changes in it[40,41].

It has been suggested[39] that the mechanism of the action of the "blues", which are charged complexes, differs from that of the non-electrolytes.



"Blues" of another type, formed when aliphatic nitriles RCN are treated with silver nitrate and kept at 37 °C for 4–6 days, have also been isolated. Blue substances insoluble in acetone exhibited the most effective antitumour properties—they increased the lifetime of mice with ascites Sarcoma 180 by 90%. It has been suggested that the nitrile is slowly hydrolysed, which yields platinum complexes of amides

. Uracil and thymine, which give rise to "pyrimidine blues", also contain a fragment having a similar structure[43]:

Also one monomeric cationic complex, which does not belong to the class of the "blues", has been found to be active[44]. The complex with spermine, a tetradentate polyamine, is active against leukaemia R-388, but is inferior to *cis*-dichlorodiammineplatinum as regards the inhibiting effect.

Certain anionic platinum(II) complexes have also been found to be active[45]. The interaction of the non-electrolytic urea complex *trans*-$[PtUr_2Cl_2]$ in an alkaline medium (pH ~ 9.5) is accompanied by the formation of an intensely blue solution, from which blue precipitates, having the composition $M[Pt_2Ur_2(Ur-H)_2(OH)_3]$, where $M = Na^+$ or K^+ and (Ur − H) is a deprotonated urea molecule, are isolated by the addition of alcohol. These substances are readily soluble in water; the complex anion remains unchanged in double decomposition reactions, which follows from the isolation of blue sparingly soluble precipitates with silver(I) and thallium(I) salts. The ionisation energy of platinum $E_{Pt\ 4f} = 73.3$ eV (according to data obtained by Nefedov[45] at the Institute of General and Inorganic Chemistry of the USSR Academy of Sciences), which corresponds to the +2 oxidation state of platinum. The electron absorption spectrum of an aqueous solution of the complex is characterised by an absorption band with $\lambda_{max} = 620$ nm and $\varepsilon_{max} = 3300$. The complexes are stable in aqueous solutions; the absorption spectrum does not change for 24 h. The position of the absorption band of these "anionic blues" differs from that of the cationic pyrimidine blues ($\lambda_{max} = 752$ nm) [40] and is close to that observed in the spectra of the blue complexes obtained on treatment of potassium chloroplatinite with the monoamide of oxalic acid $NH_2COCOOH$ ($\lambda_{max} = 620$–625 nm).[46] The following structure with two terminal and one bridging OH groups can be proposed for the anionic complexes[45]:

The anionic comples $K[Pt_2Ur_2(Ur-H)_2(OH)_3]$ has been tested for antitumour activity in relation to six strains of transplantable mouse tumours: lympholeukaemia L-1210, haemocytoblastoma La, plasmacytoma MOPC-406, the mammary gland adenocarcinoma (AK-755), the large intestine adenocarcinoma (AKATOL strain), and the flat cell cancer RshM-5 of the neck of the uterus[45]. It has been established that the complex is relatively non-toxic: the single maximum tolerance dose is in excess of 500 mg kg^{-1}. An appreciable antitumour activity of the anionic complex has been noted in relation to three strains of solid mouse tumours: AK-755 (85% inhibition of the growth of tumour), RShM-5 (81%), and AKATOL (55%). The complex proved to be inactive in relation to the two leukaemias and the plasmacytoma MOPC-406.

The above examples show that the "charge prohibition" is not insurmountable: there exist cationic and anionic complexes with a definite activity, although smaller than that of the non-electrolytic complexes. It is of interest that the active cationic and anionic complexes have a polymeric structure.

8. The Antitumour Activity of Platinum(IV) Complexes

Two active non-electrolytic platinum (IV) complexes have been described[8,9]: *cis*-$[Pt(NH_3)_2Cl_4]$ and $[PtEnCl_4]$. It has been suggested that these compounds are reduced in a biological medium to platinum(II) complexes which constitute the active principle. The possibility of such reduction follows from a comparison of the oxidation-reduction potentials of these compounds in a biological medium for which $E^0 = 0$ to 0.5 V:[30,47]

	E°, V
$[PtCl_6]^{2-} + 2e \rightleftarrows [PtCl_4]^{2-} + 2Cl^-$	+0.77
$[PtBr_6]^{2-} + 2e \rightleftarrows [PtBr_4]^{2-} + 2Br^-$	+0.64
cis-$[Pt(NH_3)_2Cl_4] + 2e \rightleftarrows$ *cis*-$[Pt(NH_3)_2Cl_2] + 2Cl^-$	+0.67
$[PtEnCl_4] + 2e \rightleftarrows [PtEnCl_2] + 2Cl^-$	+0.684

Analogous processes take place also with rhodium(III) complexes in a biological medium, where they are reduced to active rhodium(II) complexes[48].

The platinum(IV) complexes are more stable and more inert than the platinum(II) complexes, so that the attention of investigators has been concentrated on the latter. However, it has been suggested that the platinum(IV) complexes permeate more readily through a membrane. The interest in the platinum(IV) complexes increased after it had been discovered that certain non-electrolytic platinum(IV) complexes, namely the tetrachloro-complexes $[PtA_2Cl_4]$ and particularly the dihydroxo-complexes $[PtA_2Cl_2(OH)_2]$ dissolve more readily than the initial dichlorodiammineplatinum(II) complexes. In certain cases oxidation results also in an increase of solubility in $CHCl_3$, which characterises the behaviour in relation to lipids[27].

Unfortunately, comparison of the inhibiting activities and toxic properties of the platinum(II) and platinum(IV) complexes does not allow an unambiguous conclusion concerning the change in these characteristics on oxidation. Thus the platinum(IV) complexes with alicyclic ligands[27] and with 1,2-diaminocyclohexane[38] are less active and more toxic than the platinum(II) complexes. At the same time the toxicity of the platinum(IV) complexes with L = NH_3 or iso-$C_3H_7NH_2$ is smaller; for L = NH_3, the therapeutic activity of the platinum(IV) complexes is also greater.

Table 8. The antitumour activity of the complex $[Pt(NH_3Cl)_2.(OH)_2]$.

Dose, mg kg^{-1}	Interval, h	Number of injections	Increase of life of mice, %%		Inhibition of the growth of tumours on 10th day after therapy, %%		
			L-1210	haepatoma 22 (ascites)	AK-755	AKATOL	Sarcoma 180
50		1	50	*	96	45	76
25	24	5	90	*	83	87	76
15	24	5	90	160	83	87	*

*Not investigated.

In 1977 two groups of investigators discovered simultaneously and independently (in the USSR [49] and in England[27]) the high activity of the complex $[Pt(NH_3Cl)_2(OH)_2]$, which is not inferior to that of DDP. Konovalova et al.[49] investigated the compound in relation to five strains of transplantable mouse tumours and leukaemias (Table 8), while Tobe and Khokhar[27] tested it only on the plasmacytoma ADJ/PC6.

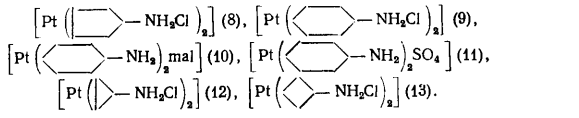
It is noteworthy that the complex $[Pt(NH_3Cl)_2(OH)_2]$ is ten times less toxic than DDP. This compound is now being investigated in depth at the All-Union Oncological Scientific Centre of the Academy of Medical Sciences of the USSR; it has been shown that the *trans*-isomer of this compound is inactive[49].

It is of interest that the anionic platinum(IV) complexes of the type $(NH_4)_2[PtHal_4(OH)_2]$ exhibit[50b] a definite activity; the maximum activity was found in $(NH_4)_2[PtBr_4(OH)_2]$. This compound appreciably inhibited (by 70%) the growth of the mouse mammary gland adenocarcinoma (strain AK-755) and increased by 65% the life of animals with leukaemia L-1210. The authors[50] explained this by the fact that the bromide-containing platinum(II) anions are more readily reduced than the chloride-containing anions and are more labile than the iodide-containing anions.

Thus the majority of investigators are inclined to the view that the mechanism of the action of the non-electrolytic platinum(IV) complexes includes a stage of their preliminary reduction to the platinum(II) complexes. However, one cannot rule out completely also the possibility of the direct action of the platinum(IV) complexes on tumour cells: two platinum(IV) complexes with substituted ethylenediamines, namely $[PtACl_4]$, are active [it has been found that TI = 3.05 for A = $(CH_3)_2N(CH_2)_2NHCH_3$ and TI = 1.7 for A = $(CH_3)_2.N(CH_2)_2N(CH_3)(C_2H_5)$], while the corresponding and non-electrolytic platinum(II) complexes are inactive[30].

9. The Most Promising Complexes

Summarising the available literature data, it is possible to distinguish approximately 30 most active non-electrolytic platinum(II) and platinum(IV) complexes with ammonia, amines, and various acido-ligands.



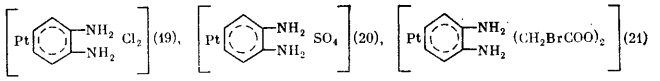
I. Platinum(II) complexes with NH_3:

$[Pt(NH_3Cl)_2]$ (1), $[Pt(NH_3)_2C_2O_4]$ (2), $[Pt(NH_3)_2mal]$ (3), $[Pt(NH_3)_2N_2O_2]$ (4), $[Pt(NH_3)_2L]$ (L = cyclobutane-1,1-dicarboxylate anion) (5).

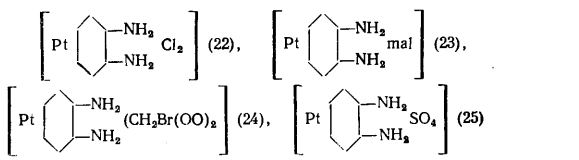
II. Platinum(II) complexes with aliphatic monoamines:

$[Pt(iso\text{-}C_3H_7NH_2Cl)_2]$ (6), $[Pt(iso\text{-}C_5H_{11}NH_2Cl)_2]$ (7).

III. Platinum (II) complexes with alicyclic monoamines:



IV. Platinum(II) complexes with heterocyclic monoamines:



V. Platinum(II) complexes with aliphatic diamines:

$[PtEnCl_2]$ (16), $[PtEn\,mal]$ (17), $[PtEnN_2O_2]$ (18).

VI. Platinum(II) complexes with aromatic diamines:

VII. Platinum(II) complexes with alicyclic diamines:

VIII. Platinum(IV) complexes:

$[Pt(NH_3)_2Cl_4]$ (26), $[PtEnCl_4]$ (27), $[Pt(NH_3Cl)_2(OH)_2]$ (28), $[Pt(iso\text{-}C_3H_7NH_2Cl)_2(OH)_2]$ (29).

IX. Platinum pyrimidine blues and certain other charged complexes (30).

However, as regards clinical tests, only approximately half of these compounds are promising: the complex must exhibit a high activity against a wide spectrum of experimental tumours, should be relatively non-toxic, and should be fairly soluble in water. Complexes (1), (5)–(13), (22)–(26), (28), and (29) possess a set of such properties to a smaller or greater extent; some of these compounds are now passing through various stages of clinical tests. The effect of DDP has been studied in detail and the second phase of tests is being completed; more than 1000 patients have been treated with this compound. Detailed data concerning the results of the clinical tests on the complexes as well as their toxic properties and the measures taken to eliminate them have been published in a review[10].

III. THE MECHANISM OF THE ANTITUMOUR ACTIVITY OF PLATINUM COMPLEXES

One of the main requirements which must be met by the experimental and clinical chemotherapy of malignant tumours is selectivity of action of the therapeutic agents on the cells of the cancer tumour and the smallest possible damaging effect of such agents on the normal cells. Compared with normal cells, tumour cells are characterised by a higher level of synthesis of DNA and the action of a number of antitumour preparations, particularly alkylating agents, is in fact directed to such macromolecules.

Molecular-biological studies *in vitro* using tritium-labelled thymidine, uridine, and leucine[51,52] and experiments *in vivo*[53] have shown that the complex $[Pt(NH_3Cl)_2]$, which exhibits an antitumour activity, selectively suppresses the synthesis of DNA but has little effect on the synthesis of RNA and proteins. Thus the target attacked by the platinum complexes in the organism has been identified at the intermolecular level.

There exist several points of view concerning the causes of the different antitumour activities of platinum complexes of different composition and structure. Biophysical factors play a definite role; the non-electrolytic complexes are more capable of permeating the cell membrane than the charged complexes, which is promoted by their higher solubility in lipids.

1. The Role of Chemical and Physicochemical Factors

The formation of stable bonds with nitrogen-containing ligands is characteristic of platinum, which makes it likely that the acido-ligands in the complex undergo nucleophilic substitution by nitrogen-containing DNA bases. However, in order to "reach" the cell DNA, the complexes must react with other biologically active ligands "on the way", namely with proteins, aminoacids, etc. This is the reason for the relation between the chemical reactivity, thermodynamic stability, and kinetic lability of the platinum complexes, on the one hand, and their antitumour activity, on the other. The available data[54] concerning the influence of the complex $[Pt(NH_3Cl)_2]$ on the physicochemical characteristics of DNA show that this interaction proceeds with participation of the aquo-form of the complex as a result of the continuous shift

of the hydrolytic equilibrium

$$[Pt(NH_3Cl)_2] + 2H_2O \rightleftarrows [Pt(NH_3Cl)(NH_3H_2O)]^+ + Cl^- + H_2O \rightleftarrows [Pt(NH_3H_2O)_2]^{2+} + 2Cl^-.$$

There is almost no hydrolysis in the intercellular liquid, where the concentration of Cl^- ions is high (0.103 M). In the cytoplasm and particularly in the nucleus the concentration of Cl^- is much lower (0.004 M); aquo-complexes are formed in the cytoplasm under these conditions and then interact further with the nitrogen-containing DNA bases. A thermodynamic study of all possible equilibria in solutions of platinum complexes and measurement of their kinetic parameters are necessary[12].

2. Thermodynamic Stability of the Platinum Complexes

In aqueous solutions of dichlorodiamineplatinum(II) complexes stepwise hydrolytic and acid–base equilibria obtain:

$$[Pt(NH_3Cl)_2] + H_2O \rightleftarrows [Pt(NH_3Cl)(NH_3H_2O)]^+ + Cl^- ,$$
$$[Pt(NH_3Cl)(NH_3H_2O)]^+ + H_2O \rightleftarrows [Pt(NH_3H_2O)_2]^{2+} + Cl^- ,$$
$$[Pt(NH_3Cl)(NH_3H_2O)]^+ \rightleftarrows [Pt(NH_3Cl)(NH_3OH)] + H^+ ;$$
$$[Pt(NH_3H_2O)_2]^{2+} \rightleftarrows [Pt(NH_3H_2O)(NH_3OH)] + H^+ ;$$
$$[Pt(NH_3H_2O)(NH_3OH)]^+ \rightleftarrows [Pt(NH_3OH)_2] + H^+ .$$

In order to determine the concentrations of all possible equilibrium forms, it is necessary to investigate quantitatively the hydrolytic and acid–base equilibria in solutions of the platinum(II) complexes and to determine the hydrolysis constants K_1 and K_2 and acid dissociation constants K_3, K_4, and K_5, which makes it possible to calculate the contents of all the equilibrium forms existing at the specified concentrations of Cl^- ions and pH values. Such a calculation has been performed for $[PtEnCl_2]$, for which all five equilibrium constants are known; $K_1 = 2.76 \times 10^{-3}$, $K_2 = 1.38 \times 10^{-4}$, $K_3 = 4.0 \times 10^{-8}$, $K_4 = 1.6 \times 10^{-6}$, and $K_5 = 3.1 \times 10^{-8}$. The concentration ratios of the different equilibrium forms in $[PtEnCl_2]$ solutions at pH 7.4 and a Cl^- concentration of 0.103 M in the plasma or 4.8×10^{-3} M in the cell are[54] given below:

	$[PtEnCl_2]$	$[PtEn\,ClH_2O]^+$	$[PtEn(H_2O)_2]^{2+}$	$[PtEn\,ClOH]$	$[PtEnH_2O\,OH]^+$	$[PtEn(OH)_2]$
Plasma	37.3	1	0.00134	1	0.053	0.0033
Cell	1.45	1	0.0345	1	1.38	0.86

It is seen from the above data that the substance exists in the plasma mainly as the dichlorodiamine complex, while in the cell all the forms (with the exception of the diaquo-complex) are present in comparable amounts. A less detailed approximate calculation has been carried out for $[Pt(NH_3Cl)_2]$ (because K_3 is unknown), from which it follows that the degree of hydrolysis of the complex in the plasma is close to 3%, while the cell contains 42% of the reactive hydrolysis products.

The equilibrium constant corresponding to the elimination of the first chloride ion is usually known for other dichlorodiamineplatinum(II) complexes. The characteristics of the acid properties of the platinum(II) complexes as well as the influence of the σ-donor and π-acceptor properties of the ligands on the acidity of the aquo-complexes have been considered in reviews[55,56].

When concentrated solutions of the platinum(II) complexes are allowed to stand for a long time, polymerisation processes, accompanied by the formation of the complexes $[(NH_3)_2.Pt(OH)_2Pt(NH_3)_2](NO_3)_2$, $\{Pt[(NH_3)_2OH]_3\}(NO_3)_3$, etc. with bridging OH groups, take place[57,58].

For a number of isomeric complexes of the type $[PtA_2Cl_2]$ (A = NH_3 or amines), the hydrolytic stability of the *trans*-isomer is greater than that of the *cis*-isomer. Thus the equilibrium constant for the elimination of the first Cl^- ion in the *trans*-isomer of $[Pt(NH_3)_2Cl_2]$ is 4–5 times smaller and in the *trans*-isomers of $[PtA_2Cl_2]$ (A = methylamine or ethylamine) it is 13–18 times smaller than the corresponding value for the *cis*-isomer[59]. The influence of the strength of binding of the acido-ligand on the antitumour activity of the non-electrolytic platinum(II) *cis*-complexes has already been mentioned. The most stable complexes are the least active: in the $[Pt(AHal)_2]$ (Hal = Cl, Br, or I) series the Pt–Hal bond strength increases and the antitumour activity of the complex falls.

A change in the nature of the amine in the *trans*-position relative to the chloride ions influences the Pt–Cl bond strength in accordance with Chernyaev's principle of *trans*-influence. When NH_3 is replaced by alicyclic ligands, the toxicity is appreciably reduced and the antitumour activity of the complexes increases (see Table 5). Owing to the very poor solubility of the platinum(II) complexes with alicyclic amines, it is not possible to measure their stability constants. A study has therefore been made[60] of the interaction of nickel(II), an electronic analogue of platinum(II), with these amines and the first formation constants β_1 of the nickel complexes were determined (by potentiometric pH titration using a glass electrode) under conditions close to biological conditions (0.150 M NaCl, 37 °C). The basic properties of the ligands increase in the same direction:

L	NH_3		
$\lg\beta_1$	2.80	5.340	6.824
pK_a	9.47	9.97	10.33

It may be that the same behaviour would be observed also for the $[PtL_2Cl_2]$ complexes. In this case the Pt–Cl bond weakens as the Pt–L bond strengthens and the complex becomes less reactive in relation to DNA. However, the use of findings obtained *in vitro* for nickel(II) complexes to explain the differences in the antitumour activities of the platinum(II) complexes *in vivo* must be treated with caution. In order to understand the mechanism of the antitumour activity of the platinum(II) complexes, data for equilibria in the systems containing these compounds together with purines or pyrimidines are particularly necessary. There have been virtually no studies of this kind; one of the causes of this may be the difficulty of the measurements associated with the slowness of the attainment of equilibrium as a consequence of the inertness of the nitrogen-containing platinum(II) complexes. An attempt has been made[61] to estimate the stability constants of the 1 : 1 complexes formed after solutions of mixtures of $[Pt(NH_3H_2O)_2]^{2+}$ with nucleosides (adenosine, guanosine, cytidine, uridine, and thymidine) have been allowed to stand for a long time (4–6 h) at 25 °C in the presence of different Pt : ligand ratios. The quantity ΔA, equal to the difference between the absorbances of the complex and its individual components, has been measured by differential spectroscopy. If it is assumed that only one complex, with the 1 : 1 composition, is formed in the system, then its stability constant K can be found from the equation

$$\frac{b(a-c)}{\Delta A} = \frac{(a-c)}{\Delta\varepsilon} + \frac{1}{K\Delta\varepsilon} ,$$

where a and b are the initial concentrations of the complex and the nucleoside, c is the equilibrium concentration of the complex, and $\Delta\varepsilon$ is the difference between the molar extinction coefficients of the complex and its constituents. By applying the iterative method to the determination of $\Delta\varepsilon$ and c, it is possible to find the optimum values of $\Delta\varepsilon$ and K. $\Delta\varepsilon$ can be determined also directly on the basis of Beer's law. The plot of $b(a-c)/\Delta A = f(a-c)$ is linear, its slope determining the quantity $1/\Delta\varepsilon$ and the intercept on the ordinate axis the quantity $1/K\Delta\varepsilon$.

When $[Pt(NH_3H_2O)_2]^{2+}$ solutions are kept in contact with pyrimidines (uridine and thymidine), no changes are observed in the absorption spectra, which led to the conclusion that there is no interaction. The formation constants of the 1 : 1 complexes with adenosine, guanosine, and cytidine are similar: $pK = 3.5–3.7$. Consequently the reaction of $[Pt(NH_3H_2O)_2]^{2+}$ with the guanosine–cytidine pair is much more probable than with the adenosine–thymine pair: $K_GK_C \cong 10^8$ for the guanosine–cytidine pair and $K_AK_T \cong 10^4$ for the adenosine–thymine pair.

This conclusion is consistent with the experimental finding that $[Pt(NH_3Cl)_2]$ is bound preferentially by DNA enriched in guanosine and cytidine. The selectivity of the reactions of DNA with bases depends on the nature of the metal: copper(II) and silver(I) ions interact preferentially with guanosine, while OsO_4, CH_3Hg(II) and Hg(II) interact preferentially with thymidine[62].

3. Kinetic Lability of the Platinum(II) Complexes

The biological reactivity of the non-electrolytic platinum(II) *cis*- and *trans*-complexes is determined by the kinetics of their hydrolysis and nucleophilic substitution reactions. The kinetic equation for nucleophilic substitution in the platinum(II) complexes has the following form[47]:

$$v = k_1c_c + k_2[L]c_c,$$

where c_c is the concentration of the complex and [L] the concentration of the entering ligand. The first term corresponds to the hydrolytic (solvolytic) pathway and the second to a second-order association reaction with the entering ligand. In the presence of an excess of the latter, we have

$$v = k_{obs}c_c,$$

where $k_{obs} = k_1 + k_2[L]$.

Table 9. Comparison of the kinetic labilities of the *cis*- and *trans*-isomers of $[Pt(NH_3)_2Cl_2]$ at 25 °C.[63–65]

Isomer	Ligand	10^5k_1, s^{-1}	Isomer	Ligand	10^5k_1, s^{-1}
cis-	H_2O	2.5	*cis*-	Cl	0.3
trans-	H_2O	9.8	*trans*-	Cl	7.8
cis-	OH^-	2.5	*cis*-	NH_3	1.0
trans-	OH^-	10.1	*trans*-	NH_3	29.0

In the light of the foregoing, the necessity for a kinetic investigation of the hydrolysis (solvolysis) of the platinum(II) complexes and their reactions with the DNA component is clear. The first process has been studied in fair detail[47]. On the other hand, there are almost no data concerning the rates of reaction of the complex platinum(II) non-electrolytes with the DNA bases and for this reason we shall characterise the kinetics of the second-order reactions using the rates of reaction of the isomeric non-electrolytes with other donor molecules of ions: NH_3, OH^-, Cl^-, etc. Table 9 lists the rate constants for the first-order acid and base hydrolytic reactions and the second-order isotope exchange and nucleophilic substitution reactions with the isomeric platinum(II) non-electrolytes. Evidently the *trans*-isomers are kinetically more labile than the *cis*-isomers. This is usually explained by the greater *trans*-influence of the Cl^- ions compared with the NH_3 molecules.

Numerous studies have been carried out in order to characterise kinetically the *trans*-influence[66,67]. The absence of antitumour activity in the *trans*-isomer can be attributed to its greater lability: on the way to nuclear DNA, the *trans*-isomer enters into rapid and non-specific exchange reactions with a series of nucleophiles. The *cis*-isomer is less labile and is able to reach the tumour cell in an unchanged form and to diffuse through its membrane. In the plasma the concentration of Cl^- ions (0.103 M) is sufficient to suppress the hydrolysis of the complex and only in the cell, where the Cl^- concentration is smaller (0.004 M), is the complex hydrolysed, which is accompanied by the reversible conversion of the aquo-complex into complexes with DNA bases.

The solvolysis of the *cis*-non-electrolytes $[Pt(ACl)_2]$, where A is an alicyclic amine, has been studied in dimethyl sulphoxide[68,69]:

It was established that, on passing from cyclopropyl- to cyclohexyl-amine, the rate of solvolysis falls by a factor of ~2.5; the basic properties of the ligands increase in this direction. The equilibrium constants of the processes

$$cis\text{-}[PtA(DMSO)Cl_2] + A \rightleftharpoons cis\text{-}[PtA_2(DMSO)Cl]^+ + Cl^-,$$
$$[Pt(DMSO)Cl_3]^- + A \rightleftharpoons trans\text{-}[PtA(DMSO)Cl_2] + Cl^-,$$

were determined by a kinetic method (by investigating the rate constants for the forward and reverse reactions).

Kinetic considerations are invoked also to account for the influence of the anion X in $[Pt(AX)_2]$ on the antitumour activity of the *cis*-complex, which decreases in the sequence $Cl^- > Br^- > SCN^- > NO_2^- > I^-$. The rates of certain substitution reactions involving the platinum(II) complexes decrease in approximately the same sequence. For example, the rate constant for the reaction[70]

$$[Pt\,dien\,X]^+ + Py \rightarrow [Pt\,dien\,Py]^{2+} + X^-$$

(dien = diethylenetriamine) diminishes by a factor of 10^6 in the sequence $NO_3^- > H_2O > Cl^- > Br^- > SCN^- > NO_2^-$. Hence one may conclude that the antitumour activity is characteristic of complexes with ligands of moderate lability (Cl^- and Br^-).

One should note that the concepts of the "lability" and "inertness" of the ligand are relative and depend on the charge of the complex and the nature of the remaining ligands and the entering group. Thus the anionic complexes $[PtBr_4]^{2-}$ and $[PtI_4]^{2-}$ are more labile with respect to hydrolysis, isotope exchange, and substitution by NH_3 than $[PtCl_4]^{2-}$:[47]

	10^4K_1, s^{-1}		10^4K_2, litre mol^{-1} s^{-1}
$[PtCl_4]^{2-} + H_2O$	0.39	$[PtCl_4]^{2-} + NH_3$	4.2
$[PtBr_4]^{2-} + H_2O$	1.75	$[PtBr_4]^{2-} + NH_3$	25.0

A more rigorous estimate of the influence of the kinetic lability of the ligand and of the geometrical configuration of the complexes on their biological activity can be obtained after determining the rate constants for the hydrolysis and the interaction with purine and pyrimidine bases of a series of *cis*-isomers $[Pt(NH_3X)_2]$ (X = acido-ligand). One of the few studies of this kind is that of Robins[71], who found that adenine, guanine, and cytosine, their nucleosides, and nucleotides react with $[Pt^{14}C\text{–}EnCl_2]$ (ethylenediamine complex), while thymine and its derivatives do not. Among nucleosides, the reaction is fastest with guanosine and slower with adenosine. This also applies to the reactions with DNA: DNA enriched with deoxyguanosine reacts faster. The presence of the phosphate group in the adenine nucleotides accelerates the interaction.

The absence of antitumour activity in the palladium complex $[Pd(NH_3Cl)_2]$ is due to its kinetic lability; palladium(II) compounds react approximately 10^5 times faster than the analogous platinum(II) complexes[7]. Nickel(II) complexes are still more labile and are therefore relatively unpromising as antitumour preparations. However, one cannot rule out the possibility that the change in the nature of the neutral and acido-ligands in the palladium(II) complexes will reduce their lability and one can then expect that such complexes would be active.

In conformity with the principle of the *trans*-influence, the lability of the ligand is in many respects determined by the nature of the *trans*-ligand. Phosphorus- and sulphur-containing ligands exhibit a strong *trans*-influence and they are responsible for an appreciable increase of the lability of the chlorine bond in *cis*-$[Pt(ACl)_2]$, which is the reason why such complexes are inactive.

Thus comparison of the physicochemical characteristics of the *cis*- and *trans*-isomers of $[Pt(NH_3)_2Cl_2]$ shows that the *cis*-isomer, which exhibits antitumour activity, is kinetically more stable than the *trans*-isomer, but at the same time its thermodynamic stability is lower. It may be that the combination of a moderate lability and a moderate stability of the Pt–Cl bond in the *cis*-isomer ensures the integrity of the complex during its journey to nuclear DNA and its interaction with the latter. While admitting the due importance of these factors, one must nevertheless emphasise that the geometrical correspondence between the *cis*-isomer and the DNA structure exerts a decisive influence on the differences between the antitumour activities of the isomers.

4. Structure Factors and the Interaction with DNA

The structure factors determine the interaction of alkylating antitumour agents (sarcolysine, cyclicphosphoramide, etc.) with DNA. The distance between the chlorine atoms in these molecules is close to 8 Å, which corresponds to the distance between two guanine molecules in two DNA helices[8]. Alkylating agents therefore induce the *interstrand cross-linking* of DNA, which prevents its replication. The structure of $[Pt(NH_3Cl)_2]$ differs from that of alkylating agents, which is reflected in the type of linkage. The distance between the two chlorine in DDP (3.3 Å [72]) approximately corresponds to the distance between the planes of the bases in the DNA helices (3.4 Å), which permits *intrastrand cross-linking* with formation of a chelate complex in which there are two molecules of the nucleoside per platinum(II) atom. The inhibition of the DNA synthesis in the presence of $[Pt(NH_3Cl)_2]$ in a single-strand bacteriophage and the formation of a chelate with the dinucleotide ApA confirm this type of linkage[13,73]. It has also been established that the antitumour activity of DDP is manifested in the proportions of 1 DDP molecule to 1000 DNA base molecules, while interstrand cross-linking requires 20 times as much of the complex[74,75]. For DDP, yet another example of the geometrical correspondence with the DNA structure has been observed. In the crystalline state the distance between the $[Pt(NH_3Cl)_2]$ molecules in the chain structure is 3.47 Å, which permits the combination of the chains of the complex with DNA in which the new double chain contains one nucleoside molecule per platinum(II) atom[76].

The possibility of the interstrand cross-linking of DNA as a result of interaction with DDP also cannot be ruled out[74,75,77], but the majority of investigators give preference to intrastrand cross-linking. They believe that the promising results obtained in the combined chemotherapy with the aid of DDP and alkylating agents are associated with the different mechanisms of their action on DNA.

The problem of which DNA bases interact with DDP and which atoms are involved in such binding has been studied in detail. According to a number of workers, among the purine bases the greatest tendency towards the reaction with DDP is shown by guanine, which is bound to platinum(II) via the $N_{(7)}$ atom[71], while among pyrimidine bases cytosine is most effective, being coordinated via the $N_{(3)}$ atom[78]. In neutral solution thymine does not react with DDP. On this basis, it is suggested that platinum complexes be used to determine the content of the gua-cyt pair in DNA and the sequence of the bases by electron microscopy.

The interaction of DDP and other platinum(II) complexes with DNA containing different amounts of guanine and cytosine has been investigated in detail in a series of studies[79–88] by physicochemical and physical methods (atomic absorption spectroscopy, the fluorescence method, the study of circular dichroism spectra, and the potentiometric determination of the concentration of Cl^- ions). It has been established[87,88] that DDP interacts specifically in the first place with the guanine (gua) of the DNA molecule, forming an intrastrand chelate:

$$[Pt(NH_3Cl)_2] + \text{gua} \rightarrow [Pt(NH_3)_2 N(7)\,\text{gua}\,O(6)]Cl_2 \quad (1).$$

This reaction is accompanied by the liberation of two Cl^- ions per molecule of the contacts, but there is no change of pH. After saturation of the guanine binding sites by the complex, the second mode of binding—the interstrand cross-linking gua $N_{(1)}$–Pt–cyt $N_{(3)}$—is observed in the second stage of the process and is accompanied by the elimination of a proton from the $N_{(1)}H$ group of guanine.

However, this type of binding is non-specific; it obtains also in other platinum(II) complexes without antitumour activity. Apart from the incorporation of the interstrand mechanism, in the second stage of the interaction of DDP with DNA there is a possibility of the formation of an intrastrand chelate with adenine via the $N_{(7)}$ atom and the NH_2 group[85]. This process proceeds via pathways of the type of reaction (1) without the elimination of the proton and with liberation of two Cl^- ions.

It is also believed[87] that DDP initially forms an intrastrand chelate with the DNA guanine, which weakens the cyt–$N_{(1)}$–gua hydrogen bonds, as a result of which a second DDP molecule can be bound to the $N_{(1)}$ atom of guanine. This distorts the initial configuration of the DNA molecule and permits interstrand cross-linking with participation of the $N_{(1)}$ atom of adenine.

The formation of a chelate between DDP and DNA with participation of the $N_{(7)}$ and $O_{(6)}$ atoms of guanine was demonstrated by the investigation of the X-ray electron spectra of the isolated solid platinum complexes of DNA: the ionisation energy of the $N_{(1S)}$ atom of guanine in the series of complexes $[Pt(NH_3Cl)_2]$, *trans*-$[Pt(NH_3)_2Cl_2]$, and $K_2[PtCl_4]$ decreases by 0.5–0.7 eV during their coordination, while the ionisation energy of the $O_{(1S)}$ atom decreases only in the case of the DNA complex with DDP, remaining unaltered in all other cases[80].

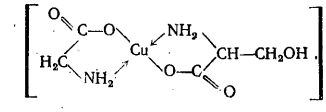
In order to examine the interaction of DDP with DNA, a comparative study was made (*in vivo* and *in vitro*) of the reactions of DNA with DDP and other, inactive platinum complexes: *trans*-$[Pt(NH_3)_2Cl_2]$, [Pt dien Cl]Cl, $[Pt(NH_3)_3Cl]Cl$, $K[Pt(C_2H_4)Cl_3]$, $K_2[PtCl_3]$, etc.[89] These complexes also react with DNA but in a different manner. On reaction with DNA, the complexes *trans*-$[Pt(NH_3)_2Cl_2]$ and [Pt dien Cl]Cl split off one Cl^- ion per platinum(II) atom, which indicates their monodentate binding to the central atom. The binding site is again the $N_{(7)}$ atom of guanine[89].

The influence of the platinum(II) complexes on the fluorescence intensity in the DNA–EtdBr system, where EtdBr is ethidium bromide, has been investigated[86]. The triammine complexes [Pt dien Cl]Cl and $[Pt(NH_3)_3Cl]Cl$, which bind to DNA as monodentate species, decrease the fluoresence intensity by only 15–20%; under the same conditions, DDP, $[PtEnCl_2]$, and their aquo-forms, which are capable of chelate formation, exert a much greater influence, reducing the fluorescence intensity by 70%. The inert complexes $[Pt(NH_3)_4]Cl_2$ and $[PtEn_2]Cl_2$ do not react with DNA. The interaction of *trans*-$[Pt(NH_3)_2Cl_2]$ with DNA is interesting: in solutions with an equimolar content of Cl^- ions this substance behaves as a monodentate ligand in relation to DNA, while in the absence of Cl^- ions it greatly reduces the fluorescence intensity and strongly influences the DNA structure. The authors[86] believe that in this case *trans*-$[Pt(NH_3)_2Cl_2]$ forms an unusal chelate with DNA via the $N_{(7)}$ atom of guanine and the oxygen atom of the phosphate group.

The atomic absorption method proved to be promising for the characterisation of the interaction of isomeric non-electrolytes with DNA; it has been observed[90] that the absorption intensity in atomic absorption spectra of the chelate complexes $[Pt(NH_3)_2N_{(7)}guaO_{(6)}]Cl_2$ and $[PtEnN_{(7)}guaO_{(6)}]\cdot Cl_2$ is lower by a factor of 2 than for complexes bound as monodentate species, for example, *trans*-$[Pt(NH_3)_2N_{(7)}guaCl]\cdot Cl$ and [Pt dien $N_{(7)}$gua]Cl_2.[90] Thus the interaction of DDP with DNA is distinguished by the following features:

(1) *In vivo* certain platinum complexes with a labile Cl–Pt–Cl *trans*-coordinate, for example, $K_2[PtCl_4]$, $K[Pt(C_2H_4)Cl_3]$, $K[Pt(NH_3)Cl_3]$, and *trans*-$[Pt(NH_3)_2Cl_2]$, are kinetically unstable in relation to many biologically active ligands (aminoacids and proteins) and do not therefore reach the nuclear DNA, since they react with these substances already in the plasma. In particular, this applies to the complex $K_2[PtCl_4]$, which is more effective in relation to proteins and enzymes than to DNA [87] and differs sharply in its physiological action from DDP; it is bactericidal, highly toxic, and inactive against tumours.

(2) *In vitro* many platinum(II) complexes are capable of reacting with DNA (with the exception of inert tetramine complexes) preferentially as a result of binding to guanine. However, complexes of different structure are formed and differ in the mode of binding. The primary binding of DDP and other *cis*-non-electrolytes leads to the formation of the intrastrand chelate $N_{(7)}guaO_{(6)}$, while *trans*-$[Pt(NH_3)_2Cl_2]$ and triamine complexes are bound as monodentate species via the $N_{(7)}$ atom of guanine. In the concluding report at the IIIrd International Symposium on the Applications of Platinum Complexes in Tumour Chemotherapy Rosenberg[89] emphasised particularly the importance of the formation of this type of chelate for the manifestation of antitumour activity by the complex.



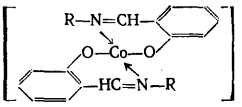
The complex $K_2[PtCl_4]$ binds to DNA via an interstrand mechanism involving the $N_{(1)}$ atom of guanine and the $N_{(3)}$ atom of cytosine, which is accompanied by the elimination of a proton from the $N_{(1)}H$ group. In the solid complex obtained by treating DNA with $K_2[PtCl_4]$ and containing a DNA molecule and two Cl^- ions per platinum atom, interstrand binding via the $N_{(1)}$ atom of adenine and the $N_{(3)}$ atom of thymine as well as monodenate binding via the $N_{(7)}$ or $N_{(3)}$ atoms of guanine and adenine are also postulated.

It follows from the foregoing that the study of the reactions of isomeric non-electrolytes and other platinum complexes with individual DNA bases can throw light on the mechanism of the interaction of these compounds with DNA.

Thus one of the principal causes of the antitumour activity of platinum complexes is inhibition of the replication of DNA. However, this interaction alone cannot ensure the complete destruction of the tumour and its metastases; this requires the operation of additional mechanisms. Such an additional mechanism is the immune system of the organism[13]. The involvement of the immune system is confirmed by the following facts: (1) in mice with grafted Sarcoma 180 and cured with DDP immunity to repeated implantation persists for 11 months; (2) the combination of DDP with an immunostimulant (zymosan) increases the therapeutic effect of the complex or the combination with an immunodepressant (hydrocortisone) lowers the antitumour activity of DDP.[91]

IV. THE ANTITUMOUR ACTIVITIES OF OTHER METAL COMPLEXES

A brief survey of studies on the antitumour activities of metal complexes before Rosenberg's discovery of antiblastoma properties of platinum complexes was given by Cleare[7]. Thus copper, nickel, and cobalt diphthalate complexes proved to be active against leukaemia[92], while iron ascorbate inhibited the growth of Ehrlich carcinosarcoma in mice[93]. The chelate copper complex of dimethylglyoxime $[Cu(DH)_2]$, where DH is the dimethylglyoximate anion, increased the life of animals with Ehrlich ascites tumour and Sarcoma 180 by 200–300%.[94] It has been suggested that coordination masks the hydrophilic oxime group and promotes the permeability of the cell membrane to the complex. An activity has been observed also in the copper(II) chelate complexes of thiosemicarbazones. It has been established[95,96] that the aminoacid complexes of bivalent copper show a definite antitumour activity *in vivo* (against the ascites form of Sarcoma 180) and *in vitro* (against lympholeukaemia L-1210). Mixed complexes with cyclically bound aminoacids (*l*-serine, glycine, *l*-alanine, and *l*-threonine) have been investigated[97] and the syntheses and structure of these compounds have been described[98–100]. They showed a pronounced therapeutic effect on mice with dense tumours of two strains—the mammary gland adenocarcinoma (AK-755) and the cancer of the neck of the uterus (RShM-5); the percentage inhibition of AK-755 was, depending on the compound, the method of injection, and time, 80–90% (on the fifth day after a single injection) and 80–50% (24 h after the end of a five day course). However, the effect is unstable and diminishes 1–2 weeks after the course. The best results were obtained for the complexes with *l*-serine and glycine.



In this case a high percentage inhibition of AK-755 after a single injection persists also on the 19th day. Certain cobalt(III) complexes, namely $[Co(NH_3)_4Cl_2]Cl$ and $[Co(NH_3)_4\cdot(CO_3)]NO_3\cdot\frac{1}{2}H_2O$ retarded the growth of Yoshida sarcoma[101]. There is evidence for the antitumour activity of cyanocobalamin (vitamin B_{12}) [102] and cobalt-protophorphyrin[103].

Complexes of Group VIII elements have been studied in greater detail (after Rosenberg's investigation of the antitumour activities of platinum complexes). Nickel(II) and palladium(II) atoms have the d^7 electronic configuration [d^8, Ed] and are electronic analogues of platinum(II), but the complexes of these elements show a much greater kinetic lability, as can be seen from a comparison of the relative rates of nucleophilic substitution reactions[104]:

Ni (II)	Pd (II)	Pt (II)
$5\cdot10^6$	10^5	1

For these reasons, one can hardly expect antitumour activity of the palladium(II) and nickel(II) complexes; this can also

be said of gold(III) complexes. When the non-electrolytic palladium(II) complexes *cis*-$[Pd(NH_3Cl)_2]$ (the DDP analogue), $[PdEnCl_2]$, $[Pd(NH_3)_2mal]$, [PdEnmal], etc. were tested, no activity against Sarcoma 180 was observed[105]. Nevertheless, one cannot rule out the possibility that palladium(II) can be stabilised by the introduction of cyclic ligands and would then prove active. It may be that this is why the complex $[Pd(dtp)_2]$, where dtp is dimethyl hydrogen thiophosphate, shows some antitumour activity against Walker sarcoma[106]. The cyclic planar cobalt(II) complexes of Schiff bases cause a moderate inhibition of the growth of Walker sarcoma in rats. The best results were observed for the complexes

where R = $(CH_2)_2CH_2OH$ (T/K = 21%) or $C(CH_3)_2CH_2OH$ (T/K = 24%).[107,108] Iridium(III) complexes are inert and inactive, like $(NH_4)_2[IrCl_6]$—an anionic iridium(IV) complex. However, photochemical activation of the latter leads to the formation of the complex *cis*-$[Ir(NH_3)_2Cl_4]$, which has some activity[109].

Rhodium(III) complexes are the most promising. The complexes *trans*-$[RhL_4X_2]Y$, where L = pyridine and its substituted derivatives, and *trans*-$[RhL_2X_2]Y$, where L = 2,2′-bipyridyl, 1,10-phenanthroline, or ethylenediamine (X = Cl, Br, or I; Y = Cl, Br, NO_3, or ClO_4), showed an antibacterial activity and caused the formation of bacterial filaments. In contrast to platinum(II) complexes, this capacity was shown to a greater extent by bromide complexes and not chloride complexes and by complexes with the *trans*-structure and not the *cis*-structure. The introduction of a lipophilic substituent into the pyridine molecule increased and the introduction of a lyophilic substituent decreased the bacteriostatic activity of the complexes. Complexes with pronounced oxidising properties (with less negative half-wave potentials $E_{1/2}$ in polarographic reduction) proved to be more active[110]. The *mer* isomer $[Rh(NH_3)_3Cl_3]$ as well as *trans*-$[RhPy_4Cl_2]Cl$ and *trans*-$[RhEn_2Cl_2]NO_3$ inhibit the growth of Sarcoma 180 and Walker carcinosarcoma (T/C = 17–40%). It has been suggested that under biological conditions the rhodium(III) complexes are reduced to active rhodium(I) complexes.

The antitumour activities of the dimeric rhodium(II) carboxylates of the type $Rh_2(CO_2R)_4$, where CO_2R are acetate, propionate, and butyrate ions, have been studied in detail (in relation to chemical properties)[111,112]. These complexes increased the life of mice with Ehrlich ascites tumour and leukaemia L-1210. The antitumour activity increases in the sequence acetate < propionate < butyrate. In the latter case the life of mice increases by 20%. Rhodium(II) carboxylate complexes inhibit preferentially the DNA synthesis in the tumour both *in vivo* and *in vitro*. However, in contrast to the platinum(II) complexes, they also influence the RNA synthesis (according to data obtained by experiments with tritium-labelled uridine). It has been established that rhodium(II) carboxylates bind preferentially to adenine and its nucleosides and nucleotides. In order to simulate the interaction of the dimeric rhodium(II) carboxylates with DNA, a study was made of their reactions with 5′-AMP, which proceed via an oxidative addition mechanism[113]:

$$[Rh_2(CO_2R)_4] + 2\,(5'\text{-AMP}) \rightarrow [Rh_2(CO_2R)_4(5'\text{-AMP})_2].$$

The changes in the absorption spectra observed in this process are analogous to those which occur on coordination of other N-donor ligands. The formation constants K_1 and K_2 of the rhodium(II) acetate and propionate complexes with 5′-AMP have been determined spectrophotometrically: the propionate complex is approximately twice as stable (K_1 = 4235) than the acetate complex (K_1 = 1893). The stability of the complexes with 5′-ADP and 5′-ATP increases in the same sequence (propionate > acetate > methoxyacetate)[113].

Ruthenium complexes are also capable of interacting with purines and biologically active macromolecules[114,115,116]. The complex $[Ru(NH_3)_5(H_2O)]^{2+}$ is reactive, reacting with purines (guanosine, 5′-GMP, xanthosine, and inosine), which involves coordination via the $N_{(7)}$ atom. In the presence of an excess of ruthenium complex adenine was found to bind via the $N_{(1)}$ atom. The reactions of $[Ru(NH_3)_5(H_2O)]^{2+}$ with DNA occurred similarly. The formation of complexes with DNA and the inhibition of its synthesis by the ruthenium complexes make them potential antitumour agents.

Antitumour activity has been found in compounds of Group III elements: $Ga(NO_3)_3$, which causes 90% inhibition of the development of many tumours, is particularly promising[117]. In contrast to platinum(II) complexes, the gallium(III) compounds accumulate selectively in tumour cells and have a cytotoxic effect on them.

The available data suggest that not only platinum complexes but also other metal complexes, capable of reacting with biologically active molecules, behave as antitumour agents.

Compared with other metal complexes, platinum complexes are stable—they do not undergo extensive hydrolysis and retain their geometric configuration in solution. These complexes served, as it were, as the "starting point" in coordination chemistry: a number of characteristics have been discovered using them—the influence of coordination on the properties of the ligands and the central atom, the mutual influence of ligands, primarily the *trans*-influence, etc. Presumably in the chemotherapy of tumours the platinum complexes will play a similar role and their study will promote the investigation and application of other metal complexes as antitumour agents.

This has been confirmed by the results of the latest studies[118–121], devoted to the search for platinum and other metal complexes and the investigation of the mechanism of their action and their physicochemical properties. Among promising complexes, 4-carboxyphthalato-1,2-diaminocyclohexaneplatinum(II) has been mentioned[122]; promising data have been obtained also for other transition metal complexes[123]. New platinum(II) complexes with pyrimidines[124], adenine, and adenosine[125,126] have been isolated. The presence of oligomers in neutral solutions of diaquodiammineplatinum(II) complexes has been demonstrated by ^{195}Pt NMR.[127] The dependence of the antitumour activity on the structure of the complexes has been analysed[128,129] and the possible mechanisms of their binding to DNA have been examined[130,131].

Certain Aspects of the Problem of the Pollution of the External and Internal Environment by Lead

V.M.Zatonskaya, F.I.Lobanov, and N.V.Makarov

Studies on the pollution of the biosphere by lead published in recent years are discussed. Numerous sources from which lead can be introduced into the atmosphere and the hydrosphere and, the problems of the contamination of the soil, plants, algae, and animal and human organisms as a consequence of the increased absorption and accumulation of lead are considered. The problem of the chemical forms of lead in the environment, including the internal environment, is described. The bibliography includes 153 references.

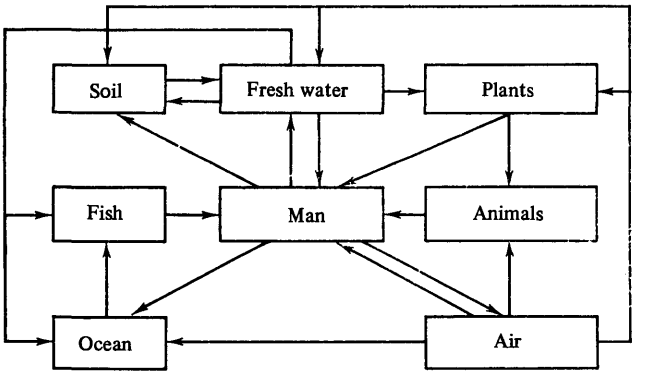
I. INTRODUCTION

The manufacture and consumption of lead in various branches of industry increase continuously; at the same time its release into the biosphere has also increased. Thus 100 000 tonnes of lead were released into the atmosphere in the USA in 1964, which amounted to 10% of the total industrial consumption of lead; the corresponding amount in 1968 was 184 316 tonnes[1]. According to UNESCO data, more than 2.3 million tonnes of lead enter the seas with river water. The atmosphere is also a source of the contamination of the Pacific Ocean by lead. According to Kutyrin's calculations[2], 200 000 tonnes of lead fall on its surface every year.

The number of publications devoted to the problem of the pollution of the environment by lead is large, because lead contaminates various areas—the atmosphere, the hydrosphere, and soils. Many plants grow on soils contaminated with lead accumulate it. The concentration of lead in such lead-enriched plants exceeds the normal content by a factor of 2–100.[3,4] The accumulation of lead by plants merits attention, since not only wild but also cultivated plants, which serve as food products for people, are enriched in lead. Lead can be concentrated at all levels of the aquatic food chain—in both algae and molluscs and fish[5]. Studies in which large amounts of lead were detected in meat and internal organs of domestic animals used as food have been published recently[6,7]. Lead enters the human organism with water and food.



The food chain is not the only source of lead in the human organism. Contamination of air by lead also promotes its penetration into the organism. An increasing number of studies have shown that the main source of lead entering the organism is air contaminated by anti-knocking additives, which contain lead alkyls[8–10]. As a part of organic compounds[11] and also in ointments and cosmetic preparations, lead penetrates through the skin, but apparently only to an insignificant extent[12]. Thus there are two main pathways leading to the chronic action of lead on man—oral and respiratory. The Figure illustrates schematically the migraton of lead in the biosphere.

The global pollution of the environment by lead is indicated by its increased content in polar ice. Thus during the last 25 years the lead content in the snow cover of Greenland has increased by a factor of 400.[13] Lead has also been found in the soil of northern forests remote from industrial regions, where it has been deposited at a rate of 305 grammes per hectare annually[14]. This shows that lead migrates in the environment via the atmosphere in the form of aerosols of lead and its compounds, and the problem of the pollution of the environment by lead has become international, since there are no state boundaries to the movement of atmospheric pollution.

II. LEAD IN THE ATMOSPHERE

1. Sources from which Lead Enters the Atmosphere

The sources of lead in the atmosphere can be divided into natural and anthropogenic. The former include windborne dust, forest fires, volcanic eruptions, sea mist, and plant decomposition products. According to Nriagu[14], the annual amount of lead entering the atmosphere throughout the world from natural sources is 24.5×10^6 kg.

Scheme illustrating the migration of lead in the biosphere.

The anthropogenic sources of lead include lead mines, factories where lead is smelted and lead-containing articles are remelted, factories where various lead compounds are

manufactured, and ferrous and non-ferrous metallurgical plant. The atmosphere is extensively polluted by lead as a result of the combustion of coal, peat, wood, and petroleum fuels used in internal combustion engines, in the combustion of waste, and in the cleaning of tanks and cisterns for the storage of petrol.

The anthropogenic emission of lead amounts to 449×10^6 kg annually[14] and exceeds the natural emission by an order of magnitude. The amount of lead entering the atmosphere on combustion of petrol, which contains anti-knock compounds, amounts to approximately 60% of the total emission from anthropogenic sources.

The total amount of lead distributed in world ecosystems through the atmosphere during the period of civilisation is 20×10^9 kg.[14] A sharp increase of lead emission was observed at the beginning of the 20th century and then in 1923 when anti-knock alkyl-containing derivatives were introduced into petrol.

2. Lead in the Exhaust Gases of Automobiles

One of the principal sources of lead in the environment is the exhaust gases of automobiles and aeroplanes. The waste from automobiles constitutes 57–95% of the pollution of air in many cities of highly developed capitalist countries, more than 40% in Moscow, and 13.3% on average in the USSR.[15] During use, an automobile releases into the environment more than 100 different compounds, the majority having a harmful effect on the environment.

The results of the study of the pollution of air by lead from compounds used as anti-knock agents for internal combustion engines have been published[17]. The authors of this study determined with the aid of ^{203}Pb the amount of lead deposited on the leaves of plants, on the soil, and on grass. It was found that fine aerosol particles (0.01–0.03 μm) are deposited on the surface of plants more readily than large particles (0.2–0.25 μm). Only 10% of the total amount of lead in exhaust gases is deposited on plants 30 m from a motorway with a traffic density of 40000 automobiles per hour; the remaining lead-containing particles remain suspended and are deposited at a much greater distance from the highway.

The anti-knock additives includes mainly alkyl derivatives of lead: $Pb(CH_3)_4$, $Pb(CH_3)_3(C_2H_5)$, $Pb(CH_3)_2(C_2H_5)_2$, and $Pb(C_2H_5)_4$. In the combustion of fuel a significant proportion of the lead bound in organic compounds decomposes and is ejected into the atmosphere in the form of inorganic salts, but a certain amount is ejected unchanged. The results of a study of the levels of organic and inorganic lead compounds in air have been published[18]. By taking samples on filters with a pore diameter of 0.01 μm and using the gas-chromatographic method of analysis, it is possible to determine the concentrations of organic and inorganic compounds of the element. It has been established that most of the lead detected in the atmosphere is present in an inorganic form, while the concentrations of organic lead compounds in air are very low, amounting to 10^2–10^3 μg m^{-3}.

In a review[19] devoted to the problem of the pollution of the atmosphere by tetraethyl-lead (TEL) and tetramethyl-lead (TML) it is noted that their content in the atmosphere is less than 5% of the total amount of lead present. The authors[19] explained this finding by two causes: the fairly rapid photochemical decomposition of these compounds and the presence in the atmosphere of substances accelerating their decomposition. Among these, the most active are NO_x, O_3, atomic oxygen, and the radicals $OH^{\cdot}$, $CO^{\cdot}$, etc., the reactions of alkyl derivatives of lead with these substances being fairly rapid also in the dark. The kinetics and mechanisms of the main homogeneous reactions of TML and TEL in the atmosphere have been investigated[20]. It has been found that the lead alkyls are relatively stable in the dark and have half-lives of 320 and 100 h for TML and TEL respectively in purified dry air. Both compounds are unstable to the action of ultraviolet light and decompose in the light via first-order reactions with photolytic decomposition rate constants of 3.4×10^{-4} min^{-1} for TML and 1.3×10^{-3} min^{-1} for TEL (after subtracting the corresponding values for the dark reactions).

Thus the rate of photolysis of TEL is almost four times greater than that of TML. This is probably why, among lead alkyls, only TML can be detected in the air over our motor highways with a high traffic density, its content amounting to 1–20% of the total concentration of lead in the air[21]. As regards the mechanism of the homogeneous reactions of lead tetra-alkyls, the authors[20] concluded that it is analogous to the mechanism of the hydrocarbon decomposition reactions. The reactions of TML and TEL with O_3, $O^{\cdot}$, and $OH^{\cdot}$ are analogous to the reactions of alkenes, particularly ethylene and propene.

The following mechanism of the reaction of TML with ozone has been proposed[20]:

$$Pb(CH_3)_4 + O_3 \rightarrow (CH_3)_3PbOOH + CH_2O^{\cdot} ,$$

The rate constant for this reaction has been determined as 1.9×10^{-3} $(p.p.m.)^{-1}$ min^{-1}. The rate constant for the reaction of TEL with ozone is 1.6×10^{-2} $(p.p.m.)^{-1}$ min^{-1}. Lead alkyls can react with atomic oxygen either via reaction (1) or via reaction (2).

$$R_4Pb + O^{\cdot} \leftarrow R_3PbO^{\cdot} + R^{\cdot} ; \quad (1)$$

$$R_4Pb + O^{\cdot} \rightarrow R_3PbCH_2^{\cdot} + OH^{\cdot} ;$$

$$R = CH_3 \text{ or } C_2H_5 . \quad (2)$$

The rate constants for the above reactions are 7.0×10^2 and 18.9×10^2 $(p.p.m.)^{-1}$ min^{-1} for TML and TEL respectively[20].

The interaction of $OH^{\cdot}$ radicals with lead tetra-alkyls most probably proceeds via the mechanism

$$R_4Pb + OH^{\cdot} \rightarrow R_2PbCH_2^{\cdot} + H_2O .$$

The rate constants are 13.3×10^3 and 11.7×10^4 $(p.p.m)^{-1} min^{-1}$ for TML and TEL respectively.

According to the data of Harrison and Perry[22], the concentration of lead tetra-alkyls in city air near motorways is on average 0.1 μg m^{-3} and constitutes less than 5% of the total content of lead, which agrees with Baba's results[19].

Between 80 and 100% of lead compounds found in the exhaust gases of automobiles consist of the lead halides $PbBr_2$, $PbCl_2$, PbBrCl, and the α- and β-forms of the double salt $2PbBrCl.NH_4Cl$. The composition and size of the particles in the exhaust gases have been studied in detail[23] using a scanning microscope. It was found that the large particles (>200 μm) contain mainly PbBrCl, $2PbO.PbBrCl$, and insignificant amounts of $PbSO_4$ and $Pb_3(PO_4)_2$; the main lead compound in 2–10 μm particles is PbBrCl. Particles with a diameter >5 μm contain 20–30% Pb, those with a diameter of 1–5 μm contain 50–70% Pb, and only 5% Pb is present in submicroparticles.

More than 90% of the particles in the exhaust gases have dimensions less than 2 μm. Thus, as a consequence of the high degree of dispersion of the particles in the exhaust gases from automobiles, there is a high probability of the penetration of lead into the organism via the respiratory pathway. We may note that the concentration of lead in city air has reached dangerous levels, bearing in mind that 1 litre of petrol contains 200–600 mg of lead, 50–70% of which is ejected into the air with the exhaust gases[24]. The possible ways of combating the pollution of the environment by lead

involve the creation of fundamentally new engines and new catalysts and the use of unleaded petrol. The results of experiments have demonstrated a decrease of the lead content in the parts of cities with a reduced automobile traffic[25].

3. The Lead Content in the Atmosphere and Its Biological Action

Although the views on the mechanism of the absorption of lead via the respiratory pathways are contradictory, it has been suggested that a considerable proportion of the lead breathed in enters the blood through the tracheobronchial system. According to the data in Ref. 21, 35% of the total amount of lead breathed in enters blood.

Results obtained in the inhalation by rats, over 40–60 min, of the aerosol of the exhaust gases from engines working on petrol with added TEL containing the ^{203}Pb isotope have been published[26]. The authors suggest that lead is absorbed by rats mainly through lungs and not through the gastrointestinal tract. It has been noted that lead assimilation processes during inhalation are fairly similar in rats and in men, but there are significant differences in the metabolism of the assimilated lead.

Cantrell et al.[27] caused baboons to inhale Pb_3O_4 dust (particle diameter 3.2 μm) at a concentration of 1.5 μg m^{-3} in the course of 4 h per day for 26 days. It was found that, whereas the initial lead content in the blood was 9.9 μg/100 ml, after 24 h of inhalation it rose to 19, and after two days to 41 μg/100 ml.

Data concerning the concentration of lead in the atmospheric dust of large cities in the industrial centres of Canada exceeding the natural concentrations by a factor of 18–300 have been published[28]. Following the inhalation of 0.1 g of dust with a lead concentration of 1500 μg g^{-1}, which corresponds approximately to its content in the dust of a medium-scale industrial city, man accumulates up to 20 μg of lead. In rural areas the absorption of lead with dust amounts to 5% of its total daily intake (with food, water, and air), while in a large industrial city it amounts to 60%.

People constantly exposed to air containing 4.5 μg m^{-3} of lead (the concentration over large industrial cities) absorb 91 μg of lead in 24 h. Depending on the particle size, the organism retains approximately 30–40% of the lead absorbed in this way, which amounts to 36 μg in 24 h.[29] In Philadelphia the level of lead in the blood of 11 women living in city areas amounted to 29 μg/100 g and more, while the concentration of lead in the city air was 1.7 μg m^{-3}.[25]

In many investigations it has been emphasised that the level of lead in the blood depends on a multiplicity of different factors and not only on the lead content in the atmosphere. Thus a detailed study of the biological action of lead aerosols on the inhabitants of Tokyo has been described[30]. The limiting concentration of lead in the atmosphere was 0.63 μg m^{-3}. The level of lead in the blood varied in the region of 16.8 to 18.7 μg/100 ml depending on the given person's place of residence and occupation. However, a positive correlation between the lead concentration in the blood and its content in the atmosphere has not been established. No correlation has been found either in a study[31] of the biological action of the lead content of the atmosphere on the inhabitants of 7 American cities. However, it has been shown[32] that the lead content in the blood of the inhabitants of Teheran is closely related to street traffic; the lead concentration in the blood increased with age and was higher in cancer patients than in healthy people. In Italy tests were made on the level in the blood of people living in industrial city regions and in the region devoted to the ceramic industry[33]. The average lead contents in the blood were respectively 26.02, 32.21, and 58.06 μg per 100 ml. The lead content in the blood was higher in men than in women and higher in male smokers than in non-smokers. Thus smoking can be regarded as one of the ways whereby lead penetrates into the human organism.

It has been shown[25] that the average level of lead in the blood increases slightly under the influence of air with a lead content of approximately 2 μg m^{-3}; in the presence of this amount of lead in air the lead concentration in the blood of most people is approximately 30 μg/100 ml. It has been calculated[34] that after exposure to an atmosphere containing lead at a concentration of 2 μg m^{-3}, the amount of lead absorbed from respiratory pathways is on average 14 μg per day. The average lead contents in the blood of city inhabitants in different countries are 12.1 μg/100 ml,[35] 25 μg/100 ml,[36] and 43 μg/100 ml.[37]

III. CONTAMINATION OF THE SOIL AND PLANTS BY LEAD

1. Lead in the Soil Near Smelting Plants, Mines, and Industrial Undertakings

The Clark level of lead in the Earth's core is 1.6×10^{-3}%.[38] In the region of abandoned lead amines, smelting plants, and industrial undertakings associated with the production of lead and its compounds, the content of this metal in the soil, particularly in the surface layers, is much higher. Extremely high concentrations of lead (>5000 μg g^{-1}) have been found in the upper layers of soils in direct proximity to industrial undertakings involved in the processing of scrap metal and used batteries and outside the storage areas of factories manufacturing batteries.

It has been shown[39] that the lead content diminishes exponentially with distance from the source of pollution. Analogous data have been quoted in other investigations. Dust and specimens of dirt collected on the surface of the Earth at a distance of 1 km from smelting plants contained 3541 to 5466 μg g^{-1} of lead, whilst at a distance of 2.5 km the content was 397 μg g^{-1}.[40] In many studies devoted to the determination of lead in soil near industrial undertakings its high content was also observed[41–43]. It is noteworthy that the lead concentrations in the soil of open spaces and playing fields remote from industrial undertakings and automobile highways were 800 μg g^{-1} (in 900 soil specimens[44]).

Lead accumulates in the soil not only as a consequence of its contamination by industrial waste, but, as mentioned above, also as a result of the pollution of air by the exhaust gases from motor transport. Near motorways, the concentration of lead in the soil and in the dust covering plants is enhanced. According to Strusinski's results[45], the highest amounts of lead have been detected at a distance of 10 m from the road; with increase of the distance from motorways, the concentration of lead diminishes. It has been shown[46] that lead accumulates on the surface of soils in layers 0–5 cm deep. Specimens taken from rice fields at a distance of 3 to 5 m from a motor highway contained 11–100 μg g^{-1} of lead; in specimens taken at a distance in excess of 3–5 m the Clark level of lead was not exceeded.

The ability of lead to be absorbed by various soils is extremely high. Thus, in a study of the distribution of metal ions between the soil and a solution, it was established[47] that in the pH range 3.5–4.5 the degree of adsorption diminishes in the following sequence: Pb > Cu > Cd ≅ Zn > Ca. The absolute amounts of adsorbed ions increase with the concentration in solution and the adsorption and desorption half-lives are in the range 5–15 s. Since soil is a complex multi-

component system incorporating fungi and enzymes in addition to organic and inorganic ingredients, it is to be expected that lead will influence them. In an experiment designed to investigate the influence of lead on the self-purifying capacity of soils it has been observed[48] that, among all the parameters of the biological activity of the soil, the activity of enzymes is the most sensitive to the action of lead. Lead at a concentration of 100 μg per 100 g of soil suppresses the dehydrogenase activity of the soil to a fairly high extent. In a study of the toxic effect of lead salicylate, acetate, and oxide on soil enzymes it was found that the salicylate causes the greatest inhibition of enzyme activity, while the oxide has the least effect[49], i.e. the most water-soluble compound exerts the greatest influence.

2. Contamination of Plants with Lead

The possibility of the stimulating effect of lead at low concentrations on plants has been pointed out in Soviet studies[50,51], but the problem of the relation between the lead concentrations in the soil and the biological effect has not been solved in the above investigations. In studies of recent years much attention has been devoted to the establishment of a correlation between the amount of lead introduced into the soil and its effect on the development of plants. Thus it has been demonstrated[52] that the introduction of lead acetate into the soil at a concentration of 100 mg kg^{-1} and of lead carbonate at concentrations of 500 and 5000 mg kg^{-1} has a positive effect on the growth and development of Khar'kovskaya-46 wheat. On the other hand, lead acetate at concentrations of 500 and 5000 mg kg^{-1} inhibited the growth of plants. The different effects of lead salts are attributed to the low assimilability of lead carbonate as a consequence of its low solubility and also to the change in the pH of the soil water after the introduction of lead salts. No data were published in the above study[52] concerning the lead content in the plant itself.

It has been stated[53] that the introduction of lead into the soil at concentrations up to 1000 μg g^{-1} does not have any effect on rye and oats sown in sandy loam. A further increase of the lead concentration leads to a sharp decrease of the rate of growth. The introduction of fertilisers does not decrease the harmful effects of lead at its concentrations in excess of 1000 μg g^{-1}.

According to Vinogradov's data[54], the Clark content of lead in plants is 1.0×10^{-4}%. In regions with soils contaminated by industrial waste and automobile transport, lead has been found to have been accumulated by plants. The accumulation of lead by plants grown on soils with its different contents has been investigated[3]. The results showed that potatoes, cabbages, tomatoes, cucumbers, onions, and carrots grown on soils with a lead content of 220–480 mg kg^{-1} contain 2–5 times more lead than the vegetables grown under the same climatic conditions but on soils with a lower lead content (18 mg kg^{-1}). The authors[3] conclude that the lead concentration in vegetables is on average smaller by two orders of magnitude than its concentration in the soil on which they have been grown and that the accumulation of lead by plants on lead-enriched soils compared with that on normal soils differs by a factor not greater than 10.

It has been established[4] that different plants are capable of absorbing different amounts of lead under identical conditions. The minimum amount of lead was found in the seeds of leguminous plants—peas and beans. The maximum amount was found in the leaves of the turnip and egg plant—16.2 and 22.4 mg kg^{-1} respectively. On average, the lead content in the majority of plants was 2–3 mg kg^{-1}. When lead was introduced into the soil in the form of an aqueous solution of its acetate in doses of 50 and 100 mg per kilogram of soil, the leaves of lettuce accumulated 17 and 32 times more lead respectively than in control plants. For the majority of plants, a proportionality has been observed between the lead content in the soil and its accumulation in the plants.

The ability of lettuce to accumulate lead in appreciable amounts has been reported in a study[55] where the species response of lettuce to lead was investigated. Nine species of lettuce were grown by the hydroponic method with addition of lead to the nutrient medium at concentrations of 0.1–50 mg kg^{-1}. It was shown that low concentrations of lead (0.1–0.5 mg kg^{-1}) stimulated the growth of the roots and leaves on the lettuce, particularly in the early stages, while concentrations in excess of 50 mg kg^{-1} significantly inhibited the growth of plants after 4–6 weeks. Differences in the responses of the lettuce species considered, characterised by similar morphological structures, were discovered, which indicates a genetic regulation of the physical mechanisms of the assimilation and transport of lead in plants. It has been suggested that species selection will make it possible to obtain plants with a reduced capacity for the accumulation of lead and hence to reduce to a minimum the risk of the introduction of lead into the organism with food. The important conclusion has been reached[56] that the lead content in pea plants grown in pots with a lead-contaminated soil is correlated with the level of the water-extractable lead and not with its total content in the soil.

As noted above, roadside plants in the vicinity of a highway with intense motor traffic or near industrial undertakings contain much more lead than plants in regions not subjected to the influence of automobile transport and industrial pollution. Thus the lead content in grain cereals grown on lead-contaminated soils is appreciably increased[57]. In the immediate vicinity of a motor highway grass was found to have a maximum lead concentration of 206 mg kg^{-1}.[58]

In the course of a number of years Ocker and coworkers[59–61] investigated the content of mercury, lead, and cadmium in specimens of wheat and rye and in their processing products. It was established that lead is present in the grain in amounts of 0.1–0.2 mg kg^{-1} and is concentrated in its outer layers. The lead content is associated with the region in which the plants are grown and is particularly high in fields located near industrial centres. In the course of the husking of the grain up to 70% of lead is removed; approximately 40% of the lead contained in the grain enters the flour in the milling of the Canadian "durum" wheat. It has been shown[60] that a daily intake of 3 mg of lead by the human organism is harmless to health. It has been pointed out that the permissible lead content in food products is $\leqslant$0.5 mg kg^{-1}. In a number of studies it has been emphasised that, provided that technical instructions as regards the growing and gathering of the crop are adhered to, there is at present no acute risk to the health of people due to the contamination of food products by lead in connection with automobile exhausts.

Studies over a period of many years[62–64] have demonstrated the ability of lichens to accumulate the radioactive isotope ^{210}Pb. Natural breakdown in the ^{226}Ra chain is the source of supply of ^{210}Pb into the biosphere. The long half-life of ^{210}Pb ensures a global distribution of the isotope in the atmosphere and its uniform deposition on the Earth's surface. The ability of lichens to accumulate lead is responsible for the increase of lead concentration in all parts of the chain lichen–deer–man. According to the data of Litver et al.[62], 1 kg of dry lichen contains 7.6×10^{-9} Ci of ^{210}Pb.

There are literature data concerning the ability of fungi to concentrate lead[65,66]. Lead at a concentration of 5.34–80.98 mg kg^{-1} has been detected in the majority of puff-balls collected at a distance of 23–24 m from an automobile highway. The metal concentration in the washed and unwashed fungi was virtually the same, its greatest amount being located in the fungal caps[65]. According to Schnellmann and Opitz[66], the greatest amount of lead is contained in the fungus *Psalliota campestris*—the common mushroom—1.0 mg per kg of dry weight.

3. Lead in Seaweed

Many types of seaweed as well as terrestial plants are able to accumulate heavy metals. It has been established[67] that, in the presence of sufficient illumination, thick growths of certain seaweed contain lead in an amount exceeding 70 g per kilogram of dry mass. Careful washing of seaweed in fresh water removed less than 10% of the bound heavy metals. Exposure of seaweed specimens to dissolved lead salts led to a rapid exchange of the Na^+, Ca^{2+}, and Mg^{2+} ions, which are intracellular cations and are bound to the outer surface of the walls and plasmatic membranes. When seaweed is exposed to lead acetate (lead concentration of 100–500 mg kg^{-1}), extremely high losses of organic material occur, which indicates cell damage[68].

Experiments with natural thickets of seaweed have shown that in the vicinity of industrial waste heavy metals such as lead can accumulate to considerable levels without any apparent physiological harm to the aqueous organisms. It may be that incorporation of heavy metals along the cell wall protects the normal state of the metabolic enzymes and the cell structure. However, no attempt has as yet been made to determine the relative abundance of the physiologically harmless lead within the cell or on its envelope. Plants collected at a site where industrial waste is released contain excess amounts of heavy metals. Thus in its habitat in the bays of the Sea of Japan, where the lead concentration in water is 0.01 mg $litre^{-1}$, the plant *Ulva fenestrata* contains 5.4 times more lead than in a control, uncontaminated bay[69].

The authors explained the increased lead content in seaweed by the affinity of lead for the sulphydryl groups of proteins. It has been noted that changes in the geochemical factors of the medium in a polluted bay led to the adaptation of the water plants to the change in its mineral composition. The slow influence of lead on cell growth as a result of its slow accumulation has also been noted in other investigations. Thus the influence of copper and lead on the growth of pigmentation of seaweed has been studied[70]. Even low lead concentrations tend to reduce the amount of chlorophyll and carotenoid. In addition, the generation of oxygen under illumination is suppressed. However, lead should not be regarded as extremely toxic to seaweed. It has been shown[71] that the accumulation of lead by seaweed and water plants is associated with the pollution of the underlying soil when snow collected from cities with intense motor traffic is disposed of in water basins.

The toxicity of TML in relation to the freshwater alga *Scenedesmus quadricauda* has been investigated[72]. When biologically generated TML from a container with a lead solution at a concentration of 5 mg $litre^{-1}$ is bubbled through a medium containing an alga, the cell growth of the latter is reduced by an amount ranging from 85 to 32%. Cells exposed to the action of lead tend to aggregate. Changes were observed in their fine structure.

IV. LEAD IN THE HYDROSPHERE

According to Chow's data[73], lead compounds are introduced into the oceans with continental water in an average amount of 1.7×10^{10} g annually. The main contribution of lead to the hydrosphere comes from industrial waste water, the precipitation of radioactive deposits, and the use in river transport of motors driven by petroleum fuels. It has been estimated[74] that the lead content in the surface layers of fresh water has increased from prehistoric times up to the present by an amount ranging from 0.5 to 5 μg $litre^{-1}$.

As mentioned in the previous sections, the transport and distribution of lead from various sources takes place mainly through the atmosphere. Large lead-containing particles are deposited along the roads and are responsible for the high level of lead in soils. Aerosols with smaller particles are transported by wind and are dispersed around the terrestial globe. On precipitation of snow and rain, these lead compounds are "washed out" of the layers of the atmosphere and enter the soil and the hydrosphere. Naturally the lead content in rain water is correlated with its local content in air, the intensity of motor traffic, and the degree of industrialisation of the region. According to the results of Drozdova and Machon'ko[75], the average concentration of lead in rain water at 16 points in the European territory of the USSR was 5.5 μg $litre^{-1}$ in 1968–1969. Andren and Lindberg[76] found that the average deposition of lead with rain is 20 g per hectare per month. The lead content in the river waters of South Western France has been determined[77] and it has been noted that it varies from 14.4 to 0.2 μg $litre^{-1}$ and that the precipitation of lead in atmospheric rain is higher than its transport in river water.

1. Lead in Polar Ice

The study of polar snow, frozen layers of which permit the determination of its chronological age, is a reliable means of estimating the anthropogenic contribution of lead to the environment as a function of time. The results of studies of the concentrations of 12 heavy metals, including lead, in the snows of Western Antarctic from 1914 to 1974 have been published[78]. It was found that snow became greatly enriched in lead, cadmium, copper, zinc, and silver as early as 60 years ago and that the enrichment factors found in 1914 were comparable to those determined at the present time. The concentrations of the heavy metals were higher than expected on the basis of their average values for the Earth's core and seawater, the values for lead being 0.018 and 0.04 μg kg^{-1}, depending on the kind of filter used. The authors[78] believe that the sources of the heavy metals in polar snows may be their emission from the surface microlayers of the oceans and from plants as well as human activity. However, they believe that the most probable source is volcanic activity, since the changes in the concentrations of metals with time agree with the historic records of volcanic aerosols. Evidence that volcanic aerosols can reach the Antarctic ice cover had been published previously[79].

The results of the above study[78] agree with those obtained by other workers. Thus, according to Murosumi et al.[80], the lead content in specimens of Antarctic snow after 1916 was 0.01 μg kg^{-1}. In northern Greenland the lead concentration proved to be higher than in the Antarctic. The lead content in the ice layers of Greenland extrapolated to 1753, which corresponds to the beginning of the European industrial revolution, is 0.011 μg kg^{-1}. This concentration exceeds by a factor greater than 25 its natural level. During the period from 1933 to 1965 the metal concentration increased

to 0.20 μg kg^{-1}, which exceeds the natural level by a factor of 500. The authors[80] explain this increase of the lead content in polar ice by the contribution of smelting operations, the combustion of coal, and the use of lead-containing antiknock additives, which began actively in 1940.

Sanak and Lambert[81] investigated the variation of the concentration of ^{210}Pb in the ice cover of the South Pole as a function of the depth from which the specimen was collected. 92 specimens collected from depths down to 18 m were analysed, which showed that between 1920 and 1954 the lead concentration increased. The authors explained this either by a change in the rate of the accumulation of snow or by an increase of the concentration of ^{210}Pb in the snow. Possibly both factors operated simultaneously.

2. Lead in Fresh Water

The concentration of lead in fresh waters depends on the site from which samples are removed, on the time of the year, and on the distance from industrial regions. A review[73] presents the results of the determination of lead in fresh waters. Lead was determined during the period 1956–1975 in 42 sources of water located in different parts of the Earth. It was found that the average lead concentrations in fresh waters vary from 1 to 24 μg $litre^{-1}$ and in the majority of rivers and lakes are in the range 1–10 μg $litre^{-1}$.

Higher amounts of heavy metals are located in the surface microlayer and in the foam generated by wind on the surfaces of rivers and lakes. The foam and the surface microlayers can also be enriched in aliphatic acids, esters, alcohols, chlorinated hydrocarbons, microelements, and organic and inorganic forms of phosphorus, nitrogen and carbon. The enrichment of the foam in heavy metals takes place as a result of the pollution of the surface of water by the metals, the retention of material particles in the surface film and in air bubbles, and the atmospheric contribution.

The foam collected in 1973–1974 at the southern and western coasts of Lake Mendota has been analysed[82]. The foam specimens were collected in plastic cylinders and, after destabilisation in the dark at 4 °C for 24 h by the voltamperometric method, the heavy metal content was determined. It was found that 27–28% of the metal from the destabilised foam is present in the dissolved phase. A considerable proportion of the dissolved metal is bound in complexes with organic substances or is associated with the colloid phase. The average lead concentration in the foam is 2.21 mg $litre^{-1}$. The average enrichment factor in the solid fractions was found to be a maximum for lead (1580), being 800, 235, and 80 for the remaining metals (Cd, Zn, and Cu respectively). It is noteworthy that the surface layers and foam have so far been little investigated from the standpoint of the accumulation of lead and other heavy metals.

At the sites of the disposal of city and industrial waste the lead concentration is appreciably increased and can reach 1000 μg $litre^{-1}$ and more. In connection with the struggle for the protection of the environment, industrial undertakings nowadays have purifying equipment to protect water resources from contamination by waste water. "Rules for the protection of surface water from contamination by waste water", defining the conditions for the disposal of waste water and specifying norms for the quality of water are operative in our country. The limiting permissible concentration (LPC) of lead in reservoirs for sanitary and domestic consumption is 0.1 mg $litre^{-1}$; tetraethyl lead must be absent (within the limits of the most sensitive research method)[83]. The following values of LPC have been established for radioactive isotopes[91]: 1×10^{-7} Ci $litre^{-1}$ for ^{203}Pb; 1×10^{-11} Ci $litre^{-1}$ for ^{210}Pb; 5×10^{-9} Ci $litre^{-1}$ for ^{211}Pb. When waste water is released within the boundaries of any inhabited site, the requirements established as regards the composition and properties of the water in a given body of water must apply to the waste water itself, since in practice one cannot hope for dilution and self-purification[84].

The limiting permissible concentration of lead in drinking water, amounting to 100 μg $litre^{-1}$, has been established by the World Health Organisation (WHO); the same quantity has been adopted as the LPC in the Soviet Union. A limiting level of 50 μg $litre^{-1}$ has been established in the USA and Canada, while in Sweden it is 20 μg $litre^{-1}$. Many investigators suggest that the LPC for lead established by WHO be reduced. Thus it has been proposed[85] that a limiting concentration of lead of 30 μg $litre^{-1}$ be established.

In certain countries where lead pipes are used in the water supply drinking water can contain increased quantities of lead. This applies to regions with soft water giving a weakly acid response in which the solubility of lead is enhanced. The average concentration of lead in such water usually varies in the range 50–100 μg $litre^{-1}$ and in certain cases it reaches ≳300 μg $litre^{-1}$. Cases of an increase of the lead concentration in water to 600 μg $litre^{-1}$ are known; when the lead pipes in the water supply were replaced, the concentration of lead in water fell to 3 μg $litre^{-1}$.[86]

3. Lead in Solid Deposits

The lead contents of solid deposits in rivers, lakes, and seas are various and depend on the geochemical conditions and the anthropogenic contribution. The concentration of lead in the solid deposits removed from various regions near Long Island (USA) varies in the range 200–350 μg $litre^{-1}$.[87] The concentration of lead on the surface of the deposits from the Lake Ontario, amounted to 120–137 mg kg^{-1}.[88]

The distribution of heavy metals in the solid deposits and waters of the Amur Bay has been investigated[89] and the degree of contamination of the deposits in the Golden Horn Bay, where there is a large anthropogenic contribution, has been established. The degree of contamination of the deposits in the latter bay decreases in the sequence Pb > Hg > Cd > Zn > Cu > Cr. The ratio of the average concentrations of the elements in the deposits of the Golden Horn and Amur Bays has been adopted as an index of the contamination of such deposits.

For lead, this quantity amounts to 11.1 (solid deposit) and 1.6 (water near the bottom). The above coefficients show that the lead content in the deposits of the Golden Horn Bay is much higher than the background concentration, which is due to the high sorption capacity of the deposits and the low mobility of the metal in the latter. The local character of the increase of the concentration of heavy elements, associated with the disposal of pollutants in the water of the bay, has been emphasised: the concentrations of the elements in the deposits removed from the mouth of the bay is reduced.

The deposits in Newport Bay (California) were analysed[90] by three independent methods. It was found that the concentrations of zinc and lead increase in the upper layers deposited since 1955, when industrial development began in the catchment area.

The compositions of the solid deposits from different bodies of water are different. In those places where argillaceous rocks predominate, the sorption of ions by clay particles takes place via ion-exchange processes and under the influence of adhesion forces. The overall sorption capacity of clays in relation to heavy metal ions depends on the mineral composition and on the pH of the medium[91]. With increase

of pH, the sorption capacity of clays as a rule increases as a consequence of the formation of stable hydroxo-complexes.

4. Chemical Forms of Lead in the Hydrosphere

The complexity of the behaviour of metals in the hydrosphere is due to the presence in water of a large amount of organic and mineral compounds of abiotic origin and those which are formed in the course of the vital activity of water organisms and as the result of their natural death or mass destruction due to unfavourable conditions. These are nitrogen-containing substances, organic acids, aminoacids, vitamins, hormones, and inorganic salts.

The determination of the overall concentration of trace metals in natural waters in order to establish the degree of their toxicity to water organisms and plants can yield erroneous results. Depending on the chemical form of the metal, water with a high lead concentration can be less toxic than another type of water with a lower lead concentration. The ionic form of lead is more toxic to organisms than lead bound in a complex and the greater the stability of the complex the lower the toxicity. The chemical behaviour of lead in the hydrosphere constitutes a problem which has been little investigated. Problems associated with the form of the chemical compounds of lead contained in the solid deposits have been inadequately studied; it is known that lead is present in the form of such compounds in fresh water and sea water.

The chemical simulation of the nature of the trace metals in water has been carried out[92]. A study was made of the behaviour of heavy metals, including lead, in the presence of inorganic ligands (CO_3^{2-}, SO_4^{2-}, Cl^-, Br^-, F^-, NH_3, PO_4^{3-}, and OH^-) and organic ligands [ethylenediaminetetra-acetic acid (EDTA), citrate ions (Cit), histidine, cysteine, and aspartic acid]. The adsorption of metals on the surface of SiO_2 has been studied. It has been established that at pH < 7.1 lead exists in the form of Pb^{2+} ions; above this pH, lead is present as $PbCO_3$ and hydroxo-species. The sum of lead carbonate and its hydroxo-complexes does not exceed 15%. The complexes with sulphate, chloride, and bromide ions exist in very small amounts. The study of the behaviour of lead in the presence of organic ligands has shown that complete binding in the complex takes place at [EDTA] = 30[Pb]. Appreciable binding of Pb^{2+} by citrate ions takes place when the ligand concentration is more than a factor of 10 greater than that of the metal; thus 30% of lead is bound in the form of complexes at [Cit] = 100[Pb]. The distribution of lead between water and the sorbing surface depends on the accessibility of the latter. With increase of the surface area, the degree of adsorption of metals increases. Copper(II) is most readily adsorbed on SiO_2 and is followed in this respect by lead(II) and mercury(II).

In a deposit–water system lead also exists in different forms. Part of the metal can remain in the intermediate water in the form of free or complex ions and can combine with soluble inorganic and organic substances, can be adsorbed on the surface of the deposits, or can be incorporated in the crystal structure of the latter.

The behaviour of different organic substances and heavy metals in the deposit–sea water system under various oxidation-reduction conditions has been investigated[93]. The authors studied three typical forms of natural solid deposits—clay, silt, sand, and the water above these deposits. The lead content in the specimens of the deposits was 177, 93.6, and 64.8 mg kg^{-1}, while the natural level is 20–50 mg kg^{-1}; the lead content in sea water corresponding to the deposits was 0.10, 0.04, and 0.08 μg m^{-3}. Oxidising conditions were established by reducing the pH from 8.2–8.4 to 7–7.5; reducing conditions were created by increasing the pH from 6.8 to 7–7.5. Under oxidising conditions, the amount of lead liberated from the deposits increased, while under reducing conditions it decreased compared with the natural level of lead in sea water. This can be explained by the formation of an insoluble sulphide. The solubilities of $PbCO_3$ and PbS (the compounds of which it is proposed to monitor), the formation constants of the principal species existing under specific conditions, and their percentage contents relative to the total concentration of soluble lead have been calculated[93]. Experimental data show that the type of deposit (clay, silt, or sand) does not control the direction of migration of the elements, which is regulated by the chemical composition of the water; the oxidising or reducing conditions are a fundamental factor.

V. THE EFFECT OF LEAD ON LIVING ORGANISMS

1. Lead in Animal Organisms

There is virtually no evidence in the literature concerning the biological necessity for lead to maintain the vital activity of an organism with the exception of a few publications. It has been reported[94] that the addition of 1.0–2.5 μg g^{-1} of lead (as the acetate) to a diet lacking this element increased the growth of rats by up to 20%; lead oxide and nitrate showed the same effect. Some data indicate that small amounts of lead have neither a favourable nor an undesirable effect. An experiment in which sheep were fed paper from newspapers and magazines (23% of their rations) in the course of 175 days has been described[95]. The lead contained in the paper accumulated in animal tissues, but histopathological studies with the aid of an electron microscope did not reveal any damage associated with the diet.

However, the majority of investigations on animals have shown that even a slight exposure to lead induces visible changes in the microstructure of the kidneys and the liver, affects the blood circulation, alters the central nervous system, and diminishes the reproductive function[96–98]. The biochemical effect includes the inhibition of the activity of erythrocyte aminolaevulinate dehydratese (ALD), an increased elimination of δ-aminolaevulinic acid (ALA) with urine, and an increased concentration of lead in the blood[99]. The reduction of the activity of ALD entails a disturbance of the synthesis of haem. In addition, lead inhibits the decarboxylases of coproporphyrinogen and uroporphyrinogen.

The inhibiting effect of $PbCl_2$ on the activity of adenosine triphosphatase has been demonstrated[100]. After the introduction of neutral lead acetate in the experimental lead intoxication of rats, an increase of the content of nucleic acid in the liver and in the kidneys was observed. The increase of the DNA and RNA concentration was proportional to the lead dose administered[101]. Lead can be regarded as a weak mutagen, since a slight increase of chromosomal aberrations was observed under the influence of the maximum dose tested (0.05 mg kg^{-1}).[102] It has also been established that lead disturbs the normal replication and genetic processes in the cell at doses much lower than those required for the appearance of signs of toxic activity[103,104].

Data concerning the lead content in the blood together with other factors determining the state of animals have been published in numerous investigations. Thus an increased content of lead in the blood, heart, and aorta of rabbits with atherosclerosis induced by a cholesterol-enriched diet[105] and

an increase of the concentration of lead in the blood of monkeys under the influence of psychological stress[106] have been reported.

It has been demonstrated on experimental animals that a deficiency of certain biogenic elements and vitamins as well as a high content of fats in food increase the toxicity of lead. Enhanced poisoning with lead occur in the presence of an excess or deficiency of protein in the diet. A deficiency of mineral components increases to the greatest extent the toxicity of lead, particularly in the presence of a deficiency of elements such as calcium, phosphorus, iron, zinc, and in certain cases copper[107,108]. A hypothetical mechanism of the enhancement of the toxic effect of lead in the presence of low contents of calcium in the food, based on the hypothesis that the observed retention of lead in the organism is due mainly to the decrease of its excretion and not an increase of its assimilation in the gastrointestinal tract, has been discussed in a review[109]. Other workers[110] arrived at the same conclusion. They did not observe significant differences in the assimilation of ^{203}Pb by rats receiving for two weeks a diet with low and high calcium contents, but in the presence of a deficiency of calcium in the diet a decrease of the excretion of lead and its accumulation in the organs and tissues were observed.

The iron deficiency in anaemia promotes an increased assimilation of lead in the gastrointestinal tract of rats[111], while in a lead-intoxicated embryo the incorporation of iron in liver haem was greatly depressed[112]. A vitamin *E* deficiency in poisoning by lead induces anaemia in rats[113,114]. Like other heavy metals, lead blocks the SH groups of enzymes[11,115].

Wild animals, fish, and birds are constantly subjected to the action of lead in the environment. Cases of acute poisoning of migratory birds by lead are known. Thus the concentration of lead in the kidneys and livers of geese, found in Canada, which were either dead or too weak to fly, proved to be 9.21–102.56 $\mu g\ g^{-1}$.[116]

An interesting method for the determination of lead in the environment has been proposed by Stone et al.[117]. In the course of two weeks, ten-day old Japanese quails received a diet containing 14.8–1223 $\mu g\ g^{-1}$ of lead. With increase in the concentration of lead in the diet, the latter accumulated in the tissues; at the end of the experiment the duodenum, the kidneys, the liver, and the shin-bone contained 16.76, 20.18, 3.8 and 1527.1 $\mu g\ g^{-1}$ respectively. The relation between the lead content in the tissues and in the diet was virtually linear. The results obtained can be used, according to the authors[117], to determine the lead content in the environment by a biological method.

It follows from the literature data that, among domestic animals, horses are most susceptible to lead intoxication[118–120]. The kidneys and liver of horses from North Western Saxony (Federal Republic of Germany) contained 0.4 and 0.9 $\mu g\ g^{-1}$ of lead respectively, which is 2–3 times more than its content in the organs of horses from Poland[120]. To prevent the risk to human health, the authors recommend that the liver and kidneys of horses be declared unsuitable for use in food and that horse meat should always be tested for lead content. Horses in regions polluted by smoke from industrial undertakings producing lead have shown symptoms of poisoning by lead and the organs and tissues of young animals were less contaminated than those of old ones. Analysis showed that hay and fodder grass were contaminated by lead in this region[118].

Attention should be drawn to the possibility of the lead poisoning of cattle grazing along highways with heavy automobile traffic. An increased concentration of lead in the internal organs of cattle, pigs, sheep, and horses has been noted in regions located near the sources of the pollution of the environment by industrial waste and under the conditions of a large consumption of green fodder. On the basis of data concerning the average annual consumption of meat, the average weekly intake of lead by the human organisms has been calculated as 0.006 mg.[119] The meat of 180 cows has been analysed[121] and the average lead content in the fresh meat proved to 0.31 mg kg^{-1}, which is higher than the maximum amounts found previously.

The considerable accumulation of ^{210}Pb in the muscles of deer in the extreme north of the USSR, exceeding its content in the muscle tissue of deer in Finland and Sweden by a factor of 10, has been noted[64]. The accumulation of ^{210}Pb in the bone of deer depends on the age of the animals. Five to six-fold seasonal variations in the content of radioisotopes have been noted—maximum amounts are observed at the beginning of spring and minimal amounts in the autumn; the average ^{210}Pb concentration in the bone of deer proved to be 8.3×10^{-9} Ci kg^{-1} according to the determinations in 1967 to 1968.[64]

It is believed[122] that the prolonged exposure of animals to lead at concentrations up to 25 mg kg^{-1} does not entail a significant intake of the element by the organisms of people utilising food products prepared from the meat or obtained from these animals. A large amount of the lead taken up by animal organisms is deposited in the bones, mainly in an inert form. In the determination of different elements in 20 specimens of the bones of domestic animals lead was found in the concentration range 1.5–8.5 $\mu g\ g^{-1}$.[123]

2. Lead in Aquatic Organisms

The toxic effect of lead on fish, molluscs, etc. depends on factors such as the form of lead, the duration of exposure, the type of water, and the specific features of the aquatic organisms. It has been established[5] that a lead concentration of 0.1–15 mg $litre^{-1}$ is acutely toxic to fish; lead arsenate at a concentration of 17.1 mg $litre^{-1}$ does not harm small fresh water fish in the course of exposure for 1 h, while at a concentration of 25 mg $litre^{-1}$ it leads to the death of the fish in the course of 24 h.

Lead can be biologically concentrated at all levels of the water food chain. The ability of sea organisms to concentrate elements at higher levels than those found in their environment has been known for many years. Lead concentration factors in the sea biosphere have been established[124]; they amount to 700 for seaweed, 40 000 for the phytoplankton, 3000 for the zooplankton, 4000 for molluscs, and 40 for the muscles of molluscs. It has been shown[125] that the lead content in the crude mass of the zooplankton varied from 0.3 to 1.5 $\mu g\ g^{-1}$ in 1972 and from 0.2 to 2.6 $\mu g\ g^{-1}$ in 1974. Approximate lead accumulation coefficients in the zooplankton amounted to 3.5×10^6 (for a lead content of 0.06 $\mu g\ litre^{-1}$ in the water of the Atlantic Ocean) and 8.8×10^4 (for a lead content in the water of 0.003 $\mu g\ litre^{-1}$).

Tissues of the oysters in the Missouri Basin contain 0.77 $\mu g\ g^{-1}$ of lead[126]. The tissues of the oysters and molluscs in the coastal waters of Tasmania contain lead within limits not exceeding the permissible sanitary norms[127]. As in the case of animals, the liver and kidneys of fish accumulate lead selectively[128]. Fish from different lakes in Poland and the Baltic Sea have been analysed[129] for heavy metals. The average level of lead was 0.199 $\mu g\ g^{-1}$ and the highest level (2.64 $\mu g\ g^{-1}$) was found in the beluga. In some investigations it has been noted that the accumulation of heavy metals by fish depends not only on the pollution of water by industrial waste but also on the species of the fish,

their age, and their size. The accumulation of metals is proportional to the length and weight of fish[130]. External tissues (shells, scale, and skin) contain higher concentrations of lead than internal organs, which is due to the partial adsorption of metals from sea water and especially to their release from the organisms in the course of detoxication. Like other heavy metals, lead probably forms complexes of mucous membranes, gills, or body surfaces.

3. Lead in the Human Organism

Food products are one of the main sources of the lead intake in the human organism under normal living conditions and the lead content must be monitored. The lead content in certain dietary products has been determined[131] by atomic-absorption spectrophotometry; the results in μg/100 g, are as follows: 90 in the tissues of the cod, 17 in the crab, 115 in the pig, 104 in the rabbit, 8 in apples, 23 in nuts, 160 in tea, and 30 in coffee. Apart from the pathways discussed previously, lead enters food products from the packing. Thus preserved orange and tomato juice absorbs lead from cans during storage—orange juice to a greater extent than tomato juice[132]. On the basis of the results of the investigation, it is suggested that the maximum permissible lead concentration in preserved fruit and vegetable juices is 0.4 mg litre^{-1}. As a result of contact with metallic caps, carbonated drinks are also contaminated with lead[133]. Lead can migrate from porcelain ware into its contents. It has been established[134] that it is extracted in greatest amounts into a 4% solution of acetic acid (0–3 mg litre^{-1} in 24 h at room temperature).

The lead content in food varies from 200 to 300 μg per 24 h.[29] Approximately 10% of the lead is extracted from food in adult humans in the gastrointestinal tract. Since the degree of absorption of lead by children is much greater than by adults (approximately 50% of the lead in food is assimilated), its daily consumption must not exceed 150 μg.[135] Analogous results have been presented in another communication[136].

Children, particularly embryos and newborn babies, constitute a group particularly susceptible to lead. This observation is associated not only with the unusual assimilation of lead by the child's organism but also with the fact that children can accidentally absorb much more lead than adults. Many instances of the poisoning of children who have eaten lead-based paint have been recorded. The lead content in four specimens of paint has been determined by atomic absorption methods[137] and has been found to be considerable; 5114, 2651, 1630, and 1350 mg kg^{-1}.

Lead enters the bodies of children also with dust and dirt. Day et al.[138] determined the potential risk to the child's body due to the lead contained in school yards, kindergartens, playing fields and city streets. The lead content in samples of dust, sand, and earth has been found by atomic absorption spectroscopy; it varies in the range 570–2130 μg g^{-1}. According to the authors[138], the increased lead content in the blood of city children up to the age of five is due to the intake of lead with street dust. The frequency of lead poisoning among children is directly proportional to the degree of industrialisation of the region and is directly related to the amount of food consumed by children. Protein deficiency in children enhances the toxic effect of lead on the organism and its deposition in tissues. Vitamins *E* and *C* and various preparations containing Ca^{2+}, Cu, Zn, Fe, and Se reduce the toxicity of lead, which can be used in the treatment of poisoning by heavy metals[139]. Numerous studies devoted to lead intoxication in children are also related to the non-specificity of the symptoms, which hinders the diagnosis of the intoxication of children, particularly at an early stage.

As in animal organisms, lead inhibits the activity of the enzyme ALD in the human organism. On the basis of the correlation observed between the level of lead in the blood and the ALD activity, it is suggested that the latter be determined to estimate the level of lead in the blood in mass investigations and in the cases where lead acts at low concentrations[140–142]. Other works[143,144] believe that the determination of Zn-protoporphyrin in the globin fraction which incorporates it in place of haem in the presence of lead is a particularly valuable method; this parameter is better correlated with the degree of damage to the nervous system and the generation of blood than the concentration of lead in the blood. Lead in the human organism interacts with nucleic acids, proteins, and cell membranes[145], accumulating in various organs and tissues. Organic lead compounds accumulate in tissues with a high lipid content, while inorganic compounds accumulate in bones[11]. According to a report[146], the levels of lead in the liver, blood, and bones of human beings not subject to lead intoxication are respectively 0.447, 0.026, and 4.002 mg kg^{-1}.

The role of urbanisation in the deposition of lead is reflected in the results of a study by Grandgean et al.[147]. It was established that the lead content in the bones of the inhabitants of Nubia is ten times lower than in the bones of the inhabitants of Denmark, while the lead content in the teeth of Nubians is thirty times lower than among Danes. Lead is one of the elements detected in dental enamel in different amounts. It proved to be the only element present in food products whose concentration is strongly and directly related to the incidence of caries.

In regions associated with the manufacture of lead, its increased content in hair has been noted[148]. It is suggested that hair be used as an indicator of the pollution of the environment by heavy metals, since these elements remain in hair for a long time after contact with them has ceased[149]. According to the data of the Pan-American Health Organisation, lead concentrations in hair less than 70 μg g^{-1} are nontoxic to man[149].

Complex forming agents such as EDTA, also employed in therapy, are used to diagnose lead intoxication. The concentration of lead is determined from the increase of the urinary excretion of the lead complex of EDTA after the injection of Na_2Ca.EDTA.[150] There have been reports of the effectiveness of the treatment of chronic intoxications with penicillamine, cysteine, and citric acid[151]. It is believed[152] to be useful to employ aqueous solutions of sodium pectate for the prophylaxis and treatment of lead intoxications. The protecting effect of tannic acid has been reported[153].

---o0o---

It follows from the data presented that lead is a complex pollutant of the environment entering the organism via different pathways. Bearing in mind the ability of lead to accumulate and the large number of sources of lead in the environment, its danger is evident. On the basis of the latest studies, many investigators suggest that the limiting permissible amounts lead established previously be reduced. Thus it has been suggested that the PLC of lead in drinking water be set at 30 μg litre^{-1};[85] for children, the authors[28] propose a norm not exceeding 1 μg m^{-3} of lead in air or 50 μg g^{-1} in dust. A norm of 40 μg/100 ml of lead in the blood has been suggested[29] as more acceptable than the previous norm of 80 μg/100 ml adopted at the XVIth Combined Committee of FAO/WHO experts on food additives.

Emulsion Polymerisation of Non-polar Monomers (Development of Ideas on Kinetics and Topochemistry)

V.N.Pavlyuchenko and S.S.Ivanchev

The kinetics, the topochemistry, and the mechanism of the emulsion polymerisation of non-polar monomers are discussed in the light of results obtained during the past decade. The part played by components of the system, features of the primary reactions, and the theory of emulsion polymerisation are considered. A list of 114 references is included.

I. INTRODUCTION

Emulsion polymerisation is widespread, technically convenient for the production of monomers, and characterised by several specific features. In its common variants the monomer is dispersed in water, but the polymer is obtained as a latex. All the advantages (and disadvantages) of emulsion polymerisation are due to the heterogeneity of the system, and the possibility of localising the primary reactions in different zones. Improvement of the technology of emulsion polymerisation—the possibility of controlling the structure and working properties of the resulting polymers—is determined by the level to which a general theory has been developed to give a correct interpretation of the kinetic and topochemical features. The difficulty of establishing such a theory is due firstly to the multiphase character of the emulsion system and secondly to the multiplicity of parameters governing the mechanism and kinetics. This diversity is due not only to differences in reactivity of the reactants in specific systems but also to differences in their distribution between the phases. All this complicates the establishment of local zones in which the primary steps take place, as well as the determination of reactant concentrations in these zones, so that kinetic description of an emulsion process becomes difficult.

Thus one of the main problems in a theory of emulsion polymerisation is to establish the sites at which the primary reactions occur and to determine the local reactant concentrations at these sites. It must be noted that a given primary reaction can take place in more than one local zone. Finding a theoretical basis for the presence of local zones, their number, and the distribution of reactants among them, establishing their reactivity as a function of their location—these are the chief tasks of a theory of emulsion polymerisation.

At the present time the greatest certainty has been achieved for the emulsion polymerisation of non-polar monomers, sparingly soluble in water, in the presence of ionogenic emulsifiers and water-soluble initiators. However, existing theories do not give a complete explanation even for this comparatively narrow range of emulsion processes. The new experimental results continually appearing undoubtedly broaden our views and deepen our understanding of the processes occurring in complicated emulsion systems.

The present Review will cover mainly research results published during the past 8–10 years and relating essentially to the emulsion polymerisation of non-polar monomers. Special attention will be paid to work which has not been subjected to detailed consideration in the review literature or has not been discussed at all. Detailed analysis of papers on the emulsion polymerisation of polar monomers will be found in Eliseeva's reviews[1,2].

Before surveying the most recent work on emulsion polymerisation we shall consider briefly existing views based on earlier investigations, as well as some of the main directions in which they have been refined and elaborated.

II. QUALITATIVE PICTURE OF EMULSION POLYMERISATION AND THE SMITH–EWART THEORY

We shall consider the most typical emulsion systems, in which polymerisation takes place by a radical mechanism in the presence of micelle-forming surface-active compounds; the dispersion medium is water, while the disperse phase is a non-polar monomer sparingly soluble in water.

The main principles underlying the technology of emulsion polymerisation in such systems were already known at the beginning of the century[3–5], but ideas on its mechanism were remote from present-day views. It was assumed that polymerisation occurred in drops of the emulsion. Fikentscher[6] was the first to abandon this view and to suggest that polymerisation takes place in the aqueous phase. Later more complete qualitative ideas on the emulsion polymerisation of non-polar monomers were developed[7,8] and supplemented independently[9,10]. We note below only the main principles that follow from this work.

1. Emulsion polymerisation is the usual radical process of polymerisation, the explanation of whose features is that the sites of reaction—micelles and polymer–monomer particles—are discrete volumes.

2. In the initial stage the emulsion system comprises a mixture of micelles of the emulsifier, polymer–monomer particles, and large drops of the monomer.

3. Polymerisation begins only in micelles, which are then converted into polymer–monomer particles, whereas drops of the monomer, in which the process hardly develops, serve

merely as a source of the monomer. Diffusion of the monomer from the drops into the polymer–monomer particles is not rate-determining, so that an equilibrium concentration of the monomer is established in the polymer–monomer particles, which is maintained as long as drops exist.

On the basis of these ideas Smith and Ewart[11] developed a quantitative theory of the emulsion polymerisation of non-polar monomers (more precisely the theory of the emulsion polymerisation of styrene by persulphate in the presence of ionogenic surface-active agents), which was then extended to other systems. Their work, published in 1948, was a most important event in the investigation of emulsion polymerisation, and remains so even to the present time. Hardly any contribution to a quantitative theory of emulsion polymerisation can avoid referring to this work.

Using the principle of quasi-stationarity Smith and Ewart suggested several solutions for the kinetic equation of emulsion polymerisation. The condition of quasi-stationarity for N_n particles containing n radicals can in general be written

$$N_{n-1}(R_i/N) + N_{n+1}k_0a(n+1)/v + N_{n+2}k_t(n+2)(n+1)/v = N_n(R_i/N) + \\ + N_nk_0an/v + N_nk_tn(n-1)v, \quad (1)$$

where R_i is the overall rate of entry of radicals into all N particles (the total number of particles in unit volume), v the volume of a particle, n/v the concentration of free radicals in a particle, a the surface area of a particle, k_0 the rate constant of escape of radicals from a particle, and k_t the rate constant of termination. Thus the left-hand and right-hand sides of Eqn.(1) comprise terms describing respectively the disappearance and the appearance of particles containing n radicals. Smith and Ewart examined three cases.

1. The condition $n \leqslant 1$ corresponds to a high rate of escape of radicals from particles or a small proportion of particles containing a radical. The total number of radicals $R = N_1$, and Eqn.(1) becomes

$$N_1k_0a/v = N_0R_i/N. \quad (2)$$

Since $N_0 \cong N$, we have

$$R \approx N_1 \approx R_iv/k_0a$$

and

$$-\mathrm{d}[M]/\mathrm{d}t = k_{gr}[M](R_iv/k_0a) \quad (3)$$

or

$$-\mathrm{d}[M]/\mathrm{d}t = k_{gr}[M]V_pc_r, \quad (4)$$

where k_{gr} is the chain growth constant, V_p the total volume of particles, c_r the total concentration of radicals in the particles, and [M] the concentration of the monomer in a particle. Thus the rate of emulsion polymerisation is proportional to the total volume of particles. However, this case is seldom realised in practice, and does not find wide experimental support.

2. When $n = \frac{1}{2}$, the rate of escape of radicals from particles is small, but the rate of chain termination is high. As a consequence a polymer–monomer particle can contain at most one radical, and each subsequent radical entering the particle causes the instantaneous recombination of two radicals. As a result, only half the particles contain a radical. In view of the assumptions made, the total number of radicals should be $\frac{1}{2}N$. Hence we obtain an equation in which the rate of emulsion polymerisation is proportional to the number of particles:

$$-\mathrm{d}[M]/\mathrm{d}t = k_{gr}[M]nN. \quad (5)$$

This conclusion is confirmed by numerous experimental results.

3. The case in which $n \gg 1$ is comparatively trivial and is described by relations characteristic of normal radical polymerisation in homogeneous systems. Equation (1) becomes

$$R_i/N = 2k_t(n^2/v), \quad (6)$$

whence after finding n we obtain

$$-\mathrm{d}[M]/dt = k_{gr}[M](V_pR_i/2k_t)^{1/2}, \quad (7)$$

i.e. the rate of emulsion polymerisation depends solely on the total volume of particles and is independent of their number.

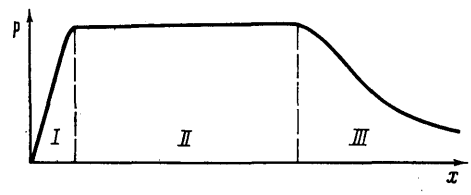

Figure 1. Dependence of rate of emulsion polymerisation on degree of conversion x of monomer into polymer.

The second case is especially interesting, being most often realised in practice and reflecting the features of emulsion polymerisation (for this reason the Smith–Ewart theory is often identified with this case). The qualitative picture and the quantitative theory provide an explanation of the kinetics. The rate curve for non-polar monomers comprises three segments (Fig.1): a comparatively short segment (I), corresponding to an increasing rate of polymerisation R_p, is followed by segment (II), with a constant rate, and segment (III), along which the rate decreases. On the basis of these views section (I), often termed the micellar stage of emulsion polymerisation, can be attributed to formation (nucleation) of polymer–monomer particles and increase in their number. After the micellar soap adsorbed on the particles has disappeared, no new particles are formed, and the R_p remains unchanged along the steady-state segment (II), as all the parameters (k_{gr}, n, N, [M]) are constant. After the monomer drops have disappeared, stage (III) begins, when all the monomer is present in polymer–monomer particles, and the rate of polymerisation falls owing to decrease in the concentration [M] in the particles.

Equation (5) thus describes the steady-state region of emulsion polymerisation, which continues as far as 50–70% conversion depending on the type of monomer. In essence it involves all the kinetic parameters—concentrations of reactants (monomer, initiator, emulsifier) and constants of primary reactions—although only k_{gr} and [M] appear explicitly. The remaining concentrations and constants are included in the parameter N, which according to the Smith–Ewart theory is given by the formula

$$N = k(R_i/\mu)^{2/5}(S_0[E])^{3/5}, \quad (8)$$

in which μ is the rate of increase in volume of the polymeric particle, S_0 the area occupied by 1 g of emulsifier, [E] the concentration of the emulsifier, and k a constant (varying between 0.37 and 0.53). It is evident that the number of particles depends on the rate of initiation, and hence on the initiation constant and the initiator concentration, as well as the emulsifier concentration. The somewhat unusual powers

to which the emulsifier concentration and the rate of initiation are raised are explained by the circumstance that, with a constant rate of increase in particle volume, the total particle surface should increase with time to the power $\frac{5}{3}$.

Equation (8) can be deduced on the postulate that all free radicals formed in the aqueous phase are captured by micelles, when

$$dN/dt = R_i, \tag{9}$$

The change in volume of a particle in the interval between time τ and t

$$v_{\tau t} = \mu(t-\tau) \tag{10}$$

is accompanied by the change in particle surface

$$a_{\tau t} = \theta(t-\tau)^{2/3}, \tag{11}$$

where

$$\theta = [(4\pi)^{1/3}/3\mu]^{2/3}. \tag{12}$$

The total surface area of all the particles will then vary in conformity with the equation

$$A_p = R_i\theta\int_0^t (t-\tau)^{2/3}\,dt = \frac{3}{5}R_i\theta t^{5/3}. \tag{13}$$

Since $A_p = S_0[E]$ at the instant t_1 of disappearance of free soap or completion of formation of particles, we can write

$$t_1 = (5S_0[E]/3R_i\theta)^{3/5}. \tag{14}$$

Hence the number of particles

$$N = R_i t_1 = R_i^{2/5}(5S_0[E]/3\theta)^{3/5} = 0.53(R_i/\mu)^{2/5}(S_0[E])^{3/5}. \tag{15}$$

It can readily be shown that, in the alternative case in which the radicals formed are captured also by particles attached to existing micelles, the formula for the number of particles will be similar but with a rather smaller value (0.37) for k.

It is noteworthy that the initiator concentration and hence the rate of initiation behave rather unusually in emulsion polymerisation. Primarily they affect the number of particles, the time of formation of which depends on the rate of disappearance of the micellar soap. After the disappearance of micelles no new particles are formed, and the rate of initiation ceases to influence the overall rate of emulsion polymerisation. Thus addition of a fresh portion of initiator in the second stage does not increase the rate of polymerisation, since the number of radicals in polymer–monomer particles cannot then change.

The termination constant k_t does not occur in the kinetic equation, since in the classic form (with $n = 0.5$) it does not limit the processes governing the lifetime of radicals and their number in a particle. If, however, it is postulated that two or more radicals may remain in a particle, this constant will play a decisive role, and its influence on n can be represented by the equation[12]

$$n = {}^4/_3 r^3\pi N_A w_i^{1/2}/k_t^{1/2}, \tag{16}$$

in which r is the particle radius and w_i the rate of initiation. In this case great importance will attach to the viscosity of the polymer–monomer particles, which is apparent in the Trommsdorff effect (increase in rate of polymerisation and molecular mass of polymer due to a decreased termination constant in viscous media). Incidentally, this effect cannot legitimately be used to explain high rates and molecular masses of polymers during emulsion polymerisation on the basis of Smith and Ewart's classic concepts: if we postulate the residence of more than one radical in a polymer–monomer particle, we thereby indicate the possibility of departures from the Smith–Ewart theory.

Publication of the theory was later followed by papers[13–15] discussing such deviations, which still continue to appear with considerations of other problems of emulsion polymerisation. For example, the possibility is examined that colloid-chemical parameters of an emulsion system may influence the constants of the primary reactions, the mechanism of formation and the morphology of the polymeric particles, etc.

To avoid becoming involved in the vast factual material and to minimise confusion in its presentation, we shall attempt to analyse the accumulated experimental results by considering in succession the parameters governing the kinetics and the topochemistry of emulsion polymerisation.

Initially we shall examine the concentration parameters [M], n, and N, analysing the reasons for their variation within certain limits and the topochemical consequences of these variations, after which we shall consider the constants of the primary reactions.

III. NUMBER OF PARTICLES IN EMULSION SYSTEM DURING POLYMERISATION

We shall consider the number of particles in the system, and also the other parameters, primarily in relation to the second stage, which is characterised by a constant rate of polymerisation. This is the most interesting stage from the point of view of theory; it usually extends from 5–10% to 50–70% conversion depending on the type of monomer and the temperature. In order that the rate should become constant, of course, the parameters in Eqn.(5) should also remain constant at this stage.

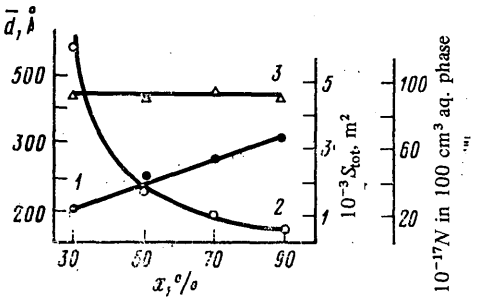

Figure 2. Effect of degree of conversion of styrene[21] on: 1) particle diameter $\bar{d}$; 2) number N of particles; 3) total particle surface S_{tot}.

Constancy of N has indeed been demonstrated in many cases[11,16], as indicated by comparatively recent results for emulsion systems differing from those investigated by Smith and Ewart. For example, in the polymerisation of styrene initiated by the oil-soluble azoisobutyronitrile, N remains constant throughout stage (II).[17] Constancy of the number of particles has also been established[18] in the emulsion polymerisation of styrene in the presence of a mixture of an ionogenic and a non-ionogenic surface-active agent. Unchangeability of the number of particles during stage (II) has been established[19,20] for such an atypical case as the emulsion polymerisation of styrene on potassium peroxodisulphate in the

absence of an emulsifier. Here stabilisation of polymer–monomer particles is achieved by charged SO_4^- end-groups of macromolecules formed by dissociation of the persulphate, and polymerisation is initiated by radical-anions. We shall discuss this work[18–20] in greater detail in connection with the structure of polymer–monomer particles.

However, besides data consistent with the ideas of Smith and Ewart, quite a few results are known that indicate change in the number of particles during the second stage of emulsion polymerisation. First to give a theoretical basis to such phenomena was Medvedev[21], who suggested that adsorbed layers on the surface of latex particles retain in some measure their capacity for interphase exchange among themselves, with a consequent interdependence of polymerisation processes occurring in different proton–monomer particles, so that emulsion polymerisation can be regarded as a quasi-homogeneous process. Medvedev supports this hypothesis with data on the variation in the number of particles, their total surface, and their diameter at various degrees of conversion of styrene and methyl methacrylate[21]. Fig. 2 shows that N falls rapidly with extent of polymerisation, whereas the total particle surface remains constant.

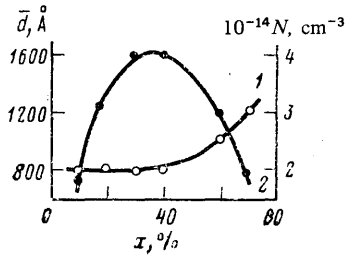

Figure 3. Influence of conversion (0.026 M Alkamon DS in aqueous phase + 0.01 M cumene hydroperoxide in styrene with ratio of monomer to water 1 : 7 at pH 3 and 60 °C [22]) on 1) particle diameter; 2) number of particles.

The Reviewers have also observed[22] variation in the number of polymer–monomer particles during the emulsion polymerisation of styrene, initiated by cumene hydroperoxide in the presence of a cation-active surface-active agent—Alkamon DS $\{C_{12-18}H_{25-37}.O.CH_2.N^+(C_2H_5)_2.CH_3\}CH_3SO_4^-$—although the dependence of N on degree of conversion was more complicated (Fig. 3). However, even in this case the total particle surface remained unchanged after a maximum value had been reached. The increase in the number of polymer–monomer particles until 30% conversion is reached in this sytem can be explained by the very high concentration of emulsifier and extension of the micellar stage to this conversion. The possibility of retaining the micellar soap until high monomer conversions are reached has also been mentioned[23].

The above results show that in several cases Smith and Ewart's postulate that latex particles are discrete is not confirmed. It has therefore been suggested that adsorbed films of emulsifier molecules are the chief site of the primary reactions in emulsion polymerisation. The occurrence of interphase exchange interaction between separate polymer–monomer particles permits the processes to be averaged with respect to the main parameter—the total quantity of soap in the system—and the kinetic scheme to be based on the usual set of reactions of radical polymerisation with reactant concentrations related to the volume of adsorbed films of such particles. In the light of these ideas Medvedev suggested kinetic equations which did not contain the number of particles. For example, with a water-soluble initiator the rate of emulsion polymerisation is given by

$$R_p = k_{gr}[I]^{1/2}[E]^{1/2}[M]^0. \qquad (17)$$

In individual cases Medvedev's theory provides a satisfactory description of qualitative and quantitative aspects of emulsion polymerisation. However, it can hardly be regarded as a more general approach to an explanation and description than is the Smith–Ewart theory, since his conclusions are based mainly on experiments undertaken in the presence of high concentrations of emulsifier and initiator, i.e. under conditions of formation in the early stages of a very large number of particles, which may flocculate because of the rapidly increasing adsorption unsaturation of the system. Similar phenomena can probably take place when the surface-active agent has an inadequate stabilising affect or with a low rate of adsorption of emulsifier on the rapidly formed surface, as occurs in the polymerisation of polar monomers[24]. Furthermore, Medvedev's suggested interphase exchange does not agree well with such a fact as emulsion polymerisation on long-lived radicals in the case of radiation initiation, followed by postpolymerisation after irradiation has ceased[25,26].

Thus Medvedev's theory is not capable of describing the whole variety of phenomena involved in emulsion polymerisation, although it well supplements the Smith–Ewart theory and can justifiably be applied if its limits are intelligently defined. However, it must be stressed that the concept of the discreteness of latex particles in the emulsion polymerisation of non-polar monomers, which usually give well stabilised particles, is more general. For this reason kinetic ideas based on the number of particles in an emulsion system and the number of radicals in them are probably more fertile, and continue to evolve at the present time.

IV. NUMBER OF FREE RADICALS IN A POLYMER–MONOMER PARTICLE

As already mentioned, a single polymer–monomer particle can in principle contain more than one free radical, which is inconsistent with the views of Smith and Ewart. As early as 1957 a theoretical basis was given to such a possibility by Stockmeyer[13], who calculated that such a particle of diameter exceeding 1000 Å can contain several radicals: i.e. the combination of a large particle volume and a high viscosity (with equilibrium swelling at 50 °C the concentration of styrene polymer in a polymer–monomer particle is 43%) makes the presence of several radicals in a particle possible because of the diminished probability of their termination. Subsequently van der Hoff[14], using formula (5) to calculate from data on the emulsion polymerisation of styrene in the presence of cumene hydroperoxide the number of radicals in a polymer–monomer particle as a function of its diameter, showed that even for comparatively small particle diameters considerable departures from $n = \frac{1}{2}$ are possible (Fig. 4).

Since the diameter and the viscosity of a particle (in stage III) increase during polymerisation, the number of radicals in a particle should also increase. Thus a similar calculation for the emulsion polymerisation of styrene has shown[27] that, although the number of radicals does not change very greatly (from 0.5 to 1.0) in the steady state, it rises rapidly after the disappearance of drops of the monomer (stage III) because of a rapid increase in viscosity

in the particle (Fig.5). Similar calculations have been made by other workers[28].

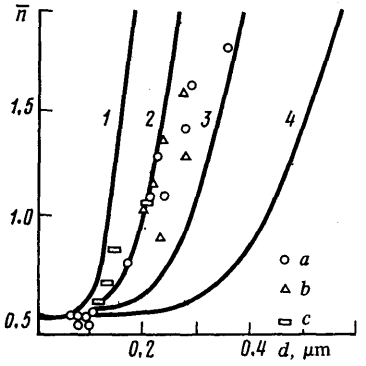

Figure 4. Mean number of radicals in a particle $\bar{n}$ as a function of particle diameter[14] indicated by experimental points for: *a*) $K_2S_2O_8$ at 50 °C; *b*) $K_2S_2O_8$ at 40 °C; *c*) cumene hydroperoxide at 50 °C. The curves have been calculated for different values of lg $[fk_d(I)/k_t]$ (k_d is the decomposition constant of the initiator and f the efficiency of initiation[33]): 1) −12; 2) −13; 3) −14; 4) −15.

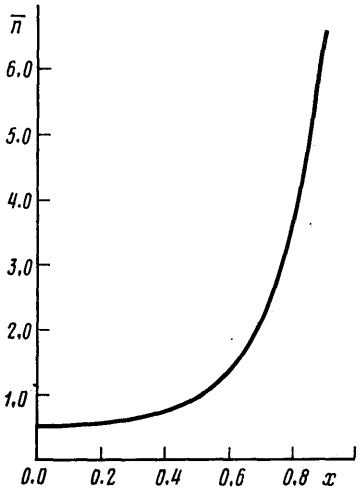

Figure 5. Theoretical dependence[27] of mean number of radicals in a particle $\bar{n}$ on conversion x.

In an investigation of the emulsion polymerisation of styrene (0.01 M) in the presence of cumene hydroperoxide and cation-active surface-active agents (0.026 M Alkamons in aqueous phase, with a 1:7 monomer–water phase ratio at 60 °C) the Reviewers have also shown[12] the possibility of finding several radicals in a single polymer–monomer particle (Table 1), with n dependent not only on particle size but also on rate of initiation. The specific action of the emulsifier made it possible, by varying the pH of the aqueous phase, to increase particle diameter with simultaneous increase in rate of initiation of polymerisation. If a particle contains several radicals, the influence of rate of initiation on n can be described by Eqn.(16).

Table 1. Influence of particle diameter d and rate of initiation w_i on number of radicals n in a polymer–monomer particle during the emulsion polymerisation of styrene[12].

pH	10^3R_p, M (in styrene) s^{-1}	10^8w_i,	$10^{-14}N$, cm^{-3}	$\bar{d}$, Å	n
3	1,62	6,60	1,02	1200	1,61
5	1,91	9,16	0,53	1500	3,27
7	1,02	2,00	0,41	1620	2,22
9	0,70	1,17	0,30	1800	2,12
11	1,40	6,34	0,17	2200	7,47
12	1,92	10,70	0,13	2400	13,4

Thus examination of yet another fundamental parameter of emulsion polymerisation indicates additional limitations on the applicability of the Smith–Ewart theory, associated with the diameter of the latex particles. The theory is fully applicable only to particles of diameter <1000 Å. Nevertheless, Eqn.(5) corrected for the number of radicals describes satisfactorily the steady stage even in the presence of larger particles (for n changes little during stage II), as the rate of initiation remains almost constant[29]).

We note in conclusion that theoretical calculations on the number of free radicals in a polymer–monomer particle are considerably complicated by the possibility of their escape from the latter. This problem is examined in some details in a recent review[30], which notes that the desorption and readsorption of radicals by particles are especially significant in the emulsion polymerisation of polar monomers such as vinyl acetate and chloride, whereas they have little kinetic influence on that of non-polar monomers, e.g. styrene.

V. CONCENTRATION OF MONOMER IN A POLYMER–MONOMER PARTICLE

Consideration of the concentration of the monomer in a polymer–monomer particle—an important parameter of emulsion polymerisation—poses several questions of fundamental significance and widely discussed during recent years—(i) what the concentration is and whether it is an equilibrium value, (ii) whether diffusion of monomer from drops into particles influences establishment of the concentration, (iii) whether the concentration is constant during polymerisation, and (iv) the distribution of the monomer within the particle—to the first three of which the Smith–Ewart theory gives unambiguous answers. The last question, which is ignored in the classical theory, is especially important, since it concerns not only the kinetic aspect of emulsion polymerisation but also the mechanism of formation and the morphology of a latex particle. All the questions certainly apply to the steady state of emulsion polymerisation, since answers to them are given primarily to explain the existence of this second stage. Since Smith and Ewart's ideas have been outlined above, we shall consider only Morton's physical interpretation of the monomer concentration in a particle[31].

The equilibrium swelling of latex particles in the presence of the free monomer is regarded[31] as analogous to the equilibrium in the swelling of a cross-linked polymer in a solvent,

but in the present case the swelling is limited not by intermolecular bonds but by the interfacial energy between particle and aqueous phase. Such a treatment will yield the equation

$$2\Phi_m\sigma/RTr = -[\ln(1-\Phi_p) + \left(1-\frac{1}{\bar{p}}\right)\Phi_p + \chi\Phi_p^2], \qquad (18)$$

similar in form to the well known Flory–Huggins relation[32], in which Φ_m and Φ_p are the volume fractions of monomer and polymer in the swollen particle, σ is the interfacial tension, R the gas constant, T the absolute temperature, χ the monomer–polymer interaction parameter, and $\bar{p}$ the number-average degree of polymerisation.

It follows from formula (18) that the view that the concentration of monomer in a polymer–monomer particle is constant is strictly not entirely accurate, since Φ_m depends on the particle radius and the interfacial tension, which change during polymerisation. Since, however, the increase in particle radius is balanced by that in the interfacial tension, such constancy can be used as a good approximation. Calculations based on Morton's equation show that the concentration varies very little with particle diameter over the range 500–1000 Å, while the emulsifier content of the particle is 2–5% of the mass of monomer[33,34].

Constancy of the monomer concentration in a polymer–monomer particle and its equilibrium character, the latter due to the ability of a polymer particle to swell in the monomer, are supported by a fair quantity of experimental results[35,36], which continue to appear. For example, after separation of drops of monomer and determination of yield of polymer the concentration of styrene in a polymer–monomer particle has been calculated[37] as 5–6 M, which corresponds to the equilibrium swelling of polystyrene in its own monomer[38]. A similar value has been obtained from kinetic data[12], by using the departure from linearity of curves representing the accumulation of polymer at the instant of disappearance of drops of the monomer and from the monomer–polymer ratio. It has been shown also[37] that establishment of the equilibrium concentration of styrene in a polymer–monomer particle is not limited by diffusion, since the rate of diffusion of the monomer into latex particles exceeds its rate of polymerisation by 100–200%, which is entirely consistent with the classical theory of emulsion polymerisation.

Table 2. Emulsion polymerisation of styrene in the presence of ethylbenzene[39]*.

Ethylbenzene, %	c, M	R_{pp}	$[\eta]$, dm^3 g^{-1}	$c^2/[\eta]^{-1}R_{pp}^{-1}$, mole^2 g h dm^{-9}
0	8.69	1.99	1.60	2.4
10	7.82	1.66	0.90	4.1
25	6.57	0.63	0 65	10.5
50	4.35	0.17	0.34	32.7

*Here c is the concentration of styrene in the oil phase, $[K_2S_2O_8] = 0.01\%$, the concentration of sodium dodecyl sulphate in the oil phase is 2 mass %, and the phase ratio of oil to water is 1 : 2.

However, recent papers have indicated that an equilibrium concentration is not established in a polymer–monomer particle even during the emulsion polymerisation of styrene. In particular, the rate of the latter process is lowered by the presence of aromatic solvents to a greater extent than would correspond to the decrease in the monomer concentration (Table 2)[39]. Since the solvent does not diminish the number of particles (on the contrary, the number is slightly increased), it is concluded[39] that the diminished rate is due rather to a lower rate of polymerisation per particle R_{pp}. The latter decrease is attributed to a diminished viscosity in the latex particle and a consequent smaller contribution by the Trommsdorff effect, which may be evidenced by the considerable drop in intrinsic viscosity $[\eta]$ of the resulting polymer with increasing concentration of ethylbenzene. The viscosity decrease cannot be attributed solely to chain transfer to the solvent, since in this respect ethylbenzene is analogous to styrene itself. Calculation of $c^2/[\eta]R_{pp}$, associated with the ratio $k_{gr}/k_t^{1/2}$, shows that its variation at different ethylbenzene concentrations can be due only to change in the bimolecular termination constant if the rate constant of chain growth remains constant, which is quite probable.

Explaining the observed phenomena in terms of the Trommsdorff effect involves postulating firstly the existence of more than one radical in a polymer–monomer particle, which we have seen to be quite possible for sufficiently large particles, and secondly variation in the viscosity in the particle with solvent concentration. If ethylbenzene and styrene are assumed to be almost identical in thermodynamic properties, changes in viscosity should not have occurred in the particle, since the ratio of monomer plus solvent to the polymer, governed by the equilibrium between the oily phase in the drops and in the particle, would have been constant independently of the presence or the concentration of the solvent. However, the opposite is indicated by the fall in viscosity in the particle with increase in solvent concentration, deduced[39] from the diminution in the gel effect: i.e. replacement of part of the monomer by solvent leads to a ratio of monomer plus solvent to polymer which exceeds that of monomer to polymer when emulsion polymerisation occurs in the absence of a solvent. This result is regarded[39] as indicating non-equilibrium swelling of the polymer–monomer particle, the non-equilibrium character strengthening on passing to the system containing styrene alone (in absence of a solvent).

Other results[40] may also indicate that the swelling of polymer–monomer particles is not an equilibrium process. Halting it by cooling to and maintaining at 10 °C a system comprising styrene with azoisobutyronitrile and Ts-40 (oxyethylated hexadecanol $C_{16}H_{33}O.[C_2H_4O]_{40}H$) results in a higher rate of emulsion polymerisation after the system has been heated to 60 °C than in the normal method of polymerisation. It is supposed[40] that holding the system at 10 °C enables the particles to achieve equilibrium swelling, whereas under the usual conditions the concentration of monomer in a polymer–monomer particle is lower than the equilibrium value. In the Reviewers' opinion, however, these results[40] can have a different interpretation: in particular, the increase in rate after the reaction has been halted can be explained not by an increase in the concentration of monomer in the particle but by a change in the dispersity, e.g. as a result of quasi-spontaneous emulsification. Such experiments would undoubtedly have been more convincing if the reaction had been halted not at the micellar but at the steady stage, when particle formation is complete.

The above results[39,40] were obtained under fairly specific conditions, and can hardly be extended to the majority of traditional emulsion systems. The postulated[39] identity in the thermodynamic properties of the systems formed by polystyrene with styrene and with ethylbenzene appears to the Reviewers not entirely correct, since the parameter χ_1

representing polymer–solvent interaction may differ significantly for these systems. Values of χ_1 for the polystyrene–ethylbenzene system have not been published. Comparison of such systems as those of polystyrene with styrene, toluene, and xylene (with χ_1 respectively 0.33, 0.428, and 0.41)[41] shows that differences in thermodynamic properties between solutions of polystyrene in ethylbenzene and in styrene may be considerable. The above doubts concerning results in Ref.40 are supplemented by the use of a non-ionogenic emulsifier at fairly high concentrations, when formation of a stable structural layer may offer a mechanical barrier to penetration of the monomer into the proton–monomer particle. Nevertheless, as shown above, results obtained for systems with an ionogenic emulsifier at moderate concentrations usually indicate equilibrium swelling of such a particle.

VI. CONCENTRATION GRADIENT OF MONOMER

It is worth paying attention not only to the concentration but also to the distribution of the monomer in a latex particle, a problem hardly discussed at all until recently and arising from the investigations of Williams et al.[29,42–47] The essence of this worker's views is that the monomer is distributed non-uniformly in a polymer–monomer particle: a shell enriched in the monomer surrounds a core in which the polymer is concentrated. Since Williams' conclusions are fundamental in character, we shall consider his results in detail, taking into account the experimental conditions.

Table 3. Dependence of induction period in the emulsion polymerisation of styrene on time of polymerisation by concentration of inhibitor[29]*.

t, min	v, % h^{-1}	Inhibitor, g	τ, min
15	12.0	0.032	32.0
60	14.2	0.008	7.0
60	13.4	0.016	13.0
60	10.6	0.032	36.0
60	10.3	0.032	36.0
120	12.8	0.032	36.0
180	15.4	0.032	36.0

*Here t is the time of polymerisation, v the rate, and τ the induction period.

The "core–shell" theory of the polymer–monomer particle appeared as a consequence of kinetic data for the emulsion polymerisation of styrene on potassium persulphate in the presence of a mixture of sodium dodecyl sulphate and Triton X-100 (octylphenoxypolyethyleneoxyethanol)[42]. Grancio and Williams pointed out that stage (II), i.e. that before disappearance of drops of monomer, terminated at 30% conversion of styrene, whereas the rate of polymerisation remained constant until 50–60% conversion. Thus the concentration of monomer in a particle was roughly halved (from 6.3 M to 3.6 M) along the steady-state segment from 30% to 60% conversion. The number of particles and the number of radicals in them remained unchanged in the steady stage. Invariability of n was regarded[42] as indicated by the absence of an increase in the rate of emulsion polymerisation on introduction of an additional portion of initiator to the system in the steady stage.

Grancio and Williams[29] demonstrated the constancy of the rate of initiation by adding an inhibitor during the polymerisation of styrene (100 g styrene + 0.15 g sodium dodecyl sulphate + 3.0 g Triton X-100 + 0.075 g potassium hydroxide + 180 g water), when the induction period was directly proportional to the inhibitor concentration (Table 3). They adduced the interesting fact that the molecular weight of the polymer increases during the steady stage (Fig.6), contrary to traditional views. They give no clear explanation of the phenomenon, and attribute it to peculiarities of polymerisation in a polymer–monomer particle in the presence of a concentration gradient of the monomer.

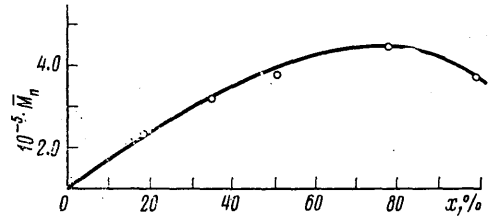

Figure 6. Variation of number-average molecular weight of polystyrene with conversion[29].

Williams explains the kinetic results by constant concentration conditions in the reaction zone, i.e. in the shell, in spite of variation in the monomer concentration calculated on the whole volume of the particle.

Kinetic data were accompanied by direct evidence of the formation of particles having a "core–shell" morphology[46]. Emulsion copolymerisation of styrene and butadiene on a polystyrene latex seed, with equilibrium saturation of the polystyrene particles by monomers added in the second stage, yielded particles comprising a polystyrene core and a shell formed from the added monomers. The structure of the particles was observed on electron micrographs of sections treated with osmium tetroxide.

Since this result appeared inconsistent with the simple thermodynamic incompatibility of polybutadiene and polystyrene, the inoculated polymerisation of styrene was undertaken[46] with a tritium-labelled polystyrene latex as seed, particles of which were saturated with styrene as before. Tritium gives β-rays of moderate penetrating power, which should be completely absorbed by a polystyrene shell 500–800 Å thick. An inoculating latex was therefore obtained having radioactive particles (diameter 1520 Å), on which non-radioactive styrene was polymerised to give a shell 1330 Å thick. The resulting particles were devoid of β-activity, from which it followed that the styrene had polymerised on the surface of the seed particles.

Williams suggested a theoretical explanation of the "core–shell" model on the assumption that the most probable, uniform distribution of polymer throughout the particle is prevented by its thermodynamic properties[45]. The latex particle is a microsystem, to which the laws of macrothermodynamics may be inapplicable. Indeed, only at the centre of a homogeneous particle can a macromolecule adopt the most probable conformation, i.e. one of high entropy. Macromolecules at the periphery, in a zone close to the interface, have diminished conformational entropy. In the "core–shell" model a macromolecule in the shell, which is a dilute

solution of the polymer, is able to adopt the most probable conformation.

The Williams theory has been seriously criticised by several well known investigators. Ugelstad[30] and Friis[27] doubted whether the kinetic data were correct, and considered that Grancio and Williams' results[29] could be explained in terms of the generally accepted increase in the number of radicals in a particle with increasing degree of conversion. Such a suggestion is quite plausible, since latex particles in the work of the Williams group were quite large ($d > 1000$ Å). In experiments with addition of initiator during polymerisation an increase in rate might have been overlooked, for it would have been only 7% under the conditions adopted.

Morton et al.[48] checked the data on the variation in molecular weight of the polymer with conversion and found that they involved experimental errors due to use of an impure specimen of the non-ionogenic surface-active agent—Triton X-100—which tended to oxidise rapidly in the air. The resulting functional groups of peroxy-type acted[48] as chain carriers, and the increase in molecular mass of the polymer could be attributed to their depletion during polymerisation. If Triton X-100 was replaced by an anion-active emulsifier (sodium oleate) or a mixture of dodecyl sulphate and the non-ionogenic surface-active agent Emulphogene BC-840 (tridecyloxypolyethylenoxyethanol), which is resistant to oxidation, no increase in molecular weight of the polymer is observed during the emulsion polymerisation of styrene.

Napper[49] accepts the existence of "core–shell" particles, but attributes formation of such a structure not to a thermodynamically improbable concentration gradient of the monomer across the particle but to specific aspects of the initiation of emulsion polymerisation by persulphates. Breakdown of a persulphate involves formation of radical-anions $SO_4^{\cdot-}$, which when initiating polymerisation fix one end of the polymer chain on the surface of the latex particle as a consequence of the strongly polar properties of the terminal sulpho-group. In inoculated polymerisation the growing macroradical attached to the surface "evacuates" monomer from the core, thereby being polymerised in the shell.

In reply to the critical comments Williams showed that the "core–shell" morphology is realised even in the initiation of emulsion polymerisation by benzoyl peroxide[46], although the thickness of the shell is substantially less than in the presence of potassium persulphate (respectively 155 and 520 Å) with inoculated polymerisation under similar conditions. In the latter case the size is almost equal to the diameter of the seed.

Gardon[50] also sharply criticised the "core–shell" theory. He considers that there are no thermodynamic grounds for expecting a concentration gradient of the monomer across the latex particle, as the coefficient of diffusion in the swollen polystyrene–styrene system should be $\sim 10^{-9}$–10^{-7} $cm^2\ s^{-1}$, so that polymerisation in the particle will be slower than diffusion. Gardon puts forward several hypotheses to explain the morphology of the particles observed by Williams: (i) the "core–shell" morphology in the system comprising inoculating polystyrene particles with styrene and butadiene is due to the incompatibility of polybutadiene and polystyrene; (ii) with tritium-labelled inoculating polystyrene particles and ordinary styrene the formation of inactive polystyrene in the shell may be expected to be due to reactions of chain transfer to the non-ionogenic emulsifier, a hypothesis supported experimentally, as shown above, by the work of Morton et al.[48]

The "core–shell" theory of particle morphology does not solve the problem of the concentration of monomer in a polymer–monomer particle. If drops of monomer disappear at 30% conversion of styrene, the monomer concentration in the particle should exceed 6 M (at 60 °C), appreciably larger than the equilibrium monomer concentration (~5 M). The reason for the complete transfer of monomer from drops to the particle at such low conversions remains completely incomprehensible, since this process is thermodynamically improbable because of the equalisation, at the instant of establishment of the equilibrium concentration in the polymer–monomer particle, of the chemical potentials of the monomer in the different phases.

Thus kinetic evidence for the "core–shell" morphology is clearly inadequate, and thermodynamic aspects also present several unresolved problems. However, there is no doubt that particles of complicated structure are formed in seeded polymerisation. The particle morphology observed by Williams may be supposed to be due, not to establishment of an improbable concentration gradient of the monomer in the particle, but to the specific conditions under which emulsion polymerisation takes place.

Although the "core–shell" theory involved several incorrect assumptions, a new line of research on emulsion polymerisation—the preparation of polymer dispersions containing particles of complicated structure—was stimulated by the work of Williams and his collaborators. It cannot be asserted that no such investigations had been made previously[51–55], but they have only recently[56–59] become at all purposeful, covering several applied fields of polymer chemistry (production of shock-resistant copolymers, novel types of rubbers, paints and varnishes). Latex particles of layered morphology enable materials of quite diverse properties to be obtained from a given pair of monomers. For example, dispersions of particles having hard cores and rubberlike shells can be regarded as a source of reinforced elastomers. Rubberlike particles having a thin solid-polymer shell give readily processable non-stick rubbers. Particles with a rubber core and a solid-polymer shell provide a typical system for the preparation of shock-resistant copolymers. Application of a thin layer of a soft polymer to a hard core is able to confer good film-forming properties on a dispersion.

Three methods are in practice available for obtaining latex particles of layered morphology in the course of inoculated polymerisation—(i) exploitation of incompatibility between seed polymer and polymer formed in the second stage, (ii) use of monomers that are pore solvents for the seed polymer, and (iii) conducting the second stage of polymerisation under conditions such that the seed particles are unable to swell in the added monomer, i.e. under conditions of competition between rates of diffusion and of polymerisation.

As examples of these procedures we may mention (i) the preparation of shock-resistant ABS copolymers by the emulsion method, (ii) the polymerisation of vinyl chloride or vinylidene chloride, and (iii) the polymerisation and copolymerisation of acrylic monomers. The last process has been developed especially successfully by Eliseeva et al.[58] However, these investigations lie outside the scope of the present Review. We note merely that realisation of the "core–shell" particle model has enabled film-forming dispersions to be obtained with properties considerably surpassing those of dispersions obtained by the random copolymerisation of acrylic monomers or by mixing two acrylic lattices[59].

VII. PRIMARY REACTIONS OF POLYMERISATION IN EMULSION SYSTEMS

The way in which primary actions occur during emulsion polymerisation differs substantially from that observed for homogeneous systems, as is apparent in the values of the constants and in the molecular characteristics of the resulting

polymers. One of the chief distinctions between emulsion and homogeneous systems lies in the possibility of segregating primary reactions in separate phases. This explains the unique feature of emulsion systems that the rate of polymerisation and the molecular weight of the resulting polymer both increase with the concentration of the emulsifier.

Since increase in emulsifier concentration entails an increase in the number of latex particles, the rate of emulsion polymerisation increases. With a constant rate of formation of free radicals in the aqueous phase the increased number of particles leads in turn to a diminished probability of entry of a radical into any polymer–monomer particle: i.e. the lifetime of a radical growing in a particle lengthens, so that the molecular weight of the polymer increases with the emulsifier concentration. We can use this feature of emulsion systems to obtain polymers differing fundamentally in properties from those obtained in homogeneous systems.

1. Initiation

As we have already seen, the number of particles in an emulsion system—one of the chief kinetic parameters—is determined in considerable measure by the rate of initiation. After the stage of formation of polymer–monomer particles is complete, the rate of the process no longer depends on the rate of formation of radicals. Thus introduction of a fresh portion of initiator in the steady stage produces no change in the rate of polymerisation. After completion of particle formation the rate of initiation affects only the frequency of acts of interconversion of particles between "dead" and active states, i.e. the molecular mass of the polymer. All these considerations apply, of course, to cases in which a particle can contain at most one radical.

The initiation of emulsion polymerisation is studied mainly on water-soluble inorganic peroxo-compounds such as ammonium and potassium persulphates, with which initiation is highly efficient (close to unity)[60]. Although many papers have appeared on the kinetics and the mechanism of the breakdown of persulphates in aqueous solution[60–64], the influence of emulsifiers on the rate has remained obscure[65–67]. In the majority of systems the presence of an emulsifier slightly accelerates the decomposition of persulphates. The considerable increase in rate in aqueous media at low pH is due to a change in the reaction mechanism[68,69].

The influence of aqueous solutions of surface-active agents on the kinetics of the decomposition of organic peroxy-compounds, e.g. hydroperoxides, is a more complicated problem. Here the increase in rate of decomposition may be due to several causes. On the one hand, the presence of an aqueous medium leads to the breakdown of association complexes of hydroperoxides, which differ in thermal stability from the monomeric hydroperoxides[70]. On the other hand, the accelerating action of the surface-active agent may be explained by the effects of micellar catalysis[71], which develops during the concentration of bifilar hydroperoxide molecules in emulsifier micelles. The action of an adsorbed film of polymer–monomer particles is probably similar, exerting a concentrating and orientating influence on hydroperoxide molecules and leaving such relatively non-polar initiators as benzoyl peroxide unaffected[72].

Artificial attachment of an initiator in the region of an adsorbed layer of polymer–monomer particles produces, independently of its polarity, a marked change in its rate of decomposition and hence in the rate of initiation of polymerisation. Thus the Reviewers have shown[114] that the graft polymerisation of styrene on particles of an inoculating latex—a copolymer of n-butyl acrylate and 1-t-butylperoxyethyl methacrylate—takes place at considerably higher rates in the emulsion than in the bulk or in a solvent at lower temperatures. It is sufficient to note the mere fact of polymerisation at a high rate under the influence of a dialkyl type of peroxide at an abnormally low temperature (in the bulk hardly any polymerisation occurs under corresponding conditions).

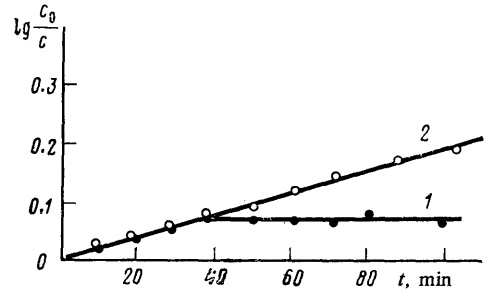

Figure 7. Semi-logarithmic transforms of kinetic curves for the decomposition of peroxy-groups in a copolymer of n-butyl acrylate and 1-t-butylperoxyethyl methacrylate (6.5 mole % of permonomer units in copolymer) in a latex of mean particle diameter 0.100 μm at 60 °C for different distributions of peroxy-groups in latex particles: 1) uniform; 2) predominantly in surface zone[73].

The decisive influence of an adsorbed film on the kinetics of initiator decomposition is also indicated by the difference in the kinetics of the breakdown of peroxy-groups in the copolymer according to their distribution through the latex particle (Fig.7)[73]. The results confirm that under selected conditions breakdown occurs predominantly at the particle surface. With a uniform distribution of peroxy-groups through the particle only the small proportion located at the surface decompose. The surface distribution of peroxy-groups achievable by proportioning the monomers in the preparation of the latex ensures that they will be almost completely decomposed.

Emulsion systems are very convenient for the use of redox initiating systems, in which phase separation of components is possible, so that radical formation can be localised at the interface. Interesting effects are obtained by the use of specifically acting emulsifiers capable of influencing the mechanism of the breakdown of peroxide initiators. Cation-active emulsifiers containing a quaternary nitrogen atom have been investigated in the greatest detail[74–78]. The activating effect of such surface-active agents on the initiation of emulsion polymerisation is attributed by most authors to conversion of the quaternary compounds into tertiary amines[21], whose accelerating action on the decomposition of peroxy-compounds is well known. Such effects were discovered on cationic surface-active agents such as alkylpyridinium halides[74–76]. The unexpectedly high rates of polymerisation in the presence of surface-active aliphatic quaternary ammonium salts were attributed to the formation of tertiary amines[22,77,79] by the Hofmann decomposition of the quaternary compounds. Direct involvement of such compounds in acts of initiation is indicated by the antiparallel dependence, unusual for emulsion polymerisation, of the rate of polymerisation of styrene and the molecular weight of the resulting polymer on the emulsifier concentration (Fig.8)[22].

We can thus consider two specific aspects of the initiation of emulsion polymerisation. Firstly an indirect influence on the overall kinetics can be expressed as the dependence of the number of polymer–monomer particles in the emulsion system on the rate of initiation, which ultimately determines the kinetics of the process. On the other hand, the rate of decomposition of the initiator, and hence the rate of radical formation, depend on the properties of the emulsion system itself, the distribution of initiator between aqueous and oil phases, the possibility of localising acts of initiation in the region of adsorbed layers of emulsifier, and in individual cases direct chemical action of the initiator on the actual acts of radical formation.

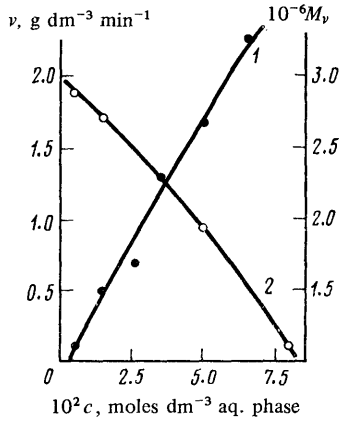

Figure 8. Effect of concentration c of emulsifier (Alkamon DS), with cumene hydroperoxide (0.01 mole cm^{-3} styrene) as initiator and phase ratio of monomer to water 1 : 7, on: 1) rate of polymerisation of styrene: 2) molecular weight of polymer[22].

Since in this work polymerisation was conducted at low temperatures, because of the presence of a redox initiating system, the reliability of these views is doubtful. According to Dunn[82] the low temperatures themselves can explain some regulating effect in the chain-growth steps, for isotactic and syndiotactic additions differ in activation energy[83]. The fact that the ratio $k_{gr}/k_t^{1/2}$ remained unchanged (Fig.9) when styrene was polymerised in the presence of Alkamons—cationic surface-active agents[12]—in media of differing pH, when the state of the adsorbed layer of emulsifier and the rate of initiation of polymerisation varied greatly owing to passage of nitrogen into the amine state, indicates that the adsorbed emulsifier film had no effect on acts of chain growth.

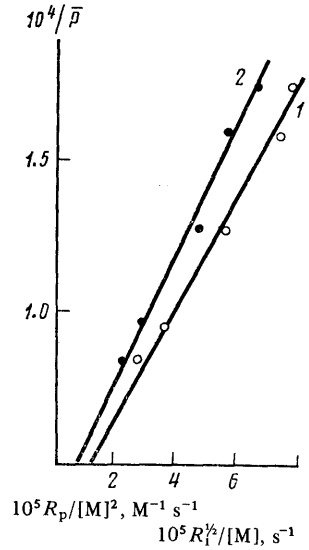

Figure 9. Dependence of reciprocal of polymerisation on $R_p/[M]^2$ and $R_i^{1/2}/[M]$, where the concentration of the monomer in the polymer–monomer particle [M] = 5 M.[12]*

2. Chain Growth

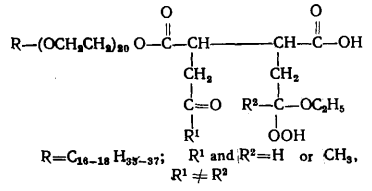
It is usually supposed that chain growth during polymerisation in an emulsion proceeds as in homogeneous systems, i.e. with the same kinetic constants. This postulate enables the chain-growth rate constant to be calculated by means of Eqn.(5) for the rate of emulsion polymerisation. In many cases the results agree well with values of k_{gr} calculated in other ways[34,38,80].

Nevertheless, the view has been expressed that an adsorbed layer of emulsifier has a direct effect on the primary acts of chain growth[21,81]. Such ideas are based mainly on studies of emulsion polymerisation in the presence of *N*-alkylpyridinium halides as cation-active emulsifiers. Thus Medvedev assumed[21] that conducting emulsion polymerisation in an alkaline medium favours conversion of quaternary nitrogen into the amine state with appearance of an initiating centre on the emulsifier molecule. A regular arrangement of charged and uncharged nitrogen atoms on the surface of a latex particle is regarded as ensuring stereocontrol of chain growth and yielding polymers of more regular structure than in the usual cases of emulsion polymerisation.

Specific emulsion systems exist in which such an effect has been quite definitely established. The emulsion copolymerisation of styrene with maleic anhydride in the presence of lecithin as optically active surface-active agent yields an optically active copolymer[84]. However, this result can be explained by separation of the two comonomers in different phases as a consequence of differences in aqueous and mutual solubility. Since maleic anhydride is incapable of homopolymerisation under ordinary conditions, it does not polymerise in the aqueous phase, despite initiation by a water-soluble initiator such as potassium persulphate. Thus copolymerisation can take place only at the interface, i.e.in the region of adsorbed layers of surface-active agent. As a result lecithin exerts a direct influence on chain growth.

Thus the above examples show that under certain conditions surface-active agents can affect acts of chain growth, although in most trivial emulsion systems such an influence is improbable if not impossible.

*It seems that the wrong diagram may have been taken from Ref.12 (Ed. of Translation).



3. Chain Termination

Clearly, it makes sense to speak of bimolecular termination of two growing macroradicals during emulsion polymerisation only when two or more radicals can in principle be present in the polymer–monomer particle. As already noted, this case occurs with sufficiently large particles (of diameter ~1000–1200 Å), in which the primary radical grows to a certain size "without terminating" an already existing macroradical in the given particle, and is able to lose mobility owing to its increase in size and the high viscosity of the particle. Several workers have shown[12,85] that in such cases the termination rate constant k_t has the extremely low values characteristic of polymerisation in highly viscous media. Furthermore, although this constant remains almost unchanged at the steady stage with a constant concentration ratio of monomer and polymer in the particle, it decreases after drops of the monomer have disappeared, owing to enhanced viscosity in the particle, which in turn causes an increase in the number of radicals in the latter[27].

When only one radical can be present in a particle, chain termination by the first radical to enter the particle takes place instantaneously. As a consequence the molecular weight of the polymer is determined solely by the frequency of entry of radicals into a particle, i.e. by the rate of initiation. Since with a high degree of dispersion of the emulsion system this frequency is not too high, the lifetime of a free radical is considerably longer in emulsion polymerisation than when polymerisation occurs in the bulk or in solution. As a result, polymers of quite high molecular weight are obtained by emulsion polymerisation.

Especially interesting effects arise when the generation of free radicals is suddenly arrested (with light or radiation as initiator). In this way the lifetime of a radical present in a polymer–monomer particle may become indefinite, and the use of postpolymerisation effects will yield polymers of exceptionally high molecular weight, provided that chain transfer to monomer, emulsifier, or impurity is not too intense. Polystyrene of molecular weight $>10^7$ can be obtained[25,86] by emulsion postpolymerisation. The latter effects can be used also to obtain graft and block copolymers[25,86–88].

It was supposed until recently that these phenomena—formation of polymers of abnormally high molecular weight and also block copolymers—are possible only with the emulsion system exposed to light or radiation. However, it has now been shown[89–95] that such effects can be obtained also with peroxide initiation of emulsion polymerisation. Quite a high rate of polymerisation is observed in the emulsion polymerisation of methyl methacrylate in the absence of specially introduced initiator[89], i.e. under the influence of peroxides formed by oxidation of the emulsifier, and the molecular mass reaches 7×10^6. Still higher molecular masses (up to 2×10^7) can be obtained by using the initiator

specially synthesised by the Reviewers[114], which possesses well defined surface-active properties.

The emulsion polymerisation of styrene goes at normal rates when the concentration of this initiator is 10^{-6}–10^{-7} M in the monomer. This phenomenon cannot be attributed to a high efficiency of initiation, since separate experiments showed that the efficiency did not exceed a few percent. The reason must be sought in a lengthened lifetime of the radical in the polymer–monomer particle, ensuring the formation of polystyrene of exceptionally high molecular mass (up to 2×10^7). It is as yet difficult to explain satisfactorily the effects arising when acts of initiation are localised in an adsorbed layer of emulsifier. It may be supposed that they are related to additional restriction of the mobility of the growing radical by the attachment of one end to the particle surface, with a consequent decrease in the termination constant. It is noteworthy also that the use of such emulsifying initiators at normal concentrations (0.01 M in the monomer), because of chemical bonding with the resulting polymer, produces polymer dispersions of enhanced resistance to electrolytes, mechanical distortion, and freezing[96].

Very interesting phenomena have been observed by the use of polymeric initiators. Mikulašova et al.[91–94] have investigated the emulsion polymerisation of styrene in the presence of a polymeric hydroperoxide obtained by the oxidation of polypropylene. The hydroperoxide was used as a powder of particle size 0.1–0.55 mm in the presence of triethylenetetramine combined with metals of variable valency to activate breakdown of the hydroperoxide. Styrene was polymerised at 20–50 °C with ionogenic (sodium alkanesulphonates) or non-ionogenic surface-active agents as emulsifier. A feature of this polymerisation system is that the molecular mass of the polymer increases with time. For example, it approximately doubled when the degree of conversion of styrene changed from 4% to 12%. When the polymeric hydroperoxide was replaced by a mixture of polypropylene and t-butyl hydroperoxide, the molecular weight of the polymer did not change with conversion and its value was some 10% of that in the system containing the polymeric hydroperoxide. Use of a polymeric initiator will yield polystyrene of exceptionally high molecular mass (2×10^7) with a very narrow molecular-mass distribution ($M_w/M_n = 1.01$). Similar results have been obtained by the same workers[95] by using oxidised powdered graphite or silica to initiate the emulsion polymerisation of methyl methacrylate.

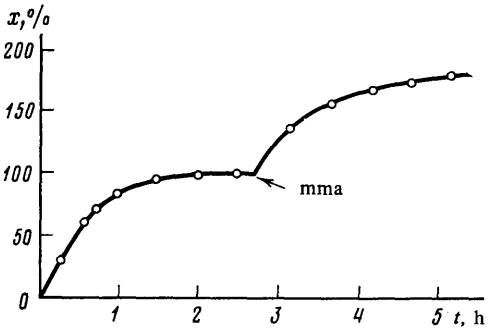


Figure 10. Kinetic curves for the polymerisation of styrene and that of methyl methacrylate (mma) on "live" polystyrene during emulsion polymerisation initiated by polypropylene hydroperoxide[90].

Another feature is the possibility of obtaining block copolymers[90]. Introduction of a second monomer following complete depletion of styrene led to a resumption of polymerisation

(Fig. 10). Formation of block copolymers has been proved by turbidimetric titration[90].

The above facts are regarded[90-94] as evidence of polymerisation without termination of growing radicals, i.e. by a mechanism of live chains. In the first stage of a suggested two-stage mechanism chain growth takes place on the surface of polypropylene, when under certain conditions grafts of polystyrene do not take because of the special mechanism of initiation by polypropylene hydroperoxide and triethylenetetramine[91]. As the molecular weight of polystyrene increases, it becomes more incompatible with polypropylene. As a result the macroradical becomes detached from the polypropylene surface and passes into the aqueous phase, to form on absorption of a monomer and stabilisation by the emulsifier a polymer–monomer particle. In the second stage the process continues in the particles by a "non-terminable" mechanism, since primary radicals from the aqueous phase do not penetrate the particle, and their formation within the particle is also excluded.

The suggested mechanism explains the results, but cannot yet be accepted without question. Other workers[97,98] have used methods similar to those of Mikulašova et al. to obtain block copolymers of vinyl chloride, but have interpreted their results on a different basis. Two types of radical-forming groups—hydroperoxy and peroxy—are present in oxidised polypropylene[97,98]. The former, which are less thermostable, initiate the emulsion polymerisation of styrene or acrylic esters in the first stage at 30–40 °C. In the second stage, after introduction of the second monomer, the process continues at 50 °C on the more thermostable peroxy-groups, whose presence in the polymer isolated after the first stage was demonstrated in separate experiments. It was also shown that such a polymer is able to initiate polymerisation not only in an emulsion system but also in the bulk, although the latter requires a higher temperature (70 °C).

In contrast to the concept of "live" radicals, the polyfunctional nature of the polymeric initiator is used[97,98] to explain the observed effects. However, the proposed mechanism is not entirely consistent with the molecular-weight characteristics of the resulting polymers. The narrow molecular-weight distribution and the M_w/M_n ratio close to unity, observed in the work of Mikulašova, are not achieved in polymers obtained on polyfunctional initiators with peroxy-groups varying in thermal stability[99], and are more typical of processes occurring on long-lived active centres without chain termination.

We note in conclusion that chain-terminating reactions are considerably slower in emulsion systems than in homogeneous polymerisation, owing to the low termination rate constants and the isolation of growing radicals in individual particles. These circumstances ensure the formation in emulsion polymerisation of polymers having exceptionally high molecular masses, and in limiting cases the occurrence of polymerisation without chain termination.

VIII. TOPOCHEMISTRY

We shall now consider the sites at which latex particles are generated and the mechanism of their formation. We have already discussed this problem in terms of the views of Harkins[7,8] and of Yurzhenko[9,10] on the appearance of particles in emulsifier micelles, a quantitative basis for which was given by Smith and Ewart. However, micellar nucleation of particles under the influence of primary radicals is by no means the only possible mechanism, is unable to **explain** several features of emulsion polymerisation, and **is quite** inapplicable to certain specific systems, e.g. emulsion polymerisation in the absence of an emulsifier. The problem of the nature of the primary radical entering the micelle was ignored in the early work. Nevertheless, the need to pose this question is evident in the initiation of emulsion polymerisation by persulphates, which generate active centres of radical-anion type. It is difficult to imagine that the highly polar charged species SO_4^- is capable of penetrating a similarly charged micelle (anionic surface-active agents have been used in almost all studies of the topochemistry of emulsion polymerisation).

These difficulties led to the view that emulsion polymerisation was initiated directly in the aqueous phase, oligomeric radicals were formed and penetrated into micelles (because they were sufficiently hydrophobic) or were precipitated into the aqueous phase on reaching a critical molecular mass, and nucleation took place by a non-micellar mechanism[100-102]. The fundamental ideas of the theory of homogeneous nucleation were developed by Fitch[101,102] and based on the postulate that radicals were formed in the aqueous phase and captured by already formed particles at the same rate. He proposed an equation in which the rate of capture of radicals ρ_c was proportional to the total particle surface. The theory was used to describe the polymerisation of methyl methacrylate in very dilute aqueous solution. In the absence of an emulsifier the primary particles are stabilised by ions formed on decomposition of the initiator. According to the theory of the homogeneous nucleation of particles the addition of an emulsifier does not increase the number of particles formed but merely tends to enhance the stability of the primary particles and prevent their flocculation. The theory was developed primarily for polar monomers readily soluble in water, but was later applied also to such sparingly soluble monomers as styrene.

Roe suggested[103] that particles are formed also outside micelles in the emulsion polymerisation of styrene, and their formation ceases at the instant when the total particle surface reaches a value at which the emulsifier concentration in the aqueous phase becomes lower than the critical concentration of micelle formation. He showed that this hypothesis leads to the same formula for the number of particles as does the Smith–Ewart theory.

Peppard showed[104] that the Fitch theory is fully applicable to the emulsion polymerisation of styrene at low emulsifier concentrations. At higher concentrations nucleation takes place both in the aqueous phase and in micelles. This theory assigns great importance to the rate of capture of oligomeric radicals by particles. In deducing the equation for this rate Fitch used collision theory, and assumed that every collision between a radical and a particle leads to capture. The rate of capture of radicals is then given by the equation

$$\rho_c = \pi r^2 L w_i N,$$

where L is the mean distance a radical diffuses in the aqueous phase before it grows to a size at which it separates from this phase as a primary particle.

Barrett has shown[105] that the Fitch formula presupposes movement of the oligomeric radical along a straight line, so that the probability of its collision with a primary particle is greatly underestimated. The rate of capture of radicals can be calculated from diffusion theory on the assumption that their adsorption is reversible, by means of the equation

$$\rho_c = 4\pi r D_j N R_j,$$

in which D_j is the coefficient of diffusion of long-chain radicals in the aqueous phase and R_j their concentration in this **phase.** This formula indicates a higher rate of capture of **radicals than** that calculated by means of the Fitch expression.

The theory of homogeneous nucleation has now been fairly well developed, but no direct experimental evidence of the existence of surface-active radicals has yet been found. One of the most convincing indications of their formation in the aqueous phase is the decrease in surface tension during the initial stages of emulsion polymerisation[106]. A recent investigation[107] of the polymerisation of styrene in aqueous medium in the presence of potassium persulphate (with an alkanesulphonate as emulsifier) at a low monomer concentration has given results that can be regarded as kinetic proof of the homogeneous nucleation of particles. In the initial stage the rate of polymerisation corresponds to an order of reaction 0.5 with respect to the initiator. The molecular mass of the resulting polymer is proportional to the initiator concentration to the power −0.5 up to 20% conversion. These results indicate bimolecular termination of growing chains, which is characteristic of steady-state kinetics of radical polymerisation in a homogeneous system. Hence it may be concluded that in the initial stage polymerisation takes place under homogeneous conditions, i.e. in the aqueous phase. In later stages the process moves from the aqueous phase into the resulting polymer–monomer particles, as is evident in the kinetics: the rate of polymerisation increases owing to the higher monomer concentration in the particles than in the aqueous phase, while the order of reaction with respect to the initiator falls to 0.26 at 30% conversion.

Table 4. Variation of particle diameter and number in unit volume with conversion[20] (0.870 M styrene + 3.69 mM $K_2S_2O_8$ at 70 °C).

t, min	x, %	$\bar{d}$, Å	$10^{-12}N$, cm^{-3}
15	0.4	700	1.90
30	0.8	930	1.23
60	2.1	1500	1.02
112	5.8	2140	0.97
175	12.9	2820	0.95
232	21.6	3250	1.04
292	32.3	3770	1.00
342	47.6	4120	1.12
1440	90.6	5030	1.18

A mechanism of homogeneous nucleation is more evident in emulsion polymerisation without an emulsifier. Interesting results indicating the existence of oligomeric radicals and the formation of primary particles on their precipitation from the aqueous phase have been obtained by Wilkinson et al.[19,20,108,109], who measured particle diameter and molecular weight of the polymer from low monomer conversions in the emulsion polymerisation of styrene in the presence of potassium persulphate. Table 4 shows that N changes appreciably only in the earliest stages of polymerisation. The molecular mass changes abruptly also only at the start of polymerisation, formation of a polymer of molecular mass ~1000 being observed in the earliest stages[20]. This last fact can probably be regarded as direct evidence of the presence of oligomeric radicals in the polymer system.

Another interesting phenomenon observed by Wilkinson et al. is the abnormal particle structure revealed on electron micrographs, shown diagrammatically in section in Fig.11. Such particles were observed by means of a scanning electron microscope, and their formation was attributed to removal of monomer from the inner region of a particle during vacuum preparation of the specimen. Particles having this structure were observed when specimens of latex were withdrawn at comparatively low conversions (~40%). This structure is supported also by results for the sorption of nitrogen by polymer particles after removal of monomer from them[19]. The total particle surface calculated by the method of Ref.17 exceeds by 17% the surface calculated from electron-microscopic data on the assumption that the particles are spherical in form.

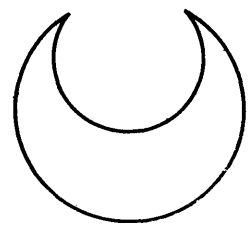

Figure 11. Structure of abnormal particle[17].

Wilkinson et al. explained the results in terms of a mechanism of the emulsion polymerisation of styrene in the absence of an emulsifier[20] involving formation in the early stages of a large number of primary particles of a polymer of low molecular weight. This is followed by flocculation of the primary particles to give stable particles, in which the usual emulsion polymerisation initiated by oligomeric radicals then proceeds. Thus the core of a particle is enriched with a polymer of low molecular weight. Since the solubility of the monomer in this polymer is higher, the inner region of the particle has a higher monomer concentration than has the outer region: i.e. a concentration gradient of the monomer is established in the polymer–monomer particle, although the concentrations themselves have equilibrium values in corresponding regions of the particle.

In a novel topochemical picture of emulsion polymerisation—the formation of polymer–monomer particles without involving emulsifier micelles—the particles are generated not in micelles but directly from drops of monomer[40] by quasi-spontaneous emulsification in conformity with the views of Taubman et al.[110] Transfer of monomer from drops to particles then takes place not by diffusion through the aqueous phase but as a result of direct contact, when obviously particle–particle contact is also possible.

Support for these views was sought[40] by using a new technique to obtain electron micrographs of latices at low conversions. The latex was frozen above the freezing point of styrene, and then the monomer was completely polymerised by exposure to fast electrons. Three kinds of particles—small (150 Å) corresponding in size to solubilised micelles, medium (600–800 Å) corresponding to polymer–monomer particles, and large (5000 Å) to drops of the monomer—can be observed on the photomicrograph. The polymerisation of styrene was conducted in the presence of the ionogenic surface-active agent E-30 (sodium pentadecanesulphonate) (4 wt.%) and azoisobutyronitrile (0.15 millimole in 1 ml of styrene) at 60 °C. As emulsion polymerisation proceeded, the size of the large particles diminished, that of the medium particles increased, and the small particles remained

unchanged. On addition of fresh portions of surface-active agent at conversions of 15% and 40% new polymer–monomer particles were formed significantly larger than micelles but smaller than the previously formed particles, with a consequent bimodal particle-size distribution (Fig.12).

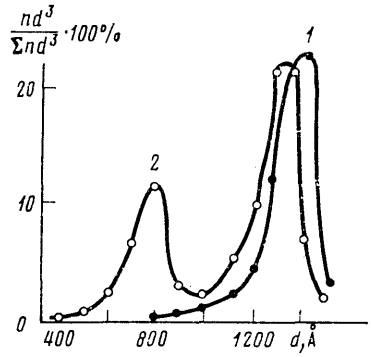

Figure 12. Size distribution of latex particles in presence of 0.15 millimole of azoisobutyronitrile in 1 cm^3 of styrene: 1) without additive; 2) after addition of Ts-40.[40]

However, these ideas are not consistent with such a well known fact as the abrupt increase in rate of emulsion polymerisation when the emulsifier concentration passes through the critical limit of micelle formation, which indicates that micelles play a definite part. Results of this type have been published recently by Smirnov et al.[111] Study of the traditional system comprising styrene with potassium peroxodisulphate and potassium laurate showed that in the region of this critical concentration a break occurs in the dependence both of rate of emulsion polymerisation and of number of particles on the concentration of surface-active agent. With regard to the results on additions of emulsifier during polymerisation, the comparatively large size of the newly formed particles can be explained by the greater rate of polymerisation in them consequent on the more developed surface and the higher probability of capture of monomer and free radicals.

The mechanism by which the small particles retain their size during polymerisation is not entirely clear. It may be supposed that the micellar stage of polymerisation was not yet complete [fairly high concentration (4%) of surface-active agent], but the phase ratio unfortunately was not given[40]. Furthermore, fine particles can be formed by the escape of radicals from polymer–monomer particles and nucleation by a homogeneous mechanism. Since homogeneous nucleation is possible at any stage of polymerisation, the apparent retention of size due to small particles may be caused by their continual regeneration during the process and flocculation with each other and with existing particles. Nucleation of particles in the aqueous phase has been used by Ugelstad et al.[112] to explain the formation of new particles finer than drops of the microemulsion obtained in the presence of the emulsifying system comprising a long-chain aliphatic alcohol with an ionogenic surface-active agent; the effect is observed whether the polymerisation of styrene in microdroplets is initiated by water-soluble or oil-soluble initiators.

Thus the results presented in Ref.40 undoubtedly indicate that microemulsification may make a certain contribution to the mechanism of the generation of polymer–monomer particles, but is not the sole cause and probably acts together with a micellar mechanism.

In a more recent study[113] on the same materials Pravednikov, Gritskova, et al. have developed the above ideas, while accepting the emphasis on the site at which polymerisation occurs in a polymer–monomer particle once formed. They worked with an oil-soluble initiator, and considered that effective polymerisation was possible only in cases in which the radicals formed were rapidly fixed in a polymer matrix, since under ordinary conditions the presence even of the two radicals produced by breakdown of a single initiator molecule cannot occur in a small polymer–monomer particle. However, the monomer content of such a particle is quite large, amounting to ~50% of its mass, and such a strongly swollen gel can hardly ensure effective fixation of radicals. This contradiction was explained on the hypothesis that the polymer separated out and formed a film at the particle–water interface. Thus a particle comprises a core strongly swollen in the monomer and a surface layer containing a small quantity of monomer, radicals being fixed in this layer.

Virtually the same arguments—bimodal molecular-mass distribution (with 10^{-6} M_n respectively 0.17 and 4.0) and formation of particles of abnormal structure—were used to support these hypotheses[113] as by Wilkinson[19,20], but with a different interpretation of the results. According to these workers[113] the polymer of low molecular weight is formed in the central region of the polymer–monomer particle as a result of rapid termination of unfixed radicals; the main site of polymerisation is the shell of the particle.

However, formation of a polymer of low molecular weight during emulsion polymerisation can be explained more simply by chain transfers to impurities that may be present in the reactants, phenomena that have been reported recently with styrene[48]. Furthermore, it is difficult to imagine the formation of a "low-molecular polymer" of molecular weight 170000 by the suggested[113] mechanism, since in a small particle termination would occur almost instantaneously with formation merely of oligomeric molecules. Since chain transfers take place predominantly in the early stages (their contribution should diminish as the carrier becomes exhausted), Wilkinson's explanation—greater solubility of the monomer in the core enriched with the lower polymer—can be accepted for the formation of abnormal particles.

Concluding our discussion of the mechanism of nucleation we note that local zones of particle generation in an emulsion system may vary depending on the specific conditions. In the absence of an emulsifier nucleation can occur only in the aqueous phase, i.e. by a homogeneous mechanism. In the presence of high emulsifier concentrations micelles form the chief site of nucleation. In the formation of microemulsions initiation of polymerisation and hence formation of polymer–monomer particles take place directly in microdrops. Even in the last two systems, however, it is probably impossible to eliminate the contribution of homogeneous nucleation.

For ordinary emulsion systems it is difficult to state unambiguously the site of polymerisation in an already formed particle (whether throughout or predominantly near the surface). However, the process can be localised predominantly in the outer zone of the particle by establishing special conditions (e.g. lower rate of diffusion of monomer into the particle). As a consequence it is entirely possible to realise a "core–shell" particle model, especially with inoculated emulsion polymerisation, when the polymer of the seed particles is thermodynamically incompatible with the polymer formed from the monomer introduced into the seed.

IX. CONCLUSION

The present Review cannot claim full coverage of published information on the theory of emulsion polymerisation that has appeared even during the past decade. The volume of information on such polymerisation increases steadily, the range of problems discussed widens, and at the same time investigators are returning to fundamental theoretical problems posed more than thirty years ago, attempting in individual cases to revise the basis of classical ideas. We have tried to examine only some of the most interesting lines of development of the theory of emulsion polymerisation.

Research on emulsion polymerisation during recent years has been characterised by experiments under special conditions enabling a specified topochemical and kinetic pattern to be modelled. Investigations in special model systems are extremely promising, since they enable individual parameters to be fixed that often are not entirely definite under ordinary conditions, and the sites at which primary processes occur to be established more precisely. Smith and Ewart's concept that the number of particles in an emulsion system is the principal kinetic factor in emulsion polymerisation remains most fruitful in current as in earlier work. Great attention is now paid to the structure of polymer–monomer particles and the site of polymerisation. The possibility under certain conditions of localising chain growth in particle shells indicates that particles of complicated structure may be formed.

The work surveyed thus shows that extremely diverse phenomena are observed during emulsion polymerisation, which cannot yet be explained in terms of a single theory. However, if we confine our attention to monomers that are sparingly soluble in water, the basis for a general theory probably does exist. The most practicable method is evidently still to seek general relations between conditions and the most important parameters (number of particles, local zone in which process occurs, primary constants). The classic Smith–Ewart theory, where such relations have been established, can be extended only to a limited number of systems. There is probably no need to revise this theory radically, as several authors attempt to do; it is advisable to define more clearly the limits of its applicability. Refinements and developments of certain of its principles are necessary and useful for obtaining more general ideas on emulsion polymerisation.

The work surveyed in this Review is not yet able to introduce full clarity into the theory of emulsion polymerisation, but is undoubtedly of both theoretical and practical interest, since it opens up new opportunities for the emulsion synthesis of polymers. In this connection we must again mention the work of Williams et al., which stimulated research on the preparation of polymer dispersions containing particles of layered structure, and the investigations of Mikulašova et al. on emulsion polymerisation in the presence of polymeric initiators, which enabled block copolymers to be obtained in emulsion systems. Research on emulsion polymerisation in the presence of multifunctional emulsifiers merits attention, in particular on surface-active initiators, which ensure the formation of polymers having exceptionally high molecular weights and latices that are highly resistant to various factors.

Conjugated Inorganic Carbon-based Polymers

I.V.Krivoshei and V.M.Skorobogatov

Polymers of different types based on dicyanogen, dithiocyanogen, carbon suboxide, and carbon subsulphide, which exhibit conducting or semiconducting properties, are examined. The methods of synthesis, the polymerisation mechanisms, and the chemical and physical properties of these polymers are discussed.
The bibliography includes 192 references.

I. INTRODUCTION

Wide interest has been manifested in recent years in the study of compounds with electronic properties and of a quasi-one-dimensional or quasi-two-dimensional character. Intense investigation of low-dimensional structures was stimulated by Little's familiar idea[1] of the possibility of creating high-temperature superconductors on their basis. Solids such as charge-transfer complexes (CTC) of the tetracyanoquinodimethane–tetrathiofulvalene type, mixed valence platinum complexes (KCP)† type, $K_2Pt(CN)_4Br_{0.30}\cdot.2.3H_2O$, etc., have since become classical examples of systems which exhibit a whole series of collective phenomena associated with their quasi-one-dimensionality[2]. These phenomena as well as the concepts developed to account for them can be transferred also to certain polymers. With the aid of chemical methods, it is possible to predict the existence of a whole class of materials with extremely remarkable electrical and magnetic properties[2]. Since 1973, polysulphonitride $(SN)_x$, which is the first example of polymers with a metallic conductivity ($\sim 10^3\ \Omega^{-1}\ cm^{-1}$ at room temperature), has been studied vigorously. Furthermore, near 0.3 K there is a transition to the superconducting state; this discovery demonstrated the possibility, in principle, of the existence of superconductivity in a system without metal atoms. Detailed investigations in recent years[3] have shown that $(SN)_x$ is not in fact a one-dimensional system; it would be more correct to regard it as a highly anisotropic solid with a two- or three-dimensional band structure. Indeed, in the case of markedly quasi-one-dimensional complexes (CTC, KCP), a transition to the non-conducting state is observed as the temperature is reduced, while $(SN)_x$ continues to exhibit metallic properties however low the temperature.

According to Ginzburg[4], quasi-two-dimensional systems are more promising in this respect. Thus, following intercalation (the introduction of extraneous molecules into the interplanar spaces), the conductivity of many transition metal dichalcogenides changes from the semiconducting type to metallic and at sufficiently low temperatures these materials become superconductors[5]. Numerous intercalated graphite compounds are also well known[6]. The results of the intercalation of graphite by SbF_5 molecules merit particular attention; the conductivity then increases to $\sim 10^6\ \Omega^{-1}\ cm^{-1}$, exceeding by 60% the conductivity of metallic copper, while the anisotropy of the conductivity becomes greater than 10^6.[7,8] The superconducting transition in potassium-intercalated graphite observed recently[9] stimulated still further the interest in low-dimensional structures.

However, the class of systems investigated has hitherto been restricted in essence to dichalcogenides and graphite. Evidently a specific search in this field is impossible without the accumulation and systematic arrangement of knowledge concerning other low-dimensional systems which have been known for a fairly long time but whose electrophysical properties have either not been investigated at all or have been investigated at random. It is not superfluous to note that $(SN)_x$ was synthesised as early as 1910, but its unique properties remained unknown for more than 60 years. We have written this review in order to draw the attention of investigators to certain polymers which have been known for a long time, but whose investigation can lead to the expansion of our ideas concerning the electronic phenomena in solids.

II. POLYCYANOGENS

A polymeric form of cyanogen was discovered by Gay-Lussac[10] in experiments on the thermal decomposition of $Hg(CN)_2$; dicyanogen $(CN)_2$ was discovered at the same time. The composition of the polymerisation product corresponding to the formula $(CN)_x$ was soon established by Johnston[11,12], who called this polymer "paracyanogen",[12] the name which is still used. Since two polymeric forms of cyanogen are known at the present time, we shall employ this term in relation to only one of these forms.

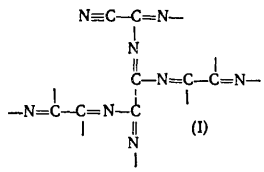
1. The Paracyanogen Formation Reaction

There exist fairly numerous reactions leading to the formation of paracyanogen, usually as one of the products. Thus the thermolysis of dry noble metal and copper cyanides, which has been the usual preparative method for synthesising dicyanogen since the XIXth century, always leads to the formation of some paracyanogen (see the thorough review of Brotherton and Lynn[13]). Heavy metal cyanamides behave

† Kalium cyanoplatinat.

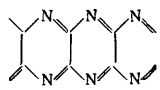
similarly[14]. Paracyanogen is formed when solid KCN interacts with the vapour of iodocyanogen[15] at the usual temperature; the reaction of chlorine with KCN at 673 K yields paracyanogen as the main product[16]. Paracyanogen arises as a side product in the pyrolysis of α-nitroguanidine,[17] *N,N'*-bis(sulphur trioxide)dicyanogen[18], cyanuric triazide[19], and melaminium hexacyanoferrate(III);[20] it is also obtained when a mixture of KCN and liquid SO_2 is stored for a long time at room temperature[21]. Considerable amounts of paracyanogen are obtained when cyanuric acid amide is acted upon by P_2O_5 [22] and in the reaction of PCl_5 with KCN or $K_4Fe(CN)_6$.[23] Paracyanogen is readily obtained on heating iodocyanogen[24] or cyanuric iodide[25] and in the interaction of CaC_2 with nitrogen[26].

The majority of the syntheses of dicyanogen[13] can apparently be used also to obtain paracyanogen *in situ*, when the reaction is carried out at a sufficiently high temperature and in a closed volume. Apart from the processes already enumerated, one may include among them the heating of dry cyanides in the presence of oxidants ($FeCl_3$, PCl_5, $HgCl_2$, etc.) and the dehydration of ammonium oxalate or oxamide under the influence of P_2O_5 or P_2S_5. Paracyanogen can also be obtained by the electrochemical oxidation of a solution of AgCN in pyridine[27].



The pyrolysis of mercury and silver cyanide is used for the preparative synthesis of paracyanogen[28-30]. The total decomposition of $Hg(CN)_2$ takes place after 72 h at 623 K, after 26 h at 713 K, and after only several minutes at 873 K; the yield is higher the lower the temperature and the higher the pressure[28,31]. In order to eliminate mercury, a stream of dicyanogen is passed over the preparation at 713 K; the resulting $Hg(CN)_2$ is then distilled off. The yield of paracyanogen from AgCN is 64% at 713 K and a pressure of 6 MPa;[28] silver is removed by treatment with nitric acid. However, it was noted later[30] that the product obtained in this way can in fact consist of a mixture of $(CN)_x$ and $Ag(CN)_x$, the content of $(CN)_x$ by weight being very low. It is possible to obtain paracyanogen by heating oxamide in an evacuated vessel at 543 K; the yield reaches 30–40% when the reaction is carried out for a week and 10% in the course of two days[29]. Paushkin and coworkers[32] suggested that paracyanogen be obtained by heating oxamide or ammonium oxalate in the presence of a large excess of $ZnCl_2$ as the catalyst and dehydrating agent. After 5 h at 673 K, the yield is 30% for oxamide and 14% for the oxalate; according to X-ray diffraction data, the degree of crystallinity of the resulting polymer is high. According to Hittorf[33], the electrolysis of an aqueous KCN solution is a very convenient way of obtaining paracyanogen, giving a quantitative yield of this product. However, other workers[34] believe that this procedure does not yield paracyanogen but the polymer $(HCN)_x$ as a consequence of the hydrolysis of the dicyanogen formed initially to HCNO and HCN and subsequent rapid polymerisation of HCN. Since elemental analyses are not given in either communication, the problem still remains obscure.

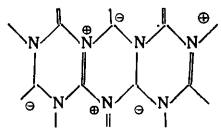
Dicyanogen is known to be a chemically reactive compound—it is one of the most reactive nitriles. It is thermodynamically unstable, because its heat of formation is positive (309 kJ mol^{-1}).[13] However, in the absence of moisture and light, pure dicyanogen can be stored indefinitely at room temperature[25]. It has been found[16,31] that at atmospheric pressure and a temperature above 583 K, dicyanogen polymerises to a slight extent; this also occurs at 493 K and pressure up to 30 MPa and paracyanogen is formed even near the critical point, although very slowly[28,31]. However, these results appear to be doubtful. Chromatographically pure dicyanogen heated to 373–1473 K does not polymerise for two weeks[36]. Apparently the results of the above investigations[16,28,31] can be accounted for by the insufficient purity of the dicyanogen employed. The catalytic activity of various substances on the polymerisation of dicyanogen has been investigated. In the presence of K_2CO_3 the polymerisation begins at a temperature as low as 393 K and the same effect is produced by $NaNH_2$, but both salts begin to interact with paracyanogen as the temperature is increased. KCN, which does not react appreciably with paracyanogen, is a good catalyst at 713 K. The surface of glass exhibits only a weak catalytic effect and quartz is even less active[16]. The polymerisation of dicyanogen is catalysed by acids (CH_3COOH, HCN, CO_2), bases (NaOH, Na_2CO_3), traces of moisture and air, and metallic copper[12,35], but surprisingly, platinised asbestos has no effect[37]. When water is saturated with dicyanogen, paracyanogen appears in the solution after the latter has been allowed to stand for a long time[38] and, when dicyanogen is passed through a concentrated KOH solution, paracyanogen is precipitated immediately[38-40].



In the absence of impurities, the polymerisation of dicyanogen is induced by ultraviolet irradiation[41-45], an electric discharge[46-48], and α-particles[49-52]. Dicyanogen also polymerises in the presence of active nitrogen[53] and in the ionisation chamber of the mass-spectrometer[54,55]. Furthermore, paracyanogen is formed when gaseous hydrogen cyanide is acted upon by electric discharges[56-60] and on photolysis of carbonyldicyanogen[61,62]. The appearance of a certain amount of paracyanogen has been noted when activated nitrogen was passed over graphite[63] and on γ-irradiation of sealed tubes containing nitrogen and graphite[64].

2. The Structure and Mechanisms of the Formation of Paracyanogen

Sidgwick[65] was the first to suggest that paracyanogen may consist of a three-dimensional system (I) or a cyclic system (II):



(I)

(II)

It has been established[29] that the infrared spectra of different paracyanogen specimens give rise to only one distinct absorption band at 1570 cm^{-1}, corresponding to a system of conjugated bonds. Having examined several structures, corresponding to linear (four-membered rings), ladder [six-membered condensed rings (II)], and parquet (ten-membered rings) polymers, the investigators selected structure (II). However, it has been justly noted that the band at 1570 cm^{-1} is characteristic of almost all substances containing the C=N bond and, contrary to the belief of Bircumshow et al.[29], provides no information whatever about the structure of paracyanogen. According to Rodewald[66], paracyanogen has a layer lattice of the type of graphite in which each second carbon atom is replaced by a nitrogen atom. The structural unit consists of a triazine and not a pyrazine ring. Thus the structure of paracyanogen can be described by a set of numerous valence structures of type (III) and its dark colour and high stability are due to resonance interactions. The parameters of the hexagonal layer lattice

(III)

a, c, and ρ_{theor}, determined[66] from X-ray measurements, are 0.136 nm, ~0.45 nm, and 2.0 g cm^3 respectively. The difference between the interatomic distances in paracyanogen and graphite is thus small, so that the nitrogen atoms in paracyanogen can be replaced by carbon atoms. As a result, the non-stoichiometric forms of paracyanogen never contain an excess of nitrogen and always contain an excess of carbon (see Section IV). With increase of the carbon content, the X-ray density ρ_{theor} increases, since the decrease of the parameter c is more than compensated by the increase of the parameter a. Similarly, the enthalpy of formation and the thermal and chemical stabilities increase, the colour deepens, and the electrical conductivity increases.

For a long time the attempts at a thermodynamic description of the interconversions in the dicyanogen–paracyanogen system were unsuccessful[28,37,67], because equilibrium is attained only when paracyanogen and not dicyanogen is used as the starting material. Rodewald explained this phenomenon[66]. Although the only product of the decomposition of paracyanogen is dicyanogen, the latter is not an equilibrium phase but constitutes a secondary product. On the other hand, the primary product is monocyanogen CN, which can be formed from paracyanogen as a consequence of the C–N bonds and from dicyanogen as a consequence of the dissociation of the C–C bonds. The enthalpy of the dicyanogen–paracyanogen transition, calculated by Rodewald, is close to 180 kJ. Taking into account the bond enthalpies in dicyanogen, the enthalpy of formation of paracyanogen is ~3.81 kJ. Since the heat of dissociation is 545 kJ mol^{-1}, the formation of paracyanogen never follows the shortest path $(CN)_2 \rightarrow (CN)_x$; an obligatory condition for the condensation of paracyanogen is the formation of monocyanogen: $(CN)_2 \rightleftharpoons CN \rightleftharpoons (CN)_x$. Thus monocyanogen can be converted either into dicyanogen (the formation of new C–C bonds) or into paracyanogen (the formation of C–N bonds). The second pathway is energetically more favourable, but it presupposes a fairly high partial pressure of monocyanogen.

Indeed all the results known to us confirm that Rodewald is right. It has been established[42,43] that the gas-phase photolysis of dicyanogen involves polymerisation and the quantum yield of the reaction is 3 mol einstein^{-1}. Such a low yield rules out a chain polymerisation mechanism. It has been suggested that the dissociation of $(CN)_2$ is followed by the reaction $CN + (CN)_2 \rightarrow (CN)_3$; the latter product is unstable and polymerises to paracyanogen. The thermal polymerisation of dicyanogen also begins[68,69] with the addition of the CN radical to the $(CN)_2$ molecule. These results can be interpreted only in the following way. The nucleophilic attack by the N atom of the highly polar monocyanogen on a C atom of dicyanogen should lead to a "head to tail" type of addition, so that the sequence of atoms CNCN... in the polymer is preserved. It is natural to expect that the $(CN)_3$ radical consists of a triazine ring, i.e. it constitutes the structural unit of paracyanogen#. The ease of formation of paracyanogen from substances containing the triazine ring[19,22,25] may be regarded as an additional argument in support of structure (III).

We may note that the unstable $(CN)_3^-$ ion, arising when the CN^- ion reacts with dicyanogen, has been detected even in an aqueous solution.

The radical mechanism of the formation of $(CN)_x$ is in many instances evident; the reaction proceeds on the wall at a rate limited by the rate of diffusion[20,53,63,71]. The catalytic effect shown on the polymerisation of dicyanogen by a wide variety of compounds or pressure has not so far been explained. One can only postulate that the transition state, in which the C–C bond is weakened, plays a significant role, particularly in the latter case. The doubled yield of paracyanogen[29] from $Hg(CN)_2$ compared with AgCN can possibly be accounted for by the catalytic effect of the HgCN radicals, which exist[72] at ~773 K.

Under the influence of ionising radiation, dicyanogen polymerises via an ionic mechanism[49–51,54,55]; the ions of the inert gases (He, Ne, Ar, Kr, Xe, N_2, and CO_2) then behave as catalysts. It has been noted[49] that Xe is incorporated in the composition of paracyanogen, but can be removed by heating to 623 K.

3. Chemical and Physical Properties of Paracyanogen

Depending on the methods of synthesis, paracyanogen is a powdered or porous substance with a colour ranging from brown to black and is insoluble in the usual solvents (see, for example, Refs. 29 and 52). The product obtained by Paushkin et al.[32] has a high degree of crystallinity. Paracyanogen films are also known[45]. The majority of the chemical properties of paracyanogen have already been described as early as the past century[11,12,28,38]. On heating in the absence of air, the substance begins to decompose to dicyanogen at 773 K. Complete depolymerisation occurs only at 1133 K and in the given range equilibrium is established at each temperature[28,37]; this process is accompanied by some decomposition of dicyanogen into the elements. On heating in a stream of nitrogen, paracyanogen decomposes into NH_3, HCN, and carbon[38] even at low temperatures, while in a stream of chlorine the product is chlorocyanogen[29,38].

Paracyanogen reacts fairly readily with Na_2CO_3, KOH, and soda-lime melts[29,38,73]; the initially brown melt is slowly converted into an orange-red melt and than a colourless melt; NH_3 is evolved and CN^-, CNO^-, and CO_3^{2-} ions are detected in the melt. Dicyanogen is probably an intermediate. Paracyanogen also interacts with $KHSO_4$ melt, giving rise to a substance with a deep red-brown colour. Fusion with potassium converts the polymer into KCN, but there is no reaction with sulphur and phosphorus melts. Paracyanogen does not react with aqueous solutions of alkalies, with ammonia, and with hydrocyanic acid[73], is partly soluble in 60% $HClO_4$ and in concentrated sulphuric and phosphoric acids, and is much less soluble in hydrochloric acid[29]. All these solutions have a deep colour and exhibit an intense pale-blue fluorescence on ultraviolet irradiation. Dilution with water leads to the precipitation of paracyanogen. We may note that these properties are more characteristic of colloidal solutions; the formation of colloids is in fact to be expected for a substance with structure (III).

The addition of a paracyanogen solution in H_2SO_4 to boiling concentrated HNO_3 entails the formation of a pale-yellow solution; the addition of $HgSO_4$ solution to the latter gives rise to a brown cheesy precipitate, which is converted on standing to yellow acicular crystals of "mercury paracyanate" C_4N_4OHg.

"Silver paracyanate" $C_8N_8O_2Ag$ is obtained similarly[12]. When paracyanogen interacts with hydrazine over a period of 20 h, the extent of its degradation is only 20% with formation of dark water-soluble substances[74].

An interesting property of paracyanogen is its ability to adsorb metals whose standard potentials are greater than −0.4 V from dilute aqueous solutions of their salts[75]. Here it

is easy to see an analogy with the behaviour of graphite or transition metal dichalcogenides.

The infrared spectra of various $(CN)_x$ specimens obtained from oxamide, $Hg(CN)_2$, and AgCN contain an intense band at 1570 cm^{-1}, which has been assigned to the conjugation system[29]. After heating in air at 723 K, this band disappears and new bands appear at 640 and 1100 cm^{-1} in the case of oxamide and at 640 and 810 cm^{-1} in the case of $Hg(CN)_2$, which have not been assigned to any particular structure. If the paracyanogen precipitated from a solution in H_2SO_4 with water is redissolved in H_2SO_4, a new band appears in this spectrum at 2070 cm^{-1}, which has been assigned to the CN^- ion[29]. Since in the latter case one is dealing only with low-molecular-weight fractions, the appearance of this band can be accounted for by the protonation of some of the N atoms with subsequent addition of the counterions CN^-, arising as a consequence of the partial decomposition of paracyanogen. These data are contradicted by the results of a study[30] where the 1570 cm^{-1} band was not observed in the spectra of specimens obtained from AgCN. The authors noted an intense absorption at 1400 cm^{-1}; furthermore, the band at 2170 cm^{-1} persisted and a strong diffuse absorption was found at 3000 cm^{-1}. If there is a considerable difference between the degrees of polymerisation of the paracyanogen specimens, then the substituents at the ends of the molecules can exert a strong influence on their symmetry and hence on the relative intensities of the bands. It has been suggested that the product obtained by Wu et al.[30] is a mixture of heterocyclic substances with different degrees of polymerisation.

Measurements of the electrical conductivity of paracyanogen also differ very markedly depending on the method employed; values of 10^{-3}–10^{-4},[76] 1.7×10^{-5},[32] 2.0×10^{-6},[77] and 5×10^{-14} Ω^{-1} cm^{-1} have been obtained[78]. Paracyanogen films ~13 nm thick transmit a current of 50 mA at a field potential of 10^7 V cm^{-1}.[45] Like all polymers with a system of conjugated bonds, paracyanogen is a paramagnetic substance with a spin concentration of 5×10^{17}–1.7×10^{18} spins g^{-1}.[32,79] The study of the nature of the paramagnetic centres led to the conclusion that they consist of free radicals[79]. Measurement of the dependence of the differential thermo-e.m.f. on temperature showed[76] that paracyanogen behaves as a typical semimetal. Its conductivity is virtually independent of temperature within wide limits[32,45]. One should note particularly that measurements of the activation energy for $(CN)_x$ films in two instances yielded a value of zero, while two other measurements gave 0.16 and 0.02 eV;[45] for a disc, the corresponding value is 0.03 eV.[32] This is fully consistent with the current ideas concerning individual coplanar conjugation blocks in macromolecules, along which charged carriers migrate with a very low resistance[74,80–83]. At their ends there is an energy barrier, which the carriers must overcome in order to jump or tunnel to the next section of continuous conjugation.

In the visible region paracyanogen exhibits photoconductivity[84]; the photocurrent decreases sharply with decrease of the degree of illumination even *in vacuo*. Paracyanogen, being a catalyst of the dark oxidation of ascorbic acid, suffers a decrease of catalytic activity in the light[85]; on passing from red to white light and further to the ultraviolet region, its effect is enhanced. The study of the action of γ-rays on paracyanogen showed[86] that a dose up to 5×10^7 J kg^{-1} does not alter its physicochemical properties. However, it has been shown[77] that storage of paracyanogen for three years in the air leads to a decrease of the electrical conductivity to less than 10^{-14} Ω^{-1} cm^{-1} and a band appears in the infrared spectrum at 3220 cm^{-1} which corresponds to absorption by the OH group. Insoluble paracyanogen fractions become fully soluble in concentrated H_2SO_4.

4. Other Polymers

Paracyanogen is not the only polymeric form of cyanogen $(CN)_x$. Not so long ago, the synthesis of a linear form of polycyanogen, which is polycyanoazopolyene (IV), was reported[87]:

(IV)

The polymer was obtained by the anionic polymerisation of dicyanogen in solution in tetrahydrofuran (THF) under the catalytic influence of butyl-lithium, naphthyl-lithium, or monolithiobenzophenone and its molecular weight is in the range 200–500. The proposed structure is consistent with infrared spectroscopic data: the spectrum of the polymer contains intense bands at 2200 cm^{-1} (due to the $-C\equiv N$ groups of the conjugated system) and at 1600 cm^{-1} (due to the $-C=N-$ conjugation chain) and has been confirmed by the results[88] of electrophoretic analysis. Compound (IV) is a dark substance soluble in water and polar organic solvents and, according to potentiometric titration data, is a mono- or di-basic acid depending on the catalyst employed. The EPR spectrum of compound (IV) consists, as for paracyanogen, of a single narrow line corresponding to a spin concentration of ~10^{18} spins g^{-1}. A fine structure is not observed either at 193 K or at high dilutions, which indicate a strong delocalisation of electrons along the conjugation chain. The electrical conductivity measured in discs is close to 10^{-11} Ω^{-1} cm^{-1} at room temperature and the activation energy is ~1.9 eV.

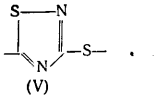
The polymerisation of dicyanogen under the influence of electric discharges leads to polymers whose composition depends on the experimental conditions[46] and can be described by the general formula $(CN_{1-y})_x$, where $y < 1$. According to other data[48], the polymer $(C_2N)_x$, whose composition is independent of the conditions of synthesis, arises under similar conditions; the reaction is of zero order with respect to dicyanogen and the polymer. The available information about the thermal and chemical stabilities of polymers is just as contradictory[46,48]. Products with the composition $(CN_{0.9})_x$ have also been obtained in the polymerisation of dicyanogen induced by α-particles[49,50].

The pyrolysis of the tetraiodo-derivative of imidazole $C_3N_2I_4$ at 453 K entails a partial elimination of iodine and the formation of a brown polymer $(C_3N_2I)_x$; the residual iodine is split off only at 723 K, giving rise to a polymer $(C_3N_2)_x$.[73,89] Both polymers are outwardly similar to amorphous carbon. After prolonged heating, the colour changes to dark grey and the substances are converted into hard graphite-like grains. The chemical properties of $(C_3N_2)_x$ resemble those of paracyanogen[73] and on heating the polymer decomposes in accordance with the equation $(C_3N_2)_x \rightarrow (CN_2) + C$. It was established later[90] that the pyrolysis of $C_3N_2I_4$ at 723 K gives rise to a product with the ratio C : N = 1.7 still containing 0.37% of iodine. The conductivity of this polymer is 10^{-9} Ω^{-1} cm^{-1}. An increase of the pyrolysis temperature to 973 or 1073 K increases the ratio C : N from 3.2 to 6.2 and the conductivity to 2.5×10^{-2} and 0.5 Ω^{-1} cm^{-1} respectively. Triiodoimidazole behaves similarly.

Black graphite-like compounds with the compositions $(C_4HNI)_x$, $(C_4HN)_x$, $(C_4IS)_x$, and $(C_4S)_x$ have also been obtained[89] (see also Ref. 91 and 92).

It is natural to suppose that polymers of the type $(CN_{1-y})_x$ have the graphite crystal lattice and can be regarded as "copolymers" of graphite and paracyanogen. After prolonged heating, $y \rightarrow 0$, which leads to an increase of entropy and the residue consists of cryptocrystalline graphite. It

appears likely that the I atoms do not enter directly into the $(C_3N_2I)_x$ lattice but are located in the interplanar spaces, which is usual for layer compounds.



The polymerisation of dicyanogen in the presence of dry ammonia[93] or an aqueous solution of cyanide and weak acids[94,95] leads to the formation of black polymers soluble only in concentrated H_2SO_4 and decomposing at 1123–1173 K with evolution of $(CN)_2$ and HCN. Their structure has not been established. The polymers have a high heat of combustion and can be used as solid rocket fuel. Yet another cyano-polymer $(CN_4)_x$ is obtained[96] in the spontaneous polymerisation of cyanazide N_3CN; when the polymer comes into contact with water, HN_3 is evolved.

III. PARATHIOCYANOGEN

Dithiocyanogen $(SCN)_2$ was first obtained in a free state by Söderbäck[97], who established that, on rapid heating, this compound is converted, sometimes explosively, into the brick-red parathiocyanogen $(SCN)_x$. Small drops and thin layers of dithiocyanogen gradually solidify, forming a transparent brick-red resin. It was later established[98] that sufficiently pure dithiocyanogen, which melts near 298 K, polymerises on rapid heating without explosion. Boron halides catalyse the polymerisation[21]. Parathiocyanogen is one of the products of the decomposition of nitrosylthiocyanogen[21,98] and cyanazide dithiocarbonate[99], and is formed on dry heating $Hg(CN)_2$ with metal sulphides[100] and on interaction of $SOCl_2$ with AgSCN.[101] Melts of thiocyanates are readily oxidised by $FeCl_3$, $K_3Fe(SCN)_6$, $CuCl_2$, $Co(NH_3)_6Cl$, $Cu(SCN)_2$, and K_2SnCl_6, giving rise to parathiocyanogen and dithiocyanogen, which rapidly polymerise in the presence of ammonia[102]. Parathiocyanogen can be obtained also as the product of the electrochemical oxidation of melts[103–106] or solutions of thiocyanates in dimethyl sulphoxide[107]. The interaction of iodine either with melts[108] or with aqueous solutions of thiocyanates[109] is apparently the most convenient method of synthesising parathiocyanogen.

Solutions of dithiocyanogen in organic solvents are stable only at low temperatures and in the dark; on heating or ultraviolet irradiation, they precipitate a deposit of parathiocyanogen[110]. Concentrated solutions of NH_4SCN behave in the same way in the light[111,112]. It appears that in all cases one must put forward a radical mechanism of the polymerisation of dithiocyanogen. The ease of the dissociation of the S–S bond is evident; the first stage in the formation of $(SCN)_x$ from the other compounds considered is the production of SCN radicals, which rapidly and irreversibly polymerise. This is confirmed also by measurements of the magnetic susceptibility of solutions of $(SCN)_2$ by Gouy's method. It has been established[113] that freshly prepared 0.5 *N* solutions in CS_2 and $CHBr_3$ are diamagnetic. After prolonged standing, the solution in CS_2 acquires a yellow colour and becomes paramagnetic; in cyclohexane the paramagnetism appears immediately.

The structure of parathiocyanogen has not been established. Söderbäck[114] proposed the following structure (V):

(V)

However, it is known[102] that the infrared spectra of $(SCN)_x$ contain bands at 2070–2080 and 1600 cm^{-1}. The first is characteristic of organic thiocyanates and isothiocyanates and the second can be assigned to conjugated –C=N– bonds. Evidently structure (V) does not agree too well with these results. We suggest that the linear structure (VI) is more probable:

(VI) (VII)

It has been shown[105] that electrodes coated by a film of parathiocyanogen become photoactive (for example, the reduction of Cd^{2+} ions at such an electrode is accelerated when the latter is illuminated), the magnitude of the photoeffect depending on the $(SCN)_x$ deposition conditions; ageing of the precipitate leads to a decrease of the photoeffect. It has been suggested[105] that the precipitate contains initially free radicals which undergo complete polymerisation after a time; the fresh precipitate is a semiconductor. Structure (VI), which we proposed, fully explains this behaviour of the precipitate. Indeed, after a time unpaired electrons at the individual carbon atoms can recombine with formation of cross-links. Furthermore, the conductivity band in structure (VI) is 1/6 filled, which agrees with the semiconductor properties. An alternative version is structure (VII).

We may note that dithiocyanogen can be regarded as a member of the homologous series of cyanosulphanes $S_n(CN)_2$, where $n = 1–8$. All cyanosulphanes are stable only at low temperatures, vigorous polymerisation occurring on heating with formation of amorphous glassy red products of unknown structure[115]. It may be that these polymers also contain chains of type (VI).

The chemical properties of parathiocyanogen have been scarcely investigated. It is insoluble in dilute acids and alkalies and in all organic solvents, decomposing above 573 K.[114]

It has been known for a long time[116] that selenocyanogen $(SeCN)_2$ is unstable both in air and in solution. Presumably it also tends to polymerise, like $(SCN)_2$, but there is no information in the literature about its polymers.

IV. CARBON SUBOXIDE POLYMERS

1. The Formation of Polymers and Polymerisation Mechanisms

Carbon suboxide C_3O_2, discovered by Diels and Wolf[117], has a linear structure and is the simplest diketone. In the early investigations it was already noted[117,118] that a characteristic property of the suboxide is a tendency towards polymerisation. A fairly pure preparation is entirely stable at low temperatures and in the dark and even brief contact of its vapour with an incandescent platinum wire does not induce reaction[119]. The polymerisation of C_3O_2 is initiated by traces of moisture and mercury[120], phosphorus oxides[121,122], H_2SO_4, $AlCl_3$, BF_2, organic compounds[123,124], methanol, HCl, and ammonia[125]. Temperature is very important[126,127].

The principal characteristics of the polymerisation of C_3O_2 in the gas phase reduce to the following[128]. The rate of polymerisation increases with increase of temperature and pressure. The polymerisation is preceded by an induction period, the duration of which depends on the temperature but cannot be predicted for any one temperature. The reaction is heterogeneous and the induction period depends strongly on the nature of the surface of the reaction vessel, decreasing sharply if the surface is acidic (for example, in the presence of traces of H_2SO_4 or P_2O_5). If the walls are coated with paraffin, the induction period lasts more than a week. The polymerisation does not require photoinitiation and its course is the same both in the dark and in the light. The polymers obtained at room temperature are yellow, those at 373–573 K are red, and those at 673 K are violet.

Further study of the thermal block polymerisation was carried out by Blake[129], who found that the activation energies for the process are 26 and 34 kJ mol^{-1} in Pyrex and quartz vessels respectively. The duration of the induction period (ranging from minutes to several days) was satisfactorily reproducible, increasing with decrease of temperature and pressure. The reaction is of first order; the addition of CO, CO_2, O_2, NO, and C_2H_4 to the system does not affect the rate of reaction; isobutane causes a slight decrease and CCl_4 a considerable decrease of the rate of reaction and give rise to a deviation from the first order. The rate of reaction depends also on the ratio of the surface of the vessel to its volume. According to Blake[129], the presence of an induction period and the nature of the influence of additives indicate a heterogeneous reaction mechanism; in the gas phase the reaction proceeds without the involvement of free radicals, although the possibility of a surface free radical reaction cannot be ruled out. Thus the presence of the polymer does not influence the rate of reaction§, while the presence of the carbonised polymer increases the rate at low temperatures, which can be attributed to a high concentration of paramagnetic centres ($\sim 10^{20}$ spins g^{-1});[130] these centres can initiate the formation of polymerisation nuclei.

The kinetics of the thermal polymerisation of C_3O_2 subjected to preliminary irradiation by light (253.7 nm) were investigated by Smith[131]. The first order of the reaction with respect to the monomer and the polymer was confirmed, i.e. the reaction is autocatalytic. According to Smith's data, the overall activation energy on a quartz surface is 26.1 kJ mol^{-1}. Yet another confirmation of the first order of the reaction was obtained in an EPR study of the polymerisation kinetics[132,133]; the experimental activation energy in a quartz vessel was 41 kJ mol^{-1}, which is close to Blake's result[129].

The thermal polymerisation of C_3O_2 can be carried out not only in the gas phase but also in non-polar[134–140] or polar[136,141] solvents. The possible mechanism was discussed by Ziegler et al.[37], who assume that the anhydride of 3-oxoglutaric acid is an intermediate, being formed in the interaction of C_3O_2 with malonic acid. Since C_3O_2 is the anhydride of malonic acid, the presence of traces of moisture is evidently required. The use of other initiators can lead to the intermediate formation of a ketencarboxylic acid or its derivatives[125]. Later the authors[142] stated that in this mechanism the high-temperature polymerisation is possible only as an exception. A mechanism involving the initial formation of the dimer $(C_3O_2)_2$, which is an alkylketen, has also been proposed[143]. Next this keten combines in succession with fresh C_3O_2 molecules. However, it has been noted[133] that this mechanism presupposes the formation of polymers with a very high molecular weight, since the reactive alkylketen is formed at each stage, and this conflicts with experimental data.

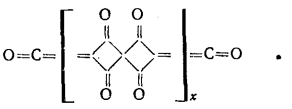
The most justified mechanism of the thermal polymerisation of C_3O_2 has recently been proposed by Snow et al.[133] The initial stage involves the formation of an activated complex between the bent C_3O_2 molecule and the surface of the polymer or, what is more difficult, the surface of the reaction vessel. Thus the induction period is determined by the probability of the formation of such a complex. Next follows the formation of a zwitter-ionic ketocarbene capable of combining in succession with monomer molecules; the termination stage then occurs via the Wolff rearrangement and the resulting macromolecule contains two ketenyl groups.

§ This is contradicted by early data[120].

The photopolymerisation of C_3O_2 has been described by Bayes[144–146], who investigated the gas-phase photolysis in the presence of ethylene and oxygen. He suggested that, when acted upon by a light quantum, the C_3O_2 molecule gives rise to an active C_2O radical, which is capable of attacking the C=C double bonds and even C–H single bonds. This results in the formation of a polymer, allene, methylacetylene, and CO. There is also a possibility of the existence of two intermediate species with different reactivities[146,147]. In the absence of additives, the photolysis products are only $(C_3O_2)_x$ and CO. It has been established[148] that the photopolymer is analogous to the thermopolymer; the addition of O_2 to the initial monomer reduces the yield of the polymer and for the ratio $O_2 : C_3O_2 = 100 : 1$ the polymer is not formed at all. The eight-stage mechanism of photolysis proposed by Smith et al.[148] includes, apart from the formation of C_2O, the generation of an activated complex C_5O_3 with a structure of diketen-cyclopropanone. It may be[131] that the light-induced thermal polymerisation of C_3O_2 also involves the formation of C_2O.

Ultraviolet irradiation of a solution of C_3O_2 in hexane results in polymerisation[149], which gives rise to a new compound containing a carbonyl group, apparently via the reaction of a hexane molecule with the C_2O radical. Indeed the EPR spectrum of solid C_3O_2 irradiated with ultraviolet light at 77 K has a singlet signal which can be attributed to C_2O. The study of the infrared spectra of the products of the photolysis of C_3O_2 at 100 K confirms the formation of C_2O as the initial species. Next, it was suggested[150] that a tricyclic compound $C_{13}O_8$ is formed, its molecule becoming the polymerisation centres on raising the temperature.

$(C_3O_2)_x$ and CO are also formed in the gas-phase γ-radiolysis of C_3O_2.[151] Since the polymer does not collect on the surface of the reaction vessel as in thermal polymerisation but on its bottom and the addition of O_2 does not influence the yield, an ionic mechanism of the polymerisation reaction, in which the C_2O^+ ions play an important role, is evident. On γ-irradiation, liquid and solid C_3O_2 do not polymerise[152]; on heating the irradiated suboxide from 77 and 180–260 K, the rate of polymerisation is low and on further heating, it rises sharply, reaching a maximum and then falling again owing to the exhaustion of the monomer. The active centres accumulated in the low-temperature radiolysis persist even in liquid C_3O_2, which is attributed to the establishment of steric hindrance which prevents chain termination. The self-acceleration of the isothermal liquid-phase polymerisation in the absence of continuous initiation may be associated with a branched chain reaction. On irradiation of solutions of C_3O_2 in halogeno-hydrocarbons by γ-rays, fast electrons, or ultraviolet light, polymers $(C_3O_2)_x$ with a high molecular weight (>10 000) are formed, temperature and pressure having very little influence on the process kinetics and the properties of the polymers; the use of ether, CO_2, and CS_2 as solvents leads to unsatisfactory results[153]. The polymerisation of C_3O_2 can be induced also by ultrasound[154].

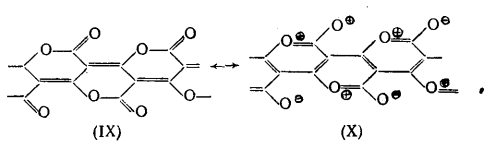


The polymers $(C_3O_2)_x$ are not formed solely from the monomer. It has been known for a long time[155] that, under the influence of a glow discharge, CO is slowly converted into $(C_3O_2)_x$ and CO_2. A thorough study[156] of this reaction showed that the polymer is formed even at 77 K and that the role of C_3O_2 in the formation of $(C_3O_2)_x$ cannot be significant. Analogous conclusions were arrived at also in the study of α-radiolysis[157] and γ-radiolysis[158] of CO; the reaction products were $(C_3O_2)_x$, CO_2, and graphite. The polymer arises from CO also as a result of ultraviolet irradiation or irradiation with fast electrons[160].

There exists a remarkable hypothesis[161], which explains the reddish colour of Mars by the presence of the polymers $(C_3O_2)_x$. Indeed the photolysis and radiolysis of CO lead to the formation of the suboxide, which rapidly polymerises. Many observations of Mars can be explained by assuming the formation of the $(C_3O_2)_x$ species on its surface and in the atmosphere[162]. It is also possible that $(C_3O_2)_x$ is the main component of the clouds of Venus[163].

In conclusion of this Section we may note that the solid red-brown substance obtained by Brodie[164] by exposing CO to the action of silent discharges (long before the work of Diels[117]) was apparently the polymer $(C_3O_2)_x$.

2. Structure and Properties

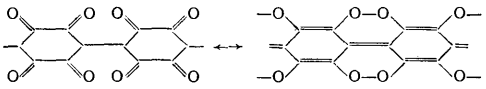


There are at present four hypotheses concerning the structure of $(C_3O_2)_x$ in the literature. The oldest is that of Hartley[165], according to which the polymerisation product is the dimer $(C_3O_2)_2$; its inapplicability from the energetic standpoint is now evident. Somewhat later Diels et al.[134] proposed structure (VIII) on the basis of the analogy between C_3O_2 and ketens. Porejko and coworkers[135,136] arrived at the same structure, justifying it with the aid of classical chemical methods and ultraviolet and infrared spectroscopy:

(VIII)

Having studied the infrared spectra, X-ray diffraction patterns, and chemical properties of $(C_3O_2)_x$, Schmidt and coworkers[138,139] proposed a completely different structure. They believe that the polymer is made up of condensed lactone and benzene rings; oxygen is located mainly in the six-membered lactone rings and at the edges of the molecule (whose diameter is close to 1 nm), there are keto- and keteno-groups. Thus the $(C_3O_2)_x$ lattice is similar to that of graphite, in which some of the C atoms have been replaced by O atoms; the distance between the planes is ~0.36 nm. However, this structure is unacceptable because 15 C_3O_2 units in it are arranged in only one possible way, as a result of which the structure cannot be built up further and less than 15 units cannot be postulated.

In order to construct a reasonable structure of the polymer $(C_3O_2)_x$, it is necessary to take into account the following factors[128]. The polymer must be formed as a result of a reaction involving C_3O_2 as the structural unit. The dimensions of the structure can be varied; all the polymers must react with water and bases to a greater or smaller extent. Since the thermolysis of polymers results in the initial evolution of CO_2, the presence of C atoms linked to two O atoms is desirable. The system of bonds must be conjugated in order to explain the intense colour of the polymers. The reaction of the polymer with ammonia should give rise to amides, whose interaction with water should lead to the appearance of carboxy-groups. A careful study[128] involving ultraviolet and infrared spectroscopy and chemical and X-ray diffraction analyses made it possible to attribute to the polymer structure (IX), which satisfies all these requirements:



(IX) (X)

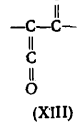
A further attractive feature of this structure is that it presupposes the existence also of an ionic pyrylium-like resonance form (X), which is highly stable and deeply coloured. Structure (IX) can be completed in different ways, but 1,2- or 2,3-addition of a C_3O_2 molecule to the ends of the macromolecule appears most likely; five-membered rings with ketenyl groups than arise.

Incidentally, an analogous structure had been proposed somewhat earlier by Ziegler on the basis of purely chemical considerations[137,167], but his work was apparently unknown to Smith et al.[128] Subsequent investigations[127,132,133,168] were consistent with structure (IX).

However, we believe that structure (IX) is not the only one possible. The resonance structures (XI)–(XII) which we put forward are entirely consistent not only with the requirements specified by Smith et al.[128] but also with infrared spectroscopic data, according to which the bands in the range 920–830 cm^{-1}, which were not identified in other studies, can be assigned to the peroxide group C–O–O–C:[169]

(XI) (XII)

In almost all the investigations which have been carried out the low stability of the polymers $(C_3O_2)_x$ was emphasised. We may note that this is true only of polymers obtained at comparatively low (less than 373 K) temperatures. Such polymers are extremly hygroscopic, water vapour altering their structure with evolution of CO_2 and the appearance in the infrared spectrum of bands due to the OH, COOH, ≡CH, and CH_2 groups; the products of the polymerisation of a moist monomer have the same spectrum[169]. The low-temperature polymers are readily soluble in water, giving red solutions. The amount of the soluble fractions diminishes with increase of the polymerisation temperature and the product obtained at 673 K is almost insoluble not only in water but also in dilute alkalies[128]. The available information about the solubility in organic solvents is contradictory. Thus polymerisation at 293 K in hexane gives rise to products which are readily soluble in ethanol but sparingly soluble in hexane; a polymer sparingly soluble in ethanol and chloroform and insoluble in hexane is formed at the same temperature in the gas phase[166]. The polymer obtained in ether[137] is readily soluble in acetone and methanol and sparingly soluble in dioxan and phenols. It has been claimed[128] that these polymers are altogether insoluble in ethanol, acetone, chloroform, carbon tetrachloride, benzene, and xylene. Effective solvents for the low-molecular-weight fractions are dimethyl sulphoxide and dimethylformamide[132,133]. At any rate it is clear that the solubility is determined mainly by the degree of polymerisation; it has been found that the polymer obtained at 373 K contains 5–10 [168] or 5–6 [133] C_3O_2 units.



The heat of formation of $(C_3O_2)_x$ from the gaseous monomer is ~137 kJ mol^{-1}.[170] The available information about the thermal stability of polymers is also contradictory. According to Diels and Wolf[117] and Porejko et al.[135], the decomposition begins at a temperature as low as 310 K and CO_2 is evolved. Klemenc and coworkers[126,127] shift the temperature limit to ~373 K. However, careful studies[128,168,171] have demonstrated the high stability of the polymers. At 373 K the polymerisation of C_3O_2 is accompanied by the evolution of small amounts (~1%) of CO_2 and CO, which rise to 2.5 and 6% respectively at 473 and 573 K, but these gases are not the products of the thermal decomposition of the monomer or polymer. The polymer itself begins to decompose only above 573 K, whereupon its colour deepens and its oxygen content falls, but even at the temperature of red heat the polymer

nevertheless still contains a certain amount of oxygen (cf. Ciusa[89]). With increase of temperature, there is an increase of the intensity of the diffraction bands; the X-ray spectrum at 1773 K resembles that of carbon black with the particles sizes L_a = 4.5 nm and L_c = 1.4 nm [168] (cf. also Schmidt et al.[138]). The polymers obtained at 373–393 K have an extremely high surface area (~20 $m^2\ g^{-1}$) and their particle size is ~100 nm according to electron microscope data[171].

According to Mrozowski and Wobshall[130] and Schmidt et al.[139], the non-heat-heated polymer does not give rise to an EPR signal. Quite different information is contained in reports of studies[132,133,172] where the EPR spectra of the $(C_3O_2)_x$ block polymers were investigated in detail. The spectra of the polymers $(C_3O_2)_x$ obtained at 303, 333, and 363 K show an intense slightly asymmetric line, whose intensity corresponds to a spin concentration of 2.5×10^{18} spins g^{-1}; the spectrum of $(C_3O_2)_x$ obtained at 378 K shows also a second line, corresponding to a spin concentration of 2×10^{19} spins g^{-1}, the relative intensities of these two lines being different in the spectra of different specimens. The paramagnetism of the polymers obeys the Curie–Weiss law. The results of the analysis of the line form, the saturation phenomenon, the *g*-factor, and the hyperfine structure of the EPR signals suggested that the paramagnetism of $(C_3O_2)_x$ is due to electronic transitions between individual conjugation regions; the spin concentration ~2.5×10^{18} spins g^{-1} corresponds to a single spin per 600 macromolecules if one assumes that the degree of polymerisation is 6. Since contact with moisture alters the colour of the polymer, causes a gradual decrease of the intensity of the ketenyl signals in the infrared spectra, and leads to a rapid disappearance of the EPR signal, presumably the keto- and keteno-groups are responsible for the generation of relatively stable paramagnetic centres. The possible structures of the resonance forms of the radical-ions have also been published[133]. Irradiation of $(C_3O_2)_x$ with visible light leads to an additional generation of paramagnetic centres; this photoprocess is reversible[132]. The fluorescence of the soluble component of $(C_3O_2)_x$ has also been investigated.

The electrical conductivities of the polymers obtained from the monomer in ethereal solution at 293 K have been studied[140]. The observed conductivities were in the range 10^{-7}–10^{-9} $\Omega^{-1}\ cm^{-1}$ and were poorly reproducible owing to the high hygroscopicity of the polymers. The observed activation energy is close to 1.8 eV. Taking into account the method of synthesis, these results can be attributed only to low-molecular-weight oligomers $(C_3O_2)_x$, which are amorphous according to X-ray diffraction measurements[140].

There may exist also another form of $(C_3O_2)_x$, obtained when the monomer is polymerised in a polar solvent such as nitromethane[136,141]. The study of the chemical properties and infrared spectra of the polymerisation products made it possible to attribute to them the structure of a polyketone (XIII) with a degree of polymerisation of 3–4:

(XIII)

A similar product is obtained in benzene[136] in the presence of catalytic amounts of H_2SO_4 or H_3PO_4. The polymerisation mechanism is neither ionic nor radical and it has been suggested[136] that the reaction proceeds via the intermediate formation of a lactone. The density of polymer (XIII) is lower than that of the usual polymer obtained in ethereal solution (1.22 and 1.61 g cm^{-3} respectively). Polymer (XIII) consists of a very hygroscopic brown powder, which is readily soluble in dimethylformamide and alkalies. However, the dark-brown colour is characteristic also of the radiation polymers $(C_3O_2)_x$, about the structure of which there is no doubt. Since structure (XIII) does not contain a system of conjugated bonds, the deep colour is so far unexplained and the results of Porejko and Gabara[141] must be treated critically.

V. CARBON SUBSULPHIDE POLYMERS

Carbon subsulphide C_3S_2, obtained for the first time by Lengyel[173] by exposing carbon disulphide CS_2 vapour to an electric arc, is a structural analogue of the suboxide C_3O_2 and exhibits an even greater tendency to polymerise. Although C_3S_2 can be obtained also by heating CS_2 vapour to 1273–1373 K in a quartz tube[174], different modifications of Lengyel's method are still being used[175,176], but any method of synthesis involves the formation of large amounts of the polymer $(C_3S_2)_x$.

At room temperature liquid C_3S_2 polymerises spontaneously in several days and at 373 K in several minutes, while on rapid increase of temperature C_3S_2 is converted into $(C_3S_2)_x$ explosively. Solutions of C_3S_2 in CS_2 at concentrations up to 1% are stable on storage in the dark but at higher concentrations slow polymerisation takes place. This also occurs in dilute solutions in sunlight[174]. Acids and alkalies have a catalytic effect[176]. At pressures ranging from 150 to 240 MPa C_3S_2 is exothermically converted into a product fully analogous to a thermopolymer, while the polymer $(CS_2)_x$ obtained from CS_2 at a pressure of 270–450 MPa and a temperature in the range 438–553 K is slowly converted into $(C_3S_2)_x$ under the usual conditions[175]. Illumination of CS_2 with ultraviolet light (253.7 nm) also yields the polymer $(C_3S_2)_x$ together with other products[177].

It has been established[174] that the rate of polymerisation depends little on the C_3S_2 concentration and is proportional to the surface area of the vessel. The order of the reaction is close to second, but in the presence of a large surface area of the reaction vessel deviations from the second order towards the first occur. One of the possible explanations is that at the beginning two C_3S_2 molecules react with one another in the gas phase and the interaction product then polymerises on the walls of the vessel[174].

The polymer $(C_3S_2)_x$ is a black graphite-like substance insoluble in all usual solvents. The product obtained at low temperatures (below 373 K) is soluble in boiling concentrated NaOH solution, being precipitated on acidification. The infrared spectroscopic data for the polymer[175,178–181] differ somewhat from one another (in some instances[180,181] this was explained by the presence of traces of moisture during polymerisation), but the results show that the $(C_3S_2)_x$ structure is fully analogous to that of $(C_3O_2)_x$; the X-ray diffraction patterns of these polymers are also similar. On heating, the decomposition of $(C_3S_2)_x$ begins near 673 K and is accompanied by the evolution of C_3S_2 and traces of CS_2, while the residue contains carbon and sulphur[180]. According to other data[175], the monomer is not evolved on vacuum pyrolysis, only the elimination of CS_2 being observed, and the residue is a dark-red carbon like product which still contains much sulphur [~39% compared with 64% in $(C_3S_2)_x$].

The EPR spectra of $(C_3S_2)_x$ obtained at 448 K give a spin concentration of 2.5×10^{20} spins g^{-1}. Heat treatment of the polymer *in vacuo* or in an atmosphere of helium at temperatures up to 973 K has little effect on the intensity of the EPR signal, while in the presence of air it leads to an increase of signal intensity up to a temperature of ~873 K.[130] The order of magnitude of the electrical conductivity of

$(C_3S_2)_x$ is ~10^{-6} Ω^{-1} cm^{-1}.[175] It is not without interest that the reaction of sulphur with anthracene at 673 K [182] yielded a polymer containing 54% of sulphur and insignificant amounts of H and O, which is also fairly close to the elemental composition of $(C_3O_2)_x$ (see also Wibaut and Kam[92]). The electrical conductivity of this product proved to be only 3×10^{-3} Ω^{-1} cm^{-1}; no data concerning the structure are available.

VI. CONCLUSION

The polymers discussed in this review, which have a system of conjugated bonds, should be in the main semiconductors. However, their properties, particularly their electrophysical properties, have so far been inadequately investigated. Their further study and the preparation on their basis of new materials with interesting properties are worthwhile. For a specific search for such materials, it is extremely important to know the properties of the initial polymers. However, it is clear that the properties described above most probably refer only to individual specimens. For example, one cannot estimate the accuracy of the electrical conductivity measurements; it is undoubtedly low owing to the inhomogeneity of the materials and surface effects. Unfortunately there are no reliable methods for determining the degree of polymerisation of insouble polymers. Reliable characteristics could be obtained for single-crystal specimens. However, there are fundamental difficulties associated with the fact that, when coplanar blocks attain a length of 35–40 units, the coplanar inclusion of subsequent units in the chain becomes energetically less favourable than the formation of a new block unconnected to the previous ones[83]. Depending on the conditions of synthesis, the distribution of blocks with respect to the effectiveness of conjugation may change significantly.

The band structure of the polymers considered is characterised by the fact that the upper valence band and the lower conductivity band are of the π-character. Their theoretical study can therefore be based on models involving the π-electron approximation. In the simplest of the models (the Hückel model) the nature of the π-bands of $(CN)_x$ in modification (II) has been discussed[183]. It has been shown that in such systems the alternation of bond lengths and hence of resonance integrals is insignificant. It is more important that the difference between the electronegativities of the C and N atoms, described by the difference between their Coulombic integrals, makes the main contribution to the energy gap of the polymer with a fully filled π-band. The electronic structure of $(CN)_x$ in modifications (II) and (IV) has also been calculated within the framework of the extended Hückel method using crystal orbitals[184]. The application of this model to modification (II) resulted in the overlap of the lower vacant π-band (conductivity band) and the upper occupied σ-band (valence band), formed by the lone electron pairs of nitrogen, which give rise to a ground state of the metallic type.

In discussing these results one should not, incidentally, neglect the fundamental defects of the method, which have been pointed out, for example, by Dewar[185] and which are particularly pronounced for heteroatomic systems of the type under consideration. It may be that the result obtained is an artefact of the Hückel model. The fact that $(CN)_x$ with structure (IV) exhibits in the same calculations a considerable stability and an energy gap of ~1.4 eV of the semiconductor type is in better agreement with experimental results. The calculation[184] on the parquet polymer $(C_3N)_x$ also led to a metallic conductivity, since, as a consequence of the odd number of π-electrons in the unit cell, the upper valence π-band is partly filled. Clearly, paracyanogen (III) should exhibit, within the framework of this model, a metallic character like graphite, which is fully consistent with experimental data[76].

According to modern ideas concerning the electronic structure of polyconjugated polymers[186], the ordered system made up of the graphite network by the replacement of certain carbon atoms by boron or nitrogen atoms should be ferromagnetic, since its total spin in the ground state is infinite. Difficulties associated with the creation of polymeric ferromagnetic materials of this kind have recently been noted by Buchachenko[187].

The band structure of the remaining polymers deals with in the review has not apparently been studied. It is clear from general considerations that the difference between the Coulombic integrals for the C, O, and S atoms should lead to the absence of overlap of the valence and filled bands and hence to semiconducting properties of the polymers, and the energy gap in the case of $(C_3S_2)_x$ should be smaller than in the case of $(C_3O_2)_x$.

It is appropriate to point out a number of considerations concerning specific ways of increasing the electrical conductivity of the polymers considered. Among purely physical methods, one may indicate the application of a high pressure[188], which, by reducing the internuclear distances and by increasing the overlap of the atomic orbitals, leads to the overlap of a number of bands, as a consequence of which a typically semiconducting system becomes metallic. A remarkable example of this kind is provided by elemental sulphur[189]. In principle, there is then a possibility of transitions to a structure with another crystal lattice. However, chemical methods are more effective and easier to apply, for example the intercalation already mentioned. The scope of this method is extremely wide, which can be illustrated by the following example. When partly oriented films of polyacetylene $(CH)_x$ are doped with donors of acceptors (Na, I_2, AsF_5, etc.), the conductivity increases from 10^{-10}–10^2 Ω^{-1} cm^{-1}, i.e. by twelve orders of magnitude, and materials of *p*- and *n*-types are obtained[190]. The results of the intercalation of hexagonal boron nitride $(BN)_x$, which is converted from a typical insulator to a conductor following the introduction of $S_2N_6F_2$, are even more striking[191].

Certain conjugated polymers have already found applications as the working materials of thermoresistors and tensotransducers, many parameters of which are superior to those of the usual industrial specimens[81]. A high-quality *p*–*n* junction with very effective rectifying properties has been prepared[192] from $(CH)_x$ films of different types. Thus one may expect interesting electrophysical properties of intercalated polymers, to the discussion of which this review has been devoted, and in the future new materials important for modern technology may be obtained. Advances in this field can depend to a large extent on the preparation of single-crystal specimens of the corresponding polymers.

Phenomenological Sorption Thermodynamics

A.M.Tolmachev

The thermodynamics of sorption of pure substances and of mixtures from the vapour or the liquid phase on sorbents of different types are discussed. The stoichiometric theory of adsorption and the osmotic theory (based on the vacancy solution model) are analysed in detail, as well as the most recent advances in the theory of volume filling of micropores. The following problems are examined: the validation of the model, and of the choice of components of the sorption solution, the methods of calculating the appropriate activity coefficients, the internal thermodynamic consistency of data on adsorption from the vapour and the liquid phase, and the prediction of equilibrium adsorption characteristics from the smallest possible amount of experimental data. Capillary phenomena are examined from the standpoint of maximising the information on the pore structure of the adsorbent. 80 references.

I. INTRODUCTION

The increasingly wide application of sorption processes in chemical industry has been responsible for recent developments in the study of adsorption, and in particular of the thermodynamic theory of adsorption. The control and optimisation of these processes, the preparation of adsorbents offering the required selectivity towards certain components of the mixture, and the identification of the mechanism of adsorption–catalytic processes have created a need for still further developments in theoretical studies of adsorption.

One of the most important theoretical problems is to develop methods of predicting the equilibrium characteristics of adsorption in one-component and multi-component systems, because the empirical approach to achieving selectivity in adsorption systems (and thus making the systems more effective and economically attractive) is laborious and impractical when the number of mixtures to be extracted, purified, or separated is very large. In principle this problem can be solved by molecular–statistical thermodynamics.

Many recent experimental and theoretical papers have dealt with intermolecular interactions in sorption systems, and with the study of the physical and physicochemical

properties of adsorbents and adsorbed molecules by modern methods of analysis. However, the complexity of the problem is such that rapid progress cannot be expected by this approach. Far more useful advances have been made in the developments of a strict phenomenological theory of adsorption thermodynamics usable in conjunction with empirical rules or non-thermodynamic considerations suggested by simple, approximate models of sorption systems.

In this review we shall examine recent achievements in that type of work. No attempt will be made to cover the literature exhaustively, but we shall try instead to clarify the present position of the thermodynamic theory of adsorption by referring to published information as required.

The symbols used in this review have their conventional meaning (unless accompanied by a statement to the contrary). We shall also use the following additional symbols:

n_i, c_i, x_i, γ_i are the number of moles, the concentration (mole litre^{-1}), the mole fraction, and the activity coefficient of the stated component in the bulk phase (the tilde sign ~ denoting the liquid solution when a vapour and a liquid bulk phase can coexist, e.g. $\tilde{c}_i$, etc.);

$\bar{n}_i$, $\bar{c}_i$, $\bar{x}_i$, θ_i, $\bar{\gamma}_i$, $\bar{\varphi}_i$, are the number of moles, the concentration (mole kg^{-1}), the mole fraction, the surface coverage, the activity coefficient, and the full chemical potential of the components of the sorption solution (the subscript R denotes the adsorbent, for example $\bar{c}_R$ is the concentration of the adsorbent); c_{is}, γ_{is}, $\tilde{c}_{0i}$, $\bar{c}_{0i}$ are the concentration (mole litre^{-1}) and the activity coefficient of the saturated vapour and of the pure liquid component and the concentration (mole kg^{-1}) of the sorption solution when saturated with the stated component; s_i, s_R, and s are the molar volumes or areas of the components of the sorption solution;

σ is the surface tension or internal pressure;

W *and* W_0 are the surface (or volume) and the specific surface (or volume) of the macroporous or microporous sorbents;

$\bar{v}_{0i}$ is the molar volume of the liquid adsorbate at the given temperature;

K_i and $\bar{K}_i$ are the equilibrium coefficient and the thermodynamic equilibrium constant for the adsorption of the i-th component;

α, K, and $\bar{K}$ are the separation coefficient, the equilibrium coefficient, and the thermodynamic equilibrium constant for the adsorption of a binary mixture;

g_i is the osmotic coefficient of component i in the sorption solution;

β_i, β, and $\beta_i(af)$ are the stoichiometric coefficients for the individual and the exchange adsorption, and the affinity coefficient of the theory of volume filling of micropores (TVFM);

α_i is the thermal expansion coefficient of the components of the sorption solution in the TVFM;

E_0 is the characteristic free energy of adsorption of the standard vapour in the TVFM;

r is the equivalent radius of the mesopores;

t and t_e are the mean square thickness of the adsorption layer in the mesopores without and with the correction (respectively) for the effect of the sorption field of the sorbent;

ω is the parameter of Tolman's equation.

II. THE SORPTION SOLUTION MODEL

Two methods of describing adsorption systems thermodynamically are known: the Gibbs surface excess method[1] and the finite thickness layer method (or, more exactly, the total content method)[2]. In the Gibbs method the real structure of the adsorption phase is ignored. Therefore the thermodynamic functions determined from the experimentally measured excess quantities apply to the sorption system as a whole and cannot be used to analyse the distribution of volume phase and of sorption phase in the adsorbents, and the thermodynamic properties of the latter. For this reason modern theories of adsorption have tended to rely on the finite thickness layer method.

In the thermodynamic analysis of sorption systems a distinction is often made between adsorption in the surface layer (macroporous sorbents) and in the volume of micropores (microporous sorbents). In a critical analysis of this approach[3] a new function (Φ) was introduced to describe both processes within the same thermodynamic model. As the present writer recently pointed out[4], the properties of both these sorption phases are similar in many ways[3,4], though they differ very substantially from those of ordinary bulk phases: the pressure in the plane of the surface layer of the bulk sorption phase is different (at least, in some directions) from the total pressure P in the system. Hence, in both cases[1,4,5] the fundamental equations should include the term σdW to allow for the additional work of formation of the surface layer (where σ is the surface tension and W is the area of the surface) or of the "volume" sorption phase in the micropores (where σ is the internal pressure and W is the volume of the sorption phase):

$$\mathrm{d}U = T\,\mathrm{d}S - P\,\mathrm{d}V + \sum_i \mu_i\,\mathrm{d}n_i + \sum_i \bar{\varphi}_i\,\mathrm{d}\bar{n}_i + \sigma\,\mathrm{d}W, \tag{1}$$

$$\mathrm{d}G = -S\,\mathrm{d}T + V\,\mathrm{d}P + \sum_i \mu_i\,\mathrm{d}n_i + \sum_i \bar{\varphi}_i\,\mathrm{d}\bar{n}_i + \sigma\,\mathrm{d}W \tag{2}$$

so that

$$-S\,\mathrm{d}T + V\,\mathrm{d}P + \sum_i n_i\,\mathrm{d}\bar{\varphi}_i + W\,\mathrm{d}\sigma = 0. \tag{3}$$

The full chemical potentials of the components of the sorption solution should be written[1,5] as

$$\bar{\varphi}_i = \bar{\mu}_i^0(T, P) + RT\ln\bar{c}_i\bar{\gamma}_i - \int_0^\sigma s_i\,\mathrm{d}\sigma = \bar{\mu}_i - s_i\sigma, \tag{4}$$

$$\bar{\varphi}_i = \bar{\mu}_i^0(T, P) + RT\ln\bar{x}_i\bar{\gamma}_{ix} - \int_0^\sigma s_i\,\mathrm{d}\sigma = \bar{\mu}_i - s_i\sigma. \tag{5}$$

The molar areas or volumes (s_i) of the components of the sorption solution depend (in general) on the composition of the solution. However, since the dependence is usually not very marked, and the form of the relevant function is not known, we can adopt the rigid sorption solution model (i.e. $s_i = \text{const}$) without affecting the thermodynamic validity of the argument. Any deviation from the assumed model can be allowed for by choosing an appropriate activity coefficient. By this approach (which is currently favoured by most workers) correct use can be made of the right-hand side Eqns.(4) and (5). We note that in the calculation of $\bar{\gamma}_i$ and $\bar{\gamma}_{ix}$ reference (standard) states differing by a factor of $\bar{c}_{0i}$ are usually used:

$$\bar{\gamma}_i,\ \bar{\gamma}_{ix} \to 1 \text{ for } \bar{c}_i \to \bar{c}_{0i}, \text{ i.e. } \bar{x}_i \to 1, \tag{6}$$

whereas $\bar{\gamma}_{ix} = \bar{\gamma}_i\bar{c}_0$ (where $\bar{c}_0$ is the total concentration of the solution), which leads to a formal difference between the numerical values of the standard parts of the chemical

potentials and of the standard thermodynamic functions derived from them[6-8].

Another important property of the sorption phase is its finite size (implicit in the finite thickness layer model). Thus, the sorption solution is a phase of limited capacity with respect to the overall combination of components of the solution. Since the inhomogeneous region at the contact between two phases extends, strictly speaking, to the whole volume[5], the fundamental problem in the total content method is a thermodynamically correct choice of the size of the sorption phase (thickness, in the case of adsorption on macroporous systems, and volume, in the case of sorption in micropores).

In the sorption of gases or vapours the excess adsorption quantities are almost identical to the corresponding total contents of components in the sorption phase. Hence the model phase can be chosen with adequate precision on the basis of the adsorption isotherm and of physically acceptable data on the effective size of the adsorbed molecules (monlayer thickness for the sorption of gases on macroporous sorbents, and micropore volume for the sorption of gases and vapours in micropores). The sorption of vapours in macropores is complicated by multimolecular adsorption and capillary condensation phenomena, and requires a special thermodynamic analysis.

Sorption from liquid solutions is a far more complex problem, because in this case the experimental data can be used reliably to calculate only the minimum capacity of the sorption phase[5,9], and this cannot be a basis for a correct choice of the size of the phase[9,10]. An interesting method for the thermodynamically correct choice of a sorption phase model in this case was proposed by Larionov[9].

1. The monolayer capacity $\bar{c}_{i(M)}$ or micropore volume $\bar{c}_{i(W)}$ is determined experimentally. Critical studies[9,10] of the methods of determining these quantities for the sorption of vapours and of liquid solutions suggest that the most reliable results are obtained by comparing data for the sorption of pure vapours with data for the sorption of their binary liquid solutions.

2. The size of the sorption phase is obtained by multiplying the $\bar{c}_{i(M)}$ or $\bar{c}_{i(W)}$ values thus obtained by the arbitrarily chosen factor k.

3. Using the experimental excess sorption isotherm of the binary liquid solution the changes in σ or in the thermodynamic wetting functions attending the transfer of the sorbent wetted with one of the components to a solution of composition $\tilde{x}_1$ are calculated by the Gibbs and the total content method. The Gibbs method, being free from any model assumptions, yields the true values of the change in the thermodynamic functions of the sorption system. In the calculation by the total content method the result obtained depends on the chosen model, i.e. on the value of k. By varying k so as to make the two sets of results coincide a thermodynamically correct model of the sorption solution is obtained.

Larionov applied this method of analysis to a large number of adsorption systems[9,11,12], and he showed that in the case of microporous sorbents the volume of the micropores is a good approximation to the volume of the sorption phase. With macroporous sorbents the best approximation is given by the monolayer volume, or occasionally by the volume of two or three layers. Thus, even in the case of sorption from liquid solutions the model of a rigid layer of finite thickness is thermodynamically justified.

The choice of components of the sorption solution is an important part of the construction of the model of the sorption phase[3,4,6,13-17]. The problem consists in defining, within the thermodynamic meaning of the term, a set of components which allows the required thermodynamic relationships to be set up in the simplest way for different sorption systems (both one-component and multi-component).

If the components of the sorption solution are identified with the substances in the bulk phase (A, B, ...), and the sorbent is not explicitly treated as a component of the sorption solution, the role of the sorbent is limited to the creation of an adsorption force field. In this case the equilibrium conditions in a closed system become (P, T = const)

$$\bar{\varphi}_i = \mu_i. \tag{7}$$

This choice of components is thermodynamically correct, but not always convenient. For example, from (5) and (7) we obtain the adsorption isotherm equation

$$\bar{c}_i\bar{\gamma}_i = c_i\gamma_i \exp[(\mu_i^0 - \bar{\mu}_i^0 + s_i\sigma)/RT], \tag{8}$$

which contains the experimentally inaccessible quantity σ. Of course, by solving Eqn.(8) simultaneously with the Gibbs adsorption equation for a layer of finite thickness

$$\sigma = -\frac{RT}{W_0}\int_0^{c_i}\sum_i \bar{c}_i\, d\ln c_i\gamma_i, \tag{9}$$

we can eliminate σ from Eqn.(8) and obtain a general form of the adsorption isotherm equation. However, this approach presents mathematical difficulties, due to the complicated dependence of σ on the composition of a multi-component sorption solution containing molecules of different size, and to the absence of an analytical expression of the type of $\bar{c}_i = f(c_i\gamma_i)$.

Complications can arise also in the analysis of systems showing evidence of chemisorption, since in this case we cannot assume that the component remains chemically identical in the two phases in equilibrium. We should stress that the stipulation commonly made in this case that the sorbent must be "inert" (i.e. that $\bar{\phi}_R$ = const) is thermodynamically incorrect, since [as we see from Eqns.(4) and (5)] σ varies during sorption. The errors caused by this assumption are discussed in Ref.14.

In the thermodynamic stoichiometric theory of adsorption (STA) developed by the present writer[4,6,13,18-22] the components of the sorption phase are taken to be the complexes formed by the adsorbate species with the sorption centres and the free sorption centres of the sorbent (AR_{s_A/s_R}, BR_{s_B/s_R}, R), whose mass is divided into the number of moles ($\bar{n}_R$) so that a molar surface or volume (s_i, s_R) can be associated with each mole of the components, and for W = const we have

$$s_i = W/\bar{n}_{0i} = W_0/\bar{c}_{0i},\quad s_R = W/\bar{n}_{0R} = W_0/\bar{c}_{0R}, \tag{10}$$

and since the sorption solution is always saturated with the sum of the components we also have

$$\sum_i s_i\bar{n}_i + s_R\bar{n}_R = W, \tag{11}$$

$$\sum_i s_i\, d\bar{n}_i + s_R\, d\bar{n}_R = 0. \tag{12}$$

[Since the value of $\bar{c}_{0R}$ is unknown we cannot evaluate s_R numerically from the expressions (10)].

This choice of components is consistent with the physically possible occupancy of several sorption centres by a sorbate molecule, it treats the adsorbent explicitly as one of the components of the system, and it is thermodynamically strict, whatever the magnitude of the adsorbate–absorbent interaction (i.e. it is equally correct whether the adsorption energy is close to the energy of a chemical bond, as in

chemisorption, or whether it is a weak dispersion interaction as in the adsorption of inert gases on graphitised carbon). It allows a fairly simple description of adsorption equilibria in different sorption systems (involving localised or delocalised physisorption or chemisorption) for the one-component or multi-component sorption of molecules of different size from bulk phases of any kind.

We should stress that Eqns.(11) and (12) apply when all the sorption centres are equally accessible to the adsorbate molecules, i.e. when molecular sieve effects are absent. If, on the other hand, in a two-component adsorption system the sorption volume W_A is available to A molecules and the sorption volume W_B to B molecules, with $W_B > W_A$, Eqns.(11) and (12) will apply only to the volume W_A, and similar expressions can be written for the adsorption of component B in the volume $W_B - W_A$.[18,21]

Simultaneous solution of Eqn.(2) (for P, T = const) and Eqn.(12) gives the basic equations of the STA:[4,6,13]

$$(\bar{\varphi}_A - \mu_A)/s_A = (\bar{\varphi}_B - \mu_B)/s_B = \ldots = \bar{\varphi}_R/s_R, \qquad (13)$$

or, using Eqn.(5)

$$(\bar{\mu}_A - \mu_A)/s_A = (\bar{\mu}_B - \mu_B)/s_B = \ldots = \bar{\mu}_R/s_R. \qquad (14)$$

Thus the choice of components for the sorption solution adopted in the STA allows us to treat adsorption processes as quasi-chemical addition reactions ($\beta_i = s_R/s_i$):

$$\beta_A A + R \rightleftarrows \beta_A AR_{1/\beta_A} \text{ etc.} \qquad (15)$$

or exchange reactions ($\beta = s_A/s_B = \beta_B/\beta_A$):

$$A + \beta BR_{1/\beta_B} \rightleftarrows AR_{1/\beta_A} + \beta B \text{ etc.} \qquad (16)$$

and therefore it makes the well developed methods of chemical thermodynamics available for the thermodynamic description of adsorption processes. On the other hand the properties of sorption solutions can be discussed in terms of the most recent advances in the theory of solutions of different-sized particles.

In the osmotic theory of adsorption (OTA) developed by Bering, Serpinskii, and others[15-17] the components of the sorption solution are adsorbate molecules and vacancies, which are identified with elements of free space in the sorption volume of micropores or in a surface layer of finite thickness. This choice of components is in many ways analogous to the previous variant, but in this case the equilibrium phases contain at least two components, which allows the methods of the osmotic theory of solutions to be applied to the analysis of one-component adsorption. Since the model assumes that in the sorption of pure substances $s_i = s_* = W_0/c'_{i,\max}$ (where s_* is the molar volume of the vacancies) on changing to multi-component adsorption we have $s_* \neq$ const, and Eqn.(12) for W = const is replaced by

$$\sum_i s_i \, d\bar{n}_i + s_* \, d\bar{n}_* + \bar{n}_* \, ds_* = 0, \qquad (17)$$

where the variations ds_* are many-valued functions of the composition of the sorption solution. This makes necessary the use of special algorithms in the thermodynamic analysis of these systems.

We also note that in the case of one-component adsorption imposing the condition $s_i = s_*$ on the model may perturb the real physical description of the solution, since according to the general statistical theory of binary solutions[6] we can write for $\bar{\gamma}_i$

$$RT \ln \bar{\gamma}_i = RT\bar{c}'_R(s_R - s_i) + (\bar{c}'_R)^2 s_R (s_R s_i)^{1/3} \Delta U_{i-R} \qquad (18)$$

(where $\bar{c}'_R$ is in mole litre^{-1}, and the subscript R is analogous to $*$), and any deviation from ideality (i.e. any deviation of $\bar{\gamma}_i$ from unity) should be associated with changes in the intermolecular interactions in solution ΔU_{i-R}, whereas such deviations could result simply from the difference in size of the component molecules with $\Delta U_{i-R} = 0$. The latter feature is, of course, entirely irrelevant to a formal thermodynamic analysis.

A very important aspect of this model is the fact that the vacancy solutions are in a state of osmotic equilibrium, i.e. the chemical potential of the solvent (vacancies) in the sorption phase is equal to the chemical potential of the pure solvent (vacancies in a vacuum). Therefore, using (5), we have[15,16]

$$\mu_* = \bar{\mu}^0_*(T, P) + RT \ln \bar{x}_* \bar{\gamma}_* - s_* \sigma = \mu^0_*(T, P). \qquad (19)$$

Since $\bar{\mu}^0_* = \mu^0_*$, and $\bar{x}_* = \bar{c}_*/\bar{c}_{i,\max} = \bar{\theta}_* = 1 - \bar{\theta}_i$, it follows from (19) and (10) that for one-component adsorption

$$\sigma W_0 = \bar{c}_{i,\max} RT \ln [(1 - \bar{\theta}_i)\bar{\gamma}_*]. \qquad (20)$$

The advantage of the OTA vacancy model is not only that the theory of bulk solutions can be applied to the sorption phase, but also that a general adsorption isotherm equation can be obtained relatively simply (without the need to integrate the Gibbs adsorption equation) by solving Eqns.(20) and (7) simultaneously after writing the latter in a form appropriate to the adsorbate A:[17]

$$\mu^0_A + RT \ln c_A \gamma_A = \bar{\mu}^0_A + RT \ln \bar{x}_A \bar{\gamma}_A - s_A \sigma. \qquad (21)$$

We note that the chemical potential of the sorbent changes during sorption, but $\bar{\phi}_*$ according to (19) remains constant for all values of $\bar{\theta}_i$. Therefore the vacancies cannot be treated as formally analogous to the sorbent, and the latter is not one of the components of the sorption solution in the OTA model.

To conclude this discussion of the model of the sorption solution we need to examine the precise definition of the limiting adsorption value.

If the $\bar{c}_{0i}$ values are found by extrapolating the linearised adsorption isotherm equations to $c_i \to \infty$ (for gases) or to $c_i = c_{is}$ (for a saturated vapour) they give only an approximate indication of the limiting adsorption under the given conditions, since the equations do not apply for $\bar{\theta}_i \to 1$. These values are termed apparent limiting adsorptions to distinguish them from the true values ($\bar{c}'_{0i}$) obtained by direct physical measurements (for example, at $c_i = c_{is}$). The latter values are of the utmost importance in studies of the physical properties of sorption solutions. In the case of delocalised adsorption both $\bar{c}_{0i}$ and $\bar{c}'_{0i}$ are, of course, functions of temperature.

The proponents of the osmotic theory of solutions[14-17] suggest that the limiting adsorption of a gas, vapour, or liquid should be treated as the maximum achievable adsorption, consisting of the maximum possible number of sorbate molecules close-packed in the sorption volume:

$$\bar{c}_{i,\max} = W_0/\bar{v}_{i,\min}. \qquad (22)$$

An obvious disadvantage of introducing $\bar{c}_{i,\max}$ is the need to evaluate this quantity from adsorption measurements. This difficulty was satisfactorily overcome[17], however, by calculating the molar volume of the substance subjected to maximum compression ($\bar{v}_{i,\min}$) from the parameter σ_∞ (the intermolecular interaction potential).

The use of the maximum adsorption values offers the obvious advantage that these quantities are independent of temperature, but the calculation of $\bar{c}_{i,\max}$ by Eqn.(22) is complicated and indeterminate to some extent, and the worth-whileness of introducing the quantity $\bar{c}_{i,\max}$ into the analysis of conventional adsorption equilibria requires

further discussion. Of course, the validity of the thermodynamic analysis is unaffected by whether the chosen model of the sorption solution does or does not rely on the quantities $\bar{c}_{0i}$ and $\bar{c}_{i,max}$.

We shall now briefly examine recent developments in the thermodynamic theories of sorption based on different models of the sorption solution.

III. THE STOICHIOMETRIC THEORY OF ADSORPTION

1. Adsorption of Pure Substances

From Eqn.(13) or (14), using Eqn.(4), we can easily obtain a general isotherm equation for one-component adsorption[6,22]:

$$\bar{K}_A = \beta_A (\bar{c}_A\gamma_A)^{\beta_A}/(c_A\gamma_A)^{\beta_A}(\bar{c}_{0A} - \bar{c}_A)\,\bar{\gamma}_R = \bar{K}_A^{*}\bar{\gamma}_A^{\beta_A}/\bar{\gamma}_R. \qquad (23)$$

Since $d\bar{c}_A = -\beta_A d\bar{c}_R$, we can write (for P, T = const)

$$\bar{c}_A\, d\ln\bar{\gamma}_A + \bar{c}_R\, d\ln\bar{\gamma}_R + (1 - 1/\beta_A)\, d\bar{c}_A = 0 \qquad (24)$$

and eliminate $\bar{\gamma}_R$ from (23):

$$\left(\frac{\bar{K}_A}{\beta_A \bar{c}_{0A}^{\beta_A - 1}}\right)^{1/\beta_A} = \bar{K}'_A = \frac{\bar{c}_A\bar{\gamma}_A}{c_A\gamma_A\,(\bar{c}_{0A} - \bar{c}_A)} \exp\left[\int_0^{\bar{c}_A}\left(\frac{\bar{c}_A}{\bar{c}_{0A} - \bar{c}_A}\right) d\ln\bar{\gamma}_A\right]. \qquad (25)$$

From the general equations (23) and (25) we can obtain special formulae for specific types of $\bar{\gamma}_i = f(c_i)$ relationship, chosen on the basis of various theories of solutions (e.g. the Hill equation, the Fowler and Guggenheim equation, etc.[22]). The following three cases are the most interesting.

1. For ideal adsorption (γ_A, $\bar{\gamma}_A$, $\bar{\gamma}_R = 1$, and therefore $\beta_A = 1$) Eqns.(23) and (25) reduce to the Langmuir equation.

2. If the sorption solution consists of non-interacting particles of equal size [$\Delta U_{i-j} = 0$, Eqn.(18)] we have

$$\bar{\gamma}_A = \exp\left[\frac{\bar{c}_R\,(s_R - s_A)}{W_0}\right] = \exp\left[\frac{\beta_A - 1}{\beta_A \bar{c}_{0A}}(\bar{c}_{0A} - \bar{c}_A)\right], \qquad (26)$$

and Eqn.(25) reduces to

$$\bar{K}'_A = \bar{K}_A \exp\left[\frac{\beta_A - 1}{\beta_A}\right] \Big/ \beta_A = \bar{c}_A^{\beta_A}/(c_A\gamma_A)^{\beta_A}(\bar{c}_{0A} - \bar{c}_A), \qquad (27)$$

which can be linearised (for $\gamma_A = 1$) in order to evaluate β_A.

Eqn.(27) has been applied[19] to published data claimed to be in satisfactory agreement with the Langmuir isotherm. Values of β_A differing significantly from unity were obtained, and it was shown that Eqn.(27) offers a better description of the experimental results. Exactly as required by Eqn.(10), the quantities $\beta_A : \beta_B : \beta_i$ were found to be in the same ratio as $\bar{c}_{0A} : \bar{c}_{0B} : \bar{c}_{0i}$, a positive confirmation of the validity of the basic assumptions of the STA. Hence the β_i values could be calculated from the expressions

$$\beta_i = \beta_j \bar{c}_{0i}/\bar{c}_{0j}. \qquad (28)$$

If an adsorbate to which Eqn.(27) is strictly applicable on the given sorbent cannot be found, the parameter β_j for any adsorbate is evaluated approximately by Eqn.(27) and all the other β_i values are found by Eqn.(28).

3. As was pointed out by Bering and Serpinskii[15], in the sorption of various adsorbates on microporous adsorbents the $\bar{\gamma}_i = f(\bar{c}_i)$ relationship can often be written

$$\bar{\gamma}_A = \bar{c}_A^{g_A - 1}, \quad \bar{\gamma}_R = \bar{c}_R^{g_R - 1}, \qquad (29)$$

where g_A and g_R are constant for $0 < \bar{c}_i < \bar{c}_{0i}$, and $g_i \to 1$ for $\bar{c}_i \to \bar{c}_{0i}$. Inserting (29) into (25) leads to the Kisarov equation[22] [since according to Eqn.(24) $g_R = \beta_A g_A$]:

$$\bar{c}_A = (\bar{K}_A/\beta_A)^{1/g_R}\bar{c}_{0A}c_A^{1/g_A}/[1 + (K_A/\beta_A)^{1/g_R}c_A^{1/g_A}], \qquad (30)$$

and after replacing $\bar{c}_{0A}$ by $\bar{c}_{A,max}$ it leads to the corresponding equation of the osmotic theory of adsorption[15]. In spite of a statement to the contrary in Ref.15, Eqn.(30) describes a more general case of sorption solution, with components of unequal size ($\beta_A \neq 1$).

If the special forms of Eqn.(25) cannot be applied satisfactorily to specific experimental results it becomes necessary, in order to use (23) or (25), not only to determine β_i from Eqn.(27) or (28) but also to evaluate $\bar{\gamma}_i(\bar{c}_i)$ and $\bar{K}_i$ from the experimental data. This problem has been resolved[8] by simultaneous solution of (23) and (24) using Eqn.(6) for the standard states.

If the temperature dependence of the adsorption is known over small temperature ranges, in which β_i can be assumed to be independent of T, full thermodynamic information on the sorption system can be extracted from the conventional equations of chemical thermodynamics. In this case it is advantageous to replace $\bar{c}_{0i}$ by $\bar{c}_{i,max}$ in Eqn.(10) and in the following equations, thus making β_i strictly independent of temperature.

2. Adsorption of Mixtures

To simplify the treatment we shall confine the discussion to the adsorption of binary mixtures. In this case we obtain from (13) or (14) and (4) general adsorption isotherm equations in the form of[6,22]

$$\bar{K} = \frac{\bar{c}_A\bar{\gamma}_A\,(c_B\gamma_B)^{\beta}}{c_A\gamma_A\,(\bar{c}_B\bar{\gamma}_B)^{\beta}} = K\frac{\bar{\gamma}_A\bar{\gamma}_B^{\beta}}{\gamma_A\bar{\gamma}_B^{\beta}} = K'\frac{\bar{\gamma}_A}{\bar{\gamma}_B^{\beta}}, \qquad (31)$$

$$\bar{K}_A = \frac{(\bar{c}_A\bar{\gamma}_A)^{\beta_A}}{(c_A\gamma_A)^{\beta_A}\,(\bar{c}_{0A}/\beta_A - \bar{c}_A/\beta_A - \bar{c}_B/\beta_B)\,\bar{\gamma}_R}. \qquad (32)$$

The parameter β is easily determined according to (10) or (16):

$$\beta = \bar{c}_{0B}/\bar{c}_{0A}. \qquad (33)$$

If molecular sieve effects are present we proceed as in Refs.18 and 21. We should stress that Eqn.(31) applies for any level of coverage of the sorbent by the sum of the adsorbates ($\bar{\theta}_{A+B}$), and also for multi-component adsorption. In the latter case it offers greater generality than other similar equations proposed earlier by various authors for the sorption of binary liquid solutions (i.e. for $\bar{\theta}_{A+B} = 1$). For specific types of $\bar{\gamma}_i = f(\bar{c}_i, \bar{c}_j)$ relationship we can easily obtain from (31) or (32) the isotherms for adsorption from binary mixtures proposed by Frumkin, Damaskin, and others[22].

In the special case of non-interacting particles of different size [$\Delta U_{i-j} = 0$ in an equation analogous to (18)] the quantities $\bar{\gamma}_i$ in a three-component sorption solution can be defined by analogy with (26), and Eqn.(32) then becomes

$$\bar{K}'_A = \bar{K}_A e^{\beta_A - 1} = \bar{c}_A^{\beta_A}/(c_A\gamma_A)^{\beta_A}\,(\bar{c}_{0A}/\beta_A - \bar{c}_A/\beta_A - \bar{c}_B/\beta_B), \qquad (34)$$

which can be treated as a generalisation of the Langmuir equation for delocalised adsorption of molecules of different size, reducing to the Langmuir equation when the mixture being sorbed consists of molecules of equal size with $\beta_A = \beta_B = 1$ and $\gamma_A = 1$.

Since in binary adsorption $\bar{\gamma}_i = f(\bar{c}_i, \bar{c}_j)$, the calculation of $\bar{\gamma}_i$ from experimental data is carried out most simply along the $\bar{\theta}_R$ = const. sections. Equations obtained as described above for any value of $\bar{\theta}_R$ = const. are given in Ref.8. In that work[8] all the calculations were carried out from the $\ln K' = f(\bar{\theta}_A)_{\bar{\theta}_R = \text{const}}$ relationship and from the adsorption isotherms of the individual components. We note that the $\bar{K}$ values [which are independent of $\bar{\theta}_R$ under the chosen

standard conditions (6)] can be calculated only from the individual sorption isotherms, since according to (15) and (16) we have

$$\bar{K} = (\bar{K}_A/\bar{K}_B)^{1/\beta_A} \quad (35)$$

or in principle they can be calculated by any analogous method[20].

Since the parameter β (unlike β_A) is practically independent of temperature[18] the temperature dependence of $\bar{K}$ or K can be used to obtain full thermodynamic information on the sorption systems of interest by applying the conventional equations of chemical thermodynamics.

IV. THE OSMOTIC THEORY OF ADSORPTION

1. Adsorption of Pure Substances

By using the concept of an osmotic equilibrium[15-17] we can easily obtain a general isotherm for individual adsorption. This involves inserting into (21) the expression for σ from (20):

$$\bar{K}_A = \bar{c}_A\bar{\gamma}_A/c_A\gamma_A(\bar{c}_{A,max} - \bar{c}_A)\,\bar{\gamma}_*. \quad (36)$$

By comparing this equation with (23) we note that (36) is a special case of (23) for $\beta_A = 1$. This is a direct consequence of the greater generality of the sorption solution model used in the STA.

Using (24) to eliminate $\bar{\gamma}_A$ (with $\beta_A = 1$) we can rewrite Eqn.(36) as[17]

$$c_A\gamma_A = \frac{\bar{\theta}_A}{\bar{K}_A(1-\bar{\theta}_A)}\exp\left[-\frac{\ln\bar{\gamma}_*}{\bar{\theta}_A} - \int_0^{\bar{\theta}_A}\frac{\ln\bar{\gamma}_*}{\bar{\theta}_A^2}\,d\bar{\theta}_A\right], \quad (37)$$

which is identical to the corresponding Eqn.(25) of the STA if $\bar{\gamma}_*$ is replaced by $\bar{\gamma}_A$ in Eqn.(37) and allowance is made for the fact that $\bar{\gamma}_A$ is referred to different concentration scales in Eqns.(25) and (37) [see Eqn.(6)].

We shall examine three special cases.

1. For ideal adsorption $\bar{\gamma}_* = 1$, and Eqn.(37) reduces to the Langmuir equation ($\gamma_A = 1$).

2. If the vacancy solution is regular, we can write from the theory of regular solutions $\ln\bar{\gamma}_* = \bar{\alpha}\bar{\theta}_A^2$ (where α is a constant), and (37) simplifies to the Fowler-Guggenheim equation

$$c_A\gamma_A = \frac{\bar{\theta}_A}{\bar{K}_A(1-\bar{\theta}_A)}\exp[-2\alpha\bar{\theta}_A]. \quad (38)$$

3. The most widely used equation is derived from (37) as described above by using Eqn.(29) (since $s_A = s_*$, it follows that $g_* = g_A$):[15,16]

$$c_A\gamma_A = \bar{c}_A^{g_*}/\bar{K}_A(\bar{c}_{i,max} - \bar{c}_A)^{g_*}, \quad (39)$$

This equation was first obtained in the OTA[15,16] by a strict thermodynamic argument. For adsorption from an ideal gas phase Eqn.(39) can be recast as

$$\ln P_A = \ln P_{A(\bar{\theta}_A=0,5)} + g_A\ln\frac{\bar{\theta}_A}{(1-\bar{\theta}_A)}, \quad (40)$$

which allows the parameters to be determined from the experimental isotherm[15,16]. As was pointed out above, Eqns.(30), (39), and (40) accurately describe the individual adsorption isotherms of many substances on microporous sorbents.

An important and interesting application of the OTA of a single substance was the successful development of a thermodynamic theory of the change in size of microporous adsorbents resulting from sorption[14,23-25]. Correctly denying the thermodynamic validity of Bangham's theory, based on the assumption that $\bar{\phi}_R = \text{const}$, Bering and coworkers[23-25] obtained some fairly strict expressions predicting both an increase and a decrease in the particle size of adsorbents as a result of adsorption.

2. Adsorption of Mixtures

The application of the OTA to mixtures causes a number of difficulties arising from the chosen model of the sorption solution. Thus, in the simplest case of binary sorption the molar volume of a vacancy [see Eqn.(17)] varies as follows with the composition of the sorption solution[17,26,27]:

$$s_*(\bar{z}) = s_A\frac{\bar{c}_A}{\bar{c}_A+\bar{c}_B} + s_B\frac{\bar{c}_B}{\bar{c}_A+\bar{c}_B} = s_A\bar{z}_A + s_B\bar{z}_B. \quad (41)$$

The desired isotherm equation is obtained by solving Eqns.(20) and (21) simultaneously[17]. In this case Eqn.(20) can be combined with (41) to give, for a solution of constant composition $\bar{z}_A$,[27]

$$\sigma W_0 = \frac{W_0}{s_A\bar{z}_A + s_B\bar{z}_B}RT\ln\bar{x}_*\bar{\gamma}_* = \bar{c}_*^0(\bar{z})\,RT\ln[(1-\bar{\theta}_A-\bar{\theta}_B)\,\bar{\gamma}_*], \quad (42)$$

where $\bar{c}_*^0$ is the limiting concentration of vacancies in the sorbent, with a molar volume corresponding to the composition $\bar{z}_A$.

Inserting σ from (42) into (21) yields the adsorption isotherm equation[17], which can be written as

$$\bar{K}_A = \bar{c}_A\bar{\gamma}_A\bar{c}_{0A}/c_A\gamma_A[(1-\bar{\theta}_A-\bar{\theta}_B)\,\bar{\gamma}_*]^{1/\beta_A(\bar{z})}\cdot\bar{c}_*^0(\bar{z}), \quad (43)$$

where $\bar{c}_*^0(\bar{z})$ and $\beta_A(\bar{z})$ depend on the composition ($\bar{z}$) of the sorption solution. Eqn.(43) is formally analogous to the corresponding Eqn.(32) of the STA (allowing for the fact that the $\bar{\gamma}_i$ values are referred to different concentration scales), but it is less convenient than the latter in that it depends on the variables $\beta_A(\bar{z})$ and $\bar{c}_*^0(\bar{z})$, which complicates its practical application even when the $\bar{\gamma}_i = f(\bar{x}_A, \bar{x}_B)$ relationships are known. We note that since $\beta_A(\bar{z})$ and $\beta_B(\bar{z})$ have identical dependences on $\bar{z}$ we can obtain Eqn.(31) by dividing the two equations (43) written for A and B respectively by each other, since $\beta_B(\bar{z})/\beta_A(\bar{z}) = \beta = \text{const}$.

General methods of finding the activity coefficients of the components of the sorption solution are not discussed in the OTA papers, but they are exactly analogous to the methods described above for the STA. The application of the OTA to the general case of adsorption from a multi-component mixture could be greatly simplified by abandoning the conditions $s_* = s_A$, $s_* = s_B$ for one-component adsorption and by assuming (as in the STA) that $s_* = \text{const} \neq s_A \neq s_B$. In particular, Eqn.(43) would correspond exactly to Eqn.(32).

V. ADSORPTION AND THE ENERGY NON-UNIFORMITY OF THE SORPTION CENTRES OF THE SORBENT

In the previous sections we have discussed adsorption equilibria in general, using the activity method to allow (in terms of the activity coefficients of the components of the sorption solution) for molecular interactions and for the energy non-uniformity of the sorption centres of the sorbent. It would be very useful, however, to have a sorption isotherm equation free from the constraints of the activity method. One variant of this approach, proposed by Zel'dovich[28] in 1935, has been examined intensively in recent years (see, for example, Refs.29–39). The basic concept is to set up a general isotherm for the adsorption of one substance

[$\theta(P)$] from local adsorption isotherms applying to energetically uniform sorption centres [$\phi(P, \varepsilon)$] together with a distribution function of the adsorption centres in free energy of adsorption [$\chi(\varepsilon)$]. In the case of a discrete distribution[29,30] we can write

$$\bar{\theta}(P) = \sum_i f_i \varphi_i(P, \varepsilon_i), \tag{44}$$

where f_i is the fractional number of centres having an energy ε_i.

If the function $\chi(\varepsilon)$ is assumed to be continuous we replace (44) by the equation[28-32]

$$\bar{\theta}(P) = \int_0^\infty \varphi(P, \varepsilon)\chi(\varepsilon)\,d\varepsilon. \tag{45}$$

Lastly, for the adsorption of a mixture of i components we have[33-35,38,39]

$$\sum_{i=1}^{i} \bar{\theta}_i(P_n) = \int_{\Delta(n)} \sum_{i=1}^{i} \varphi_i(P_n, \varepsilon)\chi(\varepsilon)\,d\varepsilon, \tag{46}$$

where $n = 1, 2, 3, \ldots, i$, integration is carried out in i-dimensional space, $\sum_{i=1}^{i}$ denotes the total and the local isotherm for the adsorption of the i components of the mixture, and $\bar{\theta}_i$ and ϕ_i are the total and the local adsorption isotherm of the i-th component.

Unfortunately, the solution of the problem in a general form meets a number of fundamental difficulties[29,34]. Since only the total isotherm [$\bar{\theta}(P)$] is available to the investigator Eqns.(44) and (45) do not offer a unique solution of the problem, because a given $\bar{\theta}(P)$ relationship can be obtained by combining $\phi(P, \varepsilon)$ functions of different types, and hence by combining different $\chi(\varepsilon)$ distribution functions. For example, a given $\bar{\theta}(P)$ isotherm can be interpreted as the the sum of a number of Langmuir isotherms for a non-uniform surface, or as an adsorption isotherm for substantial intermolecular interactions on a practically uniform surface. The distribution function $\chi(\varepsilon)$ characterises the adsorbate–adsorbent system rather than the adsorbent. Therefore Eqn.(45) cannot be used to calculate the adsorption isotherms of several adsorbates from the $\chi(\varepsilon)$ function obtained for any one adsorbate. The general solution of (46) is extremely complex[34], and therefore the problem is often simplified by considering the case of a constant difference between the free energies of the adsorbates on the different types of adsorption centre ($\varepsilon_i - \varepsilon_j = \text{const}$).[30,33,34]

Because of these difficulties the approach is usually confined to systems in which the adsorption is obviously localised and the local isotherm can be described with reasonable accuracy by the ideal Langmuir equation. In this case the form of the $\chi(\varepsilon)$ function can be established with great confidence, and the method can be used to solve various problems[35-37]. For example, an interesting application was the derivation of a general equation for the localised adsorption of a mixture on a non-uniform surface and its use in a formal kinetic analysis of heterogeneous catalytic reactions[37,39].

Nevertheless, the wide application of this approach in the description and calculation of sorption equilibria and in the determination of $\chi(\varepsilon)$ functions still presents many problems, and requires substantial further developments.

VI. CALCULATION OF THE EQUILIBRIUM SORPTION CHARACTERISTICS FROM THE MINIMUM AMOUNT OF EXPERIMENTAL INFORMATION

In addition to the strict thermodynamic analysis of adsorption equilibria, another important function of the theory is to develop methods of calculating sorption equilibria for many different systems from the smallest possible volume of experimental information. As we have already pointed out the problem could be solved, in principle, by the methods of molecular–statistical thermodynamics, but unfortunately the difficulties are such as to limit the practical application of these methods to the simplest systems for the time being. Therefore the practical solution of problems usually involves additional, non-thermodynamic relationships derived from experimental data or from very simple (and therefore approximate) physical models of the system of interest. The most successful applications of this approach have been in adsorption from a one-component gas or vapour phase.

1. Calculation of Individual Adsorption Isotherms

The most important advances in the description of isotherms for the individual adsorption of vapours on microporous sorbents were achieved by the theory of volume filling of micropores (TVFM), developed by Dubinin and his coworkers[40-42]. This theory is founded on the temperature-independence of the characteristic free energy of adsorption (E): a thermodynamic analysis shows that this condition can obtain only if the entropy of adsorption is negative, and this restricts the region of validity of the theory to coverages $\bar{\theta}_i > 0.1$.[42]

Within these limitations the equations of the TVFM, applied to monodisperse microporous sorbents and ignoring the non-ideality of the vapour phase, have the form[42-44]

$$\lg \bar{c}_i = \lg \bar{c}_{0i} - \frac{BT^n}{\beta_{i(\mathrm{af})}^n}[\lg(P_{is}/P_i)]^n, \tag{47}$$

where

$$B = (2.303R/E_0)^n; \quad \bar{c}_{0i} = W_0/\bar{v}_{0i} = \bar{c}_{0i}^0 \exp[-\alpha_i(T - T_0)] \tag{48}$$

($\bar{c}_{0i}^0$ is the limiting adsorption at $T = T_0$).

If the adsorbent has a wide distribution of pore radii (carbon sorbents) or of adsorption energies (zeolites used for small adsorbate molecules) an approximate solution is obtained by aggregating two structures with different values of the parameters n and E_0 [40-42] (corresponding to the subscripts 1 and 2):

$$\bar{c}_i = \bar{c}_{0i(1)} \exp\left[-\frac{RT \ln P_{is}/P_i}{\beta_{i(\mathrm{af})}E_{01}}\right]^{n_1} + \bar{c}_{0i(2)} \exp\left[-\frac{RT \ln P_{is}/P_i}{\beta_{i(\mathrm{af})}E_{02}}\right]^{n_2}. \tag{49}$$

For normal micropores of different size $n_1 = n_2 = 2$; for a combination of normal and super-micropores $n_1 = 2$, $n_2 = 3$; for the sorption of small molecules on type A and X zeolites $n_1 = 2$ and $n_2 = 3$ or 4.[41] The n values in (47) undergo similar changes.

Since

$$\beta_{i(\mathrm{af})} = E_i/E_0, \tag{50}$$

where E_0 is the characteristic free energy for vapour adsorption taken as a standard ($\beta_{0(\mathrm{af})} = 1$), it follows that the adsorption isotherms of a substance for various temperatures (lower than T_{cr}) can be calculated by the TVFM from the isotherm measured at a single temperature: hence the thermodynamic adsorption functions and the adsorption isotherms of other adsorbates at different temperatures can also be calculated if $\beta_{i(\mathrm{af})}$ is determined by Eqn.(50).

For calculations of the highest precision $\beta_{i(\mathrm{af})}$ should be obtained from experimental data. For this we need one point on the isotherm of the i-th adsorbate. In a somewhat **rougher** approximation the $\beta_{i(\mathrm{af})}$ values for microporous carbons **can** be expressed as the ratio of the parachors of the i-th and the standard adsorbate[43].

Since Eqns.(47) and (30) describe the same experimental data[44], the TVFM can be regarded as a special case of the STA, applicable to systems in which the $\overline{\gamma}_i = f(\overline{c}_i)$ relationships are described by Eqns.(29) with $g_i = g_R = \text{const}$. Under these conditions $\beta_{i(af)}$ allows for the difference not only in the size of the adsorbate molecules but also in the energy of their interaction with the adsorbent [through Eqn.(50)]. Hence[22]

$$1/\beta_{i(af)} = \beta_i \beta_{en} / \beta_j, \qquad (51)$$

where β_j is the stoichiometric coefficient for the standard substance, and the coefficient β_{en} characterises the difference in interaction energy between the two adsorbates and is close to unity for the sorption of substances of the same type. In this case the $\beta_{i(af)}$ values can be calculated by Eqn.(28), as confirmed by existing experimental data. We note that in systems of this type the $\overline{\gamma}_R = f(\overline{c}_R)$ relationship is the same for all adsorbates.

Dubinin and coworkers[40-42] have discussed in detail the methods of finding the parameters of Eqns.(47) and (49), and have given several examples illustrating the wide applications of the TVFM to the calculation of individual adsorption isotherms and of the corresponding thermodynamic functions. More recently[45] the possibility of extrapolating the results by 50–60 K (to the region of $T > T_{cr}$) was demonstrated.

We must stress that the TVFM offers important information on the structure of the micropores (W_0) and on the adsorption energy (E_0) for microporous adsorbents of different types. This is shown most clearly in studies of adsorption on zeolites, when an independent determination of W_0 by X-ray methods is possible.

The ability of the TVFM to describe experimental data has been improved[46,47] by using n as a variable parameter in Eqns.(47) and (49), but Dubinin showed that this approach is unsatisfactory[48,49]. In the case of carbons the agreement between experimental and calculated isotherms is worse for n values other than $n = 2$: the values of W_0 and E_0 are no longer constant, and the calculated differential heats of adsorption are very different from those measured calorimetrically.

Industrial carbon adsorbents can have a polydisperse micropore structure. Stoeckli[50] tried to apply Eqn.(47) to sorbents of this type, assuming a normal gaussian distribution to describe the distribution of micropore volumes with respect to the parameter B of Eqn.(47). However, experimental data for the sorption of nitrogen, xenon, benzene, and n-butane at different temperatures on E-02 active carbon[50] were shown[48] to be described with equal precision by the Stoeckli equation and by Eqn.(49) with $n_1 = n_2 = 2$, and therefore the two-term equation (49) of the TVFM is a fully acceptable approximation.

Several workers have pointed out that the fundamental postulates of the TVFM are also satisfied (to different extents) for equilibria in other adsorption systems. Thus, Eqn.(47) with $n = 2$ was shown[51-54] to be applicable to adsorption on carbons from aqueous solutions of sparingly soluble organic compounds if P_{is}/P_i is replaced by $\tilde{c}_{is}/\tilde{c}_i$ (where $\tilde{c}_{is}$ is the solubility at the given temperature). A method of determining the micropore volume from adsorption data for systems of this type was developed on this basis[52].

Gur'yanov and coworkers[55,56] have shown that Eqn.(47) can be used to describe multimolecular adsorption and to determine the monolayer capacity. With swelling (polymeric) sorbents Eqn.(47) again gives a satisfactory description of the adsorption isotherms, but the parameter n decreases[57,58] as the degree of crystallinity of the polymer decreases from 0.7 to 0.5 (and even to 0.33), and the temperature-independence of the characteristic free energy is retained in the temperature ranges where the structure of the polymeric sorbent remains substantially constant[58]. These results indicate that the basic postulates of the theory of volume filling are more generally applicable than the variant adopted in the classical TVFM, though further experimental and theoretical work is needed to explain in detail and to justify such a generalisation of the theory.

In the STA and the OTA, which do not stipulate a temperature-invariant characteristic energy of adsorption, thermal adsorption equations can be obtained, in principle, for any temperature range, and in particular for $T \gg T_{cr}$, where the equations of the TVFM are not applicable. This problem was analysed in detail in the original papers on the OTA, and the special forms (39) and (40) of the general OTA equation were shown to describe with good precision the adsorption isotherms for microporous sorbents[15-17]. We should point out that the possibility of determining $c_{i,max}$ by Eqn.(22) was realised relatively recently[17]. In the earlier papers from the same laboratory[49,59-61] the quantity $\overline{c}_{i,max}$ was determined as an empirical parameter ($\overline{c}_{i,emp}$) from the experimental adsorption isotherm plotted as $\ln P_i$ against $\overline{c}_i$, which according to Eqn.(40) has an inflection at the point $(\ln P_{i(\overline{\theta}_i = 0.5)}, \overline{c}_{i,emp}/2)$. The temperature independence of $\overline{c}_{i,emp}$, first established experimentally[60], was later proved by a strict thermodynamic argument. Therefore the thermal equation of the OTA is easily obtained from Eqn.(40), since $\ln P_{i(\overline{\theta}_i = 0.5)}$ is the thermodynamic equilibrium constant of the adsorption, and the function $g(T)$ should be the same as in $\ln \overline{\gamma}_*$:[59]

$$\ln P_i \gamma_i = a + a' \ln\left(\frac{\overline{c}_i}{\overline{c}_{i,emp} - \overline{c}_i}\right) - \left[b + b' \ln\left(\frac{\overline{c}_i}{\overline{c}_{i,emp} - \overline{c}_i}\right)\right] T^{-1}. \qquad (52)$$

When $\overline{c}_i = \text{const}$ Eqn.(52) gives the adsorption isostere equation:

$$\ln P_i \gamma_i = \bar{a} - \bar{b} T^{-1}. \qquad (53)$$

The determination of the five parameters of Eqn.(52) (a, a', b, b', $\overline{c}_{i,emp}$) is discussed in Refs.49 and 59. We know[59-61] that the replacement of $\ln P_i \gamma_i$ by $\ln P_i$ in Eqns.(52) and (53) extends the application of (53) to a large number of systems over a wide temperature range, in spite of the temperature dependence of the enthalpy of adsorption. This fact justifies calculation of the effect of temperature on adsorption over wide temperature ranges, as was demonstrated[59-61] for the adsorption of Ar and Xe on NaX zeolite at $150 \text{ K} \leq T \leq 600 \text{ K}$. Eqn.(52) can describe, in principle, systems in which the heat of adsorption decreases or increases with coverage, though the latter case is not covered by the equations of the TVFM.

Thus the thermal equations of the TVFM and of the OTA are mutually complementary, and depending on the specific features of the practical problem the effect of temperature on the sorption can be calculated by one of the equations given above. We note that the adsorption isotherms of several adsorbates can be calculated, in principle, from the adsorption isotherm of one substance within the framework of the STA. Appropriate methods of realising this possibility are currently being developed.

2. Calculation of the Equilibrium Characteristics of the Adsorption of Binary Mixtures

Studies of the calculation of adsorption equilibria in multicomponent mixtures have been confined almost entirely to binary systems. Many papers have dealt with the possibility

of calculating the isotherm for adsorption from a binary mixture, i.e.

$$\bar{c}_i = f(c_1, c_2) \tag{54}$$

from the experimental isotherms for the adsorption of the individual components

$$\bar{c}_1 = f_1(c_1), \quad \bar{c}_2 = f_2(c_2). \tag{55}$$

Progress in this direction has been discussed in recent review articles[62-64], and we shall not dwell on that work: we shall only mention that in the final analysis a solution of the problem (54), (55) can be found only for ideal sorption solutions or for solutions in which $\Delta U_{i-j} = 0$.[19] In the general case we need additional information on the adsorption of the binary mixture itself. One variant of this approach was recently examined in the OTA for the special case of $g = \text{const}$ when $z = \text{const}$[17,26,27]. The present writer favours a solution of the problem on the basis of experimental information on the sorption of one, two, or three standard mixtures on the given sorbent, i.e. calculation by Eqn.(31) of the values

$$K = f(\bar{c}_A, \bar{c}_B) \tag{56}$$

for a large number of different mixtures of adsorbates from the experimental relationships [Eqn.(56)] for one–three systems and from some properties of the adsorbates (molar volume, dipole moment, polarisability, etc.). Work in this direction is only just beginning, and is limited so far to the accumulation of experimental information and its analysis[6,8,11,12,20,65-68], but the results to date suggest that a solution of the problem (56) will be found.

We should mention two results obtained by the STA which should greatly decrease the need for exploratory experimental work. The first concerns the comparative evaluation of data on the adsorption of binary mixtures from the vapour phase and from the liquid phase on microporous sorbents[20,69].

As we have shown[20], under the standard conditions (6) the thermodynamic constants ($\bar{K}$) and the equilibrium coefficients (K) for sorption from the vapour and the liquid phase are related by the expressions

$$\bar{K}_{\text{vap}} = \bar{K}_{(\text{liq})} \frac{\tilde{c}_{0A} (c_{Bs}\gamma_{Bs})^{\beta}}{\tilde{c}_{0B} (c_{As}\gamma_{As})} = \bar{K}_{\text{liq}} \frac{K^{\beta}_{B,\text{evap}}}{K_{A,\text{evap}}}, \tag{57}$$

(where $K_{i,\text{evap}}$ are the equilibrium constants for the evaporation of the pure liquids), and

$$K_{\text{vap}} = K_{\text{liq}} \frac{\tilde{c}_{0A} (c_{Bs}\gamma_{Bs})^{\beta}}{\tilde{c}_{0B} (c_{As}\gamma_{As})} \cdot \frac{\gamma_A \tilde{\gamma}^{\beta}_B}{\tilde{\gamma}_A \gamma^{\beta}_B}, \tag{58}$$

which allow us to calculate $\bar{K}$ and $K = f(\bar{x}_A)$ for sorption from the vapour phase from data for sorption from the liquid phase, and *vice versa*, since γ_i and $\tilde{\gamma}_i$ are usually known or can easily be determined if necessary. We note that calculation by (58) is legitimate, strictly speaking, if $\bar{\theta}_{A+B} = 1$ for sorption from the vapour phase. However, in most cases the $K = f(\bar{x}_A)$ relationships are almost indistinguishable for $\bar{\theta}_{A+B} > 0.8$–0.9,[20,65] and therefore we can use (58) to calculate equilibria in real, practical vapour–adsorbent systems with $\bar{\theta}_{A+B} > 0.8$. From (57) we can easily obtain an equation for reciprocal calculations of the temperature dependence of sorption (for $\bar{\theta}_{A+B} > 0.8$):[20]

$$\Delta H^0_{\text{vap}} = \Delta H^0_{\text{liq}} + \beta \Delta H^0_{\text{B,evap}} - \Delta H^0_{\text{A,evap}}. \tag{59}$$

We can easily show, also, that if the separation coefficients (α) are determined for the equilibrium compositions of the phases we have[69]

$$\alpha_{\text{vap}} = \frac{\bar{c}_A c_B}{c_A \bar{c}_B} = \frac{\tilde{c}_A c_B}{c_A \tilde{c}_B} \cdot \frac{\tilde{c}_A \tilde{c}_B}{\tilde{c}_A \tilde{c}_B} = \alpha^{\text{vap}}_{\text{liq}} \alpha_{\text{liq}}. \tag{60}$$

In Refs.20 and 69 Eqns.(57)–(60) are tested on the sorption of several binary mixtures on active carbon and on zeolites, and satisfactory agreement between calculation and experiment is obtained. Thus these expressions offer a substantial reduction in the amount of experimentation needed to optimise the separation and purification of particular mixtures by sorption methods.

According to the STA [see (31) and (60)] the separation coefficient α, which is very important in practice because it characterises the selectivity of the sorbent towards the given mixture of adsorbates, is related to the equilibrium coefficient K by the expression

$$\alpha = K(c_B/\bar{c}_B)^{1-\beta}. \tag{61}$$

Therefore, when K is independent of $\bar{\theta}_{A+B}$ (as is usually the case for $\bar{\theta}_{A+B} > 0.5$–0.8) the separation coefficient can be increased to a useful extent by varying the concentration of the components in the bulk phase. In this case the α values can be calculated over a wide range of pressure. Furthermore, if one of the components (say, A) is present in trace amounts we find[70,71] that for $c_B/\bar{c}_B = \text{const}$

$$\ln \alpha = a + bm, \tag{62}$$

where m is the number of carbon atoms in the molecules of homologues present as trace components, and a and b are constants determined from experimental data for two homologues.

The validity of Eqns.(61) (and hence of the basic assumptions of the STA) and (62) was tested experimentally in a number of sorption systems[65,70,71]. Their use can substantially lighten the task of optimising empirically the conditions of separation by sorption. Of course, the calculation of adsorption equilibria for binary and for multi-component mixtures is a complex problem, still not fully resolved. However, the need to solve this problem has been highlighted by the increasing penetration of sorption methods of extracting, separating, and purifying mixtures in industrial practice, and research in this direction has been intensified.

VII. CAPILLARY PHENOMENA AND INFORMATION ON THE PORE STRUCTURE OF THE ADSORBENT

As was stated above, the thermodynamic analysis of multimolecular adsorption processes (which include the transition from pure sorption processes with a sorption volume of limited capacity to condensation processes) is still an unsolved problem. Nevertheless, detailed studies of multi-molecular adsorption and capillary condensation in mesopores (15 Å < r < 2000 Å) have been applied to the characterisation of the structure of mesopores. The theory of this phenomenon was originally developed by Deryagin in 1940; in 1967 de Boer and Broekhoff introduced an approximate correction for the effect of the adsorption field of the pore walls on the chemical potential of the sorbate in their derivation of a modified Kelvin equation; Brunauer and coworkers followed a somewhat different approach. A detailed discussion of that work, with comprehensive lists of references, can be found in Refs.72–75.

The Deryagin–Broekhoff–de Boer method has been recently improved by Dubinin and coworkers, who also allowed for the dependence of the surface tension on the mean radius of curvature of the liquid meniscus[74,75], and used a more universal form of the equation for the t-curve (which describes the dependence of the mean-square thickness (t) of the adsorption layer in the mesopores on the equilibrium relative pressure P/P_s [76,77]).

Solution of this problem requires an assumption as to the geometrical shape of the pores. Attempts to identify the geometry of the pores from the type of hysteresis loop in the isotherm produced by capillary condensation gave ambiguous results[72,73], and therefore the concept of equivalent cylindrical pores is adopted in most calculations. The problem is formulated in such a way that identical capillary evaporation isotherms are obtained for the real adsorbent (with a complex pore structure) and the equivalent adsorbent (with cylindrical pores). The equivalent pore radius (r) is usually defined as double the ratio of the normal cross-sectional area of the pore to the perimeter of the pore.

The classical method (method I) of analysing the distribution of cylindrical mesopore radii is based on the Kelvin equation

$$r_c = 2\sigma \bar{V}_{ol}/RT \ln (P_{is}/P_i), \quad (63)$$

where r_c is the radius of curvature of the spherical meniscus of the liquid adsorbate, formed in the area between the adsorption layers on the walls of a mesopore of radius r. The thickness (t) of the layers is assumed to be independent of r, and is expressed through the t-curve equation, based on the Harkins and Jura adsorption isotherm[73,74,76]:

$$\ln (P_{is}/P_i) = Mt^{-2} - \varphi(t) \quad (64)$$

where M is a constant parameter and $\phi(t)$ is a correction which can be either constant or weakly dependent on t. Hence, in this model

$$r = r_c + t. \quad (65)$$

In the Deryagin–Broekhoff–de Boer method (method II) the effect of adsorption on capillary evaporation from cylindrical pores is allowed for by the function

$$F(t_e) = \bar{\mu}_t - \tilde{\mu}_t, \quad (66)$$

the chemical potential of the adsorbate being assumed to be a function of the distance (t_e) of the liquid–vapour interface from the pore wall, with the function $F(t_e)$ defined by the t-curve (64). The surface tension of the adsorbate is assumed to be independent of the radius of curvature of the liquid meniscus.

In the method developed by Dubinin and coworkers[73–75] (method III) an additional allowance is made for the dependence of σ on r_c by using the Tolman equation (which can also be obtained by molecular statistics[74])

$$\sigma/\sigma_0 = (1 - 2\omega/\rho)^{-1}, \quad (67)$$

in which σ_0 is the surface tension of the planar liquid surface and ρ is the average effective radius of curvature of the meniscus in a cylindrical pore:

$$\rho = r - t_e. \quad (68)$$

However, a detailed analysis by Dubinin[76] of the capillary evaporation isotherm has shown that whereas all three methods should give the same value of r and $t_e \to t$ for $P_i/P_{is} \to 1$, there is a large difference between the radii calculated by methods I, II, and III for the pores from which desorption occurs under the stated conditions (up to 100–150% [79]), and also between the corresponding values of t_e and t. Calculations by methods II and III gave consistent results in this case. It was also shown[76] that the lack of agreement of calculations for $P_i/P_{is} \to 1$ is due to inadequate description of the adsorption in mesopores by the t-curve (64), and that in many systems it would be better to use a more rational equation of the Halsey type

$$\ln (P_{is}/P_i) = \bar{M} t^{-m}, \quad (69)$$

where $\bar{M}$ and m are constant parameters. By replacing (64) by (69) the discrepancy between calculations by methods I, II, and III at $P_i/P_{is} \to 1$ could be eliminated[76,77].

The equations of method III in this case become[76,77]

$$\ln (P_{is}/P_i) - \bar{M} t_e^{-m} - \sigma_0 \bar{V}_{ol}/RT (r - t_e - \omega) = 0, \quad (70)$$

$$r - t_e = \frac{2\sigma_0 \bar{V}_{ol} (r - t_e)}{RT (r - t_e - 2\omega) \ln (P_{is}/P_i)} + \frac{2\bar{M}}{(r - t_e) \ln (P_{is}/P_i)} \left[\frac{r^{2-m}}{(1-m)(2-m)} - \frac{r t_e^{1-m}}{(1-m)} + \frac{t_e^{2-m}}{(2-m)} \right]. \quad (71)$$

The calculations, described in detail in Refs.74–79, were taken as far as a minimum pore size of 16–17 Å. In the case of these micro-mesoporous sorbents the specific surface area of mesopores ($\bar{S}$, $m^2\ g^{-1}$) was determined independently by the "t/F method", developed and proposed in Refs.79 and 80. Essentially, the method consists in calculating the sorption in micropores by Eqn.(47), subtracting the adsorption calculated by the TVFM from the total adsorption experimentally observed, and thus arriving at the sorption in mesopores only. With other adsorbents $\bar{S}$ was determined also by the BET method.

The total volumes of mesopores calculated by the three methods are almost indistinguishable, but the mesopore surfaces are given more accurately by methods II and III. However, the basic difference between these three methods is in the distribution of mesopore volumes with respect to radius. The effect arises[74] from differences in the dependence of P_i/P_{is}, t, and t_e on the mesopore radius in the three methods of calculation. Thus, for $r > 150$–200 Å the P_i/P_{is} values do not differ significantly in the three methods, but the t_e values in methods II and III are similar but different from t (method I). This means that the correction for the $\sigma(\rho)$ variation (method III) is significant only for $r < 150$–100 Å. The intermediate mesopore region (radii from 100 to 50 Å) is characterised by large differences between the t_e and P_i/P_{is} values calculated by the three methods, the effects becoming even more marked for $r < 50$ Å. In this range of mesopore radii the $\sigma(\rho)$ dependence makes a substantial contribution to the final result and must obviously be included in the calculation. The correction makes the t_e values given by method III smaller than the other values. On changing from method I to method III the mesopore volume distribution curve shifts towards larger radii. The differences are large, and they give rise to large changes in the porosity characteristics which cannot be ignored, even to a rough approximation.

Thus Dubinin's variant of the calculation of the structural characteristics of mesopores is an important development of the method, though it is only a first step in the required direction and needs to be made more precise, especially in the region of 16 Å $< r <$ 30 Å. Furthermore, allowance for the real structure of the mesopores (flat, cylindrical, spherical) may also result in significant changes of the pore radius distribution function[75]. Therefore the structural characteristics obtained by methods I–III are arbitrary to a greater or lesser extent, and allowance for the real structure of the mesopores has become the most pressing of the theoretical problems.

* * *

This brief review of the present state of the thermodynamic theory of adsorption shows that substantial progress has been made in recent years towards the development of a strict thermodynamic theory of sorption. A full

thermodynamic analysis of various sorption systems is possible by the OTA, and even more so by the STA.

The TVFM, and also the OTA and the STA, have led to successful developments of methods of calculating sorption equilibria for individual adsorption from a single experimental isotherm. Important advances in this direction have been made also for the adsorption of mixtures.

Progress in methods of calculating mesopore structures from capillary condensation phenomena has been substantial.

Nevertheless the increasing application of sorption methods in the chemical industry has created a need for even greater scientific efforts in the study of two-component and multi-component adsorption. In this context the development of methods of calculating adsorption equilibria in multi-component systems from the minimum amount of experimental information becomes a major objective of the theory of adsorption.

The Paramagnetic Probe Method in Adsorption and Catalysis

V.B.Golubev, E.V.Lunina, and A.K.Selivanovskii

The application of the paramagnetic probe method to studies of heterogeneous systems is discussed. By analysing the ESR spectra of the adsorbed probes (nitroxyl radicals) information is obtained on the interaction of the probe with the surface of silica gel, aluminium oxide, alumina-silicas, etc. Special attention is paid to the formation of donor-acceptor complexes with co-ordinationally unsaturated cations of the surface, and to the mobility of molecules in the adsorption layer. 53 references

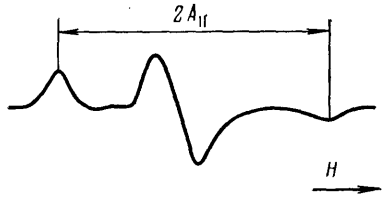
I. INTRODUCTION

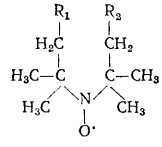
The fundamental problems in adsorption and catalysis are the formation of the adsorption layer, the nature and the number of adsorption and catalytically active centres, the type of interaction between these centres and the adsorbed molecules, and the dynamics of the adsorption layer. Significant progress towards the solution of these problems has been made by using spectroscopic methods, and in particular the ESR method. The latter method is widely applied in studies of catalysts containing paramagnetic ions and radiation-induced defects as active centres, and also in studies of the interaction of various molecules with these centres and of the radical and ion-radical states created by the interaction of some adsorbates with the active surface of solids[1,2].

The paramagnetic probe method has been used in recent years to study catalysts and adsorbents which do not contain paramagnetic centres, in particular very commonly used materials such as alumina and some other oxides, alumina–silicas, and zeolites. The method consists in adding to the system paramagnetic particles (probes) and monitoring their ESR spectra, whose changes reflect the properties of the environment which the probes experience. In this review we shall be concerned mainly with the results obtained by using stable nitroxyl radicals as probes. The theory of the ESR spectra of these radicals is adequately developed[3,4], and by analysing the ESR spectra of adsorbed nitroxyl radicals we can study the interaction of these particles with the surface adsorption centres and in many cases we can observe the adsorption centres directly. Equally important is the possibility of measuring the velocity of the rotational and translational motion of the adsorbed molecules, i.e. of studying the dynamics of the adsorption layer.

Nitroxyl radicals offer a convenient model of adsorbates of the donor type. They all contain the $>$N–O· fragment, which includes an unpaired electron as well as having normal donor properties. In addition to the $>$N–O group the radicals may contain other donor groups able to interact specifically with the active centres of the adsorbent. The presence of an unpaired electron allows the behaviour of these molecules in the adsorption layer to be monitored by ESR but does not otherwise affect the adsorption. Therefore studies of adsorption processes by the paramagnetic probe method are qualitatively applicable to a large number of adsorbates widely used in industry.

II. INTERACTION OF NITROXYL RADICALS WITH THE SURFACE OF OXIDE CATALYSTS





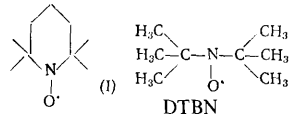


Figure 1. Determination of the anisotropy constant for the hyperfine interaction of an unpaired electron with the ^{14}N nucleus ($A_\parallel$) in the ESR spectra of randomly oriented "frozen" nitroxyl radicals[5].

The ESR spectrum of nitroxyl radicals, which include the fragment

for example, 2,2,6,6-tetramethylpiperidine-1-oxyl (I) or di-t-butylnitroxyl (DTBN)

(I) DTBN

consists of three hyperfine structure (HFS) components due to interaction of the unpaired electron with the ^{14}N nucleus (nuclear spin $I_N = 1$). The anisotropy constant $A_\parallel$ of the hyperfine interaction (HFI) of the unpaired electron with the ^{14}N nucleus (Fig.1) is a function only of the electron spin density on the nitrogen atom. If the $>$N–O· group takes part in any interaction, for example by forming a donor–acceptor or a hydrogen bond, the electron spin density

on the nitrogen atom changes, and $A_{\parallel}$ also changes[4,6]. This effect is illustrated in Table 1. When these interactions are absent or insignificant, as in solutions in non-polar solvents or in pyridine frozen to a glass at 77 K, $A_{\parallel}$ amounts to 34–35 Oe. Hydrogen bond formation raises $A_{\parallel}$ to 38 Oe, and protonation to almost 40 Oe.

Table 1. *A* values (Oe) for the ESR spectra of nitroxyl radicals in different systems.

System	DTBN (Ref.6)	Radical (I) (Ref.7)

Adsorbed monolayer of pyridine	—	36.2
Sample immersed in pyridine	35.2	—

The interaction of the radicals (I) and DTBN with SiO_2 and hydroxylated Al_2O_3 surfaces has been found to give a high (38 Oe) value of the constant $A_{\parallel}$, characteristic of the formation of hydrogen bonds with the surface OH groups. The result was not unexpected, since hydrogen bond formation between donor molecules and the surface OH groups had been observed by i.r. spectroscopy[8]. However, the ESR method can be used to monitor changes in the interaction between radicals and surfaces resulting from the adsorption of other substances. This feature is very important because optical spectroscopic methods do not usually give this information.

An excess of non-polar molecules (toluene, CCl_4) does not affect the bond between radical (I) and the OH groups of the surface ($A_{\parallel}$ is unchanged), but donor molecules (for example, pyridine) can displace the radicals from the surface OH groups by being competitively adsorbed, as shown by changes in the $A_{\parallel}$ constant. Thus, when the surface is covered with a monolayer of pyridine the $A_{\parallel}$ value of radical (I) is 36.2 Oe. The displaced radical evidently interacts with polar elements of the surface structure, since the $A_{\parallel}$ constant remains higher than for non-polar solvents. We shall arbitrarily regard the radicals displaced from specific adsorption centres as physisorbed.

Sistovaris and coworkers[9] investigated the interaction of various nitroxyl radicals with a modified silica gel surface by analysing changes in the $A_{\parallel}$ parameter.

However, information on the nature of the adsorption centre can be obtained not only through measurements of $A_{\parallel}$. Complex formation between the >N–O group and Lewis acids with cations having non-zero nuclear spin can give rise to an additional hyperfine structure in the ESR spectra[10–12]. On γ-Al_2O_3 (activation temperature $T_a > 150$ °C) the radical (I) forms a bond with the acceptor centres (coordinationally unsaturated Al^{3+} ions) to give a surface complex with the >N–O→Al< structure[13]. The ESR spectrum of this complex contains components from the interaction of the unpaired electron with the ^{27}Al nucleus ($I_{Al} = 5/2$, Fig. 2*a*). This spectrum is fully analogous to the spectrum of the complex between the radical (I) and $AlCl_3$ in a glassy toluene solution (Fig. 2*b*).

Similar spectra for the complex between radical (I) and the acceptor centres have been observed not only on Al_2O_3 but also on alumina–silicas, fluorinated alumina[11], type HY zeolite[14] (in all of which the complex is formed with the Al^{3+} ion), and on Ga_2O_3 (complex with the Ga^{3+} ion). Thus the radical (I) acts as a selective indicator of centres of this type. This is one of the few instances of direct spectroscopic observation of the adsorption centre itself.

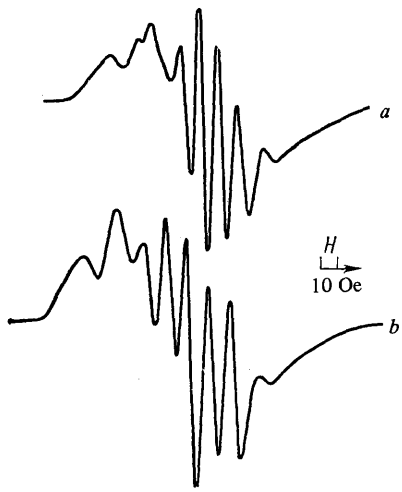

Figure 2. ESR spectra of the nitroxyl radical (I):[11] (*a*) complexed with the coordinationally unsaturated Al^{3+} ions of activated γ-Al_2O_3 at 20 °C; (*b*) complexed with $AlCl_3$ in toluene at −110 °C.

The ESR spectra of the complex with the coordinationally unsaturated Al^{3+} ion have been observed also with DTBN used as the paramagnetic probe[6]. By modelling the experimental spectra on a computer the authors were able to show that the constants of the anisotropic hyperfine interaction with the ^{14}N and ^{27}Al nuclei are somewhat different for different catalysts (Table 2). The differences are ascribed to the difference in strength of the acceptor centres of these catalysts.

Table 2. Anisotropic hyperfine interaction constants (Oe) of an unpaired electron with the ^{14}N and ^{27}Al nuclei in the complex between DTBN and the Al^{3+} ions of various catalyst surfaces[6].

Constant	Al_2O_3	Type HY zeolite	Al_2O_3·SiO_2
$A_{\parallel}^{N}$	42.5	44.6	45.3
$A_{\parallel}^{Al}$	14.6	14.8	16.4
$A_{\perp}^{Al}$	11.2	12.5	14.2

Many workers now consider not only the difference in strength of the acidic centres on different catalysts but also the distribution in strength of the acidic centres (including acceptor centres) on any one catalyst[15]. In this case the

shift of the electron density from the donor (nitroxyl radical) towards the acceptor (Al^{3+} ion) should be different for different centres on the same surface. Therefore the observed ESR spectrum of the complex between the nitroxyl radical and the acceptor centre should be the sum of a number of spectra differing in the value of the constant for the HFI of the unpaired electron with the ^{14}N and ^{27}Al nuclei. In the models[6] of the spectra of the complex between the nitroxyl radical and the Al^{3+} ions on various catalyst surfaces no allowance was made for the distribution of the acceptor centres in acidic strength, i.e. each spectrum was characterised by a single value of the anisotropic HFI constant. By varying these constants the model spectra could be made to reproduce the experimental spectra satisfactorily. These values of the HFI constant are given in Table 2.

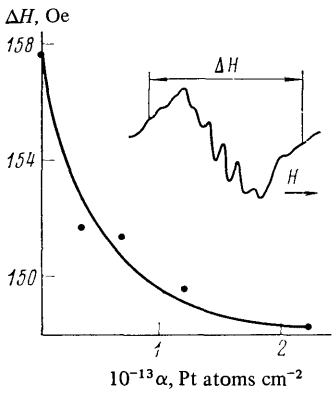

Figure 3. Variation of the parameter $\Delta H = 2A_{\parallel}^{N} + 5A_{\parallel}^{Al}$ for the ESR spectrum of adsorbed radical (I) with the concentration of platinum on a γ-Al_2O_3 surface.

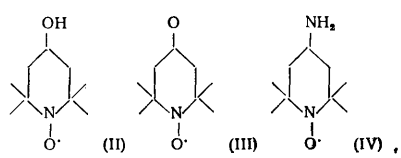
We have recently shown† that the ESR spectra of the radical (I) complexed with coordinationally unsaturated Al^{3+} ions on a γ-Al_2O_3 surface is indeed the sum of a number of spectra for the radical (I) complexed with acceptor centres of different strength. Hence the parameter ΔH (defined[6] as $\Delta H = 2A_{\parallel}^{N} + 5A_{\parallel}^{Al}$) is an average quantity which can be used as a measure of the distribution in strength of the acceptor centres (Fig.3). We note that a change in acceptor strength causes a change in the same sense in both the constants $A_{\parallel}^{N}$ and $A_{\parallel}^{Al}$. We can therefore use the parameter ΔH to describe the effect of various factors (such as the surface activation or modification temperature) on the strength distribution of the acceptor centres.

For example, when platinum is deposited on a γ-Al_2O_3 surface the ΔH parameter decreases (Fig.3), showing that the distribution of acceptor centres has been shifted towards lower strengths (i.e. that the acceptor properties of the surface have been weakened by the metal–substrate interaction). Raising the activation temperature of the γ-Al_2O_3 increases the contribution from strong acceptor centres.

The adsorption of a small amount of the radical (I) on an activated γ-Al_2O_3 surface results in almost total complexing of the radical with the acceptor centres. This observation is consistent with the general belief that Al^{3+} ions are stronger than OH groups as adsorption centres for donor molecules. Similar results were obtained by Lozos and Hoffman[6] for the adsorption of DTBN at room temperature. Somewhat unexpectedly, these workers also observed a reversible migration of the DTBN from the acceptor centres to the OH groups when the temperature was lowered to −78 °C (indicated by the appearance of a triplet spectrum for the complex). Their estimate of the change in enthalpy accompanying the transfer of the radical from an OH group to an acceptor centre is approximately +5 kcal $mole^{-1}$. This result is explained in terms of the formation of a complex[16] between a coordinationally unsaturated Al^{3+} ion and a surface hydroxyl group. This requires the breaking of a bond between the OH group and the Al^{3+} ion in order to form a complex between the radical and the acceptor centre, with a corresponding expenditure of energy. However, an attempt to reproduce Lozos and Hoffman's experiment in our laboratory did not give the same result: no changes were observed in the ESR spectrum of activated alumina samples containing DTBN or the radical (I), even after lengthy storage at −78 °C, the spectrum at all times indicating complex formation with the Al^{3+} ions.

Non-polar adsorbates do not dissociate the complex between radical (I) and the acceptor centres: the characteristic spectrum is unchanged (Fig.2*a*) by the addition of an excess of toluene to the system. Polar adsorbates with donor properties (pyridine, n-butylamine, alcohols, water, ammonia) displace the radical (I) from the acceptor centres as shown by the appearance of a triplet spectrum[13,17,18].



The displacement of the radical (I) from the acceptor centres begins at low coverages of the surface by donor adsorbates (10–30% of a monolayer)[18]. The molecules of (I) detached from the acceptor centres are held on OH groups, as shown by the change of the spectrum of the complex into a triplet spectrum with $A_{\parallel} \cong 38$ Oe.

The surface of fluorinated Al_2O_3 and of alumina–silicas contains acidic centres of two types: protonic and aprotic. The ESR spectrum of radical (I) adsorbed on these surfaces includes a contribution from the complex between the radical and the Al^{3+} ions[11]. Therefore, radical (I) is able to "discover" the acceptor centres irrespective of the protonic acidity of the catalyst. However, the ESR spectrum invariably contains a contribution from a triplet with $A_{\parallel} \cong 40$ Oe.[19] This large value of $A_{\parallel}$, almost identical to the $A_{\parallel}$ value in phosphoric acid (39.5 Oe), suggest complex formation between the >N–O· group of the radical and the protonic centres of the surface. This interpretation of the triplet with $A_{\parallel} = 40$ Oe is consistent with the observation that its contribution to the spectrum of the adsorbed radical (I) decreases when the protonic acidity of fluorinated Al_2O_3 is suppressed by exchange with Na^+ ions.

Thus radical (I) can be used for the qualitative detection of acidic centres of both the protonic and the aprotic (acceptor) type.

Donor pyridine molecules can displace radical (I) from both protonic and aprotic acidic centres, as shown by the decrease in the $A_{\parallel}$ constant of the triplet and the decreased spectral contribution from the complex produced by an increase in the coverage of the alumina–silica surface by pyridine[19].

By varying the structure of the nitroxyl radical we can model interactions of different adsorbates with the surface[7]. Thus, the radicals (II)–(IV) below contain, in addition to the N–O· group, a second donor group (oxy, oxo, and amino respectively):

†T.V.Bychkova, E.V.Lunina, A.K.Selivanovskii, and B.V.Strakhov, Zhur.Fiz.Khim. (in press).

In this case the two donor groups of a given molecule can compete for a specific adsorption centre. The spectrum of the complex between the N–Ȯ group and the Al^{3+} ions is not observed when the radicals (II)–(IV) are adsorbed on an activated Al_2O_3 surface. Hence we may conclude that the >N–Ȯ group is weaker as a donor than the oxy, oxo, or amino group. The parameter $A_\parallel = 36$ Oe suggests interactions between the paramagnetic group and the polar parts of the Al_2O_3 surface. Adsorption of the radicals (II)–(IV) on SiO_2, like their adsorption on Al_2O_3, results in bond formation between the specific adsorption centres (OH groups on the SiO_2 surface) and the second donor group (rather than the >N–Ȯ group), with $A_\parallel = 36.8$ Oe. This value of $A_\parallel$ indicates that the paramagnetic group is interacting with the polar elements of the SiO_2 surface.

Thus, for the "two-centre" molecules (II)–(IV) we must postulate a two-point adsorption model.

An excess of non-polar toluene molecules has no effect on the bond between the >N–Ȯ groups of the radicals (II)–(IV) and the SiO_2 or Al_2O_3 surface (as shown by the invariance of the $A_\parallel$ parameter). Pyridine breaks this bond, lowering $A_\parallel$ to 34.6 Oe at monolayer coverage[7].

The interaction of the nitroxyl radicals with specific adsorption centres can be detected also by observing the rotational mobility of these radicals on the surface[7]. It appears from these measurements that in order to displace from the specific adsorption centres the radicals (II)–(IV), which contain very strongly donating groups, we require higher concentrations of donor adsorbates than in the case of radical (I). Radical (IV) is more difficult to displace from the specific adsorption centres than radical (II): this reflects the more marked electron-donor properties of the amino group as compared to the oxy group.

It is clear from these results that the paramagnetic probe method can be used to monitor the distribution of typical donor molecules (the nitroxyl radicals) among adsorption centres of three types (hydroxyl groups, protonic acidic centres, and aprotic acidic centres), and to observe changes in this distribution caused by the adsorption of various substances.

III. INTERACTION OF DONOR MOLECULES WITH THE ACCEPTOR CENTRES OF γ-Al_2O_3

The displacement of radical (I) from acceptor centres by donor molecules (see above) can be used to investigate the interaction between these donor molecules and the acceptor centres[18]. After the adsorption of small amounts of donor molecules on an Al_2O_3 surface some of the acceptor centres remain free. The radical (I) (in amounts much smaller than the number of acceptor centres) is complexed with these free centres to give the ESR spectrum shown in Fig. 2*a*. If all the acceptor centres are blocked by molecules of the donor adsorbate the radical (I) has to compete with the donor adsorbate for the acceptor centres. Under these conditions some of the molecules of radical (I) are adsorbed on OH groups, and a triplet component appears# in the ESR spectrum of the adsorbed radical (I). Hence, by using the radical (I) as an indicator of free acceptor centres we can determine the amount of different donor molecules (bases) needed to fill the acceptor centres.

#The ESR spectra were recorded after lengthy (~5 days) storage of the sample at room temperature, to allow sufficient time for the redistribution of adsorbates over the adsorption centres to go to completion (see below).

It is clear from Table 3 that different surface concentrations are needed to fill all the acceptor centres of γ-Al_2O_3 with different bases. To account for this difference an independent study of each base is required, but one possible reason is the difference in selectivity of the bases with respect to the adsorption centres of the surface. Thus, pyridine is selectively adsorbed on the acceptor centres[20]. Water molecules can be strongly held by the OH groups, and have a tendency to associate on the surface[21]. The low effectiveness of alcohols in this respect is due, no doubt, to their chemisorption on OH groups with formation of alcoholates[22].

Table 3. Surface concentration of donor molecules (α) needed to fill the acceptor centres of γ-Al_2O_3 ($T_a = 470$ °C).[18]

Base	$10^{-13}\alpha$, cm^{-2}	θ*, % of monolayer
Pyridine	3±0.5	8
n-Butylamine	3±0.5	6
Ammonia	7±1	9
Isopropanol	7±1	20
n-Butanol	8±1	25
t-Butanol	7±1	22
Water	16±2	17

*θ is the degree of coverage of the surface.

The most interesting of the adsorbates which were examined is water, since it is a component of practically all catalytic systems, and the amount and form of the adsorbed water can have a profound effect on the activity of acidic heterogeneous catalysts. The number of water molecules needed to cover all the acceptor centres of γ-Al_2O_3 is $(16 \pm 2) \times 10^{13}$ cm^{-2} (see Table 3). This amount is independent of the adsorption temperature between 20 and 250 °C.[23] However, water adsorbed at 20 °C is removed from the surface much more easily than water which has been adsorbed at higher temperatures. Thus, in samples treated[23] with saturated water vapour at 20 °C for 2 days and then activated at 300 °C for 4 h in a vacuum of 10^{-5} Torr the concentration of acceptor centres§ was 2.0×10^{13} cm^{-2}. The acceptor properties of samples re-hydroxylated at a higher temperature (300 °C, 2 h, in an atmosphere of water vapour) and then activated under the same conditions (300 °C, 10^{-5} Torr, 4 h) were much less marked (0.8×10^{13} cm^{-2}).§ Evidently, the form of the adsorbed water varies with the adsorption temperature: molecular adsorption is predominant at low temperatures, and at higher temperatures the adsorption is mainly dissociative, with formation of OH groups, as indicated also by i.r. spectroscopic studies[24].

Ammonia is one of the probes most widely used in i.r. spectroscopy to analyse the acidic properties of the surface of oxide catalysts[8]. The amount of ammonia chemisorbed is taken as a measure of the concentration of acidic centres on the catalyst (in particular the aprotic centres of γ-Al_2O_3 [25]). However, the validity of this assumption requires justification: ammonia is known, from studies by i.r. spectroscopy[24], to interact not only with electron-acceptor centres (aprotic acids) but also with the surface oxygen ions of γ-Al_2O_3.

§The concentration of acceptor centres was determined by titration with pyridine, using the radical (I) as indicator[20].

The low selectivity of the adsorption of ammonia on the acceptor centres of γ-Al_2O_3 has been demonstrated also by the paramagnetic probe method[53]. 2.5×10^{13} cm^{-2} of pyridine was adsorbed on a γ-Al_2O_3 surface containing 3×10^{13} cm^{-2} of acceptor centres. 4.5×10^{13} cm^{-2} of ammonia was needed to fill the 0.5×10^{13} cm^{-2} acceptor centres which were still free. Hence, at least 4×10^{13} cm^{-2} of ammonia can be adsorbed on other centres.

We note that this amount (4×10^{13} cm^{-2}) does not change when the activation temperature of the γ-Al_2O_3 is raised to 700 °C, or when the catalyst is treated with hydrogen at high temperatures. A large volume of indirect information, as well as the results obtained by i.r. spectroscopy[24], suggests that in addition to the acceptor centres and oxygen ions on the surface of γ-Al_2O_3 can act as adsorption centres for ammonia.

IV. USE OF NITRIC OXIDE AS A PARAMAGNETIC PROBE

Many workers have used nitric oxide (NO) as a paramagnetic probe. Like the nitroxyl radicals, NO is an indicator of free acceptor centres on a catalyst. When adsorbed on these centres NO gives an ESR spectrum containing hyperfine structure from one ^{27}Al nucleus (Fig. 4*a*). However, in contrast to the radical (I), the ESR spectrum of NO can be observed only if the probe molecule is exposed to a fairly high electrostatic field gradient[27]. The NO molecules which are adsorbed on centres lacking in high crystal field gradient do not contribute to the ESR spectrum. This feature, together with the possibility of dimerisation of NO, is responsible for the low intensity of the ESR spectra of adsorbed nitric oxide, apparently uncorrelated with the number of adsorbed molecules[27-29] (unlike the ESR spectra of nitroxyl radicals). Another special feature of NO as a paramagnetic probe is that the NO molecules at room temperature are only weakly adsorbed on surfaces such as Al_2O_3, alumina–silicas, and zeolites. Substantial adsorption occurs only when the temperature is lowered to 77 K.

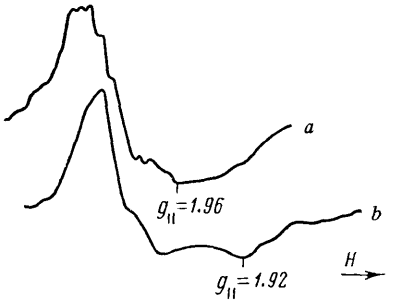


Figure 4. ESR spectra of nitric oxide adsorbed on γ-Al_2O_3 at −196 °C:[29] (*a*) adsorption on an activated γ-Al_2O_3 surface; (*b*) adsorption on a γ-Al_2O_3 surface containing 5×10^{13} cm^{-2} pyridine molecules.

This latter factor is extremely important, since in the quantitative determination of aprotic acidity by titration with bases (or in studies of the filling of acceptor centres) using nitroxyl radicals as indicators competition for the acceptor centre can occur between the titrant base (for example, pyridine) and the nitroxyl radical. This competition can distort the result of the determination. When NO is used as a probe its adsorption takes place at such low temperatures that the other adsorbed molecules are practically immobile. Therefore the competition is kinetically excluded (though it may be allowed thermodynamically). The concentrations of acceptor centres on γ-Al_2O_3 measured by pyridine titration using the radical (I) and NO as indicators [$(3.0 \pm 0.5) \times 10^{13}$ and $(4.0 \pm 0.5) \times 10^{13}$ cm^{-2} respectively] are in acceptable agreement[29]. This means that the competition between the base and the indicator does not play a major role when the number of acceptor centres is measured by the adsorption of pyridine using radical (I) as the indicator.

By using NO as the paramagnetic probe it was shown that 2,6-dimethylpyridine, like pyridine, is selectively adsorbed on the acceptor centres of a γ-Al_2O_3 surface. However, the presence of two methyl substituents makes the bond between the 2,6-dimethylpyridine molecules and the acceptor centres much weaker than in the adsorption of pyridine (steric hindrance).

When NO is adsorbed on a γ-Al_2O_3 surface two types of centre can be distinguished in the ESR spectra[26,29]. The first type are the centres containing coordinationally unsaturated Al^{3+} ions: they give an ESR spectrum with HFS from the Al nucleus. Centres of the second type also have a large crystal field gradient, but their ESR spectrum does not contain HFS from the Al nucleus (Fig. 4*b*).

It is interesting to note that in the adsorption of pyridine the centres of the first type are filled first[29]. As long as the concentration of pyridine does not exceed 3×10^{-13} cm^{-2}, centres of the first type remain free on the Al_2O_3 surface. NO is adsorbed on these centre giving the ESR spectrum shown in Fig. 4*a*. A pyridine concentration of 4×10^{13} cm^{-2} is sufficient to block all the centres of the first type. In this case the NO is adsorbed on centres of the second type, and gives the ESR spectrum shown in Fig. 4*b*. Thus, in the first instance both pyridine and NO are adsorbed on centres of the first type, leaving the second type of centre free. A similar behaviour is observed with 2,6-dimethylpyridine.

When ammonia is adsorbed, centres of the first type are observed in the ESR spectra of NO until the concentration of ammonia reaches 8×10^{13} cm^{-2}. At still higher concentrations of ammonia the ESR spectrum of NO cannot be detected. Hence, the ammonia molecules (unlike pyridine) can fill centres of both types, the probability of filling centres of the second type being equal to (or greater than) the probability of filling centres of the first type (coordinationally unsaturated Al^{3+} ions).

V. DETERMINATION OF THE CONCENTRATION OF ACCEPTOR CENTRES IN γ-Al_2O_3

When a small amount of the nitroxyl radical (I) is adsorbed on an activated γ-Al_2O_3 surface all the adsorbed molecules are bound to surface acceptor centres (only the spectrum shown in Fig. 2*a* is observed[30]). Hence, this radical is selectively adsorbed on the acceptor centres. Assuming that the OH groups are much weaker adsorption centres than the acceptor centres we can expect the acceptor centres to be filled first, followed by the OH groups, as the concentration of the radical on the surface is increased. This idealised behaviour is illustrated by the broken lines in Fig. 5. The experimental curves (full lines) are not very different, though they show a marked smoothing of the sharp breaks (Fig. 5). Since the surface complex consists of one molecule of radical (I) and one acceptor centre the number of acceptor centres in the sample can be identified with the maximum amount of radical (I) bound in the complex.

The high sensitivity of ESR allows small concentrations of acceptor centres to be determined (as in γ-Al_2O_3 samples activated at low temperatures). For example, on γ-Al_2O_3 activated in a vacuum at 150 °C a concentration of ~10^{11} cm^{-2} has been observed[30]. When the vacuum heat treatment temperature was raised to 200 °C the concentration of acceptor centres rose to 4×10^{12} cm^{-2}.[30]

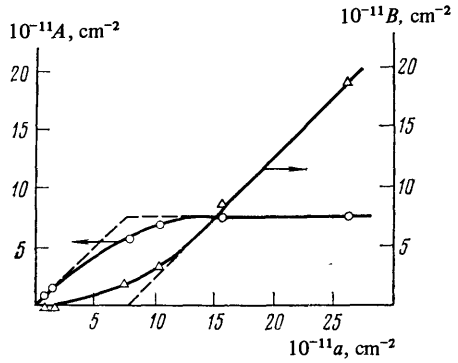

Figure 5. Dependence of the concentration of radical (I) complexed with Al^{3+} ions (*A*) and of the concentration of radical (I) not complexes with Al^{3+} ions (*B*) on the total concentration of radical (I) adsorbed on a γ-Al_2O_3 surface (*a*) activated in air at 300 °C.[30] The broken lines show the idealised dependence.

As the vacuum activation temperature is further increased the concentration of acceptor centres increases still further. The determination of these large concentrations requires the addition of large amounts of radicals. This introduces a difficulty, inherent in ESR: the dipole–dipole interaction causes broadening of the HFS of the spectrum when the radicals are closely spaced on the surface, and the spectrum is converted into a broad, structureless line. In such a spectrum it is very difficult to resolve the contribution from the spectrum of Fig. 2*a*, i.e. to determine the amount of radical (I) bound in the complex, and hence the number of acceptor centres[30]. In this case another approach can be followed: titration of the acceptor centres with an organic base (pyridine) using radical (I) as the indicator[20]. The choice of pyridine is dictated by the outstanding effectiveness of this molecule in filling the acceptor centres (see Table 3). The surface concentration of pyridine for which the filling of the acceptor centres is complete is taken as a measure of the concentration of acceptor centres. The acceptor properties of γ-Al_2O_3 activated at widely different temperatures were determined by this method: the results are summarised in Fig. 6.

However, the titration method is, to some extent, indeterminate, since the titrant base can be adsorbed also on adsorption centres other than the acceptors. The validity of the results can be estimated by analysing a similar series of samples by an independent method[20]: from the concentration of the paramagnetic donor–acceptor complex formed by anthraquinone[31]. The results are shown in Fig. 6, together with the concentrations of acceptor centres in γ-Al_2O_3 samples activated at low temperatures[31]. These values were obtained by a direct method, i.e. as the maximum concentrations of the complexed form of radical (I) (see above). As Fig. 6 shows, the agreement between the three independent methods is good. We may therefore suggest that all the acceptor centres detected by these methods are the same: coordinationally unsaturated Al^{3+} ions. In this sense the work is very different from previous publications[15,32], in which the numerical results were highly tentative.

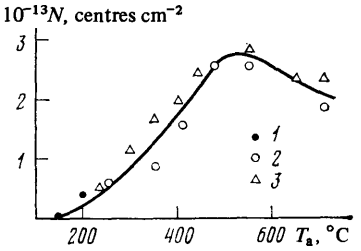

Figure 6. Dependence of the concentration of acceptor centres on γ-Al_2O_3 on the activation temperature of the catalyst[20]. Concentrations determined: *1*) as the limiting concentration of complexed radical, *2*) by titration with pyridine using the radical (I) as indicator, *3*) from the concentration of the paramagnetic donor–acceptor complex with anthraquinone.

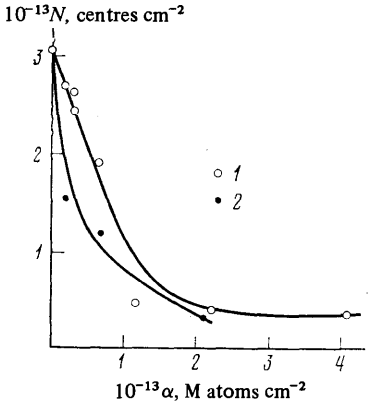

Figure 7. Concentration of acceptor centres on the surface of alumina–platinum and alumina–palladium catalysts against concentration of metal M: *1*) platinum, *2*) palladium.

Pyridine titration with radical (I) as indicator was used to measure the concentration of acceptor centres on alumina–platinum and alumina–palladium catalysts¶. We see from the results (Fig. 7) that the introduction of the metal lowers the concentration of acceptor centres very significantly, especially in the range $0.2–1.0 \times 10^{13}$ metal atoms cm^{-2}. The decrease in the concentration of acceptor centres is due to the interaction of the deposited metals with the γ-Al_2O_3 surface. The effect of the metals on the acceptor properties of the γ-Al_2O_3 is very strong. Thus, even assuming that the

¶T.V.Bychkova, E.V.Lunina, A.K.Selivanovskii, E.A.Nikel', T.Yu.Samgina, and B.V.Strakhov, Zhur.Fiz. Khim. (in press).

whole of the metal is in an atomic state and evenly distributed over the acceptor states (i.e. on the most favourable assumption) each metal atom has to block two acceptor centres at a metal concentration of 1×10^{13} atoms cm^{-2}. However, in real systems the deposited metals are known to be present as microcrystals. Therefore, the effectiveness of the suppression of surface acceptor centres by metal atoms is even greater than the above estimate. For example, in a sample containing 1.7 wt.% of platinum a single crystallite (average diameter 10 Å) can suppress the acceptor properties over an area 100 times greater than its own area, i.e. such a crystallite exhibits long-range effects. As has already been pointed out, the strength of the remaining acceptor centres also decreases very markedly.

Thus the application of the paramagnetic probe method in the study of bifunctional catalysts (Pt/Al_2O_3 and Pd/Al_2O_3) can yield technologically useful information on the interactions between the metal and the support.

On surfaces containing proton-donor centres as well as acceptor centres (for example, fluorinated Al_2O_3, alumina–silicas, decationated zeolites[11,19,38]) the radical (I) is unstable, and the concentration of acceptor centres is difficult to determine. The difficulty can be avoided by lowering the proton acidity (i.e. by exchanging the protons with alkali metal ions). This treatment stabilises the adsorbed radical (I) [19,33] without affecting the concentration of the acceptor centres, at least when the concentration of alkali metal ions is small[33].

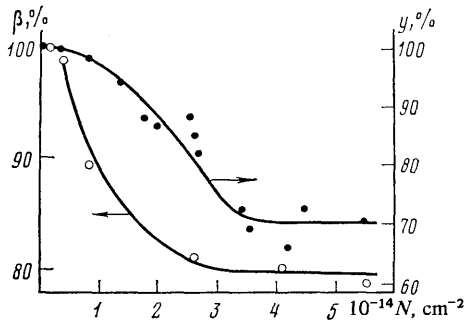

Figure 8. Dependence of the catalytic activity and of the acceptor capacity of γ-Al_2O_3 on the amount of cyclohexanol dehydrated on the catalyst surface at 150 °C: [34] y is the extent of conversion of the cyclohexanol, β is the acceptor capacity of the catalyst at the end of the experiment in arbitrary units (i.e. the contribution of the complex between radical (I) and the Al^{3+} ions to the overall ESR spectrum of the adsorbed radical (I).

VI. STUDY OF CATALYTIC PROCESSES

A very interesting possibility of the paramagnetic probe method is the study of the surface state of a catalyst during or immediately after the catalytic process. The radical (I) has been used[18,34] to indicate changes in the acceptor strength of a catalyst during the dehydration of an alcohol. Dehydration of isopropanol, n-butanol, and *t*-butanol was carried out in the adsorption layer of γ-Al_2O_3 at 100 °C.[18] The amount of alcohol adsorbed was sufficient to fill all the acceptor centres, with a slight excess. As a result of the dehydration reaction some of the acceptor centres were set free: the radicals (I) present on the surface were able to combine with these centres to form a complex. The freeing of the centres is due to the fact that the resulting alkenes are transferred to the gas phase, and water is less effective than alcohols in filling acceptor centres (see Table 3). All the acceptor centres are occupied when the amount of pre-adsorbed alcohol (and therefore the amount of water produced) is $(15 \pm 2) \times 10^{13}$ cm^{-2}. This value is almost the same as the concentration of water molecules needed to fill all the acceptor centres.

Thus, during the dehydration of alcohols the acceptor capacity of γ-Al_2O_3 is determined mainly by the concentration of water on the surface. This problem has been studied in detail[34], using as an example the dehydration of cyclohexanol on γ-Al_2O_3, and it was shown that a stationary catalytic activity and a stationary concentration of acceptor centres are set up during the catalytic experiment, depending only on temperature (Fig. 8). Evidently, the water produced by the dehydration reaction is partially desorbed from the surface, resulting in a steady state in which a definite concentration of catalytically active centres (Al^{3+} ions) remains invariant. As the temperature of the catalytic experiment decreases the desorption of water becomes more sluggish, lowering both the concentration of free acceptor centres and the catalytic activity of the sample.

The catalytic hydrogenation of di-*t*-butylnitroxyl on platinised silica gel and alumina surfaces has been studied[35] at −70 °C. The reaction product was the corresponding hydroxylamine:

$$(CH_3)_3C\diagdown\!\!\diagup N\!-\!\dot{O} + {}^1/_2 H_2 \rightarrow (CH_3)_3C\diagdown\!\!\diagup N\!-\!OH\ .$$

The progress of the reaction was monitored by ESR from the decrease in the concentration of radicals. Most of the results were obtained on SiO_2 (specific surface area $S = 340$ m^2 g^{-1}) containing 1.2% of Pt. The platinum was shown to be present as microcrystals containing an average of 5400 atoms. Therefore the average distance between Pt crystals on the surface was greater than 1000 Å. (Note that a distance of 100 Å is erroneously quoted in the original paper[35]). The coverage of the surface by the radical was fairly high ($\theta \cong 0.25$). Thus the distance between platinum crystals was almost two orders of magnitude greater than the distance between radicals. Therefore we could have expected the dehydration to be confined to those molecules in the immediate vicinity of Pt crystals, keeping the distance between the unreacted molecules constant. However, the ESR spectral changes during the hydrogenation (at −70 °C) indicate a uniform decrease in the concentration of the radical over the entire surface, i.e. an increase in the average distance between radicals. This observation implies a fairly high mobility of the particles in the adsorption layer, even at −70 °C. However, the mobile adsorbate (the radical, or an active form of hydrogen) has not yet been identified.

Nitroxyl radicals, though usually added to catalytic systems as probes or as reactants, can be generated on the surface by certain processes. The simplest is the oxidation of the corresponding hydroxylamine. It has been shown[35] that the hydroxylamine produced by reducing di-*t*-butylnitroxyl adsorbed on platinised silica gel or Al_2O_3 can be oxidised back to the initial radical by oxygen at 25 °C. Under these conditions the concentration of the resulting nitroxyl is not more than 27% of the concentration of the initial radical. Surprisingly, the nitroxyl prepared by oxidising a hydroxylamine on platinised Al_2O_3 is adsorbed on hydroxyl groups rather than on Al^{3+} ions. Apparently the Al^{3+} ions, having interacted with the initial radicals, are blocked by the water molecules produced by the oxidation.

Another, more interesting, and far more usual case is the formation of nitroxyl radicals from nitroso compounds and nitrones by free radical capture. In this way the short-lived radicals formed as intermediates by various reactions can be exploited. The method, which so far has been applied mainly in studies of homogeneous systems[36-38], has been called the spin trap method. In principle this method should give interesting information on reactions in heterogeneous systems.

The interation of *t*-nitrosobutane (TNB) with the activated surface of various oxides has been studied in our laboratory[39,40]. In these experiments the TNB was, simultaneously a reactant undergoing free-radical decomposition and a spin trap:

$$(CH_3)_3C{-}NO \xrightarrow{cat.} (CH_3)_3C^{\cdot} + NO$$
$$(CH_3)_3C^{\cdot} + (CH_3)_3C{-}NO \rightarrow (CH_3)_3C{-}\underset{\underset{O^{\cdot}}{|}}{N}{-}C(CH_3)_3 .$$

The experiments were carried out at room temperature in the dark in order to eliminate the side-reaction (decomposition of the TNB under the influence of light). The nitroxyl radicals produced by the above reaction can easily capture alkyl radicals with formation of diamagnetic adducts:

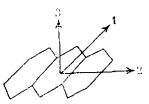
$$(CH_3)_3C^{\cdot} + (CH_3)_3C{-}\underset{\underset{O^{\cdot}}{|}}{N}{-}C(CH_3)_3 \rightarrow (CH_3)_3{-}\underset{\underset{C(CH_3)_3}{|}}{\overset{\overset{O}{|}}{N}}{-}C(CH_3)_3 ,$$

Therefore the activity of the catalysts towards the radical decomposition of TNB was estimated from the initial portion of the kinetic curve describing the formation of nitroxyl radicals, in which the latter reaction can be ignored.

Catalytic free-radical decomposition of TNB is observed on the surface of many oxides: MgO, ZnO, γ-Al_2O_3, Ga_2O_3, Y_2O_3, Sc_2O_3, La_2O_3, and SiO_2. It was shown[39,40] that the reaction occurs most readily on the surface of oxides having semiconductor properties, less readily on γ-Al_2O_3, and is almost undetectable on silica gel. These observations led to the hypothesis that the electron-donor centres on the surface are responsible for the radical decomposition process. The structure of the trapped butyl radical depends on the nature of the surface: on all the oxides except Al_2O_3 and Sc_2O_3 it is the normal *t*-butyl radical, formed by the decomposition of TNB. On γ-Al_2O_3 and Sc_2O_3 surfaces the *t*-butyl radical undergoes isomerisation to isobutyl, but the mechanism of this process has not yet been studied in detail.

The nitroxyl radicals formed by the radical decomposition of TNB also act as paramagnetic probes, and thus allow us to characterise the state of the surface. For example, the ESR spectra of these radicals formed on the surface of γ-Al_2O_3, Ga_2O_3, Sc_2O_3, and La_2O_3 include additional HFS from the nuclei ^{27}Al ($I_{Al} = 5/2$), $^{69,71}Ga$ ($I_{Ga} = 3/2$), ^{45}Sc, and ^{139}La ($I = 7/2$) respectively, i.e. the formation of donor–acceptor complexes is observed. Whereas on γ-Al_2O_3 and Ga_2O_3 these complexes can be produced by the adsorption of synthetic di-*t*-butylnitroxyl, this could not be done with Sc_2O_3 and La_2O_3. A probable explanation is that the Sc^{3+} and La^{3+} surface cations are available for the adsorption of nitroxyl radicals only during the catalytic decomposition of TNB.

These results highlight the importance of the spin trap method in studies of the mechanism of catalytic reactions and of the surface structure of working catalysts.



VII. STUDY OF THE DYNAMICS OF THE ADSORPTION LAYER

Information on the dynamics of the adsorption layer is highly relevant to an understanding of adsorption and catalytic processes. For example, if the surface mobility of the reactants is limited the effective rate constant of heterogeneous catalytic reactions is found[41] to be a function of the surface diffusion coefficient (i.e. of the velocity of translational motion). The velocity of rotation of the adsorbed molecules should also affect the rate of bimolecular catalytic reactions. For bimolecular reactions in rigid polymeric matrices this correlation between the rates of reaction and of molecular rotation has been established[42-44]. In the case of the bimolecular disproportionation of nitroxyl radicals adsorbed on alumina–silica the rate of the catalytic process was found to be determined by the mobility of the adsorbed molecules[19].

Studies of the mobility of adsorbed molecules are experimentally difficult, but significant advances have been made by the application of radio-frequency spectroscopy methods (and especially ESR).

The intensity of the rotational motion of the molecules is traditionally characterised by the correlation time $\tau_C = 1/\nu$, where ν is the rotation frequency[4]. By modelling the experimental spectra on a computer the correlation times describing the rotational mobility of the adsorbed molecules can be evaluated. This type of analysis of the ESR spectra of the cation radicals of polycyclic hydrocarbons adsorbed on alumina–silica[45] has shown that the rotation rates are quite high and the rotation is almost axially symmetrical (Table 4).

Table 4. Correlation times for the rotation of polycyclic hydrocarbon cation radicals adsorbed on alumina–silica[45].

Adsorbate	$10^{10}\tau_C$, s		
	τ_{C_1}	τ_{C_2}	τ_{C_3}
Perylene	27.5	3.9	2.75
Anthracene	21	2.1	2.1
Tetracene	42	3.5	2.8

Table 5. Correlation times τ_C for the rotation of radical (I) adsorbed from the vapour on SiO_2 at 20 °C.[23]

Adsorbent	S, $m^2 g^{-1}$	Pore radius, A	$10^9\tau_C$, s	
			$T_a = 170$° C	$T_a = 470$° C
Silica gel	660	15; 35	7.0	7.0
Silica gel	365	45	6.2	6.2
Silica gel	200	93	6.8	6.8
Aerosil	130	—	6.0	6.2

Advances in our understanding of the shape of the ESR spectra of nitroxyl radicals have led to the development of simple procedures for calculating the correlation times for rotation over the whole range of characteristic times accessible to the ESR method: $10^{-11} < \tau_C < 10^{-7}$ s.[3,4] The correlation time for rotation in non-viscous solutions is less than 10^{-11} s. Adsorption on SiO_2 surfaces strongly inhibits the rotation of nitroxyl radicals (as compared with a solution)[6,46]. The rotational mobility of the radical (I) is practically independent of both the structural characteristics of the SiO_2 surface and the vacuum activation temperature of the adsorbent in the range 150–800 °C [23] (see Table 5). Throughtout this review the anisotropy of the rotation of adsorbed nitroxyl radicals will be ignored.

The HFS components of the ESR spectra of radical (I) for samples activated at lower temperatures were found to be significantly broader than those of high-temperature samples[23]. Line broadening in low-temperature samples is probably due to the fact that the observed spectrum is a sum of spectra corresponding to different values of τ_C. This may be a consequence of the presence of different types of adsorption centre. The narrowing of the spectrum in SiO_2 samples activated at high temperatures suggests greater uniformity of the adsorption centres after high-temperature treatment.

The distribution of correlation times for the rotation of di-*t*-butylnitroxyl adsorbed on SiO_2 is clearly demonstrated in Ref.47. At low microwave powers (i.e. far from saturation) the contribution from slowly rotating molecules is predominant in the ESR spectra. At higher microwave power levels (under conditions of saturation) the major contribution comes from rapidly rotating molecules, whose rate of rotation is approximately 5 times greater. The presence of radicals differing in rate of rotation by more than 4 orders of magnitude on the SiO_2 surface (from $\tau_C > 10^{-5}$ to $\tau_C \cong 3 \times 10^{-9}$ s) has been demonstrated by the fast adiabatic pass method.

The activation energy for the rotation of the radical (I) on the surface of SiO_2 is ~2 kcal mole^{-1}.[46] A similar value (1.9 kcal mole^{-1}) is obtained for di-*t*-butylnitroxyl[6]. Allowing for the distribution of the correlation times of di-*t*-butylnitroxyl molecules Mailer and Hoffman[47] quote a value of 1.5 kcal mole^{-1} for the activation energy of rotation of the rapidly rotating molecules.

A non-polar solvent (toluene) increases the rotational mobility of the adsorbed radical (I), τ_C decreasing from 7.0×10^{-9} to 2.5×10^{-9} s.[46] This effect probably stems from a decrease in the non-specific interaction between the hydrophobic part of radical (I) and the surface.

a single value of τ_C is observed, also decreasing with increase of θ.

Sistovaris and coworkers[9] have studied the rotational mobility of different nitroxyl radicals adsorbed and "stitched" to the surface of SiO_2 samples which had been modified by "grafting" to the OH groups fragments such as $-(CH_2)_n-X$ (where X = H or NH_2, and $n = 2-8$). As the length of the hydrocarbon chain separating the paramagnetic $>\dot{N}-O$ fragment from the adsorption centre was increased the activation energy for rotation decreased from 8–10 to 2–5 kcal mole^{-1}. Non-polar solvents have almost no effect on the rate of rotation of the tracer (the paramagnetic fragment). Addition of a polar solvent increases the rotational mobility. The effect is most marked when the coverage of the surface by the polar solvent is a maximum.

Fox and coworkers[49] have used the paramagnetic probe method to study the adsorption of polymers from solution on SiO_2. From the ESR spectra of polymers labelled with nitroxyl radicals they were able to estimate the fractional number of segments actually adsorbed on the solid surface. Two values of the correlation time of the nitroxyl label are observed in the ESR spectra of these systems: a longer one, corresponding to slow rotation of the labels attached to segments of the polymer chain fixed to the surface, and a shorter one, corresponding to the faster motion of the chain fragments not bound to the surface.

When nitroxyl radicals are adsorbed on γ-Al_2O_3 or alumina–silica surfaces they form a complex with the Al^{3+} ions (as we have already pointed out) whose ESR spectrum is shown in Fig.2*a*. Lozos and Hoffman[6] estimate that the τ_C value for the rotation of di-*t*-butylnitroxyl in this case is close to the value for SiO_2 samples (6×10^{-9} s), with an activation energy for rotation of 1 kcal mole^{-1} (i.e. one-half the value for SiO_2).

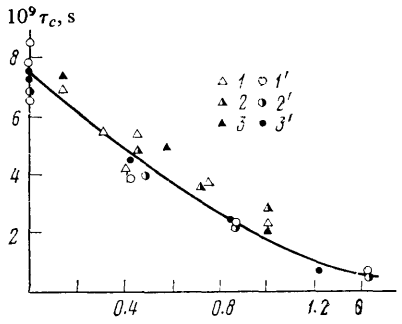


Figure 9. Mean correlation time (τ_C) for the rotation of radical (I) adsorbed on SiO_2 against coverage of the surface by adsorbed donor molecules (θ), from Ref.48: *1–3* adsorption of water, *1′–3′* adsorption of pyridine. Activation temperature of the SiO_2: 150 °C (*1* and *1′*), 300 °C (*2* and *2′*), 470 °C (*3* and *3′*).

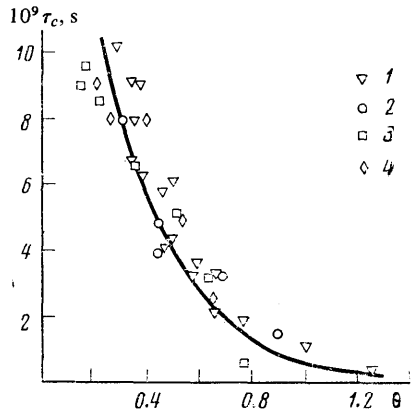

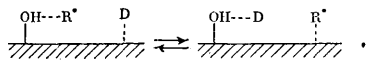

Figure 10. Mean correlation time (τ_C) for the rotation of radical (I) adsorbed on γ-Al_2O_3 ($T_a = 470$ °C) against coverage of the surface by adsorbed donor molecules (θ), from Ref.48. Adsorption: *1*) water, *2*) pyridine, *3*) n-butylamine, *4*) ammonia.

As we have already pointed out, donor adsorbates can displace the radical (I) from the surface OH groups. At surface coverages by donor molecules of $\theta \leq 0.7$ the rotational correlation times fall into two groups[48], corresponding to slow rotation of the specifically adsorbed radicals and fast rotation of the physisorbed radicals. As θ increases the proportion of physisorbed radicals increases, and the average value of τ_C correspondingly decreases (Fig.9). When $\theta > 0.7$

As in the case of the SiO_2 adsorbent, the rotational mobility of radical (I) adsorbed on activated γ-Al_2O_3 increases in the presence of a non-polar solvent (toluene)[14]. When donor molecules are adsorbed, radical (I) is displaced from the specific adsorption centres (first from the acceptor centres,

and then from the OH groups)[48]. At surface coverages of $0.3 \leq \theta \leq 1$ (as in the case of SiO_2) two forms of adsorption are observed: specific (on OH groups) and physical. Different values of τ_c apply to these forms. As θ increases the mean value of τ_c decreases because of the increased contribution from the rapidly rotating physisorbed molecules (Fig.10), and when $\theta > 1$ only one value of τ_c is observed.

These observations (the presence of one or two values of τ_c, or more probably of one or two groups of values of τ_c) can be explained by postulating an exchange between the adsorbate molecules:

In this scheme R· is a radical and D is a molecule of donor adsorbate. If this exchange is quite fast the system will have a single mean value of τ_c for rotation. The rate of exchange can be decreased by lowering the temperature of the sample. Under these conditions the ESR spectra yield two values of τ_c.[48] The situation is reversible: on raising the temperature the ESR spectrum can again be characterised by a single value of τ_c.

Thus, at the higher temperatures the life time of a molecule on an adsorption centre and the correlation time for rotation become comparable. Under these conditions it is meaningless to specify only rotational or only translational motion of the molecules, and it is more rational to consider a single rotational–translational motion. On the other hand if the molecule has a fairly long settled life time in its adsorption centre, and only seldom "jumps" from centre to centre, the two motions (rotational, and translational) can be considered separately.

ESR spectra are sensitive to the distance between the paramagnetic particles. From the dipole–dipole broadening of the spectra the average distance between nitroxyl radicals is found to be between 10 and 60 Å.[50] The time dependence of the average distance between adsorbed radicals has been used to characterise the translational mobility of the radicals.

An analysis[51] of the spectra of radical (I) adsorbed on SiO_2 has shown that the adsorption is initially very non-uniform, the distance between the nearest radicals being much smaller than the average distance. As a result of surface diffusion at room temperature these distances increase. The rate of surface diffusion is practically independent of the porosity and specific surface area of the silica gel sample. On raising the activation temperature of the sorbent the rate of increase diffusion decreases sharply. An estimate of the translational diffusion coefficients of radical (I) adsorbed on SiO_2 by the Einstein–Smoluchowsky equation gave value 12–15 orders of magnitude lower than in non-viscous liquids (10^{-20}–10^{-17} $cm^2\ s^{-1}$)[23].

In the presence of donor molecules (water, pyridine, alcohols, etc.) the translational mobility of radical (I) on a SiO_2 surface is sharply increased[48]. At a coverage by donor molecules of $\theta \cong 0.8$, and a mean distance between the radicals (I) of about 40 Å, the frequency of mutual collisions between the radicals becomes so high that exchange interaction becomes noticeable in the spectrum, as in the case of solutions in non-viscous solvents. Under these conditions the mobility of the molecules in the adsorption layer is comparable to the mobility of molecules in solution.

Because of the presence of acceptor centres the specific adsorption properties of γ-Al_2O_3 are much more marked than those of SiO_2. The radical (I) is adsorbed very non-uniformly on an activated γ-Al_2O_3 surface[52]. Localised concentrations of the radical (I) tend to disappear by surface diffusion, but whereas on SiO_2 this process is completed in a few hours at room temperature, on γ-Al_2O_3 it is still in progress after several days. The activation energy for surface diffusion is 29 ± 6 kcal $mole^{-1}$.[23] This value is close to the energy of the bond between the $\geq N-\dot{O}$ group and the acceptor centre, because this bond has to be broken when the radical (I) "jumps" from centre to centre.

The translational mobility of radical (I) adsorbed on γ-Al_2O_3 is increased (as in the case of the SiO_2 adsorbent) by the addition of donor molecules to the system[18,52]. The donor molecules displace the radical (I) from the acceptor centres, and a triplet component corresponding to radicals which are adsorbed but not complexed with Al^{3+} ions appears in the ESR spectrum as soon as a small addition of donor vapour is made to the system. Surface migration enables these radicals to form new complexes with the acceptor centres which are still free, and a spectrum similar to that shown in Fig.2*a* is gradually re-established. As a result the radical (I) becomes more evenly distributed over the surface. The relatively fast changes in the system come to an end when the radicals have become attached to the acceptor centres.

If the concentration of donor molecules is increased all the acceptor centres are occupied and some of the radicals (I) are unable to form complexes with the Al^{3+} ions: under these conditions a stable triplet appears in the ESR spectrum. The relative amounts of radical (I) which are (respectively) complexed or displaced from the acceptor centres are independent of the order in which the radical and the donor molecules were added to the system. They are determined only by the amount and the nature of the donor adsorbate, i.e. an equilibrium distribution of radical (I) and of the second donor adsorbate is gradually established over the adsorption centres of the γ-Al_2O_3.

The mobility of molecules of bases on the γ-Al_2O_3 surface can be studied by using NO as an indicator of free acceptor centres[29]. After the adsorption of 7×10^{13} cm^{-2} molecules of pyridine (i.e. almost double the amount needed to fill all the acceptor centres) a large number of free acceptor centres is observed during the first few hours in the ESR spectra of NO. Therefore the adsorption of pyridine is very non-uniform, with a large proportion of the adsorbate molecules on the outer surface of the adsorbent grains, leaving the internal surfaces free. Redistribution of the adsorbate over the surface takes place gradually, and after several days all the acceptor centres are occupied by pyridine molecules.

---o0o---

Thus the paramagnetic probe method is likely to find increasing application in studies of adsorption and catalysis. It gives clear indications of the formation of an adsorption layer, and of its dynamics, and it can be used to characterise the interaction between adsorbed molecules and the active centres of the surface, i.e. to solve the fundamental problems in the physical chemistry of heterogeneous catalysis.

Doubly Stabilised Chalcogenonium Ylides

I.D.Sadekov, V.I.Minkin, V.V.Semenov, and S.A.Shevelev

A systematic and general account is given of the methods of synthesis, structures, and reactivities of sulphur, selenium, and tellurium ylides containing two strongly electron-accepting substituents at the ylide carbon atom. The bibliography includes 166 references.

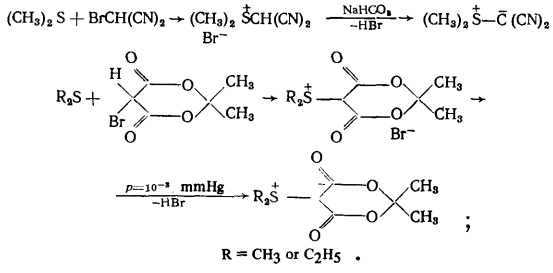
I. INTRODUCTION

Recently there has been a considerable growth of interest in ylides—compounds in which the positive charge of the onium group is stabilised by a neighbouring carbanion. This class of compounds is of interest from both theoretical (characteristics of steric and electronic structures and reactivity) and practical points of view. The importance of the Wittig reaction[1] (interaction of phosphonium ylides with carbonyl compounds), whereby one can obtain olefins with a wide variety of structures, is generally known. Sulphonium ylides of different types, which have been examined in a monograph[2], are widely used together with the ylides of other elements for the synthesis of oxirans, cyclopropanes, and five- and six-membered heterocyclic compounds.

However, the sharp increase of the number of publications on sulphonium ylides together with the appearance of communications on the synthesis and properties of their analogues in terms of Mendeleev's Table—the selenonium and telluronium ylides—made necessary a systematic account and a more detailed examination of data obtained for individual classes of chalcogenonium ylides. In the first place, one must distinguish ylides stabilised by two electron-accepting groups capable of delocalising the negative charge of the carbanion; subsequently, such ylides will be called, for brevity, doubly stabilised (distabilised) ylides (DSY). Ylides of this type, which were believed previously to be chemically inert, subsequently began to attract the attention of chemists, because it was found that they react fairly readily with different electrophiles, enter into thermolytic and transylidation reactions, undergo various rearrangements, etc., and in terms of their reactivity they frequently differ significantly from other types of ylides. In many instances the mode of reaction of doubly stabilised chalcogenonium ylides is extremely unusual and is characteristic only of such ylides, which leads to new possibilities for syntheses based on them. The unusual nature of the methods of their synthesis and reactivity requires a separate consideration of ylides of this type.

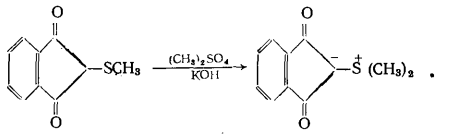
This review does not deal with carbonyl ylides, i.e. oxygen ylides. This is because, in contrast to chalcogenonium ylides, the oxygen ylides are merely short-lived extremely reactive intermediates and because both these and other related ylides have been examined in a recent review[3].



II. METHODS OF SYNTHESIS

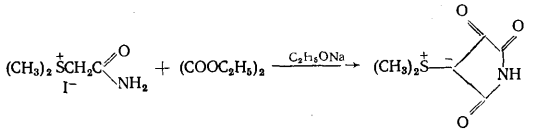
The methods of synthesis of the DSY of Group VI elements known at present are in many respects analogous to the procedures found previously for the synthesis of the ylides of Group V elements. At the same time specific methods have been developed recently for the synthesis of DSY which can evidently find applications in the synthesis of selenonium and telluronium ylides. The fundamental problem in the formation of the DSY of Group VI elements is the synthesis of the chalcogenonium component; we therefore based our classification of the methods of synthesis of DSY on the nature of the chalcogenonium component.

1. Ylides from Diorganochalcogenides R^1R^2M (M = S, Se, or Te)



(a) The Salt Method

The salt method is one of the main procedures for the synthesis of non-stabilised and singly stabilised ylides of Group V [1] and VI [2] elements; it is based on the interaction with bases of onium salts containing at least one hydrogen atom at an α-carbon atom. This method has been little used for the synthesis of the DSY of Group VI elements because of the low yields of ylides (owing to the instability of the corresponding chalcogenonium salts) and also because of the frequently poor availability of the initial salt. However, dimethylsulphonium dicyanomethylide[4] and dialkylsulphonium 2,2-dimethyl-4,6-dioxo-1,3-dioxanilides[5,6] have been obtained with the aid of this method:



The instability of salts of the type $R_2S^+CHXYHal^-$ is probably associated with the highly electrophilic properties of the 'onium cations, which leads to their ready cleavage by the counterions (Hal^-). One should also note that, in the synthesis of such salts by the alkylation of sulphides by the halogeno-derivatives of active methylene compounds, the reaction apparently does not proceed unambiguously. At the

same time DSY have been synthesised successfully[7] by alkylating a sulphide containing two-electron-accepting groups with dimethyl sulphate in an alkaline medium:

DSY have been synthesised by introducing electron-accepting groups into a pre-existing sulphonium salt during the condensation of sulphonia-acetamides with oxalate esters in the presence of alkoxides[8]:

A specific version of the salt method has been used in the synthesis of sulphonium dinitromethylides[9]: it involves the interaction of dibromodinitromethane with a large excess of dimethyl sulphide or thiourea, which leads to the formation of relatively unstable crystalline compounds, which on treatment with water give rise to the ylides $(CH_3)_2\overset{+}{S}-\overline{C}(NO_2)_2$ and $(H_2N)_2C{=}\overset{+}{S}-\overline{C}(NO_2)_2$.

(b) The Formation of Ylides from Activated Oxirans

One of the most important methods of synthesis of dicyanomethylides involves the interaction of diorganosulphides[4,10–13] and diorganoselenides[14] with activated oxirans—tetracyanoethylene oxide[4,10,11,13] or 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene oxide[4,12] (Table 1):

The reaction can proceed via two different pathways and, depending on the nature of the groups at the sulphur atom, can lead to ylides or sulphoxides[11,13]:

The preferred pathway depends on steric factors—for bulky sulphides, the possibility of the reaction with carbon atoms shielded by the cyano-groups is hindered, so that the interaction involves the oxygen atom. The ease of formation of ylides diminishes in the sequence $Alk_2S > AlkSAr > Ar_2S$ and the yields of sulphoxides as a rule increase.

1,1-Dicyano-2,2-bis(trifluoromethyl)ethylene oxide is a more convenient donor of the dicyanomethylene group than tetracyanoethylene oxide, since in its reactions hexafluoroacetone, which is less reactive than the dinitrile of mesoxalic acid, is split off. In the study of 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene oxide, side reactions are therefore reduced to a minimum and the yield and purity of the resulting ylides (particularly those obtained from thiourea and its derivatives) are appreciably increased[12]:

(c) The Carbene Method

One of the comparatively new methods of synthesis of DSY is based on the reaction of highly electrophilic carbenes, obtained from the corresponding diazo-compounds by thermal or photochemical methods, with compounds of a bivalent chalcogen. The method, used mainly to synthesise sulphonium ylides, has been recently examined in a review[15] (Table 2):

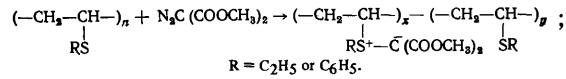
The best yields of ylides are usually attained in the thermal generation of carbenes in the presence of anhydrous copper sulphate of copper powder, which reduce the decomposition temperatures of the diazo-compounds[18,21]. Thus, in

the photochemical decomposition of dimethyl diazomalonate in diphenyl sulphide, the corresponding diphenylsulphonium dimethoxycarbonylmethylide is obtained in 12% yield, while in the thermal decomposition the yield is 85%.[18,21] Furthermore, in the photochemical synthesis of the carbenes the yields of the ylides are greatly reduced when branched sulphides are used in the reaction[18,21]. It is also of interest that, according to the data of Nikolaev et al.[29], cyclic diazoketones completely fail to form sulphonium ylides in the course of their photolysis in alkyl sulphides—the resulting carbene merely undergoes the Wolff rearrangement. The reason for this is probably that the *trans*-disposition of the diazogroups and neighbouring substituents, which is fixed in the molecules of these diazoketones, ensures a higher (compared with acyclic diazoketones) capacity of the alkyl groups for migration (the Wolff rearrangement). In the photolysis of acyclic 2-diazo-1,3-diketones, the formation of the corresponding sulphur DSY is accompanied also by the formation of the products of the Wolff rearrangement, the product ratio depending on the bulk of the alkyl substituents in the ketone: an increase of the bulk of the substituents lowers the yield of the ylides[29].

The addition of a singlet carbene to the sulphur atom is postulated in the thermal and non-sensitised photochemical decomposition reactions of diazo-compounds[21]. At the same time, the ready formation of sulphonium ylides in the benzophenone-sensitised photolysis of dimethyl diazomalonate in alkyl sulphides is evidence, according to the authors[21], of the involvement of a triplet carbene in the reaction. The ylide can be formed either via the attack by the triplet carbene on the sulphur atom with subsequent inversion of spins or via a preliminary conversion of the triplet carbene into a singlet carbene in the presence of dialkyl sulphides with subsequent addition to the sulphur atom[21]. Nor can one rule out the possibility that the ylides are synthesised via the intermediate formation of sulphur azines[11], analogous to the formation of phosphine azines in the reaction of phosphines with diazo-compounds[31]:



The use of dialkoxydisulphides[22] as catalysts makes it possible to obtain ylides from diazo-compounds at room temperature without irradiation. However, this method has no special advantages over the photochemical and even less so the thermal methods of generating ylides, because many ylides cannot be obtained by this method at all.

Unsaturated sulphides (allyl-, vinyl-, and ethynyl-substituted sulphides) are also capable of forming sulphonium ylides on reaction with carbenes[15,26,32]. However, the DSY derived from allyl sulphides readily undergo the allyl rearrangement[32–35] (see Section III), while in vinyl and ethynyl sulphides the sulphur is less reactive than in alkyl sulphides, owing to conjugation with the double or triple bond and it is therefore not always possible to obtain the sulphonium DSY.[26] Furthermore, the addition of carbenes to the double bond has been observed. Nevertheless, the carbene generated from dimethyl diazomalonate is "captured" by the weakly basic sulphur of thiophen (and its derivatives) or dibenzothiophen to give the corresponding S-ylides[15,21,26,27,28]. The sulphonium ylides formed from carbenes and four- or five-membered non-aromatic cyclic sulphides cannot be isolated, because they readily undergo the Stevens rearrangement with ring expansion; on the other hand, the ylides derived from six-membered sulphides are entirely stable[15,21,32].

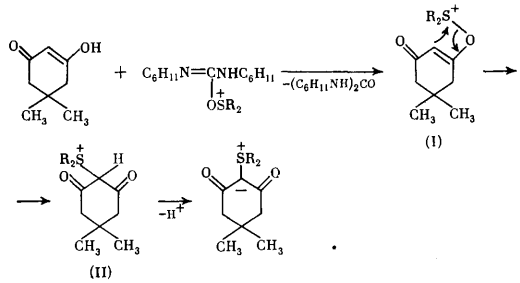
The synthesis of polyvinylsulphonium ylides should be mentioned[36]:

Thiocarbonyl compounds can also "capture" carbenes[37]:

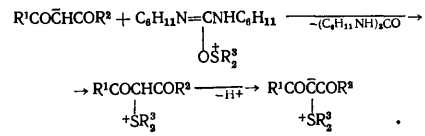
The high stability of thiocarbonyl ylides obtained from 4,5-dicyano-1,3-diazacyclopentadiene is also noteworthy[38,39]:

2. Synthesis from Diorganochalcogen Oxides R^1R^2MO (M = S, Se, or Te)

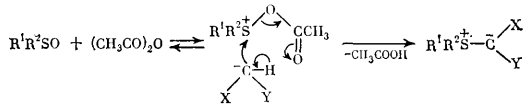
One of the most thoroughly developed methods for the synthesis of the DSY of Group VI elements involves the interaction of diorganochalcogen oxides with compounds containing active methylene groups (Table 3):



The course of the reaction and the yields of the ylides are influenced significantly by the basicity of the chalocogen oxides. Indeed, whereas in the case of sulphoxides dehydrating agents have to be used, frequently under relatively severe conditions [treatment with hot acetic anhydride[7], P_2O_5 in triethylamine[45,46], aryl cyanates[42], thionyl chloride[4], sulphur trioxide[49], and dicyclohexylcarbodi-imide (DCCD) in the presence of anhydrous phosphoric acid[41]], the more basic diaryl selenoxides[58] readily give rise to the corresponding ylides in the presence of acetic anhydride at room temperature[52,53], DCCD,[55,56] anhydrous sodium sulphate in chloroform[51,54], and (as in the case of diaryl telluroxides[57]) even in the absence of dehydrating agents[54]. The reactions of asymmetric selenoxides with dimedone in the presence of anhydrous sodium sulphate and 10-*d*-camphorsulphonic acid have been used to synthesis optically active selenonium ylides[51].

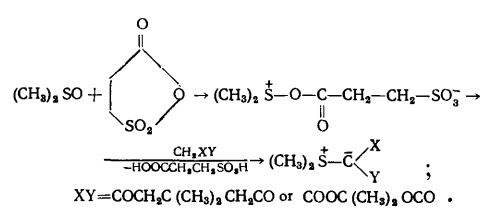


The C–H acidity of the active methylene compounds is also important. Thus, whereas fairly acidic compounds with active methylene groups form ylides, the less acidic compounds (phenylacetonitrile, fluorene, and tetraethyl methylenebisphosphonate) are inert under the usual reaction conditions[41]. However, in the synthesis of ylides from aryl esters of methionic acid, electron-donating substituents X in the aromatic ring, which lower acidity, promote the formation of ylides, while electron-accepting substituents hinder it (with X = *p*-NO_2, the reaction does not occur at all[47]):



It has been suggested that, when DCCD is used, the reaction of sulphoxides with compounds containing active methylene groups proceeds via the intermediate formation of an adduct of the sulphoxide with DCCD; nucleophilic attack on the adduct by an enol gives rise to an enolsulphonium derivative (I). The latter rearranges to the diketosulphonium derivative (II) and, by losing a proton in a polar medium, is converted into the corresponding ylide[41]:

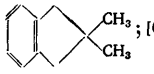
Another possible reaction mechanism involves the nucleophilic attack on the adduct by a carbanion with subsequent loss of a proton[41]:



Ylides are formed via a similar mechanism from sulphoxides and active methylene compounds in acetic anhydride[6,46]:

It is of interest to note that, in contrast to diaryl sulphoxides, diaryl telluroxides react with acetic and other anhydrides to form the corresponding diacylates in quantitative yields[59,60].

The use of acetic anhydride as the dehydrating agent lowers the yields of sulphonium ylides somewhat as a consequence of a side reaction—the Pummerer reaction. The best results are therefore obtained, particularly in the case of dimethyl sulphoxide, when DCCD is used. In fact, whereas in the presence of acetic anhydride the malonic ester does not form an ylide with dimethyl sulphoxide and the cyanoacetic ester gives rise to an ylide in a yield of only 2%, in the presence of DCCD the yields of ylides greatly increase and amount to 40 and 62% respectively[41] (other examples have also been quoted[41]).



The inner anhydride of γ-sulphopropionic acid, which is apparently free from the disadvantages characteristic of acetic anhydride, has been recently proposed as the condensing agent for the synthesis of sulphonium ylides[61]. The betaine formed on interaction with the sulphoxide is made to react with active methylene compounds:

An unusual method of synthesis of the DSY of Group VI elements from diorganochalcogen oxides involves the interaction of the latter with dimethyl acetylenedicarboxylate[14,62,63] or tetracyanoethylene[14]:

$$R_2MO + CH_3OOCC \equiv CCOOCH_3 \rightarrow R_2\overset{+}{M}-\bar{C}\begin{matrix}COCOOCH_3\\COOCH_3\end{matrix}$$

M=S: R=CH_3 [62]; M=Se: R=$C_6H_5CH_2$ [14],

[63]

$$R_2SeO + (NC)_2C{=}C(CN)_2 \rightarrow R_2\overset{+}{Se}-\bar{C}(CN)_2\ ;$$

R=$C_6H_5CH_2$ [14] or p-$CH_3C_6H_4CH_2$,[14]

3. The Formation of Ylides from σ-Chalcogenuranes $R^1R^2MZ_2$ (Z = Hal)

The reaction of σ-selenuranes and σ-telluranes with active methylene compounds in the presence of bases has recently come to be used widely for the synthesis of selonium and telluronium ylides[55,64-69] (Table 4):

$$R^1R^2MZ_2 + CH_2\begin{matrix}X\\Y\end{matrix} \xrightarrow[-2HZ]{base} R^1R^2\overset{+}{M}-\bar{C}\begin{matrix}X\\Y\end{matrix}\ .$$

Note. Here and in the other tables the numbers in square brackets denote references (Ed.of Translation).

This reaction is apparently inapplicable to the synthesis of sulphonium ylides—possibly because the corresponding σ-sulphuranes do not exist in the form of covalent structures with a bisphenoid bond configuration, like the selenium and tellurium compounds, but in the form of charge-transfer complexes[70,71]. In the synthesis of selenonium and telluronium ylides from σ-chalcogenuranes the bases employed were KOH in methanol[66], pyridine[66,67], triethylamine[64,68,69], and sodium ethoxide[55].

Another version of the use of σ-chalcogenuranes in the synthesis of DSY involves their interaction with two equivalents of the sodium salts of active methylene compounds[72]. This reaction, which so far has been investigated only in relation to a single example, can evidently involve the following mechanism:

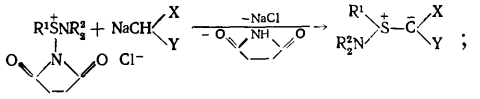
$$(C_6H_5)_2SeCl_2 + NaCH(COCH_3)_2 \xrightarrow{-NaCl} (C_6H_5)_2\overset{+}{Se}CH(COCH_3)_2\ Cl^- \rightarrow$$
$$\xrightarrow[-NaCl,\,-CH_3(COCH_3)_2]{NaCH(COCH_3)_2} (C_6H_5)_2\overset{+}{Se}\bar{C}(COCH_3)_2\ .$$

4. Ylides Obtained from Alkoxy- and Aza-sulphonium Salts

A number of DSY of sulphur have been synthesised by the reaction of alkoxydiorganosulphonium fluoroborates[46] or perchlorates[73] with the sodium salts of active methylene compounds:

$$R^1R^2\overset{+}{S}-OC_2H_5Z^- + NaCH\begin{matrix}X\\Y\end{matrix} \xrightarrow[-C_2H_5OH]{-NaZ} R^1R^2\overset{+}{S}-\bar{C}\begin{matrix}X\\Y\end{matrix}\ ;$$

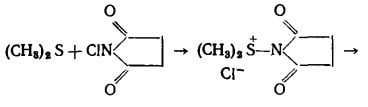
Z=BF_4^-, X=Y=$COCH_3$: R^1=R^2=CH_3 [46]; X=$COCH_3$, Y=COC_6H_5: R^1=CH_3, R^2=C_6H_5 [46];
X=$COCH_3$, Y=$COOC_2H_5$: R^1=CH_3, R^2=CH_3, R_2=CH_3 or C_6H_5 [46];
X=$COOC_2H_5$, Y=CN: R^1=CH_3 or C_6H_5 [46]
Z=ClO_4^-: X=Y=$COOCH_3$, R^1R^2=2.2′-$C_6H_4OC_6H_4$ [73]



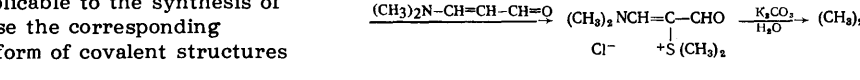
A more convenient modification of this method, not requiring the use of alkoxysulphonium salts prepared beforehand, involves the employment of t-butoxydiorganosulphonium chlorides obtained when sulphides are treated with t-butyl hypochlorite at low temperatures[74-77]:

$$R^1R^2S + t\text{-}BuOCl \rightarrow R^1R^2S\begin{matrix}Cl\\OBu\text{-}t\end{matrix} \xrightarrow[t\text{-}BuOH,\ -NaCl]{NaCHXY} R^1R^2\overset{+}{S}-\bar{C}\begin{matrix}X\\Y\end{matrix}\ ;$$

X=Y=$COOCH_3$: R^1=CH_3, R^2=2-$CH_3OC_6H_4$ [74], 2-$CH_3C_6H_4$ [74];
X=Y=CN: R^1=R^2=CH_3 [76] .



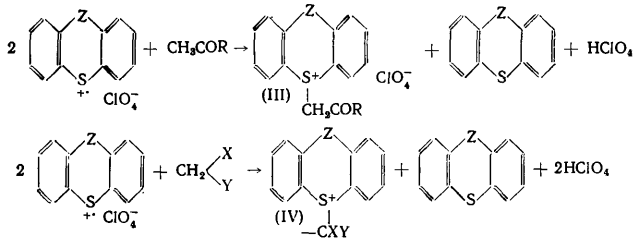
When the reaction is carried out in the presence of menthol, asymmetric induction takes place and optically active sulphonium ylides are obtained[74,75].



Azosulphonium salts behave similarly to alkoxysulphonium salts. Treatment of alkyl- or aryl-(dialkylamino)(succinimido)sulphonium chlorides[77,78] with sodio-derivatives of active methylene compounds leads to the corresponding ylides[77]:

R^1=C_6H_5, R^2=CH_3 or R_2^2=$CH_2CH_2OCH_2CH_2$ or $(CH_2)_5$;
R^1=C_2H_5, R_2^2=$CH_2CH_2OCH_2CH_2$; X=$COOCH_3$, Y=$COOCH_3$, $COOC_2H_5$ [77]; X=Y=$C_6H_5SO_2$ or CH_3SO_2;
XY=$COCH_2C(CH_3)_2CH_2CO$ [77]

Another version of the method, with azasulphonium salts as intermediates in the synthesis of DSY, has been demonstrated[79]:



The conversion of diorganochlorosulphonium salts into compounds of the type $R_2\overset{+}{S}CHXYZ^-$, from which one can obtain, for example, sulphur-containing DSY, has been described[80]:

X=Y=CN; X, Y=CON(CH$_3$)CON(CH$_3$)CO .

5. Synthesis Via S-Radical-cations

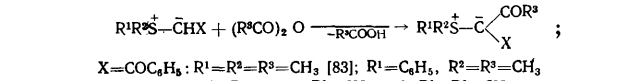
A specific method of synthesising sulphur-containing DSY involves the interaction of the perchlorates of thianthrene and phenoxathi-in radical-cations with various keto-compounds, which lead either to β-ketosulphonium salts (III) or to sulphur-containing DSY (IV), depending on the nature of the keto-compounds:

Z=O: X=Y=COCH$_3$ [82],
Z=S: X, Y=COCH$_2$C(CH$_3$)$_2$CH$_2$CO [81]; X=COC$_6$H$_5$, Y=COOC$_2$H$_5$ [81] .

It is noteworthy that in the case of dibenzoylmethane the product is the sulphonium salt (II) and not the ylide (IV), whose formation might have been expected by analogy with the reactions of acetylacetone and dimedone. It may be hoped that the reaction under consideration will be useful for the synthesis of chalcogenium ylides whose precursors are capable of forming radical-cations.

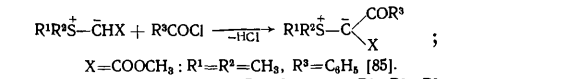
6. Preparation of Doubly Stabilised Ylides from Singly Stabilised Compounds

Doubly stabilised ylides of Group VI elements can be obtained by treating various singly stabilised ylides with electrophiles such as carboxylic acid anhydrides and chlorides, sulphonyl halides, isocyanates, and benzoyl isocyanates via the following mechanism:



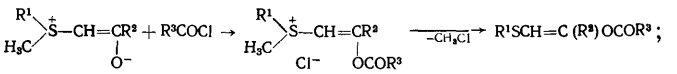
where X and Y are different electron-accepting groups.

The same DSY can be obtained in two ways via these reactions from different singly stabilised ylides and electrophiles. However, hitherto mainly sulphonium ylides have been obtained by this method.



Acylation of Ylides

Singly stabilised sulphonium ylides containing the COOR, COR, and PO(OR)$_2$ substituents at the ylide carbon atom are smoothly acylated by carboxylic acid anhydrides with formation of sulphur DSY:

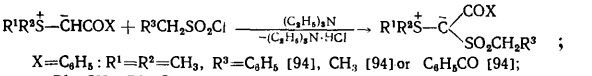


X=COC$_6$H$_5$: R^1=R^2=R^3=CH$_3$ [83]; R^1=C$_6$H$_5$, R^2=R^3=CH$_3$ [84]; R^1=R^3=C$_6$H$_5$, R^2=CH$_3$ [84]; R^1=R^2=CH$_3$, R^3=C$_6$H$_5$ [83, 85, 86]or iso-C$_4$H$_9$ [87]; R^1=R^2=C$_6$H$_5$, R^3=CH$_3$ [88]; R^1=R^3=CH$_3$, R^2=C$_2$H$_5$ [83]; R^1=CH$_3$, R^2=C$_2$H$_5$, R^3=C$_6$H$_5$ [83]; X=COOCH$_3$: R^1=R^2=CH$_3$, R^3=C$_6$H$_5$ [85], X=COOC$_2$H$_5$: R^1=R^2=R^3=C$_6$H$_5$ [89]; CH$_3$ [90], R^1=R^2=C$_6$H$_5$, R^3=CH$_3$ [89]; R^1=R^3=C$_6$H$_5$, R^2=CH$_3$ [89]; R^1=C$_6$H$_5$, R^2=R^3=CH$_3$ [89]; R^1=R^3=CH$_3$, R^2=C$_6$H$_5$ [90] X=PO(OC$_2$H$_5$)$_2$: R^1=R^2=CH$_3$, R^3=CH$_3$ or C$_6$H$_5$ [91] .

Carboxylic acid chlorides[85,90-92] and esters[92] react similarly to singly stabilised ylides containing the alkoxy carbonyl[85,89,90], diethoxyphosphoryl[91], and cyano-groups[92]:

X=COOCH$_3$: R^1=R^2=CH$_3$, R^3=C$_6$H$_5$ [85].
X=COOC$_2$H$_5$: R^1=R^2=CH$_3$, R^3=C$_6$H$_5$ [90]; R^1=R^2=R^3=C$_6$H$_5$ [89]; R^1=R^3=C$_6$H$_5$, R^2=CH$_3$ [89]; R^1=R^3=CH$_3$, R^2=C$_6$H$_5$ [89]; R^1=R^3=CH$_3$, R^3=C$_2$H$_5$ [90] or CHCl$_3$ [90].
X=PO(OC$_2$H$_5$)$_2$: R^1=R^2=CH$_3$, R^3=CH$_3$ or C$_6$H$_5$ [91];
X=CN: R^1=CH$_3$, R^2=C$_2$H$_5$, R^3=CH$_3$ or C$_6$H$_5$ [92] .

The behaviour of sulphonium ketoylides in interactions with acyl chlorides is unusual. As a consequence of the considerable contribution of resonance structures of the type $R_2S^+CH{=}C(R)O^-$, they usually yield *O*-acylation and not *C*-acylation products on treatment with acyl chlorides. In the presence of at least one methyl group at the onium sulphur atom, methyl chloride is in most cases eliminated from the resulting sulphonium salt and the products are enol acylates of the corresponding α-mercaptoketones[84-86]:

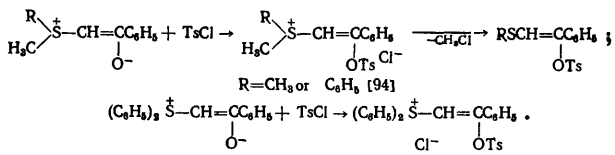


R^1=R^2=R^3=C$_6$H$_5$ [84]; R^1=R^2=C$_6$H$_5$, R^3=CH$_3$ [84];
R^1=CH$_3$, R^2=R^3=C$_6$H$_5$ [85, 86] .

On the other hand, the reaction involving diphenylsulphonium phenacylide stops at the stage involving the formation of the sulphonium salt[88].

The Sulphonation and Cyanation of Singly Stabilised Ylides

On treatment of alkoxycarbonyl- or keto-sulphonium ylides with alkanesulphonyl chlorides in the presence of triethylamine, the initial ylides are *C*-sulphonated with formation of sulphur DSY:[88,93,94]



X=C$_6$H$_5$: R^1=R^2=CH$_3$, R^3=C$_6$H$_5$ [94], CH$_3$ [94]or C$_6$H$_5$CO [94];
R^1=CH$_3$, R^2=C$_6$H$_5$, R^3=H [94], CH$_3$ [94], C$_6$H$_5$ [94]or C$_6$H$_5$CO [94]; R^1=R^2=C$_6$H$_5$, R^3=H [88].
X=CH$_3$: R^1=R^3=CH$_3$, R^2=C$_6$H$_5$ [94]; R^1=R^3=C$_6$H$_5$, R^2=CH$_3$ [94].
X=OC$_2$H$_5$: R^1=R^3=CH$_3$, R^2=C$_6$H$_5$ [94]; R^1=R^3=C$_6$H$_5$, R^2=CH$_3$ [94]; R^1=R^2=C$_6$H$_5$, R^3=CH$_3$ [94] or C$_6$H$_5$ [94].

The yields of the doubly stabilised ylides are sometimes extremely low owing to the occurrence of many side reactions[94].

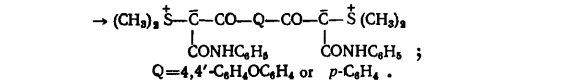
In contrast to aliphatic sulphonyl chlorides, aromatic sulphonyl chlorides (particularly the tosyl chloride) give rise to *O*- and not *C*-derivatives on reaction with sulphonium phenacylides. Dialkyl(arylalkyl) sulphonium ylides give rise to the enol sulphonates derived from α-mercaptoketones as a result of the elimination of methyl chloride from the

intermediate sulphonium salt[94], while diphenylsulphonium phenacylide yields the corresponding sulphonium salts[88]:

Cyanomethylides can be synthesised by the direct introduction of the cyano-group into singly stabilised ylides[95]:

Reactions of Singly Stabilised Ylides with Isocyanates

The interaction of singly stabilised ylides with isocyanates is widely used for the synthesis of DSY, since singly stabilised ylides containing different electron-accepting substituents at the carbanionic carbon atom readily undergo this reaction (Table 5):



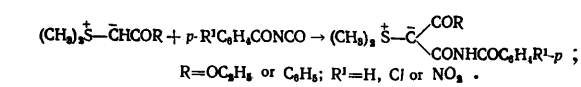


Table 5.

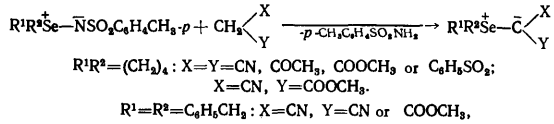
The reaction is sometimes used for the identification of comparatively unstable or difficult to purify ylides[94]. Chiral sulphonium DSY have been synthesised by this method from chiral singly stabilised ylides[83]. The reaction with isocyanates is suitable for the preparation of stable bis-DSY:[99]

Singly stabilised ylides also readily react with benzoyl isocyanates, giving rise to stable benzoylcarbamoylsulphonium ylides[100], whose pyrolysis in decalin leads to substituted oxazoles[100]:

On the other hand, the interaction of dimethylsulphonium phenacylide with thiobenzoyl isocyanate even at room temperature immediately yields a substituted thiazole—via the decomposition of the intermediate ylide[100]:

7. Transylidation

The transylidation reaction involves the exchange of heteroatomic groups between the DSY of any elements and organochalcogenides:



where M is the heteroatom and M′ the chalcogen (S, Se, or Te).

These reactions have found fairly limited applications in the synthesis of the DSY of Group VI elements and it is therefore more useful to consider them in the discussion of the chemical properties of the DSY.

8. Synthesis from Imides

A new method of synthesis of DSY by the reaction of active methylene compounds with comparatively readily available selenium imides has been proposed recently[54]:

The authors[54] note the absence of a linear correlation between the pK_a of the active methylene compounds and the rates of their reaction with selenium imides. Evidently, the stability of the resulting selenonium ylides plays a significant role here.

III. STRUCTURE AND PHYSICOCHEMICAL PROPERTIES

1. Molecular and Crystal Structure

The structures of six doubly stabilised chalcogenonium sulphur[27,41,101,102], selenium[72,103,104], and tellurium[105] ylides have now been investigated by X-ray diffraction, the results being presented in Figs. 1–6. They permit a number of conclusions.

A. As was to be expected, the DSY of Group VI elements have the structure of a trigonal pyramid containing the chalcogen atom at the vertex. On passing from sulphur to tellurium ylides, the distance from the central atom to the plane passing through three neighbouring atoms increases,

its values being as follows: 0.73 Å for (V), 0.74 Å for (VI), 0.78 Å for (VIII), 0.91 Å for (IX), and 0.98 Å for (X).

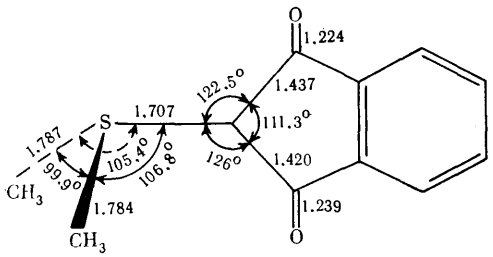


Figure 1. 2-Dimethylsulphuranylideneindan-1,3-dione (V).[102]

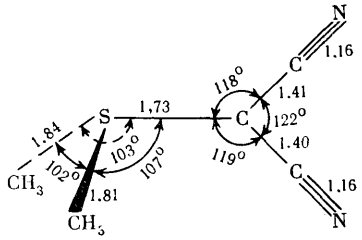

Figure 2. Dimethylsulphonium dicyanomethylide (VI).[41,101]

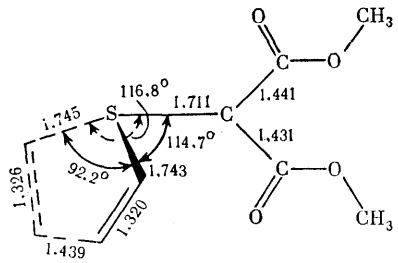

Figure 3. Thiophenium dimethoxycarbonylylide (VII).[27].

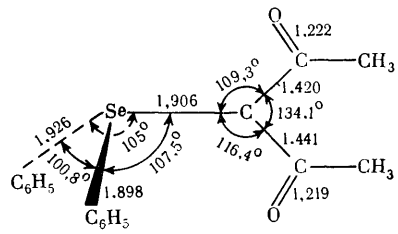

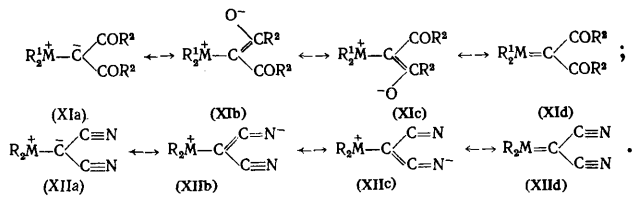

Figure 4. Diphenylselenonium diacetylmethylide (VIII).[72]

B. Analysis of the bond lengths between the chalcogen and the ylide carbon atom and of the bond lengths in the electronegative substituents C=O and C≡N (Figs. 1–6) shows that the electronegative groups play an important role in the delocalisation of the negative charge of the carbanion. In other words, the contribution of the resonance structures (XI, b and c) and (XII, b and c) to the ground state of the ylide molecules is important for diketo- and dicyano-methylides:

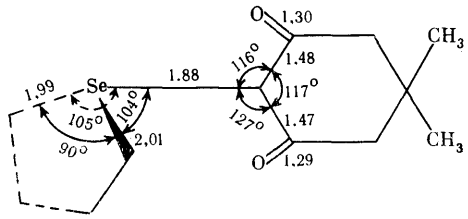

Figure 5. Tetramethyleneselenonium-4,4-dimethyl-2,6-dioxocyclohexanilide (IX).[103,104]

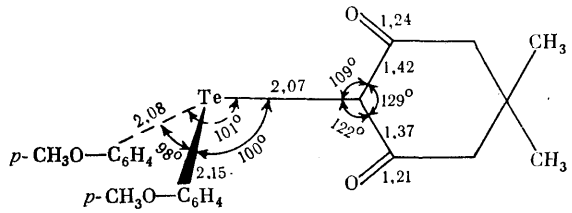

Figure 6. Di(*p*-anisyl)telluronium 4,4-dimethyl-2,6-dioxocyclohexanilide (X).[105]

A number of workers believe that the ylide linkage has a definite double bond character as a consequence of the employment of vacant *d* [101,102,104] or π* orbitals of sulphur and selenium[106].

C. In the case of selenium[104] and tellurium[105] dimedone ylides the oxygen atoms of the dimedone fragment are displaced from the plane of the ring in one direction or another by 0.15 and 0.24 Å (selenium) or 0.11 and 0.16 Å (tellurium) as a result of steric hindrance. Some non-equivalence of the arene rings in the ylide (X) is striking. This is manifested by the fact that one of the methoxy-oxygen atoms is displaced from the plane of the benzene ring by 0.16 Å, while the other lies in the plane of the corresponding ring. This is evidently a consequence of the bending of the dimedone ring, noted also for the corresponding selenonium ylide, and the characteristics of the crystal packing (particularly since in solution both benzene rings and methoxy-groups are completely equivalent judging from the ^{1}H NMR spectra[69]).

2. Ultraviolet Spectra

The ultraviolet spectra of doubly stabilised chalcogenonium ylides have been studied in a number of investigations[6,9,11,12,30,41,46,48,50,52,55,64,66,69,73,79,84,89,94], but these data have usually not been interpreted and the ultraviolet spectra of sulphonium ylides derived from dimedone and benzenesulphonylacetophenones have been examined in greater detail in only one study[30]. The authors[30] believe that the significant displacement of the maximum in the spectra of ylides relative to the spectra of the sodium salts of the initial carbonyl compounds is due to the shift of electron density in the carbanionic part of the ylide under the influence of the sulphuranylidene substituent. An analogous shift has been observed in the ultraviolet spectra of dinitromethylides[48].

Some data on the ultraviolet spectra of doubly stabilised chalcogenonium ylides are presented in Table 6. The replacement of the phenyl group by the methyl group leads to a bathochromic shift of the absorption band of the carbanionic fragment for all the chalcogenonium ylides—evidently as a consequence of the greater compensation of the positive charge on the chalcogen atom by alkyl substituents compared with the phenyl substituent. One should also note that, on passing from sulphur ylides to the selenium and tellurium ylides with similar structures, the long-wavelength absorption band of the ylides undergoes a bathochromic shift, probably as a consequence of the weakening of the electron-accepting properties of the groups R_2M^+ in the sequence $R_2S^+ > R_2Se^+ > R_2Te^+$.

Table 6. The ultraviolet spectra of the ylides $R^1R^2M^+C^-(X)Y$.

3. Infrared Spectra

The infrared spectra of doubly stabilised chalcogenonium ylides provide one of the most convincing pieces of evidence for the considerable involvement of electronegative substituents in the delocalisation of the negative charge on the ylide carbon atom[4,6,12,21,24,25,27,30,41,43,46,48,49,53,56,65,66,69,72,73,77,79,84,89,91,94].

The absorption frequencies of the electronegative substituents at the carbanionic carbon atom of ylides (COR, COOR, CN, NO_2, or SO_2R) are appreciably lower than in the spectra of the corresponding methylene compounds. If the ylide molecule contains two different electron-accepting substituents, the vibrations of the two groups can be usually readily distingiushed under these conditions. Certain vibrational frequencies of electronegative substituents in ylides are presented in Table 7.

Table 7. The vibrational frequencies of the substituents X and Y in the ylides $R^1R^2M^+-\bar{C}(X)Y$.

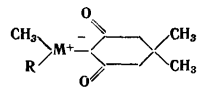
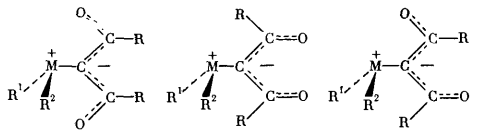
It is noteworthy that the absorption frequencies of the same compounds quoted by different workers are frequently very different. This has been explained[108] by the existence of ketoylides in several stable conformations, which is strongly reflected in the infrared spectra (disappearance of individual absorption bands of CO or the appearance of new bands when the solvent or the state of aggregation of the given substance are altered).



4. ^1H NMR and ^{13}C Spectra

The ^1H [6,30,41,43,46,54–56,69,94] and ^{13}C [24,29,48,111] NMR spectra of doubly stabilised chalcogenonium ylides make it possible to determine the characteristics of their steric and electronic structures. In particular the ^1H and ^{13}C NMR spectra of a number of ylides containing the benzyl, ethyl, and isopropyl groups at the chalcogen atom represent the AB spectrum of the methylene or methyl protons, while the methyl groups of the isopropyl substituent are manifested in the ^{13}C NMR spectrum of isopropylmethylsulphonium methoxycarbonylmethylide as doublets as a consequence of the trigonal-pyramidal structure of the ylide molecule. The magnetic non-equivalence of chemically identical methylene protons and methyl groups of the isopropyl substituent is due to the influence of the solvent[41,69,94]. Indeed, p-anisylbenzyltelluronium 4,4-dimethyl-2,6-dioxocyclohexylide in

methylene chloride gives rise to a signal of the methylene group of the benzyl substituent in the form of a narrow singlet, while in nitrobenzene solution the expected AB spectrum is obtained[69]. The difference between the chemical shifts of the magnetically non-equivalent protons usually diminishes with increase of the number of bonds between the chalcogen atom and the protons active in NMR.[41,69,94,109]



It is of interest to follow the variation of the chemical shifts of the signals due to the methyl groups in dimethyl- and phenylmethyl-chalcogenonium ylides, which have structures of the same type. The available data concerning this problem refer solely to dimedone ylides and are compiled in Table 8. The data presented in Table 8 show that, on passing from sulphur to tellurium, the deshielding effect of the groups RM^+-C^- diminishes, which can be evidently attributed to the weakening of the electron-accepting properties of the groups quoted above on moving from above downwards within the limits of a single Group in Mendeleev's Table.

C_6H_5	Te	2.65 [69]

The question of the conformations of acyclic diketoylides, which can exist in solution as one conformer or a mixture of three possible conformers (XIII, a–c) formed on rotation about the C^-–C bonds, has been raised in a number of studies:

(XIIIa) (XIIIb) (XIIIc)

On the basis of data for the temperature variation of the ^1H NMR spectrum of dimethylsulphonium diacetylmethylide (a singlet due to the acetyl methyls at room temperature and a doublet with an integral intensity ratio of 1 : 1 at −60 °C), the *cis,cis*-conformation (XIIIa) was attributed to this ylide in solution[46]. Despite the repulsion of the two methyl groups, the stabilisation of this conformer is caused, according to the authors, by the strong Coulombic interaction of the unlike charges on the oxygen and sulphur atoms. When one of the acetyl methyl groups is replaced by the bulky mesityl residue, the corresponding ylide exists in solution as a mixture of two conformers—*cis,cis* (XIIIa) and *cis,trans* (XIIIc) in proportions of 1 : 1 at temperatures between −50° and +50 °C.

The broadening of the signals of the acetyl methyl groups in the ^1H NMR spectrum of dimethylsulphonium diacetylmethylide at −25 °C made it possible to estimate the energy barrier to rotation about the S^+-C^- bond as 50 kJ mol^{-1}.[72] In the diphenylselenonium analogue of this ylide, the broadening of the signal due to the methyl groups was not observed even at −60 °C, which shows that the height of the barrier to rotation about the Se^+-C^- bond is less than 41.9 kJ mol^{-1}.[72] The above data (showing that the barrier to rotation in selenonium ylides is lower than in the sulphonium ylides) are consistent with the results of quantum-chemical calculations on different π-chalcogenuranes (oxides, imides, and ylides) and with the fact that in the sulphur–selenium–tellurium series the barriers to rotation about the M^+-C^- or M^+-N^- bonds are lowered, while the barriers to the inversion of the pyramid at the onium atom increase[110].

*Solvents: [a] $CDCl_3$; [b] DMSO-d_6; [c] $CHCl_3$; [d] acetone.

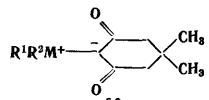
The ^{13}C NMR spectra of doubly stabilised chalcogenonium ylides have been very little investigated[24,29,48,111]. Certain data on these spectra are presented in Table 9, from which follow certain results of interest for the chemistry of ylides.

A. The signal of the ylide carbon atom in dialkoxycarbonylmethylides shifts upfield relative to diketoylides, which indicates a greater contribution of the betaine structures to the ground state of diketoylides compared with dialkoxycarbonylmethylides.

B. Whereas the chemical shift of the ylide carbon atom in sulphonium ylides is independent of the nature of the solvent, in telluronium ylides it varies by approximately 1.5 p.p.m. on passing from chloroform to acetone. This may be an indication of the greater basicity of the telluronium ylides compared with sulphonium ylides.

C. In chalcogenonium ylides containing isotypical electronegative substituents at the ylide carbon atom the chemical shift of the latter is displaced upfield on passing from sulphur to tellurium.

D. The chemical shift of the carbon atom of the methyl group in methylphenyltelluronium ylides (1–3 p.p.m.), which can be accounted for by the influence of the heavy atom, and the pronounced paramagnetic shift of the signal of the ylide carbon atom in *S*-dinitromethylide, located in the region of the signal of the carbon of the dinitrocarbon, are striking[48].



5. The Basicity of Ylides

In contrast to the singly stabilised sulphur ylides[112–114], no systematic studies have been made on the basicity of the series of doubly stabilised sulphonium and selenonium ylides. There exist only scattered data on the pK_a of sulphonium[7,55,115–119] and selenonium[48,120] ylides. It has been shown on the basis of spectroscopic data that sulphonium dimethoxycarbonylmethylides are protonated at the carbon atom[115], while the sulphonium dimedone ylides are protonated at the oxygen atom[118]; sulphonium diphenylacylmethylides[116] and acetylethoxycarbonylmethylides[117] are protonated at both oxygen and carbon atoms. Selenonium diketoylides are protonated at the oxygen atom[120], while sulphonium and selenonium dinitromethylides are protonated at the carbon atom[48].

The basicities of a systematic series of diorganotelluronium ylides have been determined[69] (Table 10) and the correlation between the basicity constants of diaryltelluronium ylides and the polar influence of the substituents has been investigated using different types of σ constants. The data in Table 10 show that the telluronium dimedone ylides are relatively strong bases, whose strength is comparable to that of aromatic amines. Indeed the pK_a for diphenyltelluronium dimedone ylide (10.59) is virtually equal to the pK_a of aniline determined under identical conditions[122]. It is of interest to compare the basicities of the DSY of Group VI elements differing only by the onium atom. Table 10 shows that the basicity of the ylides increases in the sequence S < Se < Te, i.e. with decrease of the electronegativity of the onium atom and with increase of its size. These data are consistent with the determinations of the basicities of the ylides of Group V elements having structures of the same type (the arsenic ylides are more basic than the phosphorus ylides[113]).

The best correlation in the case of symmetrical diaryltelluronium dimedone ylides is obtained using σ^0 constants[69] (the constants of substituents free from polar conjugation), although usually in the interaction of substituents with an electron-deficient centre the best correlation is observed when the electrophilic constants of the substituents are employed[123]. This permits the conclusion that the *p*-substituents in the arene rings interact with the onium tellurium atom mainly via an inductive mechanism[69]. It is noteworthy that many workers arrived at an analogous conclusion on the basis of the pK_a for singly stabilised sulphonium ylides. The data of Goetz et al.[44], who concluded that there is an appreciable mesomeric interaction between the benzene rings and the onium tellurium atom on the basis of a comparison of calculated and measured dipole moments of a series of sulphonium dicyano- and indandione ylides, therefore appear doubtful.

6. Dipole Moments

Comparatively few studies have been made on the dipole moments of the doubly stabilised chalcogenonium ylides[4,44,69,120]. The available literature data on the dipole moments of the DSY of Group VI elements are presented in Table 11. The relatively low dipole moments of diketochalcogenonium ylides[69,120], in the range 2–5 D, are striking. The authors[69] explained this by the fact that the M^+-C^- and C=O bond moments in ylides of this type are pointing in different directions and to a large extent cancel out. Indeed, sulphonium dicyanomethylides, in which the moments of the S^+-C^- and C≡N polar bonds are pointing in the same direction and hence undergo vector addition, have higher dipole moments (7–8 D).[4,44] Quantum chemical calculations on certain dimethylsulphonium and dimethyl selenonium ylides[111] confirmed these hypotheses.

On the basis of the experimental dipole moments of ylides, the ylide bond moments have been calculated in a number of studies[44,120]. However, very drastic assumptions were then made, which greatly diminishes the reliability of the results, In fact, the ylide bond moments were obtained by subtracting from the experimental dipole moment of the ylide $R^1R^2M^+-C^-(X)Y$ the sum of the moments of the corresponding diorganochalcogenide R^1R^2M and the precursor of the carbanionic fragment of the ylide $H_2C(X)Y$, ignoring thereby the significant changes in the M–C and C–X and C–Y bond moments on passing from isolated molecules to ylides where considerable charges appear on the chalcogen and carbon atoms.

7. Mass Spectra

In contrast to the mass spectra of the doubly stabilised sulphonium ylides, those of diketoselenonium[124] and telluronium dimedone ylides[111] have been investigated in fair detail. Without going into the details of the mode of fragmentation of these ylides, which are in many respects similar in all cases, we may note the following features of the mass-spectrometric behaviour of the selenonium and telluronium ylides.

Table 11. The dipole moments of the ylides $R^1R^2M^+-C^-(X)Y$.

A. The stability of the molecular ions of the ylides depends on the structure of the carbanionic fragment. Among the diketoylides (diacetyl and dibenzoylmethylides, dimedone ylides), the dimedone derivatives are the most resistant to electron impact[124].

B. The intensity of the molecular ion peaks in the total ionic current of the molecules depends in many respects on the nature of the chalcogen atom. Whereas the intensity of the molecular ionic peak is 0.1% in the case of diphenyl- and methylphenyl-telluronium dimedone ylides, the intensities of their selenonium analogues are 25.9 and 14.8% respectively.

C. The mass spectra of the selenonium ylides are characterised by the presence of rearranged ions, formed via the migration of the group linked to the selenium atom to the oxygen atom of the carbanionic fragment. Ions of this type are hardly observed in the mass spectra of tellurium-containing dimedone ylides[69,111]. This difference in the behaviour of selenonium and telluronium ylides is comparable to their behaviour in thermolysis (see below).

IV. CHEMICAL PROPERTIES

The reactivities of the doubly stabilised ylides of Group VI elements differ appreciably from those of the singly stabilised ylides. The significant diminution of the nucleophilic properties of the DSY compared with the singly stabilised ylides results in the failure of the DSY of Group VI elements to enter into reactions characteristic of singly stabilised ylides such as those with aldehydes, ketones, nitrosobenzene, etc.[1,2] On the other hand, they undergo a whole series of other reactions characterising the unusual features of ylides of this class.

Certain DSY, for example diorganosulphonium dicyanomethylides[4], diorganosulphonium dinitromethylides[48], organodialkylaminosulphonium ylides[77], and diorganotelluronium dimedone ylides[69], are highly stable compounds resistant to the action of alcohols[4], water[4,69,77], and aqueous solutions of alkalis[69]. On the other hand, certain other DSY readily react with these nucleophiles[17,53]:

$$C_6H_5(CH_3)\overset{+}{S}-\bar{C}(SO_2C_6H_5)_2 \xrightarrow[CH_3OH]{KOH} C_6H_5SCH(SO_2C_6H_5)_2 + CH_3OCH_3\ ;$$

$$n\text{-}CH_3C_6H_4(R)\overset{+}{S}-\bar{C}(COOCH_3)_2 \xrightarrow[CH_3OH]{KOH} n\text{-}CH_3C_6H_4SCH_2COOH + ROCH_3\ ;$$

R=CH_3 or $C_6H_5CH_2$ [17];

$$(C_6H_5)_2\overset{+}{S}e-\bar{C}(NO_2)X \xrightarrow{H_2O} (C_6H_5)_2SeO + XCH_2NO_2\ ;$$

X=NO_2, $COOCH_3$ or COC_6H_5 [53].

Reactions with fairly strong electrophiles and with compounds containing multiple bonds, thermolysis, rearrangements (the Stevens, Pummerer, and allyl rearrangements), transylidation, and certain other reactions are the most characteristic of the doubly stabilised chalcogenonium ylides.

1. Reactions With Electrophiles

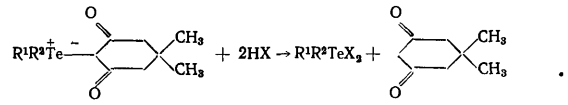
(a) Interaction With Acids

Weak inorganic acids in most cases do not have an effect on the DSY, whereas strong inorganic acids readily react with them, the nature of the interaction depending both on the nature of the substituents at the ylide carbon atom and on the reaction conditions. Thus, whereas sulphonium dicyanomethylides[4] are cleaved by sulphuric acid in the cold into sulphides and unidentified products, the treatment of the same ylides in benzene with gaseous HX (X = Cl or Br) results in the formation of salts having the composition $R_2S^+-\bar{C}(CH)_2 \cdot 2HCl$.[119]

Sulphonium[48,125,126], and selenonium[53] dinitromethylides are protonated by strong acids containing weakly nucleophilic anions, giving rise to the corresponding salts:

$$R_2\overset{+}{M}-\bar{C}(NO_2)_2 + HX \rightarrow R_2\overset{+}{M}-CH(NO_2)_2\ X^-\ ;$$

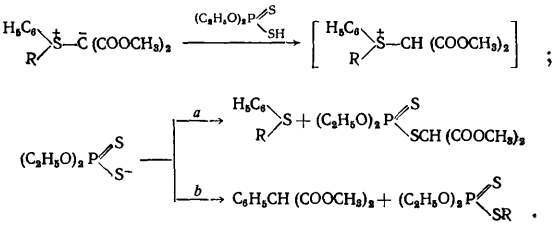
M=S or Se; $X^-=SO_3F^-$, BF_4^- or HSO_4^-.



However, when sulphonium and selenonium dinitromethylides are treated with acids having highly nucleophilic anions, the M^+-C^- bond is ruptured. The intermediate onium salt is then capable of being cleaved both by the counterion (pathway *a*) and by yet another electrophile molecule (pathway *b*):[63,107,125,126]

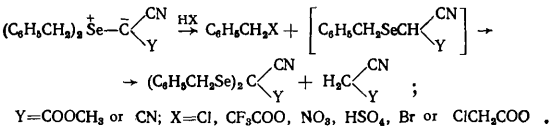
$$R_2\overset{+}{M}-\bar{C}(NO_2)_2 \overset{HX}{\rightarrow} R_2\overset{+}{M}-CH(NO_2)_2\ X^- \begin{cases} \xrightarrow{a} R_2M + XCH(NO_2)_2 \\ \xrightarrow[HX]{b} R_2MX_2 + CH_2(NO_2)_2 \end{cases};$$

M=S or Se; X=Cl or Br.



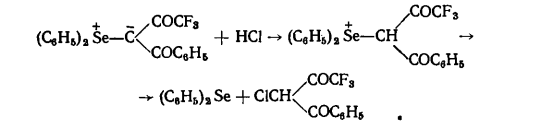
In the case of sulphonium dinitromethylides the reaction proceeds almost wholly via pathway *a*, while in the case of the selenonium compounds both pathways are followed to an approximately equal extent. The enhancement of the nucleophilic properties of the counterion (on passing from HCl to HBr) tends to increase the yield of the nucleophilic cleavage products (pathway *a*). On the other hand, tellurium-containing dimedone ylides always give rise to the corresponding σ-telluranes and dimedone on treatment with HX (X = F, Cl,

Br, or I) regardless of the nature of the substituents at the tellurium atom[127]:



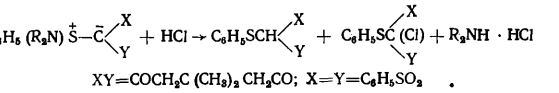
The ability to be cleaved via pathway *b* has hitherto been observed only for DSY. The ease of this process increases in the sequence S < Se < Te, which is probably associated with the greater stability of the tetracoordinate derivatives of tellurium and selenium compared with the analogous sulphur compounds[70,71].

When sulphonium dimethoxycarbonylmethylides are treated with HBr [25] or diethyl hydrogen phosphorodithioate[128], the reaction proceeds with the dissociation of either the S^+-C^- or $R-S^+$ bond depending on the nature of the substituent R at the onium sulphur:



When R = C_6H_5, pathway *a* is followed exclusively, in the presence of R = $C_6H_5CH_2$ pathway *b* is followed exclusively, while in the presence of R = CH_3 both pathways are used to an equal extent.

Dibenzylselenonium dicyanomethylides are cleaved by various acids only at the $C_6H_5CH_2-Se^+$ bond[129]:



Y=$COOCH_3$ or CN; X=Cl, CF_3COO, NO_3, HSO_4, Br or $ClCH_2COO$.

However, the diphenyl-substituted trifluoroacetylbenzoylselenonium ylide is cleaved at the Se^+-C^- bond on treatment with HCl:[56]

Dialkylarylaminosulphonium ylides react with HCl in an unusual manner, the S^+-N bond being ruptured and not S^+-C^-:[77]

XY=$COCH_2C(CH_3)_2CH_2CO$; X=Y=$C_6H_5SO_2$.

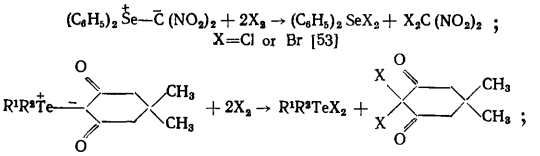
Thus the mode of cleavage of the DSY of Group VI elements by acids (and other strong electrophiles—see below) depends both on the nature of the carbanionic component and on the nature of the substituents at the onium atom. There is no doubt that the nature of the onium centre itself has an effect (cf. the cleavage of the tellurium ylides described above).

A single instance of the nitration of the DSY at the ylide carbon atom is known[130]:

Treatment with N_2O_4 gives rise to tetranitromethane[130]. When the selenonium dinitromethylide is acted upon by nitronium fluoroborate, only tetranitromethane is formed[53].

It has been shown recently[73] that dimethylsulphonium diformylmethylide readily forms 1 : 1 adducts with certain inorganic salts, for example with ZnI_2.

(b) Reactions With Halogens and Other Halogenating Agents

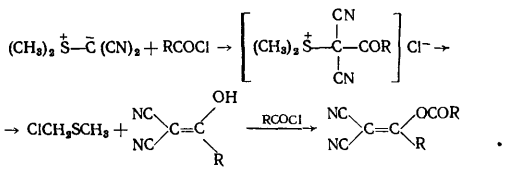


Under mild conditions, the ylide bond in doubly stabilised sulphonium dicyanomethylide[119] and dinitromethylide[126] is ruptured by halogens: Cl_2, Br_2, the mixed halogen BrCl, and their derivatives—S_2Cl_2 and SO_2Cl_2, which leads to diorganosulphides and dihalogenodinitromethanes or dihalogenomalononitriles:

X=Y=NO_2 [126] or CN [119] .

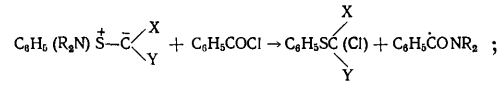
α-Chloromethyl sulphide, formed evidently on chlorination of the methyl group of the sulphide or the ylide, and a certain amount of side products, whose structure depends on the nature of the carbanionic fragment, have also been isolated from the reaction mixture. On the other hand, sulphonium dimethoxycarbonylmethylides are cleaved by halogens not only at the ylide bond but frequently also at the bonds linking other substituents to the onium sulphur[25]. The mode of these reactions depends on the nature of the organic substituents at the sulphur atom.

On treatment with halogens[53,127] or SO_2Cl_2 [53] in inert solvents, the selenonium[53] and telluronium[127] DSY yield the corresponding σ-chalcogenuranes:[53,127]



X=Cl, Br or I [127] .

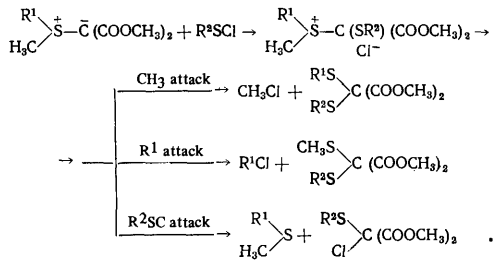
Compounds with a "positive" halogen, namely *N*-chloro and *N*-bromosuccinimides, SO_2ClF, and others, react with sulphonium and selenonium dinitromethylides in an unusual manner[53,107,126]. Here the reaction products are the corresponding dihalogenodinitromethanes, i.e. the cleavage of the above dinitromethylide proceeds in such a way that the two "electrophilic" components of the reactant become linked to the carbanionic fragment, as happens in the interaction of DSY with HX (see above).



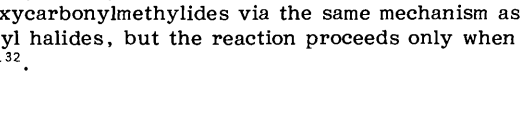
(c) Reactions With Acyl Chlorides

The interaction of the DSY of Group VI elements with acyl chlorides has been studied in a number of investigations[77,119,126,131] and it has been found that the sulphonium dinitromethylides do not react with carboxylic acid chlorides[126] while dicyanomethylides give rise to the dicyanovinyl ester of the carboxylic acid together with the salt $(CH_3)_2S^+-\bar{C}(CN)_2.2HCl$ and chloromethyl methyl sulphide[119]:

The interaction diorganosulphonium dimethoxycarbonylmethylides with acetyl chloride proceeds differently depending on the nature of the substituents at the sulphur atom[131]. Whereas the diphenyl derivative yields diphenyl sulphide (the second reaction product was not indicated), in the methylphenyl and benzylphenyl analogues the S^+–Alk bond is cleaved with formation of $C_6H_5SC(COCH_3)(COOCH_3)_2$ and alkyl chlorides.



As in the reactions with HX, the S^+–N bond is ruptured in aryl(dialkylamino)sulphonium ylides[77]:

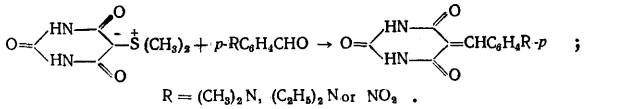


XY=$COCH_2C(CH_3)_2CH_2CO$; X=Y=$C_6H_5SO_2$.

(d) Interaction With Sulphenyl Halides and Sulphenyl Derivatives

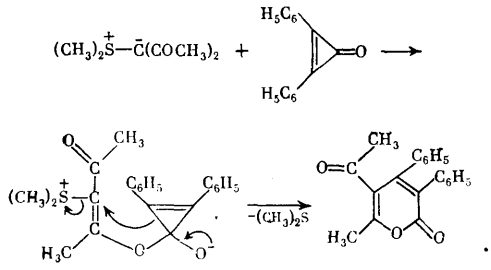
The interaction of the ylides of Group VI elements with electrophiles of the type RSX (X = Cl or Br) has been studied in relation to a series of sulphonium[25,125,126] and selenonium[53] ylides. Under the influence of sulphonyl halides, sulphonium dimethoxycarbonylmethylides are initially sulphenated at the carbanionic centre and the resulting salt can be cleaved by the counterion X^- in three ways; the preferential occurrence of a particular reaction depends on the nature of the substituent at the sulphur atom and the nucleophilic properties of X^-:[25]

Electrophiles such as HBr and the halogens react via an analogous mechanism[25]. Sulphonium[125,126] and selenonium[53] dinitromethylides are converted into dinitrodi(phenylthio)-methane and the corresponding chalcogen dichlorides on treatment with benzenesulphenyl chloride. The cause of this effect of C_5H_5SCl is that the chalcogenonium salt formed in the first stage does not have sufficient time to be cleaved by the counterion Cl^- and is in fact cleaved by a second electrophile molecule at the M^+–C^- bond[53,126]:



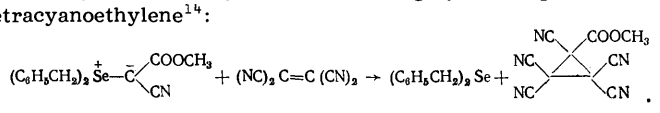
M=S or Se .

Sulphenyl thiocyanates RSSCN react with sulphonium dimethoxycarbonylmethylides via the same mechanism as sulphenyl halides, but the reaction proceeds only when R is an aryl[132].

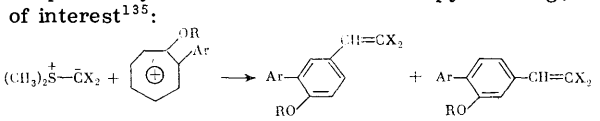


2. Interaction With Compounds Containing Multiple Bonds

Owing to the considerable delocalisation of the negative charge of the carbanion by the two electronegative substituents, the nucleophilic properties of the doubly stabilised chalcogenium ylides are weakened so much that, in contrast to the singly stabilised ylides, they do not usually interact with carbonyl compounds. In essence, there exists only one example of this reaction[133]:

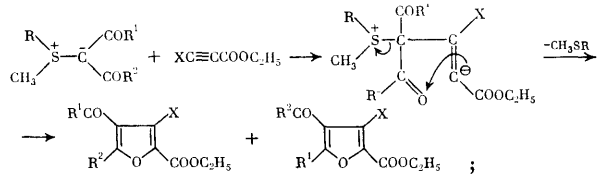


R = $(CH_3)_2N$, $(C_2H_5)_2N$ or NO_2 .



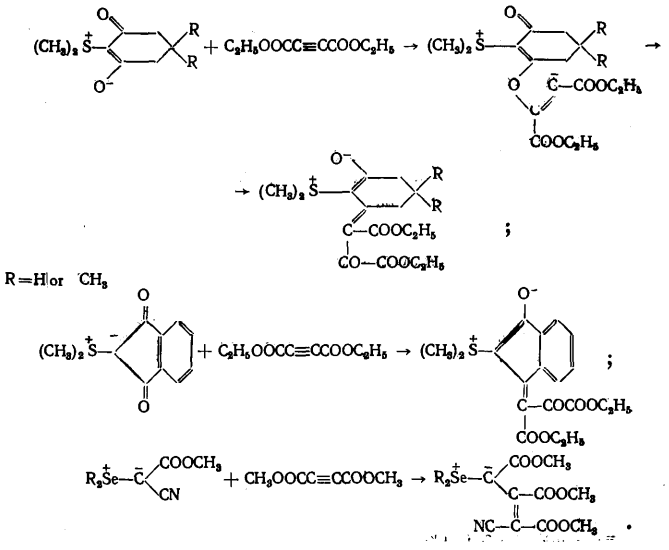
The reaction of the dimethylsulphonium ylide with the highly electrophilic diphenylcyclopropenone proceeds under extremely severe conditions and not via the classical mechanism, because the carbonyl group of the ketone is in fact preserved[134]:

The low nucleophilicity of the doubly stabilised chalcogenonium ylides is manifested by the fact that, in contrast to the singly stabilised ylides, which give rise to cyclopropanes on reaction with activated olefins (dibenzoylethylene, dimethyl fumarate, and acrylonitrile),[1,2] the DSY usually do not react with these compounds. However, substituted cyclopropanes have been obtained in high yields on reaction of dibenzylselenonium ylides with the highly electrophilic tetracyanoethylene[14]:



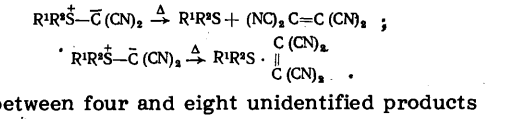
The fairly ready alkylation of dimethylsulphonium dicyano- and diethoxycarbonylmethylides by tropylium cations, which is accompanied by the contraction of the tropylium ring, is also of interest[135]:

The ratio of the reaction products depends on the nature of R and X. For example, the compound with X = CN gives rise exclusively to the isomer in which the dicyanovinyl group is in the *para*-position relative to the RO group.



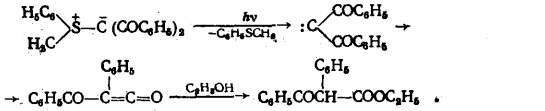
In contrast to compounds with a double bond, ethoxycarbonylacetylenes react with various sulphur[87,136] and selenium[120,121] DSY with at least one keto-group, the products being furans:

M=S [87, 136] or Se [120, 121]; R=CH_3 or C_6H_5;
R^1=Alk, C_6H_5 or OC_2H_5; R^2=Alk or C_6H_5;
X=H or $COOC_2H_5$.



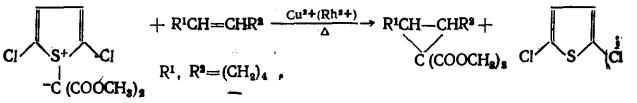
Ylides with two different keto-groups ($R^1 \neq R^2$) give rise to mixtures of two isomeric furans in different proportions, while keto(alkoxycarbonyl)sulphonium ylides ($R^1 = OC_2H_5$,

R^2 = Alk or C_6H_5) yield only one substituted furan—the alkoycarbonyl group is not involved in the cyclisation[87,136]. Cyclic sulphonium diketoylides derived from indandione and dimedone[87,136], as well as selenium ylides with substituents other than carbonyl groups at the carbanionic carbon, react with diethylacetylenedicarboxylate in an extremely unusual manner[14]:



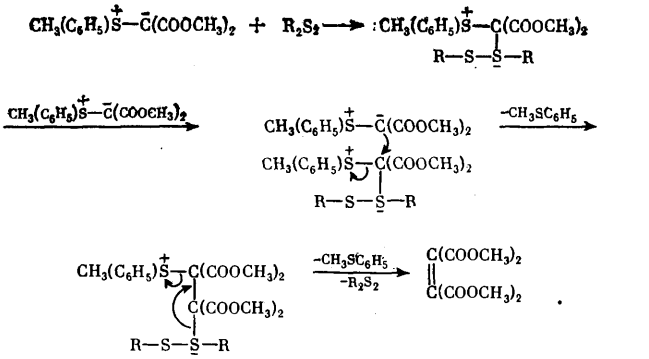
3. Thermolysis and Catalytic Decomposition of Ylides

Although the DSY of Group VI elements are highly stable with rare exceptions (certain selenonium nitroylides[53,107]) under the usual conditions, nevertheless at high temperatures they frequently decompose into diorganochalcogenides and the dimerisation products of the carbanionic fragment (thermolysis). Thus sulphonium dicyanomethylides[4,119] are cleaved, at temperatures exceeding by 30–50 °C their melting points, to give sulphides (if the latter are relatively volatile) and tetracyanoethylene[4,119]; if the sulphides are relatively involatile, charge-transfer complexes are formed between the sulphides and tetracyanoethylene[119]:

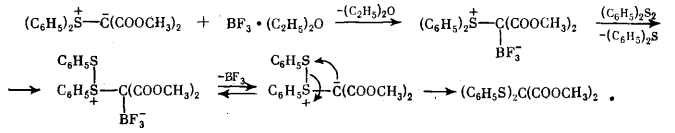


In addition, between four and eight unidentified products are also formed[4].

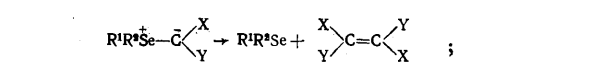
It has been suggested[119] that the thermolysis of the above ylides proceeds via a carbene formation stage. The possibility of the formation of carbenes on dissociation of the ylide linkage has also been indicated by data for the photolysis of a sulphonium dicarbonyl-stabilised ylide, since the product of the Wolff rearrangement was observed[137] (see also Trost[138]):



More significant evidence for the formation of carbenes on thermolysis of DSY is provided by the conversion of olefins into cyclopropane derivatives on treatment with 2,5-dichlorothiophenium dimethoxycarbonylmethylide in the presence of copper or rhodium catalysts[139]:

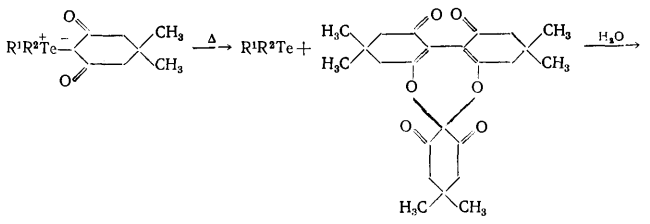


On interaction with activated (with respect to electrophilic substitution) aromatic compounds under analogous conditions, this ylide gives rise to products which are formally a result of the insertion of dimethoxycarbonylcarbene in a C–H bond of the aromatic ring[139,140].

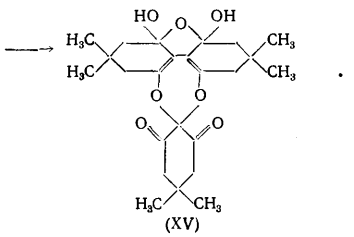


However, there is a possibility also of the catalytic decomposition of the DSY at the ylide linkage under milder conditions. Thus phenylmethylsulphonium dimethoxycarbonylmethylide readily decomposes at 35 °C into a sulphide and tetramethoxycarbonylethylene[141] in the presence of certain disulphides containing electron-accepting substituents: $(AlkO)_2S_2$,[142] $(C_6H_5CO)_2S_2$,[142] and $(CF_3)_2S_2$,[141] while on heating in the absence of a catalyst the ylide undergoes the Stevens rearrangement[20,21] (see below):

One should note that, in the presence of boron trifluoride etherate, the ylide indicated above reacts with disulphides which do not contain electron-accepting substituents at the sulphur atom (for example, with diphenyl disulphide) in a completely different manner[143]:



Different DSY readily decompose into the corresponding selenides and dimerisation products of the carbanionic fragment on treatment with catalytic amounts of tetramethylthiourea[144], thioamides[145], and episulphides[146]:



R^1=R^2=$C_6H_5CH_2$: X=CN, Y=$COOCH_3$ [144–146];
X=CN, Y=$COOC_2H_5$ [144] ;
R^1, R^2=$(CH_2)_4$: X=CN, Y=CN [144]/or $COOCH_3$ [144, 146].
R^1=R^2=CH_3: X=CN, Y=$COOCH_3$ [146] .

The mechanisms of all the above reactions involve the initial addition of the thio-derivatives to the ylide linkage with their subsequent elimination[144–146].

The anomalous course of the thermolytic reaction from the standpoint of the structure of the conversion product of the carbanionic fragment has been observed for diorganotelluriumdimedone ylides[147]. When these ylides were refluxed in *p*-xylene, the corresponding tellurides and a compound to which the structure of the trimerisation product (XV) of the carbanionic fragment was attributed from spectroscopic data, were isolated in almost quantitative yields. The reaction probably proceeds via a carbene mechanism and compound (XV) is evidently formed as a result of hydration (in the course of the reaction or on subsequent treatment of the reaction mixture) of the compound (XIV) formed initially:

(XIV)

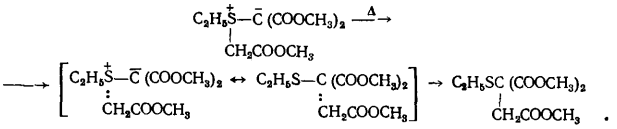
(XV)

Examples of this type of hydration are well known in the carbohydrate chemistry[148].

The unusual behaviour of dialkylaminoarylsulphonium ylides in different reactions has already been noted[77]. Their thermolysis, involving the rupture of the S^+–N bond and not the ylide linkage, also proceeds differently to the cases discussed above[77]:

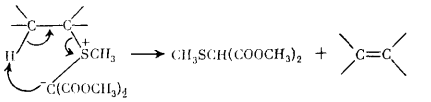
X, Y=$COCH_2C(CH_3)_2CH_2CO$; X=Y=$C_6H_5SO_2$.

4. Rearrangements



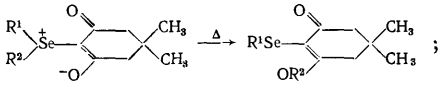
(a) The Stevens Rearrangement

One of the characteristic features of the sulphonium DSY is their ability to form products resulting from the migration of the corresponding groups from the sulphonium centre to the neighbouring carbanionic carbon atom[19,21]. The reaction proceeds under extremely severe conditions requiring heating (for 5–20 h) at 160–200 °C in sealed tubes:



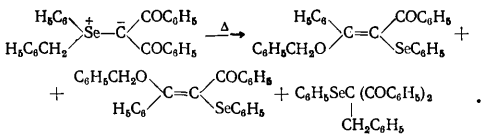
R^1=R^2=CH_3; R^1=C_6H_5, R^2=CH_3; R^1=CH_3, R^2=$C_6H_5CH_2$; R^1=C_2H_5, R^2=CH_3OCOCH_2 .

The observation of a CINP signal (in the region characteristic of methylene protons) on rearrangement of ethylmethoxycarbonylmethylenesulphonium methoxycarbonylmethylide[21] suggested that the reaction proceeds via the homolytic cleavage of the ylide with formation of an intermediate radical pair, which subsequently recombines to the rearrangement product:

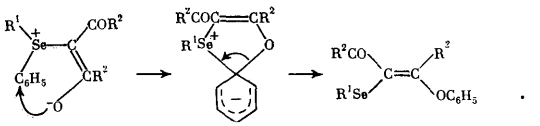


This mechanism has been confirmed by the finding that the groups capable of the resonance delocalisation of the unpaired electron ($C_6H_5\dot{C}H_2$, $\dot{C}H_2COOCH_3$) migrate most readily.

Alkylmethylsulphonium dimethoxycarbonylmethylides in which there is at least one hydrogen atom at the β-carbon atom of the alkyl groups (C_2H_5, n-C_4H_9, t-C_4H_9) undergo the Hofmann elimination on heating, leading to the formation of dimethylmethylthiomalonate and the corresponding olefins, and not the Stevens rearrangement[19,21]. This reaction probably proceeds via a five-membered cyclic transition state:



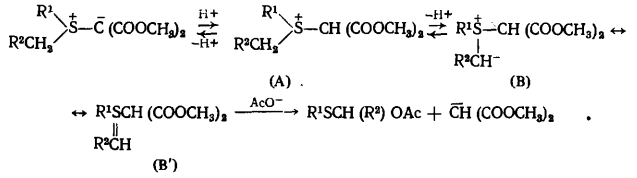
The migration of groups in selenonium diketoylides[149] and dimethylsulphonium formylmethylide[79] takes place differently. Under relatively mild conditions (refluxing in benzene or xylene) (compared with sulphonium ylides), the benzyl and phenyl groups in phenylbenzyl- and phenylmethyl-selenoniumdimedone ylides migrate to the oxygen atom (O-migration) and not the ylide carbon atom (Stevens rearrangement):



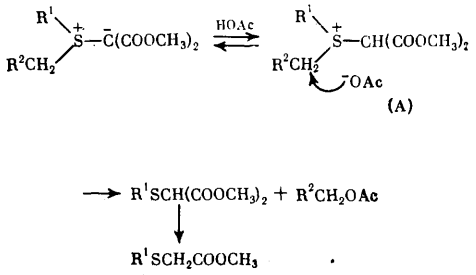
R^1=C_6H_5, R^2=$CH_2C_6H_5$; R^1=CH_3, R^2=C_6H_5; R^1=R^2=C_6H_5 .

In the rearrangement of methylphenylselenonium dibenzoyl methylide (the phenyl group migrates) and diphenylselenonium benzoylmethylide O-migration also takes place and the C-migration product (Stevens rearrangements) is formed only in the case of phenylbenzylselenonium dibenzoylmethylide together with the products of the O-migration of the benzyl group (a mixture of the benzyl ethers of the *cis*- and *trans*-enols of 1,3-diphenyl-2-phenylselenopropane-1,3-dione):[149]

It is believed[149] that the rearrangement of the phenylbenzylselenonium ylides proceeds via a mechanism similar to that for the sulphur ylides, while the migration of the phenyl group in methylphenyl- and diphenylselenonium ylides proceeds via a mechanism involving intramolecular nucleophilic substitution in the benzene ring:



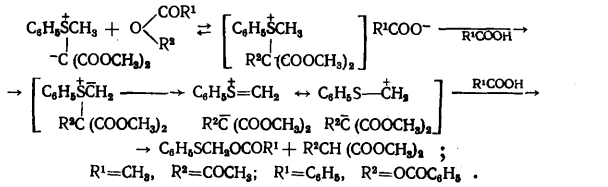
The O-migration in dimethylsulphonium diformylmethylide takes place under very severe conditions[79]:



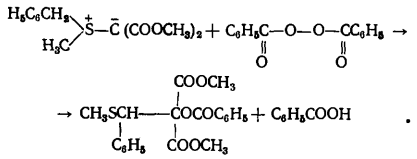
It should be noted yet again that tellurium-containing dimedone ylides undergo only thermolysis on heating regardless of the nature of the substituents at the tellurium atom[147].

(b) The Pummerer Rearrangement

The similarity of the structures of the ylides and sulphoxides containing the semipolar S^+-C^- and S^+-O^- bond suggests the similarity of the chemical properties and in particular the ability of ylides to undergo the Pummerer rearrangement. Indeed sulphonium dimethoxycarbonylmethylides containing sufficiently acidic methylene groups (R^2 = COOR) undergo the Pummerer rearrangement on heating with acetic acid, giving rise to alkoxycarbonyl (alkylthio)methyl acetates and dimethyl malonate[23]. In the presence of acids the ylides are in equilibrium with sulphonium salts A and the less stable but more nucleophilic than the initial compounds ylides (B and B'), nucleophilic attack on which by the acetate ion leads to the final products:

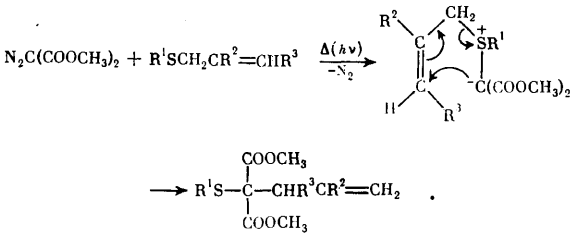


Ylides with less acidic CH_2 groups (R^1, R^2 = Alk or Ph) do not give rise to the products of the Pummerer reaction on heating in acetic acid, forming instead methoxycarbonylmethyl sulphide and alkyl acetates[23]:

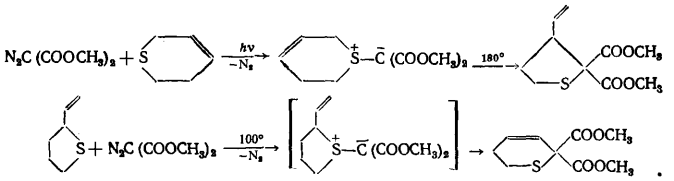


The cause of this mode of reaction is the weaker acidity of the CH_2 groups in the initial ylides, which reduces sharply the concentration of the nucleophilic ylides (B) and drives the reaction via the pathway involving nucleophilic substitution in the sulphonium salt (A), which is present in large amounts. It has been shown[23] that the mode of the Pummerer or substitution reactions depends on the strength of the acids employed: in strong acids (CF_3COOH and $CHCl_2COOH$) ylides of the first type (with alkoxycarbonyl substituents at the onium sulphur atom) undergo the substitution reaction, while in acids weaker than acetic (CH_3CH_2COOH) ylides of the second type can undergo the Pummerer rearrangement together with substitution.

The Pummerer rearrangements have been investigated[150,151] for arylmethylsulphonium dimethoxycarbonylmethylides in the presence of acetic anhydride and benzoyl peroxide. These reactions involve the initial formation of a sulphonium salt as a result of nucleophilic attack on the ylide carbanion, the deprotonation of the salt, the heterolysis of the S^+-C^- bond (rate-determining stage), and the interaction of the intermediate formed with the anion[150,151]:



We may note that, in contrast to its methylphenylsulphonium analogue, benzylmethylsulphonium dimethoxycarbonylmethylide undergoes an unusual rearrangement in the presence of benzoyl peroxide via the following mechanism[151]:

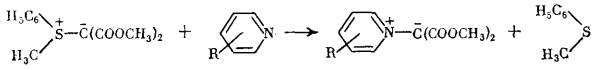


(c) The Allyl Rearrangement

A characteristic feature of doubly stabilised ylides—the intermediates formed in the thermal and photochemical interaction of carbenes and allyl sulphides—is their ability to undergo the allyl rearrangement, from the products of which one in fact infers the intermediate formation of the ylides[32-34]:

This mechanism has been confirmed by the isolation of a stable ylide derived from a cyclic allyl sulphide and its subsequent allyl rearrangement under other conditions[32,35]:

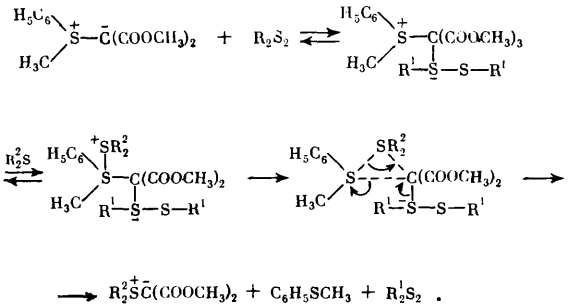
5. Transylidation



Transylidation is a reaction in which one onium group in ylides is replaced by another. Such reactions are influenced significantly by the nature of the onium group in the ylide and of the element in the reagent, the nature of the substituents at the ylide carbon atom, and the reaction conditions (solvent and catalyst).

The influence of various factors on the transylidation of sulphonium ylides by sulphides and pyridine has been studied in detail[141,142]. In the presence of catalytic amounts of

certain disulphides, methylphenylsulphonium dimethoxycarbonylmethylide undergoes smooth transylidation with various sulphides:



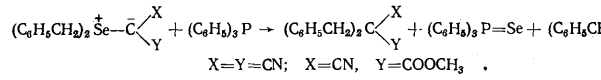
In the absence of a catalyst, the transylidation of the methylphenylsulphonium ylide with dimethyl sulphide (present in a 15-fold excess) proceeds very slowly and does not go to completion. On the other hand, in the presence of a catalyst the transylidation of alkylphenylsulphonium ylides and dialkyl sulphides proceeds readily, that of dialkyl ylides with dialkyl sulphides is much more difficult, and that of dialkylsulphonium ylides with alkyl phenyl sulphides (and probably diphenyl sulphides) hardly occur at all[142]. In other words, as the nucleophilic properties of the sulphides are reduced (Alk_2S < AlkSPh < Ph_2S), their ability to effect transylidation is sharply diminished. The marked influence of the nucleophilic properties of the organoelemental component on transylidation also follows from the results of a study of the reaction of methylphenylsulphonium dimethoxycarbonylmethylide with pyridine and its derivatives[142]:

Whereas the yields of the pyridinium ylides in the reaction with 3- and 4-picolines and pyridine are 96–100%, the yield of the reaction with the weakly basic 4-cyanopyridine is only 7%.

The nature of the electronegative substituents at the carbanionic carbon plays a significant role in transylidation. The more nucleophilic the ylide carbon, the greater the ease of the transylidation. Diketoylides, for which the contribution of the betaine structure is relatively important, are transylidated to a much smaller extent than dimethoxycarbonylmethylides with a more nucleophilic carbanionic carbon (owing to the smaller contribution of betaine structures). One should also note that the yields of ylides also depend on their resistance to thermolysis. Indeed, in the reaction of dimethylsulphonium dicyanomethylide with diethyl sulphide, a new ylide was not detected, while the yield of dimethyl sulphide was 95%.

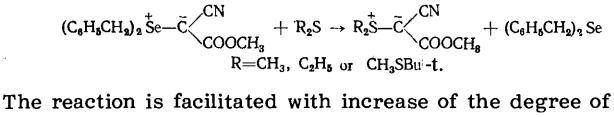
The above transylidation reactions proceed fairly readily only in the presence of catalysts—disulphides with powerful electron-accepting substituents at the sulphur atom (OR, C_6H_5CO, C≡N,[142] and CF_3 [141]). The authors[141,142] therefore proposed the following catalytic mechanism of the transylidation reaction: as a result of the nucleophilic attack on the electron-deficient sulphur atom of the disulphide by the ylide carbon atom, an unstable intermediate complex is formed. Nucleophilic attack on this complex by the sulphide or pyridine leads to a trimolecular complex, which then decomposes to the final ylide and a disulphide[142]:

The influence of external conditions (solvent and catalyst) on transylidation can be illustrated by the reaction[152]:



This reaction proceeds neither in benzene, nor in carbon tetrachloride, nor in acetic acid. Only in the presence of a catalyst (BF_3) in acetic acid does transylidation take place fairly readily[152].

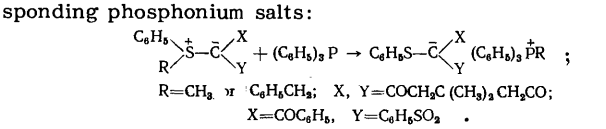
In many instances transylidation is accompanied by side reactions—transalkylation and dechalcogenation. Thus, when sulphonium cyanomethylides interact with triphenylphosphine, the products of the competing desulphuration of the ylide, mainly triphenylphosphine sulphide and dialkylmalononitriles, are formed together with triphenylphosphonium dicyanomethylide and sulphides[153–155]:



In certain cases dechalcogenation is the main pathway in the reaction between ylides and organoelemental compounds. In the reaction of dibenzylselenonium ylides containing two electron-accepting substituents with triphenylphosphine in CH_2Cl_2 mainly triphenylphosphine selenide is formed together with the products of the alkylation of the carbanionic fragment and a small amount of dibenzyl diselenide[156]:

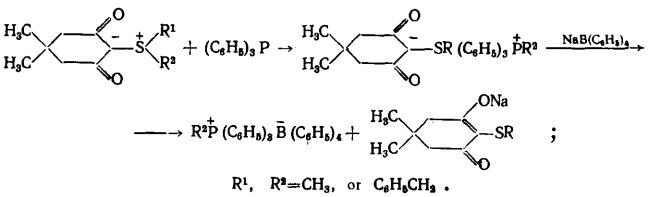
It is noteworthy that mainly the usual transylidation takes place in the reaction between dibenzylselenonium *N*-tosylimide and triphenylphosphine[156]:

On the other hand, selenonium ylides are transylidated with sulphides, but only in the presence of CS_2, and do not form transalkylation products at all[157]:



The reaction is facilitated with increase of the degree of branching of the substituent in the sulphide.

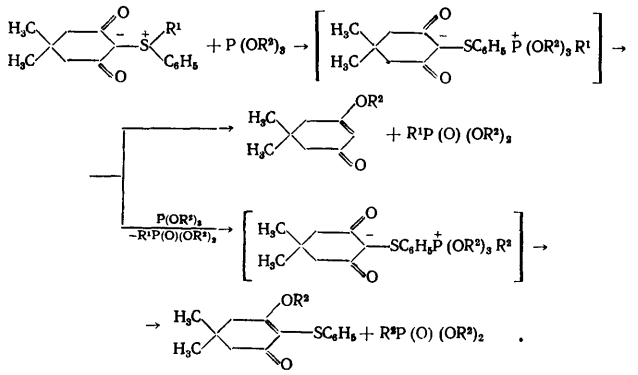
The influence of the substituents at the ylide heteroatom can be followed in relation to the interaction of selenonium dinitromethylides with thiourea[107]:



Thus tetramethylselenonium dinitromethylide gives rise to the corresponding thiuronium ylide in a high yield and in the absence of a catalyst. For R = $C_6H_5CH_2$, a 1 : 1 complex with thiourea is formed, while for R = C_6H_5 the reaction does not occur at all.

In the study of the interaction of sulphonium ylides derived from dimedone and phenylsulphonylacetophenone with triphenylphosphine a third possible pathway in the reaction of ylides with organoelemental compounds was discovered[157,158]. This reaction, which can be regarded as partial dealkylation of sulphonium ylides, leads to the formation of the corresponding phosphonium salts:

In the interaction of dialkylsulphonium dimedone ylides with triphenylphosphine the phosphonium salts could not be isolated probably as a consequence of their lability, but their



formation was demonstrated by carrying out the reaction in the presence of sodium tetraphenylborate:

R^1, R^2=CH_3, or $C_6H_5CH_2$.

Tris(dimethylamino)phosphine reacts similarly with sulphur-containing DSY.[159,160]

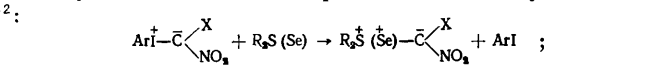
The reactions of sulphonium diketoylides with trialkyl phosphites take place via the intermediate formation of quasi-phosphonium salts and lead ultimately to alkyl phosphinates and 3-alkoxy-2-benzenesulphenyl-5,5-dimethylcyclohex-2-enone:[161]

This reaction is a new example of the non-classical Arbuzov rearrangement.

Thus the transylidation reaction can be regarded as a special case of the interaction of the DSY of Group VI elements with organoelemental compounds.

The transylidation reactions examined above are of interest from the standpoint of the chemical properties of ylides, but have not found fairly wide synthetic applications. It is evident, however, that the transylidation of relatively readily available aryliodonium ylides can find applications in the synthesis of certain types of chalcogenium ylides.

For example, thiuronium ylides, which are otherwise difficult to obtain, can be synthesised readily and in the absence of a catalyst[9,162,163]:

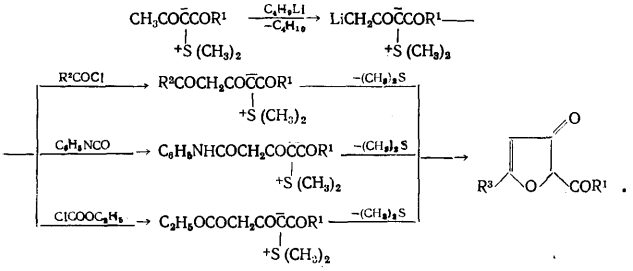


X, Y=$COCH_2C(CH_3)_2CH_2CO$ [163]; X=Y=NO_2 [9] .

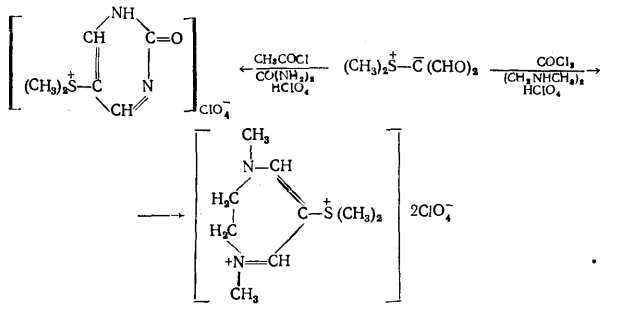
Various dimethylsulphonium ylides derived from β-dicarbonyl compounds have been obtained via iodonium ylides in the presence of copper salts[115-118] and toluene-*p*-sulphonic acid[164] as catalysts:

X=Y=$COCH_3$ [115], COC_6H_5 [116]; X=$COCH_3$, Y=$COOC_2H_5$ [117]; XY=$COCH_2C(CH_3)_2CH_2CO$ [118], $COOC(CH_3)_2OCO$ [164] .

Furthermore, iodonium nitromethylides can serve as reagents for the synthesis of various sulphur and selenium ylides[9,107,162]:



Ar=C_6H_5, or *p*-$O_2NC_6H_4$; X=$COOCH_3$, COC_6H_5, or NO_2; R=CH_3, n-C_4H_9, $C_6H_5CH_2$, or R_2=$(CH_2)_4$.



It is noteworthy that diphenyl chalcogenides do not enter into this reaction.

6. Other Reactions of the DSY

The reactions discussed above (with the exception of salt formation and the interaction of certain types of DSY with compounds containing multiple bonds) proceed with dissociation of the M^+–C bond. New reactions of the DSY, in which the groups linked to the onium atom are transformed without the dissociation of the M^+–C bonds, have been discovered recently. Thus at temperatures from −10° to −15 °C various sulphonium diacetylmethylides are readily substituted by lithium in the methyl group of the acetyl residue by reaction with butyl-lithium or lithium isopropylamide in THF, giving rise to monolithio-derivatives[165,166]. Treatment of these compounds with various reagents leads to new sulphur DSY; some of these compounds readily cyclise to furans[165,166]:

Certain heterocyclic compounds can be obtained from dimethylsulphonium diformylmethylide[79]:

After the manuscript had been sent to the editors, a number of studies on doubly stabilised sulphur and selenium ylides were published[167-179]. Condensation of dimethyl sulphoxide with methanedisulphonyl fluoride yielded a new type of sulphur ylides with two sulphonyl fluoride groups at the ylide carbon atom[167]. An unusual method of synthesis of aminosulphonium methylides by the interaction of arenesulphinic acids with active methylene compounds has been developed[168] and it has also been shown that these ylides undergo a Stevens type rearrangement[168]. The reaction of dicarbonyl-stabilised sulphonium ylides with sulphides[169] and the synthesis of thioxanthenium ylides and their base-catalysed rearrangement[170] have been studied and yet another example of the synthesis of a sulphur ylide from an iodonium ylide has been described[171]. The onium structure of doubly stabilised chalcogenonium ylides with complete delocalisation of the negative charge over the carbanionic fragment and with a single bond between the sulphur and the ylide carbon has been confirmed in relation to sulphonium dinitromethylides by X-ray diffraction, by the dipole moment method, and by quantum-chemical calculations[172]. Polarographic oxidation of sulphur-containing nitromethylides proceeds with abstraction of a single electron from the carbanionic fragment

and the formation of the corresponding radical-cations[173]. In the polarographic reduction of dicarbonyl-stabilised selenium ylides the bond between selenium and the ylide carbon atom undergoes two-electron cleavage with formation of a selenide and a dicarbonyl compound[174]. Analogous products are obtained in the chemical reduction of selenium ylides by mercaptans and mercaptoacids[175]. Thermolysis of selenonium ylides based on dimedone and indan-1,3-dione in the presence of copper sulphate proceeds via the corresponding carbenes, judging from the reaction products[176]. The unusual class of doubly stabilised sulphur and selenium ylides with the onium group at the carbanionic carbon atom, namely ylide salts, has begun to be studied systematically in recent times[177-179]. Their synthesis by the reaction of sulphoxides and selenoxides with phosphonium and sulphonium salts containing an active methylene group[177], their protonation, their cleavage by acids[178], and their rearrangements[179] have been described. Ylide salts are cleaved by hydrogen chloride with reformation of the initial active methylene compounds and dichloroselenide[178], i.e. via the same mechanism as sulphur- and selenium-containing dinitromethylides and doubly stabilised tellurium ylides and in this respect they differ from the vast majority of the chalcogenonium ylides.

The Structure and the Electron-donating Properties of Tertiary Arsine Oxides

A.N.Laskorin, V.V.Yakshin, and N.A.Lyubosvetova

The complex-forming and physicochemical properties of tertiary arsine oxides are analysed in connection with the significant differences between them and the closest organophosphorus analogues. Attention is focused on the reactivities of organoarsenic ligands in complex-formation reactions with acids and metal salts. The specific features of the steric and electronic structures of arsine oxides and the mechanism of the transmission of the influences from groups via the arsenic atom to the reaction centre (the arsenyl oxygen) are discussed. Heterophase reactions in the extraction of acids and salts are considered within the framework of a single model of donor-acceptor processes in solution.
The bibliography includes 274 references.

I. INTRODUCTION

The chemistry of organoarsenic compounds (OAC) is now going through a period of new advance due to the appearance of realistic prospects for the practical utilisation of these derivatives in various branches of science and technology. At the same time, the development of this field is held back by the lack of review publications dealing with the numerous but extremely varied studies on the characteristics of the behaviour of the OAC in many important chemical reactions. This applies fully to the study of the properties of tertiary arsine oxides R_3AsO in reactions of the electron donor–electron acceptor (EDA) type in which the molecular complexes of R_3AsO with organic and inorganic Brønstedt and Lewis acids are formed. Such reactions constitute the basis of the complex formation processes in the homogeneous solutions and heterophase systems, where R_3AsO behave as strong ligands of the neutral type.

This valuable property of R_3AsO has for a long time attracted the attention of specialists in the field of coordination chemistry, who believe that the central problem is the search for relations between the electronic and steric structures of the substituents R at the arsenic atom and the reactivity of the R_3AsO in processes of the EDA type. The extensive experimental data accumulated hitherto have not so far been surveyed and arranged systematically, which limited the application of these compounds in complex formation and extraction processes. This review fills this gap and is devoted to the latest advances in the theory of the structure of the OAC and the applications of tertiary arsine oxides and ligands in the formation of EDA complexes.

Numerous methods of synthesising compounds of tetracoordinate arsenic have been described in detail in specialist publications and monographs[1-60].

II. THE ELECTRONIC STRUCTURE OF ORGANOARSENIC MOLECULES

The Group VB elements—nitrogen, phosphorus, arsenic, antimony, and bismuth—have similar structures of the outer electron shells, consisting of two *s* and three *p* levels. In tervalent compounds of these elements ER_3 three *p* bonds of the heteroatoms E with the groups R should therefore be at 90° angles relative to one another and the free electron pair should be of the pure *s* type. In reality the 2*s* orbital of the electron pair in nitrogen compounds is hybridised with the 2p orbitals, which leads to the formation of four equivalent hybrid sp^3 orbitals. For other Group VB elements, the hybridisation of the *s* and *p* levels is not observed, while the R–As–R valence angles are in the range from 91.8° in AsH_3 to 101° in AsF_3 and AsI_3 (for the majority of the derivatives, the angle is 96°)[61]. The valence angle hardly changes on oxidation of tertiary arsines to arsine oxides, i.e. on passing to the tetracoordinate state $R_3As^+-O^-$.[62]

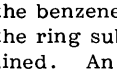
One of the popular models of the arsenyl group involves the cooperative interaction between the arsenic and the oxygen in the $\geq As^+-O^-$ σ-bond and the $p_\pi-d_\pi$ conjugation of the unshared electron pairs of oxygen with the highest vacant 4*d* orbitals of arsenic. As a result of this, the $\geq As\ldots O$ bond acquires partial double bond character depending on the extent of the $p_\pi-d_\pi$ conjugation. This model has been confirmed in the study of the dipole moments of arsenyl compounds[63-65].

The study of a number of oxo-bases R_3NO, R_3PO, and R_3AsO ($R=C_8H_{17}$) by X-ray electron spectroscopy showed that[66] the spectra of R_3NO and R_3AsO are similar, while the spectrum of R_3PO differs significantly as a consequence of the $p_\pi-d_\pi$ interaction of the oxygen in the phosphoryl group with the 3*d* orbitals of the phosphorus atom. This permits the conclusion that, if the $p_\pi-d_\pi$ interaction actually occurs in the arsenyl group, its extent is small and at any rate significantly smaller than in phosphorus compounds. Comparison of the reactivities of compounds of the above series in the formation of charge-transfer complexes with molecular iodine in inert solvents leads to the same conclusion[67]. In this case the reaction constants, the interaction energy, and the degree of charge transfer are similar for R_3NO and R_3AsO, while the corresponding quantities for R_3PO are appreciably smaller.

In order to resolve this contradiction, most varied physicochemical methods, such as ^1H and ^{19}F nuclear resonance[68-71] ^{75}As [72-74] and ^{35}Cl [75] nuclear quadrupole resonance, photoelectron X-ray spectroscopy[76], and electron and vibrational

spectroscopy[77-80] have been used. However, unambiguous conclusions cannot be reached owing to the evident discrepancies between the results obtained by different methods. The solution of this problem was hindered also by the lack of reliable bond lengths and valence angles in arsenic compounds, which were determined accurately only very recently[81-84].

The first mention of the vibrational frequency of the arsenyl group was made in a study[85] where intense absorption maxima in the infrared spectra of tertiary arsine oxides (TAO) at 815 and 844 cm^{-1} were assigned to the AsO groups. The intense absorption bands in the range 815–910 cm^{-1} have also been assigned[86-89] to the As–O linkages. Having studied the infrared spectra of compounds of the type Ph_3MX (M = P, As, or Sb; X = O, Se, or S) in the range 400–3000 cm^{-1}, Jensen and Nielsen[90] determined the absorption frequencies of the As = O (881 cm^{-1}) of $Ph–As_{(as)}$ (474–479 cm^{-1}) groups. The infrared spectra of organoarsenic ligands (L) and complexes of the type ML_2X_2 (L = Ph_3AsO or Ph_2MeAsO; X = Cl or Br; M = bivalent metals ranging from Mn to Zn) have been investigated and discussed[91]. Having discovered that the stretching vibration frequencies ν(As–O) occur in the range 840–910 cm^{-1}, the authors[91] determined them experimentally in the range from 855 to 910 cm^{-1}. The earlier assignments of the intense absorption band in the spectra of triphenylarsine oxide[86-88,92] were confirmed in a study[93] of iso-substituted compounds.



Deacon and Green[94] synthesised and investigated by infrared spectroscopy in the range 200–1650 cm^{-1} the complexes of triphenylarsine oxide with zinc, manganese, cobalt, and mercury ions (saturated solutions in chloroform) and obtained a satisfactory agreement with the results of other studies[90-93]. The absorption maximum at approximately 880 cm^{-1}, assigned to the stretching vibrations of the AsO bond, is resolved into a doublet with frequencies of 885 and 877 cm^{-1} in the spectrum of the solid specimen. A special method for the synthesis of virtually anhydrous complexes made it possible to isolate preparations giving rise to a weak peak in the region of 3300 cm^{-1}; the water absorption bands in the range 200–1650 cm^{-1} are entirely absent.

The infrared spectra of a large number of aromatic and aliphatic derivatives of tetracoordinate arsenic have been published[95]. All the spectra have been interpreted qualitatively and the influence of the vibrations of the benzene ring, the substituents at the arsenic atom, and the ring substituents on the ν(AsO) absorption bands was examined. An equation relating the stretching vibration frequencies of the M = X bonds to the bond order was derived for molecules of the type $R_3M–X$ (where R = alkyl: M = P, As, or Sb; X = O, S, Se or Te), taking into account the molecular masses[96]. The force constants and bond orders have been calculated from the Raman and infrared spectra of the compounds $(CH_3)_3MO$ (where M = N, P, or As). According to the authors[95], there is extensive $p_\pi–d_\pi$ interaction, which is particularly characteristic of the phosphorus and arsenic compounds[97], while according to other data[98], the extent of the interaction is small.

It is noteworthy that many studies on the vibrational spectroscopy of organic compounds of arsenic are to a large extent descriptive and in only some of them has an attempt been made to relate the spectroscopic data to the structures and properties of the compounds. Such comparisons were made for the first time in a number of investigations[77,79,99-102], whose authors were able to determine experimentally the characteristic spectroscopic features of the arsenyl group, to measure its vibrational frequencies for the class of compounds investigated, to find the relation between ν(AsO) and the nature of the substituents at the arsenic atom, and to investigate the influence of solvents on ν(AsO). However, the study of the vibrational frequencies does not yield complete information about the molecular structure. The characteristics of the structure of the electron shell are manifested most completely in the intensities (A) and polarisation of the spectral lines and bands.

The integral stretching vibration band intensity of the arsenyl group $A_{As=O}$ was first calculated[93] for triphenylarsine oxide. Subsequent careful determination of the $A_{As=O}$ for different TAO showed that the band has a high intensity comparable to the integral intensities of the bands due to the phosphoryl and carbonyl groups[100-102]. It has been noted[100] that, on passing from tertiary arsine oxides to arsonic acid esters, the integral intensity of the absorption band diminishes. This indicates an increase in the multiplicity and the strengthening of the AsO bond in the esters.

Hypotheses concerning the fractional AsO bond order in TAO have been put forward in several investigations. Thus, having calculated the force constants and the stretching vibration frequencies of the As–O and As = O bonds (770 and 964 cm^{-1} respectively), an experimental stretching vibration frequency of approximately 880 cm^{-1} was obtained on the basis of the study of the vibrational spectra[91,103]. The AsO bond order calculated from the formulae of Gordy and Siebert proved to be 1.5.[97] In the calculation of the stretching vibration frequency, Shagidullin et al.[99] introduced a correction for the ionic shortening of the bond. The experimental AsO bond length in Ph_3AsO is 1.66 Å,[104] which is intermediate between the values calculated from the Shomaker–Stevenson formula for single and double bonds (1.74 and 1.58 Å respectively). The authors[104] also suggested that the multiplicity of the AsO bond can change under the influence of the electronic properties of substituents by virtue of the polarisation of the $d_\pi–p_\pi$ linkage. On the basis of the equation relating the stretching vibration frequency of the AsO bond to the overall electronegativity of the substituent R at the arsenic atom, it has been concluded that the bond under consideration is more polar than the PO bond[104].

On the basis of calculations of the parameters of the correlation of the stretching vibration frequency shift and the known reaction constants of the substituents and taking into account data indicating that the ν(As = O) vibrations are highly characteristic, Shagidullin and Lamanova[100] concluded that the substituent X is conjugated with the As = O group in the chain X—  —As = O. Since the conjugation has a significant influence on the parameters of the electronic transitions in molecules, such effects should be manifested in the ultraviolet spectra of the test compounds. There are no systematic literature data of this kind and it is only known that the unshared electron pair of the central atom in the phenyl derivatives of Group VB element interacts weakly with the π orbitals of the benzene ring[105-107], and, when the central atom does not have such electrons, there is no resonance interaction at all[108].

The overall electronic effect of the arsenyl groups is electronegative and in aromatic derivatives they behave as *meta*-directing substituents[69,109], i.e. as electron acceptors in relation to the benzene ring. If account is taken of the fact that the electronegativity of the arsenic atom is lower than that of the carbon atom (2.10 and 2.60 according to Pauling[110]), then the most acceptable hypothesis which will explain the above effect may be that of $p_\pi–d_\pi$ conjugation. Furthermore, it has been found that[69,109], the shifts of the p absorption band caused by substituents in the series of arsines and their oxides are analogous to the shifts for the corresponding derivatives of aromatic ketones. Since the keto-group is a typical *meta*-directing substituent, the results can be regarded as additional confirmation of the above hypothesis.

Comparison of the frequencies $\nu(As=O)$ with the additivity constants of the substituting groups obtained for organophosphorus compounds showed[111,112] that a linear relation between $\nu(As=O)$ and $\Sigma\chi$ (where χ is the constant of the phosphoryl shift) holds also for organoarsenic derivatives within the limits investigated. This confirms the analogy, noted previously, between the structures and properties of phosphorus and arsenic and also shows that the interactions of the PO and AsO bonds of the substituents are of the same type. The σ constants of arsenic-containing substituents can be found in Lobanov's thesis[113] and in all cases where substituents exhibit electron-accepting properties.

However, despite the fact that the amount of information which can be used for theoretical and semiempirical descriptions of compounds of the type R_3AsO is considerable[114], it is still insufficient for an unambiguous solution of the problem of the multiplicity of the As=O bond in organic compounds of arsenic. In conclusion of the discussion of the results of studies on the electronic structure of compounds of tetracoordinate arsenic, we may note that many most important problems in the chemistry of arsenic have still not been solved. Thus there have been virtually no quantum-mechanical calculations on the structures of arsenic compounds and the amount of double bond character in the arsinyl group and its dependence on the nature of the substituents at the arsenic atom has not been finally established, there are few data on the transmission properties of arsenic in different valence states, and the amount of information on its stereochemistry is insufficient[115-123]. The lack of these data complicates the specific synthesis of new organoarsenic preparations and retards their introduction into various branches of science and technology. In this connection one may hope that, as the theory of the structure of arsenic compounds develops, new fields of practical applications of this interesting class of organoelemental derivatives will be discovered.

III. THE BASICITY OF ARSENIC-CONTAINING EXTRACTANTS IN AQUEOUS AND NON-AQUEOUS SOLUTIONS

The adducts of tertiary arsine oxides with protic acids have been known for a long time. Stable complexes with nitric acid[124,125], chloroacetic acids[126,127], perchloric acid[128], and hydrogen halides[126,128] have been described. The first data concerning the basicity of TAO were obtained in 1941, when Nylen[129] determined the acid dissociation constants of the conjugate acids of trimethylarsine oxide ($pK_a=3.75$) and triethylarsine oxide ($pK_a=3.71$) in water at 20 °C. A wider set of TAO was investigated by Chernokal'skii et al.[130], who determined the basicities of a series of *para*-substituted aryldiethylarsine oxides having the general formula $p\text{-}XC_6H_4As(O)(C_2H_5)_2$ with a variable electronic structure of the substituent X. It was noted that all the TAO investigated are weak bases in water and that their basicity depends on the structure of the Group X. While the length of the hydrocarbon chains of the groups X has almost no influence on the basicity, there is a linear relation between the pK_a of the TAO and the Hammett constants. Analysis of the relations obtained enabled the authors to conclude that the tetracoordinate arsenic atom is capable of transmitting inductive and resonance effects but is a weaker conductor than carbon.

In order to refine the relations between the nucleophilicity of trialkylarsine oxides and their basicity, the pK_a of a series of TAO were determined in water[131]. It was found that oxides of the type Alk_3AsO are moderately strong bases in aqueous solutions, their thermodynamic protonation constants pK_a^T being in the range 3.59–4.03 depending on the structure of the alkyl groups. The lengths of the hydrocarbon groups in the range from $Alk=CH_3$ to $Alk=C_4H_9$ has almost no influence on the basicity, while their steric structure does have an influence. Using a series of oxides of *para*-substituted 10-aryl-5,10-dihydrophenarsazines, the influence of substituents in the *para*-position of the benzene ring on the basicity of the arsinyl oxygen was investigated[132] with the aid of $\sigma\rho$ analysis. The test oxides proved to be fairly weak bases, as shown by the absence of a sharp potential jump at the neutralisation point, with low values of pK_a^T even on titration in aqueous alcoholic media. The observed low reaction constant ρ confirms the earlier conclusion[130] that the electronic conductivity of arsenic is smaller than that of the elements in the Second Period. However, the data[132] concerning the relation between the structure of the compounds and their basicity cannot be regarded as correct for a number of reasons, the principal of which are the low basicity of the majority of the TAO in aqueous solutions, the inadequate accuracy of the measurement of pK_a^T under these conditions, and the short range of variation of ΔpK_a^T as the structure of the groups attached to arsenic is varied. The study of the basicity of the TAO in differentiating organic solvents, among which nitromethane and acetic anhydride are outstanding, is much more promising from this point of view[133].

In the study of the acid–base properties of organoelemental bases in non-aqueous media, the high basicity of the TAO in nitromethane and acetonitrile was noted[134,135]. These observations were fully confirmed in the determination of the basicity ($pK_{B,HX}$) of the oxo-bases in acetic anhydride by the spectrophotometric method and on comparing their electron-donating capacities in the formation of intermolecular hydrogen bonds with thiocyanic acid, deuterophenol, methanol, indole, methylaniline, and phenylacetylene[136]. The results show that triphenylarsine oxide (TPAO) becomes a fairly strong base on non-aqueous solutions, whose strength approaches that of tertiary amines such as triethylamine and trioctylamine.

The rules governing the formation of the basicity of the organoelemental oxo-bases R_nXO with X=S, Se, N, P, or As have been established in a series of studies[136-138]. Particular attention was devoted to the search for relations between the polar effects of the substituents and the basicity or the extracting capacity of the oxo-bases and also to the study of the distribution of the oxides between different phases as the H_2SO_4 concentration in the two-phase system is varied. The constants K_a were determined by Arnett's method. The results of the study showed that the extraction capacity of the oxo-bases is determined to a large extent by their basicity, which is influenced by the nature of the element X in the group XO and by the type of the substituent R. Among both aliphatic and aromatic derivatives, the strongest bases proved to be the oxides of arsenic, antimony, and selenium.

Potentiometric titration of the oxides of substituted aryldihydrophenarsazines in a mixture of acetic acid and acetic anhydride showed[139] that this medium does not have a differentiating effect on the basicities of the test compounds. More hopeful results are obtained when the basicities of the TAO of the type $XC_6H_4As(O)(C_2H_5)_2$ in acetic anhydride and nitromethane are compared[140]. The authors established that acetic anhydride exhibits a differentiating effect and that the pK_a of arsine oxides vary markedly as a function of the structure of the substituents X in the benzene ring. The mixture of nitromethane and acetic anhydride[141], which permits the titration of a wide variety of compounds of tetracoordinate arsenic, possesses such properties.

The determination of the basicity of weak bases in nitromethane by potentiometric titration with perchloric acid became possible after the improvements proposed in a number of investigations[142-144]. The study of the protonation of the oxides of organic derivatives of Group VB elements (nitrogen, phosphorus, and arsenic) by the above procedure made it possible for the first time to determine the pK_a in nitromethane for the derivatives investigated[145]:

$(C_8H_{17})_3PO$	9.72
$(C_8H_{17})_3NO$	16.85
$(C_8H_{17})_3AsO$	16.14

It was found that the protonation reaction proceeds in steps:

$$2R_3EO + H^+ \overset{K_{a_1}}{\rightleftarrows} R_3EO \ldots \overset{+}{H} \ldots OER_3;$$

$$R_3EO \ldots \overset{+}{H} \ldots OER_3 + H^+ \overset{K_{a_2}}{\rightleftarrows} 2R_3\overset{+}{E}OH.$$

On the titration curve, this is manifested by two distinct potential jumps corresponding to 50% ($E^{I}_{0-50\%}$) and 100% ($E^{II}_{50-100\%}$) neutralisation. The use of *N,N'*-diphenylguanidine as the reference standard ($pK_a = 17.2$) made it possible to adjust the observed half-neutralisation potentials $E^{I}_{1/2}$ and $E^{II}_{1/2}$ to the basicity constant scale of the test compounds in nitromethane, which permits in its turn the calculation of the overall basicity constants of the compounds and the equilibrium association constants of the bases in solution ($\lg K_{ass}$). Comparison of the pK_a obtained shows that trioctylphosphine oxide is a weaker base than the corresponding nitrogen and arsenic oxides whose basicities are similar.

Developing this concept further, Laskorin and coworkers determined the pK_a for a series of tertiary arsine oxides and sulphides in nitromethane[146,147]. It follows from the results that the basicity of arsine oxides in both water and nitromethane increases with increasing length of the hydrocarbon group R at the arsenic atom. The pK_a values in water and in nitromethane are linearly related which suggests that the mechanism of the protonation of arsine oxides in water and in non-aqueous neutral solvents is the same. It is noteworthy that the Ka of arsine oxides in nitromethane are higher than in aqueous solutions approximately by a factor of 10^{11} and that trialkylarsine oxides behave in this solvent as organic bases whose strength is not inferior to that of trialkylamines. The replacement of arsenyl oxygen by sulphur on passing from TAO to a trialkylarsine sulphides $R_3As(S)$ reduces the basicity of these compounds approximately by a factor of 10^9 compared with the corresponding arsine oxides. This confirms the adopted mechanism of the protonation of arsenyl compounds at the oxide oxygen, where the pK_a of arsine oxides constitute a relative measure of the electron density at the oxygen of the arsenyl group. The latter has been confirmed also by the linear relations between the pK_a and the σ constants of the substituents at the arsenic atom for a series of aliphatic-aromatic TAO (Table 1). The best correlations are achieved when the σ^{ph} and σ^* constants are used, the slopes of the resulting relations for the TAO being close to the slopes ρ for tertiary phosphine oxides[149]:

$$pK_a = 3.08 - 1.608\Sigma\sigma^{ph}; \quad r = 0.993, \quad n = 30$$
$$pK_a = 8.26 - 1.570\Sigma\sigma^*, \quad r = 0.980, \quad n = 30.$$

This demonstrates the similarity of the mechanisms of the transmission of the electronic influences via the phosphorus and arsenic atoms and eliminates the need for the introduction of specific arsenic substituent σ constants. A similar confirmation was obtained also in the study of the nucleophilicity of the TAO in the reactions with alkyl halides[150-172], where the rate of formation of the complexes is correlated with the constants σ^{ph}.

IV. ELECTRON-DONATING PROPERTIES OF TERTIARY ARSINE OXIDES

The electron-donating properties of the oxo-bases $RnEO$ (E = N, P, As, or Sb) are determined by the presence of the unshared (lone) electron pairs (LEP) of the oxide oxygen in the upper, energetically low-lying, non-bonding orbital. The first ionisation potentials I_D of these compounds, which determines their electron-donating capacities, refer to the removal of an electron from the molecular orbital (MO), the p_π orbitals of the oxygen atom making the dominant contribution.

Table 1. Parameters of the correlations between the acid dissociation constants of the conjugate acids of arsine oxides and the reaction of constants of substituents: $pK_a = pK_{a_0} - \rho\Sigma\sigma_i$.

σ_i	pK_{a_0}	ρ	r	s	n
σ *para.*	12.654	4.94	0.923	0.44	5
σ^{ph}*	9.619	1.742	0.964	0.33	10
$\sigma^{ph'}$*	8.932	1.835	0.982	0.23	7
σ^*	15.145	1.534	0.958	0.35	9
σ_I^{ph}*	12.996	0.807	0.941	0.42	10
$\sigma_I^{ph'}$*	16.629	0.718	0.989	0.17	8

* σ^{ph}, $\sigma^{ph'}$, σ_I^{ph}, and $\sigma_I^{ph'}$ were taken from Laskorin and coworkers[146,147].

The energies of formation $\Delta H°$ of the donor–acceptor bond (DA bond), the overlap integrals of the interacting atoms DA, and the ionisation potentials of the compounds I_D can serve as measures of the electron density at the donor atom whose LEP are involved in the formation of the donor–acceptor bond. Comparison of these data[173] with the pK_a values shows that none of the above parameters is correlated with the basicity of the compound. The absence of a linear relation between the basicity and the effective charge on the oxygen of the oxide group (δ_O) should be noted particularly, which conflicts with the widely held conviction that the two parameters are equivalent.

Consequently the electron-donating properties of the molecules cannot be characterised with the aid of the basicity of the compounds but require special consideration. Comparison of the enthalpies of formation of the DA complexes between the bases of the type of oxo-bases (B) and acceptors (A) leaves no doubt that there is no direct relation between the quantity δ_O and $\Delta H°_{AD}$. Many investigators believe that the enthalpy of formation of DA complexes is the most suitable parameter for the description of the electron-donating capacity of compounds in processes of the EDA type. Such processes may include the formation of intermolecular hydrogen bonds (IRHB). The most well-founded method of estimating the electron-donating capacity of molecules in the formation of IRHB involves the determination of the thermodynamic parameters of the formation of hydrogen-bonded complexes with a standard acid—phenol in solution in carbon tetrachloride. Bearing in mind that the entropy of this reaction is virtually constant, one may conclude that the change of Gibbs free energy in the series of compounds investigated is caused by the change in the energy of the DA bond formed. Thus the enthalpy $\Delta H°$ is a quantitative characteristic of the electron-donating properties of the TAO in processes of the donor–acceptor type (Table 2).

It has been established[176] that aliphatic arsenic oxides form solid 1:1 complexes with phenol, which have been isolated and recrystallised from appropriate solvents. After the interaction of TAO with catechol, complexes were isolated and their structure was investigated by X-ray diffraction; the strength of the hydrogen bond in these complexes is so great that they sublime without decomposition[177,178]. The products of the interaction of TPAO with aromatic amines and with acid amides are stable 1:1 adducts. Their structure has been established by infrared spectroscopy; they are molecular compounds with an $R_3AsO...H_2NR^1$ hydrogen bond[179]. Complexes with a similar composition are formed when TAO are mixed with toluene-*p*-sulphonamide : $R_3AsO...H_2NSO_2C_6H_4.CH_3$.[180] Much attention has been devoted to the study of complexes of TAO with hydrogen peroxide, which are formed when arsenic oxides are produced by the oxidation of tervalent arsenic derivatives. Infrared spectroscopic data established that the adducts of H_2O_2 with TPAO and triphenylphosphine oxide (TPPO) have similar structures and have a component ratio of 1:2; the components are linked via a hydrogen bond[181]. The presence of a strong TPAO...HO–OH hydrogen bond, much stronger than in the complex with phosphine oxide, has been demonstrated by a study of the infrared spectra of the solution of TPAO in methanol in the presence of an excess of H_2O_2.[51] The adducts of hydrogen peroxide with TAO are therefore formed quantitatively simply on mixing arsenic oxides in solution in toluene with 30% hydrogen peroxide[1].

Table 2. Thermodynamic parameters of the complex formation reactions between tertiary oxides and phenol in solution in carbon tetrachloride[174,175].

Compound	$-\Delta H^\circ$ (ΔA)	$-\Delta H_f^\circ$	K°_{298}	$-\Delta G^\circ_{298}$	$-\Delta S^\circ$
	kJ	kJ	litre mol^{-1}	kJ mol^{-1}	kJ K^{-1}
$(C_6H_5)_3AsO$	—	—	352	14.5	—
$(C_6H_5)_2As(O)C_8H_{17}$	33.4	29.7	3030	19.8	56.0
$C_6H_5As(O)(C_8H_{17})_2$	31.8	33.6	7960	22.2	47.0
$(C_8H_{17})_3AsO$	35.0	36.0	7840	22.7	47.6
$(C_2H_5)_3AsO$	35.7	—	2518	19.4	59.5

$(C_{12}H_{25})_3AsO$	32.4	—	10000	22.7	44.6
$(C_{16}H_{33})_3AsO$	31.0	—	19596	24.4	37.9
$(cyclo\text{-}C_6H_{11})_3AsO$	35.5	38.3	20000	24.5	41.5
$(C_4H_9CH(C_2H_5)CH_2)_3AsO$	31.5	—	7062	21.9	46.7

Among the other molecular complexes of TAO, mention should be made of the adducts with sulphur trioxide formed in the absence of atmospheric moisture[182], the complexes with iodocyanogen, which exist in solution in two different forms[183], and molecular compounds with iodine[67,184,185]. The last compounds are the most important, since the energy of their formation and their physicochemical properties were studied in detail by Mulliken[186] in connection with the development of the theory of charge-transfer complexes. The energy of the DA bond in the complexes of TAO with molecular iodine depends on the structure of the group attached to the arsenic atom and varies within wide limits[67,184].

The examples examined show that the TAO are some of the strongest electron donors and form stable molecular complexes with molecules having a deficiency of electron density at one of the atoms or vacant orbitals. The wide variety of the possible products of such processes is still far from exhausted; presumably further development of this field will open up new prospects for the theoretical and practical employment of organoarsenic compounds.

V. COMPLEXES OF TERTIARY ARSINE OXIDES WITH METAL SALTS

The complex-forming properties of arsenic oxides in relation to metal ions have been known for a long time and tertiary arsine oxides are therefore widely used as ligands in coordination chemistry. The properties of TPAO, from which numerous complexes of different structure and stoichiometry have been obtained, have been investigated in greatest detail. The structure of the complexes of metal salts with triphenylarsine oxide has been studied in fair detail by Goodgame and Cotton[86]. On mixing alcoholic solutions of copper(II) salts with a solution of TPAO, the complexes $[Cu(TPAO)_2Cl_2]$ and $[Cu(TPAO)_2Br_2]$ were obtained. It has been suggested on the basis of the reflection and absorption spectra of these complexes in the visible and infrared regions, X-ray diffraction patterns of the powders, and a comparison of the results of the available data for complex nickel[187], cobalt[188,189], and manganese(II)[87] salts that the complexes synthesised have a tetrahedral configuration.

The enthalpies of solution of the complex $[Cu(MePh_2AsO)_4.ClO_4]ClO_4$ in 0.02M solution of ethylenediamine in dimethylformamide have been measured calorimetrically at 25 °C. Measurements have also been made of the enthalpies of solution of $MePh_2AsO$ and water in the above solvent. The enthalpies of formation of the solid complexes and the reactants in the condensed state have been calculated. Furthermore, calculations have been made of the dissociation energies of the gaseous complex ions and the stabilisation energies of the metal ions in the crystal field[190]. The possibility of synthesising complexes with transition metals by direct precipitation from acetone solution has been investigated[191]. The complexes $CuCl_2(TPAO)_2$ and $CoCl_2(TPAO)_2$ obtained have been identified by elemental analysis. The compounds have been compared with their analogues synthesised by the available literature methods. The synthetic procedures, compositions, and infrared spectra of the complexes of TPAO, trimethylarsine oxide (TMAO), and trioctylarsine oxide (TOAO) with copper have been described[88,192,193].

The complexes of cobalt(II) salts with TPAO and the bidentate compound $Ph_2As(O)(CH_2)_n(O)AsPh_2$ (henceforth designated by L) have been isolated. It has been established that the TPAO forms complexes with a tetrahedral structure in perchlorate solutions and with a distorted octahedral structure in nitrate solutions. The reaction of the dioxide with cobalt(II) gives rise to complexes of the type $LCo(NO_3)_2$ (I), $[L_2(H_2O)_2Co](ClO_4)_2$ (II), and $[L_2Co](ClO_4)_2.2H_2O$ (III). The crystal structures of the complexes have been determined by magnetic and spectrophotometric analysis. It has been suggested[194] that complexes (I) and (II) have the octahedral structure and complex (III) the tetrahedral structure[194]. Somewhat earlier the cobalt complexes were obtained also by other workers[195]. The ligands employed were trimethyl- and tribenzyl-arsine oxides. The cobalt complexes with various TAO have also been examined in a number of other studies[88,192,193,196–198].

Studies of the infrared spectra of the complexes of TPAO with bivalent metal salts of the type ML_2X_2 (where X = Cl, or Br; M = Mn, Fe, Co, Ni, Cu, or Zn), showed that the stretching vibration frequencies of the AsO bonds occur in the range 840–910 cm^{-1}.[88] The authors believe that the coordination of the oxide to the metal salts increases the $\nu(As=O)$ frequency as a result of the superposition of the arsenic–oxygen

and metal–oxygen bond vibrations, which alter only slightly the position of ν(As=O) in the spectrum. In the spectra of similar complexes with methyldiphenylarsine oxide ν(As=O) is at 875 cm^{-1} and there is a shoulder at 866 cm^{-1} as a result of the superposition of the vibrations of the methyl group and the stretching vibrations of the AsO bond.

Phillips and Tyree[193] obtained a whole series of coordination compounds of TPAO with chromium(III), manganese(II), iron(III), cobalt(II), nickel(II), zinc(II), mercury(II), tin(IV), antimony(III), and antimony(V) salts. In their studies on the infrared spectra of these compounds, the authors concluded that the arsenic–oxygen bond has some double bond character as a result of the p_π–d_π overlap of the occupied *d* orbitals of oxygen with the vacant *d* orbitals of arsenic. The coordination of the oxide to electron acceptors reduces the electron density of the π orbital and diminishes at the same time the bond multiplicity and the ν(As=O) frequency.

Generally speaking the ν(As=O) frequency tends to decrease on complex formation, which indicates a decrease of the bond order; the spectra shift on complex formation can be fairly significant. Thus the shift in the spectrum of the complex $HgCl_2$.TPAO reaches 70 cm^{-1}.[92] The change in the ν(As=O) vibrational frequency on complex formation with manganese salts, where the shifts can be both bathochromic[88] and hypsochromic[87,88], is an exception.

The complexes of zinc salts with TPAO and TMAO have been investigated[87,88,189,192,193,196]. The complex $Ni(TPAO)_4.(ClO_4)_2$ was first synthesised in 1971 [199] and was found to have three different isomers. The magnetic moments of all the isomers were determined, chemical analysis was carried out, and the melting points, electronic absorption spectra, and reflection spectra were measured. The results of the study of the nickel complexes with different TAO have been published[17,87,88,189,192,193]. The complexes of molybdenum(V) with TAO,[200] obtained by methods proposed previously[22,201], have been investigated by EPR. Compounds analogous to those already described[22,201] are formed in solution. Analysis of the EPR spectra led the authors to propose two possible structures of the molybdenum complex with a *cis*- and *trans*-disposition of the arsenic-containing ligands in the coordination sphere. The molybdenum(V) complexes of triphenylarsine oxide were also examined in another study[202].

The interaction of $UO_2(CH_3COO)_2.2H_2O$ with TPAO on refluxing in ethanol led to the isolation of the complexes $UO_2TPAO.nC_2H_5OH$.[203] The presence of the 860 cm^{-1} band in the infrared spectra of the complexes confirmed that the formation of complexes with UO_2^+ involves the oxygen of the AsO group. Bearing in mind the high melting point and low solubility of the complex in organic solvents, a polymeric structure was proposed for it with bridging oxygen atoms. The synthesis of the monomeric complexes $UO_2(CH_3.COO)_2.L_2$ and $UO_2[(C_2H_5)_2NCS]_2.L$ and the dimeric complex $[UO_2(CH_3COO)_2.L_2]_2$, where L=TPAO, has been described in a series of communications[204–208]. X-Ray diffraction studies have been made on the compounds obtained, their lattice parameters have been calculated, their molecular weights and molar conductances have been determined, and their infrared spectra have been measured. It has been established that the uranium atoms in the monodentate complex occupy positions at the centres of symmetry of the crystal lattice. The structural parameters of the dimeric complex have been determined by X-ray diffraction and it has been established that uranium(VI) has a coordination number of 7 and that dimerisation takes place via bridging acetate groups.

The complexes of $[UO_2(C_4H_2S_2N)_2]^{2-}$ with TPPO and TPAO have been synthesised and identified by elemental analysis and on the basis of their physicochemical characteristics (colour, melting points, electrical conductivities, and infrared spectra)[209]. It was established that TPAO is a more powerful donor and that the U–O bond in its complex is therefore weakened to the maximum extent. The infrared spectra (in the range 200–500 cm^{-1}) of the complexes $UO_2X_2L_2$ (L=TPAO or TPPO; X=Cl, Br, NO_3, or NCS) have been studied in detail[210]. Comparison with the spectra of the caesium and rubidium complexes[210] enabled the author to carry out new or corrected assignments of the absorption bands. Thus the intense band in the range 247–265 cm^{-1} was assigned to the O–U–O deformation vibrations instead of the metal–nitrate stretching vibration proposed previously. The U–O stretching vibration frequencies in the complexes were found to lie in the range 435–440 cm^{-1}, which indicates unambiguously a stronger bond in the complex with TPAO compared with TPPO. The infrared spectra of TPAO with uranyl nitrate and uranyl chloride have been investigated. In all the cases studied the asymmetric stretching vibration frequency of the AsO group decreases. The values of ν(As=O) have been published for the complex $UO_2(NO_3)_2.2TPAO$, namely 868 cm^{-1} [211] and 862–870,[212,213] while the frequency found for the complex $UO_2Cl_2.2TPAO$ was found to be 848 cm^{-1}.[212] The symmetrical stretching vibration frequency of the U–O group is observed in all cases in the range 910–925 cm^{-1}.

Recent conductimetric and potentiometric studies in anhydrous media demonstrated yet again[214,215] that the ligands containing AsO exhibit a greater capacity for the substitution of chloride ions in the coordination sphere of the uranium atom in UCl_4 than their analogues with the PO linkage. It has been shown by X-ray crystallography that the crystal structure of the complex $UCl_4.2TPPO$ varies as a function of the type of the phosphine oxide substituent[215]. By analogy, the authors decided to investigate the structure of the complex of an arsine oxide with UCl_4. They decided to determine whether or not the strong interaction of the oxygen with uranium leads to a decrease of the U–O bond length. The first compound in the test series was the complex of UCl_4 with triethylarsine oxide. The resulting molecule proved to be centrally symmetrical with four chlorine atoms located in the same plane as uranium and two oxide ligands coordinated to the uranium atom in the *trans*-positions, which leads to the distortion of the tetragonally octahedral arrangement. The bond lengths and the angles are similar to those found previously, but it was discovered that the increase in the length of the UCl bond in the complex with arsine oxide is accompanied by actual shortening of the U–O bond. All the measurements demonstrated convincingly that the interaction with U–O in the example investigated is much stronger than those observed in a wide variety of complexes of phosphine oxides with UCl_4.

The complex of triphenylarsine oxide with $Pu(NO_3)_4$, having the composition $Pu(NO_3)_4.2TPAO$, has been studied in detail[216]. The above communication gives the method of synthesis and infrared spectroscopic data in the range from 200 to 4000 cm^{-1}. It has been established that on complex formation the asymetric stretching vibration frequency of the AsO bond decreases, which is consistent with data obtained previously in the study of the formation of complexes of uranyl nitrate with TPA.[211–213]. As a rule the ν(As=O) frequency is not split on complex formation and in the spectrum of a plutonium complex of TAO there is an intense single band at 850 cm^{-1}. The spectrum of the complex in the visible region indicates the presence of only tetravalent plutonium, although its coordination number is 10. High coordination numbers of the thorium(IV) and thorium(III) complexes had been found previously by X-ray diffraction, amounting to 11 and 12 respectively[217].

Comparison of the frequencies of the nitrato-groups in the plutonium complex with those found earlier for $UO_2(NO_3)_2$. .2TPPO [218] showed that the agreement between them is satisfactory. Bullick[211] assigned the bands at 1515, 1282, 1028, 1032, and 809 cm^{-1} to nitrato-groups, which is fully consistent with data obtained for the plutonium(IV) complex of triphenylarsine oxide[216], where the nitrato-group exhibits bidentate coordination. The 420 cm^{-1} band, observed in the plutonium complex of TPPO, is absent from the spectrum of the TPAO complex. However, a band at 377 cm^{-1} appears in the spectrum of the latter complex, which the authors[216] assigned to the asymetric stretching vibration of the Pu–O bond in the plutonium–oxygen–arsenic group. This assignment is in good agreement with the results of an earlier study of the complexes $MCl_2(TPAO)_2$, where M = Mn, Fe, or Co.[88]

By mixing boiling alcoholic solutions of TPAO and salts of the type $M(NO_3)_3$ (in different molar proportions), where M(III) represents lanthanide elements and yttrium, crystalline complexes of different compositions were obtained[219]. The authors suggested that the alcohol molecule in the complex is coordinated to the M atom and that the complex is a polymer containing NO_3 bridging groups. Infrared spectroscopic data led to the conclusion that the TPAO–M bond is much more stable than the analogous bond in the complexes with triphenylphosphine oxide. A considerable thermal stability of the complexes with the organoarsenic compound compared to the analogous complex with TPPO was noted.

Complexes of lanthanum(III), neodymium(III), and samarium(III) oxides with ethyldiphenylarsine oxide (L) have been synthesised[220]. The complexes isolated were investigated by elemental, magnetic and spectrophotometric analyses. It was established that they are consistent with the fundamental formula $Ln_2Cl_6L_3.xH_2O$ ($x = 0–2$). The high melting points and limited solubilities of the majority of the organic diluents indicate the polymeric nature of the complexes.

More than 25 complexes of the type SnX_4L_2 (where X = Cl, Br, or I; L = TPPO or TPAO) have now been obtained[221]. All the complexes synthesised have been characterised by their infrared spectra and it has been established that in the above series only the *trans*-isomers are produced, with the exception of bidentate structures. A strengthening of the Sn–O bond has been noted and the authors[221] believe that this is caused by the smaller electronegativity of arsenic, the higher polarisability of TPAO, and the smaller contribution of π-bonding in AsO. The tin complexes of triphenylarsine oxide have also been investigated in other studies[193,222–224]. Apart from tin halides, the TAO also react with organotin compounds to form singly- and doubly-charged cationic complexes[225,226], whose structure has been investigated by infrared and ^1H NMR spectroscopy.

It is noteworthy that there is no literature data for the complexes of TAO with alkali metal cations. The complexes $SbCl_3$.2TPAO, $SbCl_3$.2TPPO, $BiCl_3$.2TPAO, and $BiCl_3$.2TPPO have been synthesised and their vibrational spectra investigated in the range 30–1700 cm^{-1}. The structural effects have been examined in terms of the principle of the correspondence between the ν(P=O) and ν(As=O) frequency shifts and the Lewis acidity and basicity of the ligands and the coordination numbers have been calculated. It was established that the difference between AsO and PO is as expected, i.e. TPAO is a stronger base, which is confirmed also by the difference between the metal–oxygen stretching vibration frequencies. A polymeric structure, characteristic also of complexes of heavier elements[227,228], has been proposed for the above complexes. The study of the complex $HAuCl_4$.2TPPO established that the phosphine oxide molecules are not coordinated directly to the metal atom but form a bond with a proton of the chloroauric acid. The complex $[H(TPAO)_2]$. .$AuCl_4$, whose structure is close to that of the complex examined above, was synthesised by an analogous procedure and investigated[229].

The determination of the heats of complex formation made it possible to set up a series based on the electron-donating capacities of different ligands in relation to antimony pentachloride ($Ph_2SeO \cong Ph_3AsO > Me_3PO > Me_2SO$) and tin tetrachloride ($Ph_2SeO \cong Ph_3AsO > Me_3^1PO > Ph_3PO$).[230] The most probable cause of the change in the electron-donating activity is the decrease in the above series of the negative charge on the oxygen atom of the ligand molecule and hence an increase of the multiplicity of the EO bond. The example quoted shows that TPAO is in both cases a fairly powerful ligand, i.e. a compound with a considerable charge at the oxygen atom and a relatively small multiplicity of the bond between the arsenic and oxygen atoms.

Complexes of the type $M(O–O)F_3(TPAO)_2$, where M = Nb or Ta, have been synthesised by a standard method[231]. They are sparingly soluble in organic solvents. The molar conductances indicate a molecular structure of the complexes, which were characterised by the results of elemental, X-ray diffraction, and spectroscopic analyses[231]. The interaction of niobium and tantalum pentachlorides with TPAO led to the formation of complexes with a polymeric structure[232].

Several complexes of manganese(II) salts with TPAO and TPPO are now known, but their stability in air and at room temperature is limited, which significantly hinders their investigation[233]. Our knowledge about their stoichiometry and magnetic and spectroscopic properties is therefore extremely incomplete. The ligands mentioned above have high dipole moments, which in some cases favours the stabilisation of the transition metal complexes, as, for example, in the case of manganese(III) salts. In this connection, synthetic procedures, the results of elemental analyses, and the spectroscopic and magnetic properties of the complexes $Mn(TPPO)_3Cl_3$ and $Mn(TPAO)Cl_3$ have been described. The complexes synthesised are stable in most solvents. Data have been published[233] on their molar conductances in acetone and nitromethane and on their infrared spectra in the range 250–4000 cm^{-1}. The manganese compounds have also been investigated in other studies[87,88,189,192,193].

The reversible and irreversible reactions of iron(III) with the organic bases TPPO and TPAO have been investigated[234] and the equilibrium constants for the formation of 1:1 complexes of TPAO have been determined. It was established that the formation reaction of the complex is a first-order process. The spectra of the adducts have an absorption maximum in the region of 510 nm (TPAO) and 480 nm (TPPO). Complexes of TPAO with iron(II) [235] and mercury(II) [236] salts have been obtained. It has been established that the compounds synthesised have a tetrahedral structure. The iron(II) and iron(III) complexes with trimethyl- and triphenylarsine oxides have been investigated[88,192,193,236].

Rhenium complexes have been described[237,238]. Studies have been made of the complexes of BF_3 with sulphoxides and amine, phosphine, and arsine oxides of the type $R_nXO.BF_3$ (R = Me or Et).[239] The ^1H, ^{11}B, and ^{19}F NMR spectra (at different temperatures) and the ^{31}P NMR spectra have been measured[239]. Data have been published on the complex-forming properties of tribenzylarsine oxide[240].

In conclusion of the discussion of the numerous studies on the complexes of TAO with different metals, one should note that the bond in the complexes investigated is in all cases stronger than in the analogous complexes with organophosphorus compounds. This property of TAO has been used widely in coordination chemistry for the synthesis of new

complexes, which extends our ideas concerning complex formation in aqueous and non-aqueous solutions.

VI. EXTRACTION OF PROTIC ACIDS AND WATER

The greatest number of studies in this field are associated with the extraction of nitric acid. The ability of trialkylarsine oxides or their hydrates to interact with dilute nitric acid in an alcoholic medium has been pointed out in a number of studies[30,241,242]. As a result of such interaction, it has been possible to obtain crystalline salt-like adducts [Alk_3.AsOH]NO_3. The adducts of nitric acid with alkylarylarsine oxides[14,29,30,121] and trialkylarsine oxides[30,57,89,243] are also known.

Numerous X-ray diffraction, infrared spectroscopic, and spectrometric data for the adducts of acids with TAO established two possible structures of the latter in the solid state:

(a) $R_3AsO...HX$—structure presupposing the presence of a hydrogen bond;

(b) $[R_3AsOH]^+X^-$—ionic structure.

The structure of the 1:1 adducts of TAO with acids depends in each specific case on numerous factors, the principal of which are the nature of the acid anion and the strength of the base.

In a study of the electrical conductivity of the adducts of triphenylarsine oxide with nitric acid in acetonitrile it was established[243] that the adduct partly ionises under the influence of the solvent. In addition, the interaction of Rh_3AsO or its hydrate with concentrated HNO_3 yielded triphenylarsine dinitrate $Ph_3As(NO_3)_2$. The compound is extremely hygroscopic and readily hydrolyses in the presence of traces of moisture. A crystalline complex of triphenylarsine oxide with nitric acid precipitates from a solution of triphenylarsine dinitrate in acetone treated with petroleum ether. A detailed study of the extraction of nitric acid has been carried out[244] and the authors showed that the interaction of the acid and the organic base takes place in steps and reduces to a gradual substitution of the water molecules in the structure of the hydrated extractant. Thus at a HNO_3 concentration of 0.1–1.0M the product is a 1:1 adduct with coextraction of water. With increase of the acid concentration, the acid : reagent ratio increases with a corresponding decrease of the water : acid ratio.

It has been suggested[244] that the complex has the composition $R_3AsO.XHNO_3.YH_2O$ with variable values of X and Y depending on the concentration of nitric acid in the aqueous phase and of the extractant in the organic phase. The nature of the associated species formed by water and nitric acid with the organic base has been studied in detail[245,246]. The extraction of HNO_3 into solutions of triphenylarsine oxide in dichloroethane has been studied by both partition and infrared spectroscopic methods. The fractions of free, hydrated, and protonated oxide were determined as logarithmic functions of the ionic activity of nitric acid in the aqueous phase, which was calculated from the corresponding (adjusted to the equilibrium activity of water in the aqueous phase) hydration constants, the protonation constant, and the ionic activity of nitric acid. It was noted that in the case of trioctylphosphine and triphenylarsine oxides the concentration of free oxide (relative to triphenylphosphine and tribenzylphosphine oxides) is too low to be taken into account.

The determination of the energetic characteristics of the hydration of neutral arsenyl compounds is necessary both from the point of view of understanding and a quantitative description of the extraction processes and for the establishment of the electron-donating capacities of these derivatives using water as the reference electron acceptor[247]. For this purpose, the standard enthalpies ΔH°, entropies ΔS°, free energies ΔG°_{298}, and equilibrium constants K^θ of the process[248]:

$$R_3As(X) + H{-}O{-}H \rightleftarrows R_3As(X)\ldots HOH \quad (X=O,\ S)$$

were determined in CCl_4 solution by infrared spectroscopy.

When water is added to solutions of TAO in CCl_4, a narrow intense band at 3700 cm^{-1} (ν_S) and a broad diffuse band at 3280–3300 cm^{-1} (ν_{as}) appear in the infrared spectra, their intensity increasing with increasing concentration of water in the solution. At the same time the stretching vibration frequency of the arsenyl group $\nu(As=O)$ shifts from 890 cm^{-1} to 875 cm^{-1}, which implies that the complex $R_3AsO...H_2O$ is formed under the experimental conditions via an intermolecular hydrogen bond between the water protons and the unshared pairs of the oxygen atom of the arsenyl group.

The calculated hydration constants of arsine oxides are significantly higher than those obtained for phosphine oxides[247]. Contrary to expectation, the replacement of alkyl groups at the arsenic atom by aryl group has little effect on the hydration constants, which decrease only slightly in the sequence trioctylarsine oxide > dioctylphenylarsine oxide > octyldiphenylarsine oxide. The sequence of hydration constants for arsine oxides is fully consistent with the reactivity series calculated on the basis of the complex formation reaction with phenol. The hydration of arsine oxides in solution in CCl_4 is an isoenthalpic reaction, like their complex formation reaction with phenol[174].

In contrast to arsine oxides, arsine sulphides $R_3As=S$ are weaker bases and the constants for the formation of their complexes with water are lower. In solution in CCl_4 it is impossible to determine the hydration constants of these compounds owing to the low concentration of the hydrated form even under the conditions of the complete saturation of the organic solution with water. The equilibrium constant for the process changes little with the length and structure of the groups at the arsenic atom and these changes are wholly determined by entropic factors. In contrast to this, the thermodynamic characteristics of the hydration reaction of phosphoryl compounds depends significantly on the nature of the substituents at the phosphorus atom[249]. Thus the changes in the reactivity of the organophosphorus and organoarsenic extractants in the hydration reaction are due to different causes, which must be taken into account in determining the relation between the electronic structure of these compounds and their reactivity.

The infrared spectra of organic solutions of TPPO and TPAO saturated with nitric acid (equilibrated with an aqueous HNO_3 solution) have two fundamental features[245,246]: (a) with increase of the activity of nitric acid, the intensity of the characteristic absorption bands of the monohydrate falls; (b) the PO and AsO stretching vibrations are displaced towards lower frequencies. The latter data yield reliable information about the nature of the bond between nitric acid and the phosphoryl or arsenyl oxygen in the protonated form. More detailed information about the nature of the bond in the complex $TPAO.HNO_3$ was obtained with the aid of the infrared spectra of the organic phase equilibrated with 2M acid and also the infrared spectra of the solid deposit $TPAO.HNO_3$ in an emulsion with hexachlorobutadiene[246]. The considerable (~100 cm^{-1}) splitting of the ν_3 band due to the antisymmetric vibration of the nitrate ion at 1380 cm^{-1} indicates the interaction of the nitrate ion with the cation. The authors attribute it to a protonated structure of the type $TPAO...H^{\delta+}-NO_3^{\delta-}$ with incomplete transfer of the proton. The possible structure of the mixed associated species can be represented

in the following form on the basis of the analysis of the infrared spectra:

$$\begin{matrix} \text{TPAO}\ldots\text{H} \\ \text{TPAO}\ldots\text{H} \end{matrix}\!\!>\!\text{O}\ldots\text{H}^{\delta+}\!-\!\text{NO}_3^{\delta-}\ .$$

The hypothesis of the partial proton transfer from the acid to the oxygen atom of water was subsequently confirmed by the absence of bands due to the H_3O^+ ion in the spectrum of the mixed associated species. Analogous results had been obtained earlier[244]. According to Rozen and Nikolotova's data[250], the complex TPAO.HNO_3, where nitric acid fully displaces water from the organic phase, is extracted into the latter. Similar conclusions were reached in the study of the infrared spectra of solutions of trioxylarsine oxide in CCl_4 after contact with water and nitric acid[251]. The decrease of the intensity of the absorption bands due to the stretching vibrations of free and bound water at 3695 and 3350 cm^{-1} and the $\nu(As=O)$ band at 890 cm^{-1} indicates the displacement of nitric acid by water from the organic phase and the formation of the monosolvate $R_3AsO.HNO_3$.

When the benzene ring is replaced by the octyl group under comparable conditions, the HNO_3 extraction constant increases by a factor of almost 7 in the sequence of $Ph_3AsO < Ph_2As(O)Oct_2 < PhAs(O)Oct_2 < Oct_3AsO$.[251] The extraction constant also increases with increasing length of the group R on passing from aliphatic to alicyclic substituents (Table 3). The extraction capacity of arsine oxides is linearly related to their reactivity in processes of the donor–acceptor type, which confirms in its turn the qualitative conclusions concerning the decisive role of the basicity of arsine oxides in the liquid extraction of inorganic acids and salts. At the same time there are no grounds for isolating trialkylarsine oxides in a separate group of extractants, extracting nitric acid via special mechanisms different from that of extraction by TPAO. It is most probable that one is dealing with a purely quantitative increase of the extraction constant as a result of the replacement of aryl groups by alkyl groups. In this case arsine oxides are full analogues of phosphine oxides for which such properties are well known.

Table 3. Effective constants for the extraction of nitric acid from aqueous solutions by solutions of arsine oxides in carbon tetrachloride[251].

Extractant	$\bar{K}_{HNO_3}$	Extractant	$\bar{K}_{HNO_3}$
$(C_6H_5)_3AsO$	2 220*	$(C_8H_{17})_3AsO$	16 020
$(C_6H_5)_2As(O)C_8H_{17}$	7 630	$(C_9H_{19})_3AsO$	21 390
$C_6H_5As(O)(C_8H_{17})_2$	10 910	(cyclo-$C_6H_{11})_3AsO$	37 250

* In dichloroethane.

The results obtained demonstrate a sharp (by a factor of 10^3) increase of the extraction capacity of arsine oxides compared with their organophosphorus analogues. This phenomenon is difficult to account for, particularly since some workers have adopted the concept of the p_π–d_π conjugation of the unshared electron pairs of the arsenyl oxygen with the vacant 4d orbitals of the arsenic atom. In this case the entire difference between the organophosphorus and organoarsenic compounds reduces to a slight difference between the electronegativities of the phosphorus and arsenic atoms (2.19 and 2.18) and the longer bond lengths for arsenic owing to the greater radius of the latter ($r_P = 1.10$ Å, $r_{As} = 1.21$ Å), while the hybridisation is virtually the same.

These differences do not explain the considerably greater basicity and reactivity of the arsenyl compounds and also the different energy and force constant of the $\geqslant$As–O bond. The model of the arsenyl group with the coordinate bond $\geqslant As^+-O^-$ and only slight conjugation of the arsenyl oxygen with arsenic is more justified. In this case TAO are more likely to be analogues of *N*-oxides than phosphine oxides, which is manifested when the reactivities of these classes of compounds are compared.

Bearing in mind that one of the causes of the increase of the reactivity of the compound R_3EO is the size of the atom E, a number of workers[252–256] attempted to classify the changes in extraction capacity in the series R_3NO–R_3PO–R_3AsO–R_3SbO ($r_N = 0.75$ Å, $r_P = 1.11$ Å, $r_{As} = 1.24$ Å, $r_{Sb} = 1.41$ Å). The increasing basicity of oxygen when phosphorus is replaced by arsenic is caused, in their view, by the decrease of the energy of the element–oxygen bond, as shown by the infrared spectroscopic data for the oxides of the trialkyl derivatives of Group VB elements: $\nu(P=O) = 1170$ cm^{-1} and $\nu(As=O) = 884$ cm^{-1}. The force constant for AsO is smaller by a factor of 1.47 than for PO. The bond energy is reduced as a consequence of the increase of the interatomic distance and also apparently owing to the difficulty of the interaction of the 2p electrons of oxygen with a vacant 4d orbitals of arsenic. Furthermore, the changes in extraction capacity in the series $R_2CO < R_2SO < R_3PO < R_3AsO < R_3SbO$ is explained also by the different electronegativities of the elements, which decreases in the above series of extractants as a consequence of the variation of the amount of ionic character of the element–oxygen bond, the degree of covalence, and bond strength.

The structure of the groups R at the arsenic atom has a significant influence on the partition of nitric acid between water and organic phases. The claim[252] that the mechanism of the extraction of nitric acid changes abruptly on passing from aryl to alkyl organic derivatives of tetracoordinate arsenic is problematical. The authors put forward the variant[252] in which the increase of the basicity of the compound leads to the replacement of the hydrogen bond by proton transfer. Incidentally, in the last study by the same investigators[257], devoted to the formation of complexes by nitric acid with phosphine, arsine, and amine oxides, a linear relation was established between the degree of extraction of nitric acid and the number of phenyl substituents in the molecules of TAO, which disproves an abrupt alteration of the properties in the given reaction series.

Noting the appreciable progress in the study of the extraction of nitric acid by TAO achieved by Rozen et al.[257], we may remark that their conclusions[257] and those of the present authors[251] are quite identical although the two groups of investigators base them on different extraction mechanisms (solvate and ionic respectively). It is extremely probable that the properties of nitric acid extracts in the systems investigated depend significantly on the experimental conditions such as temperature, the type of diluent employed, and the concentrations of the extractant and acid. One can claim with much justification that the extraction of nitric acid by dilute solutions (<0.01M) of TAO in CCl_4 at 25 °C and an HNO_3 concentration <0.01M proceeds via the solvate mechanism. This is supported by the internally consistent linear relations between the free energy of the extraction of HNO_3 and the analogous quantities for donor–acceptor processes[258].

The parallel variation of the free energies of all the reactions considered with the structure of the groups attached to the arsenic atom for a constant reaction centre (arsenyl oxygen) shows that there is no doubt that the donor–acceptor

processes involving TAO obey linear free energy relations (Table 4). For the reactions of arsenyl compounds with acids in organic solvents, the best results have been obtained using the constants σ^*, which ensure high correlation coefficients r for low values of s. The use of the resonance constant σ_R and the overall constants σ, describing the joint inductive and resonance influence of the substituents on the reaction centre, proved successful only for Kabachnik's overall constants σ^{ph} introduced for substituents attached directly to the phosphorus atom.

Table 4. Relation between the free energies (kJ mol^{-1}) of donor–acceptor processes and the reaction constants of substituents: $-\Delta G_i = \Delta G_0 + \rho\Sigma\sigma_i$.

ΔG_i	σ_i	ΔG_0	ρ	r	s	n
$-\Delta G^0_{HNO_3}$	σ^*	23.65	−0.5494	0.94	0.1824	5
$-\Delta G^0_{HNO_3}$	σ^Φ	13.73	−0.7779	0.96	0.1499	5
$-\Delta G^0_{H+(CH_3NO_2)}$	σ^*	6.72	−0.0643	0.97	0.0124	9
$-\Delta G^0_{H+(CH_3NO_2)}$	σ^Φ	5.76	−0.0751	0.96	0.0145	10
$-\Delta G^0_{H+(H_2O)}$	σ^*	3.06	−0.1546	0.99	0.0182	6
$-\Delta G^0_{H+(H_2O)}$	σ^Φ	0.78	−0.1861	0.95	0.3122	6

Thus, within the limits of the series of compounds investigated, the description of the reactivity of arsenyl compounds in processes of the EDA type does not require the introduction of new constants for substituents attached directly to the arsenic atom and one can employ the tabulated σ^* and σ^{ph} constants. The above correlation analysis also permits the conclusion that the mechanism of the transmission of electronic influences in the molecules of organoarsenic compounds is predominantly inductive. At any rate, the resonance interaction between the benzene ring and the arsenic atom observed by physicochemical methods in aromatic arsine oxides does not have an appreciable influence on the reactivity of the organoarsenic compounds. The correlation of the electron-donating capacity of arsine oxides with the overall constants σ^{ph} does not conflict with the inductive model of the transmission of the electronic influences in the molecules of organoarsenic compounds[259], since according to some investigators[258] the inductive component predominates in σ^{ph}.

It is noteworthy that no less attention has been devoted to the study of the products of the interaction of TAO with hydrogen halides than to the extraction with nitric acid. However, the proposed extraction system with HCl has still been relatively little investigated. The model of the extraction with HCl is analogous to that proposed previously for nitric acid, i.e. with increase of the concentration of the acid its molecules displace water molecules combined with the organic base[244]. The infrared spectra of the solid adduct of hydrochloric acid with TPAO have been investigated and the authors observed a complex high-intensity absorption in the range 2000–2750 cm^{-1}, which is a feature of the hydroxy-group involved in a strong hydrogen bond [57]. The behaviour of the adduct in acetonitrile made it possible to classify it as a weak electrolyte.

The oxides of 10-alkyl(aryl)-5,10-dihydrophenarsazines react with HCl in an aqueous alcoholic medium or boiling benzene and give rise to a 1:1 adduct[260]. According to the authors, the structure of the adduct presupposing the presence of a hydrogen bond without proton transfer is the most probable. A detailed study of the HBr and HI systems showed that the extraction behaviour of the two acids is similar[244]. Thus, at an initial concentration of the aqueous acid of 0.1–2.0 M they give rise to 1:1 adducts. The coextraction of one mole of water for each mole of the acid is observed also below the concentration indicated. The tertiary arsine oxide–HBr and HI systems have also been studied in other investigations[57,89,260]. Special experiments[261] demonstrated the possibility of isolating tertiary arsine dihalides as a result of the interaction investigated. It was found that, in the presence of a sufficient excess of the acid, the dihalides become the main reaction products, which is only possible when their resistance to hydrolysis is fairly high.

Among all the acids investigated, perchloric acid exhibited the most distinctive extraction characteristics[244]. Saturation is attained at an acid concentration of 0.1 M and the resulting adduct has the composition $R_3AsO : HClO_4 = 1:1$. It has also been established that each mole of water is coextracted with a mole of perchloric acid entering the organic phase. The interaction of perchloric acid with TPAO has been studied in detail[57]. The compound obtained contained the triphenyloxyarsonium cation, since the high measured conductivity in acetonitrile (λ, cm^2 equiv.$^{-1}$ Ω^{-1} > 100) showed that the compound has an ionic structure. It is known that chloroacetic acids can be arranged in the sequence monochloroacetic acid < dichloroacetic acid < trichloroacetic acid in terms of their strength. Spectroscopic study of the products of the interaction of TAO and the acids in proportions of 1:1 showed that the infrared spectra of the solid adducts can be divided into three types[89,134,262].

1. The infrared spectrum of the adduct of the base with the weak monochloroacetic acid contains three main bands in the range 1800–3000 cm^{-1}. The intensity of these bands changes in accordance with the strength of the acid or the base. A weak hydrogen bond is characteristic of such adducts.

2. The bases investigated form adducts with the strong trichloroacetic acid, whose spectrum does not contain bands characterising the hydroxy-group but there is a broad and intense band in the region of low frequencies. The $\nu(As=O)$ band shifts towards lower frequencies. The spectrum is analogous to those of substances with symmetrical hydrogen bonds without proton transfer to the oxygen of the base. According to the above investigators, the strongest hydrogen bond is characteristic of such adducts. It has also been established that a change in the state of the substance does not entail considerable changes in the spectrum. Analogous results were also obtained by Abalonin et al.[260].

3. The spectrum of the adducts of dichloroacetic acid with TPA changes with the state of the substance[262]. The authors regard this as an intermediate spectrum between the two spectra discussed above. The study of the infrared spectrum of the adducts of dichloroacetic acid with trimethylarsine oxide demonstrated a strong hydrogen bond with proton transfer[262]. A triplet at 1720, 1655, and 1580 cm^{-1} in the region of the band of the antisymmetric vibrations of the CO_2 group was isolated in the spectrum. The addition proton bands at 1720 and 1580 cm^{-1} disappear on deuteration.

The ability of tertiary arsine oxides to interact with picric acid with formation of a crystalline salt is frequently used to isolate them[29,263–265]. It has been established that methylenebis(diphenylarsine) oxide reacts with picric, styphnic, and picrolonic acids, forming the corresponding hydroxypicrates, hydroxystyphnates, and hydroxypicrolonates[16].

The data considered in this Section show that the interaction of TPAO with protic acids (Brønsted acids) is a complicated process whose mechanism is determined by the type of

acid considered. Changes in the structures of the groups attached to the arsenic atom have little influence on the extraction capacity of the compounds, causing purely quantitative alterations within the limits of a single extraction mechanism. On the other hand, a change in the type of acid extracted frequently alters the nature of the interaction of the acid with the extractant from complexes with a weak hydrogen bond to the formation of purely ionic structures. This property of organoarsenic extractants must be carefully taken into account in the study of the extraction of metal salts from acid aqueous solutions.

VII. EXTRACTION OF METAL SALTS

The study of the complex-forming capacity of different classes of organoarsenic compounds led to the discovery of certain effective extractants among them. Thus in a series of studies Rozen and coworkers[250,252-256] investigated the influence of the structure of the reaction centre on the extraction and compared the extraction capacities of trioctylphosphine, triphenylarsine, and trioctylarsine oxides. They established that the reaction capacities of the organophosphorus and organoarsenic oxides are approximately described by a common equation, the maximum extraction capacity being virtually obtained for arsine oxides. It was noted that, in contrast to the extraction with R_3PO, inorganic acids cannot displace metals from the organic phase containing aromatic arsine oxides[250,252-256].

The extraction of metal anions of the type ReO_4^- and TeO_4^- from a 1M solution of hydrochloric acid has been studied. The extraction constants obtained differentiate appreciably the organoarsenic compounds from their phosphorus-containing analogues. The authors[252-256] see the cause of this finding in the different capacities of the oxides for protonation due to the nature of the PO and AsO bonds[137].

The possibility of the extraction of more than 40 elements by trioctylarsine oxide was tested by activation analysis and a detailed study was made of the extraction of iron(III), zinc(II), cadmium(II), hafnium(IV), and zinc(IV).[266] The authors' determination for the equilibrium constants for the formation of the zinc and cadmium halide complexes are of great importance for the estimation of the reactivity of the extractant. At the same time it was established that the extraction of hafnium and zirconium differs appreciably from the extraction of the above elements by phosphine oxides. The principal difference consists in the exceptional stability of the ion $(Oct_3AsOH)^+$, formed with the increase of the acid concentration, whose presence in solution sharply reduces the degree of extraction of metal ions[266].

In order to elucidate the nature of the interaction between the extracted metal and trioctylarsine oxide, a study was made by vibrational spectroscopy of the composition of the extracts formed in the extraction of molybdenum(VI) from sulphuric acid solutions. It was shown that trioctylarsine oxide effectively extracts molybdenum(VI) from sulphuric, hydrochloric, and nitric acid solutions. Regardless of the type of acid, the maximum extraction is observed in the pH range 2–3. It has been established[267] that molybdenum(VI) is extracted from sulphate solutions in the form of molybdenum-containing acids. The above data are fully consistent with the results of the study of the extraction of $CoCl_2$ by R_3NO, R_3AsO, and R_3PO solutions in benzene and CCl_4.[66] The effective constant for the extraction of cobalt decreases by five orders of magnitude, regardless of the solvent, on passing from R_3NO, to R_3AsO, and R_3PO.

The possibility of the quantitative extraction of uranyl nitrate was first investigated by Pietch and Nagl[268]. In the study of a solution of TPAO in chloroform they showed that uranyl ions are fully extracted from nitric acid solutions at pH 2–3. The addition of $NaNO_3$ or $Ca(NO_3)_2$ increases the partition coefficient and extends the limits of effective extraction. The use of EDTA in the process permits the selective extraction of uranium[269]. A study was published later in which methods for the selective extraction of iron(III), in particular in the presence of uranium(VI), were considered at a hydrochloric acid concentration ≥ 8 M.[270]

Among the transuranium elements (M^{3+}), a study has been made of the extraction of americium(III), curium(III), and promethium(III) into cyclohexane solutions of trioctylarsine oxide from aqueous solutions with a variable content of nitric acid and lithium nitrate[271]. The similarity of the dependences of the partition coefficients of M^{3+} on the concentrations of HNO_3 and $LiNO_3$ at constant concentrations of trilaurylamine and trioctylarsine oxide as extractants led the authors to the conclusion that the compound extracted is the complex $TOAO.HNO_3$. It has also been established that, in the case investigated, the extraction properties of trioctylarsine oxide differ significantly from those of its phosphorus-containing analogue. In extraction with a mixture of trilaurylamine and trioctylarsine oxide a synergistic effect is observed, its magnitude depending little on the ratio of the extractants and the nature of M^{3+}. When the organoarsenic compound in the above mixture is replaced by the analogous phosphorus-containing ligand, both synergistic and antisynergistic effects are observed.

The extraction of actinides with TAO has been studied in greatest detail[272] in relation to the partition of trace amounts of uranium, plutonium, and neptunium in different oxidation states between aqueous nitric acid solutions and solutions of aliphatic and aromatic arsine oxides in dichloroethane. On the basis of the linear relations between $\overline{K}_{HNO_3}$ and the constants for the extraction of the actinides (An) by trialkylarsine oxides, one should expect in the given reaction series a parallel increase of $\overline{K}_{An}$ with a sharp increase of the extraction constants owing to the transition to an ion-exchange process mechanism. It has been shown[272] that all the tertiary arsine oxides investigated are powerful extractants of transuranium elements and have values of $\overline{K}_{An}$ ranging from 10^8 to 10^{11} depending on the type of ion extracted, its oxidation state, and the structure of the extractant investigated. The extraction constants of the actinides increase in the sequence Pu(IV) < Np(IV) < Np(VI) < U(VI) < Pu(VI), reaching 10^{11} mol^2 litre^{-2} in the extraction of plutonium(VI).

These values exceed by more than three orders of magnitude the constants for the extraction of the actinides by the isomeric phosphine oxides and are among some of the highest of all those known at the present time. The sequences corresponding to the extractability of metals by phosphine oxides and arsine oxides are the same, which is an argument in support of a single mechanism of the extraction of the actinides by the organoelemental extractants R_3EO with E = P or As. The fact that, regardless of the degree of oxidation, the partition coefficients K_D and extraction constants $\overline{K}_{An}$ of all the actinides investigated decrease on substitution of the phenyl groups in the arsine oxide molecule by octyl substituents merits special attention[273].

The quantitative relations between the basicities of a number of TAO with aromatic and aliphatic substituents at the arsenic atom and the constants for the extraction of the actinides from aqueous nitric acid solutions have been investigated[274]. The linear relation between $\overline{K}_{HNO_3}$ and pK_a implies that the partition of protic acids between aqueous and organic phases under standard conditions for the given

series of compounds is determined by the basicity of the arsenyl oxygen and hence can serve as a measure of its electron-donating capacity. On passing from protic to aprotic metal salts, the linear relations between the pK_a of the compounds and the extraction constants persist, but the increase of the basicity of the TAO (in contrast to their phosphorus-containing analogues) is accompanied by a decrease of the extraction capacity in relation to all the actinides investigated.

The attempt to describe the extraction of the actinides in terms of indices of the electron-donating capacity ($K_{HOC_6H_5}$ and ΔH_T°) proved less successful, since the correlation parameters of these equations were somewhat impaired. It has also been established[274] that the values of $\overline{K}$ for HNO_3 and the actinides are linked by linear relations, but, in contrast to the organophosphorus extractants, they vary in opposition, i.e., after the successive substitution of the aryl groups R by alkyl groups, the extraction capacity of R_3AsO increases in the extraction of protic acids and decreases in the extraction of the actinides.

Thus arsenic compounds have specific features which distinguish them from organophosphorus derivatives and are related to the specific features of the electronic and steric structures. Both these factors can give rise to the observed effect, but, in the absence of non-empirical quantum-chemical calculations for arsenic compounds and thermodynamic parameters of the extraction equilibria involving organoarsenic derivatives, one cannot at the present time give preference to any one of the possible explanations. However, the results obtained leave no doubt that the use of organoarsenic extractants in the far-reaching elimination of radioactive and toxic elements from aqueous solutions is promising. It may be hoped that, with expansion of studies using TAO, other applications of this interesting class of organoelemental compounds will be discovered in both analytical and coordination chemistry and in hydrometallurgical sorption-extraction processes.

Synthesis of Nitrogen-containing Compounds by the Interaction of Nitro-compounds with Carbon Monoxide

V.I.Manov-Yuvenskii and B.K.Nefedov

The methods and catalysts for the synthesis of nitrogen-containing compounds (oximes, Schiff bases, amides, imides, amines, ureas, urethanes, isocyanates, and azo-compounds) by the interaction of nitro-compounds with carbon monoxide are considered. The reaction mechanisms are discussed and the characteristics of the synthesis of mono- and di-isocyanates are noted.
The bibliography includes 128 references.

I. INTRODUCTION

The catalytic interaction of nitro-compounds with carbon monoxide, which is a new and little investigated field of organic catalysis, has become in recent years one of the currently most important fields of industrial organic synthesis. The reason for this is that a whole series of industrially important compounds can be obtained from nitro-compounds and carbon monoxide in a single stage: azo-compounds, amides, amines, oximes, urethanes, ureas, and isocyanates.

The synthesis of oximes by the reduction of aliphatic nitro-compounds with carbon monoxide constitutes a new approach to the solution of the problem of synthesising intermediates in the manufacture of caprolactam. Urethanes and ureas are important final products and intermediates in the synthesis of fertilisers and pesticides and the development of a method of the direct synthesis of these compounds is of undoubted interest.

Aromatic mono- and di-isocyanates are valuable intermediates in the manufacture of pesticides, rigid and elastic polyurethane foam plastic (widely used in building, furniture, refrigeration, and transport industries), synthetic leather, adhesives, and coatings[1-3]. The world production of isocyanates during the period from 1970 to 1975 doubled and according to predictions will continue to grow at the same rate[4]. In the USA the annual increase is 9% and by 1980 the total production based on isocyanates will exceed 1 million tonnes annually[5]. However, the requirement for isocyanates is by no means fully satisfied, since their modern production is based on the obsolete method involving the treatment of amines with phosgene. In the course of the last decade intense research has therefore been prosecuted in order to develop a new and much more economical method of synthesising isocyanates by carbonylating nitro-compounds. The assembly of the first experimental plant is already being completed in Japan and in 1980 it is planned to begin the manufacture of isocyanates by the new method[6].

This review gives a systematic account of the advances in the last 7–10 years in the field of the catalytic synthesis of nitrogen-containing compounds (oximes, Schiff bases, amides, imides, amines, ureas, urethanes, isocyanates, and azo-compounds) by the interaction of CO and nitro-compounds. Attention is concentrated on the catalysts and the process conditions; furthermore the synthetic possibilities of the method involving the carbonylation of nitro-compounds and the prospects for its employment in organic synthesis are demonstrated.

II. THE PRINCIPAL FACTORS INFLUENCING THE INTERACTION OF NITRO-COMPOUNDS WITH CARBON MONOXIDE

When an attempt is made to arrange systematically the reactions of nitro-compounds with CO (see Table), two principal types of interactions can be distinguished: the reduction of nitro-compounds without the addition of CO to the latter and the addition of a CO molecule to the intermediates in the reduction process (carbonylation). The reaction pathway is in many respects determined by both the catalyst and the reaction conditions, on the one hand, and by the nature of the third component, which in most cases plays the role of the reaction medium, on the other.

The interaction of CO with nitro-compounds is a thermodynamically favourable process[7], but in the absence of a catalyst it proceeds with much difficulty. This is probably due to the high activation energy for the reaction with the reactants being readily activated when adsorbed on the catalyst.

By varying the nature of the catalyst, the reaction medium, and the reaction conditions (temperature, pressure, and reaction time), it is possible to alter both the reaction pathway and the yield of products and the selectivity of their formation. We shall consider the influence of the principal factors on the interaction of nitro-compounds with carbon monoxide.

Catalyst

Transition metals (as a rule Group VIII metals), copper salts, sulphur, and selenium and its compounds, which are capable of forming complexes with both CO and with the nitro-compound, catalyse the reactions of nitro-compounds with carbon monoxide. In the vast majority of cases the reaction proceeds in the liquid phase in the presence of homogeneous catalysts, although instances of the use of heterogeneous catalysts of analogous composition are known.

Despite the lack of data on the comparative activities of the known catalysts, analysis of the available publications (frequently contradictory) permits the conclusion that best results are obtained using palladium and rhodium compounds. Here one should note that the activity of the same compound is greatly influenced by the type of promoting additive and its amount, the nature of the third component, temperature, and carbon monoxide pressure. Tertiary amines, for example pyridine, quinoline, and their derivatives, quaternary ammonium salts, phenylphosphines, and salts of Group IIB, V, VI, and VIII transition metals, particularly vanadium, molybdenum, tungsten, copper, and iron, as well as lanthanide compounds can be used as activators of the palladium and rhodium catalysts.

Synthesis of nitrogen-containing compounds by the catalytic interaction of nitro-compounds with carbon monoxide.

Catalyst	Third component	t, °C	p, atm	Reaction product
—	—	250	3000	Azobenzene

Se and its compounds	Alcohols	170	50	Urethanes

*In aqueous solutions of highly basic amines.
** On a carrier with added $FeCl_3$ and (or) pyridine.
*** With activating additives.
**** In pyridine.

The reduction and carbonylation reactions of nitro-compounds can also proceed stoichiometrically under mild conditions if CO is first bound in active carbonyl complexes, for example of the type of $Fe(CO)_5$ or iron acyl carbonyls.

Temperature

The process temperature is selected depending on the catalyst employed, the third component, and the CO pressure. For example, in the presence of $PdCl_2$ as the catalyst and activators, the carbonylation of nitro-compounds to give substituted ureas in solution in amines proceeds at 90 °C and atmospheric pressure; in order to synthesise isocyanates in an inert solvent or urethanes in alcohols, a temperature of 150—200° and a pressure of 50—100 atm are required. When $RhCl_3$ is employed as the catalyst in the presence of promoting agents, amines are formed at 150 °C (50—120 atm), ureas at 190 °C (200 atm), isocyanates at 120—200 °C (up to 300 atm), and urethanes at 150—230 °C (100—400 atm).

The process temperature influences in its turn both the degree of conversion of the initial nitro-compounds and the selectivity of its transformation. In the general case one should note that, in order to obtain practically acceptable yields of the desired product with a sufficiently high selectivity, the reaction must be performed at 100—200 °C under an increased CO pressure. At a lower temperature the rate of reaction is low, while an increase of temperature above 200 °C as a rule leads to undesirable side reactions, in particular to tar formation, which lowers the selectivity and deactivates the catalyst.

Carbon Monoxide Pressure

The working pressure depends on the nature of the nitro-compound, the catalyst, the third component, and the temperature. For example, mononitro-compounds are converted into isocyanates at a pressure of 50—100 atm, while, other conditions being equal, the dinitro-compounds require 200 to 300 atm. The reduction of nitro-compounds to amines, azo-compounds, amides, and imides proceeds at a lower pressure than their carbonylation to urethanes or isocyanates, which is apparently associated with the activating effect of the third component on the catalyst.

In addition, an increased CO pressure is necessary to maintain the catalytic complex in an active equilibrium state, which is characteristic of the majority of catalytic reactions of organic compounds involving carbon monoxide and occuring in the presence of carbonyl complexes of transition metals. In the synthesis of isocyanates by the carbonylation of nitro-compounds an increase of pressure (beyond the minimum value required for each catalyst) increases the productivity and makes it possible to reduce the reaction temperature to some extent.

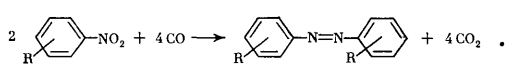
The Third Component

The presence of the third component in the reaction system influences both the reaction pathway and the activity of the catalyst. The third component can be a reactant and (or) the reaction medium. Typical third components which are reactants in the reactions of nitro-compounds with CO are H_2 and aldehydes; hydrogen donors such as water, alcohols, and amines are also used as both the reactant and the reaction medium, while inert solvents, for example, aromatic and aliphatic hydrocarbons, chlorobenzene, or dichlorobenzene are used as inert solvents.

If the nitro-compound reacts with CO in an inert solvent, then mainly isocyanates are formed, two out of the three reacting CO molecules functioning as reductants. In the presence of H_2 in the reaction system, the nitro-compound is as a rule reduced to the amine; sometimes substituted ureas are formed together with the amine, possibly as a result of the carbonylation of the amine formed initially. Aldehydes and hydrogen donors such as amines and alcohols interact either with the catalyst in the complex with the deoxygenation product of the nitro-compound or with the isocyanate formed, giving rise to the corresponding derivatives. Stable compounds, for example, Schiff bases, ureas, and urethanes, can be isolated from the reaction mixture as the products; unstable compounds, for example carbamic acids or their anhydrides, which can be formed in water or acetic acid,

decompose with the evolution of CO_2 and the formation of carboxylic acid amides.

One should bear in mind that the majority of the known third components are effective complex-forming agents. When homogeneous metal-complex catalysts are used, they can therefore enter into the coordination sphere of the transition metal together with the nitro-compound and CO and thereby facilitate or hinder their activation. Consequently the third component can fulfill yet another function: it can regulate the activity and selectivity of the catalyst and can even alter the type of interaction of the nitro-compound with CO.



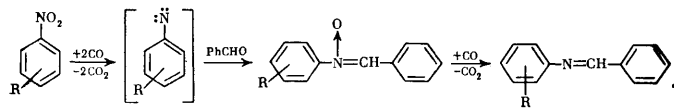
It would be premature to reach a final conclusion concerning the scientific justification of the subdivision of the catalytic reactions of nitro-compounds with CO into reduction without the addition of CO to the nitro-compound and carbonylation, because this new field of organic catalysis has been inadequately investigated. However, this approach permits a more clear-cut estimate of the fundamental achievements in this new field of industrial organic synthesis and a deeper understanding of the mechanism of the reactions of nitro-compounds and CO in the presence of catalysts and also enables one to outline ways of improving and developing the reactions under consideration.

III. REDUCTION OF NITRO-COMPOUNDS

1. Synthesis of Azo-Compounds

The interaction of carbon monoxide with nitro-compounds in the absence of a catalyst proceeds with much difficulty. Thus the conversion of nitrobenzene into azobenzene requires a high carbon monoxide pressure—3000 atm.[8] On the other hand, carbon monoxide bound in a carbonyl complex readily interacts with aromatic nitro-compounds, converting them into azobenzene derivatives[9,10]. The reaction takes place at atmospheric pressure. Under the influence of $Fe(CO)_5$, azobenzene, 2,2′-dimethyl-, 3,3′-dimethyl, and 4,4′-dimethylazobenzenes are formed in 48–76% yields from nitrobenzene and *o*, *m*, and *p*-nitrotoluenes respectively; 1,2-dinitrobenzene is converted to the extent of 11% into 2,2′-diaminoazobenzene.

Iron pentacarbonyl is an active catalyst of the reduction of nitro-compounds with carbon monoxide. In its presence the synthesis of azo-compounds from nitrobenzene and its derivatives takes place at 200 °C and a pressure of 100–200 atm [11]:



Azoxy-compounds are formed as intermediate. Nitrobenzene is reduced most selectively (the yield of azobenzene is 79%). 4-Chloro- and 4-bromonitrobenzenes are converted into 4,4′-dichloro-, and 4,4′-dibromo-azobenzenes to the extent of 55–56%. Azo-compounds are formed in yields of 18–32% from 4-fluoro- and 4-iodo-nitrobenzenes and in yields of 44–45% from 4-nitrotoluene and 4-nitroanisole[11].

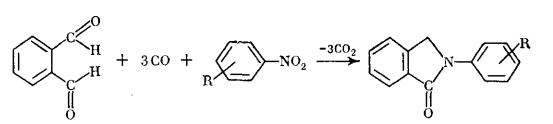
2. Synthesis of Oximes

Nitropropane, nitrobutane, and nitrocyclohexane are reduced quantitatively by carbon monoxide to oximes in aqueous amine solutions of copper salts at 85 °C and atmospheric pressure. The reaction takes place only in the presence of highly basic amines, for example, ethylenediamine. Copper(I) salts are catalytically more active than copper(II) salts. Silver(I) salts are active only at an increased CO pressure, while mercury, cobalt, nickel, and manganese salts do not exhibit catalytic activity in this reaction[12–14].

3. Synthesis of Schiff Bases

The reduction of aromatic nitro-compounds (nitrobenzene, 4-nitroanisole, 4-nitro-*N*,*N*′-dimethylaniline, 2-, 3-, and 4-nitrotoluenes, and 4-nitrobiphenyl) by carbon monoxide under a pressure of 150 atm at 170 °C in the presence of benzaldehyde leads to the formation of Schiff bases in yields of 60–85%.[15] The reaction is catalysed by $Rh_6(CO)_{16}$ in pyridine. It is believed[15,16] that a nitrene is formed from the nitro-compound and CO in the first stage and then reacts with the aldehyde and carbon monoxide to give the final product:

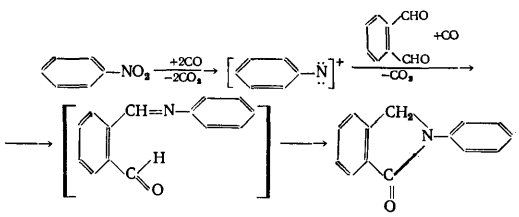
4. Synthesis of Amides and Imides



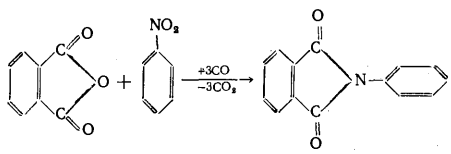
When primary and secondary aliphatic nitro-compounds are heated with iron pentacarbonyl in dry diglyme at 120 °C for 15 h, formamides are formed in low yields (3–20%). On replacing $Fe(CO)_5$ by $Fe_2(CO)_9$, the reaction takes place even at room temperature, but, instead of formamides, the nitrene complexes $(RN)_2Fe_3(CO)_9$, $(RN)_2Fe_2(CO)_6$, and $(RN)_2Fe_2(CO)_7$ are formed from the nitro-compounds and are then converted on heating in diglyme into formamides and urea derivatives[17].

Acetanilide, propionanilide, and benzanilide are obtained in high yields (68–86%) when nitrobenzene interacts with iron acyl carbonyls. The reaction proceeds at room temperature and in an inert atmosphere[18].

Acetanilide can be obtained catalytically in 68% yield from nitrobenzene in acetic acid in the presence of iron, cobalt, or nickel carbonyls at 310 °C and a pressure of 100 atm. With decrease of temperature, the yield of acetanilide falls sharply:

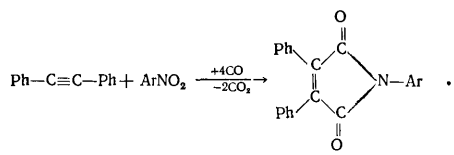


The carbonylation of nitrobenzene with carbon monoxide (150 atm, 170 °C) in the presence of *o*-phthalic aldehyde results in the formation of *N*-phenylisoindolinone[20]. Apart from nitrobenzene, 4-nitroanisole, 3- and 4-nitrotoluenes, and 3-chloronitrobenzene enter into this reaction:



R = H (58%), 4-MeO (42%), 3-Cl (55%), 3-Me (40%), or 4-Me (46%).

The reaction is catalysed by $Rh_6(CO)_{16}$ in pyridine. It apparently proceeds via a stage involving the reduction of the nitro-compound to a nitrene complex, which interacts



with one aldehyde group to form a Schiff base with subsequent ring closure:

The reduction of nitrobenzene with carbon monoxide (120 atm, 170 °C) in the presence of phthalic anhydride and the same catalyst [$Rh_6(CO)_{16}$ in pyridine] gave *N*-phenylphthalinide in 90% yield[16]:

In the presence of diphenylacetylene, the *N*-phenylimide of 2,3-diphenylmaleic acid is formed under the same conditions in 75% yield[16,21]. 3- and 4-Nitrotoluenes, 3-chloronitrobenzene, and 4-nitroanisole react similarly:

5. Synthesis of Amines

In the synthesis of azo-compounds from 2- or 3-nitrotoluene and $Fe(CO)_5$ in dibutyl ether, small amounts of 2- or 3-toluidine (6–13%) are formed as side products[10]. If the reaction is carried out in methanol which serves as a source of hydrogen, then aromatic amines can be obtained from nitrobenzenes and $Fe_3(CO)_{12}$ in 60–90% yield[22]. In the absence of methanol the reaction stops at the stage where the nitrene complex $(PhN)_2Fe_3(CO)_9$ is formed. The nitro-group is reduced both as a result of the oxidation of carbon monoxide to the dioxide; and as a result of the partial oxidation of iron. The reaction is undergone by 2- and 4-nitrotoluenes, 2- and 4-chloronitrobenzenes, 2-bromonitrobenzene, 1,3-dinitrobenzene, 3-nitroaniline, 4-nitrophenol, 4-nitroanisole, etc.[22]. In aqueous alkaline solutions 4-nitrotoluene, 4-chloronitrobenzene, 4-nitroanisole, and 4-acetoxynitrobenzene are also reduced to the amines under the influence of $Fe_3(CO)_{12}$ (yield 60–92%).

Nitro-compounds are reduced catalytically with carbon monoxide to amines using $Rh_6(CO)_{16}$, $[Rh(CO)_2Cl]_2$, Rh_2O_3, $RhCl_3$, $Ru_3(CO)_{12}$, $Fe(CO)_5$, and copper salts as catalysts.

In the reduction of 4-nitroaniline, 4-nitrophenol, α-nitronaphthalene, and 2-ethylnitrobenzene by carbon monoxide in the presence of $Fe(CO)_5$ in benzene (100–200 atm, 200 °C) the yield of amines is low (less than 30%)[11]. The addition of hydrogen to carbon monoxide to give proportions of 1:1 does not increase the yield. In the presence of $Ru_3(CO)_{12}$ the reaction of nitrobenzene is more selective: at 160 °C and a pressure of 200 atm of the 1:1 $CO + H_2$ mixture the yield of aniline reaches 66%; the yield falls with decrease of the hydrogen concentration[24]. Up to 85–95% of aniline is formed in the reduction of nitrobenzene in the presence of rhodium compounds [$RhCl_3, Rh_6(CO)_{16}$, etc] at 150 °C and a CO pressure in the range 50–120 atm in aqueous pyridine or *N*-methylpyrrolidine[25]. In methanol the reaction proceeds less effectively—the yield of aniline does not exceed 25%. It has been shown[26] that, when copper salts are used as catalysts, nitrobenzene, 2-nitroanisole, 2-chloronitrobenzene, 4-nitrobenzoic acid, and nitromethane are reduced only in highly basic amines containing water. The reduction of nitrobenzene with carbon monoxide to aniline (1 atm CO, 85 °C) takes place to the extent of 50% in aqueous ethylenediamine, 16% in aqueous 1,2- or 1,3-propylenediamine, and 30% in aqueous NH_4OH. The rate of reduction of nitrobenzene increases with increase of the concentration of the copper salt[26].

IV. CARBONYLATION OF NITRO-COMPOUNDS

1. Synthesis of Ureas

The formation of substituted ureas has been frequently observed in the carbonylation of nitro-compounds. For example, prolonged heating of nitroparaffins with a stoichiometric amount of $Fe(CO)_5$ at 130 °C results in the formation of up to 20% of ureas[17]. Diphenylurea has been synthesised in 86% yield by carbonylating nitrobenzene in an aqueous solution at 200 °C and a CO pressure of 70 atm in the presence of SCO.[27] When nitrobenzene, 4-nitroanisole, 4-chloronitrobenzene, 4-nitrotoluene, and nitrocyclohexane were allowed to react with $Fe(CO)_5$ and phenylmagnesium bromide at 0 °C and in an inert gas atmosphere, the corresponding symmetrical *N,N'*-substituted ureas were obtained in yields of 60–99%.[28] *N,N*-Dimethyl-*N'*-phenylurea was synthesised in 86% yield from nitrobenzene and $Me_2NCOSNHMe$ at atmospheric CO pressure[29].

Substituted ureas can also be obtained by the catalytic carbonylation of nitro-compounds. Thus in the presence of $Rh_6(CO)_{16}$ as the catalyst in pyridine, nitrobenzene, 3- and 4-nitrotoluenes, and 4-nitrobiphenyl are converted into the corresponding symmetrical ureas in 70–80% yield at 150–200 °C and a pressure of 100–200 atm under the influence of the 25:1 $CO + H_2$ mixture[16]:

$$2ArNO_2 + 5CO + H_2 \rightarrow ArNHCONHAr + 4CO_2 .$$

When $Ru_3(CO)_{12}$ was used as the catalyst, the highest yield (54%) of *N,N'*-diphenylurea was obtained for the ratio of $CO : H_2 = 9 : 1$, the yield of urea decreasing with increase of the H_2 concentration[24]. Up to 80% of *N,N'*-diphenylurea is formed from nitrobenzene under the influence of the 10:1 $CO + H_2$ mixture in the presence of the 0.5% Pd/Al_2O_3-$FeCl_3$ catalyst[30]. The carbonylation of nitrobenzene in piperidine led to the isolation of *N*-pentamethylene-*N'*-phenylurea:

$$PhNO_2 + 5C_5H_{10}NH + 3CO \rightarrow PhNHCONC_5H_{10} + 2C_5H_{10}NCONC_5H_{10} + 2H_2O .$$

The reaction proceeds at atmospheric CO pressure in the presence of copper(I) salts. Nitrobenzene is reduced by piperidine, which is converted into the symmetrical *N,N'*-bispentamethyleneurea[31].

Palladium salts activated by triphenylphosphine and tetraethylammonium chloride permit the synthesis of substituted ureas by the catalytic carbonylation of aromatic nitro-compounds under mild conditions—at 90 °C and atmospheric pressure[32]. *N,N'*-Diphenylurea, *N,N'*-di(4-methylphenyl)urea, and *N,N'*-di(4-chlorophenyl)urea are formed respectively from nitrobenzene in aniline, from 4-nitrotoluene in 4-toluidine, and from 4-chloronitrobenzene in 4-chloroaniline. Carbonylation of 4-chloronitrobenzene in aniline leads to a

mixture of *N*-(4-chlorophenyl)-*N'*-phenylurea, *N,N'*-di(4-chlorophenyl)urea, and *N,N'*-diphenylurea; the carbonylation of the nitro-group may be accompanied by the carbonylation of the C–halogen bond, which leads to the formation of a further two products: the *N*-phenylamide of 4-nitrobenzoic acid and the corresponding urea 4-$PhNHCOC_6H_4NHCONHPh$.[33]

In the presence of $RhCl_3$ the carbonylation of nitrobenzene in aniline takes place at 190 °C and a CO pressure of 205 atm, *N,N'* diphenylurea being formed in 77% yield[34].

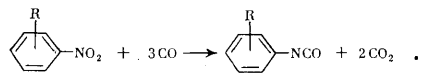
2. Synthesis of Urethanes

Urethanes are formed in the carbonylation of aromatic nitro-compounds in alcohols using palladium or rhodium compounds as well as metallic selenium as catalysts. The reaction is carried out for 0.3–20 h under a pressure of 50–400 atm at 150–230 °C:

$$ArNO_2 + 3CO + ROH \rightarrow ArNHCOOR + 2CO_2 \ .$$

In the presence of $RhCl_3$ the products obtained from nitrobenzene and 1-butanol are 4% of n-butyl *N*-phenylcarbamate, 34% of aniline, and 12% of a mixture of butylamines, while nitrobenzene and methanol give rise to 28% of methyl *N*-phenylcarbamate[35]. The addition of metallic iron[36] or $FeCl_3$ [37] to $RhCl_3$ (in proportions of 1:5) increases the yield of methyl *N*-phenylcarbamate to 54 and 81% respectively. The reaction can be carried out in toluene or in an excess of methanol[36,37]. In the presence of the cyclo-octadienylrhodium complex $[C_8H_{12}RhCl]_2$ activated with $FeCl_3$ (1:5), the yield of methyl *N*-phenylcarbamate is 47%.[38]

When $[Rh(CO)_2Cl]_2$ with added iron or copper chloride was used as the catalyst, phenyl *N*-phenylcarbamate was synthesised in 28% yield in phenol, in 1-butanol the product was n-butyl *N*-phenylcarbamate (82% yield), in methanol the product was methyl *N*-phenylcarbamate, while 1,3-dinitrobenzene in methanol gave rise to dimethyl 1,3-phenylenedicarbamate[39]. Ethyl *N*-phenylcarbamate is formed in a low yield (10%) on carbonylation of an ethanol solution of nitrobenzene containing $Rh_6(CO)_{16}$ and pyridine[15].



In the presence of the $PdCl_2$–pyridine (1:70) catalyst in ethanol, diethyl 2,4-tolylenedicarbamate was synthesised from 2,4-dinitrotoluene (yield 46–78%), while 1,5-dinitronaphthalene yielded diethyl 1,5-naphthylenedicarbamate. Carbonylation of 2,4-dinitrotoluene in phenol, pentyl alcohol, or ethylene glycol led to diphenyl or dipentyl 2,4-tolylenedicarbamate and ethylene 2,4-tolylenedicarbamate respectively[42–44]. The $Me(COO)_2Pd$–pyridine, $HRh(CO)(PPh_3)_3$, and PtO–pyridine catalysts are less effective.

In the presence of the 5% Pd/C and 5% Pd/Al_2O_3 heterogeneous catalysts activated with $FeCl_3$ carbonylation of nitrobenzene in methanol and of 2,4-dinitrotoluene in ethanol led to the synthesis of methyl *N*-phenylcarbamate (50%) [37] and diethyl 2,4-tolylenedicarbamate (89%) respectively[43,44]. In the presence of pyridine these catalysts are stable and can be used 10–16 times[45]. The analogous rhodium and ruthenium catalysts are less effective than the palladium catalysts (the yield of diurethane is 8–11%).[45] Apart from $FeCl_3$, copper and aluminium chlorides and copper bromide can be used as promoting agents. The carbonylation of ethanol solutions of nitrobenzene, 4-nitrotoluene, and 2,4-dinitrotoluene in the presence of the 5% Pd/C–$FeCl_3$–pyridine catalyst led to the synthesis of ethyl *N*-phenylcarbamate (yield 93%), ethyl *N*-(4-tolyl)carbamate (yield 92–95%), and diethyl 2,4-tolylenedicarbamate (yield 67–82%) respectively[45].

Selenium catalysts exhibit a high activity and selectivity in the synthesis of urethanes. In the presence of selenium and added aniline, trithylenediamine, diphenylurea, acetic acid, and potassium or sodium acetate, nitrobenzene and 2,4-dinitrotoluene in ethanol were converted into ethyl *N*-phenylcarbamate and diethyl 2,4-tolylenedicarbamate in 91–98% yield. The reaction proceeds rapidly (0.5 h) and under relatively mild conditions (50–70 atm, 170 °C).[46,47]

3. Synthesis of Aromatic Monoisocyanates

In 1967 Hardy and Bennett[48] reported for the first time that the carbonylation of aromatic nitro-compounds (nitrobenzene, 2- and 4-nitrotoluene, 3-chlorobenzene, and 3-trifluoromethylnitrobenzene) in benzene under a CO pressure of 500 atm and 190 °C in the presence of palladium and rhodium catalysts results in the formation of aromatic isocyanates (phenyl isocyanate, 2- and 4-tolyl isocyanates, 3-chlorophenyl isocyanate, and 3-trifluoromethylphenyl isocyanate respectively):

The reaction has a characteristic feature—the yield of the product passes through an extremum as a function of temperature, pressure, reaction time, and the amount of catalyst, which is due to the instability of the isocyanate under the conditions of the synthesis.

The catalyst plays a most important role in the formation of isocyanates from nitro-compounds and CO. A wide search has therefore been carried out for effective reaction catalysts. The following compounds were tested: CoI_2,[49] $Co_2(CO)_8$,[50–53] PdO,[54] $PdCl_2$,[55] $RhCl_3$,[56] $PdCl_2 + RhCl_3$ mixture[57], $Pd(PPh_3)_3.Cl_3$,[56] $Pd(C_5H_5N)_2Cl_3$, $Pd(quinoline)_2Cl_2$, $Pd(3,5\text{-dimethylpyridine})_2Cl_2$, and other pyridine complexes of palladium[58], as well as palladium, rhodium or ruthenium on a carrier (Al_2O_3, activated charcoal, $CaCO_3$, pumice, and $BaSO_4$).[59–63] The highest yields of phenyl isocyanate were obtained in the presence of $Co_2(CO)_8$ (46%), $Rh(PPh_3)_3Cl_3$ (40%), and $Pd(3,5\text{-dimethylpyridine})_2Cl_2$ (63%). Heterogeneous catalysts containing ruthenium, palladium, or rhodium on a carrier as well as the chlorides of these metals and PdO are catalytically relatively ineffective.

The activity of palladium and rhodium compounds increases when inorganic and organic compounds are added. In the carbonylation of nitrobenzene in the presence of $RhCl_3$ with added CoI_2 at 200 °C and a CO pressure of 100 atm, 21% of phenylisocyanate is formed[64]. In the presence of the $RhCl_3$–$CuBr_2$–V_2O_5 catalyst at 190 °C and 125 atm, the yield of the isocyanate is higher (45%), but the catalyst must be treated with carbon monoxide for 1–2 h under a pressure of 210 atm and at a temperature of 190 °C before the reaction[65]. The $PdCl_2$–V_2O_5 catalyst also requires a preliminary activation with carbon monoxide under pressure; In its presence the yield of phenyl isocyanate reaches 78–85% but the productivity of the catalyst is low (3–6 g of the product per gram of $PdCl_2$ per hour)[55]. Without preliminary activation with carbon monoxide, the selectivity of this catalyst is low (the yield of the isocyanate with respect to the reacted nitrobenzene is 58%)[66].

When 5% (relative to the weight of nitrobenzene) of phosphine, thionyl chloride, benzoyl chloride, sulphuryl chloride, or vanadium oxide chloride is introduced into the reaction system, and the $PdCl_2$–V_2O_5 catalyst not activated with carbon monoxide is used (190 °C, 145 atm), the yield of phenyl isocyanate is 45–70%.[66] Up to 68% of phenyl isocyanate is formed in the presence of $RhCl_3$–V_2O_5 with added $COCl_2$ or $POCl_3$.[67] In the presence of an excess of phosgene or thionyl chloride the carbonylation of nitrobenzene on the PdO,

$PdCl_2$, $PdCl_2$–$CoCl_2$, $TiCl_4$ and $SnCl_4$ catalysts under a CO pressure of 110–145 atm for 3–37 h leads to the formation of a mixture of isomers of dichloro- and trichloro-phenyl isocyanates with an overall yield of 10–28% instead of phenyl isocyanate[68]. Chlorophenyl isocyanates are also formed in the vapour-phase carbonylation of nitrobenzene in the presence of the catalyst comprising 5% $PdCl_2$–5% $CuCl_2$ on silicon carbide[69].

It has been suggested that aliphatic and aromatic nitriles, triphenylphosphine, quinoline, pyridine, alkyl and bromo-pyridines, and *N*-methylpyridinium iodide be used as organic activators. Patent data[57,70] concerning the activating effect of nitriles have not been confirmed; in fact the inhibiting effect of these additives has been noted[71]. When triphenyl-phosphine is added to PdO, $PtCl_4$, $RhCl_3$ and $PdCl_2$, the yield of phenyl isocyanate increases by a factor of 1.5–2.5 and amounts to 9–34%.[56,71]. The activity of $PdCl_2$ increases sharply after the introduction of quinoline, pyridine, and ethyl, methyl, dimethyl- and dibromo-pyridines: the degree of conversion of nitrobenzene and the yield of phenyl isocyanate increase by a factor of 4–8.[72] Triethylamine, urotropine, and 2,2-bipyridyl deactivated $PdCl_2$.[71]

The low activity of $PdCl_2$ when it is used without additives is due to the ease of conversion of this salt under the reaction conditions into a catalytically inactive form–the polynuclear carbonyl $[Pd(CO)Cl]_n$ [73,74] which decomposes in the presence of pyridine and is evidently converted into the catalytically active complex of the type $Pd(CO)_x(C_5H_5N)_yCl$:

$$\begin{array}{ccc} PdCl_2 & \xrightarrow{\text{pyridine}} & Pd(C_5H_5N)_2Cl_2 \\ \downarrow CO & & \downarrow CO \\ [Pd(CO)Cl]_n & \xrightleftharpoons{\text{pyridine}} & Pd(CO)_x(C_5H_5N)_yCl \end{array}.$$

Indeed the $[Pd(CO)Cl]_n$, which is inactive without additives, makes it possible to obtain phenyl isocyanate in 50% yield and with a nitrobenzene conversion of 64% in the presence of pyridine at 190° and a CO pressure of 100 atm. The $PdCl_2$–pyridine and $Pd(C_5H_5N)_2Cl_2$–pyridine catalysts give rise to similar results under these conditions[50]. When $PdCl_2$ is heated in chlorobenzene containing pyridine, the complex $Pd(C_5H_5N)_2Cl_2$ is formed readily and at an elevated CO pressure is apparently converted into $Pd(CO)_x(NC_5H_5)_yCl$. The catalytically active pyridine palladium carbonyl chloride complexes can be obtained also directly from $PdCl_2$ and pyridine under CO pressure[75].

Complexes having the general formula PdL_2Cl_2 [58] (L = pyridine and quinoline derivatives) are active in the synthesis of phenyl isocyanate and can be arranged in the following sequence in terms of the yield of the isocyanate: Pd(3,5-dimethylpyridine)$_2Cl_2$ (63%) >Pd(4-methylpyridine)$_2Cl_2$ (45%) >Pd(4-ethylpyridine)$_2Cl_2$ (38%) >Pd(pyridine)$_2Cl_2$ (28%) >Pd(2-methylpyridine)$_2Cl_2$ (16%) >Pd(2,3-dimethylpyridine)$_2Cl_2$ (11%) > Pd(quinoline)$_2Cl_2$ (10%) >Pd(2-methylquinoline)$_2Cl_2$ (5%) > Pd(2-ethylpyridine)$_2Cl_2$ (4%) >Pd(3,5-dibromopyridine)$_2Cl_2$ (0%), Pd(2,2-bipyridyl)Cl_2 (0%).

Electron-donating alkyl substituents in the β- and γ-positions in the ligand of this complex increase and those in the α-position decrease the degree of conversion of nitrobenzene and the yield of phenyl isocyanate. In the presence of palladium complexes with ligands more bulky than pyridine (quinoline and 2-methylquinoline) the yields of isocyanate are lower by factors of 2.8 and 5.6 respectively. When an electron-accepting substituent, for example, bromine, is introduced in the β-position of the pyridine ligand, nitrobenzene is not carbonylated.

Bulky substituents in the α-position of the pyridine ring should reduce, like electron-accepting substituents, the capacity for coordination, the former due to steric hindrance and the latter due to the decrease of the electron density at the nitrogen atom. Evidently equilibrium is established under carbonylation conditions between the catalytically active pyridinepalladium carbonyl chloride complexes and the inactive $[Pd(CO)Cl]_n$; the greater the capacity of the ligand for coordination to palladium, the greater the displacement of the equilibrium in the direction of the active complexes, and the higher the degree of conversion of the nitrobenzene and the yield of phenyl isocyanate. The introduction of an excess of the free ligand into the reaction mixture should also increase the amount of the catalytically active complexes and hence the degree of conversion of the nitro-compound and the yield of the isocyanate. Indeed the addition of a sevenfold excess of the ligand L to the PdL_2Cl_2 complexes and to the $PdCl_2$–pyridine system (molar ratio 1:2) increases their activity[58,71]. Under these conditions, the effect of the excess ligand is manifested particularly sharply for complexes which give rise to a small yield of the isocyanate in the absence of the free ligand. Thus the yield of phenyl isocyanate in the presence of the complexes Pd(2-ethylpyridine)$_2$.Cl_2, Pd(quinoline)$_2Cl_2$, and Pd(pyridine)$_2Cl_2$ increases by factors of 14, 4, and 1.7 following the addition of the corresponding ligand, while in the case of the complex Pd(3,5-dibromopyridine)$_2Cl_2$ the yield increases from 0% to 50%. The addition of the excess ligand to the palladium complexes with 4-methyl, 4-ethyl, and 3,5-dimethyl-pyridines results in an increase of the yield of phenyl isocyanate only by a factor of 1.1–1.6.[58]

2,2′-Bipyridyl forms stable chelate complexes which are evidently incapable of being converted into catalytically active complexes under the influence of carbon monoxide. The addition of 2,2′-bipyridyl therefore not only does not activate the complex Pd(2,2′-bipyridyl)Cl_2,[58] but actually fully deactivates $PdCl_2$ and the $PdCl_2$–pyridine catalyst[71].

The activity of $PdCl_2$ increases sharply in the presence of *N*-methylpyridinium iodide or the pyridine–MeI mixture capable of forming a salt[76], which makes it possible to synthesise phenyl isocyanate in a high yield (76–90%) at 160 °C and a CO pressure of 100 atm. The promoting effect of *N*-methylpyridinium iodide is evidently based on the formation of complexes preventing the conversion of $PdCl_2$ into the catalytically inactive state $[Pd(CO)Cl]_n$ and on the decomposition of the palladium carbonyl chloride already formed (the effect is similar to that of other ammonium salts)[74].

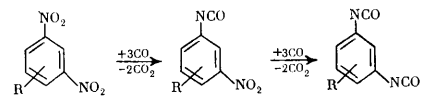
Among all the known catalysts of the carbonylation of nitrobenzene, the three-component catalysts of the type $PdCl_2$–pyridine–inorganic activator (V_2O_5, V_2O_4, MoO_3, and lanthanide molybdates) are the most active and selective in the synthesis of phenyl isocyanate.

The dependence of the activity of the $PdCl_2$–pyridine–metal oxide catalytic system on the nature of the transition metal oxides has been studied systematically[77] and it has been established that the effect of the oxide of the metal in each transition series of the Periodic System changes consistently: with increase of the number of the Group from III to V and VI, the degree of conversion of nitrobenzene and the yield of phenyl isocyanate increase. The maximum degree of conversion of the nitro-compound and the maximum yield of the isocyanate were obtained in the presence of the oxides V_2O_4 and V_2O_5 [Group (V)]in the first transition series, Nb_2O_5 and MoO_3 (Groups V and VI) in the second transition series, and Ta_2O_5 and WO_3 (Groups V and VI) in the third transition series. With further increase of the number of the Group, the activity in the metal oxide in the

first transition series falls: the degree of conversion of nitrobenzene and the yield of phenyl isocyanate also decrease.

All the metal oxides investigated can be divided into three groups in terms of the activity of the catalyst of the type of $PdCl_2$–pyridine: 1) oxides activating the catalyst (V_2O_4, V_2O_5, MoO_3, and also certain lanthanide molybdates, which increase the rate of carbonylation of nitrobenzene by a factor of 3–4); 2) oxides which do not have an appreciable influence on the activity of the catalyst (Cr_2O_3, Fe_2O_3); 3) oxides which reduce the activity of the catalyst—a large group which includes the remaining transition metal oxides[77,78].

In the presence of the best catalysts, for example $PdCl_2$–pyridine–MoO_3 (or V_2O_5, $La_2O_3.4MoO_3$, $Nd_2O_3.MoO_3$, and $Pr_2O_3.2MoO_3$) the selectivity of the synthesis of phenyl isocyanate at 185–200 °C and a pressure of 100 atm reaches 90–98%.[72,78] These catalysts are active also in the synthesis of substituted phenyl isocyanates: in their presence at 200 °C and a pressure of 100 atm, 2-, 3-, and 4-nitrotoluenes are converted into 2-, 3-, and 4-tolyl isocyanates in yields of 82 to 90% respectively, while 2-, 3-, and 4-chloronitrobenzenes, 3,4-dichloronitrobenzene, and 4-bromonitrobenzene are converted respectively into 2-, 3-, and 4-chlorophenyl isocyanates (yield 70–90%)[74,80–85], 3,4-dichlorophenyl isocyanate (83%), and 4-bromophenyl isocyanate (32%).



A whole series of monoisocyanates have been synthesised in yields less than 25% by carbonylating 2,4,5- and 2,4,6-trichloronitrobenzenes, 4-fluoronitrobenzene, 3-trifluoromethylnitrobenzene, 2-nitrofuran, 4-nitroanisole, 2-nitronaphthalene, and 5-nitropyrimidine in the presence of $PdCl_2$ and 5% Pd/Al_2O_3 at a high CO pressure (700–1000 atm)[59,61,70,79]. In the absence of activators the palladium catalysts are ineffective at low CO pressures; even in the presence of added activators (pyridine and metal oxides) it is impossible to synthesise isocyanates at atmospheric pressure. A single catalyst, namely $[RhCl(CO)_2]_2$–$MoCl_5$, active in the synthesis of isocyanates at a pressure of 1 atm, is known. Di-, tri-, and tetra-methylphenyl isocyanates are formed in its presence at 120 °C with a low selectivity (less than 50%) from the corresponding nitrobenzenes[86]. Carbonylation is accompanied by the reduction of the nitro-compounds to the amines.

4. Synthesis of Aromatic Di-isocyanates

Group VIII metal compounds have been patented as the main components of catalysts of the synthesis of di-isocyanates by the carbonylation of aromatic dinitro-compounds, but di-isocyanates have been obtained only using catalysts based on palladium and rhodium compounds. Thus the carbonylation of dinitronaphthalene, di(3-nitrophenyl)methane, and di(3-methyl-4-nitrophenyl)methane in the presence of the 5% Pd/Al_2O_3 catalyst results in the formation of a mixture of the corresponding mono- and di-isocyanates[87], while the carbonylation of 1,3-dinitrobenzene in the presence of $PdCl_2$ gives 14% of phenylene 1,3-di-isocyanate[88].

1,3-Phenylene di-isocyanate, 1,4-phenylene di-isocyanate, 2,4-tolylene di-isocyanate, 1,5-dimethyl-2,4-phenylene di-isocyanate, 1,3,5-dimethyl-2,4-phenylene di-isocyanate, and 1,2,4,5-tetramethylene-3,6-phenylene di-isocyanate have been synthesised in yields of 32–75% by the carbonylation of the corresponding 1,3- and 1,4-dinitro-compounds in the presence of the PdO, MoO_3, and Fe_2O_3/Al_2O_3–pyridine catalysts[89]. The yield of the di-isocyanate depends on the relative positions of the nitro-groups in the aromatic ring of the initial compound: di-isocyanates have been obtained from *meta*-dinitro-compounds in yields twice as great as those from *para*-dinitro-compounds.

The synthesis of di-isocyanates proceeds via the intermediate formation of mononitromonoisocyanates, which can be isolated in yields up to 50%:

The yield of di-isocyanates passed through an extremum as a function of temperature, CO pressure, amount of catalyst, and the concentration of the nitro-compound[90,91], which is apparently due to the instability of the di-isocyanates. The optimum conditions for the formation of di-isocyanates in the presence of different catalysts are various: 300 atm and 210 °C for the PdO, Fe_2O_3, and MoO_3/Al_2O_3–pyridine catalysts, 300 atm and 170 °C for the $PdCl_2$–pyridine–Fe_2O_3–MoO_3 catalyst, and 250 atm and 260 °C for the $Pd(pyridine)_2.Cl_2$–Fe_2O_3–V_2O_5 catalyst. Under conditions milder than the optimum conditions, mononitromonoisocyanates are formed, while under more severe conditions tar is produced[90,91].

Among the di-isocyanates, 2,4-tolylene di-isocyanate is of greatest practical importance and the principal data concerning the development of catalysts for the synthesis of di-isocyanates have therefore been obtained for the carbonylation of 2,4-dinitrotoluene. $Co_2(CO)_8$, NiI_2, and $Ni(quinoline)_2I_2$, which have been tested as catalysts of the carbonylation of 2,4-dinitrotoluene with carbon monoxide[92,93], give rise to the mononitromonoisocyanate in a low yield (less than 25%) instead of the di-isocyanate, when $Fe(CO)_5$ is used, isocyanates are not formed at all[10].

At 150–200 °C and a pressure of 175–300 atm the salts $PdCl_2$ and $RhCl_3$ are relatively ineffective in the absence of promoting agents. A number of organic compounds, introduced into the reaction mixture together with the solvent in amounts of 1–10 moles per mole of the catalyst, are used to activate palladium and rhodium chlorides. Compounds such as thiophen, thionaphthene, benzothiophen, dimethyl sulphoxide, diphenyl sulphoxide, sodium sulphite and thiosulphate[94,95], derivatives of furan[96], carbodi-imide[97], aniline[98], formamide and urea[99], cyanamide[100], as well as isocyanates[97], nitroso-compounds[101], and mononitriles[57,70] proved to be relatively ineffective. In their presence less than 10% of 2,4-tolylene di-isocyanate is formed. Activation of $PdCl_2$ by aromatic dinitriles increases the yield to 24%.[102] The best organic activator of $PdCl_2$ is pyridine, whose introduction into the reaction mixture increases the yield of 2,4-tolylene di-isocyanate to 50–68%.[90] Inorganic compounds have a weak activating effect on $PdCl_2$ and $RhCl_3$. Thus, when $PdCl_2$ with added iron, molybdenum, or vanadium oxides, the CuBr–MoO_3 and Fe_2O_3–MoO_3 mixtures, as well as the iron molyb-

dates $Fe_2Mo_7O_{24}$ and $Fe_2(MoO_4)_3$ are used, the yield of di-isocyanates formed from 2,4-dinitrotoluene is 10–20%.[55,65,103] The $PdCl_2$–MoO_3–$CuBr_2$ catalyst subjected to preliminary activation with carbon monoxide in the presence of phosgene makes it possible to obtain up to 40% of 2,4-tolylene di-isocyanate[65]. The attempts to activate palladium and rhodium chlorides with organoelemental derivatives of lead, silicon, germanium, boron, and copper, in the presence of which the yield of di-isocyanate does not exceed 32%, were relatively unsuccessful[54].

The joint use of organic and inorganic activators proved to be the most effective. When chromium, iron, or molybdenum oxides, the Fe_2O_3–MoO_3 mixture, or a mixture of iron (manganese) molybdates is added to the $PdCl_2$–pyridine catalyst, the yield of 2,4-tolylene di-isocyanate is 60%,[104–106] 75%, 85%, 92%, and 73–78%[103] respectively.

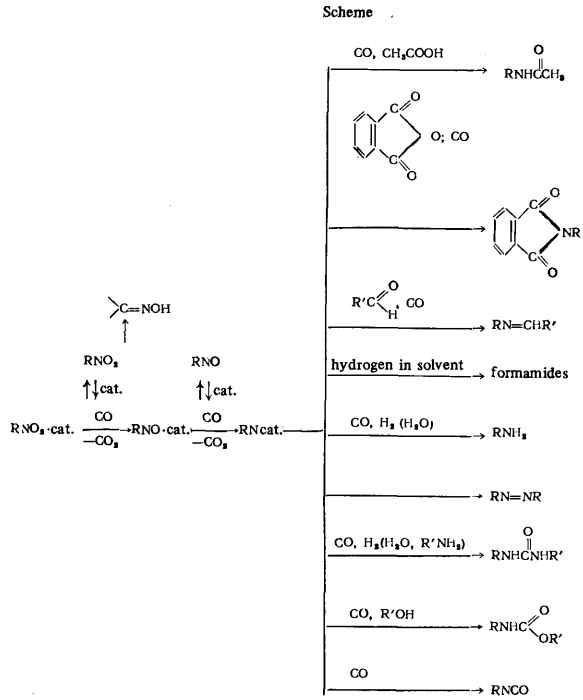
Apart from palladium and rhodium chlorides, certain other complexes of the above elements are used as catalysts for the synthesis of 2,4-tolylene di-isocyanates. The complexes $Pd(pyridine)_2(NCS)_2$, $Pd(pyridine)_2(NCO)_2$, $Pd(isoquinoline)_2.(NCS)_2$, $Pd(isoquinoline)_2Cl_2$, and $Rh(pyridine)_3Cl_3$ are relatively inactive without additives; in their presence the yield of the di-isocyanate does not exceed 10%.[107–109]. The complexes of $PdCl_2$ with dimethylcyanamide, dibenzylcyanamide, and diphenylcyanamide made it possible to obtain 4, 5, and 31% of di-isocyanate respectively[100,110]. In the presence of $Pd(pyridine)_2Cl_2$, $Pd(CO)_2Cl_2$, $Pd(CO)(pyridine)Cl_2$, $Pd(CO).(pyridine\ oxide)Cl_2$, $Pd(CO)(2,5\text{-lutidine})_2Cl_2$ and $Pd(CO).(isoquinoline)Cl_2$, 20–40% of 2,4-tolylene di-isocyanate is formed[109,111–114]. It has been suggested that the complexes $Pd(pyridine)_2Cl_2$, $Pd(isoquinoline)_2Cl_2$, and $Rh(pyridine)_3Cl_3$ be activated[108] with hydrogen, water, and formic, oxalic, hydrochloric, and boric acids, which, however, are relatively ineffective (the yield of di-isocyanate is not greater than 44%). Up to 57% of 2,4-tolylene di-isocyanate is obtained in the presence of $Pd(pyridine)_2Cl_2$–MoO_3 to which diphenyl carbonate has been added[115], while in the presence of added diarylurea the yield is only 23%.[116]

One of the most active and selective catalysts of the carbonylation of 2,4-dinitrotoluene with carbon monoxide is the $Pd(pyridine)_2Cl_2$–Fe_2O_3–V_2O_5 system (the yield of di-isocyanate is up to 90%).[117]

Metal chlorides have been tested as activators of the catalyst $Pd(isoquinoline)_2Cl_2$[118]; They can be arranged in the following sequence in terms of the yield of the di-isocyanate: $SbCl_5$ (2%) < $ZnCl_2$ (4–10%) < $PbCl_2$ (11%) < $BiCl_3$ (15%) < $CrCl_3$ (18%) < $MoCl_5$(20%) < VCl_4 (23%) < $TiCl_4$ (25%) < $FeCl_3$ (26%) < $HgCl_2$ (27%) < $ZrCl_4$ (28%) < $MnCl_2$ (32%) < $GeCl_4$ (56%). When Fe_2O_3–CrO_3, CrO_3, or $Cr(CO)_6$–MoO_3 is added to the complex $Pd(isoquinoline)_2Cl_2$, the yield of 2,4-tolylene di-isocyanate increases to 54–65%.[119,120].

The known heterogeneous catalysts of the carbonylation of 2,4-dinitrotoluene are less effective than the homogeneous-heterogeneous catalysts examined above[90,117]. The yield of di-isocyanate on the 9% $RhCl_3/C$-V_2O_5 catalyst in the presence of phosgene does not exceed 29%.[121] The complex $Pd(pyridine)_2Cl_2$ deposited on CrO_3/Al_2O_3 is still less selective (the yield of di-isocyanate is 15%).[122] Not more than 10% of di-isocyanate is formed in the presence of $Pd(pyridine)_2Cl_2$ adsorbed on the copolymer of divinylbenzene, styrene, and 4-vinylpyridine[123,124]. Less than 13% of 2,4-tolylene di-isocyanate has been obtained in the presence of a catalyst containing palladium or rhodium on Al_2O_3, silica gel, activated charcoal[97,125], or $CuBr_2/MoO_3$.[65,126] The heterogeneous catalyst PdO–MoO_3–Fe_2O_3/Al_2O_3 promoted with pyridine exhibits the highest activity and selectivity; in its presence 2,4-tolylene di-isocyanate is formed at a rate of 70 g/g Pd h and with a yield of 70%.[89]

V. THE MECHANISM OF THE TRANSFORMATION OF NITRO-COMPOUNDS UNDER THE INFLUENCE OF CARBON MONOXIDE



The mechanism of the interaction of CO with nitro-compounds has so far been inadequately studied and it would be premature to reach final conclusions. However, the available data make it possible to formulate a working hypothesis which explains the fundamental features of the process and enables one to outline ways of seeking effective catalysts and new reaction pathways.

In the synthesis of the majority of nitrogen-containing substances (amines, amides, imides, Schiff bases, azo-compounds, substituted ureas, and isocyanates) by the carbonylation of nitro-compounds, one of the intermediates is believed to be a nitrene in a free state or in the form of complexes. Nitrenes are highly reactive short-lived species which exist in the singlet or triplet (biradical) states. The formation of nitrenes is usually inferred from the final reaction products, but it is sometimes possible to detect them in the form of unstable complexes. Thus the nitrene complexes $(RN)_2Fe_2(CO)_6$, $(RN)_2Fe_2(CO)_7$, and $(RN)_2Fe_3(CO)_9$ were isolated in the reduction of aliphatic nitro-compounds with iron nonacarbonyl $Fe_2(CO)_9$; on heating they are converted into formamide and ureas[17]. Under the influence of $Fe_3(CO)_{12}$, nitrobenzene also gives rise to the nitrene complex $(RN)_2Fe_3.(CO)_9$, which is converted into aniline in the presence of a source of hydrogen[22].

The catalytic reduction of aromatic nitro-compounds in the presence of $Fe(CO)_5$, leading to the formation of amines and (or) azo-compounds (depending on the reaction conditions and the nature of the nitro-compound), evidently also proceeds via the intermediate formation of nitrene complexes with iron carbonyl. This is indicated by the formation of side products specific to the nitrene mechanism (carbazole, etc.)[11]. An analogy has been established between the catalytic (on $PdCl_2$) carbonylation of nitro-compounds and the reactions of aryl azides (a classical source of nitrenes): the selectivity of the synthesis of isocyanates increases with increase of the CO pressure and identical side products are formed[79,127]. Indirect evidence for the nitrene mechanism has also been obtained in the carbonylation of nitrobenzenes on rhodium catalysts. It was found (see Table) that the reaction pathway depends on the composition of the reaction medium: under identical conditions, in the presence of hydrogen in the gas phase, ureas are formed, in ethanol a mixture of an amine, urea, and urethane is obtained, in the presence of mono- or di-aldehydes Schiff bases and amides are isolated respectively, while in the presence of diphenylacetylene the products are the *N*-arylimides of 2,3-diphenylmaleic acid[15,16,20,21,25].

On the basis of the data available at the present time, the overall mechanism of the carbonylation of nitro-compounds can apparently be represented as follows. Under the influence of the reducing medium (CO), the metal complex catalyst is converted into one of its reduced forms, for example $[HFe(CO)_{11}]$,[23] $[RhCl(CO)_2]_2$,[86] and $Pd(CO)_x(pyridine)_yCl$,[58] and interacts with the nitro-compound and then with the nitroso-compound, forming a charge-transfer complex[86,128], in which an electron is transferred to the nitro-, or nitroso-group. As a result of deoxygenation within the coordination sphere, a nitrene complex is then formed, and depending on the reaction medium, the nature of the central atom, the ligands in the complex, temperature, and CO pressure is converted into the final products (see the Scheme).

Scheme

Thus the catalytic reduction of nitro-compounds by carbon monoxide makes it possible to obtain a whole series of valuable nitrogen-containing products. This field in the chemistry of nitro-compounds is still not adequately investigated, but the results already obtained indicate the great synthetic possibilities of the carbonylation methods. In the first place the development of an industrial method of synthesising isocyanates is at present of practical importance. There is no doubt about the importance of the above reactions for the theory of homogeneous and heterogeneous catalysis and also for nitrene chemistry.

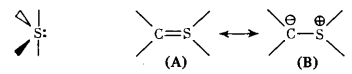
The Chemistry of Stabilised Sulphonium Ylides

Yu.V.Belkin and N.A.Polezhaeva



The review is devoted to the chemistry of stabilised sulphonium ylides, i.e. ylides with substituents at the carbanionic carbon atom capable of delocalising its negative charge. The physical properties of compounds of this class are examined and the methods of synthesis of stabilised sulphonium ylides, their rearrangements, and their reactions with electrophiles and nucleophiles are described. The structures and reactivities of the complexes of stabilised sulphonium ylides with transition metals and their organometallic derivatives are considered. The practical applications of the stabilised sulphonium ylides are indicated.
The bibliography includes 272 references.

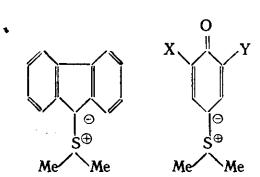
I. INTRODUCTION



The organic chemistry of sulphur ylides is one of the most vigorously developing branches of organic chemistry. Ylides are compounds in which a negatively charged carbon atom is linked directly to a heteroatom carrying a positive charge[1]. There is at present no systematic nomenclature of sulphur ylides, but the majority of investigators regard them, on Johnson's suggestion[1], as derivatives of the hypothetical sulphurane SH_4. Hence one can consider two classes of sulphuranes: σ-sulphuranes with four σ-bonds and an unshared electron pair, and π-sulphuranes (ylides) having two σ-bonds, one π-bond, and an unshared electron pair. The structure of π-sulphuranes can be described in terms of resonance between ylene (A) and ylide (B) structures:

σ-sulphurane π-sulphurane

In order to avoid ambiguity in the names of σ- and π-sulphuranes, in the present review we shall use the suffix "yl" in the names of the former and the suffix "ylidene" in those of the latter. Thus a substituent containing tetracoordinate sulphur will be referred to as sulphuranyl and one with tricoorindate sulphur will be called sulphuranylidene.

The first representatives of stable σ-sulphuranes having electronegative substituents at the sulphur atom have been obtained recently by Martin and coworkers[2-4]. The first stable π-sulphurane is believed to be dimethylsulphuranylidenefluorene (I),[1,5] which was synthesised[6] approximately 50 years ago. However, there is no doubt that the thioniaquinones (II), synthesised much earlier, belong to this class[7,8]:

(I) (II)

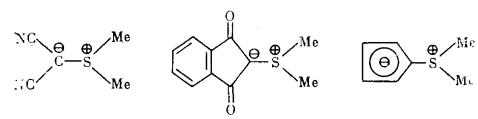
X = Br or NO_2; Y = Br, NO_2, or Me.

Up to the beginning of the 1960's, the chemistry of π-sulphuranes was hardly investigated and this class of compounds became the subject of continued attention by investigators only after the brilliant research of Corey[9] and Franzen[10,11] undertaken in an endeavour to extent the Wittig reaction to sulphur ylides.

At the present time there are a series of reviews in the literature on the chemistry of sulphur ylides[1,4,5,12-25], among which only one has been translated into Russian[1]. However, they are devoted not only to sulphonium ylides, among which attention is concentrated on the non-stabilised ylides, but also to many related compounds, for example sulphoxides, sulphilimines, oxosulphonium ylides, sulphenes, sulphines, etc., which made it impossible to cover sufficiently fully the chemistry of sulphonium ylides.

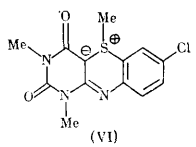
This review is devoted to the chemistry of stabilised sulphonium ylides, i.e. ylides containing electronegative substituents at the carbanionic carbon atom capable of delocalising its negative charge. The decrease of the nucleophilicity of the carbanionic carbon atom in ylides leads to an appreciable alteration of their chemical properties compared with unstabilised sulphonium ylides, which makes it possible to regard the chemistry of stabilised sulphonium ylides as an entirely independent branch of organic chemistry.

II. PHYSICAL PROPERTIES



The main question to which investigators turned their attention in the study of the physical properties of sulphonium ylides was that of the nature of the ylide linkage. Initially the majority of investigators assumed that the *d* orbitals of sulphur are effectively involved in the stabilisation of the negative charge on the carbanion via $p_\pi-d_\pi$ bonding[1,18,19] and it was believed that the $p_\pi-d_\pi$ bonding is favoured by the presence of a positive charge on the sulphur atom of the ylide or of strongly electron-accepting substituents linked to the sulphur atom or the α-carbon atom[26-28]. In relation to the simplest sulphonium ylide SH_2CH_2, the problem of the involvement of the 3*d* orbital of sulphur in the formation of the C–S ylide linkage has been recently examined. Using the Hartree–Fock molecular orbital method, it was

concluded that the use of *d* orbitals for the formation of the highest occupied molecular orbital of the ylide results in an appreciable energy gain. Furthermore, the involvement of the *d* orbitals in the formation of the C–S ylide linkage is confirmed, according to the authors[29], by the distribution of charges in the ylide molecule. These data are analogous to those obtained earlier for phosphorus ylides[30].

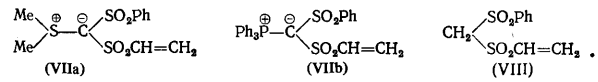


Studies[5,31–34] in which the involvement of the *d* orbitals of Third Period elements (P, S, and Si) is questioned or rejected have been published in recent years. The differences between the properties of the phosphorus, sulphur, and silicon compounds, on the one hand, and those of their analogues in the Second Period, on the other, are explained by the difference between the effective dimensions of their *s* and *p* orbitals[31], the accessibility of the low-lying π^* orbitals of the phosphonium and sulphonium cations[32], or the possibility of the expansion of the valence shell of the heteroatom only as a result of the combination of *s*- and *p*-type orbitals [33,34].

Thus the question of the involvement of the *d* orbitals of the Third Period heteroatoms in the formation of bonds and in particular of the C–S ylide linkage remains open at present.

The physical properties of stabilised sulphonium ylides have been studied very thoroughly. Thus the molecular structure of dimethylsulphuranylidenedicyanomethane (III), [35,36] 2-dimethylsulphuranylideneindan-1,3-dione (IV),[37] dimethylsulphuranylidenecyclopentadiene (V),[38] and 7-chloro-1,3,5-trimethyl-5*H*-pyrimido(5,4-*b*[[1,4]benzothiazine-2,4-[1*H*,3*H*]dione (VI) [39] have been established on the basis of X-ray diffraction data:

(III) (IV) (V)



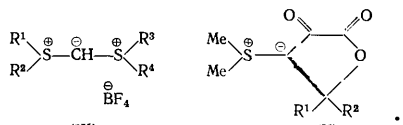
(VI)

The sulphur atom in ylides is pyramidal and the length of the C–S ylide bond (1.71–1.72 Å) is smaller than that of a single C–S bond (1.809 Å) [19] and close to that of the C–S bond in ethylenethiourea (1.708 Å), in which the amount of double bond character has been estimated as approximately 20%.[39] It is noteworthy that in sulphonium salts, where the negative charge is concentrated on the anion, the lengths of all the C–S bonds are close to that of a standard single bond[38]. The bonds between the carbanionic carbon atom and the neighbouring carbon atoms are shortened (1.40–1.43 Å) and the C–O bonds of the carbonyl groups attached to the carbanionic carbon are lengthened (1.23–1.24 Å), compared with the usual values for the C–C and C–O bonds[19,39,40]. In the case of the ylide (V) the distribution of bond lengths in the cyclopentadiene ring approaches the equalised distribution and resembles that in the structure of the analogous phosphorus ylide, for which the proportions of the ylide (~80%) and ylene (~20%) structures have been estimated[38]. The ratio of the latter in the sulphonium ylide is approximately the same, which has been confirmed by ^{13}C NMR spectra obtained recently for the corresponding sulphonium and phosphonium ylides[41].

It follows from X-ray diffraction data that the sulphonium and electron-accepting groups at the carbanionic carbon atom are involved in the delocalisation of its negative charge.

This is also reflected in the infrared spectra of the sulphonium ylides, where in the case of the carbonyl-,[35,42,43] cyano-,[35,44] sulphonyl-,[45] phosphoryl-,[46] and nitro-stabilised[47] sulphonium ylides the stretching vibration bands in these groups are displaced towards lower frequencies compared with the corresponding sulphonium salts[35,42,44,45] and other carbonyl, nitryl, sulphonyl, phosphoryl, and nitro-compounds[48], which is similar to the situation observed for phosphorus ylides[1].

The ultraviolet spectra of the dimethylsulphuranylidene derivatives (VIIa) and the triphenylphosphoranylidene derivatives (VIIb) of benzenesulphonylethylenesulphonylmethane[44] show a broadening of the phenyl band of the ylides and a smoothing of its fine structure compared with the initial methylene compound (VIII):

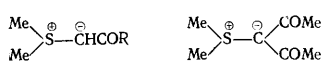


(VIIa) (VIIb) (VIII)

This is evidence for a relatively high electron density on the carbanion in ylides, i.e. ylides exist predominantly in the ylide form (B). Analysis of the ultraviolet spectrum and calculation of the energies of the transitions of dimethylsulphuranylidenecyclopentadiene (V) showed[49,50] that the ylide structure (B) makes an 83% contribution to the ground state and that the latter is stabilised relative to the ylene structure (A) by 1.038 eV (24 kcal). Analogous data were obtained in other studies[51–53]. The ultraviolet spectra of carbonyl-stabilised sulphonium ylides exhibit an absorption which is similar, in terms of the intensity and position of the bands, to that of the enolic form of the corresponding methylene compound but differs appreciably from the absorption of the corresponding sodium salts of the enolic forms[43].

The charge distribution in sulphonium ylides can be inferred from data obtained by the dipole moment method, which are available for the sulphuranylidene derivatives of dicyanomethane[35,54], indan-1,3-dione[54], fluorene[1], and cyclopentadiene derivatives[53,55]. The high dipole moment (4–8 D) shows that the charges in the sulphonium ylides are appreciably separated. However, the dipole moments of ylides are smaller than the value calculated for the ylide structure (B),[1] i.e. the ylene structure (A) makes an appreciable contribution to the ylide–ylene resonance. The dipole moment of the ylide depends on the nature of the substituent at the sulphur atom. Thus replacement of an alkyl group at the sulphur atom by the phenyl group increases the dipole moment of the ylide by 0.4–0.8 D.[54] The introcution of a methoxy-group in the *para*-position of the *S*-phenyl group of the methylphenylsulphuranylidene derivatives of indan-1,3-dione and dicyanomethane increases the dipole moment of the ylide relative to that of the unsubstituted analogue and the introduction of a halogen or the acetyl group lowers the dipole moment of the ylide[54], which indicates the polarity of and ready polarisability of the ylide linkage. In contrast to the data presented above, in their study of the dipole moments of sulphonium, phosphonium, and arsonium ylides derived from cyclopentadienes, Lumbroso et al.[55] concluded that the ylene structure (A) predominates in these compounds.

NMR data are important for the understanding of the geometry and electronic interactions in sulphonium ylides. The positive charge on the sulphur atom leads to the deshielding of the substituent linked to it[42,43,56–58]. The asymmetry of the tetrahedral sulphur atom is responsible for the non-equivalence of the methylene protons of the benzyl or ethyl substituents, which depends on the nature of the solvent[43,59–61], as has been noted for sulphonium salts



and many other sulphur compounds[62]. In the dimethylsulphuranylidene derivatives of acetophenone and β-dicarbonyl compounds the non-equivalence of the protons of the *S*-methyl groups is not observed even at −60 °C,[59] which can probably be accounted for by the ease of inversion at the sulphur atom. Hindrance of the pyramidal inversion at the sulphur atom should lead to the non-equivalence of the *S*-methyl groups, which has been demonstrated recently for a series of 1,3-bis-sulphonium ylides (IX) in the temperature range 40–80 °C.[63] It was established that the activation energy for this process at 80 °C is 19.8 kcal mol^{-1} and that the barrier to inversion is reduced by approximately 5 kcal mol^{-1} on passing from the salt to the ylide. The non-equivalence of the protons of the *S*-methyl groups can be due to the presence of a chiral centre as the carbanionic carbon atom, which has been observed for the derivatives of 4-dimethylsulphuranylidene-2,3-dioxotetrahydrofuran (X) ($\Delta\delta \cong 0.16$ p.p.m.) and the non-equivalence does not disappear in the temperature range 30–100 °C:[64]

(IX)

(X)

As shown in the study of the molecular structures of the stabilised sulphonium ylides (see above), the bonds between the carbanionic carbon atom and the neighbouring substituents are shortened, so that the existence of rotational isomers may be expected for the stabilised sulphonium ylides. This possibility was demonstrated in an ^{1}H NMR study on dimethylsulphuranylidenemethyl carboxylate (XIa) [58] and dimethylsulphuranylideneacetylacetone (XII),[59] where the non-equivalence of the protons of the methylidyne and *C*-methyl groups was observed as the temperature was altered. The presence of such isomers of dimethylsulphuranylideneacetophenone (XIb) was demonstrated chemically, since its methylation with trimethyloxonium tetrafluoroborate led to the formation of a mixture of the *cis*- and *trans*-vinyl ethers in proportions of 94 : 6:[65]

(XI) (a) R=OMe; (b) R=Ph

(XII)

^{13}C NMR spectra yield extremely valuable information about the reactivities of stabilised sulphonium ylides, their study permitting infereneces about the electronic structure of the carbon atoms in the ylide molecule[41,66–69]. The spin–spin coupling constant of the carbanionic carbon atom with the methylidyne proton in the ylide (XIb) ($J_{^{13}C-H_2} = 179.7$ Hz) confirms that this atom is sp^2-hybridised. The upfield shift of the signal due to the nucleus of the carbonyl carbon atom in carbonyl-stabilised sulphonium ylides relative to the signal of this carbon atom in the corresponding sulphonium salts (−9.5–11.8 p.p.m.) permits the conclusion that the contribution of the ylide structure (B) to the ylene–ylide resonance is important[66]. The substitution of the methylidyne hydrogen atom in the ylide by an electron-accepting substitutent results in a downfield shift of the signal of the carbanionic carbon atom and a reduction of the nucleophilicity of such ylides[66,67].

Important data on the electronic interactions in sulphonium ylides can be obtained by studying the basicity of the latter or the acidity of the corresponding sulphonium salts. Thus the basicity of the sulphuranylidene derivatives of acetophenone decreases after the introduction of electron-accepting substituents in the *para*-position of the S-phenyl or phenacyl group[70,71]. Similar data have been obtained for the phosphonium analogues[72]. The basicity of the sulphonium ylides diminishes in the following sequence of substituents at the sulphur atom: Me > Et > iso-Pr > Ph, i.e. the dialkylsulphonium group is less involved in the delocalisation of the negative charge in the carbanion than the dephenylsulphonium group[73–75]. Thus the introduction of groups stabilising the ylide leads to a decrease of its basicity owing to the greater delocalisation of the negative charge on the carbanion.

The basicity of sulphonium ylides is lower than that of the corresponding phosphonium and ammonium analogues and increases in the sequence S < P < N,[70,71] which depends on the degree of involvement of onium groups in the stabilisation of the carbanionic system of the ylide. The dependence of the stabilising effect of the onium group on the nature of the heteroatom (S ≅ Se ≫ P > As > Sb) has been determined in a study of the ^{1}H NMR and ultraviolet spectra and of the basicities of the corresponding cyclopentadiene ylides[55,75–77]; the analogous series S > P > As > N has been obtained in a study of the rates of isotope exchange of onium salts with D_2O.[78] These data are frequently quoted as evidence for the delocalisation of the negative charge of the carbanion over the *d* orbitals of sulphur[1,55,70], but Kissel et al.[71] regard this as doubtful, since the properties of the ylides examined above can be accounted for also without invoking the "concept of *d* orbitals".

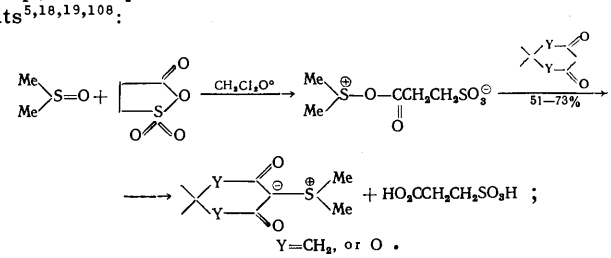
The synthesis of optically active stabilised sulphonium ylides is of great interest. The first attempt at their synthesis was unsuccessful[59], evidently owing to the ease of their racemisation. Theoretical calculation of the barriers to pyramidal inversion and the internal rotation relative to the formally double C=S ylide bond showed that the automerisation of ylides proceeds as a two-stage process[79]. The inversion of the sulphur pyramid is preceded by the rotation about the C–S ylide bond and the *gauche*-conformation constitutes a transition state. The calculated barrier to the inversion of the pyramid at the sulphur atom (35.3 kcal mol^{-1}) corresponds to the condition for its configurational stability; the barrier to rotation about the C–S ylide bond is 8.7 kcal mol^{-1}.[79] Optically active (−)-ethylmethylsulphuranylideneacetophenone has been obtained[80] and it has been shown that it racemises at 90 °C 200 times faster than the corresponding sulphonium salt and approximately 10^{11} times faster than methyl *p*-tolyl sulphoxide. The enthalpy of activation of the ylide is 23.3 kcal, while for sulphonium salts it is 25 to 29 kcal and for sulphoxides 35–43 kcal.[80,81] The greater ease of racemisation of the ylide can be explained by the fact that the interaction of the sulphonium centre with the carbanionic component of the ylide stabilises the transition state for its inversion[80,81]. The fact that the racemisation of the ylide proceeds via the pyramidal inversion mechanism has been confirmed[82]. It was found that the activation volume for this process is close to zero ($\Delta V^{\neq} \cong 0$) in contrast to the t-butylethylmethylsulphonium ion ($\Delta V^{\neq} = +6.4$), whose activation volume corresponds more closely to a transition state involving partial dissociation. A number of optically active sulphonium ylides stabilised by two carbonyl groups were later obtained[83,84].

Thus, stabilised sulphonium ylides are an extremely **unusual class** of organic compounds. They are highly polar **and their stability** is due to the degree of delocalisation of the electron density in the molecule.

III. METHODS OF SYNTHESIS

Several method of synthesising stabilised sulphonium ylides are now known: the "salt method", the "iodonium method", the reaction of sulphides with diazo-compounds, and other less general methods.

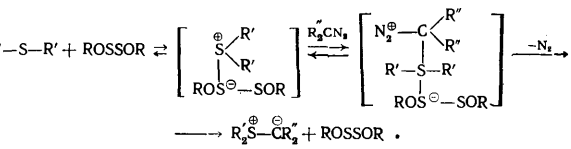
The salt method consists in the deprotonation of sulphonium salts already prepared or synthesised *in situ* by means of a suitable base:



The choice of the base, which can be potassium carbonate, amines, alkoxides, sodium hydride in DMSO, etc.[5,85], is determined by the acidity of the proton at the α-carbon atom of the salt. This method has been used successfully to synthesise a number of carbonyl-stabilised sulphonium ylides[42,86–89]. The applicability of the "salt method" to the synthesis of stabilised sulphonium ylides is limited by the availability of the sulphonium salts and the occurrence of side reactions involving β-elimination and the formation of σ-sulphuranes[5].

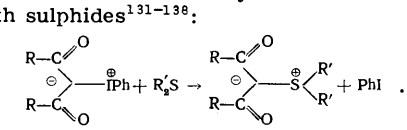
The method based on the substitution of the proton at the carbanionic carbon atom of the ylide is a variety of the "salt method". The attempts to alkylate the sulphuranylidene derivatives of acetophenone by methyl iodide, benzyl bromide[42,56,57], and α-halogenoketones[90,91] were unsuccessful, since the reactions were accompanied by the dealkylation of the sulphonium salt formed. The reactions of similar ylides with picryl chloride[92], aromatic amine oxides (*C*-arylation),[93] vinyl ethers (*C*-alkenylation),[94] benzenesulphenyl chloride[95], and *N*,*N*-diethylbenzenesulphenamide[96] (sulphenylation), which led to new stabilised sulphonium ylides, proved more successful.

Carbonyl-stabilised sulphonium ylides can be obtained by acylating ylides with a proton at the carbanionic carbon atom. Acid anhydrides[42,97–99], isocyanates[59,90,99,100], acid azides[101,102], aldehydes, α-diketones, α-ketoacid esters[63], and acyl halides[42,64,95,98,99,103–107] can be used as acylating agents. The employment of acyl halides for the acylation of monocarbonyl-stabilised sulphonium ylides is limited by the formation of *O*-acylation side products, which is evidently associated with the enolate stabilisation of ylides[42].



The salt method also includes the condensation of sulphoxides with compounds containing an active methylene group, which proceeds via the intermediate formation of salts[5,18,19,108]:

This reaction takes place under conditions typical for dehydration reactions in the presence of dehydrating agents such as sulphopropionic anhydride[108], acetic anhydride[5,14,18,19] (although in the presence of the latter the yield of the ylide is low owing to the competing Pummerer reaction[109]), phosphorus pentoxide[59], thionyl chloride[59,100], aryl cyanates[111–113], sulphur trioxide[114,115], and dicyclohexylcarbodi-imide[35,52,116,117]. All these reagents form sulphonium salts or complexes with sulphoxides, which readily react with compounds containing an active methylene group. This has been confirmed by the reactions of the stable betaine formed when DMSO reacts with sulphopropionic anhydride[108] and by the reactions of stable sulphonium salts[59,118] with compounds containing an active methylene group or their sodium salts, which led to the formation of the corresponding sulphonium ylides. The yield of the ylide and the rate of its formation when the condensation is carried out in acetic anhydride can be increased by adding to the reaction mixture alkali metal perchlorates, which facilitate the formation of the acyloxysulphonium salt[119]. The reaction of organic selenide dihalides with compounds containing an active methylene group has been used successfully recently to synthesise stabilised selenonium ylides[120]. The attempts to employ this method for the synthesis of sulphonium ylides proved unsuccessful, since the intermediate sulphonium salts readily decomposed with formation of an olefin and an α-halogenocarbonyl compound[121].



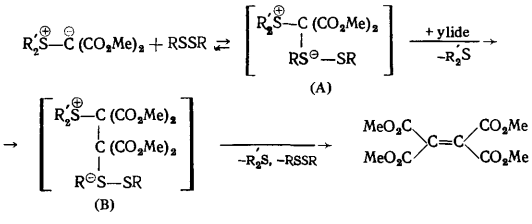
The thermal, photolytic[17,25,66,122–126], or catalytic decomposition[127] of diazo-compounds in the presence of sulphides constitutes a direct method of synthesis of stabilised sulphonium ylides. The reaction evidently proceeds via the nucleophilic attack by the sulphide on the singlet carbene formed on decomposition of the diazo-compound; the high stereoselectivity of this process has been demonstrated[128]. The thermal decomposition of diazo-compounds is usually carried out in the presence of anhydrous copper sulphate or metallic copper powder. This method is applicable to the synthesis of ylides from weakly nucleophilic sulphides such as diaryl sulphides or dibenzothiophen[129]. It is noteworthy that dialkyl sulphides are approximately 4–6 times more reactive in this reaction in relation to the carbene than olefins[126,129].

The catalytic decomposition of diazo-compounds in the presence of sulphides takes place readily at room temperature in the absence of light, provided that dialkoxydisulphides have been added to the reaction mixture[127]; the process probably proceeds via the following mechanism:

The formation of a complex of the sulphide with a dialkoxy disulphide has been observed in the reaction of tetramethylene sulphide with dimethoxy disulphide[127]. In all cases the yield of the ylide decreases with decrease of the nucleophilicity of the sulphide and with increase of the degree of branching of its hydrocarbon groups. Furthermore, the decrease of the yield of the ylide can be caused by the rearrangements and processes involving the cleavage of the ylide under the reaction conditions[17,25,129,130] (see Section IV).

The "iodonium method" of synthesising stabilised sulphonium ylides consists in the transylidation of the iodonium betaines with sulphides[131–138]:

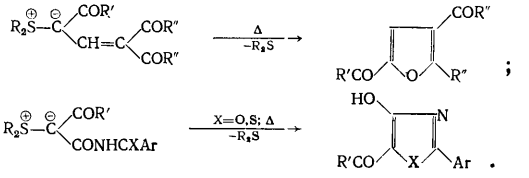
These reactions are catalysed by copper(I) or copper(II) salts[131–135,138] and toluene-*p*-sulphonic acid[136,137]. Although the mechanism of this reaction has not been investigated, when copper salts are used it probably proceeds via the intermediate formation of a carbene or, in the presence of toluene-*p*-sulphonic acid, the intermediate iodonium salt is cleaved by the nucleophilic sulphide at the C–I bond and the resulting sulphonium toluene-*p*-sulphonate is deprotonated further by the counterion, which leads to the corresponding ylide.



A number of less general methods are also suitable for the synthesis of stabilised sulphonium ylides. Thus ylides can be obtained by the transylidation of other sulphonium ylides in the presence of disulphides activated by electron-accepting groups (dialkoxydisulphides, thiocyanogen, etc.)[139] or electrophilic monosulphides (aryl thiocyanates, *p*-hydroxyphenyl trifluoromethyl sulphide, etc.)[69] as well as by the transylidation of selenonium ylides with sulphides in the presence of carbon disulphide[140]. Stabilised sulphonium ylides can be obtained by adding DMSO to acetylenedicarboxylate[103] or, in the case of the sulphuranylidene derivatives of dicyanomethane, by the interaction of sulphides with tetracyanoepoxyethane[44,110].

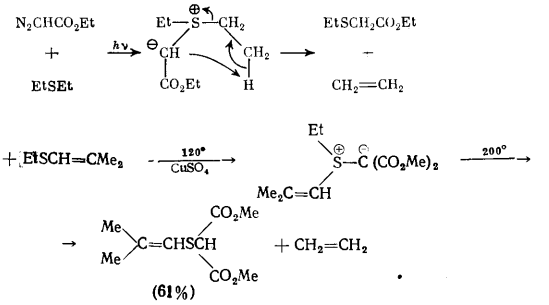
IV. CHEMICAL STABILITY. REARRANGEMENTS

It was pointed out above that the stability of sulphonium ylides is determined mainly by the degree of delocalisation of the electron density in their molecules under the influence of electron-accepting substituents.



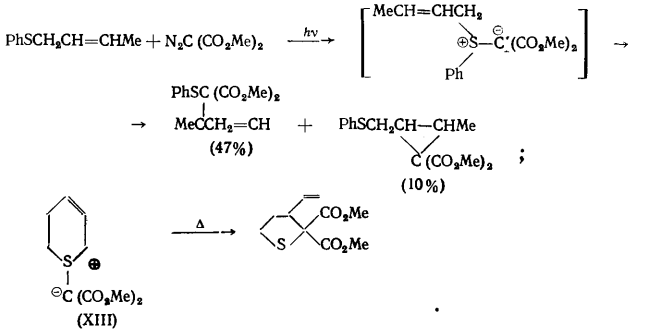
Nothing is so far known about the oxidants on stabilised sulphonium ylides. In a few studies[103,141-143] the reduction reactions have been investigated. When ylides are hydrogenated or are acted upon by sodium hydride, the ylide linkage is cleaved with formation of a sulphide and a hydrocarbon residue. In only one case was the reduction of the carbonyl group without the involvement of the ylide linkage observed[143]. The hydrolytic stability of stabilised sulphonium ylides has been studied in greater detail; it will be examined below in Section VI.

Stabilised sulphonium ylides can be decomposed thermally, photolytically, and catalytically; this very often involves different types of rearrangements. The catalytic decomposition of ylides proceeds readily in the presence of disulphides activated by electron-accepting substituents[144]. Ylides then decompose in the following sequence in terms of the decrease of their reactivity: $R_2\overset{\oplus}{S}-\overset{\ominus}{C}HCOPh > R_2\overset{\oplus}{S}-\overset{\ominus}{C}(\overset{\ominus}{C}O_2Me)_2 \approx R_2\overset{\oplus}{S}-\overset{\ominus}{C}(CN)_2 \gg R_2\overset{\oplus}{S}-\overset{\ominus}{C}(CO_2Me)(COMe)$, which is similar to the series based on the decrease of the nucleophilicity of the carbonionic carbon atom. The decomposition of the ylide, involving its complex with a disulphide, can be represented by the following scheme:



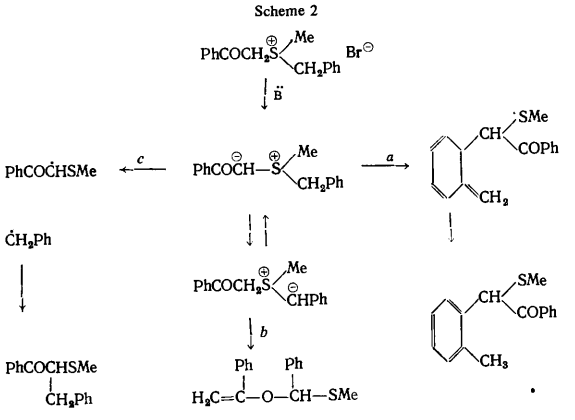
Thus an olefin is formed in the decomposition of the complex (B) obtained as a result of the nucleophilic substitution of the sulphonium group of the complex (A) by another ylide molecule. In the case of highly nucleophilic sulphuranylidene derivatives of acetophenone the olefin formed reacted with the the initial ylide with formation of the corresponding cyclopropane derivatives[144]. The possibility of the formation of cyclopropane derivatives from ylides and olefins has been confirmed by a study of the decomposition of acyldiazo-compounds in the presence of sulphides[144-146].

The thermal and photolytic decomposition of monocarbonyl-stabilised sulphonium ylides leads to the corresponding *trans*-substituted cyclopropane derivatives[18,56-58,98,147-151]. To account for this process, a "carbene" mechanism has been proposed in the case of the photolytic decomposition of the ylide[148,149] and both "carbene" and "ionic" mechanisms have been put forward for the thermal decomposition[56,147-150] and both have been confirmed experimentally: the carbene mechanism by trapping the intermediate carbene with dimethylbenzylamine[56,57], triphenylphosphine[149], cyclohexene[147,148], and other compounds which readily react with carbenes[152] and the ionic mechanism by converting dimethylsulphuranylideneacetophenone (XIb) into *trans*-tribenzoylcyclopropane, the reaction being catalysed by a phenacylsulphonium salt[56,147,150,151]. (For further details of these mechanisms, see Reid[18].) It is noteworthy that sulphonium ylides stabilised by two electron-accepting groups are not converted into cyclopropanes as a result of the low nucleophilicity of the carbanionic carbon atom[144]. However, if one of the stabilising groups is an allyl acetate group or a (thio)carbamoyl group, intramolecular cyclisation of the ylide, leading to furan, oxazole, or thiazole derivatives, becomes possible[100,153]:

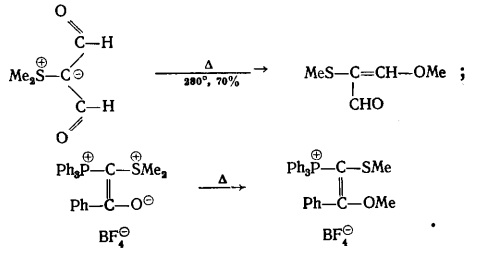


When a substituent with β-hydrogen atoms (ethyl or t-butyl group) is attached to the sulphonium sulphur atom, β-elimination processes are observed instead of conversion into a cyclopropane derivative, which results in the formation of alkyl thioacetates or alkenyl thiomalonates and olefins (Scheme I).[126,154,155] For further details about the β-elimination processes, see Ando[17,25]:

Scheme 1



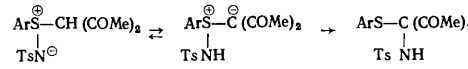
When stabilised sulphonium ylides are decomposed, various rearrangements may occur together with the reactions involving conversion into a cyclopropane derivative, cyclisation, and β-elimination. Thus the thermal or photolytic decomposition of *S*-allyl-substituted sulphonium ylides, including the cyclic ylide (XIII), entails [2,3]-sigmatropic rearrangements leading to the formation of homoallyl sulphides[130,154]:



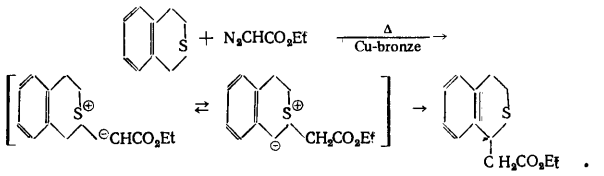
These rearrangements are allowed by the orbital symmetry[156] and occur on heating or photolysis of ylides with complete inversion of the allyl substitutent[130,154]. The method of successive [2,3]-sigmatropic shifts has been used recently in the synthesis of eight- and eleven-membered heterocycles[157]. It is noteworthy that similar [2,3]-sigmatropic rearrangements are observed also for unstable oxonium, ammonium, and halogenonium compounds[130,158].

The Sommelet–Hauser rearrangement, leading to a product substituted in the aromatic ring (pathway *a*),[1,159] and the 1,5-rearrangements of carbonyl- or cyano-stabilised sulphonium ylides, occurring with formation of enolic monothioacetals in the case of carbonyl-stabilised ylides (pathway *b*),[159,160] or keten imines[161], can be included among rearrangements of this type; in the last instance the alkyl group migrates from the sulphur atom to the nitrogen atom of the nitrile group:

Scheme 2

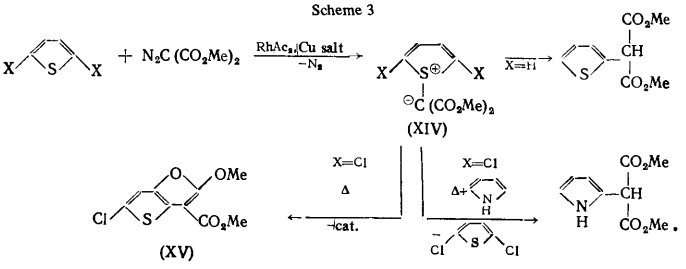


These rearrangements are favoured by a protic solvent, which promotes the proton transfer processes occurring under these conditions. The ratio of the products formed via pathways *a* and *b* depends on the rate of attainment of equilibrium between the two ylide forms and can be controlled by the concentration of a base[159]. The possibility of the 1,5-migration of the alkyl group has been demonstrated not only for monocarbonyl-stabilised sulphonium ylides but also for ylides stabilised by two carbonyl or carbonyl and phosphonium groups[85,162]:

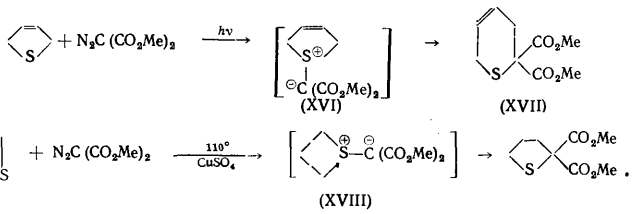


When an aprotic solvent is used, the [1,2]-sigmatropic shift (pathway *c*) of the *S*-alkyl group (the Stevens rearrangement) begins to compete with the above rearrangements (pathways *a* and *b*) and it has been noted that the Stevens rearrangement is favoured by an increase of temperature[159]. Furthermore it has been shown recently for sulphuranylidene derivatives of pyrimido-1,4-benzothiazine[163] that the type of rearrangement depends on the nature of the substituents in the ylide and the reaction conditions (thermolysis or photolysis).

The Stevens rearrangement was discovered in 1932 [164] and consists in the conversion of methylbenzylsulphonium bromide in a methanol solution of sodium methoxide into α-methylthio-β-phenylpropiophenone (evidently via the intermediate formation of an ylide). The concerted mechanism of the thermal Stevens rearrangement is prohibited by orbital symmetry[156], so that the mechanism involving a dissociation–recombination process is more probable. This is confirmed by the finding that the reaction is characterised by a very low value of ρ if the substituents in the benzene ring of the benzyl group are varied[165,166] and by the appearance in the ^{1}H NMR spectrum of benzyl protons of chemically induced dynamic nuclear polarisation[129,165–167]. An interesting example of a 1,2-shift has been observed recently[168] for a new type of sulphonium ylides with an amino-group attached to the sulphonium sulphur atom:



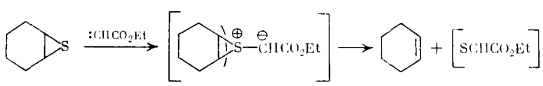
The inclusion of the sulphur atom in a six-membered ring partly makes the 1,2-migration of the *S*-alkyl group energetically unfavourable, since it should occur with formation of a thiepan ring. In this case migration is observed from the methyleneethoxycarbonyl substituent and not the *S*-alkyl substitutent, evidently via an intermediate formation of an unstable ylide[169]:



Recently a similar migration of the dimethylmalonate group has been observed in the thermal rearrangement of ylides derived from thiophen occurring on heating them in the presence of rhodium or copper catalysts[170]. Under these conditions, when the α-positions of the thiophen ring are substituted, then in the presence of the above catalysts the ylide dissociates into a sulphide and a carbene; the latter was trapped with activated aromatic compounds (pyrrole, indole, anisole, etc.).[152] It is noteworthy that the ylide (XIV), carefully freed from the catalyst, does not decompose into a sulphide and a carbene but undergoes an intramolecular rearrangement involving the migration of the malonate substituent from the copper atom to the α-position of the thiophen ring with subsequent ring closure, elimination of HCl, and the formation of methyl 5-chloro-2-methoxythieno-[3,2-*b*]furan-3-carboxylate (XV):[171]

Scheme 3

Thus the inclusion of the sulphonium sulphur atom in the ring has a significant effect on the mode of the composition of the ylide. The influence of ring size and the ring substituents on the stability of ylides and the mode of their decomposition can be illustrated by the following examples. Sulphonium ylides obtained from thiophan, tetrahydrothiapyran, thiepan, and dimethyl diazomalonate do not decompose on heating at 235 °C in the course of 10 h.[129] As pointed out above, ylides obtained from derivatives of thiophen



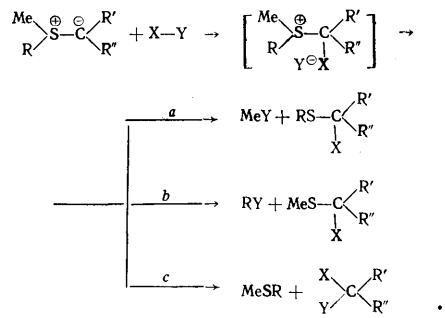
(XIV) or Δ^3-dihydrothiapyran (XIII) and dimethyl diazomalonate behave differently. The former undergoes a 1,2-shift of the malonate group or decomposes into a sulphide and a carbene[152,170,171], while the latter gives rise to products of the [2,3]-sigmatropic rearrangement accompanied by ring contraction[130]. The opposite behaviour has been observed for the ylide (XVI) obtained from 2,5-dihydrothiophen and dimethyl diazomalonate: the Stevens rearrangement, leading to the stable Δ^3-5,5-dimethoxycarbonylthiapyran (XVII) is more favourable than the [2,3]-sigmatropic rearrangement, which leads to the sterically strained thietan[130]:

(XVI) (XVII)

(XVIII)

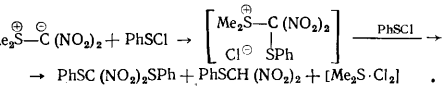
The sulphonium ylide (XVIII), formed in the reaction of the thietan with dimethyldiazomalonate readily rearranges to 2-dimethylcarbonyltetrahydrothiophen[129]. This process is evidently caused, on the one hand, by the transition of the sulphur from the quadrivalent to the bivalent state and, on the other, by the formation of a less strained five-membered ring. The reactions of ketocarbenes with oxetans proceed similarly[172]. If the sulphur is incorporated in the thi-iran ring, then a stable ylide is also not formed in the reaction of such a sulphide with a carbene. The Stevens rearrangement would lead in this case to a strained thietan, so that α-fragmentation, leading to an olefin and a thiocarbonyl compound, is more favourable under these conditions[173]. Analogous reactions had been observed earlier between carbenes and oxirans[172] and aziridines[174]:

It is noteworthy that the stability of ylides and the mode of their decomposition are influenced also by the nature of the substituents at the carbanionic carbon atom. Thus sulphuranylidene derivatives of dicyanomethane decompose on heating into a sulphide and tetracyanoethylene regardless of the nature of the substituents at the sulphur atom (alkyl, phenyl, tetrahydrothiapyranyl, etc.).[142]



Thus the possibility of the rearrangements must also be taken into account when sulphonium ylides are used in organic synthesis. At the same time the rearrangements of stabilised sulphonium ylides constitute a new method of forming carbon–carbon bonds.

V. REACTIONS WITH ELECTROPHILES

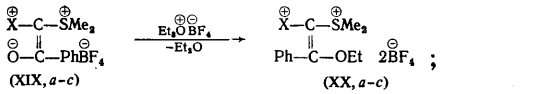


The reactions of stabilised sulphonium ylides with electrophiles are due to the presence of a carbanionic centre in the ylide molecule; with increase of the degree of delocalisation of the negative charge on the carbanion, the reactivity of the ylide with respect to the electrophiles diminishes.

It was started in Section III that one of the main methods of synthesising sulphonium ylides is the "salt method". The reverse reaction involving the regeneration of the sulphonium salt by the addition of hydrogen halides is also possible[13], but the sulphonium salt frequently decomposes under the influence of the nucleophilic counterion in a way which depends both on the substituents in the ylide and on the nature of the nucleophile. A detailed study of these reactions[143,175–179] showed that the sulphonium salts can decompose via three pathways (*a*–*c*). Pathway *a* involves attack by the nucleophilic counterion on the carbon atom of the S–Me group, pathway *b* involves attack on the carbon atom of the S–R group, and pathway *c* involves attack on the carbon atom of the C–X group.

The study of the reactions of dimethylsulphuranylidinedinitromethane with electrophiles (halogens, hydrogen halides, water, sulphuryl chloride, benzenesulphenyl chloride, *N*-halogenoamides, *N*-chloroalkylnitramine, etc.) showed[175–177] that the intermediate sulphonium salt decomposes only via pathway *c*. The formation of products of pathways *a* and *b* is not observed, although this may be caused by their decomposition in the course of the reaction, because it is known that α-polynitroalkyl sulphides are cleaved by both nucleophiles and electrophiles[28,180].

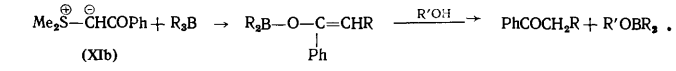
It is noteworthy that the intermediate sulphonium salt can be cleaved not only by the nucleophilic counterion but also by the initial electrophile[176,177]:



When halogens, sulphuryl chloride, and sulphur monochloride are used in this reaction, competitive halogenation of the *S*-alkyl group takes place[142,176].

In the reactions of sulphuranylidene derivatives of malonic ester with electrophiles (halogens, hydrogen halides, arenesulphenyl thiocyanates, etc.)[178,179] the products of all the above pathways (*a*–*c*) are observed. In the general case the mode of decomposition of the intermediate sulphonium salt depends on the structure of the sulphonium cation (the nature of the groups R and X) and on the nature of the nucleophile. If X is a heteroatomic group, then the substituents at the sulphur atom can be arranged in the following sequence in accordance with the increase of their reactivity with respect to nucleophiles: Me (1.0) ≅ Et (0.6) < iso-Pr (3.0) ≪ CH_2Ph ≅ CH_2SMe (∞). This sequence is different from the sequences based on the reactivity of the substituents in the reactions of alkyl bromides with the bromide anion in acetone at 25 °C: CH_2Ph = Me (1.0) > Et (0.013) > iso-Pr (0.0086), and in reactions of alkylmethylphenylsulphonium perchlorates with the iodide anion in acetone at 50 °C: Me (1.0) > Et (0.20) > n-Pr (0.16) > iso-Pr (0.05),[178] for which the S_N2 mechanism has been established. The higher reactivity of the benzyl and methylthiomethylene groups relative to the methyl group shows that these reactions can proceed via an S_N1 type mechanism[178,179].

In contrast to the reactions of sulphuranylidene derivatives of dinitromethane and malonic ester with electrophiles discussed above, the protonation or alkylation of phenacylide salts (XIX) by acids or triethyloxonium tetrafluoroborate does not take place at the carbanionic carbon atom but

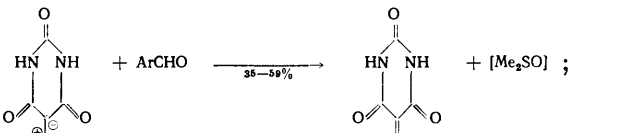


involves the more electronegative end of the carbanionic system—the carbonyl oxygen atom, with formation of the corresponding bis-salts (XX):[162]

(XIX, *a-c*) (XX, *a-c*)

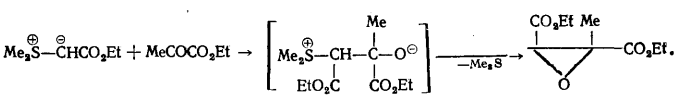
X = (a) Ph_3P, (b) Me_2S, or (c) Ph_2Se.

The reactions of sulphonium ylides with simple electrophiles such as trialkylboranes are of interest[181,182]. The trialkylborane can attack either the carbanionic carbon atom with subsequent C–O rearrangement or directly the oxygen of the enolate form of the ylide, leading to an alkoxydialkylborane after the elimination of the sulphide. It has been established that the alkyl group migrates from the boron atom to the carbon atom in the form of an anion[183]:



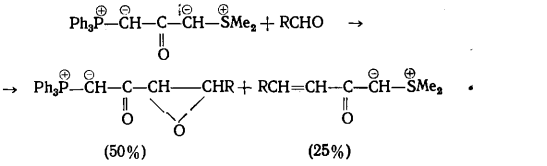
(XIb)

The reactions of sulphonium ylides carrying a proton at the carbanionic carbon atom with acyl halides and alkyl halides have been examined in detail in Section III. Ylides stabilised by two electron-accepting groups also react with them to form sulphonium salts. The structure of the final product is influenced significantly by the nature of the substituents in the sulphonium ion[142,162,184,185]. The reactions of sulphonium ylides with acyl peroxides proceed similarly[186].



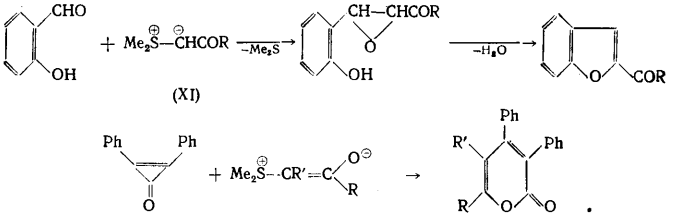
In the study of the chemical properties of stabilised sulphonium ylides much attention was devoted to their reactions with carbonyl compounds and compounds containing multiple bonds[5]. The study of the reactions of ylides with carbonyl compounds was stimulated by the endeavour to extend the Wittig reaction to sulphur ylides. However, instead of the expected olefins, oxirans were obtained in this case. This is probably caused by the lower stability of the S–O bond (E_{diss} = 89 kcal mol^{-1}) compared with the P–O bond (E_{diss} = 128 kcal mol^{-1}) and different tendencies of the sulphide and phosphine groups to be eliminated[1].

The occurrence of the Wittig reaction has been reported in only two instances[187,188]:

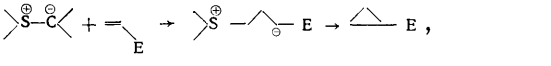


Ar = 4-$Me_2NC_6H_4$, 4-$Et_2NC_6H_4$, or $2O_2NC_6H_4$.

The epoxidation of carbonyl compounds by sulphonium ylides involves the reversible attack by the carbanionic carbon atom of the ylide on the electrophilic carbon atom of the carbonyl group. The resulting unstable betaine either decomposes into the initial compounds or gives rise to an oxiran via nucleophilic substitution of the sulphide group by the anionic oxygen atom. The mode of decomposition is determined by the nature of the substituents in both the ylide and in the carbonyl compound. It is noteworthy that stabilised sulphonium ylides give rise to oxirans only by reacting with very reactive carbonyl compounds such as dicarbonyl compounds, α-halogenoaldehydes, etc.[109,189]:



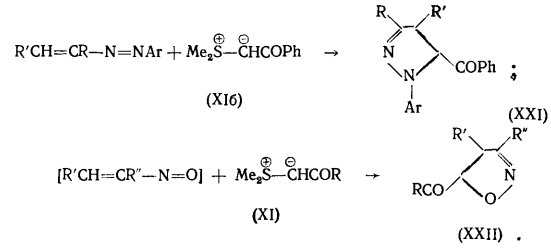
The introduction of a phosphoranylidene substituent in the α-position with respect to the carbonyl group of the sulphonium ylide increases the reactivity of the latter by reducing the involvement of the carbonyl group in the delocalisation of the negative charge over the sulphuranylidene fragment. This ylide reacts readily with carbonyl compounds, epoxidation predominating over "olefination":[190]



(50%) (25%)

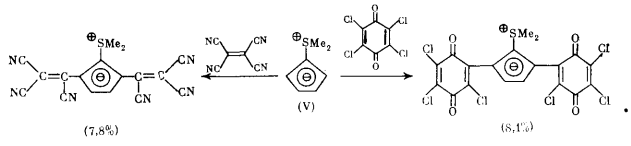
The reactions of sulphonium ylides with aldehydes having a nucleophilic centre located close to the carbonyl group are of interest. Thus oxiran, formed when salicylaldehyde is used, is converted into benzofuran derivatives[191]. The reaction of sulphonium ylides with diphenylcyclopropenone, leading to 2-pyrones, is also unusual[192]:

(XI)



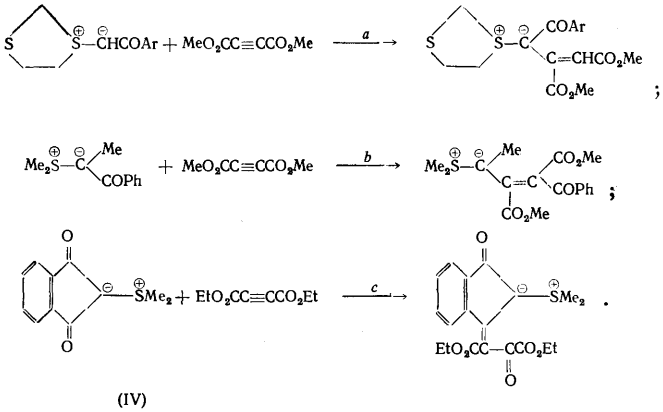
Stabilised sulphonium ylides react readily with olefins activated by electron-accepting substituents and in the case of α,β-unsaturated carbonyl compounds the conversion into a cyclopropane derivative predominates over epoxidation. Here one should note immediately that one is dealing only with the conversion of olefins into cyclopropane derivatives by fairly nucleophilic ylides stabilised by a single electron-accepting group, since in the presence of two such groups the ylide does not react with an extremely reactive chalcone[5]. The role of the electron-accepting substituent in the olefin consists not only in activating the double bond but also in stabilising the intermediate betaine. The specific synthesis of analogues of the latter confirmed the ready conversion of such betaines into cyclopropane derivatives[193]:

where E is an electron-accepting group.



In recent years the reactions of stabilised sulphonium ylides with activated olefins have been used successfully to synthesise cyclopropyl-substituted heterocycles[194–196], sugars[197–200], phosphonium ylides[190], phosphonates[46], and phosphonium salts[201]. It is noteworthy that, when olefins with a conjugated system of multiple bonds are used in reactions of this kind, there is a possibility of the formation of not only the 1,2-addition products but also of 1,4-addition products, which can be due to the stereochemistry of this reaction[5,198–200]. The formation of 1,4-addition products has been recently demonstrated in the reactions of azoalkenes[202], nitrosoalkenes[203,204], and nitroalkenes[197–200] with sulphonium ylides, whereupon derivatives of 4,5-dihydropyrazoline

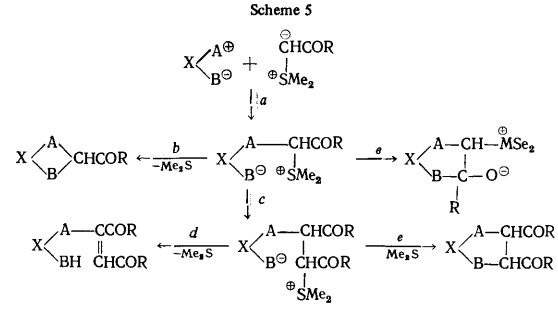
(XXI), Δ^2-isoxazoline (XXII), and Δ^2-isoxazoline *N*-oxide respectively were obtained:



The reactions of sulphuranylidene derivatives of cyclopentadiene (V) with tetracyanoethylene and chloranyl entail the condensation of the latter two compounds at the β-carbon atom of the cyclopentadienyl ring, leading to products of the Michael addition (albeit in a low yield):[185]

Scheme 4

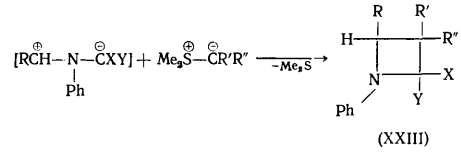
Stabilised sulphonium ylides react readily with alkynes, activated by electron-accepting groups, via pathways *a–c*, which depend on the structure of the ylide and the reaction conditions:



The use of protic solvents and ylides with a proton at the carbanionic carbon atom leads to the formation of new ylides via proton transfer (pathway *a*).[205] In aprotic solvents and for ylides with a disubstituted carbanionic carbon atom, new ylides are formed via the 1,3-migration of the acyl group (pathway *b*).[206] It is noteworthy that allyl-substituted ylides, formed via pathways *a* and *b*, can be cyclised into furan derivatives on heating or using DMSO as the solvent[206].

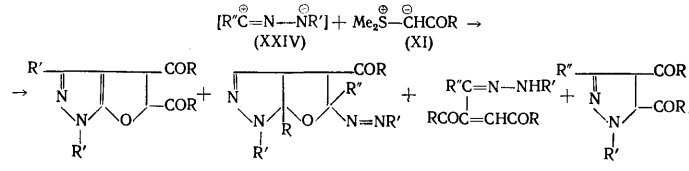
Pathway *c* obtains in reactions of sulphuranylidene derivatives of cyclic β-dicarbonyl compounds[207]. Here the alkyne adds to the carbonyl group of the enolate form of the ylide with formation and subsequent opening of the oxetan ring, which leads to products resulting from the transfer of the carbonyl oxygen.

One of the most important methods of synthesis of heterocycles is known to involve 1,3-dipolar cycloaddition reactions[208]. The reactions of 1,3-dipolar compounds with sulphonium ylides give rise to new possibilities in this sense.



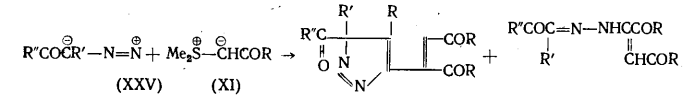
The study of the available literature data makes it possible to formulate six principal reactions of ylides with 1,3-dipolar compounds (*a–f*):

Scheme 5



where $\overset{\oplus}{A}-X-\overset{\ominus}{B}$ are 1,3-dipolar compounds (for examples, see below).

In all cases the reaction begins with nucleophilic attack by the carbanionic carbon atom of the ylide on the electrophilic centre of the 1,3-dipole (*a*). The further course of the reaction depends on the nature of the 1,3-dipole and the substituents in the ylide. Thus azetidines (XXIII) are readily formed in the reactions of azomethine and sulphonium ylides (*b*):[209]

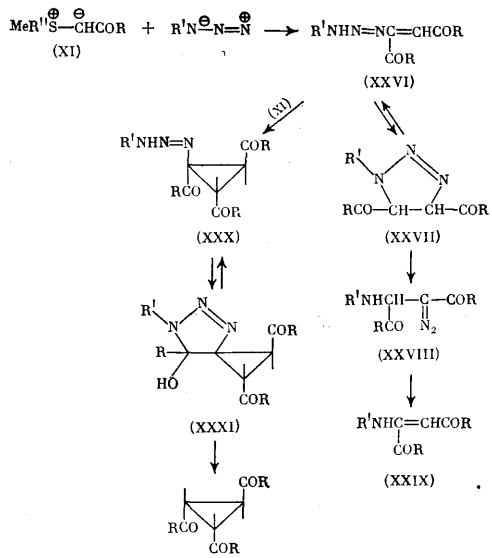


Pathway *b* is unfavourable when the 1,3-dipole contains two or three heteroatoms (nitrile imines, diazocarbonyl compounds, and azides), probably owing to the instability of the corresponding four-membered heterocycles. Depending on the structure of the ylide and the 1,3-dipole as well as the reaction conditions, products of pathways *c–f* are formed in this case.

The following products have been isolated in the reactions of sulphonium ylides with nitrile imines (XXIV):[204,210]

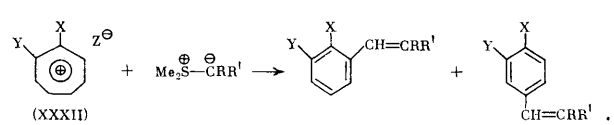
The formation of bicyclic adducts in this reaction shows that the growth of the "ylide chain" takes place not only in the betaines formed in reactions *a* and *d*, but also in the product of reaction *c*, both sulphonium and nitrile imine ylides being involved in its formation.

The reaction of ylides with diazocarbonyl compounds (XXV) is analogous albeit less varied (simple diazo-compounds do not undergo this reaction)[204,211]



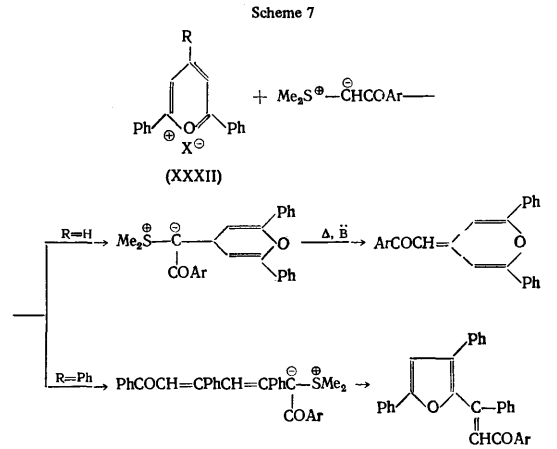
The difference between the structures of the products formed in the reactions of ylides with nitrile imines and diazocarbonyl compounds is evidently due both to the opposite polarisations of the corresponding 1,3-dipoles and to the

different relative reactivities of the 1,3-dipole compound and the intermediate betaines.



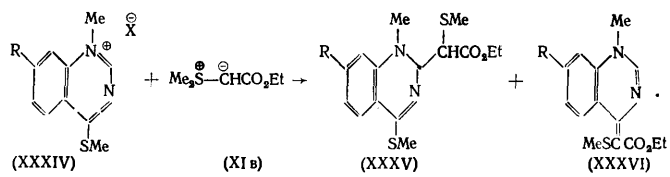
With the exception of alkyl azides[101,204], azides react with sulphonium ylides via pathways *d* and *f*.[101,102,204,212,213] The betaine (XXVI), formed via pathway *d*, can be stabilised by cyclisation to Δ^2-triazoline (XXVII), these forms being readily interconverted. In the presence of bases Δ^2-triazoline (XXVII) is unstable and decomposes to the diazo-compound (XXVIII) and then further (with loss of nitrogen) to the enamine (XXIX). Furthermore, the betaine (XXVI) can combine with a third ylide molecule to form cyclopropane derivatives of triazene (XXX) or Δ^2-triazoline (XXXI). The latter can decompose into the initial azide and a cyclopropane derivative:

Scheme 6



Studies devoted to the reaction of sulphonium ylides with tropylium[214–216], pyrylium[88,217,218], quinazolinium[219], oxathiolium, and dithiolium[220] have been published in recent years.

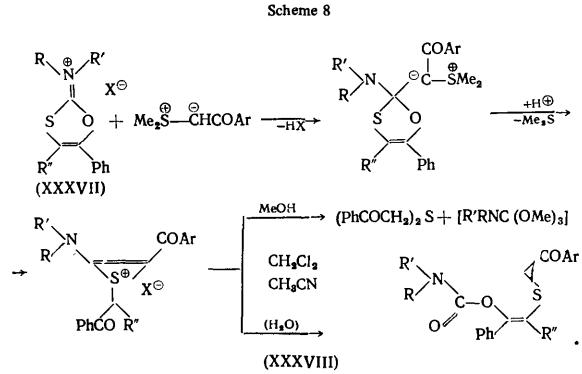
The reaction of sulphonium ylides with tropylium cations (XXXII) proceeds under mild conditions with formation of substituted styrenes[214–216]. The driving force of this reaction is provided by the formation of a stable benzene ring. By varying the substituents in the reactants, it has been shown that the mode of reaction is influenced by the steric hindrance arising during it and not by the nucleophilic properties of the ylide carbanion[214,215]. The attempts to isolate the intermediate sulphonium salts in these reactions proved unsuccessful, which can be accounted for by the ready elimination of the sulphide[216]:



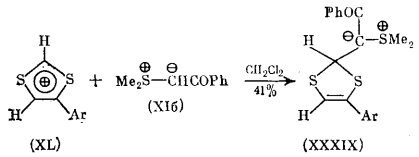
Pyrylium salts (XXXIII) are attacked by the ylide carbanion in the 2-position[88,217,218] or the 4-position[217] of the pyrylium heterocycle. The resulting sulphonium ylides decompose further to furan and 4-phenacylidenepyran derivatives respectively:

Scheme 7

In the reactions of sulphonium ylides with quinazolinium salts (XXXIV) the ylide attacks the 2- or 4-position in the heterocycle with formation of sulphonium salts. The latter are dealkylated by the nucleophilic counterion to give the products of $C_{(2)}$-substitution [compound (XXXV)] and $C_{(4)}$-substitution [compound (XXXVI)] in proportions which are determined by the nucleophilic properties of the anion[219], instead of the expected 1,4-benzodiazepines:



The yields of products (XXXV) and (XXXVI) are given below:

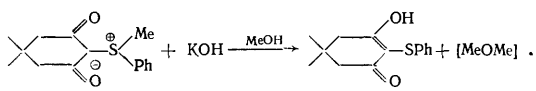


X	Yield of (XXXV), %	Yield of (XXXVI), %
OH	80	—
NO_3	0÷5	90

The oxathiolium cations (XXXVII) are highly reactive electrophiles. The structure of the products formed in their reactions with sulphonium ylides depends on the nature of the solvent employed. Carbamate esters (XXXVIII) are formed in aprotic solvents and diphenacyl sulphide is the product in protic solvents[220]. The overall mechanism of these reactions is presented in Scheme 8.

Scheme 8

The reaction proceeds via the nucleophilic attack by the ylide carbanion on the 2-position in the oxathiole ring. This has been confirmed by the isolation of the intermediate ylide (XXXIX) in the reaction of the dithiolium cation (XL) with the sulphonium ylide (XIb):



The rearrangement of the ylide, accompanied by the elimination of the sulphide, gives rise to the thi-irenium cation, whose hydrolysis and alcoholysis take place differently and lead to the observed products. The possibility of the existence of the thi-irenium cation has been recently confirmed by the synthesis and investigation of the stable 2,3-di-t-butyl-1-methylthi-irenium tetrafluoroborate[221].

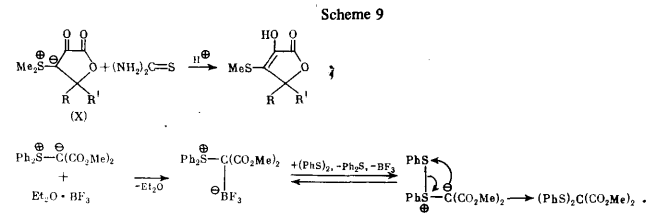
Thus the reactions of stabilised sulphonium ylides with electrophiles constitute a convenient method of synthesising a wide variety of organic compounds, in the first place various carbocycles and heterocycles.

VI. REACTIONS WITH NUCLEOPHILES

The reactions of sulphonium ylides with nucleophiles lead in most instances to results similar to those described for their reactions with electrophiles. This is not surprising, since the reactions of ylides with water, alkoxides, and mercaptans proceed via the initial protonation of the ylide and subsequent attack by the nucleophile on the resulting sulphonium salt. The mode of decomposition of the latter depends both on the nature of the substituents at the sulphonium centre and on the nature of the nucleophile.

Thus the hydrolysis and alcholysis of ylides result mainly in the dealkylation of the sulphonium cation[222–226]:

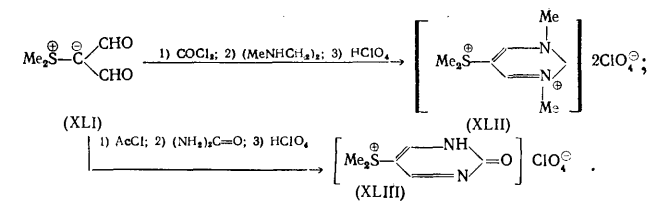
If the ylide has been stabilised by ester groups, then the dealkylation is accompanied by hydrolysis and the elimination of ester groups[222]. The latter occurs sometimes even without the cleavage of the C–S ylide linkage, leading to the formation of a sulphobetaine[56,57,160,227,228].



In constrast to what has been stated above, the reactions of sulphonium ylides with mercaptans lead mainly to the cleavage of the C–S ylide linkage[64,141,229,230]:

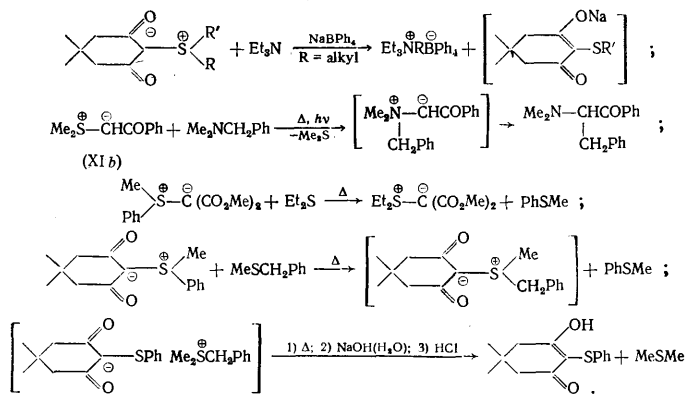
$$R_2\overset{\oplus}{S}-\overset{\ominus}{C}(COR')\,R'' + R'''SH \rightarrow R'''SCH(COR')\,R'' + R_2S\ .$$

The reactions of sulphonium ylides with cyanide[141] and phosphorodithioate[231] anions as well as the anions of compounds containing an active methylene group[232] take place similarly.



The reactions of thiourea[64] and disulphides[233] with sulphonium ylides take place only in the presence of a proton donor[64] or boron trifluoride etherate[233], i.e. they also involve the intermediate formation of sulphonium compounds:

Scheme 9

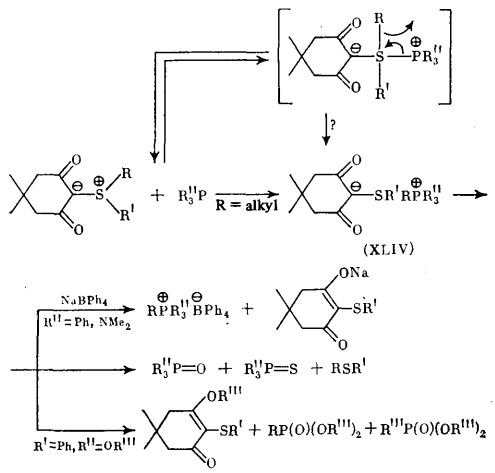


It is noteworthy that more nucleophilic monocarbonyl-stabilised ylides react with disulphides in the absence of a catalyst[233]. In this case the disulphide apparently reacts as an electrophile in a manner similar to that described in Section V.

The reactions of dimethylsulphuranylidenemalonic aldehyde (XLI) with urea and *N,N'*-dimethylethylenediamine are of interest; under these conditions, the condensation reactions lead to the formation of heterocyclic sulphonium salts (XLII) and (XLIII).[85] The authors noted that phosgene and acetyl chloride are used in these reactions to convert the ylide into a more reactive form:

Stabilised sulphonium ylides react in two ways with tertiary amines[57,234] and dialkyl sulphides[139,235], giving rise to transylidation products[57,139] or the product of the dealkylation of the ylides[234,235]:

Scheme 10

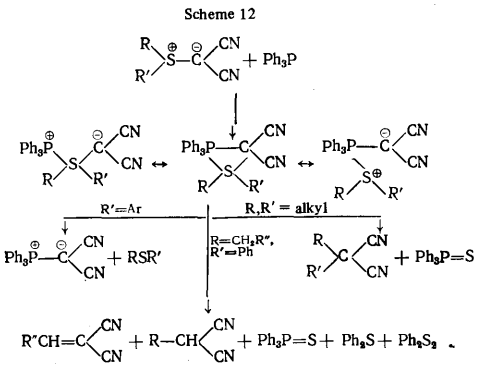


The transylidation reactions of sulphonium ylides with amines and sulphides can be greatly facilitated by carrying them out in the presence of catalytic amounts of dialkoxydisulphides, thiocyanogen, aryl thiocyanates, *p*-hydroxyphenyl trifluoromethyl sulphide, etc.[69,139,144,236]

Stabilised sulphonium ylides react with Ph_3P,[162,237–243] $(Me_2N)_3P$,[242–244] and $P(OR)_3$.[243,245] The structures of the products formed in these reactions depend both on the

nature of the substituents in the ylide and on the nature of the substituents in the phosphorus(III) derivative. In the reactions of sulphuranylidene derivatives of dimedone and benzenesulphonylacetophenone with phosphorus(III) derivatives the ylide is dealkylated, which leads to phosphonium salts with an enolate anion[240–245]. Alkyltriphenylphosphonium salts, obtained in the reactions of *S,S*-alkylphenylsulphuranylidine derivatives of dimedone (XLIV) and benzenesulphonylacetophenone were isolated from the reaction products. In the remaining cases they decomposed in the course of the reaction with formation of the products presented in Scheme 11:[214,243,246]:

Scheme 11

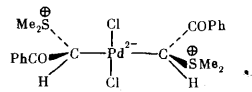


The reaction of the phenacylide salt (XIXa) with Ph_3P proceeds similarly[162]:

The replacement of the carbonyl and sulphonyl groups in the ylide by nitrile groups in the reactions of sulphuranylidene derivatives of dicyanomethane with Ph_3P leads to transylidation or ylide transalkylation–desulphurisation products[237–239]. The mode of reaction is determined by the nature of the substituents at the sulphonium sulphur atom:

Scheme 12

The phosphonium salts formed in the dealkylation of ylides can be obtained either by the intermediate formation and decomposition of σ-sulphuranes or by the direct attack of the phosphorus nucleophile on the electrophilic carbon atom of the *S*-alkyl group. The latter pathway appears to us to be preferable.



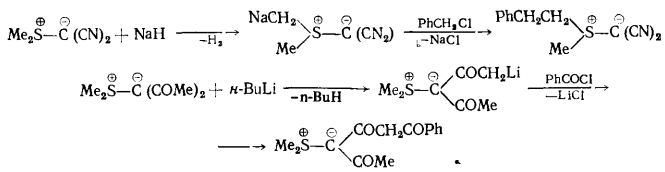
The formation of all the products detected in the reactions of sulphonium ylides with phosphorus(III) derivatives can be accounted for by the intermediated formation and decomposition of phosphonium salts[243,246]. The reactions of diarylsulphuranylidenedicyanomethanes with Ph_3P, where the attack of the latter on the sp^2-hybridised carbon atom of the *S*-aryl group is hindered, constitute an exception[247]. In such cases the mechanism involving the insertion of Ph_3P in the C–S ylide linkage apparently takes place with formation of a resonance-stabilised triad, whose decomposition leads to the observed products[237–239].

It is noteworthy that carbonyl-stabilised sulphonium ylides are dealkylated not only by phosphorus(III) and nitrogen derivatives[234,240–245] but also by tertiary arsines[248], triphenylstibine, and triphenylbismuth[234].

VII. ORGANOMETALLIC DERIVATIVES AND COMPLEXES

It was stated in Section V that stabilised sulphonium ylides react only with olefins activated by electron-accepting substituents. However, it is known that the electrophilic properties of an olefin are enhanced when it forms complexes with transition metal (platinum and palladium) salts[249]. This stimulated attempts to convert olefinic ligands into cyclopropane derivatives in transition metal complexes. However, it was found that, instead of the formation of a cyclopropane derivative, the olefin is readily substituted by the ylide under these conditions[250,251]. Such complexes can be obtained not only by ligand exchange[250–255] but also by their direct synthesis from ylides and metal salts[19,256,257], the structure of the complex formed depending on the nature of the metal, the structure of the ylide, and, in the case of exchange reactions, the structure of the initial complex. Thus sulphuranylidene derivatives of acetophenone form 2 : 1 adducts with $PdCl_2$ or $PdBr_2$,[68,250–252,256,257], 2 : 1 or 1 : 1 adducts with PtCl, depending on the method of synthesis[253,256], and dimers of 1 : 1 adducts with $HgCl_2$, evidently incorporating bridging chlorine atoms[256]. The formation of 1 : 1 adducts is also observed in the formation of complexes of sulphuranylidene derivatives of cyclopentadiene with HgI_2, $ZnCl_2$, and $AgNO_3$,[19] and of the dimethylsulphuranylidene derivative of malonic aldehyde (XLIII) with ZnI_2.[85]

The study of the ^1H and ^{13}C NMR and infrared spectra of the complexes of sulphuranylidene derivatives of acetophenone showed that the metal is coordinated to the carbanionic carbon atom of the ylide[68,250–253,256]. According to the results of X-ray diffraction analysis, the 2 : 1 complexes with $PdCl_2$ have the square planar *d,l-trans*-configuration[250,251]; when they are dissolved, epimerisation takes place readily and the ^1H NMR spectra demonstrate the existence of a mixture of *meso*- and *d,l-trans*-forms:[251]



The structure of the complexes of PtX_2 with ylide ligands is influenced by the nature of the halogen[252,253], the amount of the *trans*-isomer increasing under these conditions in the sequence X = Cl < Br < I, which is analogous to that observed for the complexes $PtX_2.(Et_3P)_2$.[258]

The metal atom can be coordinated not only to the carbanionic carbon atom of the ylide but also to a sulphur atom[19,259] or a nitrogen atom, for example in complexes of dimethylsulphuranylidenedicyanomethane (III) with $PdCl_2$.[259] The absence of the coordination of the metal to the carbon atom in the latter case is probably caused by its reduced nucleophilicity due to the delocalisation of the electron density

over the electron-accepting cyano-groups. In the sulphuranylidene derivatives of cyclopentadiene (V) the metal can be coordinated not only to the sulphur atom[19] but, as shown recently in relation to their complexes with chromium, molybdenum, and tungsten carbonyls[260], also to the cyclopentadienyl system.

It was noted in Section VI that the coordination of Lewis acids to the carbanionic carbon atom of the ylide facilitates their reaction with nucleophiles. In this connection attempts were made to investigate the reactions of nucleophiles with ylides functioning as ligands in transition metal complexes. However, it was found that this entails only ligand exchange reactions. Thus it has been found[251] that pyridine substitutes one ylide ligand in the cold and both ylide ligands on heating 2 : 1 complexes of sulphuranylidene derivatives of acetophenone with $PdCl_2$.

Organometallic derivatives of stabilised sulphonium ylides are readily formed on metallation of ylides with BuLi, iso-Pr_2NLi,[261,262] or NaH,[142] a proton being substituted both in the substituent at the carbanionic carbon atom[261,262] and at the *S*-alkyl group[142]. Their further reactions are of the usual type for organometallic compounds:

VIII. PRACTICAL APPLICATIONS

Intensive investigation of the chemistry of sulphonium ylides began approximately 15 years ago and during this relatively short period interesting practical results have been obtained. Sulphonium ylides proved to be effective nucleophiles for the epoxidation of carbonyl compounds and the conversion of olefins into cyclopropane derivatives[5,263]. This constitutes an important addition to the methods for the epoxidation and conversion into cyclopropane derivatives by electrophilic carbenes[264]. The use of ylides for the synthesis of heterocycles is also extremely important[265]. This review presents the results of synthetic applications of stabilised sulphonium ylides. However, this does not exhaust their applications. It has been suggested that sulphonium ylides be used as catalysts of the liquid-phase oxidation of hydrocarbons[266]. There are data showing that 4-dialkylsulphuranylidene-2,6-di-t-butylcyclohexadienones[267] effectively alkylate compounds containing an acidic proton[268]. Diphenylsulphuranylideneacetone and its analogues make it possible to obtain products used to prepare modifying agents for paper, textiles, and leather as well as substances used in the manufacture of polyamides, polyesters, alkyd resins, and plant protecting agents[269].

Sulphuranylidene derivatives of cyclopentadiene accelerate the dyeing of polyester, polyamide, and other fibres by anionic dyes[270]. Dimethylsulphuranylidene-*p*-nitrophenacyloxyethoxycarbonylmethane exhibits a fungicidal activity[271], while 3-dialkylsulphuranylidene-2-oxo-1,4-naphthoquinones exhibit an anti-inflammatory inactivity and can be used in the treatment of arthritis, erythema, oedema, etc.[272]

Thus the range of applications of sulphonium ylides is wide and varied extending from reagents for organic syntheses to effective physiologically active preparations. New studies in this field will undoubtedly lead to a wider practical utilisation of these substances.

Chromatography in the Gas-Liquid Crystal System

M.S.Vigdergauz, R.V.Vigalok, and G.V.Dmitrieva

The analytical and physicochemical aspects of chromatography using liquid-crystal sorbents are examined and it is concluded that liquid crystals exhibit a unique separating capacity in the analysis of structural isomers. The possibility of using liquid crystals as universal sorbents with a controllable selectivity and suitable for the solution of various analytical problems is demonstrated. The results of the study of the thermodynamics of the sorption of substances by liquid crystals, phase transitions and preceding effects, etc. are presented.
The bibliography includes 178 references.

V. Thermodynamics of the sorption of substances by liquid crystals 509

I. INTRODUCTION

Liquid crystal compounds have been known for about 100 years, but their application in gas chromatography began comparatively recently[1]. The interest in liquid crystals for chromatography is due to the possibility of using them as selective sorbents for the separation of structural isomers, particularly *p*- and *m*-substituted benzenes, whose separation is difficult on the usual isotropic liquids. Reviews have been devoted to the use of liquid crystals in chromatography[2-7]. There is no doubt that *meta*–paraselectivity should be regarded as the principal parameter of the operation of such stationary phases. However, at the present stage of the investigation of the liquid-crystal sorbents it is no longer possible to restrict the treatment to this characteristic. This review deals with problems concerning a more far-reaching study of the sorption properties of mesomorphic compounds in all regions of their phase state, the determination of the position of liquid crystals among other stationary phases, the discovery of the analytical possibilities of liquid-crystal sorbents, the study of phase transitions of the thermodynamics of the dissolution of substances in the isotropic and anisotropic regions, and of the thermal stability of liquid crystals, the investigation of their viscous properties and the associated efficiency of chromatographic columns, the study of mixed phases based on liquid crystals, etc.

The term "liquid crystal" was first introduced by Lehmann[8] for compounds which are characterised, within a certain temperature range, simultaneously by the properties of both liquids (high fluidity, the ability to form drops, etc.) and crystals (optical, magnetic, and electrical anisotropy).

A liquid does not have the three-dimensional order characteristic of a crystal. However, the idea of a liquid as a completely amorphous phase in which the molecules are distributed at random, like the molecules of a gas, is not correct. Studies on the scattering of light and X-rays[9] have shown that there is a short-range order in the arrangement of the molecules in a liquid, i.e. they possess the elements of a crystal structure. The similarity between the liquid and solid states increases when the molecules of the given substance have a planar and extended shape. This favours a more compact packing of the latter and, in the presence of sufficient attraction forces, can lead to the formation of large numbers of molecules oriented in parallel planes. Mesomorphism is observed most often among aromatic compounds. Liquid-crystal compounds containing benzene and naphthalene rings are known. An important group of liquid crystals can be made up of derivatives of cholesterol or compounds with a cyclopentanoperhydrophenanthrene group.

Thus the liquid-crystal state, characteristic of compounds whose molecules have an elongated linear shape with polarisable groups in the structural skeleton, is distinguished by a specific orientation of these molecules in space, involving the arrangement of their longitudinal axes parallel to one another. Liquid crystals are most often formed by compounds whose molecules consist of extended chains incorporating planar aromatic rings with substituents in the *para*-position in the benzene ring; in the presence of substituents in the *ortho*- or *meta*-position, the capacity for the formation of the liquid crystal disappears. An example of a liquid-crystal compound with a single benzene ring is provided by *trans*-*p*-methoxycinnamic acid. The tendency towards mesomorphism increases with increase of the number of connected benzene rings. Groups connecting benzene rings into a chain play a major role. Compounds forming liquid crystals have been described in a series of reviews and monographs[2,3,10-14] and the physical properties and classification of liquid crystals have also been described[2,10,11]. Liquid crystals are much more rarely formed by aliphatic compounds. The explanation is probably the relative flexibility of the long chains in compounds of the paraffinic series.

Liquid crystals can be divided into two main groups. Those in one group are classified as thermotropic liquid crystals; compounds in this class are obtained by heating a solid and exist only in a specific temperature range. Lyotropic liquid crystals constitute the second group and are obtained by mixing two or several components, an amphiphile being usually one of the components. Since only thermotropic liquid crystals are at present used in chromatography, we confine ourselves to the consideration of this class of mesomorphic substances, which include two main types: smectic and nematic; the cholesteric phase is assumed to be a variety of the nematic phase.

When many substances melt, a smectic phase is formed initially in which the molecules are not only arranged parallel to one another but also are fixed in layers; at higher temperatures there is a transition to the nematic phase where this additional order disappears. Cholesteric liquid

crystals are characterised by a helical molecular structure. A single substance has been found containing both nematic and cholesteric phases although individual substances can exist as smectic-nematic or smectic-cholesteric mesophases. The mesophase exists within a specific temperature range characteristic of each substance. When the temperature changes outside the limits of this range, either the usual solid crystal (decrease of temperature) or the isotropic liquid (increase of temperature) is formed.

The most important characteristics of liquid crystals are the melting point involving the transition from the solid state to the mesophase, the point of transition from one mesophase to another, and the clarification point (transition from the liquid-crystal state to the isotropic liquid). Studies have not as yet led to the discovery of a rigorous relation between the structure of the liquid-crystal substance and the type of mesophase, on the one hand, and the selectivity with respect to the *meta*- and *para*-isomers, on the other. Intense investigation of this problem by comparing the experimental results for the variation of molecular structures as well as studies of the influence of a substituent in homologous series led to the discovery of a series of necessary conditions ensuring the maximum steric effect of the mesophase.

II. ANALYSIS OF STRUCTURAL ISOMERS

The first studies of the chromatographic characteristics of liquid crystals already demonstrated their probable usefulness as sorbents for gas chromatography[1,15]. The interaction forces in a sorbate–liquid-crystal melt system, due to the ordered arrangement of molecules in the temperature range of the mesophase, promote the separation of aromatic *meta*- and *para*-isomers with similar boiling points. This effect, first observed by Kelker[1,15] and Dewar and Schroder[16] using *p,p'*-azoxyanisole, proved to be characteristic of many liquid crystals; it is associated with the fact that the more closely linear form of the molecule of the *para*-isomer compared with the *meta*-isomer enables the former to penetrate more readily into the lattice of the liquid crystal and is accordingly more strongly retained by the latter in the temperature range of the mesophase. Above the clarification point, the order of elution of isomers is usually determined by their boiling points[5].

The results of the above investigations led to extensive analytical use of liquid-crystal sorbents[15–71]. The following mixtures have been analysed on columns of liquid crystals: isomeric xylenes[1–6,15–19,22–28,31–44], butylbenzenes[45], vinyltoluenes[46,47], divinylbenzenes[48], mono- and dimethylnaphthalenes[26,46,49], various derivatives of benzene[22,39,41,42], naphthalenes[50–54], and phenol[55], isomers of benefin [*N*-(n-butyl)-*N*-ethyl-2,6-dinitro-α,α,α,-trifluoro-*p*-toluidine] and trifluralin (2,6-dinitro-*N*,*N*-di-n-propyl-α,α,α-trifluoro-*p*-toluidine)[56], isomers of benoxaprofen [2-(4-chlorophenyl)-α-methylbenzoxazole-5-acetic acid][57], terpenes and their derivatives[58], enantiomers of *N*-perfluoroacyl-2-aminoethylbenzene[59,61], steroids[62], heterocyclic aza-compounds[63], polyaromatic hydrocarbons[53,64–66,69–70], cholic acids and α,β-steroid epimers[64,67,68], and pheromone isomers[71]. At the same time extensive studies have been made on the sorption characteristics of liquid crystals and the thermodynamics of the sorption of different substances by the latter. Studies on these lines have been carried out by Kelker and coworkers[2,17,20,21], Dewar and Schroeder[22,23], Barrall et al.[24], Vigdergauz and coworkers[25–28], Chow and Martire[29,30], etc. Studies have been made on the sorption properties of *p,p'*-azoxyphenetole, a homologue of *p,p'*-azoxyanisole, with a nematic phase existing in the range 138–168 °C, in relation to a large number of paraffinic, naphthenic, and aromatic hydrocarbons[2,15].

A remarkable property of the nematic mesophase of *p,p'*-azoxyphenetole is its high selectivity with respect to positional isomers. Thus the ratio of the retention volumes of *p*- and *m*-xylenes on the above sorbent in the region of the mesophase at 140 °C is $\sigma_H = 1.09–1.10$. Comparison of this quantity with the values obtained[72] for phenanthrene and 7,8-benzoquinoline, used previously for the separation of xylene isomers, indicates a greater selectivity of *p,p'*-azoxyphenetole. Among other aromatic compounds used for the separation of isomeric xylenes, one may mention halogenophthalates, α-naphthylamine ($\sigma_H = 1.089$), 1,8-diaminonaphthalene ($\sigma_H = 1.09$), m-phenylenediamine ($\sigma_H = 1.05$), α,α'-bipyridyl ($\sigma_H = 1.06$), and *p*-aminoazobenzene ($\sigma_H = 1.05$).[73] These substances proved to be less selective stationary phases than *p,p'*-azoxyphenetole.

The ratios of the retention volumes of the isomeric xylenes (σ_H) on Bentone-34 modified with a silicone oil (in 1:1 proportions) and dinonyl phthalate (60:40) are 1.13 and 1.14 respectively[73]. However, one should point out that Bentone-34 is a technical product consisting of bentonite clay treated with an ammonium base; in particular, Bentone-34 is dimethyloctadecylammonium bentonite. The characteristics of the clay vary from batch to batch, giving rise to difficulties in the exchange reaction with the ammonia base, whence follows the poor reproducibility of the retention characteristics. The non-uniformity of the distribution of isomeric xylenes requires the modification of bentone with a silicone or dinonyl phthalate in appropriate proportions. As a consequence of the non-reproducibility of the results, this ratio also varies from batch to batch. Compared with bentones, liquid crystals have the following advantage: being individual organic compounds and being fairly pure, they ensure the reproducibility of the selective properties and a uniform distribution of isomeric xylenes on the chromatogram[73–76].

The analytical possibilities of *p,p'*-azoxyphenetole have been illustrated in relation to the separation of bicyclic hydrocarbons—mono- and di-methylnaphthalene. The employment of the usual stationary phases, such as cable oil, Apiezon, poly(ethylene glycol)-2000,[77,78] etc. precludes the complete separation of dimethylnaphthalenes as a consequence of the equality of the retention times of 2,6- and 2,7-, 1,3- and 1,6-, and 1,4-, 1,5-, and 2,3-dimethylnaphthalenes. On the other hand, these groups of isomers can be readily separated in the liquid-crystal region of *p,p'*-azoxyphenetole[26]. The retention volumes of alkylnaphthalenes measured in the range 110 to 150 °C indicate their different sorbabilities when the stationary phase passes from the solid to the liquid-crystal state and then to the isotropic liquid state. The elution sequence of alkylnaphthalenes for the solid and isotropic liquid states of the stationary phase is determined by their boiling points and the same dimethylnaphthalene isomers are non-separable as on columns with the usual stationary phases.

The situation is different for the liquid-crystal state of *p,p'*-azoxyphenetole. Here there is a distinct steric effect, which is seen already in relation to monomethylnaphthalenes where the α-isomer is eluted before the β-isomer at 137 °C, although it has a higher boiling point, i.e. the elution sequence is determined by the steric structure of the sorbates. The elution sequence is inverted also in the case of dimethylnaphthalenes. However, one should note that the comparatively low temperature of the analysis, corresponding to the maximum structural selectivity of

azoxyphenetole (137 °C), required a prolonged duration of analysis in the separation of such high-boiling compounds (2.5–3 h). The bisphenetidylterephthalaldehyde liquid crystal used for this purpose is characterised not only by a shorter separation time at 205 °C (down to 15–20 min) but also by a higher selectivity in relation to the isomers indicated[46].

Alkylnaphthalenes were later separated[49] in the nematic and supercooled region of *N,N'*-bis(*p*-methoxybezylidene)-α,α'-bis-*p*-toluidine with a temperature range of the nematic mesophase of 181–320 °C. This liquid crystal is extremely effective also in the separation of benephine from trifluralin[56], the benoxaprofen isomers[57], heterocyclic azacompounds[63], steroids[64,67,68], and polycyclic aromatic compounds[64–66,69–70]. Other examples of the use of the supercooled region of mesophases for the separation of isomers are available in the literature[18,22,24,33,79]. Among the liquid crystals synthesised, mention should be made of the asymmetric azoxyether *p,p'*-ethoxymethoxyazoxybenzene and *p*-methoxybenzylidene-*p'*-butyrylaniline[33,46].

It has been shown[33] that, for a temperature of the analysis close to the melting point of *p,p'*-ethoxymethoxyazoxybenzene, the ratio of the characteristics for *p*- and *m*-xylenes reaches 1.125–1.13, which leads to a significant improvement in the chromatographic separation of the isomers and to a uniform distribution of the peaks of aromatic hydrocarbons on the chromatogram. Isomeric vinyltoluenes have been separated on ethoxymethoxyazoxybenzene[46]. The use of columns with *p*-methoxybenzylidene-*p'*-butyrylaniline permitted the complete separation of aromatic C_8 isomers and isopropylbenzene[46]. It is noteworthy that isopropylbenzene is usually eluted together with *p*-xylene on the liquid-crystal azoxyethers investigated previously.

The elucidation of the influence of the width of the temperature range of the mesophase on the selectivity with respect to positional isomers and of the influence of the nature of the mesophase on the solvent power of the sorbent revealed a relation between these quantities and the *meta–para* selectivity, demonstrating the advantages of compounds with broad regions of the liquid-crystal state. This follows from the data of Kelker et al.[19] (Table 1).

Table 1.

Compound	t_{clar}, °C	t_m, °C	σ_H
4-Methoxybenzylidene-4'-cyanoaniline	117	106	1.03
p,p'-Azoxyanisole (I)	134.5	117	1.04
4-Methoxybenzylidene-4-acetoxyaniline	107	83	1.05
p,p'-Azoxyphenetole (II)	168	13	1.09
60% (I) + 40% (II) eutectic	146	97	1.10

Notation: t_{clar} = clarification temperature, t_m = melting point, and σ_H = selectivity coefficient defined at the ratio of the reduced retention times of the *m*- and *p*-complexes.

The temperature range of the mesophase can be expanded either by synthesising the appropriate liquid-crystal compound or by employing mixed phases forming a eutectic. In the latter case there is a corresponding decrease of the phase transition temperatures together with the expansion of the mesophase region. However, the results of subsequent studies[79,80] showed that the conclusion that the selectivity in relation to isomers varies in parallel with the width of the temperature range of the mesophase is valid only for liquid crystals with similar structures. This is evidently associated with the additional influence of the chemical nature of the sorbent on the selectivity.

This is why the compounds investigated by Kelker[53,81,82], Dewar and Schroeder[16,22], and Vigdergauz and coworkers[80,83] with the width of the temperature range of the nematic mesophase corresponding to 100 and more degrees, exhibit a much lower selectivity in relation to the positional isomers of xylene than *p,p'*-azoxyphenetole. The wide temperature range of the mesophase does not therefore alone guarantee a high selectivity of the sorbent in relation to positional isomers. Nevertheless the synthesis and use of such phases are promising from the analytical standpoint. The retention characteristics of substances on columns with sorbents at high temperatures (above 200 °C) and with broad temperature ranges of the nematic melt have been published[2]. In particular, one can recommend bisphenetidinylterephthalaldehyde (nematic region in the range 198–323 °C), which can be used successfully for the separation of high-boiling components: α- and β-naphthols, α- and γ-benzopyridines, dimethylphthalate, and dimethyl ethers derived from phenanthrene, anthracene, and carbazole, as well as "difficult" pairs of dimethylnaphthalenes[2,19,37,46]. Interesting results have also been obtained on 4,4-bis(benzylidene)benzidine and bis(*p*-methoxybenzylidene)-*trans*-4,4'-diaminostilbene[19].

Liquid-crystal compounds with a nematic mesophase have been most thoroughly investigated. There exist only a few examples of the use of liquid crystals of the smectic and cholesteric type. According to the theory of the liquid-crystal state, the smectic mesophase is characterised by a higher degree of order among the molecules; it therefore appears quite evident that it should exhibit a higher selectivity with respect to positional isomers compared with a nematic melt. However, the opposite behaviour has been most frequently observed in practice and unfortunately the higher order has not been fully realised. The explanation is that the majority of substances are highly viscous in the smectic state, the viscosities sometimes reaching values which cannot be measured on the usual viscometers and the phase transition from the smectic mesophase to the nematic mesophase is measured as the melting point. In this case the smectic region can be observed only by special methods (thermo-optics, thermography, etc.).[84,85]

Naturally the high viscosity of the smectic phase greatly hinders the diffusion of the components analysed for the latter, as a result of which the contribution of adsorption becomes decisive. Two competing factors act in the smectic region: the high degree of order of the molecules leads to the intensification of the *meta–para* selectivity, while viscosity has the opposite effect. Nevertheless one should point out the use of liquid crystal sorbents of the smectic type: ethyl *p,p'*-azoxybenzoate, ethyl *p*-ethoxybenzylideneaminocinnamate, and 4,4'-di-n-hexyloxy- or 4,4'-di-n-heptyloxy-azoxybenzene[15,16,22]. Unusual results have been obtained for a smectic ester, *p*-phenylene bis-*p'*-heptyloxybenzoate, which has a broad region corresponding to the existence of the smectic (79–125 °C) and nematic (125–199 °C) phases[22]. It has been shown that at 68 °C (the solid crystal region) the ratio of the retention parameters of *p*- and *m*-xylenes is 1.10, i.e. corresponds to the experimental structural selectivities of *p,p'*-azoxyphenetole in the eutectic mixture.

Dewar and Schroeder[22,23] noted short retention times of the sorbates and asymmetry of the peaks (the presence of tails) at 68 °C. The elution sequence is *m*- → *o*- → *p*-isomers. The chromatographic characteristics of *p*-phenylene bis-*p'*-heptyloxybenzoate were also examined in other studies[80,83]

in relation to a wide set of paraffinic, naphthenic, and aromatic hydrocarbons in the range 30–220 °C and it was shown that the *meta–para* selectivity of the ester began to be manifested only at 80 °C; this is apparently associated with a decrease of viscosity of sufficient for the contribution of adsorption forces to the retention of sorbates to become significant. The ratio of the retention parameters of *p*- and *m*-xylenes in the smectic region did not exceed 1.03, while in the region of the nematic phase (at 130 °C) it was 1.05.[83]

In the separation of hydrocarbons on *p*-(n-heptyloxy)-benzoic acid[83] an increased solubility of *p*-xylene in both the smectic (92–99 °C) and nematic (99–146.5 °C) mesophases was noted. At 94 °C the ratio of the retention parameters is 1.05 and remains the same at 100 °C (nematic region), i.e. the structural selectivities of both varieties of the mesophase are the same. The much lower selectivity of the acid with respect to the isomers compared with the eutectic mixture of *p,p'*-azoxyanisole and *p,p'*-azoxyphenetole shows that the equality of not only the temperature ranges but also of the absolute melting points and clarification temperatures does not guarantee identical structural selectivities of the sorbents.

An example of the practical utilisation of smectic liquid crystals is provided by the separation of optical isomers carried out by Lochmüller and coworkers[59–61] using optically active mesophases, namely the isopropyl ester of carbonylbis-D-leucine or the alkyl esters of L-valine. However, they showed that the efficiency of separation is in this case determined by chemical reactions, by the intermediate formation of diastereoisomers—hydrogen-bonded association complexes between the stationary phase and the pair of enantiomers. It is known that, apart from liquid crystals, another class of optically active compounds, namely dipeptides, have been used[86,87] for the separation of enantiomers.

The solvent power of cholesteric liquid crystals has been investigated by a number of workers[2,22,24,29,58] as well as Vigdergauz and coworkers[51,88]. A unique property of this mesophase is its high optical activity. In many instances the specific rotation of the plane of polarisation of light is 60000–70000 deg mm^{-1}, while in the case of the usual organic liquids it rarely exceeds 300 deg mm^{-1}. Such a high optical activity is due to the twist in the structure of cholesteric liquid crystals, i.e. a consistent "rotation" of the molecules in their mutual arrangement. It has been suggested that this structure of the mesophase permits the resolution of a racemic mixture into optically active isomers. However, such resolution could not be achieved[2]. Cholesteric liquid crystals did not exhibit an appreciable selectivity with respect to positional isomers either. Nevertheless, one should note that Porcaro and Schubiak[58] used successfully cholesteryl cinnamate together with other smectic and nematic mesophases for the separation of terpene derivatives.

When cholesteryl acetate was used as the stationary phase, the optical isomers of (±)-γ-lactones were separated[89]. The results of studies of the chromatographic characteristics of cholesteryl benzoate (the region of the mesophase is in the range 149–179.5 °C), cholesteryl acetate (94.5–116.5 °C), cholesteryl valerate (93–101.5 °C), and cholesteryl nonanoate (smectic region in the range 77.5–80.5 °C and cholesteric region in the range 80.5–92 °C) in relation to the separation of C_7–C_{10} paraffinic hydrocarbons and aromatic hydrocarbons (benzene, toluene, and ethylbenzene) have also been published[17,24]. The esters investigated exhibited the same features on dissolution of the sorbates as other types of liquid-crystal mesophases, altering the retention characteristics in the case of phase transitions.

The data of Barrall et al.[24], who established a relation between the group selectivity of cholesterol esters in the region of the mesophase and the length of the paraffin chain of the esters, are of interest. Thus, in their isotropic state (120 °C) these cholesterol ester sorbents gave rise to virtually identical retention characteristics of the paraffinic and aromatic hydrocarbons, while in the region of the mesophase the retention of paraffins by cholesteryl nonanoate was much stronger than by other esters. This is apparently a consequence of the interaction of paraffins with long-chain esters, since the retention of aromatic-hydrocarbons is in this case weaker than that of aliphatic hydrocarbons with the same number of carbon atoms in the molecules.

Extensive analytical possibilities arise when mixed sorbents based on liquid crystals are used. Thus, a detailed study has been made[18] of the chromatographic and thermo-optical behaviour of a mixture of cholesteryl benzoate and *p,p'*-azoxyphenetole in relation to the separation of isomeric xylenes. A detailed investigation has been made[88] of the properties of binary sorbents, in the first place those in which one of the ingredients is a liquid-crystal compound [for example, in the separation of dimethylnaphthalenes on compound columns containing *p,p'*-azoxyphenetole and poly(ethylene glycol)-2000; the ratio of the amounts of the stationary phases then corresponds to the ratio of the lengths of the compound column sections indicated] and, in the second place, those in which both ingredients are in the liquid-crystal state. Thus, the authors[88] examined binary mixtures incorporating *p,p'*-azoxyphenetole, *p*-(n-heptyloxy)benzoic acid, the ester of hydroquinone and *p*-(n-heptyloxy)benzoic acid, and cholesteryl cinnamate; the sorbates employed were C_9–C_{11} n-paraffins and *m*- and *p*-xylenes. Deviations were observed from additivity in the retention of sorbates as a function of the composition of the mixed stationary phase. The corresponding deviations are determined both by the energy of the interaction of the components of the stationary phase and by the additional energy of the interaction of the sorbate with the mixture formed.

Eutectic mixtures of nematic mesophases are of greatest interest for chromatography. Studies in this field have been carried out by Kelker[2,19] and the authors of the present review[26,35]. Thus the eutectic mixture *p,p'*-azoxyanisole and *p,p'*-azoxyphenetole in molar proportions of 60:40 was characterised by a high selectivity in the separation of *p*- and *m*-xylenes (the ratio of the reduced retention times was $\sigma_H = 1.11$). Similarly Vigdergauz et al.[26] investigated mixtures of liquid crystals in molar proportions of 20:80, 55:45, 60:35, and 80:20. Andrews et al.[38] studied binary mixtures made up to *p,p'*-dimethoxyazoxybenzene (azoxy-anisole), *p,p'*-diethoxyazoxybenzene (azoxyphenetole), *p,p'*-dibutoxyazoxybenzene, and *p,p'*-dihexyloxyazoxybenzene. The composition of the eutectics of the above liquid crystals was found by recording the phase diagrams. All the eutectics without exception exhibited a much greater structural selectivity than their components. The greatest selectivity was shown by the mixture of *p,p'*-azoxyphenetole and *p,p'*-dibutoxyazoxybenzene (molar ratio 38:62, $\sigma_H = 1.13$). Deviations were then found from additivity in the relation between the retention of the sorbates and the composition of the eutectic. Thus, deviations from the relations governing the variation of the characteristics of the retention of the sorbate by the mixture of *p,p'*-azoxyanisole and *p,p'*-azoxyphenetole, caused by the formation of a eutectic, can be illustrated in relation to s-butylbenzene (Fig.1).

The study of the chromatographic characteristics of binary sorbents with low melting points and a high selectivity in relation to the *meta*- and *para*-isomers are of greater interest[35]. In the preparation of low-melting liquid-crystal mixtures the main component was *p,p'*-ethoxymethoxyazoxybenzene previously recommended for analytical purposes[33], having shown the maximum values $\sigma_H = 1.125-1.13$. The second component consisted of azoxyethers. Binary mixtures based on *p,p'*-ethoxymethoxyazoxybenzene with di-n-hexyloxyazoxybenzene proved to melt at lower temperatures than the main component. Furthermore, it has been shown that the fairly high selectivity, found for the first mixture and equal to 1.115, persists over a comparatively wide temperature range. Thus the use of a binary mixture of liquid crystals as the stationary phase ensures virtually the same selectivity in the separation of *m*- and *p*-xylenes as that of *p,p'*-azoxyphenetole and *p,p'*-ethoxymethoxyazoxybenzene usually employed for these purposes, but at a much lower temperature.

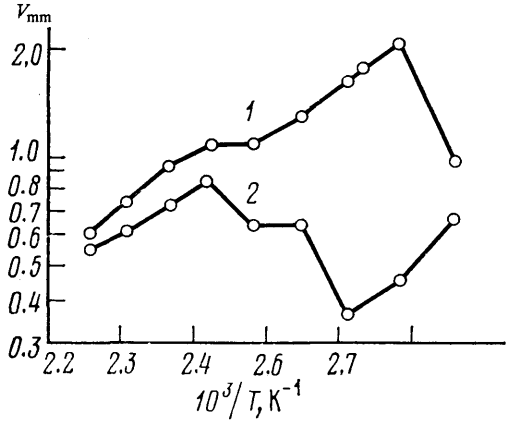

Figure 1. Dependence of the molar retention of s-butylbenzene on the reciprocal of the absolute temperature for a column with a eutectic mixture of *p,p'*-azoxyanisole and *p,p'*-azoxyphenetole[5]: *1*) experimental curve; *2*) curve plotted assuming the additivity of the retention volumes.

III. THE USE OF LIQUID CRYSTALS AS STATIONARY PHASES WITH A CONTROLLABLE SELECTIVITY

Numerous studies in the field of the above liquid crystal stationary phases showed that they are promising as universal sorbents with a controllable selectivity; this is an exceptionally important advance in the application of liquid crystals in gas chromatography in view of the usefulness of such compounds in all regions of their existance: solid, liquid-crystal, and isotropic liquid. Thus, when *p,p'*-azoxyphenetole is used, the chromatographic separation of s-butylbenzene and isobutylbenzene is attained only in the temperature range corresponding to the solid state of the stationary phase[45]. In the separation of cyclohexane and heptane it can also be valuable to ensure conditions corresponding to the solid crystal state of ethoxymethoxyazoxybenzene; the liquid-crystal region is best for the separation of heptane and iso-octane, as well as *m*- and *p*-xylenes, while the isotropic liquid phase of the substance is most selective in the separation of *p*-xylene from isopropylbenzene.

Thus the mesophase should not be regarded as a phase representing a single temperature range suitable for the analytical application of liquid crystals. In the possession of a single column with a liquid-crystal sorbent we have virtually as many stationary phases as the number of states characteristic of the given sorbent. Consequently liquid crystals, behaving as universal stationary phases can, on the one hand, greatly reduce the assortment of general purpose sorbents and, on the other hand, they can be employed for the solution of specific problems.

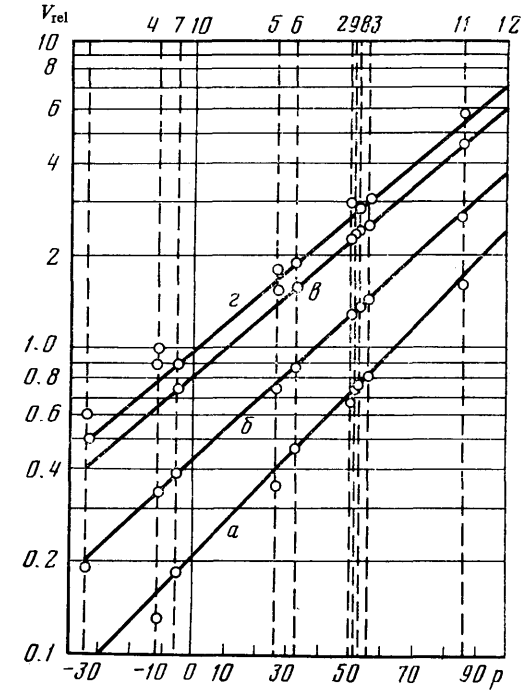

Figure 2. Dependence of the relative retention volumes of alkylbenzenes (on a logarithmic scale) on the conventional polarity of the stationary phases[80]: *1*) eutectic mixture of *p,p'*-azoxyphenetole and *p,p'*-azoxyanisole at 50 °C (SC); *2*) ditto at 100 °C (LC); *3*) ditto at 145 °C (IL); *4*) p-(n-heptyloxy)benzoic acid at 50 °C (SC); *5*) ditto at 100 °C (LC); *6*) ditto at 150 °C (IL); *7*) *p,p'*-azoxyphenetole at 110 °C (SC); *8*) ditto at 140 °C (LC); *9*) ditto at 170 °C (IL); *10*) squalane at 140 °C; *11*) poly(ethylene glycol)-2000 at 100 °C; *12*) 1,2,3,4-tetrakis(β-cyanoethoxy)neopentane at 140 °C; sorbates: *a*) benzene; *b*) toluene; *c*) *p*-xylene; *d*) *o*-xylene; notation: SC—solid crystal region; LC—liquid crystal region; IL—isotropic liquid.

1. The Conventional Chromatographic Polarity of Liquid Crystals

In order to estimate the selectivity of liquid-crystal sorbents in different phase states, the conventional chromatographic polarities were determined, by analogy

with Rohrschneider[90], by comparing the retention characteristics of the substances analysed (benzene, toluene, and *p*- and *o*-xylenes relative to n-nonane) on the test and standard sorbents. Fig.2 presents the relations between the logarithms of the relative retention volumes of the sorbates and the conventional chromatographic polarities of the stationary phases. *p,p'*-Azoxyphenetole, *p*-(n-heptyloxy)benzoic acid, cholesteryl cinnamate, squalane, and 1,2,3,4-tetrakis-(β-cyanoethoxy)neopentane were chosen as the stationary phases. Zero polarity was assigned to squalane at 140 °C and 100% polarity was assigned to 1,2,3,4-tetrakis-(β-cyanoethoxy)neopentane at the same temperature. Fig.2 shows that the conventional chromatographic polarity of the liquid crystal varies within wide limits with the phase transitions. In particular, for azoxyphenetole, it increases from -6 (the solid crystal region) to 50 (the anisotropic and isotropic liquid regions).

Thus, whereas in the fused state azoxyphenetole behaves as a moderately polar phase, below the melting point it functions as a non-polar sorbent, ensuring the elution of hydrocarbons virtually in accordance with their boiling points. The conventional chromatographic polarity can vary by 60 units for azoxyphenetole, by 40 units for the acid, and by 25 units for cholesteryl cinnamate. The intermediate values of the conventional chromatographic polarity can be obtained by using a compound column whose sections are filled with the same sorbents but operate at different temperatures. One of the authors of this review attempted to classify the liquid-crystal stationary phases in terms of the general classification based on the Rohrschneider polarity factors by introducing an additional factor *gf* characterising the *meta–para* selectivity of the mesophase[91]. The Rohrschneider equation then assumes the following form:

$$I = I_0 + ax + by + cz + du + es + gf,$$

where *a*, *b*, *c*, *d*, *e*, and *f* are the characteristics of the sorbate and *x*, *y*, *z*, *u*, *s*, and *g* are the characteristics of the sorbent; in particular *g* is the difference between the logarithmic retention indices of *m*- and *p*-xylenes. The following liquid crystals were investigated: *p,p'*-ethoxymethoxyazoxybenzene, *p,p'*-azoxyphenetole, and a binary sorbent consisting of *p,p'*-ethoxymethoxyazoxybenzene and *p,p'*-dibutoxyazoxybenzene[35]. For comparison, data for other stationary phases were also used[76,83,92,93]. It was shown that, in terms of the values of the linear analogues of polarity factors (*X*, *Y*, *Z*, *U*, *S*), the liquid-crystal stationary phases are sorbents of moderate polarity.

In the solution of many practical problems involving the separation of both a group of sorbates and individual positional isomers, it is necessary to select a liquid-crystal stationary phase which possesses fairly high values of the factor *g*, characterising the *meta–para* selectivity of the phase, and of the factor *x*, characterising the conventional chromatographic polarity. In this connection account was taken of the dependence of *g* on *x*, on the basis of which one can select the optimum stationary phase. Fig.3 shows that, although the binary sorbent based on a mixture of dinonyl phthalate and bentone-34 is characterised by a high selectivity in the separation of positional isomers ($g = 16.6$ units of the Kovats index), it is nevertheless a less polar sorbent ($x = 1.25$) than a liquid-crystal phase such as *p,p'*-ethoxymethoxyazoxybenzene ($x = 1.78$ and $g = 15.1$ units of the Kovats index).

The "conventional chromatographic polarity" of a liquid crystal changes abruptly in phase transitions, i.e. on passing from the solid to the liquid-crystal state and then to the isotropic state, increasing as a rule. Within the framework of the same phase state, "the conventional chromatographic polarity" increases with increasing temperature. As regards the *meta–para* selectivity, its magnitude is a maximum at the melting point and then monotonically decreases with increase of temperature. For example, when *p,p'*-azoxyphenetole passes from the solid state (100 °C) to the liquid-crystal state (140 °C), its polarity factor *x* increases from 0.1 to 1.9 units of the Kovats index, while the factor *g*, measured as the difference between the retention indices of *m*- and *p*-xylenes, increases from 2.5 to 14.8 units of the Kovats index. Within the limits of the liquid-crystal state, an increase of temperature from 140° to 150 °C entails a decrease of the *meta–para* selectivity of azoxyphenetole from 14.8 to 12.5 units of the Kovats index.

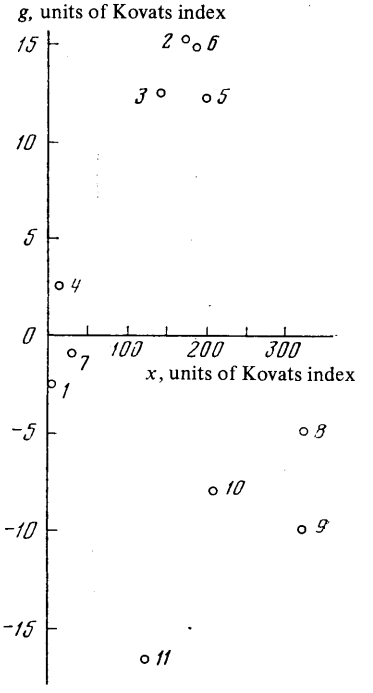

Figure 3. Dependence of the factor *g* on the polarity factor *x*.[91] Stationary phases: *1*) squalane; *2*) *p,p'*-ethoxymethoxyazoxybenzene; *3*) binary phase (*p,p'*-ethoxymethoxyazoxybenzene + *p,p'*-dibutoxyazoxybenzene); *4*) *p,p'*-azoxyphenetole, $t_c = 100$ °C; *5*) *p,p'*-azoxyphenetole, $t_c = 150$ °C; *6*) *p,p'*-azoxyphenetole, $t_c = 140$ °C; *7*) Apiezon L; *8*) PEG-4000; *9*) Rheoplex-400; *10*) Yucon-50NV-2000; *11*) binary phase (dinonyl phthalate + Bentone-34).

Thus the use of the above classification makes it possible to select stationary phases which, together with the extremum values of the factor *g*, have the necessary values of the other polarity factors. According to Herington[94], the selectivity in the separation of sorbates 1 and 2 is characterised by the ratio of their reduced retention times:

$$\sigma_s = t'_{R_2}/t'_{R_1} = (\gamma_1 p_1^0)/(\gamma_2 p_2^0),$$

where p_1^0 and p_2^0 are the vapour pressures of sorbates 1 and 2 and γ_1 and γ_2 are their activity coefficients in solution in the

stationary phase. This polarity index, which we mentioned previously, was used to estimate the *meta–para* selectivities of binary sorbents consisting of *p,p'*-ethoxymethoxyazoxybenzene and di-n-alkoxyazoxybenzenes[35], the influence of the vapour pressures and the activity coefficients of the sorbates (aromatic hydrocarbons–benzene, toluene, ethylbenzene, *o*-, *m*-, and *p*-xylenes) on the separation of the sorbates being estimated.

2. The Influence of Various Factors on the Structural Selectivity of the Liquid-Crystal Stationary Phases

The influence of various factors (temperature, pressure, and sorbate concentration) on the structural selectivity of the mesophase has been examined[95,96]. The temperature dependence of the structural selectivity of liquid-crystal stationary phases has been demonstrated in relation to azoxyethers. The maximum ratio of the retention characteristics of *p*- and *m*-xylenes is observed at the melting point of the liquid crystal and decreases monotonically as the clarification point is approached; above this point, xylenes are eluted as an overall peak. The temperature dependence of the *meta–para* selectivity in the liquid-crystal melt can be accounted for by the analogous dependence of the parameter *S*, which characterises the extent to which the molecules are arranged in parallel[3]; depending on the temperature, the value of *S* for the nematic phase varies in the range from 0.3 to 0.8, but, even at a temperature somewhat below the clarification point, the liquid crystal retains an appreciable tendency towards an ordered mutually parallel arrangement of molecular axes. The transition to the isotropic liquid is accompanied by an abrupt alteration of the sorption characteristics.

Kelker[2] recommends that one should work 2.3 K above the melting point of the substance (the reliability range). However, a detailed examination on the dependence of the retention parameters of the hydrocarbon analysed on temperature showed that there exists a broad region (5–6 K) with the maximum steric effect. Thus the ratio of the retention volumes of *p*- and *m*-xylenes on *p,p'*-azoxyphenetole is 1.096 at 134 °C, 1.10 at 136 °C, and 1.085 at 138 °C. This finding is important, since it shows that the liquid crystals used in gas chromatography do not require any special conditions for the maintenance of the column temperature, so that one can use ordinary commercial chromatographic apparatus. It has been shown that an increase in the concentration of the sorbate and in the carrier gas pressure in the column influence the *meta–para* selectivity in the same direction: the selectivity decreases with increasing concentration of the sorbate and the pressure of the carrier gas, the rate of decrease depending on the nature of both the liquid crystal and the carrier gas. This influence is associated with the breakdown of the ordered structure of the liquid-crystal melt as a consequence of the incorporation of the molecules of extraneous substances.

3. The Viscous Properties of Liquid Crystals

The low viscosity of nematic mesophases such as those of *p,p'*-azoxyanisole, *p,p'*-azoxyphenetole (1.47 cS), their eutectic mixture, and ethoxymethoxyazoxybenzene (3 cS) ensures high efficiency of the operation of chromatographic columns with the above sorbents.

4. Thermal Stability of Liquid Crystals

The use of liquid crystals as sorbents for gas chromatography requires the estimation of their volatility and thermal stability—factors which determine the upper temperature limit of the existence of the stationary phases. The upper temperature limits for the employment of a series of liquid-crystal stationary phases, determined by the derivatographic method, are 180 °C for *p,p'*-azoxyanisole, 200 °C for *p,p'*-azoxyphenetole, 195 °C for the eutectic mixture, 190 °C for *p*-heptyloxybenzoic acid, 270 °C for the ester of hydroquinone and *p*-(n-heptyloxy)benzoic acid, 220 °C for cholesteryl cinnamate, etc.[97,98]. Mention should be made of the work of Dewar and Schroeder[22] specially devoted to the synthesis of thermostable liquid-crystal compounds with high transition temperatures (among 19 new esters – *p*-phenylene alkoxybenzoates, *p,p'*-biphenylene-*p*-alkoxybenzoic acids, or *p*-alkoxycarbonylbenzoic acids - ten had mesomorphic regions extending over more than 90 K and the lowest transition temperature was 205 °C). Kelker et al.[19] studied high-temperature liquid-crystal sorbents. Investigations of the use of bis(*p*-methoxy-. *p*-butoxy-, *p*-hexyloxy-, *p*-phenylbenzylidene)-α,α'-bis-*p*-toluidines for the gas-chromatographic separation of polycyclic compounds[64,66–70] are instructive in this respect.

Naturally in many cases it is useful to carry out the chromatographic analysis at low temperatures, whence follows the necessity for seeking stationary phases in the state of the mesophase in the corresponding temperature range. An example of liquid crystals, with low melting points and clarification temperatures is provided by certain azo-compounds, azoxy-compounds, and azomethines[82,99,100], among which mention may be made of *p*-methoxybenzylidene-*p'*-butylaniline (the temperature range of the mesophase is from 21° to 47 °C), *p*-ethoxybenzylidene-*p'*-butylaniline (from 36 to 80 °C), and their eutectic mixture (from −16° to 50 °C).

Since the vapour pressure is of decisive importance in the estimation of the thermal stabilities of the stationary phases, the study[101] of the temperature variation of the vapour pressure of *p,p'*-azoxyanisole is of interest (Fig. 4).

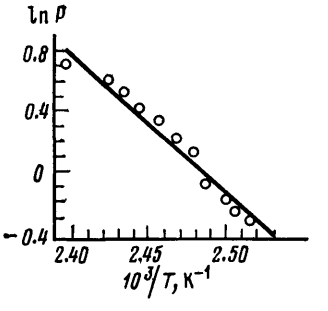

Figure 4. Dependence of the partial vapour pressure (mmHg) on the reciprocal of the absolute temperature[101].

The synthesis of high-temperature crystals holds out extremely great promise, because it extends the region of the analytical applications of mesophases in gas chromatography. Pitch mesophases constitute a fundamentally new type of high-temperature liquid crystals. They can be obtained in two ways: (1) by the carbonisation of coal and

petroleum tars; (2) by the joint carbonisation of individual organic compounds[102–106]. The formation of the liquid-crystal structure in the carbonisation of graphitisable substances is an irreversible process. The pitch mesophase obtained in the range 400–450 °C retains its liquid-crystal structure after complete setting and solidification[102,103]. Thus the temperature range of the existence of the pitch mesophase is much wider than in the other known systems. Brooks and Taylor[102,103] synthesised a series of pitch mesophases based on petroleum products and also by the joint carbonisation of organoelemental compounds and their mixtures (11 specimens); the analytical possibilities of these mesophases were also investigated and their likely usefulness in gas chromatography was demonstrated.

5. Dependence of the Efficiency of a Column with a Liquid Crystal Sorbent on Different Factors

The temperature dependence and the efficiency of a column containing a liquid-crystal sorbent have been studied by many investigators[46,49,79]. It has been shown that the efficiency decreases with decrease of temperature. Thus Fig. 5 presents the temperature variation[46] of the selectivity and efficiency of diundecyloxyazoxybenzene. When the above azoxyether is used for the separation of *m*- and *p*-xylenes at low temperatures, a "favourably" high value of σ_H and an "unfavourably" low value of HETP are obtained. A similar behaviour has been observed[49] in the separation of alkylnaphthalenes on *N*,*N*'-bis(*p*-methoxybenzylidene)-α,α'-bis-*p*-toluidine (BMBT). The authors determined the necessary number (*n*) of theoretical plates in the column for the separation of "difficult" pairs of alkylnaphthalenes on different stationary phases (Table 2).

Table 2.

Stationary phase	Pairs of alkylnaphthalenes*	*n*
Poly(phenyl ether)	1,4- and 2,3-DMN	
	2,3- and 1,5-DMN	85000
p,*p*'-Azoxyphenetole	2,3- and 1,2-DMN	92000
	1,3- and 1,4-DMN	42000
Graphitised thermal black	1,2- and 2,6-DMN	92000
	2,6- and 2,3-DMN	190000
N,*N*'-BMBT	1-EN and 2-MN	6500
	2-EN and 1,3-DMN	6500

*EN and MN = ethyl- and methyl-naphthalenes respectively and DMN = dimethylnaphthalene.

Grushka and Solsky[79,107,108] pointed out different changes in the height equivalent to a theoretical plate *H* as a function of the changes in temperature on a nematic liquid crystal. In particular, using *p*,*p*'-azoxyanisole as the stationary liquid phase on a capillary column[79], they noted the occurrence of temperature hysteresis of *H* (Fig. 6). *H* initially decreases with increasing temperature down to the melting point, where it increases sharply, falls again, and then rises once more in the nematic–isotropic transition. Two different values of *H* were obtained at the same temperature depending on whether the column was heated or cooled, the value of *H* being smaller in the cooling cycle than in the heating cycle. This conclusion is extremely important, since it indicates a high rate of mass transfer to the stationary phase in the cooling cycle (a clear-cut separation of *m*- and *p*-xylenes was in fact achieved in the supercooled region of azoxyanisole on a capillary column at 102 °C).

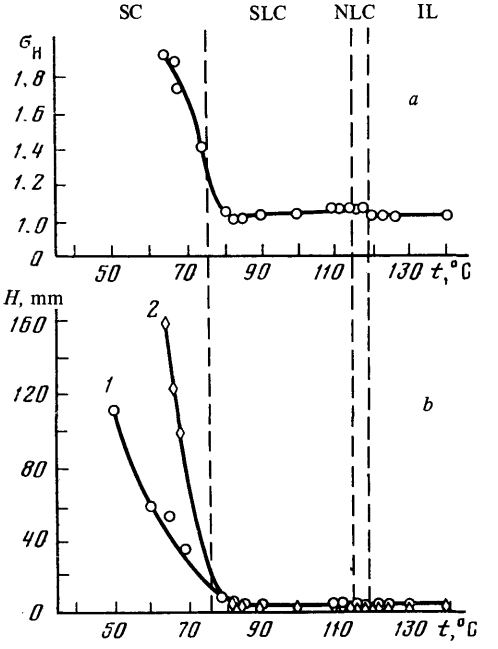

Figure 5. Temperature variation of the selectivity (*a*) and efficiency (*b*) of a column with *p*,*p*'-di-n-undecyloxyazoxybenzene[46]: *1*) *m*-xylene; *2*) *p*-xylene; SLC—smectic liquid crystal region; NLC—nematic region.

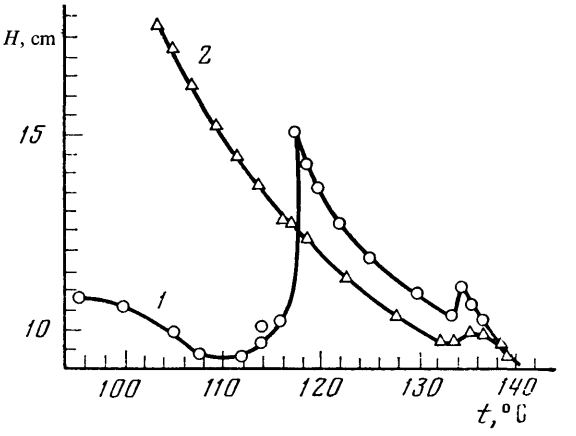

Figure 6. Temperature dependence of the height equivalent to the theoretical plate (HETP):[79] *1*) heating; *2*) cooling.

Grushka and Solsky[79] also showed that the minimum value of *H* is observed for lower flow rates of the carrier gas in the region of the mesophase; for example, in the case of *p*,*p*'-azoxyanisole on a capillary column the minimum value, H_{min}, is attained at a temperature of 120 °C, corresponding to the

liquid-crystal state, while at 90 °C (the solid crystal state of the substance) H_{min} has the same value, but is now obtained at higher carrier gas flow rates. H also decreases with decrease of the amount of stationary phase in the column. On a column with 0.1% of *p*-(*p*-ethoxyphenylazo)phenyl undecylenate (deposited on neutral glass grains), a lower value of H was obtained than on columns containing 0.27 and 0.69% of the stationary phase.

The possibility of the successful use of capillary columns with a liquid-crystal stationary phase has also been demonstrated in a study[40] whose authors used glass capillaries with a length between 8 and 27 m and 0.3 mm in diameter. Treatment of the capillaries with NaOH, NH_3, acids, HF, etc. did not lead to success, and only special treatment with EP-9 epoxy-resin ensured the complete impregnation of the capillary with the liquid crystal and the formation of an effective film. The epoxy-resin mixed with a hardener in proportions of 1:4 was dissolved in *o*-dichlorobenzene and a 10% solution was passed slowly through the capillary with the aid of a water pump. In addition 15 ml of *o*-dichlorobenzene was introduced, after which the capillary was dried at 120 °C in a stream of argon. The liquid-crystal compound was then dissolved in a suitable solvent and was introduced into the capillary by the piston method. The film of the liquid crystal within the capillary was dried in a stream of argon at a slowly rising temperature.

In their study of the retention of sorbate molecules on polymeric sorbents modified with liquid crystals, Zelenkova et al.[109] also showed that the HETP decreases with increase of temperature and with decrease of the amount of the stationary phase. The greatest increase of the sorbent efficiency is observed when 5–20% of the liquid crystal is deposited on the polymeric sorbents.

6. The Influence of the Impregnation of the Carrier

The optimum amount of the stationary phase, deposited on a solid carrier, is determined by the influence of a number of competing factors associated with the selectivity, efficiency, and duration of the analysis. Low degrees of impregnation of the carrier, which make it possible to reduce the HETP and to shorten the duration of the analysis, are preferable. However, in order to obtain exact and reproducible retention parameters (particularly when these are to be used for the calculation of the thermodynamic functions of dissolution), the amount of the stationary phase must be sufficient to achieve the complete coverage of the carrier and to eliminate the distorting influence of adsorption on the surface of the solid.

The influence of the molecular packing density of the test substance on the dependence of the retention parameters on the amount of the stationary phase and also the influence of the solid carrier on the selectivity of the liquid-crystal stationary phase was demonstrated by Gabitova and Vigdergauz[110] for azoxyethers in the separation of *m*- and *p*-xylenes and aromatic and paraffinic compounds using columns with different contents of the stationary phase.

Fig.7 presents the variation of the specific retention volume of toluene on *p,p'*-azoxyphenetole with the degree of impregnation in different phase states. The nature of the curves shows that the contribution of adsorption factors to the retention of sorbates by isotropic and anisotropic liquids is negligibly small for a degree of impregnation exceeding 10%, i.e. above this value the retention parameters are almost independent of the amount of the stationary phase. On the other hand, in the solid crystal state the retention is naturally determined by the area of the adsorbing surface and, since the latter depends only slightly on the amount of the stationary phase, the specific retention volume is inversely proportional to the degree of impregnation V_g. The results permitted the determination of the lower limit of the possible amount of the liquid-crystal stationary phase. They demonstrated a relation between the jump in the retention parameters at the melting point and the degree of their impregnation, while at the clarification point the jump is determined solely by the nature of the substance analysed. Furthermore it has been shown that (1) with decrease in the degree of impregnation the *meta–para* selectivity of the liquid-crystal sorbent diminishes and (2) the temperature of the transition of the stationary phase from the solid state to the liquid-crystal state decreases with decrease in the degree of impregnation.

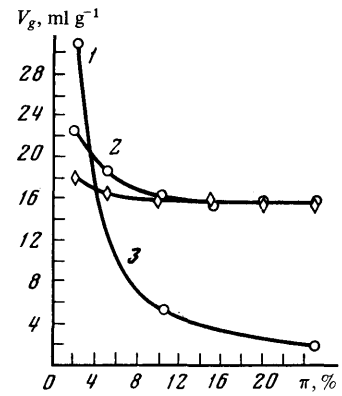

Figure 7. Dependence of the absolute specific retention volume of toluene on the amount of *p,p'*-azoxyphenetole (% relative to the mass of Chromosorb P) at different temperatures (°C): *1*) 100; *2*) 140; *3*) 170.[80]

The principal studies with liquid-crystal sorbents in gas chromatography have been carried out in columns using virtually inert solid carriers which have a specific porosity, are mechanically stable, and have a specific surface of ~10 $m^2 g^{-1}$. The use of liquid crystals deposited in the form of a monolayer on an active solid carrier—macroporous Silochrome with a high specific surface—has been described recently[43,44]. It has been shown that the use of thin, nearly monomolecular layers of nematic and smectic as well as cholesteric stationary phases leads to the observation of a fairly high *meta–para* selectivity and to a shift of the selectivity maximum towards lower temperatures relative to those corresponding to the usual impregnation process (i.e., as in the studies of Serpinet[111,112], a change in the phase transition temperature is observed). Apparently when a monolayer is employed, the support plays an extremely active and possibly a decisive role in the separation of the substances analysed.

The role of an active sorbent with a high surface area in the gas-chromatographic separation of mixtures has been demonstrated by Averin et al.[47], who increased the efficiency of the separation and reduced the temperature of the separation process at high concentrations of the substances analysed by employing an active adsorbent

(Silochrome) impregnated with a liquid-crystal stationary phase (azoxyphenetole) in the separation *m*-, *p*-, and *o*-isomers of vinyltoluene and noted a further series of advantages of this method of separation. In this connection one must also mention studies[109,113] in which polymeric sorbents, such as Polysorb-1 and Chromosorb-101 modified with liquid crystals, for example *p,p'*-azoxyphenetole and *p,p'*-ethoxymethoxyazoxybenzene, were used for the gas-chromatographic separation of various classes of organic compounds—paraffinic and aromatic hydrocarbons, alcohols, ketones, aldehydes, acids, lactones, etc., aromatic compounds being retained on these sorbents more tenaciously than paraffinic hydrocarbons. The separation of *o*- and *m*-xylenes, *o*- and *m*-cresols, etc. has been achieved[109,113], while the *m*- and *p*-isomers were not separated. The influence of the amount of the azoxyphenetole liquid crystal on the principal characteristics of the gas-chromatographic process, on the corrected retention volumes V_R of the sorbates, on the HETP, and on the asymmetry coefficient has been investigated.

The influence of the nature of the solid carrier on the chromatographic behaviour of the mesophase has been noted[79,107,108]. The authors of these investigations suggest that the anomalous effects [the influence of the rate of heating of the liquid crystal on its melting point, the time dependence of the coefficients *K* (the partition coefficient of the sorbate) and the HETP (the efficiency of the separation) near the melting point, the form of the variation of the retention parameters for two ways of varying the temperature in experiments using the capillary column[79] and glass grains of different types[107,108] as the solid carrier] can be explained by the influence of surface orientational forces of the carrier and the inner wall of the capillary tube. Furthermore, it has been shown that the nature of the orienting of the molecules of the liquid crystal on the surface of glass grains is determined by the extent of the diffusion of the sorbate molecules, i.e. the diffusion of solutions in which the molecules of the liquid crystals are oriented parallel to the surface of the glass grains is usually more extensive than the diffusion of solutions with a perpendicular arrangement of liquid crystal molecules on this surface.

The influence of the surface of the solid carrier on the thermodynamic functions of the dissolution of substances has been studied[30,114]. The absence of effects at the solid–liquid crystal interface and the occurrence of only very weak interactions in the gas–liquid crystal system, which can be neglected for a film thickness of at least ~1000 Å, has been demonstrated.

7. The Influence of an Electric Field on the Selective Properties of Liquid Crystals

Under the influence of an electric or magnetic field, the degree of order among the molecules of the liquid crystal changes in the region of the mesophase[115], which leads in its turn to an alteration of the retention characteristics of the substances analysed. In 1963 one of the authors of this review suggested that the chromatographic process be carried out in an electromagnetic field[116]. Under the influence of the field, the molecules of the stationary liquids (and in many instances also the components being separated) are polarised and their sorption properties are therefore altered. Evidently the introduction of an additional factor into the chromatographic process should increase the scope for controlling the selectivity of the stationary phase and permit the study of a new range of sorption phenomena.

The relevant investigations have been carried out by Taylor and coworkers[117–119] using short capillary columns containing mixtures of cinnamate esters and cholesteryl myristate as the stationary phases. An electric field up to 500 V was applied to the column by means of external electrodes attached by means of a special paste and aluminium foil. The authors investigated the dependence of the shape of the peaks and retention times of hydrocarbons and oxygen-containing compounds on the electric potential, its frequency, the analytical temperature and the content of the stationary phase. Application of an electric field increased the retention times of the substances analysed and the peaks became more symmetrical.

Vigdergauz and coworkers[120,121] investigated the influence of an electric field on the chromatographic retention of diethyl ether, acetone, ethyl methyl ketone, n-hexane, heptane, cyclohexane, and benzene, by a liquid-crystal stationary phase—cholesteryl laurate at 86 °C. The length of the spiral column designed by Taylor et al.[117] was 10 m and the potential applied to the electrodes was 500 V. In order to estimate the effect of the electric field, the difference between the free energies of sorption of the test substances $\delta(\Delta F^0)$ in the presence and absence of the field was calculated:

$$\delta(\Delta F^0)\ \text{cal mol}^{-1} = RT \ln \frac{\Gamma'_{500}}{\Gamma'_0} = 714 \ln \frac{\Gamma'_{500}}{\Gamma'_0},$$

where Γ'_{500} and Γ'_0 are the partial Henry coefficients for the sorbates in the presence and absence of the field respectively [$\Gamma' = (t_R/t_0) - 1$, where t_R and t_0 are the retention times of the sorbate and the non-sorbed substance respectively].

The results of the calculation permitted the conclusion that $\delta(\Delta F^0)$ can reach 400–500 cal mol^{-1}, which corresponds, in absolute magnitude, to the value of $\delta(\Delta F^0)$ for the transition from the isotropic liquid to the mesophase[5] and also to the values of $\delta(\Delta F^0)$ for neighbouring homologues, i.e. 100 units of the Kovats index. The use of the above effect for analytical purposes is possible only after the development of a column design ensuring an adequate efficiency. The results justify the hypothesis that, together with familiar external factors such as temperature and pressure, the application of an electric field can also be used for the specific regulation of the selectivity of the chromatographic column.

The following features of the data described above on the analytical application of liquid crystals must be noted:

(1) Despite the fact that extensive studies have been made on the utilisation of liquid-crystal sorbents in gas chromatography, the general characteristics relating the chromatographic selectivity to the structure of the liquid crystal have not so far been discovered[122–124].

(2) The majority of the liquid crystals investigated are designed for the solution of the narrow problem of the separation of *meta*- and *para*-isomers and exhibit a weak group selectivity. Consequently one must direct attention to the synthesis of mesophases exhibiting both specific and general selectivity.

The question arises of the requirements which must be met in the synthesis of liquid-crystal stationary phases:

(a) These must be liquid crystals of the nematic type. The wide-scale employment of smectic liquid crystals will become possible only in the case of very high selectivity. The introduction of new stationary liquid-crystal phases into chromatographic analysis is justified only in those cases where these phases have a significant advantage.

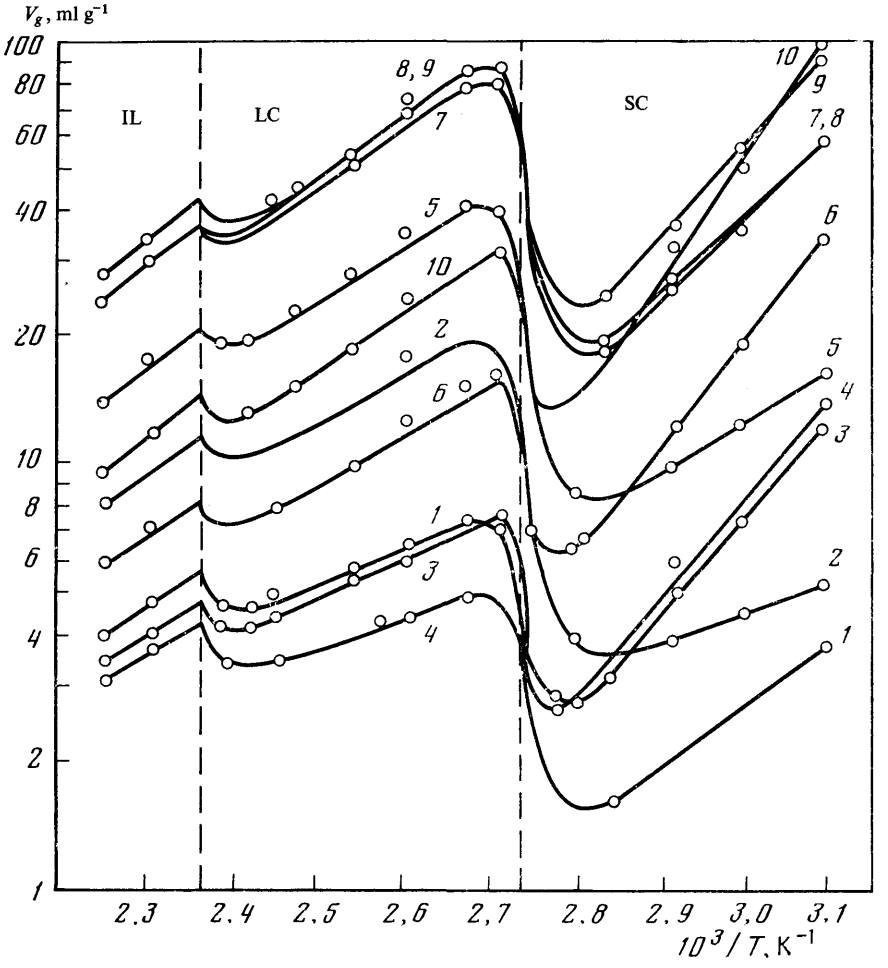

Figure 8. Dependence of the specific retention volumes of hydrocarbons on the reciprocal of the absolute temperature of a column with *p,p'*-ethoxymethoxyazoxybenzene[46]: *1*) cyclohexane; *2*) benzene; *3*) heptane; *4*) iso-octane; *5*) toluene; *6*) octane; *7*) *m*-xylene; *8*) *p*-xylene; *9*) isopropylbenzene; *10*) nonane.

(b) The liquid crystal synthesised must contain highly polar functional groups. Certain examples have been described[125–127], but the analytical scope of such liquid crystals has not so far been estimated. Unfortunately the liquid-crystal stationary phases already investigated are phases of moderate polarity or in practice one has to deal with the separation of a multicomponent mixture consisting of compounds of different classes.

(3) Liquid-crystal stationary phases must have a wide and controllable temperature range of the mesophase. It can be extended either by synthesising the appropriate liquid-crystal compound or by using mixed phases forming a eutectic. The majority of the liquid crystals synthesised are medium-temperature stationary phases the range of the existence of the mesophase of which extends up to 200 to 300 deg. Hence follows the interesting problem of the synthesis and utilisation of the high-temperature phases—the so-called pitch mesophases.

(4) The study of the influence of field effects (electrical and magnetic) on the chromatographic processes in a sorbate–liquid crystal system is of very great interest.

IV. CHROMATOGRAPHIC STUDY OF THE PHASE TRANSFORMATIONS OF LIQUID CRYSTALS

The retention volume and the corresponding retention time (V_R and t_R) in gas chromatography are fundamental characteristics of the sorbate. Fig.8 presents the relations between the logarithm of the specific retention volume and the reciprocal of the absolute temperature of the column containing ethoxymethoxyazoxybenzene[46]. The retention parameters of the substances analysed are extremely sensitive to phase transitions of the sorbent as a consequence of which the plot clearly reveals three regions of its phase state: solid, liquid-crystal, and isotropic liquid. The phase transitions are accompanied by sharp changes in the retention parameters. Under these conditions, the retention volumes increase at the melting point by a factor of 4–10 and at the clarification temperature by 15–20%. The melting point, clarification temperature, and transition temperature between different mesophases are characterised by an abrupt alteration of the retention parameters; on the other hand, there are cases where

there is no maximum, for example, when *p*-phenylene bis-*p'*-(n-heptyloxy)benzoate passes from the solid state to the smectic mesophase, which is due to the high viscosity of the latter[5,83].

Within the framework of the same temperature range between the phase transition temperatures, there is a gradual decrease of the retention volumes as the temperature rises. The transition from the solid to the liquid-crystal state leads to a change of the overall selectivity, which is expressed by an inversion of the elution sequence of aromatic, naphthenic, and paraffinic hydrocarbons. The same relations determining the temperature variation of the retention were observed by Kelker[15] for *p,p'*-azoxyphenetole, by Dewar and Schroeder[16] for *p,p'*-di-n-hexyloxyazoxybenzene, and by Barrall et al.[24] for cholesteric liquid crystals. In particular, Barrall et al.[24] noted that the elution times of the sorbates increase by a factor greater than 3.5 on transition from the cholesteric mesophase to the isotropic liquid.

Further studies demonstrated that there is a more complex relation between the retention and temperature. Thus, when the solid-crystal phase of ethoxymethoxyazoxybenzene is heated[33] and its isotropic liquid phase is cooled in the range 70–100 °C, hysteresis is observed, i.e. the retention of the sorbates and the selectivity of their separation are linked to the "memory" of the column. Other workers have also observed hysteresis[49,79].

The high sensitivity of the sorption characteristics and the associated retention parameters of the substances analysed to the phase state of the sorbent permits the solution also of the converse problem—the determination of the phase transition temperatures and also of the accompanying structural changes with the aid of chromatographic apparatus. This advanced gas chromatography to the forefront of the effective methods for the investigation of physicochemical properties and phase transformations in liquid crystals[24]. The likely usefulness of the combined study of phase transitions in liquid crystals by thermography and a combination of gas chromatography and the thermo-optical method was first demonstrated by Vigalok and coworkers[46,85].

Fig. 9 presents the thermo-optical curve for the dependence of the logarithm of the retention of hydrocarbons on the reciprocal of the temperature of the column with *p,p'*-heptyloxyazoxybenzene and a thermogram of this substance. The graphical data demonstrate the full agreement within the limits of 1–2 K of the phase transition temperatures determined by all three methods: sorption, optical, and thermal, despite the fact that the principle of each is different. As regards the additional information which can be obtained with the aid of chromatography, one should note the possibility of the study of the prefusion process and the accompanying structural changes in the crystal as well as a quantitative estimate of these changes (Kelker[20] pointed out earlier the occurrence of prefusion effects in liquid crystals which were treated by various investigators either as homogeneous processes or as processes involving heterogeneous fluctuations[128,129]).

Using a combination of the chromatographic and thermo-optical methods, the phase transitions in binary liquid-crystal sorbents have also been determined. It has been shown that the greatest shift of the phase transition temperature towards low values, amounting to 30 K, has been observed for the eutectic mixture of *p,p'*-ethoxymethoxyazoxybenzene and di-n-butoxyazoxybenzene, while the corresponding shift for the mixture with di-n-hexyloxyazoxybenzene amounts to 18 K.[35] The phase transition temperatures can also be determined by differential scanning calorimetry combined with gas–liquid chromatography (GLC).[30]

The idea of nematic order in poly(vinyl chloride) has been confirmed by chromatographic studies[130]. It has been shown that the nature of the separation of the *cis*- and *trans*-decalins differs markedly in the experimental temperature range (35–170 °C) and that the elution sequence of the isomers undergoes inversion as a function of the phase state of the sorbent.

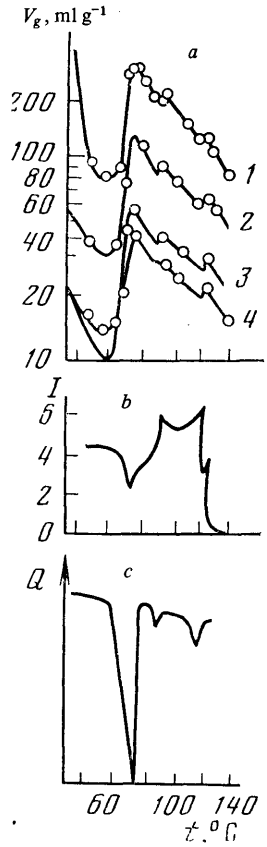

Figure 9. Chromatographic (*a*), thermo-optical (*b*), and thermographic (*c*) curves for *p,p'*-heptyloxyazoxybenzene[46]. Sorbates: *1*) *p*-xylene; *2*) toluene; *3*) n-pentane; *4*) benzene.

V. THERMODYNAMICS OF THE SORPTION OF SUBSTANCES BY LIQUID CRYSTALS

The possibility of the analytical and preparative separation of compounds with similar boiling points by chromatography in a gas–liquid crystal system is due to the significant differences between the thermodynamic functions of the sorption of isomeric compounds by liquid crystals. Gas chromatography is therefore an effective method for the investigation of the properties of the solvent and the behaviour of the solute in the liquid crystal, as well as the determination of the thermodynamic parameters of mesophases; one can then determine from chromatographic data the thermodynamic parameters under conditions close to infinite dilution, where no disruption of the structure of the liquid-crystal phase is observed[29,30,48,114,131–136]. Furthermore, the absence of an influence on the accuracy of the

determination of the thermodynamic parameters by effects on the solid–liquid crystal and gas–liquid crystal interfaces for a thickness of the liquid crystal film of ~1000 Å was noted above.

On the basis of the analysis of the activity coefficients γ^{∞} of the sorbates at infinite dilution, a molecular theory of the solubility of substances in liquid crystals has been developed[135]. The activity coefficients have been interpreted at the molecular level by means of statistical mechanics. As usual, the thermodynamic calculations are based on the determination of the specific retention volume V_g.

In their study of the effects of the dissolution of xylenes in cholesteryl myristate, which can exist in the state of both smectic and cholesteric mesophases, Martire et al.[29] established that only the smectic phase gives rise to the selective separation of *m*- and *p*-xylenes. Kelker[18] also pointed out the absence of selectivity in the cholesteric phase, while Vetrova and coworkers[43,44] achieved a fairly clear-cut separation of *m*- and *p*-xylenes on cholesteryl pelargonate deposited in a monolayer on an active adsorbent. Unfortunately, the authors of the present review were unable to reproduce these results.

Jeknavorian and coworkers[139,140] derived the same relations for the solubilities of the above compounds in liquid-crystal sorbents as Chow and Martire[135] on the basis of an analysis of the activity coefficients for the dissolution of n-alkanes and aromatic hydrocarbons, including xylenes and *cis*- and *trans*-isomeric alkyl cyclohexyl ethers on the *p*-(*p'*-ethoxyphenylazo)phenyl heptanoate nematic liquid crystal.

The phase transition temperatures are known to be preceded by pretransformation periods. Kelker and coworkers[20,21] showed that the effects preceding the phase transitions can be investigated by chromatographic methods; azoxyethers (azoxyanisole, azoxyphenetole, and their eutectic mixtures) can be investigated by chromatographic methods. Prefusion processes have been described[128,129]. Pretransition effects have also been demonstrated by measurements of viscosities[141], specific heats[142], coefficients of linear expansion of NMR signals[143], and infrared spectra[144]. Bauer and Bernamont[145] found in relation to *p,p'*-azoxyanisole that the pretransformation period occurred ~10 K below the clarification temperature. To account for the pretransition effects, Kelker used the molecular-statistical theory developed by Tsvetkov[146], Weber[143], and Maier and Saupe[147]. The pretransition behaviour of nematic phases can be described also with the aid of the Frenkel's two-phase concept[148].

The thermodynamics of the dissolution of substances in liquid crystals has been studied[42] by capillary gas chromatography. On the basis of the molecular theory of solubility[135], the authors investigated the influence of the length of the alkyl chains in the homologous series of liquid-crystal ketoximes on the molar enthalpy Δh^0 and entropy Δs^0 of the solution and the excess functions of the dissolution of the above substances.

It has been shown[42] that the partial molar enthalpies and entropies of all the sorbates (alkanes, aromatic hydrocarbons, xylenes, and disubstituted benzenes) exhibit a clear alternation in the homogous series of ketoximes with inversion at the clarification temperature. Compounds with an even number of carbon atoms had lower values of Δh^0 and Δs^0 at a higher clarification temperature. The disubstituted benzene isomers used as sorbates were fully separated and the *p*-isomers exhibited higher values of Δh^0 and lower values of γ^{∞} in the region of nematic liquid crystals.

The thermodynamic functions of the sorption of different sorbates on liquid crystals have been studied by Vigdergauz and coworkers[5,26,83,85,88]. Calculations showed that the transition from the anisotropic to the isotropic region is accompanied by an increase of the heat of sorption and that, whereas in the isotropic region the values of Δh for the isomers are similar, in the case of the mesophase there are significant differences due to the molecular structure of the sorbates.

Kelker showed for alkylbenzenes[15] that the heat of mixing of xylenes with *p,p'*-azoxyphenetole is an order of magnitude higher than the heat of mixing with the usual stationary liquids. Thus, the heats of mixing of *o*-xylene with the azoxyphenetole mesophase, benzylbiphenyl, and 7,8-benzoquinoline are 5400, only 520, and 850 cal mol^{-1} respectively. The heat of mixing is always higher by ~3000 cal mol^{-1} in the mesophase than in the isotropic liquid; consequently the dissolution process in an anisotropic composition requires more energy, i.e. the dissolution of substances in both the liquid-crystal and isotropic regions of the sorbent is accompanied by the adsorption of heat and the mesophase is more endothermic in all instances apart from the eutectic mixture.

The corresponding difference for *p,p'*-azoxyphenetole[83,85] amounts to 2–3 kcal mol^{-1}, which agrees with the data of Kelker[15], who, however, used in the calculation the latent heats of vaporisation λ at the boiling points of the sorbates and not at the column temperature. The change in the degree of endothermicity on transition from the isotropic liquid to the mesophase decreases for *p*-(n-heptyloxy)-benzoic acid, the ester of hydroquinone and *p*-(n-heptyloxy)-benzoic acid, and cholesteryl cinnamate to 0.5–1 kcal mol^{-1}, while in the case of the eutectic mixture the corresponding difference for paraffins is close to zero and for the remaining alkylbenzenes and cycloparaffins it amounts to ~1 kcal mol^{-1}.

Comparison of the heats of sorption and the excess enthalpies of mixing with those observed in the case of the isotropic phase and the mesophases (smectic and nematic) of the ester of hydroquinone and heptyloxybenzoic acid showed that the smectic region is the most endothermic: $\Delta h \cong 4$ kcal mol^{-1} (in the nematic region $\Delta h = 1.2$–2.3 kcal mol^{-1}) The results can be accounted for by the higher degree of order in the structure of the smectic region, so that the penetration of extraneous molecules into the mesophase of the smectic liquid crystal requires a greater expenditure of energy than in the case of the nematic state. For anisotropic melts of azoxyphenetole, the entropy of mixing Δs is greater by 8–10 e.u. than for the isotropic phase.

Thus the transition of the sorbent to the liquid crystal region is accompanied by a sharp change of both the entropy of mixing of the sorbate with the stationary liquid (which corresponds to an abrupt alteration of the retention characteristics in the temperature range of the phase transition) and of the enthalpy of mixing (which corresponds to a dependence of the logarithms of the retention characteristics on $1/T$). The set of these changes ensures extensive possibilities for the regulation of the selectivity in the separation of mixtures incorporating isomers with similar boiling points.

As already mentioned, a considerable scope for the regulation of selectivity arises from the use of mixed stationary phases[5,26,35,88]. The nature of the intermolecular interaction in such a system depends on whether the binary system includes one or two liquid-crystal compounds, on whether they form a eutectic mixture, and on the type of mesophase of the mixed liquid-crystal ingredients. It is noteworthy that the absolute difference between the heats of sorption of the substances analysed in the isotropic and anisotropic regions on the individual sorbents is greater than on the mesophase. This effect had been noted earlier by Kelker[2] in relation to *o*-xylene

and shows that the mixing process is accompanied by a change in the energy of the system. The excess free energy of the mixed phase $\Delta f'$ can be calculated on the basis of published data[149,150] from the formula

$$\lg V_{mm} = x_1 \lg V_{mm1} + (1-x_1) \cdot \lg V_{mm2} + \Delta f'/4.57T,$$

where $V_{mm} = V_g M/22400$ is the molar retention, x_1 the mole fraction of the individual phase in the mixture, T the column temperature (K), and M the molecular weight of the stationary phase.

For the sorbates investigated, the above relation is represented by curves with a maximum corresponding to the 60 : 40 eutectic mixture; the maximum value of $\Delta f'$, calculated from the dependence of the molar retention on the phase composition, then corresponds to 100 °C, i.e. a temperature close to that of eutectic fusion (Fig. 10). The effective value of Δf, obtained for a 10% degree of impregnation of Chromosorb on the basis of the retention characteristics of n-paraffins, proved to be 630–640 cal mol^{-1}. The value of $\Delta f'$ calculated from the retention characteristics of polar compounds are significantly greater, since they include the energy of the specific interaction of the sorbate with the eutectic.

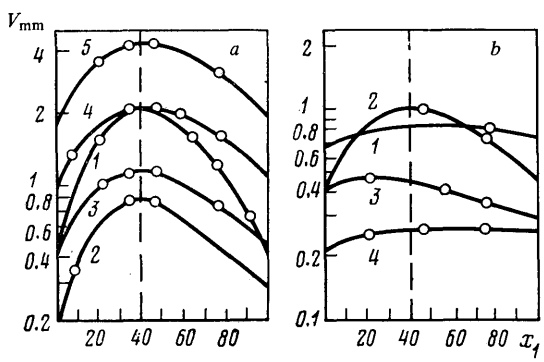

Figure 10. Dependence of the molar retention of sorbates (on the logarithmic scale) on the content of p,p'-azoxyphenetole x_1 in its mixture with p,p'-azoxyanisole[5]. The dashed lines correspond to the eutectic mixture: *a*) retention of s-butylbenzene (curve *1*), butyl acetate (curve *2*), n-decane (curve *3*), n-undecane (curve *4*), and n-dodecane (curve *5*) at 100 °C; *b*) retention of n-decane at different temperatures (°C); *1*) 90; *2*) 100; *3*) 140; *4*) 170.

The excess free energies of mixing of the individual components $\Delta f'$ (from the data for n-paraffins) as well as the values of $\Delta f'$ characterising the additional energy of the interaction of xylenes with binary solvents were calculated for binary systems incorporating p,p'-azoxyphenetole (I), p-(n-heptyloxy)benzoic acid (II), p-phenylene bis-p'-(n-heptyloxy)benzoate (III), cholesteryl cinnamate (IV), poly(ethylene glycol)-2000 (V), and squalane (VI).[5,88]

In the first place the determination of the dependence of $\Delta f'$ and $\Delta f''$ on the composition of mixtures of p,p'-azoxyphenetole with poly(ethylene glycol) and squalane permitted the conclusion that the values of the calculated functions are determined by the phase state of the liquid-crystal ingredient. Thus, whereas at temperatures of 170° and 190 °C corresponding to the isotropic liquid state the values of $\Delta f'$ are virtually the same (Table 3)[88], transition to the temperature at which the mesophase exists (140 °C) entails an increase of $\Delta f'$ by 400 cal mol^{-1}. A negative value of $\Delta f''$ for xylenes has been observed in the case of the p,p'-azoxyphenetole–squalane pair, which is characterised solely by the dispersion interaction between the components.

Table 3. Experimental values of $\Delta f = \Delta f' + \Delta f''$ (cal mol^{-1}) for binary systems of phases[88].

Sorbates	(I)–(V) 140° C	(I)–(V) 170° C	(I)–(V) 190° C	(I)–(VI) 140° C	(I)–(II) 136° C	(II)–(III) 100° C	(III)–(IV) 156° C
n-Paraffins	560	150	140	770	270	520	—160
m-Xylene	730	310	300	450	260	800	—120
p-Xylene	320	320	320	400	260	830	—110

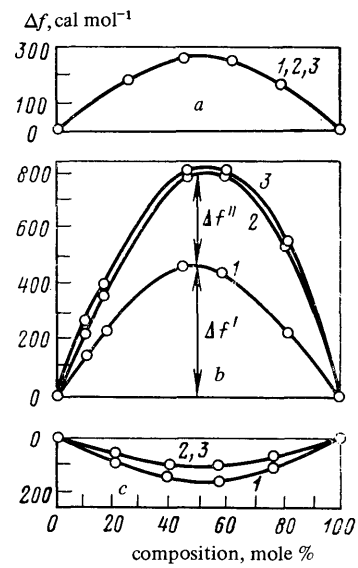

Figure 11. Dependence of the quantity $\Delta f = \Delta f' + \Delta f''$ on the composition of a binary liquid crystal phase[88]. Systems: *a*) (I)–(II); *b*) (II)–(III); *c*) (III)–(IV). Sorbates: *1*) n-paraffins ($\Delta f'$); *2*) *m*-xylene; *3*) *p*-xylene.

The values of $\Delta f'$ for the liquid-crystal mixtures (I)–(II) and (II)–(III) are positive, while those for the (III)–(IV) mixture are negative. One cannot rule out the possibility that the latter is associated with the transition of the entire (III)–(IV) system to the state of a cholesteric mesophase (by analogy with Friedel's data[151]). Fig. 11 presents relations between Δf and the composition of a binary liquid-crystal phase. Evidently in the (I)–(II) system the curves corresponding to n-paraffins and xylenes coincide. This indicates an additive variation of the selectivity in the separation of xylenes as a function of the composition of the phase and the absence of additional specific interactions ($\Delta f'' = 0$). The coincidence of the curves corresponding to

xylenes in the (III)–(IV) system is a consequence of the virtual absence of selectivity in both components of the mixed phase at the temperature of the measurement. In the (II)–(III) system an anomalous increase of selectivity is observed with a maximum corresponding to an ether content of 10 mole %. This composition of the mixed phase yields a ratio of the retention volumes of *p*- and *m*-xylenes of 1.065–1.070, while for the individual phases (II) and (III) the ratios are respectively 1.05 and 1.02.

* * *

During the period when the manuscript was with the editors, a number of studies devoted to various theoretical and applied aspects of chromatography in the gas–liquid crystal system were published. The separation of structural isomers of various substituted dialkylbenzenes has been achieved[152–159] on columns with mesophases containing azo- and azoxy-groups. The isomeric dimethylnaphthalenes have been analysed[160–162] and polycyclic aromatic hydrocarbons, in particular anthracene, phenanthrene, benzo phenanthrene, benzopyrenes, and perylene have been investigated[160–165]. Substances of biological origin—cholic acids and their derivatives, steroids, and phenolic metabolites of benzo[*a*]pyrene—have been investigated with the aid of high-temperature nematic liquid-crystal phases[166,167]. In addition enzymes have been analysed[168] and enantiomeric *N*-pentafluoropropionamides have been separated on smectic mesophases[169]. Problems of the influence of the solid carrier on the chromatographic characteristics of liquid-crystal stationary phases have been studied[154,160,170–172] and a number of investigations have been devoted to the thermodynamics of the dissolution of sorbates in mesophases[173–176].

The study of the influence of an electric field on the separating capacity of liquid crystals has been continued[177] and capillary columns have been used[164,178].

Electronic Processes Induced by Radiation in Solid Organic Systems

A.P.Tyutnev, V.P.Sichkar', and A.V.Vannikov

We shall discuss the behaviour of charged particles produced by radiation and their role in physical and chemical processes (e.g. electrical conduction, recombination luminescence, and various optical properties). By analysing existing physico-chemical theories and concepts we can describe these processes quantitatively (at least to a first approximation) as well as gaining a deeper understanding of their mechanism. 402 references.

I. INTRODUCTION

The fundamental importance of ion–molecule reactions during the radiolysis and photolysis of condensed phases was demonstrated during the late 1960's.[1-4] In particular, detailed studies were made of the electrical phenomena accompanying the radiolysis of hydrocarbons[1,5], such as induced electrical conductivity, recombination luminescence, and thermally stimulated and photo-stimulated processes in low-molecular hydrocarbon glasses previously irradiated at low temperatures. Since that work was reported much progress has been made in understanding the role of charged particles (and especially electrons) in the radiolysis of liquid, non-polar molecular systems[6,7], and the mobility and reactivity of excess electrons in liquid hydrocarbons have been fully investigated[8,9].

We have used the results of experimental and theoretical studies of organic (and inorganic) liquids to analyse the electronic processes induced by radiation in solid organic systems such as glasses and polymers. In this review we shall examine the experimental (and, to a lesser extent, the theoretical) work on charge generation, stabilisation, and recombination mechanisms which has been published since the end of the 1960's, as well as studies of charge transfer under the influence of an external or an internal (coulombic) electric field in solid organic systems. By analysing this information we have been able to assess the current level of understanding of these problems and to identify the topics to which more attention should be devoted.

II. CHARGE GENERATION

In this Section we shall discuss the theories by which the yield of free charges (and of charges contributing to electrical conduction) may be calculated for the radiolysis or photolysis of organic materials in a condensed phase with

allowance for the energy spectrum of the secondary electrons. This treatment explains both the changes in electrical conductivity of the medium produced by irradiation and the direction of the radiation-chemical reactions involving the charged particles. In some cases it is important to be able to calculate the total yield of charged particles (called the initial ionisation yield).

In flash photolysis the energy of the electron produced by the ionisation process is not usually sufficient to cause further ionisation of a molecule of the matrix: often it cannot even excite the molecule to an excited state. In this case we are dealing with the generation of isolated ion pairs. An analogous situation exists under radiolysis, but only for the secondary δ-electrons, whose energy is less than a few eV. However, in contrast to the photolysis case, during radiolysis with γ-quanta or fast electrons of 1–10 MeV energy the fraction of the energy expended in forming isolated pairs is quite low (a figure of ~30% has been suggested[10-13]). About 40% of the energy is spent in the generation of "spurs", containing 2 or more pairs of charges (up to 10), and 10% in the formation of spherical, multiply-charged ionisation regions containing 10–50 ion pairs. Lastly, the remaining 20% of the energy is dissipated in forming short cylindrical tracks with an ionisation density approaching that of 1–2 MeV protons but less strong than that of α-particles ($E_\alpha = 3-5$ MeV). Of course, the tracks of the δ-electrons are very much shorter than those of heavy charged particles[14-18].

The Onsager and the Poole–Frenkel' theory are often used to calculate the yields of free charges from isolated pairs. The yield of charges from the tracks of heavy charged particles and from spurs can be described in terms of the theoretical concepts developed by Jaffe and Lea.

Whereas in the radiation chemistry of water and other polar liquids the real structure of the track of a fast electron is allowed for in the calculation of the yield of charges into the bulk of the liquid, in the radiation chemistry of non-polar solid or liquid organic systems (mostly, hydrocarbons) all the calculations so far have assumed radiolysis by the ion-pair mechanism. However, the need to allow for the contribution of formations with multiple charges to the observed radiolytic effect is being increasingly recognised[6,7,19-21].

1. Ion Pair Generation

a) Onsager's theory

Onsager[22,23] considered the probability of dissociation of a pair of charges in thermal equilibrium with a medium of temperature T and static dielectric constant $\varepsilon\varepsilon_0$ in an electric field E_0 for an initial separation of the pair of charges r_0. The subsequent motion of the charges was assumed to be determined by diffusion (diffusion coefficient $D = D_+ + D_-$) and drift in the combined field $E_0 + E_C$ (where E_C is the coulombic field due to two unlike charges having a mobility $\mu = \mu_+ + \mu_-$). To solve this problem Onsager used Smoluchowsky's equation and expressed its stationary solution as a power series.

The problem was subsequently discussed many times[6,7,24-46], and for an isotropic initial distribution of thermalised electrons the probability of dissociation of a bound pair in the weak field approximation was shown to be

$$\Phi(r_0, E_0) = \Phi(r_0)\left[1 + \frac{e^3}{8\pi\varepsilon\varepsilon_0 k^2 T^2} E_0\right], \qquad (1)$$

where e is the electronic charge, k is Boltzmann's constant, T is the absolute temperature (K), and $\Phi(r_0) = \exp(-r_C/r_0)$, where $r_C = e^2/4\pi\varepsilon\varepsilon_0 kT$ is the Onsager radius. The coefficient $\beta_0 = e^3/8\pi\varepsilon\varepsilon_0 k^2 T^2$ has been called the Onsager field constant. In the presence of strong electric fields this approximation is not valid, and $\Phi(r_0, E_0) \to 1$ when $E_0 \to \infty$.

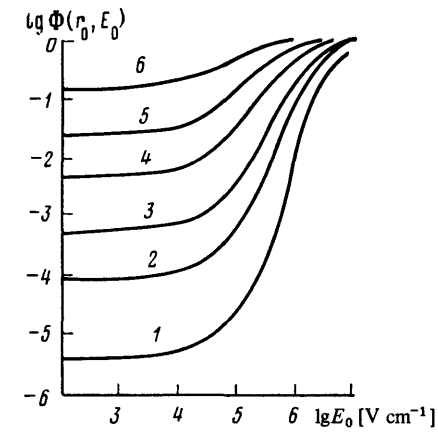

Figure 1. Dissociation probability Φ of a bound pair against E_0 for different initial distances: *1*) 1.5, *2*) 2.0, *3*) 2.5, *4*) 3.5, *5*) 5, *6*) 10 nm; $\varepsilon = 3.0$, $T = 300$ K[29].

For the typical values $\varepsilon = 3.0$ and $T = 300$ K the constants r_C and β_0 become 18.5 nm and 3.6×10^{-5} cm V^{-1} respectively. Numerical calculations of $\Phi(r_0, E_0)$ (Fig. 1) show a strong field and temperature dependence for small values of r_0 ($\lesssim 5.0$ nm).

If $g(r_0)$ is the probability density of the distribution of the bound pair with respect to initial separation ($\int_0^\infty g(r_0) 4\pi r_0^2 dr_0 = 1$) and G_0 is the initial ionisation yield it follows that the yield of free charges $G_{fi}(E_0)$ in the electric field E_0 can be expressed as

$$G_{fi}(E_0) = G_0 \int_0^\infty g(r_0)\,\Phi(r_0, E_0)\, 4\pi r_0^2 dr_0. \qquad (2)$$

Noting that $\Phi(r_0, E_0)$ in the weak field region is a linear function of E_0, and β_0 is independent of r_0, we can easily show that

$$G_{fi}(E_0) = G_{fi}(0)\,[1 + \beta_0 E_0], \qquad (3)$$

where $G_{fi}(0)$ is the yield of free charges in the absence of the electric field. Thus the dependence of G_{fi} on E_0 in the weak field region is linear, and therefore both $G_{fi}(0)$ and β_0 can be easily determined. This conclusion from the Onsager theory has been widely used as a test of the theory in concrete cases[47-49].

The above approach has proved very fruitful in explaining various phenomena observed in liquid-phase radiolysis, quantitative as well as qualitative agreement with experiment being obtained in many cases[6,7,50-53]. In the absence of a strict theory of the retardation and thermalisation of electrons in a condensed phase[54-62] the experimental dependence of the yield of free charges on the temperature T or on the field E_0 is often used to determine the form of the distribution function $g(r_0)$ (usually in the one-parameter approximation). The following distribution functions are most commonly used[30]:

1) the δ-distribution

$$g(r_0) = \delta(r_0 - R)/4\pi r_0^2;$$

2) the undistorted Gaussian distribution (UG)

$$g(r_0) = \pi^{-3/2} R^{-3} \cdot \exp(-r_0^2/R^2);$$

3) the distorted Gaussian distribution (DG)

$$g(r_0) = (4\pi^{3/2}\sigma R^2)^{-1} \cdot \exp(-(r_0 - R)^2/\sigma^2),$$

with the usual assumption that $\sigma = 0.25\ R$, and R is the mean thermalisation length of the electron;

4) the exponential distribution (ED)

$$g(r_0) = (4\pi R r_0^2)^{-1} \cdot \exp(-r_0/R).$$

Table 1. Values of the parameter R for different $g(r_0)$ distributions and other characteristics of organic liquids at ~296 K.[6,30]

* By applying a correction to Onsager's theory for the dependence of the mobility μ on the electric field E_0 (assuming $E_0 \geq E_{cr}$) Mozumder obtained[63] an R value of 7.7 nm for neopentane. This result is obviously controversial.
** At 219 K.

Numerical values of the parameters used to determine the yield of charges in various organic liquids at room temperature ($T = 296$ K) are given in Table 1. We note that the parameter R is much higher in neopentane than in n-hexane. Direct measurements[59] of the relaxation length (i.e. the distance over which the flow of photo-generated electrons decays by a factor of e) in films of these two compounds at low temperatures gave l_{rel} values of 3.0 and 15.7 nm respectively. Thus we can assume that the mobility of electrons is much greater in neopentane than in n-hexane.

In addition to describing accurately the stationary radiolysis ($t \to \infty$) results, Onsager's theory correctly interprets the kinetics of the process, and also the concentration dependence of the electron trapping processes[6,7]. Mozumder[64], using the prescribed diffusion method, obtained the following expression for the probability $F(t)$ which determines the relative number of bound pairs whose lifetime (before recombination) is $\geq t$:

$$F(t) = \exp\left\{-\frac{r_c}{r_0}\left[1 - \operatorname{erf}\frac{r_0}{(4Dt)^{1/2}}\right]\right\}. \quad (4)$$

As expected, $F(0) = 1$ and $F(\infty) = \exp(-r_c/r_0) = \Phi(r_0)$. Other approximate methods of calculating $F(t)$ are known[6,37,38]. A very simple method of estimating the recombination time of bound charges in a pair is an extension of the Stokes–Einstein relation to the case of the coulombic field of an ion, assuming that the terminal velocity is reached instantaneously[65]. This method leads to the "r_0^3" formula

$$t_{rec} = \frac{4\pi}{3}\frac{\varepsilon\varepsilon_0 r_0^3}{e\mu}.$$

For the distance $r_0 = r_c$ we obtain $t_{rec}^{max} = r_c^2/3D$.

A numerical solution of the non-stationary Smoluchowski equation is given in Ref.66 for a model dielectric having the parameters $D = 9.27 \times 10^{-3}$ cm² s⁻¹, $\varepsilon = 2.023$, $r_c = 27.9$ nm, and $r_0 = 8.0$ nm. It is shown† that $t_{1/2} \cong 10^{-11}$ s irrespective of E_0 (as long as $E_0 \leq 10^5$ V cm⁻¹). The field E_0 begins to influence the recombination kinetics of the charges when $t \geq 2 \times 10^{-11}$ s.

The Laplace transform has been used[67,68] to establish the relationship between the concentration dependence of the trapping probability $F(c)$ and the probability density of the lifetime of the bound pairs $dF(t)/dt$, and experimental data on electron trapping in non-polar liquids have been fully analysed[69,70]. Since

$$1 - f(c) = \int_0^\infty \frac{dF(t)}{dt}\exp(-kct)\,dt \quad (5)$$

(where k is the rate constant of the reaction between an electron and the acceptor, and c is the concentration of the acceptor, $f(c) = (\alpha c)^{1/2}/[1 + (\alpha c)^{1/2}]$, and α is a constant), we can apply the inverse Laplace transform and obtain

$$dF(t)/dt = \lambda[(\pi\lambda t)^{-1/2} - \exp(\lambda t)\operatorname{erfc}(\lambda t)^{1/2}]. \quad (6)$$

In this expression $\lambda = k/\alpha$, and $\operatorname{erfc}(x) = 1 - \operatorname{erf}(x)$. Hence we arrive at

$$F(t) = \exp(\lambda t)\operatorname{erfc}(\lambda t)^{1/2},$$
$$F(t) \approx (\pi\lambda t)^{-1/2} \quad \text{for} \quad \lambda t \geq 100. \quad (7)$$

Thus the initial decrease in the number of bound pairs in a non-polar liquid is very fast (with a half-life $t_{1/2}$ defined by the expression $\lambda t_{1/2} \cong 0.59$), but this is followed by a slower decay. According to Zador and coworkers[71] $t_{1/2} = 0.6 \times 10^{-12}$ s for cyclohexane at room temperature ($\lambda = 0.9 \times 10^{12}$ s⁻¹), but a later paper from the same laboratory[72] gives $t_{1/2} \cong 1.3 \times 10^{-12}$ s. At time $t = 10^{-8}$ s only 0.6% of the original number of bound pairs is still present ($G_0 = 4.0$), which is less by a factor of ~5 than the number of free charges in the liquid ($G_{fi}(0) \cong 0.12$).

In the general case we have, for non-polar liquids,

$$G(t) = G_{fi}(0) + [G_0 - G_{fi}(0)] \cdot F(t). \quad (8)$$

Several workers[73–75] have used the r_0^3 formula to calculate the distribution function $F(t)$ in liquid hydrocarbons, as well as the exponential form of the probability density distribution $g(r_0)$[73] or a similar expression[74]. It was shown that $t_{1/2}$ for n-hexane at room temperature is 3.5×10^{-12} s with $G_0 = 4.0$. On lowering the temperature $t_{1/2}$ is found to increase, reaching 0.13×10^{-9} s at −80 °C. The authors[74] point out that the expected diffusion-determined relationship $F(t) \propto t^{-1/2}$ at $t \to \infty$ is not obeyed; this is a consequence of using the r_0^3 formula, which ignores diffusion. However, at large values of r_0 (approaching r_c) the importance of diffusion increases, while the role of drift in the coulombic field of the ion becomes less important.

An analysis[76] of the validity of the Laplace transform for real liquids, in which the mobility is determined by trapping processes, suggests that Eqn.(5) is not applicable in general. However, the asymptotic behaviour of $F(t)$ at $t \to \infty$ or of $f(c)$ at $c \to 0$ is unchanged. We should also mention a series of papers[77–79] in which Onsager's theory is used to calculate the field dependence of the quantum yield of hot electrons injected into a dielectric by a metallic electrode. In the one-dimensional problem (but not in the three-dimensional problem) it is found that $G_{fi}(0) = 0$.

† $t_{1/2}$ is the time in which $F(t)$ decreases by a factor of 2 from 1.0 to 0.5.

The Poole–Frenkel' theory

The classical Poole–Frenkel' effect refers to the non-linear increase in electrical conductivity in strong electric fields (in the dark). One possible explanation of this effect relies on the lowering of the energy barrier opposing the ionisation of the neutral donor in the direction of the applied field E_0 by an amount $\Delta W = \beta E_0^{1/2}$, where $\beta = (e^3/\pi\varepsilon\varepsilon_0)^{1/2}$ is the Poole–Frenkel' constant. In this case the probability of thermal ionisation of the neutral donor in the field E_0 increases by a factor of $\exp(\beta E_0^{1/2}/kT)$. This simple model has been used to explain the non-linear behaviour of the photo-current in strong fields[80,81]. By allowing for the recombination of the pairs Tabak and Warter[81] obtained an approximate expression for the quantum yield of free charges:

$$\eta = \left[1 + (\nu t_{rec})^{-1} \exp\left(\frac{E_a - \beta E_0^{1/2}}{kT}\right)\right]^{-1}, \quad (9)$$

where ν is the frequency factor, E_a is the activation energy (height of the potential barrier), and t_{rec} is the mean recombination time.

The model has been developed further[82,83] (see also Refs. 31, 47, 84, 85). The thermalisation length of the electron has been calculated by the diffusion approximation (equating the rate of energy loss to $h\nu_p^2$, where ν_p is the phonon frequency and h is Planck's constant), so that $r_0 = (Dt)^{1/2}$. Allowing for the energy of the coulombic and of the externally applied field changes the form of Eqn.(9), since

$$E_a = e^2/4\pi\varepsilon\varepsilon_0 r_0 + eE_0 r_0;$$

and r_0 is given by the expression

$$\frac{h\nu_p^2}{D} r_0^2 = (\hbar\omega - E_g) + \frac{e^2}{4\pi\,\varepsilon\varepsilon_0 r_0} + eE_0 r_0,$$

where E_g is the width of the forbidden gap of the dielectric. With these corrections the expression for η gives a qualitatively correct description of the dependence of the photo-ionisation quantum yield on the photon energy ($\hbar\omega$) and on the strength of the externally applied field. However, a quantitative comparison of theory and experiment is complicated by the large number of undetermined parameters (t_{rec}, ν_p, ν) which cannot be obtained directly from experimental results.

In some recent publications the descriptions of the photolysis of various substances by the Onsager and the Poole–Frenkel' theory are compared[31–33,86–97]. In every case the Onsager theory is preferred. However, it has been pointed out[91,95] that both the Onsager and the Poole–Frenkel' mechanism may be operative in most cases. Depending on the value of r_0, and hence of the mean free path λ, either of these mechanisms could be predominant. When r_0 is much smaller than λ (and the diffusion of the electron within the Onsager sphere plays the major role) the yield of free charges from the bound pairs is directly described (for both radiolysis and photolysis) by the Onsager theory. On the other hand if r_0 is large (and of the same order as r_c) the decrease in height of the coulombic potential barrier under the influence of the external field (Poole–Frenkel' mechanism) becomes predominant. Furthermore, in the case of photo-excitation we should allow for surface recombination[89,92,93], which can cause large discrepancies in the yield of free charges at low field strengths from the values predicted by Onsager's theory[89].

2. Tracks and Multiply Charged Spherical Formations

Classical calculations of the yield of charges in the volume from tracks and from multiply charged spherical formations have been published by Jaffe and Lea[98–100] (see also the review articles in Refs.6, 7, and 19). In these calculations ions of opposite signs are assumed to be distributed in equal concentrations according to a Gaussian law with respect to the axis of the track or to the centre of the agglomerate (depending on the type of geometry). It is also assumed that the distribution curve remains Gaussian, but the width of the distribution changes with time as $r(t) = (b^2 + 4Dt)^{1/2}$, where b is the initial radius of the track (at the instant of formation). With these assumptions the authors calculate the decrease in the total number of charges as a function of time, which in the limit of $t \to \infty$ gives the relative number of charges reaching the volume of the sample. No allowance is made for polarisation by the external electric field. When the track is perpendicular ($\perp$) to the field E_0, and $t \to \infty$, the yield of charges from the tracks into the volume is given by

$$f_{tr}^{\perp} = \left[1 + \frac{k_r N_0}{8\pi D} (\pi/z)^{1/2} S(z)\right]^{-1}, \quad (10)$$

where

$$z = b^2\mu^2 E_0^2/2D^2, \text{ and } S(z) = \frac{1}{\pi^{-1/2}} \int_0^{\infty} \frac{\exp(-s)\,ds}{[s(1 + s/z)]^{1/2}};$$

$k_r = (e/\varepsilon\varepsilon_0)\mu$ is the recombination coefficient, and N_0 is the initial linear ionisation density in the case of the track.

Values of the function $(\pi/z)^{1/2}S(z)$ are given in graphical form in Refs.101–103. In the case of a short cylindrical track, with $N_0 = 5 \times 10^7$ cm^{-1} ($b = 10^{-6}$ cm) and $\mu = 10^{-5}$ cm^2 V^{-1} s^{-1} (say), we find that for E_0 values of 0, 10^2, 10^3, 10^4, 10^5, and 10^6 V cm^{-1} the $f_{tr}^{\perp}$ values are 0, 10^{-3}, 1.6×10^{-3}, 3.7×10^{-3}, 2.1×10^{-2}, and 19.4×10^{-2} respectively. For $r_0 =$ 5.0 nm we have $\Phi(r_0, E_0) \geq f_{tr}^{\perp}(E_0)$, the difference being largest in weak electric fields# ($E_0 \leq 10^4$ V cm^{-1}).

By using the prescribed diffusion method Mozumder[105,106] showed that Eqn.(10) is valid even on the assumption that the positive ions are distributed only along the axis of the track. He also showed that the rates of recombination of the charges in short tracks and spurs containing 10 pairs of charges are approximately equal, and that in a medium in which the diffusion coefficient of trapped electrons is $\sim 2 \times 10^{-3}$ cm^2 s^{-1} (i.e. $\mu_{dr} = 10^{-1}$ cm^2 V^{-1} s^{-1} at 300 K) the half-life $t_{1/2}$ is $\sim 3 \times 10^{-12}$ s (assuming an initial charge density in the tracks and spurs of $\sim 5 \times 10^{18}$ cm^{-3}). The yield of charges into the volume after irradiation with α-particles having energies of several MeV has been shown[107] to be ~ 10 times lower than after irradiation with fast electrons or γ-rays: this is because the N_0 parameter for δ-electrons of 1.0–5.0 keV energy is ~ 10 times lower than for the tracks of α-particles[19].

III. PROCESSES INVOLVING THE MOTION OF CHARGES UNDER THE INFLUENCE OF AN EXTERNAL(OR INTERNAL) ELECTRIC FIELD

As stated above, ionisation during radiolysis or photolysis is accompanied by the appearance of non-equilibrium (excess) charges whose motion in an external field is responsible for the induced conductivity. Extensive experimental investigations have shown that, in addition to the normal charge

The estimated values of $f_{tr}^{\perp}$ are probably much too high because no allowance was made for the polarisation of the track[104].

transfer and recombination processes, charge trapping can occur on relatively deep traps of physical or chemical origin. The trapped (stabilised) charges can persist for very long times, especially at low temperatures, thus giving rise to a whole series of new properties in the irradiated material (photo-stimulated conduction (PSC) in the visible and i.r. regions, thermally stimulated currents (TSC) when the sample is allowed to warm up, a sharp increase in recombination luminescence under i.r. illumination or on applying a strong electric field—the electro-photoluminescence phenomenon or Gudden–Pohl effect). The intensity of all these processes decreases with time to the initial values, characteristic of the non-irradiated materials. Therefore re-irradiation of the material is required each time one of these effects is to be observed.

1. Radiation-Induced Electrical Conductance

Measurements of electrical conductivity are one of the most direct methods of observing the charged particles during the early (physicochemical) stage of the radiolysis[108,109] §. In principle the method allows the properties of a quasi-free ("dry") electron to be studied before its solvation or capture by the medium. However, at the moment the time resolution of this method is greatly inferior to that of the optical method of detecting short-lived particles (0.2×10^{-9} s and 10^{-12} s respectively)[110–112].

Measurements of the radiation-induced electrical conductivity of polymeric dielectrics, using both pulsed and continuous radiation, are reported in Refs. 19, 102, and 113.

According to modern ideas, the instantaneous component (rise and fall time ≤ 1 ns) of the radiation pulse electrical conductance (RPEC) in disordered solid systems is associated with the quasi-free state of the electron, characterised by a microscopic mobility μ_0 (1–100 $cm^2\ V^{-1}\ s^{-1}$). This interpretation is confirmed by the observation that the proportionality coefficient K_{inst} between the volume conductivity (γ_{inst}) and the dose of radiation absorbed (P) is independent of the intensity of the applied electrical field E_0 ($\leq 5 \times 10^5$ V cm^{-1}), and is only weakly dependent on temperature[19,102].

Table 2. Values of K_{inst} ($ohm^{-1}\ cm^{-1}\ Rad^{-1}\ s$) for some polymeric materials[114–120].

Material	$10^{19}K_{inst}$	ε (Ref. 121)
Poly(tetrafluoroethylene) (PTFE)	31	2.0
Low-pressure polyethylene (LPPE)	11	2.2–2.4
High-pressure polyethylene (HPPE)	3.0	
Polypropylene	3.0	2.15–2.35
Poly(ethylene terephthalate) (PETP)	2.0	3.10–3.40
Polystyrene	1.4	2.6
PM-1 polyimide	1.2	4.0
Crystalline poly(chlorotrifluoroethylene) (F-3)	0.4	3.0
Poly(vinylidene fluoride) (F-3)	0.20	3.0
Poly(vinylidene fluoride) (F-2)	0.18	9.5
Poly(vinylidene chloride)	0.20	2.85
Poly(vinyl chloride) (PVC)	0.12	3.05
Poly(methyl methacrylate) (PMMA)	0.16	3.20

The K_{inst} values for a number of polymeric materials at room temperature are given in Table 2. We note that the K_{inst} values for non-polar polymers are higher than those for polar polymers (for example, two orders of magnitude higher for PTFE than for PMMA). Furthermore, an increase in the degree of crystallinity of a given material produces a slight increase (approximately 2-fold) in K_{inst}.[114,120]

The parameter K_{inst} is defined by the equation

$$G\mu_0\tau_s(cm^2\ V^{-1}) = \frac{10^7}{\rho}K_{inst}(ohm^{-1}\ cm^{-1}\ Rad^{-1}\ s), \qquad (11)$$

where τ_s is the life time of the quasi-free electron, and ρ is the density of the dielectric (g cm^{-3}). Taking $G = 1.0$ (for $E_0 = 5 \times 10^5$ V cm^{-1}) and $\mu_0 = 10\ cm^2\ V^{-1}\ s^{-1}$ we find that $\tau_s = 2 \times 10^{-13}$ s for PTFE (and an even smaller value for PMMA). This estimate confirms that the lifetime of the quasi-free charge carriers is comparable with the thermalisation time (10^{-13}–10^{-14} s). It has even been suggested[120,122–127] that the life time could be shorter than the thermalisation time.

The experimentally observed lack of dependence of K_{inst} on the dose per pulse (in the range 1–10^6 Rad)[128] suggests a very high concentration of electron (or hole) traps (10^{18}–10^{21} cm^{-3}). Somewhat different results were obtained by Hughes[129–132] after a study of the RPEC of amorphous (fused) SiO_2 (quartz). By using very pure amorphous SiO_2 he was able to determine μ_0, τ_s, and G_0 independently (20 $cm^2\ V^{-1}\ s^{-1}$, 14 ns, and 3.6 respectively). The dependence of G on E_0 predicted by Onsager's theory was observed for $r_0 = 10.0$ nm.

In contrast to pulse irradiation, for which K_{inst} is independent of E_0 ($< 5 \times 10^5$ V cm^{-1})[117–119], in the case of continuous irradiation the electrical conductivity increases with E_0[133] as predicted by the Onsager theory.

Systematic studies of the relaxation of RPEC in polymers and in ceramic materials[116,134,135] have confirmed previous reports of the independence of the kinetics on the dose of radiation. Thus, changes in the dose per pulse of more than three orders of magnitude had no effect on $\tau_{1/2}$ for PTFE and the UF-46 ceramic[134,135]. Similarly, in the case of polystyrene an increase in the dose from 1 to 4×10^6 Rad (Refs. 136 and 137 respectively) caused an increase in $\tau_{1/2}$ from 3 to 8 μs, probably due to the change in pulse length from 0.1 to 4.0 μs.

These results suggest that the recombination of charge carriers is inhomogeneous at short irradiation times. This conclusion is confirmed by the kinetics of photocurrent decay in hydrocarbons previously subjected to radiolysis at 77 K.[138]

Explanations of two types have been proposed for these features of the process (the dose-independent, hyperbolic decay of the RPEC, and the lack of dependence of K_{inst} on E_0). In the first approach the inhomogeneity of the recombination kinetics is ascribed to the neutralisation of charged particles in isolated bound pairs, and the induced electrical conductivity to the motion of electrons under the influence of the external field and of the coulombic field of the parent ion (E_C).[138–146] This model also explains the decay kinetics of the i.r.-stimulated current in frozen and irradiated hydrocarbons. The conditions for the validity of this model are defined by the inequalities $\mu_0\tau_s \leq 10^{-10}\ cm^2\ V^{-1}$ and $G_g \geq G_{fl}$ (where G_g is the yield of bound charges).

Of course, electric currents involving these non-dissociated pairs are self-polarising. Unlike the classical types of dielectric polarisation (electronic, ionic, and Maxwell–Wagner polarisation) this polarisation should produce (after the irradiation) negative currents in spite of the presence of an external field[127]. However, the present writers doubt whether negative currents can ever be observed in real systems because of the slowness of the pair recombination process.

§ See also the recently published monograph: A.K.Pikaev, S.A.Kabakchi, I.E.Makarov, and B.G.Ershov, "Impul'snyi Radioliz i Ego Primenenie" (Pulse Radiolysis and Its Applications), Atomizdat, Moscow, 1980, p. 279.

The second approach[104,116,134,135] relates the inhomogeneity of the RPEC decay kinetics to the recombination of charge carriers in track-like formations (mainly, in short cylindrical tracks), and it assumes that the contribution from electrons in bound pairs to the electric current is much smaller than that of free electrons, so that the recombination kinetics of charges in the pairs are not reflected in the decay of the radiation-induced current. The yield of charges able to contribute to the electric current is determined not only by the yield of free charges from bound pairs as a result of thermal dissociation and separation in an electric field (as in Onsager's theory), but also by the total yield of charges in the short tracks. The ratio of the yields of triplets and singlets in the irradiation of tetracene by α-particles was found to be 3 : 1, which is characteristic of the recombination of random partners[147,148]. This means that no correlation exists within the tracks between the electron and the parent ion, i.e. the track can be treated as a dense solid-state plasma region. The polarisation of the track in an electric field by the motion of its constituent charges is of the classical Maxwell–Wagner type, and should not cause the appearance of negative currents after completion of the irradiation in the presence of the electric field E_0.

However, a consequence of this model is that in strong electric fields ($\sim 10^6$ V cm^{-1}) the yield of free charges from isolated pairs may be greater than the yield of charges in the short cylindrical tracks. Thus we would expect an increase in K_{inst} in very strong fields[117]. Furthermore, the model can be used to calculate (using experimental data on the delayed component of the RPEC) the initial density of charges in the short cylindrical track and μ_{dr}. In the case of polyimides these two parameters were found[118] to be 4.5×10^{18} cm^{-3} and 3.6×10^{-7} cm^2 V^{-1} s^{-1} (for $E_0 = 10^6$ V cm^{-1}), in good agreement with published data[149,150].

2. Recombination Luminescence

Recombination luminescence (RL) is one of the most fully investigated effects accompanying the radiolysis or photolysis of solid organic systems. A detailed discussion of the results obtained up to 1970 can be found in a number of monographs and review[1-3,151,152]; more recent results have also been included in review articles[153-158].

The emission of light has been shown to be a direct consequence of the evolution of energy attending the recombination of opposite charges (whether free, or bound), the intensity of the luminescence being proportional to the rate of disappearance of charges through recombination[159-161]. (Some anomalies in this proportionality are considered in Ref.156.) Although the quantum yield of RL is usually small, the method is extremely sensitive ($\sim 10^7$ quanta, as compared to 10^{11}–10^{13} spins in the ESR method and 10^{15}–10^{16} molecules in the absorption spectroscopy method), and therefore it has been widely used to study charges stabilised in a condensed phase. The following are the main areas of research in which the method has been most successfully applied: 1) studies of charge recombination mechanisms, and estimates of the relative contributions of diffusional and tunnelling transport to the process; 2) influence of the nature of the medium on the ionisation potential of an impurity; 3) studies of the mechanism of elementary reactions leading to the emission of light quanta; 4) studies of the effect of various external factors (temperature, electric field, illumination) on the recombination process.

The diffusion approach to the calculation of the decay kinetics of isothermal recombination luminescence (IRL) during photo-ionisation of aromatic amines in polar solvents (water, methanol, glycerol, or their mixtures) at 77 K was used in Ref.162 without allowance for the effect of the coulombic field of the parent ion on the diffusional motion of the electron. By selecting a suitable initial distribution of the electrons in pairs with respect to the distance (r_0) from their corresponding ion a relationship similar to that observed experimentally was calculated between the IRL intensity (L_{IRL}) and the time elapsed after the end of the u.v. irradiation:

$$L_{IRL} = Kt^{-m}, \tag{12}$$

where K and m are constants, with $m \cong 1.0$.

Subsequently the diffusion model (modified by the inclusion of a term for the coulombic interaction between charged particles) was used successfully to explain a wide range of phenomena.

Abell and Mozumder[163] concluded from an exact solution of the Smoluchowski equation that Eqn.(12) can be applied only over a narrow range of t values (no more than 1.5–2 orders of magnitude), whatever the initial distribution $g(r_0)$ of the electrons in the pairs: this conclusion differs from that of Debye and Edwards[162], who did not impose any limits on their range of t. The expression for L_{IRL} becomes

$$L_{IRL} \propto t^{-3/2}, \tag{13}$$

which follows directly from Eqn.(7). Under these conditions the diffusional recombination process should be activation-limited, and therefore strongly temperature-dependent. However, neither of these predictions of the diffusion theory is fulfilled in practice. The IRL decay kinetics are independent of temperature over times between 10^{-6} and 10^3 s[164,165]: the decay curve is accurately described by the expression

$$L_{IRL}(0)/L_{IRL}(t) = 1 + K_1(t-t_0). \tag{14}$$

Similar results have been obtained by other workers[166-181]. The hypothesis that charge recombination (especially at low temperatures) is the result of a tunnelling transition of the electron from the anion to the cation has been put forward increasingly in recent years. It is suggested[182] that the tunnel effect can extend over relatively large distances (up to 50 Å), by analogy with the recombination of an F-centre electron in alkali halide crystals[183]. Approximate theories of this phenomenon have been proposed by many workers[184-206].

It has been shown[207-209] that the presence of a slight activation energy ($E_a \cong 0.02$ eV) is not inconsistent with a predominantly tunnelling transfer mechanism, since the many possible equilibrium configurations of a trapped electron in frozen organic systems probably have a finite spread in energy.

By assuming an exponential distribution function $g(r_0)$ (see Section I) the following expression for L_{IRL} has been obtained[187,189]:

$$L_{IRL} = \alpha\nu \frac{a}{b} \Gamma\left(1 + \frac{a}{b}\right) N_0 (\nu t)^{-(1+a/b)}, \quad \nu t \gg 1, \tag{15}$$

where a is the damping parameter of the wave function, b is the parameter of the distribution function $g(r_0)$, ν is the frequency factor, N_0 is the initial concentration of isolated pairs, α is a constant, and $\Gamma(x)$ is the gamma-function. Since $a \ll b$ Eqn.(15) reduces to (12) for $m = 1.02$. The frequency factor is very large, and therefore the condition $\nu t \gg 1$ is always satisfied. The time dependence of $g(r_0, t)$ is illustrated in Fig.2.

It is thought[184] that the tunnel mechanism of recombination can explain the very low limiting concentrations of ions which are stabilised during low-temperature radiolysis (10^{17}–10^{18} cm^{-3}, which is only a small fraction of the total number of traps[1,143]). The limiting concentrations of free radicals for

similar doses of radiation are substantially higher (10^{19}–10^{20} cm^{-3}).

The tunnelling hypothesis has allowed satisfactory explanations to be proposed for a number of experimentally observed features of electron trapping in frozen matrices which could not be explained by the classical diffusion theory[171,186,195,200,202,210–213].

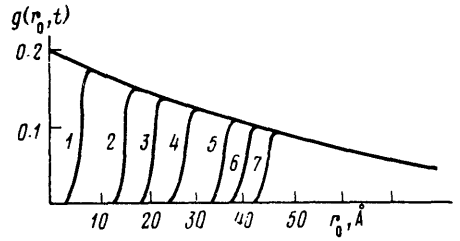

Figure 2. Plots of $g(r_0,t)$ for different times (*1*) 1 ps, *2*) 1 ns, *3*) 1 μs, *4*) 1 ms, *5*) 1 s, *6*) 1 min, *7*) 1 h) in the tunnelling mechanism for the recombination of bound pairs during low-temperature radiolysis or photolysis; $\nu = 10^{15}$ s^{-1}, $a = 1$ Å, $b = 50$ Å.[189]

It was established that the decay kinetics of L_{IRL} are relatively insensitive to the type of radiation (photolysis, or radiolysis)[214,215]. In photolysis studies a more uniform ionisation density over the thickness of the initial matrix is often achieved by using additives[152,156,216] requiring two quanta for ionisation of the molecule. The commonest of these additives are *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) and tryptophan. The physical characteristics of the TMPD–methylpentane (3-MP) solid solutions which have been used[217–222] at 77 K are summarised below:

Parameter	Value
Concentration range of TMPD in 3-MP	(1.0–3.0) × 10^{-3} M; (0.6–2.0) × 10^{18} cm^{-3}
Density	0.88 g cm^{-3}
Viscosity	10^{12} Pa s
Glass formation temperature	77 K
Static dielectric constant	2.3
Onsager radius r_c	95 nm
Field constant β_0	5.7 × 10^{-4} cm V^{-1}
Red absorption edge TMPD	360 nm (3.44 eV)
Ionisation potential of TMPD in the gas phase	6.7 eV
Ionisation potential of TMPD in the solid solution	5.9 eV
Lifetime of the triplet state	2.3 ± 0.3 s

As we have already pointed out, the photo-ionisation of the TMPD molecules takes place in two steps: initially the molecule is excited into a singlet state ($\lambda \leq 360$ nm), from which it passes into the triplet state by intersystem crossing, and the absorption of a second light quantum ($\lambda \leq 400$ nm) in the triplet state causes ionisation of the molecule. Two-quantum ionisation of commercial polyethylene under u.v. irradiation has been reported also in Ref. 223.

Characteristic decay curves of L_{IRL} of a TMPD–3-MP solid solution after u.v. irradiation ($\lambda = 313$ nm) for different times (τ_1, $2\tau_1$, $20\tau_1$) are shown in Fig. 3. On the linear portion of the plot of L_{IRL} against exposure time τ the slope is proportional to the square of the intensity of u.v. radiation, as expected for a two-quantum ionisation process. For $\tau \leq 2\tau_1$ (≤ 30 s) the charges are generated mainly as bound pairs, and the yield of free charges is very small. In this range of exposures the TMPD–3-MP solution displays electrophotoluminescence (EPL)[224,225]: the application of a strong electric field ($> 2.2 \times 10^5$ V cm^{-1}) produces a flash of recombination radiation, and a second application of a field of equal strength but opposite polarity produces another flash. Further observation of the effect is possible only if the sample is irradiated again. The amplitude of the RPL flash is exponentially dependent on the strength of the electric field:

$$L_{EPL}(0) = A \exp(\alpha E_0/kT), \qquad (16)$$

where $\alpha \approx 0.9$–1.7 Å. (An explanation of the EPL phenomenon with allowance for electron tunnelling is given in Refs. 196 and 226–230.)

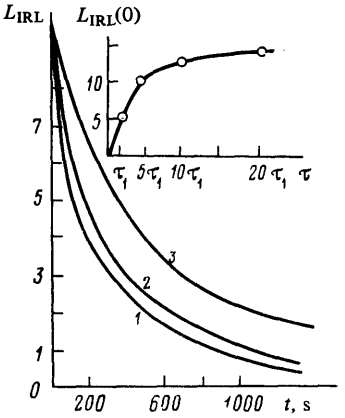

Figure 3. Intensity of isothermal recombination luminescence (L_{IRL}) against time; $\tau_1 = 15$ s, $T = 77$ K[152]; $\tau = \tau_1$ (*1*), $\tau = 2\tau_1$ (*2*), and $\tau = 20\tau_1$ (*3*).

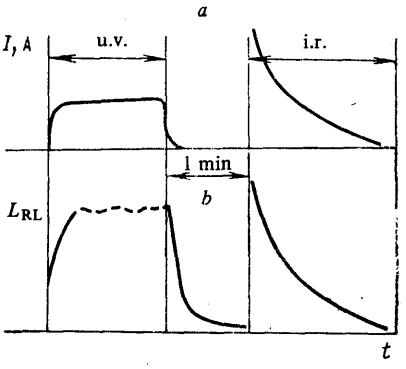

Figure 4. Comparison of the kinetics of photo-stimulated conduction (*a*) and recombination luminescence (*b*) in TMPD–3-MP at 77 K; $\lambda_{u.v.} = 313$ nm, $\lambda_{i.r.} = 694$ nm.[234]

By using a distorted Gaussian distribution centred on $\bar{r}_0 = 32$ Å, with a dispersion parameter of 6.2 Å and a life time for a trapped electron of 10^3 s, the kinetics of the decay in frozen TMPD–3-MP solutions have been described quantitatively[231–233] to an accuracy of 3%. It has been suggested that the lifetime of the trapped electrons decreases exponentially as the strength of the external field increases, thus increasing the probability of a tunnelling transition to the parent ion[196].

Experimental results reported in Refs. 221 and 234 (Fig. 4) give additional information on the possible contribution from electrons in bound pairs to the observed electric current. It has been established that during i.r. irradiation ($\lambda = 694$ nm) only ~50% of the bound pairs initially formed by u.v. irradiation are able to recombine (higher-energy radiation is needed to cause annealing of the remaining pairs). Since at 77 K the number of bound charges is much greater than the number of free charges, the photo-current produced by u.v. irradiation should be due to the polarisation of the bound pairs in the external electric field E_0 ($\ll E_C$).[139] However, in that case the net charge flowing in the external circuit as a result of the current stimulated by i.r. radiation should be negative, since the current is produced by the depolarisation of the bound pairs and is equal to one-half of the charge flowing through the external circuit in the case of u.v. illumination. Furthermore, the kinetics of the negative current (Fig. 4a) should be similar to the kinetics of the photo-stimulated IRL (Fig. 4b), as is found experimentally. However, the sign of the photocurrent observed in practice is the opposite to that predicted by the theory. It is also found that the recombination time of a bound isolated pair after the trapped electron has been set free by i.r. light is not greater than ~1 ns.[235]

On the assumption that only free charges can contribute to the photocurrent under u.v. irradiation[152,234], and noting that the lifetime of these charges before capture by a trap is less than 1 μs,[221] we can resolve the above inconsistency. By the same argument we can explain also the experimental finding[140] that i.r. irradiation of 3-MP previously exposed to low-temperature (77 K) radiolysis in the presence of an external electric field E_0 causes a negative current to flow when $E_0 = 0$. Thus, the appearance of a negative current can be ascribed to depolarisation of the short tracks (see Section II and Ref. 127).

As we have already pointed out, under u.v. irradiation the formation of free charges giving rise to the observed photocurrent is due to the ionisation (with a very low probability) of excited triplet molecules of TMPD, and in the case of i.r. irradiation it is due to optical ionisation of stabilised bound pairs (again, with a very low probability). In order to describe the experimental results quantitatively as well as qualitatively (Fig. 4) we have to postulate a relatively high drift mobility for the free electron formed as a result of u.v. or i.r. irradiation (a low-energy electron with energy ≤1 eV).

It is found[236] that the type of radiation used (light, or X-rays) has no effect on the decay kinetics of the recombination-induced phosphorescence of tryptophan in a frozen mixture of water and ethylene glycol, or on the thermo-luminescence curve. Similar results have been reported for less polar matrices[214,215,237]. However, there are regions of high local concentration of charge[236,239] produced by electron irradiation of the material: in strongly polar matrices these regions begin to disappear[240] only at times $>10^{-9}$ s. The need to allow for these effects in studies of the kinetics of IRL is stressed.

Recently published work[241] shows that the recombination probability of charges produced by u.v. irradiation is higher (by approximately 2) than when γ-radiation is used, at least in the case of a frozen solution of tryptophan in a mixture of ethylene glycol and water. It is also reported that the type of radiation (α or β radiation) can affect the decay kinetics of L_{IRL} in methylcyclohexane at 77 K, so that Eqn. (14) does not apply[242] at times between 1 and 500 ns (see also Refs. 243–245).

Neither the type of emitting centre nor the nature of the luminescence is yet fully understood. It is usually assumed that the recombination (followed by light emission) involves the scheme

$$A^+ + B^- \rightarrow A^* + B,$$
$$A^* \rightarrow A + h\nu, \qquad (17)$$

where B^- could be a trapped electron or an anion, and A is a molecule of solvent, solute, or radiolysis product. In some polymeric materials (polyethylene, polystyrene, PTFE, polypropylene) the luminescence centres can be carbonyl groups attached to the ends of molecular main chains or side chains[167]. However, the energy set free by the recombination process can be transferred to the impurity acting as a recombination centre[219,246]. It has been suggested[166,201] that radiative recombination by the scheme

$$A^+ + B^- \rightarrow A + B + h\nu, \qquad (18)$$

can explain the RL in pure alkenes during radiolysis. According to this mechanism photon emission and recombination occur simultaneously. The excited state of the luminescence centre is assumed to be formed by transfer of the recombination energy of the charges in the initial matrix[247–256].

Studies of the recombination-induced emission generated by the scheme (17) have shown that both fluorescence and phosphorescence of the molecule A can occur in non-polar matrices[165,170,219], but in strongly polar solvents only phosphorescence is possible[170] (see also Refs. 257 and 258).

Photo-excitation may occur through the ejection of a bound electron from a trap, and its recombination, or by a tunnelling transition of the electron from the excited state in the trap[177] at longer wave lengths ($\lambda > 900$ nm). In the former case we can expect both the triplet and the singlet level of the molecule A to be excited, whereas in the latter case the triplet state is preferentially excited. A study[160] of the effect of short illumination periods ($\lambda > 450$ nm), repeated at 20 s intervals, on the IRL curve of polybutadiene failed to detect a significant change in the population of the traps responsible for the isothermal decay of L_{IRL} at 90 K. However, a longer period of illumination (~7 min) can markedly increase the RL intensity observed as the sample is allowed to warm up to room temperature (especially at low temperatures). These experiments have confirmed the hypothesis that traps are present in large numbers, and with a depth distribution. Other workers came to a similar conclusion[223].

When a sample exposed to low-temperature hydrolysis is allowed to warm up the $L_{IRL} = f(T)$ curve contains several peaks whose position on the temperature scale can be correlated with the type of molecular motion which becomes "unfrozen" in this temperature range[256,259,260] or with structural changes associated with that motion[261–267]. The correlation can be explained by assuming a proportionality between the probability of setting the charge carriers free from their traps and the frequency factor of the appropriate molecular motion (note that thermal emission from a trap is accompanied by partial or total collapse of the trap as a result of the structural changes involved). An alternative explanation is possible: the softening of the matrix associated with the temperature rise allows faster diffusion of the trap (containing a captured electron) in the field of the cation. A 10 Å change in the distance between the two species is equivalent to an increase of 10^4–10^5 times in the probability of electron tunnelling[175], which can easily account for a strong peak in the radiothermoluminescence curve.

IV. STABILISATION AND CHARGE TRANSFER

The energy spectrum of the charged particles formed in a condensed phase during radiolysis is extremely broad, extending from the primary electron energy (several MeV)

to a few hundredths of an electron-volt. In the case of photolysis the energy spectrum is very much narrower ($E_e \leq 10$ eV).

It is usually assumed that as a result of collisions the electron rapidly loses its excess energy (in $\sim 10^{-14}$ s) to the level of 1–5 eV, and somewhat more slowly (in 10^{-13}–10^{-12} s) to the level of kT. This excess electron in the process of losing energy (or being thermalised), also known as a "dry" or quasi-free electron, is responsible for a number of physical and chemical processes in the condensed phase[8,108,110]. In the majority of condensed media the quasi-free state of the excess electron is unstable, and the electron is captured (solvated) by the medium. Early capture theories such as the Pekar–Deigen–Davydov polar theory and the "cavity" capture theory are reviewed in Ref.3. More recently the total energy (E_t) of the system (medium + excess electron) has been defined[268,269] as $E_t = E_c + E_m$, where E_c is the electronic component of the total energy, and E_m is the reorganisation energy of the medium (≥ 0). For the quasi-free state, which is described by a plane wave being scattered by the atoms and molecules of the medium, $E_m = 0$, and therefore $E_t = V_0$, where V_0 is the energy level of the bottom of the conduction band of the medium measured from the vacuum level, determined by the relative magnitude of the short-range repulsive forces and the long-range polarisation interaction forces. In the case of a localised electron the wave function is $\psi(R) \propto \exp(-R/R_0)$, where R is the configurational coordinate and R_0 is the radius of the coordination sphere (or cavity). The stability of this state is defined by two necessary conditions:

1) $\partial E_t/\partial R = 0$ for $R = R_0$ (configurational stability), and

2) $E_t(R_0) < V_0$ (energy stability).

Exactly analogous arguments can be applied to the stability of the excited states of a trapped electron. V_0 values of 1.32 and −0.63 eV have been calculated[269] for liquid ^{4}He and Ar respectively, as compared with experimental values of 1.05 and −0.33 eV. According to these values the drift mobility of electrons in these liquids should be 2.2×10^{-2} and 470 cm^2 V^{-1} s^{-1} (in the latter case the electron is, obviously, quasi-free). The satisfactory agreement between calculation and experiment for the parameters of the bound state of an electron in liquid helium is illustrated in Table 3.

Table 3. Calculated and experimental physical parameters of trapped electrons in liquid ^{4}He.[269]

Property	Experiment	Theory
Radius of cavity (0 atm), A	16	15.5
Radius of cavity (20 atm), A	10.5	11.5
Mobility, cm^2 V^{-1} s^{-1}	0.02	0.01
Photo-ionisation threshold, eV	0.9—1.0	0.92
Critical density of liquid for transition to the bound state ($E_t < V_0$), mole cm^{-3}	$(1.5—2.0)\cdot 10^{-3}$	$1.0\cdot 10^{-3}$

The properties of trapped electrons in metal–ammonia solutions, in polar liquids, and in glasses have also been explained successfully[153,155,269–271]. Calculations show that the cavities in which the electron is stabilised have diameters of several Ångstroms. In the theoretical calculations for non-polar alkanes the dipole moment of the C–H bond is used[153,272–274] in place of the dipole moment of the whole molecule (as in the case of polar matrices). In other respects the method of calculation is standard. In polymeric materials the cavities are larger than in alkane glasses, because the width of the singlet in the ESR spectra (which characterises the interaction between the captured electron and the surrounding protons on the surface of the cavity) is narrower in these materials, and the spin–lattice relaxation time is longer.

Experimental and theoretical results on the mobility of electrons in non-polar liquids are reviewed in Refs.8, 9, and 275, in polar liquids in Ref.276, and in solid matrices in Ref.277.

Table 4. Characteristics of an excess electron in non-polar liquids[9].

Liquid	T, K	V_0, eV	μ, cm^2 V^{-1} s^{-1}
Methane	109	0.0	400
Neopentane	293	−0.43	50—70
Ethane	120	0.22	0.01
n-Pentane	293	−0.01—0.04	0.14
Cyclopentane	293	−0.21	1.1
Tetramethylsilane	293	−0.59	90—100

As was pointed out above, the main characteristics of an excess electron in the quasi-free state are the energy of the state with respect to the vacuum level (V_0) and the mobility of the electron (μ). Theoretically, a correlation between these two characteristics can be expected. As a rule, higher values of μ correspond to negative values of V_0 (see Table 4). Mobilities $\mu \geq 10$ cm^2 V^{-1} s^{-1} indicate a stable quasi-free state, whereas lower values ($\mu \leq 1$ cm^2 V^{-1} s^{-1}) indicate stability of the bound (localised) state of the excess electron.

A correlation between V_0, μ, and the yield of free charges G_{fl} has also been demonstrated[278]: for $\mu \geq 50$ cm^2 V^{-1} s^{-1} we find $G_{fl} \cong 1.0$ (see Refs.8 and 279).

Two theoretical models have been used to allow for the thermal energy responsible for the transfer of an electron from a localised state (in systems where such a state is stable) into a quasi-free state. The first model (partial localisation model)[280,281] assumes an equilibrium between electrons in the bound and in the free state. The relationship between the observed value μ and the true mobility μ_0 is given by the formula

$$\mu = \mu_0(1-P), \tag{19}$$

where P is the probability of localisation. The second model[282] treats the medium as a complex conglomerate of two different types of region, one transparent and one opaque to excess electrons, and assumes that the volume fraction of the transparent region is a function of V_0 (see Ref.8).

Experimental measurements[283–286] of μ and V_0 in mixtures of alkanes (neopentane/n-hexane) can be explained satisfactorily by both these models.

Experimental data on μ and V_0 in the solid phase are scarce. The main method of determining V_0 in a solid solution is an indirect (complicated, and laborious) measurement of the ionisation potential of TMPD or tryptophan in different solvents[287–293], using the formula

$$\Delta I = I_g - I_s = -P^+ - V_0, \tag{20}$$

where I_g and I_s are the ionisation potentials in the gas and the solid phase, $P^+ = -e^2/2r_0(1-1/\varepsilon_{opt})$ is the polarisation energy of the cation (and r_0 is its radius), and ε_{opt} is the optical dielectric constant. Tentative results obtained in this way for various glasses frozen at 77 K are given in Table 5.

These results suggest a very high mobility for ice and for the 10 M KOH–H_2O alkaline glass, as has been found experimentally[295]: the Hall (i.e. the true) mobility in these media is $\mu_0 \cong 5$ cm^2 V^{-1} s^{-1}. The increase in mobility at low temperatures is consistent with the motion of electrons by the band mechanism. Unfortunately, mobility measurements by the Hall effect are impossible for the majority of frozen hydrocarbons, and experimental results are confined to the drift mobility.

Table 5. Experimental data used to determine V_0 for some glasses at 77 K.[294]

Glass	ΔI, eV	ϵ_{opt}	$-P^+$, eV	V_0, eV
Methylcyclohexane	0.85	2.28	2.09	1.24
3-Methylpentane	0.85	2.22	2.05	1.20
2-Methyltetrahydrofuran (MTHF)	1.08	2.23	2.06	0.98
Ethanol	1.70	2.08	1.94	0.24
Methanol	1.85	1.97	1.84	−0.01
Ice	2.0	1.78	1.64	−0.36
10 M KOH–H_2O	2.2	1.96	1.83	−0.37

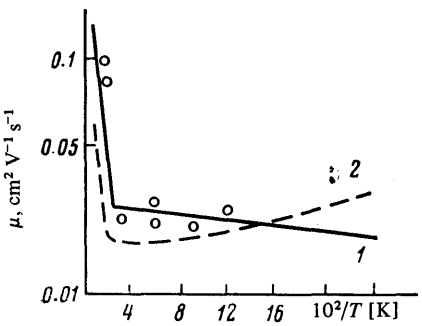

Figure 5. Temperature dependence of mobility: *1*) 3-MP,[296] *2*) MTHF.[297]

Experimental results[296,297] on the mobility of charge carriers in 3-MP and 2-methyltetrahydrofuran (MTHF) are shown in Fig.5. The measurements were by photo-injection of electrons[296] from a TMPD film electrode, or by pulse photolysis[297] of previously γ-irradiated MTHF. The results for the 35–77 K range are interpreted in terms of the Holstein hopping model[298], and those for temperatures below 35 K by the band model. It has been suggested[299] that the transition from hopping conduction to band conduction should occur at the Debye temperature (see Refs.300–302), which for 3-MP and MTHF is close to 35 K, i.e. to the break point in the curves of Fig.5. The reported[296,297] values of μ cannot be compared with the (much lower) values given by the trap-controlled diffusion mechanism for the motion of the carriers[303–306]:

$$\mu = \mu_0 \tau_3 / (\tau_B + \tau_3), \qquad (21)$$

where $\tau_3 \cong 10^{-12}$ s, $\tau_B \cong 10^3$ s at 77 K, and $\mu_0 \cong 1$ cm^2 V^{-1} s^{-1}.

In Ref.307 the drift mobility of electrons in 3-MP at 77 K, measured by injection of high-energy electrons, is given as $\sim 10^{-15}$ cm^2 V^{-1} s^{-1}, which formally agrees with the trap-controlled diffusion mechanism if we take $\mu_0 \tau_3 = 10^{-12}$ cm^2 V^{-1} [138] and $\tau_B = 10^3$ s[138,231,232]. These large discrepancies between the mobility values of a given material require an explanation.

Large discrepancies between experimental values of μ are observed also in polymeric materials. Thus, in the case of polyethylene, which has been investigated intensively[149,150,308–313], μ values between 10^{-4} and 10^{-14} cm^2 V^{-1} s^{-1} have been reported. The higher values (10^{-4}–10^{-6} cm^2 V^{-1} s^{-1}) are usually observed when the chosen measurement method involves the injection of low-energy, "cold" electrons (≲1 eV). Furthermore, the activation energy of the drift mobility (E_a) for these high mobility values is much lower (~0.2 eV) than for the low values of μ obtained after injection of high-energy, "hot" electrons ($E_a \geq 0.5$ eV). These differences between the μ values for hot and for cold electrons are probably associated with the chemical and physical features of the structure with which the excess electrons are interacting. For example, large differences between hot and cold electrons are not observed in PTFE[309,314], whereas in PMMA drift mobilities differing by several orders of magnitude have been reported for the injection of cold[315] and of hot electrons[316], the values being higher for the cold electrons.

It has been found[317] that benzene as the acceptor of a dry electron lowers the yield of solvated electrons (e_s^-) in methanol caused by the two-quantum ionisation of anthracene (or pyrene), but it has no effect on processes induced by laser radiation of wave length corresponding to the absorption band of e_s^-. The authors[317] conclude that the dry electron is not formed in the latter case. Nevertheless we can again postulate that benzene is an effective acceptor of hot dry electrons (two-quantum ionisation of anthracene) but does not react with thermal electrons (see Ref.318). Similar conclusions follow from the work of Kostin and coworkers[319,320].

In general the mobility of an electron in a disordered system depends on the energy of the electron. At some threshold energy E_C' ($E_C' > E_C$) the mobility suddenly increases to a terminal value[321,322] determined only by phonon scattering; under these conditions $\mu_0 \cong 3\lambda$ (where λ is the mean free path of the charge carrier), so that for $\lambda = 30$ Å we have $\mu_0 \cong 100$ cm^2 V^{-1} s^{-1}. For electron energies higher (by ~0.2 eV) than the bottom of the conduction band E_C but not higher than E_C' the motion of the electron can be highly hindered, because some of the space is not available for its motion[323–326]. In this case we are dealing with the continuum problem of the theory of flow[327], in which the mobility is determined by the expression[328]

$$\mu_0 = \frac{eD}{kT} = \frac{1}{6}\left(\frac{e}{kT}\right) a^2 \nu,$$

where a is the lattice parameter. For $a = 3$ Å, $\nu = 10^{15}$ s^{-1}, and $T = 300$ K we obtain $\mu_0 \cong 1$ cm^2 V^{-1} s^{-1}. According to the theory of flow, characteristic mobility values for this mechanism of motion should be in the range 0.01–1.0 cm^2 V^{-1} s^{-1}. Lastly, for electron energies $E_e < E_C$ the motion of the electron takes the form of a series of jumps from trap to trap in the forbidden gap (the hopping conduction mechanism), and $\mu \leq 10^{-5}$ cm^2 V^{-1} s^{-1}.

In disordered systems such as amorphous or partly crystalline glasses and polymers, energy bands are always assumed to be present[321,322,329], because these materials show short-range order in the relative position of atoms and molecules. However, the band edges can be diffuse in this type of material, i.e. they can have tails in which the electrons exist mostly in localised states. Because of the high density of these states their wave functions are able to overlap, and the electron can move by jumping from one localised state to another as a result of interaction with the thermal

fluctuations of the matrix energy. At low temperatures (below the Debye temperature) barrierless tunnelling transitions between localised states become predominant[277,321], causing a sharp change in the temperature dependence of the mobility (see Fig. 5).

In recent years important developments have taken place in the theory of the motion of current carriers in solid amorphous materials (including polymers) in the presence of an external electric field. These developments have been aimed mainly at explaining some special aspects of the drift mobility of electrons and holes determined by the crystal counter method[330–342]. The theory is being developed along two main directions. The earlier approach[343–346] relies on the jump (hopping) mechanism of motion of the electron in amorphous dielectrics, assuming the following distribution of jump times:

$$\psi(t) \propto t^{-(1+\alpha)}, \qquad (22)$$

where α is a constant ($0 < \alpha < 1$). This is the Scher–Montroll stochastic jump model[343]. The function (22) is quite different from the exponential function $\psi(t) \propto \exp(-at)$, used in the classical (diffusion) jump theory, in which the average jump time is assumed to be $t_{aver} = a^{-1}$. A not very convincing account of this theory is given in Refs. 347 and 348. Several critical comments on the Scher–Montroll model are made in Refs. 349–354.

In the second approach the motion of the electron is treated by the classical band model in the presence of a continuous distribution (in energy) of charge traps[355–364]. The equivalence of these two approaches has been demonstrated by several workers[345,359,361,365]. The special features of the non-gaussian diffusion and drift of charge carriers in amorphous matrices are extremely important, because they give a correct formulation of the early stages in the recombination of isolated ion pairs[367] as well as explaining the shape of the initial portion of the current decay curve after irradiation[118,119,368].

Perlman and Bamji[369] stress the need for the utmost care in interpreting experimental results obtained by the crystal counter method in polymers (especially in polyethylene).

One of the models proposed for the motion of a solvated electron e_S^- in a liquid may also find application in the solid state. This is the so-called configuration coordinate model of the motion of e_S^- by diffusion[370–372]. According to this model the orientation polarisation function is arbitrarily fixed, and the total energy E is calculated. A diffusion jump between states with an orientation polarisation function for which the total energy E is a minimum is treated as a continuous change in the polarisation P between the values P_0 and P_1, such that

$$P_u(r) = (1-u)P_0(r) + uP_1(r),$$

where u can vary from 0 to 1.

In full agreement with experiment, the calculated activation energy for the motion of the electron in ice is 0.16 eV. This model avoids the discrepancy with experimental values of the activation energy for electrical conduction found in the earlier models. Thus, in the transition

$$e_s \rightarrow e^- + \text{full orientation relaxation}$$

the activation energy for water is ~0.5 eV. If on the other hand we assume a vertical transition (i.e. a transition in which the orientation is not perturbed) the activation energy is even higher, and coincides with the energy of the optical transition (usually ≥ 1 eV).

The above model is based on the rotation of the molecular dipoles. It is difficult to believe that this rotation can take place at 77 K. However, at room temperature the mechanism may be generally applicable, especially in the case of polymeric materials. The presence of dipoles (due to various structural imperfections and chemical impurities) even in non-polar polymers has been demonstrated by measurements of pyroelectric properties[373]: it is now accepted that substantial changes in dipole orientation can occur even below the glass transition temperature. Thus the conditions in polymers at room temperature are not inconsistent with the proposed mechanism of the drift mobility of a trapped electron in a condensed phase.

---o0o---

During the preparation of this review several new publications have appeared, with critical comments on many of the topics discussed above. We shall briefly discuss the most important of these.

The validity of the classical ideas on the diffusion and drift of charged particles in interpreting the results of electron trapping measurements and pair recombination in a condensed phase is challenged[374], in spite of the allowance for non-gaussian diffusion of electrons in amorphous matrices[367,375–383]. An attempt is also made[379,380,382] to explain the kinetics of the disappearance of ion radicals in frozen organic glasses in terms of the Scher–Montroll model rather than by the tunnel effect.

A study of the photo-ionisation of TMPD in non-polar solvents has led to the conclusion[384,385] that the precursor of the free electron is not an ion pair but an excited state of the solute molecule. This result is directly relevant to the problem of the contribution of electrons from isolated pairs to the electric current (see Refs. 104, 127, 386).

The influence of the dose ($\leq 10^3$ Rad) on the induced electrical conductivity during pulsed (~50 ns) irradiation of crystalline ice is discussed in Ref. 387, mainly in terms of the formation of free OH radicals. These results agree very well with those of Nikol'skii and coworkers[262], who showed that in polyethylene electron capture (mainly on radicals) begins at doses as low as $\sim 10^5$ Rad. It is suggested that the formation of stabilised electrons, characterised by the i.r. absorption spectrum, involves electron capture by pre-existing traps not only in solid[388] but also in liquid polar matrices[389]. The possibility of explaining the "blue" shift of the absorption spectrum of a trapped electron in terms of its motion within the ion pair is discussed[390]. However, Rice[391] believes that in molecular frozen glasses the migration of trapped electrons is unlikely, though such migration has been demonstrated experimentally in frozen alcohols[392] with observation times ≤ 750 ns (see also Ref. 393).

The lowest reported values ($\leq 3 \times 10^{-13}$ cm^2 V^{-1}) of $G\mu_0\tau_3$ have been observed in polar polymers[114,120]. This has been interpreted[126] as evidence that the conduction is due to hot electrons with energy ≤ 10 eV, and a far-reaching analogy between RPEC and electrical breakdown in dielectrics has been proposed[394] (see also Refs. 104 and 120). Vaisburd's model of the electrical conduction induced in dielectrics by powerful electron beams[395,396] should also be mentioned here.

We have been unable, through lack of space, to deal adequately with the generation of current carriers from excited neutral states of the polymer molecule or from complexes, which plays a fundamental role in photolysis[397] and may also be important in radiolysis. The study of these states has been made much easier by our improved understanding of spin effects in the elementary processes of high-energy chemistry, due mainly to the work of Frankevich and coworkers (see review articles in Refs. 398 and 399). The energy structure of ionised and excited states in organic molecular crystals is now known in great detail[400–402].

Therefore we can hope for similar advances, in the near future, in our understanding of disordered organic matrices, including polymers.

Oxidation of Alkyl Derivatives of Aromatic Hydrocarbons by Transition Metal Salts

I.P.Beletskaya and D.I.Makhon'kov

The oxidation reactions of aromatic compounds and their alkyl derivatives under the influence of salts of variable-valence transition metals are examined.
The bibliography includes 204 references.

I. INTRODUCTION

Reactions involving the oxidation of aromatic compounds by transition metal salts have attracted much attention in recent years. These reactions, which have come to be called "stoichiometric oxidation", make it possible to obtain in many instances mainly one of the oxidation products, i.e. to "functionalise" aromatic compounds selectively[1].

Substituted benzenes and condensed aromatic systems without substituents capable of being oxidised have always given rise to products with functional groups, which are linked directly to the aromatic nucleus. Another important class of substrates are alkyl derivatives of aromatic compounds, which yield, on oxidation, the products of monosubstitution in the α-position of the side chain as well as the corresponding oxo- and carboxy- derivatives, apart from the compounds of the type mentioned above.

There is an extensive literature on problems of liquid-phase and stoichiometric oxidation and the number of original publications in this field continues to increase rapidly. This review summarises data on the oxidation of aromatic compounds and their alkyl derivatives by variable valence metal ions (the literature up to the middle of 1979 is included). We shall not consider oxygen-containing metal compounds in the highest oxidation states (such as the salts of chromic and manganic acids), which have been used for a long time and which have been fairly thoroughly investigated, as well as substrates which exhibit specific features in oxidation processes (phenols, aromatic alcohols, amines, etc.), with the exception of those cases where the oxidation involves only the aromatic system and (or) alkyl substituents in these compounds.

II. GENERAL MECHANISMS OF OXIDATION BY METAL SALTS

Silver(II), copper(II), palladium(II), cobalt(III), manganese(II), iron(III), thallium(III), lead(IV), and cerium(IV) compounds used as oxidants can be divided into two groups: one-electron and two-electron oxidants; their standard electrode potentials vary within wide limits [the values of E^0 (V) are listed below]:

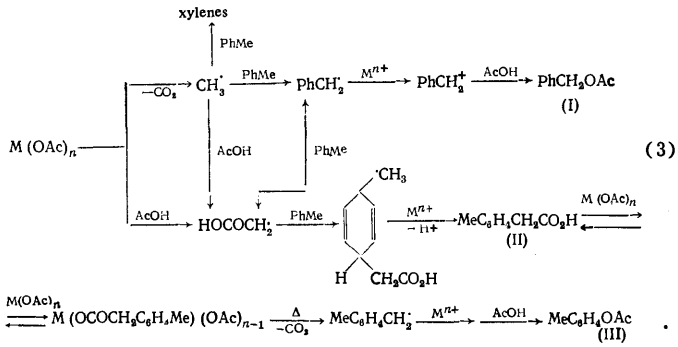
Ag^{2+}/Ag^{+} 1.91	$Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ 0.36
Co^{3+}/Co^{2+} 1.808	Cu^{2+}/Cu^{+} 0.167
Ce^{4+}/Ce^{3+} 1.61	Pb^{4+}/Pb^{2+} 1.694
Mn^{3+}/Mn^{2+} 1.509	Tl^{3+}/Tl^{+} 1.252
Fe^{3+}/Fe^{2+} 0.771	Pd^{2+}/Pd^{0} 0.987

One should note that a characteristic feature of variable-valence metal compounds is the occurrence in solutions of complex equilibria involving hydrolytic and complex formation reactions and the formation of dimers and polymers, which alter the oxidation-reduction potentials and the activities of the above compounds. Depending on the structural characteristics of the salt, the specific features of the metal and its ligand environment, the type of aromatic compound, and the conditions (for example, temperature, and the nature of the solvent), the oxidant and the substrate can interact via several different mechanisms.

1. Electron transfer from the π-electron system of the substrate to the metal atom with formation of a radical-cation of the aromatic compound. This process can proceed after the inclusion of the substrate molecule in the coordination sphere of the metal (inner-sphere transfer, *a*) or without the breakdown of this sphere (outer sphere transfer, *b*):

$$CH_3ArH + M^{n+} \begin{cases} \xrightarrow{a} [CH_3ArH \ldots M^{n+}] \rightarrow [(CH_3ArH^{\cdot+}) \ldots M^{(n-1)+}] \\ \xrightarrow{b} CH_3ArH^{\cdot+} + M^{(n-1)+} \end{cases} \quad (1)$$

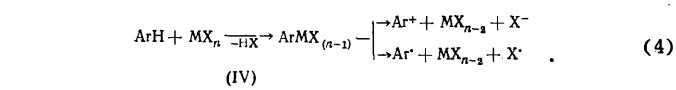
2. Homolytic decomposition of the substrate–oxidant complex with simultaneous transfer of an electron and a ligand and the formation of a benzyl type radical (2*a*) or the product of radical addition to the substrate (2*b*):



$$HArCH_3 + M^{n+}X^- \begin{cases} \xrightarrow{a} HArCH_2^{\cdot} + HX + M^{(n-1)+} \\ \xrightarrow{b} H_3CAr^{\cdot}\!\!\begin{array}{l}H\\X\end{array} + M^{(n-1)+} \end{cases} \quad (2)$$

Processes of this kind appear, in particular, in oxidation by complex cerium(IV) salts, copper(II) and iron(III) halides, etc. (see below).

3. Oxidation initiated by free radicals arising in the decomposition (photochemical or thermal) of the oxidant molecule (usually the metal carboxylate).

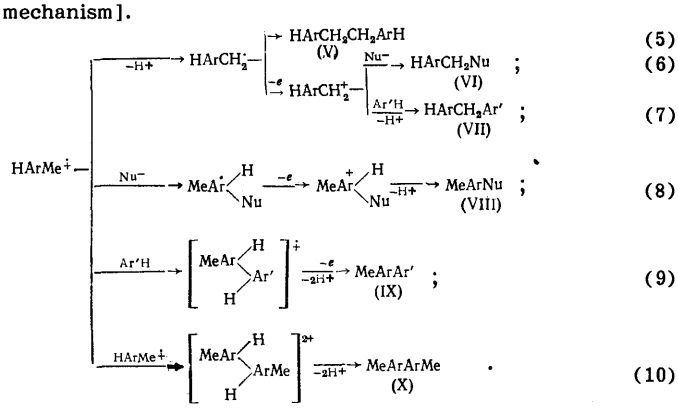


Depending on the nature of the metal, the structure of the carboxylate ion, and the solvent used, such decomposition is accompanied by decarboxylation leading to alkyl or aryl radicals and (or) the formation of carboxyalkyl radicals. Both types of radicals initiate the process, giving rise to alkylation, carboxyalkylation, acyloxyalkylation, etc. products in proportions determined by the specific characteristics of the intermediates, which can be illustrated by the general mechanism of the oxidation of toluene in AcOH by

lead(IV), manganese(III), and cerium(IV) acetates (for further details, see the appropriate sections of the review):

(3)

4. Metallation of the aromatic substrate with a metal salt and subsequent decomposition of the organometallic compound with formation of an aryl radical or an aryl cation:



(4)

(IV)

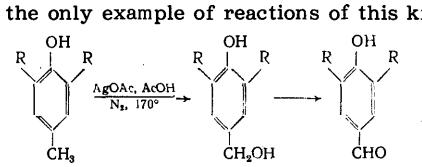
Processes of this type are characteristic of lead(IV), palladium(II), and particularly thallium(III) salts (see below).

Thus the first stage of the reaction of the aromatic substrate with a metal complex leads to the formation of a radical, cation, or a radical-cation, depending on the mechanism. The transformations of radicals on interaction with the metal compounds have been discussed in detail in reviews[2,3]. They are usually terminated either by oxidation via a ligand transfer mechanism [analogous to mechanism (2)] or by oxidation to a cation, which subsequently reacts with a suitable nucleophile (see below).

The fate of the radical-cation formed via mechanism (1) merits a more detailed investigation. In the presence of an alkyl (particularly methyl) group in the molecule, the radical-cation usually loses a proton with formation of a radical of the benzyl type, which is then oxidised to a cation, reacting with an anion or a solvent molecule to form a product of substitution in the α-position of the side chain [mechanism (6)]. When the stability of this radical is high, 1,2-diarylethanes of type (V) are also formed. In a weakly nucleophilic medium (in the presence of strong acids or in the heterophase oxidation in an excess of the substrate) the cation formed attacks a second substrate molecule with formation of diarylmethanes via mechanism (7) [in principle the formation of compound (VII) is also possible as a result of the oxidation of the radical adduct comprising $HArCH_2^{\cdot}$ and $HArCH_3$, but the available literature data concerning the high regioselectivity of reaction (7) are inconsistent with this mechanism].

(5)
(6)
(7)
(8)
(9)
(10)

An alternative reaction pathway involves direct attack by an anion or a solvent molecule on the radical-cation and the formation of the ring-substituted product (VIII) via mechanism (8). In the absence of alkyl substituents from the substrate molecule or when factors (for example, steric factors) hindering the formation of a benzyl radical operate, this reaction pathway becomes dominant in highly nucleophilic media. The dimerisation of the radical-cation or its interaction with another molecule of the aromatic compound leads to the formation of biphenyl derivatives via mechanisms (9) and (10). The oxidative dehydrodimerisation pathway, leading to products of types (VII), (IX), (X), depends on the structure and on the distribution of the positive charge (in a substituted or unsubstituted position of the aromatic ring) of the initial radical-cation. Reactions of this type are frequently accompanied by polymerisation and disproportionation.



Reactions (5)–(10) frequently take place simultaneously, but the choice of conditions (variation of the temperature parameters and solvents, the introduction of nucleophilic additives, strong acids, complex-forming agents, etc.) makes it possible to drive the process in the required direction and to obtain a product with a high selectivity.

The specific features of such processes are considered below in relation to various types of oxidants in conformity with the classification adopted for the latter (see above) in order of their decreasing oxidation-reduction potentials.

III. VARIABLE-VALENCE METAL IONS AS OXIDANTS FOR ALKYLARENES

1. Silver(I), Silver(II), and Silver(III)

The use of silver(I) salts and Ag_2O for the oxidation of hydroquinones and aldehydes is well known, but the stepwise oxidation of the methyl group of 2,6-dialkyl-*p*-cresols is apparently the only example of reactions of this kind†.

R = t-Bu or Me.

Silver(II) compounds are strong oxidants, but their use in organic syntheses is fairly limited[6].

Many oxidation processes take place successfully in the $Ag^+–S_2O_8^{2-}$ system, but do not occur in the absence of silver ions. As suggested previously, the role of the latter is not exhausted by the formation of $SO_4^{\cdot-}$ radical-anions. The latest studies[7,9] have shown that Ag^{2+} ions make an appreciable contribution to the oxidation of the substrate. The process involves a series of oxidation-reduction reactions:

$$S_2O_8^{2-} + Ag^+ \rightarrow SO_4^{2-} + SO_4^{\cdot-} + Ag^{2+} ;$$
$$SO_4^{\cdot-} + RH \rightarrow SO_4^{2-} + R^{\cdot} + H^+ ;$$
$$SO_4^{\cdot-} + Ag^+ \rightarrow SO_4^{2-} + Ag^{2+} ;$$
$$Ag^{2+} + RH \rightarrow Ag^+ + RH^{+\cdot} .$$

†There exist also patent data[5] concerning the oxidation of toluene to benzyl alcohol by passing oxygen through a solution in acetic anhydride containing catalytic amounts of silver acetate.

The Ag^{2+} and $SO_4^{\cdot-}$ species act in these reactions as oxidants with different selectivities[8] and the contribution of the oxidation by Ag^{2+} ions increases with increasing Ag(II)/substrate ratio.

The stability of organic silver(II) complexes increases appreciably with increasing acidity of the medium and in the presence of nitrogen-containing ligands[6,7]. Thus bis(2,2-bipyridyl)silver(II) peroxydisulphate in acetic acid acetoxylates alkylarenes in the ring and (or) in the α-position of the side chain[7,8] via mechanism (11) in ~300% yield with respect to silver(II) (two oxidants are involved in the reaction):

$$3ArH + 2Ag(II) + 2S_2O_8^{2-} + 3AcO^- \rightarrow 3ArOAc + 2Ag(I) + 4SO_4^{2-} + 3H^+ \quad (11)$$

In addition, methylbenzenes give rise to small amounts of benzaldehydes. Silver(II) salts without the $S_2O_8^{2-}$ anion react analogously[10]. Silver(II) picolinate (pyridine-2-carboxylate) $Ag(pic)_2$ and bis(2,2-bipyridyl)silver(II) trifluoromethanesulphonate $Ag(bipy)_2(CF_3SO_3)_2$ oxidise *p*-methylanisole to a mixture of the corresponding alcohol and aldehyde (3:1) in quantitative yields. The rate of oxidation increases greatly in the presence of potassium acetate, which has been attributed[10] to the buffer effect of the acetate ion [see mechanism (11)] and (to a greater extent) to the increased solubility of the silver(II) complexes in the presence of potassium acetate.

The results of the competitive oxidation of *p*-substituted toluenes yield $\rho = -3.4$ and the kinetic isotope effect, which is absent in the acetoxylation of the ring, amounts to 5.9 for α, α, α-d_3-*p*-methoxytoluene. Thus, in the absence of the peroxydisulphate ion, the oxidation of arylmethanes involves electron transfer with formation of a radical-cation [mechanism (1)], which then loses a proton in the rate-determining stage of the reaction[10].

Silver(II) picolinate can also be used in neutral media[11,12]: the oxidation of alkylarenes by an aqueous suspension of $Ag(pic)_2$ gives rise to carbonyl compounds[11], while the reaction with PhMe in dimethyl sulphoxide (DMSO) at 65 °C[12] makes it possible to obtain $PhCH_2OH$, PhCHO, and $PhCO_2H$ in succession, depending on the amount of the oxidant (the yields are 60, 15 and 45% respectively in each case).

In principle, the reactions of silver(II) salts may involve the participation of silver(III) species formed via the reaction

$$2Ag(II) \rightleftarrows Ag(I) + Ag(III).$$

However, it has been shown that this equilibrium is greatly displaced to the left and silver(III) plays an insignificant role in the processes occurring, for example, in the $Ag^+-S_2O_8^{2-}$ system[8]. Such reactions follow second-order kinetics, which is inconsistent with the involvement of silver(III).

At the same time it is known that stable silver(III) compounds can be obtained in the form of complexes of AgX_3 ($X = HSO_4$, NO_2, ClO_4, or OH) with biguanidine, ethylenebiguanidine, etc. and also in the form of the oxide Ag(I).$\cdot$Ag(III)O_2.[13] A solution of Ag_2O_2 in mixtures of aqueous acids (H_3PO_4, AcOH) oxidises methylarenes to the corresponding aldehydes in fairly high yields (54% for PhMe and 90% for *p*-MeC_6H_4OMe).[14] It is of interest that diphenylmethane is inert under these conditions, while the yield of Ph_2CO in the oxidation in the $Ag(pic)_2-H_2O$ system is 43%.[11]

It is noteworthy that, according to Crivello's data[15], Ag_2O_2 in a trifluoroacetic acid–trifluoroacetic anhydride mixture oxides aliphatic hydrocarbons and in the case of adamantane, for example, gives rise to 1-adamantyl trifluoroacetate in 98% yields.

2. Cobalt(III)

Like silver(II), cobalt(III) is a powerful oxidant in acid media. A study of the Co(III)/Co(II) oxidation-reduction potential in aqueous solutions of HCl, H_2SO_4, AcOH, and $HClO_4$ showed that the potential of the above pair decreases with increasing acid concentration[16].

Like Ag_2O_2, cobalt(III) hydroxide in aqueous solutions of acetic and phosphoric acids oxidises methylarenes to the corresponding aldehydes in yields ranging from 25% (mesitylene) to 95% (*p*-methylanisole). Toluene is inert under these conditions[16]. An advantage of this process is its relatively high selectivity.

Cobalt trifluoride oxidises benzene at 200–250 °C to a mixture of cyclic polyfluoro-derivatives (25–30 products), mainly octafluorocyclohexanes[18]. It has been shown that the first stage of the reaction is electron transfer with formation of a radical-cation[18]. Under the same conditions, potassium tetrafluorocobaltate gives rise to a mixture of polyfluorocyclohexenes[19]. The proportions of the products in the case of the tetrafluorocobaltates of other alkali metals depend greatly on the nature of the cation[20]. The reaction requires increasing temperatures on passing from lithium (100–130 °C) to caesium (250 °C) and only in the last case does the reaction mixture contain, apart from the products of the successive saturation of the aromatic system (mainly 3,3,6,6-tetrafluorocyclohexadiene), polyfluorobenzenes, including hexafluorobenzene (6%).[20] It remains obscure how the variation of the cationic component influences the structure of the salt and its reactivity. However, it is of interest that, according to the data of Edwards et al.[20], potassium hexafluorocobaltate is inert under the same conditions.

The study of the heterogeneous oxidation of toluene and xylenes with potassium 12-tungstocobaltate(III) $K_5[CoO_4W_{12}\cdot O_{36}].H_2O$,[21] which gives rise to mixtures of diarylmethanes, monoaldehydes, and the corresponding alcohols, showed that the radical-cation of the aromatic compound is formed as a result of an outer-sphere electron transfer [mechanism (1*b*)]. The subsequent transformations of the radical-cation proceed via mechanisms (6) and (7).

Under homogeneous conditions (AcOH–H_2O), the reactions of potassium 12-tungstocobaltate(III) with aromatic compounds are in many respects analogous to the anodic oxidation processes and reactions involving silver(II) salts[22]. Thus anisole, biphenyl, and naphthalene gives rise to aromatic ring acetoxylation products in the presence of potassium acetate, the oxidation of 4-fluoroanisole in the same system being accompanied by the substitution of fluorine by the acetoxy-group. Mesitylene is also partly acetoxylated in the ring under these conditions (as in anodic oxidation), although in the reaction with cobalt(III) carboxylates, even in the presence of potassium acetate, only α-acetoxylation is observed (see below). Toluene, xylenes, and hexamethylbenzene give rise to only α-hydroxy- and acetoxy-derivatives in the absence of potassium acetate, while 4-methoxytoluene also forms the dehydrodimer 2-(4-methoxybenzyl)-4-methylanisole. In the presence of potassium acetate the rate of oxidation falls and oxidative coupling is fully suppressed by toluene and xylenes give rise also to acetoxymethylation products [see mechanism (3)] whose yield increases sharply in anhydrous acetic acid. The isotope effect in the oxidation of α,α,α-d_3-*p*-methoxytoluene, amounting to ~6, has been interpreted[22] as evidence for a reaction mechanism involving the concerted transfer of an electron and the proton of the α-C–H bond to the oxygen atom of the heteropolyion as the rate-limiting stage.

However, simpler cobalt(III) salts—the perchlorate and carboxylates—are frequently used. In aqueous $HClO_4$ cobalt(III) perchlorate steadily oxidises benzene with formation of a mixture of *p*-benzoquinone, muconic acid, and its lactone[23]. The reaction kinetics obey the equation

$$-\frac{d[Co(III)]}{dt} = \left(k_1 + \frac{k_2}{[H^+]}\right)[Co(III)][PhH].$$

This has been interpreted[23] as evidence for the involvement in the process of two types of oxidising species—the aquo-complex of cobalt(III) and the more active hydroxy-complex $Co(OH)^{2+}$.

In the $HClO_4$–H_2O–MeCN system cobalt(III) perchlorate oxidises alkylarenes to mixtures of the corresponding alcohols, aldehydes, and acids. According to the data of Cooper and Waters[24], the reaction of toluene involves outer-sphere electron transfer and is accelerated with increase of the concentration of acetonitrile in the solvent. In the mixture with 50% MeCN the products resulting from the oxidation of the methyl group are formed exclusively, but in the presence of higher contents of acetonitrile the formation of methylbenzophenones and benzylbenzaldehyde—the products of the reaction of toluene with the benzyl radical arising in the oxidation of benzaldehyde—was also noted. The reactivity of the substrates increases in the sequence p-$NO_2C_6H_4CH_3 < PhCH_2CH_2Ph \cong PhMe \cong PhEt < Ph_2CH_2 <$ t-$BuC_6H_4CH_3 < Ph_2$.

It is of interest that benzyl alcohol is oxidised faster under these conditions than diphenylmethanol. This phenomenon has been attributed[24] to the steric characteristics of the complexes formed on direct coordination of alcohols to a cobalt atom; it is suggested that the electron transfer takes place in this instance via an inner-sphere mechanism [see mechanism (1*a*)].

The oxidation of toluene by cobalt(III) perchlorate is appreciably accelerated when aliphatic acids are introduced into the reaction mixture[25].

The slow electron transfer from the toluene molecule is replaced under these conditions by the rapid abstraction of hydrogen from the methyl group by the alkyl radical formed via the reaction

$$RCOOH + Co(III) \rightarrow R^{\cdot} + CO_2 + Co(II) + H^+ . \qquad (12)$$

The benzyl radical is rapidly oxidised further via mechanism (6) and partly dimerises with formation of bibenzyl [mechanism (5)].

Aryl-substituted aliphatic acids are oxidised by cobalt triacetate (CTA) with formation of a radical-cation [mechanism (1)] and then a benzyl-type cation [mechanism (6)].[26] Under these conditions, γ-phenylbutyric acid gives rise to an intramolecular oxidation product—γ-phenylbutyrolactone:

$$PhCH_2(CH_2)_2CO_2H \xrightarrow[-H^+]{2Co(III)} PhCH(CH_2)_2CO_2H \xrightarrow[-H^+]{} \text{lactone} .$$

In the presence of LiCl or trifluoroacetic acid the yield of the lactone increases from 25 to 60%.[26]

In the presence of arylacetic acids the radical-cation formed is decarboxylated and gives rise to substituted benzyl acetates, in conformity with mechanism (6):[26]

$$[ArCH_2CO_2^-]^{\cdot} \xrightarrow{-CO_2} ArCH_2^{\cdot} \xrightarrow{Co(III),\ AcO^-} ArCH_2OAc .$$

Cobalt(III) carboxylates oxidise alkylbenzenes to the corresponding benzyl carboxylates[26–37] and the ligand environment of Co^{3+} plays a significant role in this reaction, whose first stage is believed[27–30] to involve the insertion of the substrate in the inner coordination sphere of cobalt(III). Neutral ligands, which strongly coordinate cobalt(III)—bipyridyl, pyridine, and acetonitrile—lower the rate of reduction of cobalt(III) with increase of their concentration in the reaction mixture up to the complete suppression of the oxidation process[27]. When water is added, the rate of reduction of cobalt(III) initially increases and then falls to the initial value at $[H_2O] > 2.2$ M. With increase of the size of the carboxylate anion, the electron transfer of the cobalt(III) atom is suppressed and the main reaction pathway becomes the decomposition of the oxidant [via a mechanism analogous to mechanism (12)], whose contribution is 82% for pelargonic acid and 100% for isobutyric acid[27]. The ligand effect is in this case attributed to the steric hindrance in the formation of the Co(III)–RH complex and not to the decrease of the oxidation potential of cobalt(III).[27]

The addition of potassium acetate accelerates the oxidation of toluene by CTA in acetic acid[31,32] but has little influence on the proportions of the products (31% $PhCH_2OAc$, 7% PhCHO, and 2% of bibenzyl are formed at 37 °C [31]). An increase of temperature lowers the overall yield of products and is accompanied by the formation of small amounts of xylenes and methylbenzyl acetates [see mechanism (3)]. The thermolysis of CTA in acetic acid is accompanied by the liberation of CO_2 and small amounts of methane and is almost completely suppressed in the presence of aromatic substrates[31], which differs sharply from the behaviour of manganese(III), lead(IV), and cerium(IV) acetates under analogous conditions (see below). On oxidation with CTA, 2-methylnaphthalene gives rise also to 1-acetoxy-2-methylnaphthalene (18%) apart from the products formed as a result of the oxidation of the methyl group (~50%) [see mechanism (8)].[31]

The kinetics of the oxidation of aromatic compounds by cobalt triacetate are described by the following equation according to a series of data[28,29,30]:

$$-\frac{d[Co(III)]}{dt} = k_{obs}[ArH][Co(III)]^a[Co(II)]^{-1},$$

where k_{obs} is independent of the association energy of the C–H bond of the substrate but is correlated with its ionisation potential and its ability to coordinate to the cobalt(III) ion[28].

In the presence of O_2 the kinetic parameters of the reaction remain unchanged[33], but the products are the corresponding aldehydes and acids. Thus the presence of oxygen does not affect the rate-determining stage of the reaction—the loss of a proton by the radical-cation formed via mechanism (1). The reactivity of arylalkanes decreases in the sequence p-xylene > PhMe > PhEt > PhPr-iso > p-ClC_6H_4Me. [31,32]. The rate of reaction increases in the presence of AcO^- and decreases as cobalt(II) accumulates in the reaction mixture[28,32]. The latter factor demonstrates, in particular, the possibility of electron transfer in reaction (1).

Another explanation of the inhibiting effect of cobalt(II) involves the formation of dinuclear Co(III)–Co(II) complexes with a greatly reduced oxidation-reduction potential[27–35]. According to Kawai and Kamiya[34], the addition of manganese, platinum, and cerium acetates in both the highest and lowest oxidation states also reduces the oxidising capacity of cobalt(III) up to the complete disappearance of activity for certain molar proportions. The inhibition sequence is as follows: Mn(II) > Mn(III) ≅ Ce(IV) > Cu(II). The formation of polynuclear cobalt(III) complexes has also been confirmed by spectroscopic methods[34]. However, it is of interest that the Co(III)–Co(II) combination, which is inactive in the oxidation of toluene, exhibits the same activity as cobalt(III) in the oxidation of 1-methylnaphthalene[34].

The activity of cobalt(III) increases appreciably in the presence of halide ions (Cl^- and Br^-) [31,38-40] and also organic bromo-derivatives—bromobenzene, dibromoethane, butyl bromide, etc.[38] It has been shown[39] that in the presence of an excess of chloride ions in the CTA–AcOH system the highly reactive hexachlorocobaltate(III) anion is formed and decomposes rapidly with formation of Cl_2 and $CoCl_2$. In the presence of smaller amounts of Cl^- the formation of mixed cobalt(III) acetate-chloride complexes, which also exhibit an enhanced reactivity, is more likely. The existence of such complexes has been confirmed by spectroscopic data[31].

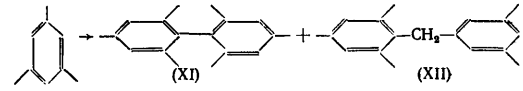
The main product of the oxidation of toluene by CTA in the presence of LiCl is benzyl chloride, but, with increase of the Cl^- concentration, its yield falls as a consequence of the formation of ring-chlorination products[31]. The reaction of 2-methylnaphthalene proceeds analogously[31]. On the other hand, in the presence of Br^-, toluene gives rise exclusively to benzyl bromide[40].

It is of interest to note that the interaction of CTA with Br^- in acetic acid at 70 °C is complicated, which is believed[41] to be due to the presence in solution of two forms of CTA—$[Co(AcOH)_6]^{3+}(OAc)_3$ and $[Co(OAc)_3(AcOH)_3]$ in proportions of ~1:1. It has been suggested that the oxidation of Br^- takes place after the exchange of the ligands of the cobalt atom from bromide, the first form reacting rapidly with Br^- and the second form slowly, i.e. the rate of reaction is limited by the ligand exchange stage.

On the other hand, X-ray diffraction studies[42] have shown that CTA has the structure of an O-centred trimer $[Co_3O(OAc)_6(AcOH)_3]OAc$ containing two types of acetoxy-groups—bridging and chelate, which may also be the cause of the existence of two stages in the reaction of cobalt(III) with Br^-.

The formation of benzyl bromide in the oxidation of toluene in the presence of Br^- is attributed[33,41] to the simultaneous reactions involving the bromination of the substrate by the liberated bromine and the "cobalt bromide" complex via the mechanism

$$\mathrm{Co\,(III) + Br^- \rightleftarrows [Co\,(II)\ldots Br^{\cdot}]}\ ;$$
$$\mathrm{RH + [Co\,(II)\ldots Br^{\cdot}] \rightarrow Co\,(II) + R^{\cdot} + Br^- + H^+}\ ;$$
$$\mathrm{R^{\cdot} + [Co\,(II)\ldots Br^{\cdot}] \rightarrow RBr + Co\,(II)}\ .$$

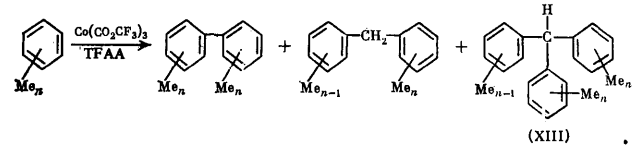


The Co(III)–Br^- system is widely used as a catalyst in industrial liquid-phase oxidation of alkyl derivatives of aromatic compounds, but the mechanism of the so-called cobalt bromide catalysis is still controversial (see, for example, Emanuel' [1] and Zakharov[43]).

The oxidising properties of cobalt(III) increase appreciably in the presence of strong acids. The addition of H_2SO_4, CCl_3CO_2H, $HClO_4$, H_3PO_4, and BF_3 increases the rate of oxidation of alkylarenes by cobalt(III) acetate so much that these reactions can be carried out at room temperature[36]. Thus, in the oxidation in acetic acid in an inert atmosphere, the reaction products are substituted benzyl acetates, while in the presence of O_2 they are aldehydes and acids[36]. The activating effect of strong acids has been explained[36,44] by the destruction of the cobalt(III) cluster complexes (see above), by the formation of monomeric species, and by the enhanced electrophilic properties of the metal atom. However, one should note that the increase of the concentration of strong acid increases the activity of cobalt(III) so much that the oxidation of the solvent (acetic acid) becomes a competing process at 25 °C.[36]

The benzyl acetate formed in the oxidation of toluene in the CTA–AcOH–$HClO_4$ system reacts with toluene when the temperature is raised (up to 114 °C), giving a mixture of phenyltolylmethanes[45]. Under these conditions, other alkylbenzenes (PhEt, p-$ClC_6H_4CH_3$, xylenes, and mesitylene) also give rise to mixtures of diarylmethanes and small amounts of monoaldehydes, whose relative content increases in the presence of oxygen[45].

Trifluoroacetic acid (TFAA) occupies a special place among acid activators. The formation of complexes involving charge transfer between cobalt(III) and the aromatic substrate has been discovered in TFAA solutions[46]. The dissociation products of such complexes are cobalt(II) and the substrate radical-cation [see mechanism (1)] stabilised by the TFAA.[46] The efficiency of such stabilisation is so great that it makes it possible to obtain well resolved EPR spectra of the radical-cations even in the case of the relatively unstable dialkylbenzenes[46].



On the other hand, the breakdown of the cluster structure of the CTA and the ligand exchange in the interaction between CTA and TFAA are fairly slow, so that solutions of cobalt(III) acetate and trifluoroacetate in TFAA exhibit different reactivities[48,49]. The reaction of mesitylene with cobalt triacetate in TFAA proceeds via the mechanism

(13)

and yields 2% of compound (XI) and 20% of compound (XII), while in the analogous reaction with $(CF_3CO_2)_3Co$ the yields of compounds (XI) and (XII) are respectively 16 and 9%. It is of interest that the yield of compound (XI) increases in the latter case with decrease of temperature and reaches 41% at −12 °C with simultaneous formation of 21% of nonamethyl-*m*-terphenyl.[49] When reaction (13) is carried out in the $(CF_3CO_2)_3Co$–TFAA–$C_2Cl_2H_4$ system (80 °C), the product ratio (XI):(XII) varies from 0 to 1.8 as the TFAA concentration rises from 0 to 100% [in pure $C_2Cl_2H_4$ and in mesitylene compound (XII) is formed in 28% yield].[49]

The oxidation of toluene, xylenes, pseudocumene[49], and durene[48] proceeds via the general mechanism

The biaryls (X) are hardly formed in the case of toluene, p-xylene, and durene, while the yield of compounds (XIII) and (X) is a maximum for *m*-xylene and pseudocumene.

The use of this reaction for the oxidation of mixtures of aromatic hydrocarbons[48] can be regarded as a valuable method of synthesising asymmetric biaryls and diarylmethanes (see, for example, Kozhevnikov and Matveev[50]). Under analogous conditions, benzene is readily oxidised to phenyl trifluoroacetate (the yield reaches 90%,[51,52] falling in the presence of an excess of benzene owing to the formation of a mixture of polyphenyls). Chlorobenzene and trifluoromethylbenzene are formed similarly albeit in lower yields[52].

The oxidation of aromatic substrates by cobalt trifluoroacetate in the presence of inorganic anions makes it possible to obtain in high yields the products of nucleophilic substitution in the aromatic ring via mechanism (8).[54] Thus the oxidation of benzene in the TFAA–LiCl–$Co(OCCF_3)_3$ system yields a mixture of phenyl trifluoroacetate and chlorobenzene (~1:1) for the ratio $Co(III)/Cl^- = 1$. An increase of the Cl^- concentration fully suppresses trifluoroacetoxylation, while the yield of chlorobenzene reaches 90%. Bromo- and iodobenzenes can be obtained analogously but in lower yields[53].

The oxidation of toluene under these conditions leads to a complex mixture containing chlorotoluenes, benzyl chloride, and compounds of types (X), (VII), and (XIII).[53] It is of interest that in the presence of air the main products are chlorotoluenes, while in an inert atmosphere benzyl chloride is mainly formed. The reaction thus involves processes described by mechanisms (5)–(10). The reactions of $Co(OCOCF_3)_3$ in the presence of F^-, CN^-, NO_2^-, and NO_3^- have also been studied[53].

In aqueous solutions of trifluoroacetic acid in the presence of halide ions, even toluenes containing strongly electron-accepting substituents can be oxidised by cobalt(III) acetate. Thus *p*-toluic acid is oxidised in the $CF_3COOH–H_2O–Hal$ system at room temperature and gives rise to the products of the oxidative halogenation of the aromatic ring and (or) the side chain[54,55]. In the presence of KCl the main product is 3-chloro-4-methylbenzoic acid, while the reaction in the presence of NaBr gives rise mainly to 4-carboxybenzyl bromide[54]. In the latter case the side products are hydroxy-, acetoxy- and trifluoroacetoxy-methylbenzoic acids. 4-Hydroxymethylbenzoic acid—a valuable monomer for the synthesis of polymeric materials, which are superior as regards many parameters to the analogous materials based on terephthalic acid—can be obtained by hydrolysing the above reaction mixture[55].

The use of cobalt(III) chelates (acetylacetonate, benzoate, δ-quinolinate, etc.) makes it possible to carry out the reaction in non-polar solutions[56–58]. Thus the oxidation of 2,6-xylenol with cobalt(III) salicylideneaminates in toluene proceeds via an oxidative coupling mechanism and gives rise to a mixture of 4,4′-dihydroxy-3,5,3′,5′-tetramethylbiphenyl and the corresponding quinone[57]. It has been suggested[54] that the reaction involves the dimerisation of a radical formed via the mechanism

$$CoL_3 + RH \rightleftarrows CoL_2 + R^{\cdot} + HL \quad .$$

The kinetics of the oxidation of cumene by cobalt(III) chelates have been studied[58], but there are no data on the products of this reaction.

3. Manganese(III)

The reactions of manganese triacetate (MTA) in acetic acid with *p*-methoxytoluene[59] or toluene in the presence of NaBr[40] and with alkylbenzenes in the presence of strong acids[36] proceed analogously to the corresponding reactions of cobalt triacetate and are characterised by the same kinetic features i.e. they include the stage of the reversible electron transfer to the metal atom [mechanism (1)].

Like cobalt(III) acetate, manganese(III) acetate oxidises *p*-toluic acid in trifluoroacetic acid in the presence of chloride and bromide ions with formation of products of the oxidative halogenation of the aromatic ring and (or) side chain, but in this instance the reaction in the $Mn(III)–Cl^-$ system leads almost exclusively to a 3-chloro-4-methylbenzoic acid (yield ~100%).[54]

In the absence of activators, the reactions with manganese(III) salts require increased temperatures and are accompanied by radical substitution reactions because of the lower oxidising capacity of the metal ion (Table 1). The thermolysis of manganese(III) carboxylates proceeds, in conformity with mechanism (3), via two pathways, depending on the structure of the ligand[60]. The formation of carboxymethyl radicals is the preferred pathway (98 to 100%) for MTA. In the reaction involving manganese(III) propionate the alternative pathway involving decomposition with formation of $CH_3\dot{C}H_2$ makes a contribution of ~6%, while the thermolysis of phenylacetate proceeds almost exclusively via this pathway [see mechanism (3)].[60] Thus, on oxidation with MTA in acetic acid (110 °C), benzene and chlorobenzene give rise to mixtures of the corresponding phenylacetic acids, benzyl acetates, benzylidene acetates, and benzaldehydes, while toluene gives rise to methylbenzyl acetate (67%), benzyl acetate (10%), benzaldehyde (3%), and traces of bibenzyl[61]. Acetoxymethylation products also arise from the oxidation at 100 °C of anisole[60,62], dimethoxybenzenes[61], and 2-methylnaphthalene[60].

The thermolysis of MTA (including electrolytically generated MTA[63]) in acetic acid can also be used for the introduction into the aromatic substrate molecule of other radicals generated via the mechanism

$$RH + \dot{C}H_2CO_2H \rightarrow R^{\cdot} + AcOH \quad .$$

For example, the nitromethylation ($R = CH_2NO_2$) [63,64] and acetylmethylation ($R = CH_3COCH_2$) [65] of toluene and substituted benzenes have been achieved in this way.

It is of interest that the oxidation of methylferrocene with MTA in acetic acid does not yield acetoxymethylation products, but leads to a mixture of diarylmethanes[66]:

$$AcOH \xrightarrow{MTA} \dot{C}H_2CO_2H \xrightarrow{RCH_3} RCH_2^{\cdot} \xrightarrow{MTA} RCH_2^{+} \xrightarrow{RCH_3} RCH_2R' \quad ,$$

where R = ferrocenyl and R′ = 2-methylferrocenyl, 3-methylferrocenyl, or 3′-methylferrocenyl.

In the oxidation of substrates with fairly low ionisation potentials (<8 eV) an electron transfer process competes with radical substitution. Thus 1- and 2-methoxynaphthalenes are acetoxylated in the ring at 100 °C,[67] while *p*-methoxytoluene yields mainly *p*-methoxybenzyl acetate[59,60]. The selectivity of the reaction can therefore be regulated by suppressing or activating one of these processes.

The thermolysis of MTA in acetic acid (140 °C) is accelerated by a factor of 3–4 when potassium acetate is added[62] and also increases appreciably when acetic anhydride is added to the reaction mixture[68] or anhydrous MTA is used[60,68]. The relative yield of the acetoxymethylation product also increases following the addition of manganese(II), which retards the electron transfer reaction, as in the case of cobalt(III) (see above)[60].

On the other hand, radical processes are fully suppressed in the presence of strong acids, which makes it possible to reduce the reaction temperature to 20–40 °C.[36] The products of the oxidation of alkylarenes under these conditions are, as for cobalt(III), benzyl acetates in an inert atmosphere and carboxy-compounds in the presence of oxygen.

The oxidation of alkylbenzenes in boiling acetic acid in the presence of H_2SO_4, CF_3SO_3H, and particularly $HClO_4$ leads to the formation of diarylmethanes in high yields[45]. Under these conditions, the effect of MTA is analogous to those of CTA (see above) and the iron(III) perchlorate normally employed in this reaction (see below), differing, however, by a greater selectivity (the amount of disproportionation and polymerisation products is in this instance minimal), which makes the process synthetically valuable.

In contrast to alkylbenzenes, *p*-methoxytoluene yields under these conditions biaryls, but in the presence of weaker acids (CCl_3CO_2H, CF_3CO_2H) or at lower $HClO_4$ concentrations the main products become diarylmethanes[42]. It is of interest that in the analogous reaction with $Fe(OAc)_3$ only diarylmethanes are formed in both cases. The different behaviour of manganese(III) and iron(III) acetates has been explained[42] by the different stabilities of the trinuclear clusters of the type $[M_3O(OAc)_6L_3]OAc$ (L = AcOH for manganese and H_2O for iron), which act as bases in the reaction involving the elimination of a proton from the radical-cation (see above).

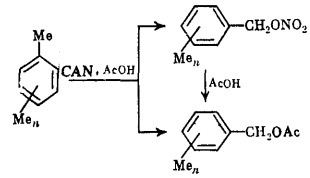
Manganese(III) trifluoroacetate reacts with mesitylene[48,49] and durene[49] in TFAA with formation of mixtures of dehydrodimers [see mechanisms (7)–(10)], but, in contrast to cobalt(III) (again see above), mainly diarylmethanes are formed in this instance and the reactivities of MTA and $Mn(OCOCF_3)_3$ solutions in TFAA are virtually identical[48].

Manganese(III) sulphate oxidises the methyl group in 1-methylnaphthalene, giving rise to the corresponding aldehyde and 1,4-naphthoquinone, but in the case of 2-methylnaphthalene the oxidation does not involve the methyl group and the reaction products are only 2- and 6-methyl-1,4-naphthoquinones[69].

The oxidation of 1-bromonaphthalene under these conditions is accompanied by a 1,2-shift to the substituent and the formation of 2-bromo-1,4-naphthoquinone, as in the oxidation with cerium ammonium sulphate (see below).

Like CoF_3, manganese(III) fluoride oxidises benzene to a mixture of cyclic polyfluoro-derivatives[18], but it acts more selectively and yields mainly polyfluorocyclohexenes.

4. Cerium(IV)



The first data on the oxidation of substituted toluenes to benzaldehydes by cerium dioxide in H_2SO_4 were obtained at the beginning of this century[70,71], but the yields of these reactions were not indicated and the yield of benzaldehyde in the oxidation of toluene by electrolytically generated cerium(IV) sulphate, described much later[72], amounted to only 8%.

Systematic studies of the oxidation of alkyl derivatives of aromatic compounds by cerium(IV) salts probably began towards 1965 when the quantitative oxidation of benzyl alcohols to benzaldehydes by cerium ammonium nitrate (CAN) in 50% acetic acid solution was described[73]. It was later shown[74] that under these conditions benzaldehydes are the main products of the oxidation of toluenes (benzyl alcohols and benzyl acetates are formed simultaneously). The yield of benzaldehydes increases on passing from toluene to *p*-xylene from 36 to 73%, but the introduction of stronger electron-donating substituents (OH, NH_2, or OMe) leads to the charring of the reaction mixture. Electron-accepting substituents lower the overall yield of oxidation products and in the case of *p*-chlorotoluene a simultaneous increase of the fraction of *p*-chlorophenylmethanol was observed[73]. In 100% acetic acid the main reaction products are benzyl acetates, whose yield also falls on passing to *p*-halogenotoluenes with a simultaneous increase of the fraction of carbinols and aldehydes in the reaction products; *p*-nitrotoluene is not oxidised at all under these conditions, but the replacement of acetic acid by 6 *N* $HClO_4$ or 3.5 *N* HNO_3 makes it possible to oxidise to aldehydes even chloro- and nitro-toluenes (with yields up to 75 and 50% respectively)[74,75]. Under the same conditions, toluene and mesitylene give rise to monoaldehydes in a quantitative yield, while ethylbenzene and diphenylmethane are oxidised to acetophenone and benzophenone with yields of 78 and 76% respectively[75]. The quantitative synthesis of anisaldehyde in 90% acetic acid from *p*-methylanisole, which completely charred in 50 and 100% acetic acid according to Trachanovsky and Young[74], has also been described[75].

The reactivity in the oxidation by CAN in aqueous acetic acid solutions decreases in the sequence *p*-xylene > *m*-xylene > *o*-xylene > toluene[76]. The reaction is accelerated in the presence of HNO_3 and is retarded by the addition of AcO^-, the rate of oxidation being a maximum in ~85% of acetic acid in all cases. The activating effect of HNO_3 is attributed[76] to the formation of the cation $Ce(NO_3)_2^{2+}$, but the inhibiting effect of added AcO^- is believed to be due to a decrease of oxidising activity when the ligands in the hexanitratocerate(IV) anion are exchanged for acetate ions[76].

The kinetics of the oxidation of toluene[77,78], xylenes[78], and nitro- and chloro-toluenes[76] by cerium(IV) in an AcOH–$HClO_4$ mixture are described by a second-order equation and the reaction mechanism is said to include[77,78] electron transfer and the formation of a benzyl-type radical as the rate-limiting stage. However, it is of interest that *p*-chlorotoluene is oxidised faster than toluene under these conditions; this has been explained[77] by the "specific features of the resonance interaction". The primary and main products of the oxidation of substituted toluenes by CAN are benzyl nitrates, which can be isolated in a fairly satisfactory yield when the reaction is carried out in hydrocarbon solvents, but in reactions in aqueous acids they are rapidly hydrolysed to carbinols, which are subsequently oxidised to aldehydes[79]. In the case of *o*-xylene the nitrate/aldehyde ratio varies from 1.5 to 4, the yield and ratio of the products depending on the rate of addition of the CAN solution, the nature of the acid (HNO_3, H_2SO_4, or AcOH), and the presence of an aliphatic hydrocarbon solvent. It is believed[79] that the reaction involves the formation of a cyclic transition state with a dimeric cerium(IV) complex, leading to nitrates and carbinols as a result of the transfer of two electrons and a proton. In the case of toluene and *p*-xylene, containing a sterically unshielded methyl group, the nitrates formed are more labile and both reactions terminate with formation of an aldehyde.

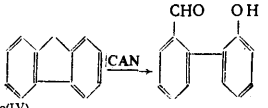
The oxidation of polymethylbenzenes (mesitylene, isodurene, hemimellitol and hexamethylbenzene) by CAN in acetic acid is described by a similar mechanism[80]:

The required stoichiometric ratio CAN/substrate = 2 decreases in the presence of oxygen. The nitrate/acetate ratio depends on the reaction time and the rate of solvolysis of the nitrate and varies from 1.5 for mesitylene to 5 for hemimellitol, increasing with increase of the fraction of undissolved CAN under heterogeneous conditions and being virtually independent of the structure of the substrate in the presence of NH_4NO_3 in the reaction mixture.

The proportions of the products in the case of isodurene and hemimellitol show that the oxidation involves mainly the 2-methyl group, which confirms the formation of a substrate radical-cation (the radical substitution takes place mainly in the 5-position[81]). The benzyl radical formed in the second stage of the reaction is oxidised further, according to the data of Baciocchi et al.[80], but not via carbonium ion [mechanism (6)]; it results from ligand transfer and proceeds via an intermediate with a Ce(IV)–CH_2Ar linkage, undergoing subsequently competitive oxidative solvolysis with formation of the acetate or with oxidative substitution yielding the nitrate#.

According to Eberson and Oberrauch[82], the anodic oxidation of isodurene in the AcOH–Bu_4NNO_3 mixture and the reaction of isodurene with CAN give virtually identical results, but the authors[82] suggest that the first stage in the

#For further details about the mechanism of oxidative substitution and solvolysis, see C.L.Jenkins and J.K.Kochi, J.Amer.Chem.Soc., 92, 856 (1972).



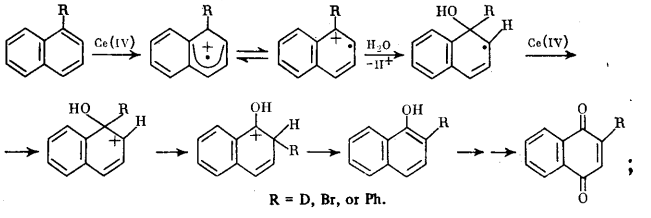
reaction with CAN involves the transfer of an α-hydrogen from the substrate molecule via mechanism (2*a*) (X = NO_3).

Among all the polymethylbenzenes, only mesitylene undergoes ring acetoxylation apart from benzyl oxidation, the yield of 2,4,6-trimethylphenyl acetate amounting to 50% of the beginning of the reaction and falling to 25% towards its end[78] (however, one should note that the oxidation of mesitylene by CAN in acetonitrile gives rise only to 3,5-dimethylbenzyl nitrate[83]). The formation of a "ring" acetate in the case of mesitylene is consistent with data for the oxidation of methylbenzenes by cerium(IV) trifluoroacetate in the presence of $LiOCOCF_3$, which leads to the preferential formation of biaryls (X) (40%) [together with diarylmethanes (VII) (10%) and benzyl trifluoroacetate (~1%)—see mechanisms (6)–(10)][84], the ratio (X) : (VII) falling with increase of reaction temperature and with increase of the $LiOCOCF_3$ concentration. Under these conditions, benzene is oxidised with difficulty (8% of phenyl trifluoroacetate and 1% of biphenyl are formed), toluene gives rise only to a mixture of phenyltolylmethanes (15%) and benzyl trifluoroacetate (15%), *p*-xylene yields methylbenzyl trifluoroacetate (8%) and diarylmethanes (10%), while durene is converted into biduryl (2%) and diarylmethanes (97%).[84]

Another example of ring acetoxylation is the oxidation of anisole by CAN in acetic acid (40 °C, N_2),[85] which leads to a mixture of *o*- and *p*-acetoxyanisoles (*o*/*p* = 0.82). The reaction is of first order with respect to PhOMe and CAN and of the reciprocal order with respect to cerium(III); it is greatly accelerated by the addition of ammonium nitrate. The reaction products do not contain nitrates and the proportions of the isomeric acetates are consistent with the distribution of electron density in the anisole radical-cation [the EPR spectra of the aromatic radical-cations obtained by oxidation with cerium(IV) salts have been described[86]]. The reactions have mechanism (8) (see above).

In 90% trifluoroacetic acid in the presence of alkali metal chlorides and bromides CAN reacts fairly readily with *p*-toluic acid to form products of the oxidative halogenation of the aromatic ring—3-halogeno-4-methylbenzoic acids[54]. It has been suggested that the occurrence of a reaction via mechanism (8) is facilitated in this instance by the formation of cerium(IV) complexes containing ligands in steric proximity—halides and 4-methylbenzoate ions[54]. It is of interest that, with increase of the water content in the reaction system, the yield of ring halogenation products falls owing to the formation of the corresponding benzyl halides, which is associated, according to the authors[54], with the displacement of arenecarboxylate ligands from the inner coordination sphere of the oxidant by water.

In the oxidation of 1,2-diarylethanes by CAN in 70% aqueous acetonitrile[87] the first stage also involves the formation of a radical-cation, which decomposes into a benzyl radical and a benzyl cation, leading to benzaldehydes, benzyl nitrates, and benzyl alcohols. The rate of reaction increases after the introduction of electron-donating substituents into the aromatic ring and falls when electron-accepting substituents are introduced. The oxidation of fluorene[88] and aryl triarylmethyl ketones by CAN in acetic acid also involves the oxidative cleavage mechanism[89]:



$$Ar_3CCOAr' \xrightarrow[-2Ce(III)]{2Ce(IV)} Ar_3C^+ + Ar'CO^+ \rightarrow Ar_3COH + Ar'CO_2H \ .$$

In the first stage of its oxidation with CAN in methanol or acetic acid[90], anthracene gives rise to 9-anthryl nitrate, whose reaction with the anthracene radical-cation produces 9-anthryl nitrite and the anthrol radical, which is then converted into bisanthrone or is oxidised by CAN to 10-acetoxy- and 10-methoxy-anthrols and also to anthraquinone (via 9,10-dihydro-10-oxo-9-anthryl nitrate). On the other hand, it has been shown[91] that the analogous reaction in acetonitrile gives rise to a 3 : 1 mixture of anthraquinone and 9-nitroanthracene. Ring nitration products are formed under these conditions also from benzene, nitrobenzene, toluene, and naphthalene.

The oxidising properties of CAN can be used successfully also in reactions of alkylarenes with acyl peroxides, for example, via the mechanism[92]

$$(iso\text{-}PrCO_2)_2 + 2[Ce(NO_3)_6](NH_4)_2 + PhMe \rightarrow o\text{-}MeC_6H_4Pr\text{-}iso + 2Ce(NO_3)_3 + 4NH_4NO_3 + 2HNO_3 \ .$$

An interesting reaction (a 1,2-shift of the substituent) has been discovered in the study of the oxidation of 1-substituted naphthalene by cerium ammonium sulphate[93]. The anodic oxidation of the same substrates proceeds analogously[94]:

R = D, Br, or Ph.

Cerium pyridinium chloride $(C_5H_5N)_2CeCl_6$ (CPC) has been used to oxidise polymethylbenzenes in methanol and ethanol[95]. In the case the oxidant consists of the products Ce(IV) $(Cl)_x(RO)_y$ of the ligand exchange between CPC and the solvent, which exhibit different reactivities depending on R. The rate of the oxidation and "spontaneous" reduction of CPC in methanol is higher by two orders of magnitude than in ethanol. In the absence of oxygen, the reaction products are the corresponding benzyl chlorides and alkoxymethylbenzenes, the latter becoming the sole reaction product after more prolonged refluxing of the reaction mixture, which makes this process valuable from the synthetic point of view. It is of interest that, in contrast to hexamethylbenzene and durene, which give satisfactory yields of products, mesitylene is almost inert with respect to oxidation under these conditions.

The ratio of the chloro- and methoxy-derivatives in the oxidation of durene by CPC in methanol remains constant during the reaction, increasing after the addition of LiCl, but under these conditions methoxylation is not fully suppressed, which confirms the ligand transfer mechanism in the benzyl radical oxidation stage proposed by the author[95] (see above). In the reaction in the presence of oxygen, the dimethylacetate of 2,4,5-trimethylbenzaldehyde is formed from durene, but hydrolyses during isolation (the yield of aldehyde is 65%). It is of interest that the oxidation of Cl^- to Cl_2, which takes place with difficulty in alcohols, occurs readily when CPC is refluxed in acetonitrile.

Like cobalt(III) and manganese(III) fluorides (see above), cerium tetrafluoride is used to synthesise cyclic polyfluoro-derivatives from benzene (250–480 °C). However, this results in a mixture containing polyfluorobenzenes, polyfluorocyclohexenes, and polyfluorocyclohexadienes[18,96].

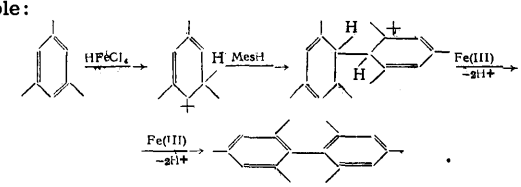
Cerium tetra-acetate reacts with toluene in acetic acid (110 °C) via the general mechanism (3) and give rise to three products: (I)–(III).[97] The thermolysis of $Ce(OAc)_4$ in acetic acid takes place in the same way as for $Mn(OAc)_3$

with formation of carboxymethyl radicals, but, in contrast to manganese(III), the acetoxymethylation is in this case suppressed by the addition of acetic anhydride and potassium acetate. The reaction with benzene and chlorobenzene yields only arylacetic acids (41 and 36%). The authors suggest[97] that the role of acetic anhydride consists in binding the acids produced into mixed anhydrides, which are resistant to oxidation.

It is of interest that the photolysis of $Ce(OAc)_4$ is accompanied by decarboxylation and the formation of methyl radicals [see mechanism (3)].[97]

5. Iron(III)

Potassium hexacyanoferrate(III) $K_3Fe(CN)_6$ and iron(III) chloride $FeCl_3$ are most frequently used as oxidants. The hexacyanoferrate(III) is normally employed in aqueous solutions and, being a weak oxidant, is capable of oxidising only aromatic compounds with a fairly low ionisation potential (such as methylphenols[98,99] and alkoxybenzenes[99]), giving rise thereby to substituted biphenyls.



Under alkaline conditions (DMSO–H_2O–OH^-), substituted toluenes containing powerful electron-accepting groups (NO_2 or Me_3N^+) can also be oxidised as a result of the formation of benzyl anions:

$$ArCH_3 \xrightarrow[DMSO]{OH^-} ArCH_2^- \xrightarrow{Fe(III)} ArCH_2^{\cdot} \xrightarrow{Fe(III),\ H_2O} ArCH_2OH \ .$$

The rate of reaction increases with increase of the DMSO content in the solvent and after the introduction of halide ions (Cl > Br > I).[100]

In contrast to the hexacyanoferrate(III), anhydrous iron(III) chloride is a fairly powerful oxidant and interacts with aromatic compounds to form chlorination and dehydrodimerisation products. These reactions have been known since the end of the last century and have been discussed in fair detail in reviews[101,102]. It is noteworthy that interest in reactions of this type has not flagged. Thus conditions have been found for the polychlorination of benzene with iron(III) chloride in a melt with NaCl in the presence and absence of O_2.[103] The oxidative coupling of alkylarenes by iron(III) salts is being particularly vigorously investigated[49,104–107].

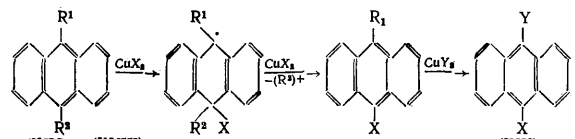
The mechanism of the formation of biaryls proposed by Kovacic and coworkers[102] presupposes the protonation of the substrate by the HCl–$FeCl_3$ complex and further transformations of the type of cationic polymerisation, for example:

The reactivity of polymethylbenzenes should thus be determined by their basicity, but it has been shown[104–106] that the ionisation potential of the substrate is of decisive importance in these reactions and the formation of biaryls and diarylmethanes under the influence of $FeCl_3$ has much in common with anodic oxidation and includes therefore electron transfer [mechanism (1)] and electrophilic attack on the substrate via mechanisms (7), (9), and (10).

The oxidation of polymethylbenzenes by iron(III) chloride leads to the formation of diarylmethanes in all cases, except for *m*-xylene and mesitylene[49,103–106]. A detailed study of the oxidation of mixtures of methylbenzenes under these conditions showed that radicals of the benzyl type and hence diarylmethanes [see mechanism (6)] are formed from radical-cations with a high charge density in the substituted position of the aromatic ring (for example, in the case of durene). Accordingly, durene in mixtures with benzene, *p*-xylene, toluene, and mesitylene yields only diarylmethanes[103], while the analogous reaction of naphthalene can serve as a preparative method for the synthesis of 1-arylnaphthalenes[105]. The yield of products in the latter case depends on the nucleophilic properties of the alkylarene relative to the naphthalene radical-cation.

It is of interest that even durene and xylene give rise to ring-chlorinated compounds only as side products on treatment with $FeCl_3$.[49,102] Only mesitylene is appreciably chlorinated in the ring under these conditions[49]. The yield of chloromesitylene decreases with increase of the reaction temperature and in the presence of water and also increases with increase of the $FeCl_3$ mesitylene ratio. Chlorination thus probably proceeds via ligand transfer in the complex of $FeCl_3$ with the substrate radical-cation and not via mechanism (5).[49] The reactions under the influence of copper(II) halides takes place similarly (see below).

The oxidation of methylbenzenes by various iron(III) salts (chloride, nitrate, sulphate, acetate, and perchlorate) in boiling acetic acid in the presence of $HClO_4$ also leads to the selective synthesis of diarylmethanes[45,106]. It is of interest that the yield of diarylmethanes increases in the sequence PhPr-iso << PhEt < *p*-ClC_6H_4Me, while in the reactions of $FeCl_3$ with the same substrates in the absence of a solvent the opposite sequence obtains: PhMe < *p*-ClC_6H_4Me < PhEt < PhPr-iso.[101] The catalytic nature of the reaction in relation to the iron(III) salt in the presence of $HClO_4$, noted in many instances[105], has been shown[107] to be caused by the oxidation by perchloric acid of the $FeCl_2$ produced, so that the synthesis of diarylmethanes can be carried out in the $FeCl_2$–$HClO_4$ system[107].



6. Copper(II) §

Copper(II) halides are usually employed as halogenating agents under both heterogeneous[107–117] and homogeneous[117–126] conditions. The photolysis of $CuCl_2$ in toluene affords benzyl chloride (86%) via the mechanism

$$PhCH_3 + Cl^{\cdot} \rightarrow PhCH_2^{\cdot} \xrightarrow{CuCl_2} PhCH_2Cl + CuCl \ .$$

Small amounts (0.5%) of chlorotoluenes and bibenzyl are formed at the same time[108].

The heterogeneous reactions of copper(II) salts usually involve the oxidation of a radical intermediate formed as a result of ligand transfer in the first stage [mechanism (2)]. The halogenation of anthracene and 9-substituted and 9,10-disubstituted anthracenes (XIV)–(XVIII) in non-polar solvents (PhCl, CCl_4, etc.) takes place in this way[109,110]:

(14)

(XIV) – (XVIII) (XIX)

X,Y = Cl or Br

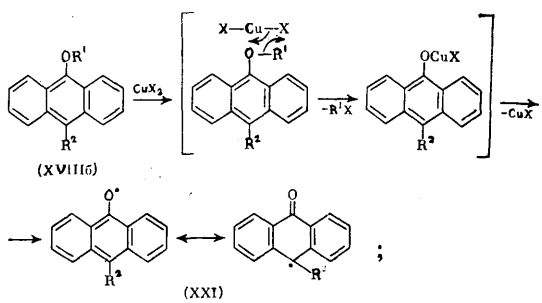
(XIV) a) R^1 = X, Y, Alk or Ar; R^2 = H; b) R^1 = X or Y; R^2 = Alk or Ar;
(XV) a) R^1 = OAlk or COAlk; R^2 = H; b) R^1 = H, R^2 = COAlk;
(XVI) R^1 = Alk or Ar; R^2 = Ar, Et or CH_2Ph;
(XVII) R^1 = Ar, Et, CH_2Ph, X or Y; R^2 = Me;
(XVIII) a) R^1 = OAlk or COAlk; R^2 = Me; b) R^1 = OAlk or OCOAlk; R^2 = H, Ph, Et or CH_2Ph.

§ The use of copper(III) complexes of oxidants has been described only for ascorbic acid and catechol [see Y.Yano, S.Takano, V.Kato, and W.Tagaki, J.Chem.Soc., Perkin Trans.II, 1227 (1979)].

According to mechanism (14), these reactions are accompanied by "transhalogenation" or substitution of hydrocarbon [compounds (XVI) [111,112]] or acyl [compounds (XVb) [113]] groups by the halogen. 9-Methylanthracene also reacts via mechanism (14),[109] but 10-substituted 9-methylanthracenes (XVII) and (XVIIIa) form under these conditions radicals of the benzyl type in the first stage[111,112] via the mechanism

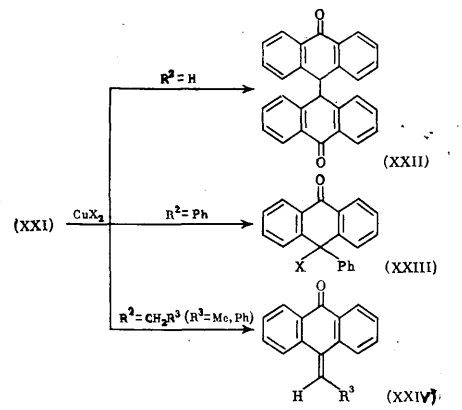
(XX)

In the case of substrates (XVII) the radical (XX) is oxidised further via mechanism (5) to a halogenomethyl derivative $ArCH_2X$. More stable radicals containing an acyl or alkoxy-group [compounds (XVIIIa)] dimerise to the corresponding diarylethanes under these conditions via mechanism (6).[114]



In the case of 9-alkoxy- (particularly methoxy) and 9-acyloxy-anthracenes (XVIIIb) there is also a possibility of the mechanism invclving the "radicalisation" of the substrate[115].

Depending on the substituents in the 10-position, the radical (XXI) dimerises further to bianthronyl (XXII), is halogenated to halogenoanthrone (XXIII), or gives rise to quinomethides (XXIV).[115]

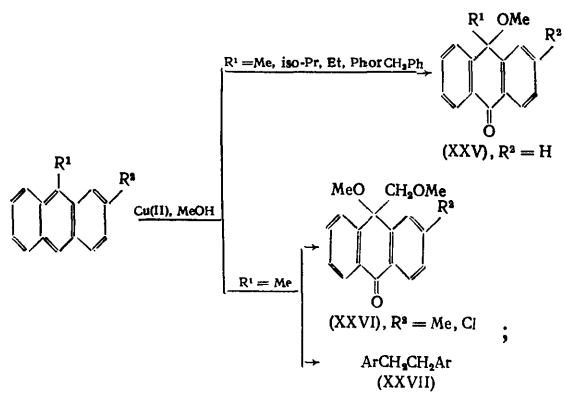


The reaction between $CuBr_2$ and 2-benzyloxynaphthalene proceeds analogously to reaction (15).[116] The product is a mixture of 2-benzyloxy-1-bromonaphthalene (17%), 1-bromo-2-naphthol (61%), di-β-naphthol (1.4%), and benzyl bromide (10%). It is of interest that $CuCl_2$ yields only products of the chlorination in the 1-position under these conditions. The reaction of $CuBr_2$ with 2-ethoxy- or 2-methoxy-naphthalene takes place in the same way[116]. The halogenation of pyrene, perylene, and tetracene by anhydrous copper(II) halides in non-polar solvents has also been described[117,118]. It has been suggested[116] that the reaction proceeds as homolytic decomposition of a π-complex of $CuCl_2$ with a substrate molecule. It is of interest that the oxidation proceeds in this instance in PhCl but not in CCl_4.[118]

Under homogeneous conditions, the CuX_2 molecule is as a rule solvated and cannot participate in the ligand transfer. In this case the mechanism involving electron transfer becomes more probable [mechanism (1)].

Thus, on treatment with CuX_2 (X = Cl or Br) in MeOH, 9-alkyl- and 9-aryl- anthracenes are converted by successive three-stage oxidation via mechanisms (1) and (8) into 10-alkyl and 10-aryl-10-methoxyanthrones (XXV).[119] As in other cases, when a methyl group is present, a benzyl-type radical is also formed from the substrate radical-cation and is converted via mechanisms (5) and (6) into methoxymethyl derivatives and diarylethanes (XXVII) (see above).

(XVIIIб) (XXI) (15)



(XXI) (XXII) (XXIII) (XXIV)

It is of interest that the products of type (XXVI) and (XXVII) are not formed in the presence of a substituted methyl group R^1, which is believed[119] to be due to steric factors, preventing the stabilisation of the radical ArĊHR.

Under homogeneous conditions, copper(II) bromide brominates 3,4,5-trimethylanisole in the ring[120]. Alkylbenzenes react similarly with anhydrous $CuBr_2$, but in the presence of even small amounts of water the main products are diarylmethanes (benzyl bromides are also formed in smaller amounts). Mesitylene gives rise to only bromomesitylene in both cases[121].

The heterogeneous oxidation of toluene, *p*-xylene, and mesitylene with copper(II) chlorides also proceeds via a radical-cation formation stage according to Cummings and Milner[122] and leads to the formation of diarylmethanes and ring-chlorination products in conformity with mechanisms (7) and (8), the yield of the latter increasing with increase of the stability of the radical-cation and amounting to 20% for $C_6H_4Me_2$ and 90% for $C_6H_3Me_3$.

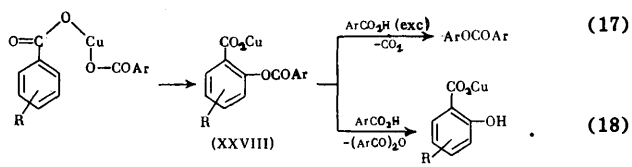
(XXV), $R^3 = H$; (XXVI), $R^3 = Me, Cl$; $ArCH_2CH_2Ar$ (XXVII)

$Ar = C_{14}H_9$, 2-$MeC_{14}H_8$ or 2-$ClC_{14}H_8$.

The yield of diarylmethanes decreases correspondingly from 90% for C_6H_5Me to 80% for $C_6H_4Me_2$. Diarylmethanes are formed exclusively when *p*-xylene is refluxed with $Cu(OAc)_2$ in acetic acid containing $HClO_4$.[45]

The ability of $CuCl_2$ to react via the ligand transfer mechanism [mechanism (2*b*)] has been used to oxidise the radical-cations generated by other oxidants[123]. The reaction of methylbenzenes with the peroxydisulphate anion in aqueous acetonitrile in the presence of $CuCl_2$ yields exclusively ring-chlorination products[123], while the pathway followed in the reaction of Cl^- with the corresponding radical-cations depends on the stability of the latter and the contributions of α-chlorination in the sequence mesitylene < *m*-xylene < *p*-xylene ≅ toluene are 25, 90, 100, and 100% respectively[123].

On the other hand, in the reaction of methylbenzenes with peroxydisulphate in acetic acid containing 9% of TFAA, the introduction of copper(II) acetate suppresses ring acetoxylation and promotes the formation of substituted benzyl acetates and trifluoroacetates. In the case of mesitylene the relative yield of the corresponding product is 92% [33% in the absence of copper(II)].[124]



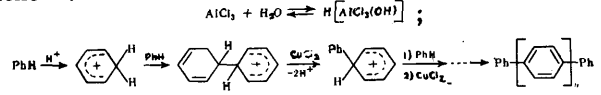
In conformity with the electron transfer mechanism, the oxidation of *p*-cymene in the $AcOH-S_2O_8^{2-}-Cu(OAc)_2$ system leads to isopropylbenzyl acetate[125]. The oxidation of the radical intermediate by copper(II) via mechanism (8) plays an important role in the acetoxylation of naphthalene under the same conditions. In the absence of copper(II) the reaction does not occur and the replacement of copper(II) by iron(III) leads to the formation of methyl- and acetoxymethyl-naphthalenes[125].

Copper(II) carboxylates introduce the acyloxy-group into the rings of alkyl derivatives of aromatic substrates via the following mechanism[126,127]:

$$2(R^1CO_2)_2Cu + PhR^2 \rightarrow R^2C_6H_4OCOR^1 + 2R^1CO_2Cu + R^1CO_2H \quad (16)$$

The yield of acyloxy-derivatives increases in the presence of copper(II) oxide, reacting with the liberated acid and (or) oxygen, which regenerates the copper(II) salt[127,128].

Substituted copper(II) benzoates can also be oxidised by an intramolecular mechanism with formation of *o*-benzyloxybenzoates (XXVIII):[128]



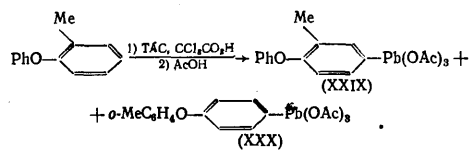
(17)

(18)

In the presence of water and an excess of acid, compound (XXVIII) is decarboxylated [mechanism (17)] with formation of the corresponding phenol after hydrolysis. Thus *o*- and *p*-toluic acids yield *m*-cresol under these conditions and *m*-toluic acid gives rise to a mixture of *o*- and *p*-cresols[126]. The thermolysis of copper(II) benzoate in benzoic acid produces phenyl benzoate, whose yield can be increased in the presence of oxygen, which regenerates copper(II). This reaction constitutes the basis of an industrial method for the synthesis of phenol from toluene via benzoic acid[126-128]. In aprotic media (Ph_2O, Ph_2CH_3, cyclohexane, etc.) the decarboxylation is suppressed and the reaction of compound (XXVIII) with the liberated acid molecule leads to the formation of salicylates [mechanism (18)].[126]

The interactions of alkylbenzenes (and also benzene, anisole, and diphenyl ether) with copper(II) benzoates usually yield the products of all three reactions. Thus in the case of toluene 51, 16, and 33% of the products correspond to the contributions of reactions (16), (17), and (18) respectively[126].

An interesting variant of the utilisation of the oxidising capacity of copper(II) is the application of $CuCl_2$ in combination with $AlCl_3$ for the cationic polymerisation of benzene[129]:



7. Lead(IV)

The reactions of aromatic compounds with lead(IV) salts include three main types of transformations depending on the type of substrate, nature of the ligands, and the conditions of synthesis: (a) the substitution of lead (plumbation) in the aromatic ring via S_E-type reactions, leading to the formation of aryl lead(IV) tricarboxylate[130-142], which then decomposes via heterolytic[138-142] or homolytic[130-137] mechanisms; (b) radical substitution via mechanism (3) under the conditions of thermal[128,143-154], photochemical[143-145], or radical-initiated[147] decomposition of lead(IV) carboxylates; (c) electron transfer from the substrate molecule via mechanism (1) with subsequent transformations of the radical-cation via mechanisms (5)–(10).[45,49,140,141,147]

Plumbation is usually less important in the reactions of lead(IV) carboxylates than, for example the substitution of thallium (thallation) in the case of thallium(III) (see below), but the contribution of this reaction becomes appreciable with increasing nucleophilicity of the aromatic ring in the presence of strong electron-donating substituents. Anisole and dimethoxybenzenes[130-133] are plumbated even on treatment with lead tetra-acetate (LTA) in acetic acid at 80 °C. Acetoxylation via a one-electron transfer mechanism with formation of a radical-cation [mechanisms (1) and (8)] and giving rise to acetoxyanisoles in the case of anisole (*o*/*p* = 35/65) is a competing reaction under these conditions. *m*-Dimethoxybenzene, which is the most reactive in plumbation reactions, exhibits the smallest tendency towards acetoxylation under these conditions[133]. The role of plumbation increases also with the increase of the electrophilicity of the lead(IV) atom as a result of the addition of strong acids. The replacement of acetic acid by halogenoacetic acids leads to the formation of lead(IV) halogenoacetates, giving rise to plumbation products even at room temperature[134-137]. The plumbation of 2,4-dimethoxybenzene by lead(IV) monohalogenoacetates leads to the trishalogenoacetates $ArPb(OCOCH_2X)_3$ (X = Cl, Br, or I) in yields of 94–99%.[134] The reaction with aromatic ethers PhOR (R = Me, Et, n-Bu, or Ph) proceeds similarly, but, when they are isolated from reaction mixture, hydrolysis products are formed—the oligomers of plumboxanes $\{[ArPb(OCOR)_2]_2O_2\}_m$, which readily form aryl-lead triacetates on treatment with acetic acid[134-137].

An increase of the number of halogen atoms in halogenoacetic acids makes possible direct plumbation of *o*-halogeno-substituted (F, Cl, Br, or I) anisoles and phenetoles, derivatives of diphenyl ether, alkylbenzenes, biphenyl, benzene, and halogenobenzenes[137]. It is of interest that the oxidation of iodobenzene with LTA in trichloroacetic acid yields iodosobenzene diacetate $PhI(OAc)_2$ (after treating the reaction mixture with acetic acid) and not the plumbation product[137]. The plumbation reactions involving substituted benzenes are highly selective and lead almost exclusively to *p*-derivatives. Monosubstituted diphenyl ethers are usually plumbated in the *p*-position of the unsubstituted ring. Only in the case of 2-methyl-1-phenoxybenzene were two products obtained [(XXIX)/(XXX) = 7/3]:[137]

The high selectivity of the plumbation reaction has been explained[137] by the increased reactivity of the *m*- and *o*-isomers in the protodeplumbation reaction under the influence of the acid in the reaction mixture, although this explanation is inconsistent with the reactivity sequence of other organometallic compounds in the protodemetallation reaction[146]. When the substrate is highly nucleophilic, the $ArPbX_3$ formed can react as an electrophile and can give rise to the products Ar_2PbX_2 or $ArAr'PbX_2$.[137]

On treatment with TFAA, aryl-lead tricarboxylates decompose rapidly with formation of aryl trifluoroacetates or (in the presence of aromatic substrates) biaryls via the mechanism[138,139]:

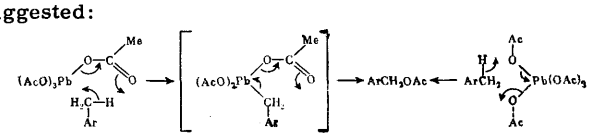
$$ArPb(OCOCF_3)_3 \underset{HOCOCF_3}{\overset{H^+}{\rightleftharpoons}} Ar\overset{+}{P}b(OCOCF_3)_2 \xrightarrow{-Pb(OCOCF_3)_2} Ar^+ \begin{cases} \xrightarrow[-H^+]{Ar'H} ArAr' \\ \xrightarrow[-H^+]{TFAA} ArOCOCF_3 \end{cases}$$

The rate of decomposition of aryl-lead tristrifluoroacetates is proportional to the relative stability of the aryl cations formed, so that the derivative of *m*-nitrophenyl-lead is most resistant to the action of TFAA.[138] It is of interest that the rate of formation of biaryls under these conditions is higher than the rate of trifluoroacetoxylation; this has been explained[139] by the preliminary formation of a π-complex between the hydrocarbon molecule and the species in which the Ar–Pb band is still preserved. The yield of biaryl increases with increase of the number of electron-donating substituents in the substrate ring.

It is noteworthy that the oxidation of xylenes, durene, mesitylene, and hexamethylbenzene by lead(IV) trifluoroacetate in the TFAA–CH_2Cl_2 system yields, apart from biaryls, also diarylmethanes (together with products of acetoxylation in the ring and in the side chain), i.e. the process also includes an electron transfer stage and the formation of radical-cations [see mechanisms (1), (7), and (9) [49,140,141]]. The oxidation of toluene with lead tetraacetate in TFAA produced after hydrolysis a mixture of cresols (28%),[140–142] bitolyls (4.5%), and *p*-tolylphenylmethane (0.6%), the yield of bitolyls increasing with increase of the ratio TFAA/LTA.[140,141]

In the absence of strong acids, the reactions of alkylarenes with LTA in acetic acid at 80 °C lead exclusively to α-acetoxylation products[132,149–152]:

$$R^1\text{—}C_6H_4\text{—}CH_2R^2 \rightarrow R^1\text{—}C_6H_4\text{—}CHR^2OAc\ ;$$

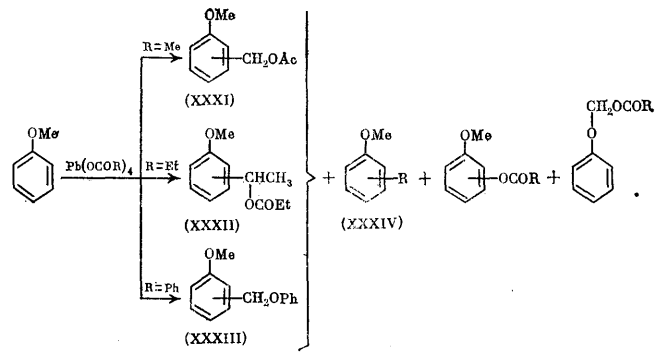


R^1 = H, OMe, Me, t-Bu, Br, or NO_2; R^2 = H or Me.

Di- and tri-phenylmethanes, fluorene, and hexamethylbenzene react similarly. According to Radhakrishnamurti and Mohapato[152], the reaction kinetics are described by the equation

$$-\frac{d[Pb(IV)]}{dt} = k[ArH]^n[Pb(IV)],$$

where $n = 2$ for substituted toluenes (R^1 = H, OMe, or Me and R^2 = H) and $n = 1$ for Ph_2CH_2, Ph_3CH, and fluorene. The rate of reaction remains unchanged in the presence of small amounts of H_2O (5% in acetic acid) and increases when acetic acid is replaced by propionic acid and also in the presence of Cl^-, Mn^{2+}, and dimethylformamide (DMF). The addition of other solvents inhibits the reaction: Me_2SO > MeCN ≅ cyclohexane > CH_2Cl_2 > $PhNO_2$ > PhH.[152]



The detailed mechanism of this reaction has still not been elucidated. It is believed that the principal stage is the decomposition of the complex of the substrate with LTA[149–152] involving a cyclic transfer of an electron pair, which results in the immediate formation of the two-electron oxidation product. The intermediate formation of a benzyl derivative of lead, i.e. plumbation of the side chain, has actually been suggested:

On irradiation (at 20–30 °C) and at temperatures above 80 °C, the reaction has a distinct radical character. Thermal[149,151,153] and photochemical[143,144,154] decomposition of lead(IV) carboxylate is accompanied by decarboxylation and the formation of aryl or alkyl radicals. The rate of decarboxylation increases in the presence of pyridine[144] and alkali metal acetates[101] and halides[144]. In conformity with mechanism (3), LTA oxidises toluene in acetic acid at 100 °C with formation of benzyl acetate, a mixture of xylenes, methylbenzyl acetates, and toluooylacetic acid[153]. The yield of benzyl acetate increases with increase of the ratio PhMe/AcOH and diminishes with increase of reaction temperature. Benzyl acetate is also formed in the photochemical reaction at room temperature[143,144]. Under these conditions, benzene gives rise to a mixture of toluene, benzyl acetate, and bibenzyl[145].

It is of interest that, when *p*-toluic acid is refluxed with LTA in trifluoroacetic acid in the presence of alkali metal chlorides or bromides, products of the oxidative halogenation of the aromatic ring are formed in high yields—3-halogeno-4-methylbenzoic acids[54]. Since the selectivity of this reaction is extremely high (>90%) for a purely radical process, the authors[54] do not rule out an appreciable contribution of the reaction via mechanism (8) with participation of mixed halide–arenecarboxylate complexes of lead [cf. the analogous reaction for cerium(IV)—see above].

In the presence of radical reaction initiators (monomethyl oxalate, di-isopropyl peroxydicarbonate), even substrates such as anisole can be oxidised via a radical mechanism[146]. The reactions with lead(IV) tetracarboxylates proceed under these conditions via the mechanism

It has been shown that, when the products (XXXI), (XXXII), and (XXXIV) are formed via mechanism (3), acyloxylation involves the intermediate formation of an anisole radical-cation [see mechanisms (1) and (8)]. The radical $PhOCH_2^{\bullet}$, formed from this radical-cation, reacts with the substrate to give compound (XXXIII).

Lead(III) derivatives formed via the mechanisms

$$RCO_2Pb(IV) \rightarrow R^{\bullet} + CO_2 + Pb(III)\ ;$$
$$R^{\bullet} + RCO_2Pb(IV) \rightarrow [R^+] + RCO_2Pb(III)$$

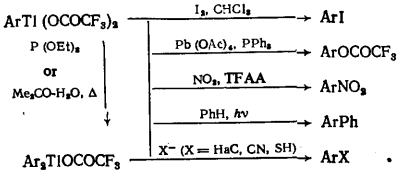
play an important role in the radical reactions. These derivatives act further either as one-electron oxidants or as sources of radicals[144,146].

As already mentioned above, one-electron oxidation processes, particularly acyloxylation in the ring and in the side chain and the formation of diarylmethanes in oxidative coupling reactions, compete with electrophilic and radical substitution processes. The role of such reactions increases with diminution of the ionisation potential of the substrate and with increasing electrophilicity of the oxidant. As for cobalt(III) (see above), LTA in an AcOH–$HClO_4$ mixture[45]

and lead(IV) trifluoroacetate in dichloroethane[49] oxidise mesitylene, pseudocumene, durene, and other methylarenes only to diarylmethanes. In contrast to toluene, 2-methylnaphthalene undergoes ring acetoxylation on treatment with LTA in acetic acid to a greater extent (~33%) than α-acetoxylation (~16%) or α-oxidation (~11%).[128] Finally at 105 °C LTA in acetic acid oxidises selectively the methyl group in 4-isopropyl-1-methylanisole to give the corresponding benzyl acetate in 55% yield[147].

8. Thallium(III)

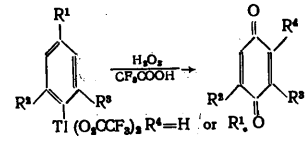
The reactivity of thallium(III) salts depends greatly on the nature of the ligands. Thus the covalent thallium(III) sulphate and chloride are almost inert in reactions with aromatic hydrocarbons[155,156]. The slow reaction of alkylarenes with thallium(III) acetate in acetic acid is appreciably accelerated in the presence of H_2SO_4, HNO_3, BF, and particularly $HClO_4$.[156] The main product in the last case is the organothallium compound $ArTl(OAc)ClO_4.H_2O$. Biaryls, benzyl acetates (from methylarenes), bibenzyl (from PhMe), and diarylmethanes (in the case of *p*-xylene) are formed in smaller amounts[155,156].



Under the same conditions, thallium(III) nitrate nitrates benzene (1.6%) and toluene (13%), but the reaction with *p*-xylene leads to a mixture of *p*-toluic acid (16.2%), toluic aldehyde (7.5%), and nitroxylene (6.1%).[156]

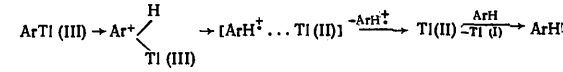
Thallium(III) carboxylates decarboxylated photochemically with formation of alkyl radicals. In the presence of benzene the photolysis of $Tl(OAc)_3$ gives a very low yield of a mixture of xylenes and phenylacetic acid[157].

The ionic thallium(III) trifluoroacetate (TTFA) shows the highest reactivity. The mode of its reaction with aromatic compounds is determined primarily by the oxidation potential of the substrate. Benzene, alkylbenzenes, and other compounds with fairly high ionisation potentials (>8 eV) react with TTFA to form products of S_EAr reactions—arylthallium bistrifluoroacetates[158–160].



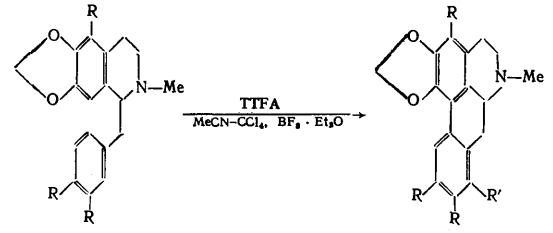
Dithallation on treatment with an excess of TTFA in TFAA has been observed only for anisole[161]. It is of interest that the monothallium derivative, formed in the presence of an equimolar ratio of the reactants (−25 °C, 15 min), is partly converted into 2,4-di(bistrifluoroacetoxythallium)anisole on standing for a week; the authors[161] explained this result by the stabilisation of the *o*-derivative as a result of the formation of a four-membered chelate ring. The thallation of 2,3,5,6-tetrafluoroanisole with TTFA does not occur in TFAA, but can be carried out in the presence of CF_3SO_3H.[162]

The kinetic and mechanistic aspects of thallation have been discussed in detail by Robey[155] and in reviews[158,160]. On the basis of arylthallium bistrifluoroacetates, McKillop and Taylor developed a whole series of valuable synthetic methods, particularly those represented schematically below:



These reactions have been described in fair detail in reviews[159,160]. Methods have also been found for the synthesis of aryl fluorides [by treating compound (XXXV) with KF in the presence of BF_3][163] and areneboronic acids (by reaction with diboranes in tetrahydrofuran)[164].

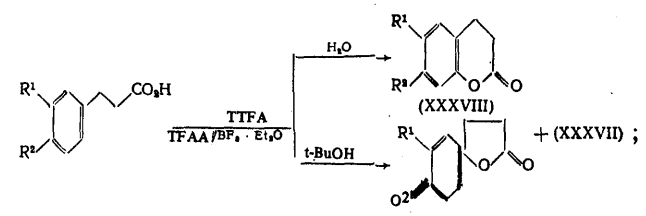
Treatment of compound (XXXV) with a solution of 90% H_2O_2 in TFAA gives rise to *p*-quinones, the reaction being accompanied by the migration or elimination of substituents in the aromatic ring:



Elimination is observed for R^1 = Cl or OMe and also for R^1 = Me in the case of mesitylene. In other cases the group R^1 migrates to the 2-position (R^1 = H, Me, Et, or t-Bu)[165].

The final product of the reduction of thallium(III) is always a thallium(I) salt. In this case the transfer of two electrons [as for lead(IV)] can probably take place both synchronously and consecutively. According to Elson and Kochi[166], in the reaction of TTFA with alkylbenzenes thallium(III) acts as a one-electron oxidant and in the first stage gives rise via mechanism (1) to radical-cations of aromatic substrates, which were detected by EPR [the authors[166] also noted that thallium(III) makes it possible to generate a wide variety of radical-cations under static conditions, in contrast to the reaction of cobalt(III), which requires the use of a flow technique[47]]. Further reactions of the complex $ArH^{\ddagger}$ ... Tl(II) can be described by the following mechanism[167], depending on the substrate:

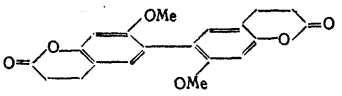
The reactions of TTFA via mechanisms (1) and (9) with substrates having low ionisation potentials (<8 eV) (polyalkoxybenzenes, naphthalenes, etc.) in TFAA, CCl_4, and acetonitrile give symmetrical biaryls in yields up to 99%.[167] The oxidation of durene in TFAA[167] and of *p*-xylene in the $Tl(OAc)_3$–AcOH–$HClO_4$ system leads to the formation of diarylmethanes[44,45].



Oxidative coupling can also take place intramolecularly[168], which has been used, in particular, in the synthesis of alkaloids of the type of homoaporphine and aporphine (XXXVIa):

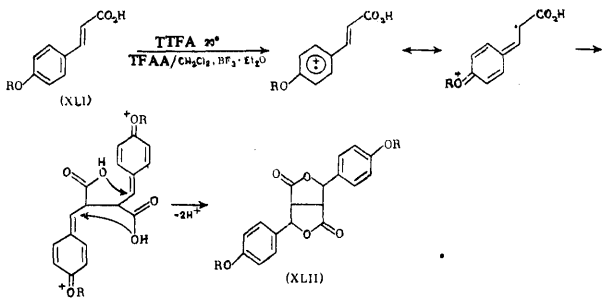
(XXXV) (a) R′ = H, (b) R′ = OAc

It is of interest that the replacement of TTFA by $Tl(OAc)_3$ leads to the ring acetoxylation product (XXXVIb) under the same conditions[168].



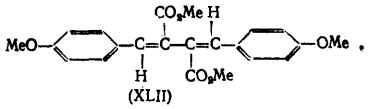
One should also note that the aromatic radical-cation can react intramolecularly with a carboxy-group to form dihydrocoumarins (XXXVIII) and spirolactones (XXXIX) [(XXXVII) : (XXXIX) = 3 : 1]:[169]

(XXXVI) (XXXVIII) (XXXIX)



(a) $R^1 = R^2 = OMe$; (b) $R^1 = OMe$, $R^2 = H$; (c) $R^1 = H$, $R^2 = OMe$.

Not only the presence of the CO_2H group [the methyl ester of the acid (XXXVIIa) yields only the corresponding 2,2-biaryl] but also the position of the methoxy-group is important for the course of the reaction. Thus, under the reaction conditions, compound (XXXVIIb) only dimerises, while compound (XXXVIIc) gives rise to the product (XL) of simultaneous cyclisation and dimerisation[169]:

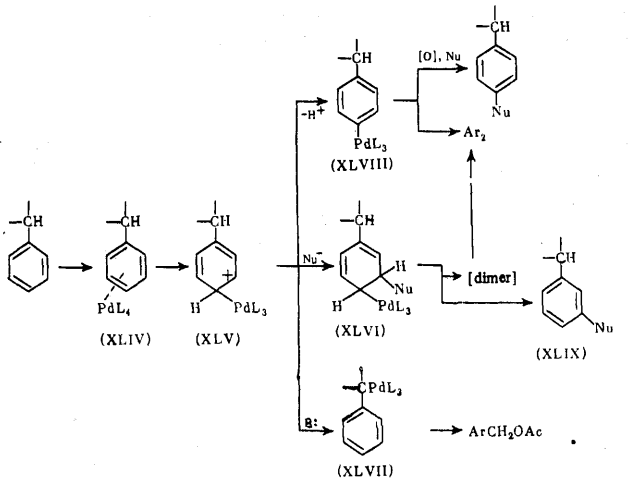


(XL)

The synthesis of the bislactone (XLII) is also extremely elegant[170]:

(XLI) (XLII)

The unsubstituted acid PhCH = CHCOOH does not react via this mechanism, while the methyl ester of the acid (XLI) yields the diene (XLII) as a result of the deprotonation of the radical dimerisation product:

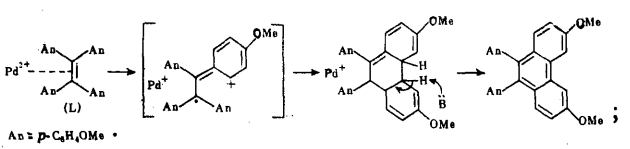


(XLII)

9. Palladium(II)

Palladium occupies a special place in the series of oxidants examined. Having the lowest oxidation potential, it exhibits the maximum selectivity in reactions with aromatic compounds and readily undergoes secondary oxidation on treatment with fairly mild oxidants, which makes it possible to use it in catalytic processes. On the other hand, the chemistry of palladium complexes is the most complicated and the mechanisms of its reactions are still controversial. The extensive applications of palladium(II) complexes in fine organic synthesis and technological processes have been described in a number of monographs[101,171,172] and reviews devoted to acetoxylation[128,173] and oxidative coupling[50,173,174] and for this reason the present review includes mainly general postulates concerning the mechanisms of the reactions of palladium(II) and new data not included in the reviews mentioned above.

The rate and mode of the reactions of alkylarenes with palladium(II) complexes depend very markedly on the composition of the palladium(II) coordination sphere. According to the existing ideas[171-175], the first stage in these reactions is the formation of the π-complex (XLIV) which, depending on the reaction conditions, is then converted into a σ-arylpalladium intermediate (XLV) and is attacked by a nucleophile with formation of the adduct (XLVI) or (in the presence of α-hydrogen and under the influence of a base) is converted into an α-substitution product—the benzylpalladium intermediate (XLVII):

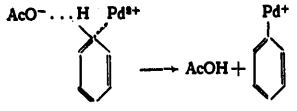


(XLIV) (XLV) (XLVI) (XLVII) (XLVIII) (XLIX)

On the basis of a comparison of the kinetics of the oxidative coupling and arylation reactions of olefins in the presence of palladium(II), it has also been suggested that palladium(II) can be inserted in the aromatic C—H bonds with formation of the species $ArPdH^{2+}$, whose stability has been explained[176] by the presence of a three-centre two-electron bond. According to the authors[176], a reaction of this type may constitute an intermediate stage in the slower reaction involving the formation of compound (XLVII), but there are as yet no data confirming this hypothesis.

The formation of π-complexes of benzene with $PdSO_4$ in 90% H_2SO_4 (23 °C) has been confirmed spectroscopically[177]. According to Rudakov et al.[177], the decomposition of these complexes leads to oxidative coupling products, benzene, and benzyl complexes of palladium(I), whose hydrolysis gives rise to zerovalent palladium, palladium(II), and benzene in proportions of 1:1:2.

The electron transfer in complexes of type (XLIV) proceeds, according to Eberson and Gonzalez[175], only in the presence of bases. Thus, on treatment with water, the complex (L) decomposes with liberation of the π-donor (tetra-anisylethylene), but on treatment with a stronger base (lutidine) it gives rise to an oxidation product:



An = p-C_6H_4OMe .

The deprotonation of the complex (XLV) leads to the S_EAr reaction product—the arylpalladium compound (XLVII), which then decomposes with formation of a biaryl. The detailed mechanism of the last reaction is still not clear. It is

known that palladium(II) halides are inert in reactions with alkylarenes and that only $PdCl_2$ gives rise to oxidative coupling products in the presence of a fivefold excess of an alkali metal acetate in acetic acid[171-181]. It is believed[174,175,179-181] that the reaction proceeds in this case via the intermediate (XLVI) and involves its dimerisation with formation of bridge bonds involving chloride ions. The subsequent decomposition of the dimer gives rise to biaryl, zerovalent palladium, palladium(II), and acetic acid (Nu = OAc). At the same time the rate of oxidative coupling increases greatly in the presence of $HClO_4$, whereupon AcO^- is displaced from solution and the reaction proceeds via the usual S_EAr mechanism ($k_H/k_D = 5$ has been obtained for C_6H_6 and C_6D_6 [179,181] as in mercuration). It is believed[179] that in this instance the coupling reaction proceeds via a stage involving the formation of a mixed arylpalladium(II)–arene complex:

$$[Ar{-}Pd^+ \ldots ArH] \rightarrow Ar{-}Ar + H^+ + Pd\,(0)\ .$$

On the basis of the study of the kinetics of the oxidation of PhH to Ph_2 with palladium(II) perchlorate in the H_2O–AcOH–$HClO_4$ mixture[176], it is concluded that the rate-limiting stage of the reaction under these conditions is electrophilic attack on the aromatic ring by the $Pd(OAc)^+$ ions with simultaneous proton transfer to the coordinated or free acetate ion:

The σ-phenylpalladium cation disproportionates further to zerovalent palladium, palladium(II), and Ph_2. The rate of reaction decreases when acetic acid is replaced by TFAA and when Cl^- or Br^- is introduced. The activity of palladium(II) adsorbed on a carboxylic acid cation-exchange resin increases with increasing fraction of neutralised carboxy-groups[178].

The presence of an excess of acetate ions is not, however, essential for oxidative coupling. The complexes of $PdCl_2$ with ethylene, styrene, and cyclohexene give rise to Ph_2 in yields of 99, 63, and 3% respectively on oxidation of benzene, i.e. the yield varies in parallel with the decrease of the stability of the complexes (the yield in the absence of the olefin is 40%). The activity thus depends on the rate at which benzene exchanges with the olefin and $AgNO_3$ plays the role of a chloride ion acceptor and the co-oxidant (NO_2 is evolved in the reaction)[182,183].

Oxidative coupling under the influence of palladium(II) salts takes place readily with organic derivatives of boron, thallium, mercury etc., the arylpalladium intermediates being formed as a result of the substitution of the metal by palladium[171-174].

The scope of the method is extended by the fact that substituents in the aromatic ring have only a weak influence on the rate of the coupling reaction ($\rho = -0.4$).[184] A whole series of methods of synthesis of biaryls under the influence of palladium(II) complexes (including the sulphate and carboxylates[50,171-174,178] and the β-diketo-complexes[185,186]) in combination with thallium(III) and mercury(II) salts[187,189], metallic copper[188], and zirconium compounds[192] in stoichiometric[50,175,181] and catalytic[174,190] amounts in solvents (usually acetic acid) or in their absence[174,190] have been developed. The side reactions in the oxidative coupling (usually acetoxylation—see below) are effectively suppressed when the process is carried out under oxygen pressure (50–100 atm), which renders catalytic oxidation methods especially promising. In particular, the presence of heteropolyacids (HPA)—compounds soluble in water and organic solvents (HPA can contain phosphorus, silicon, arsenic, boron, etc.; the vanadium, molybdenum, and tungsten compounds are the most reactive) makes it possible to regenerate palladium at lower O_2 pressures (~25 atm) and in the absence of Cl^- ions and thus to avoid the chlorination of the substrate[191].

The second pathway in the decomposition of the intermediate (XLVI) involves its conversion into the product (XLIX) of nucleophilic substitution in the ring. The formation of acetoxy- and nitro-arenes under the influence of palladium(II) nitrate in acetic acid probably proceeds via this mechanism[192]. The addition of H_2O, $HClO_4$, and iron(III) salts shifts the reaction towards oxidative coupling.

Benzene, toluene, and chlorobenzene can be nitrated with preparative yields in the $Pd(NO_3)_2$–$NaNO_2$ and $Pd(OAc)_2$–$NaNO_2$ systems (100 °C, RCOOH; R = t-Bu, Me, or $ClCH_2$).[193] The reaction leads to a mixture of nitro- and acyloxy-arenes, the yield of nitration products being a maximum when palladium(II) and $ClCH_2COOH$ are used. On replacing $NaNO_2$ by N_2O_4, the nitration reaction in the presence of $Pd(OAc)_2$ takes place under catalytic conditions[193]. The analogous reaction in acetic acid (100 °C) yields in the case of benzene a mixture of nitrobenzene and phenyl acetate, whose proportions vary from 1:2 to 2:1 depending on the conditions[194].

The acetoxylation of alkylarenes under the influence of palladium(II) acetate requires, according to Eberson and Gonzalez[175], the involvement of the monomeric $Pd(OAc)_2$. The trinuclear cluster $Pd_3(OAc)_6$ is stable in the solid state and in acetic acid at temperatures below 35 °C (in benzene—below 80 °C) and decomposes on treatment with acetates [the monomeric $Pd(OAc)_2$ is formed on treatment with Et_4NOAc, while alkali metal salts give rise to the dinuclear complexes of $Pd(OAc)_2$ or MOAc promoting α-acetoxylation—see below][175].

In the absence of an excess of AcO^- the "nuclear" acetate can be obtained as the main product ($MeArOAc/HArCH_2OAc = 7/3$) when MeArH in boiling acetic acid is treated with $Pd(OAc)_2$ in the presence of O_2.[175] Although the reaction is catalytic, it is too slow for practical purposes[175]. In conformity with the structure of compound (XLVI), acetoxylation takes place preferentially in the *m*-position in the presence of *o*- and *p*-directing substituents in the substrate molecule (naphthalene gives rise to a mixture of different amounts of α- and β-acetates). The yield of aryl acetate greatly increases in the presence of co-oxidants. The best results were obtained for $Pd(OAc)_2$ using $K_2Cr_2O_7$, but LTA, $KMnO_4$, CrO_3, ClO_3^-, and O_2 are also fairly effective[195-198]. The isomeric composition of the ring acetoxylation products is determined under these conditions by the ratio of the rates of oxidation of the arylpalladium intermediates (XLVI) and (XLVII) and depends both on the reaction conditions (the yield of the *m*-isomer usually increases with increase of reaction temperature[195-198]) and on the nature of the co-oxidant).

In the presence of $Hg(OAc)_2$ the first stage involves the mercuration of the substrate. The subsequent transmetallation leads to compound (XLVII), whose oxidation in the presence of AcO^- gives rise to the acetoxylation product which retains the structure (XLVII). Thus mainly *p*-cresyl acetate is formed from toluene in the $Pd(OAc)_2$–$Hg(OAc)_2$–$K_2Cr_2O_7$ system[195]. The modification of this reaction using mercury derivatives of arenes and a number of nucleophiles makes it possible to obtain a wide variety of oxidative nucleophilic ring-substitution products (Nu = OAc, N_3, Cl, Br, NO_2, CN, or SCN).[193]

Potassium peroxydisulphate is particularly effective as a co-oxidant in the presence of palladium(II) complexes with

N-containing ligands (2,2-bipyridyl, pyridine, and isoquinoline), the ratio *o*/*p* amounting to 39/6 for pyridine and 5/44 for 2,2-bipyridyl [198] for the same yield of the *m*-isomer in both cases (54–51%).

An increase in the number of alkyl substituents in the substrate molecule shifts the reaction in the $K_2S_2O_8$–AcOH–$Pd(OAc)_2$–2,2′-py_2 system towards α-acetoxylation, whose contributions for toluene and *o*- and *p*-xylenes amount to 10, 39, and 86% respectively. Under these conditions, mesitylene and durene produce only the corresponding benzyl acetates under these conditions. The yield of the α-acetoxylated products also increases in the presence of an excess of acetate ions[196–198].

The practical value of the ring-acetoxylation process is very great, in particular as regards the development of methods for the direct oxidation of arenes to phenols. We may note that the oxidation of benzene to phenyl acetate via the reaction $PhH + AcOH + \frac{1}{2}O_2 \rightarrow PhOAc + H_2O$ requires the use of metallic palladium in combination with bismuth, selenium, cadmium, iridium, rhodium, ruthenium, and gold (in the latter case the conversion of PhH reaches 70–75%),[172] while according to the data of Venkateswar and Rao[199] the analogous process involving $PdCl_2$ on SiO_2 [in the presence of NaOAc and $Cd(OAc)_2$ at 170 °C] gives PhOAc in 8.43% yield and a selectivity of 100%.

The acetoxylation of a side chain constitutes yet another pathway in the reactions of alkylarenes with palladium(II) salts. In the absence of co-oxidants an increase of the AcO^- concentration and the $PdCl_2$–MOAc–AcOH–ArMe leads to the suppression of the oxidative coupling by α-acetoxylation. In the oxidation of toluene the ratio $MeC_6H_4C_6H_4Me$: $PhCH_2OAc + PhCH(OAc)_2$ changes from 38 to 0.0074 as the ratio NaOAc/$PdCl_2$ varies from 5 to 20.

According to Eberson and Gonzalez's data[175], α-acetoxylation is promoted by the formation of dinuclear complexes, which give rise to steric hindrance to attack by an external nucleophile in the stage of the intermediate (XLIV) or favour the reaction involving the formation of $ArCH_2OAc$ when the nucleophile is bound in the π-complex (XLIV) as the ligand. The yield of the substituted benzyl acetate depends both on the amount of MOAc and on the nature of the M^+. In most cases the maximum activity is shown by Pd/Rb system[175].

α-Acetoxylation is favoured by the addition of Ph_3P, in the presence of which two stable benzylpalladium complexes of the type of (XLVII) have been isolated[175]: $PdCl(Ph_3P)_2 \cdot CH_2Ph$ and $Pd_2Cl_2(Ph_3P)_2(CH_2Ph)_2$. On treatment with potassium acetate in acetic acid, both compounds give rise to benzyl acetate, while treatment with silver acetate under the same conditions results in the formation of benzyl acetate and benzylidene acetate.

In contrast to the weak influence of substituents on the rate of oxidative dimerisation[182,184], the "benzyl" oxidation depends markedly on this factor. Thus the reaction of PhMe with $Pd(OAc)_2$ in acetic acid (at 90 °C) leads to $PhCH_2OAc$ (80%), PhCHO (4%), and $PhCH(OAc)_2$ (6%), while p-$CH_3C_6H_4CH_3$ gives rise to 96% of the corresponding benzyl acetate and p-$NO_2C_6H_4CH_3$ gives 2% of this derivative[200].

Under these conditions, xylenes form a mixture of α-acetate and α,α- and α,α′-diacetates[180]. *o*- and *m*-Xylenes react more slowly than *p*-xylene but yield analogous products. The reactivity of methylarenes decreases in the sequence toluene > xylene > mesitylene > durene > hexamethylbenzene, i.e. contrary to the ability of the substrate to generate the radical-cation.

In the presence of $Sn(OAc)_2$ and solid carriers with a high surface area (wood charcoal, Al_2O_3) the acetoxylation of toluene under oxygen pressure becomes a catalytic reaction[171,172]. According to the data of Starchevskii et al.[201], the active centres under these conditions are cluster species containing palladium in the lowest oxidation states and not palladium(II) complexes.

The influence of oxygen on reactions in the $ArCH_3$–$PdCl_2$–MOAc–AcOH system has not so far found a satisfactory explanation. In the presence of O_2 and for low values of the ratio $AcO^-/PdCl_2 \cong 5$, the rate of oxidative coupling increases and acetoxylation slows down[172,175]. On the other hand, inhibition is not complete even at 50 atm O_2 [175] (the radical reactions of LTA, for example, are inhibited by even traces of molecular oxygen[175]), while the replacement of $PdCl_2$ by $Pd(OAc)_2$ results in the formation of aryl acetates in the presence of O_2 as the main reaction products[175]. Furthermore, the inhibiting effect of O_2 is absent for higher values of $AcO^-/PdCl_2$, amounting to 10–20, and under these conditions α-acetoxylation can be carried out catalytically (see above). Finally, on oxidation in the presence of O_2, aldehydes are formed only in the case of polymethylbenzenes[175]. The role of oxygen complexes of palladium(II) and zerovalent palladium[175] has so far been scarcely investigated in these reactions.

As for other oxidants, palladium(II) trifluoroacetate occupies a special place[202,203]. Trifluoroacetoxylation proceeds smoothly only in the case of naphthalene (120 °C) and yields exclusively 1-naphthyl trifluoroacetate[150] (the acetoxylation of naphthalene requires increased temperatures and gives rise to a mixture of two isomers—see above). In the case of benzene the analogous reaction proceeds in the presence of alkali metal trifluoroacetates and is suppressed by water[203]. In the absence of additives, fluoro-, chloro-, and nitrobenzenes give rise to biaryls, while benzene produces biphenyl and terphenyl (the relative yields depend on the reaction time)[203]. In the reaction with $Pd(OAc)_2$ in TFAA alkylarenes form mixtures of biaryls and diarylmethanes in the case of toluene, xylenes, hemimellitol, and pseudocumene, while in the case of durene and mesitylene biaryls are formed exclusively[204].

* * *

Thus analysis of the literature data shows that the oxidation of aromatic compounds by variable-valence metal complexes has been the subject of increasing attention by investigators during the last fifteen years. The range of reactions in which aromatic substrates can be involved is extremely wide and their products, which are in many instances obtained in preparative yields and are distinguished by a high selectivity, are just as varied. In addition to clearly synthetic problems, these processes make it possible to solve problems associated with the reactivity of highly active intermediates—aromatic radicals, radical cations, cations, as well as organometallic compounds and charge-transfer complexes.

There is no doubt that further development of this field of transition metal chemistry will prove to be extremely fruitful for the development of new synthetic methods and syntheses of compounds with valuable properties, for example, bifunctional monomers, derivatives of biphenyl and diphenylmethane, and phenols.

Rearrangements in Vinyl Cations

A.A.Shchegolev and M.I.Kanishchev

The literature data on the rearrangements of vinyl cationoid intermediates arising in the solvolysis of various vinyl derivatives and in the addition of cationoid reagents to the triple bond are examined and the differences between the rearrangements of vinyl cations and those of the "usual" saturated carbonium ions are demonstrated. The influence of the structure of vinyl cationoid intermediates on the rate and mode of rearrangements of various types (the migration of alkyl and aryl groups, shifts via the double bond and to a double bond, and higher-order shifts) are discussed. The bibliography includes 87 references.

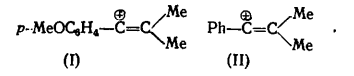
IV. Higher-order shifts in vinyl cations 561

I. INTRODUCTION

Vinyl cations belong to the class of "hot" carbonium ions and it proved possible to detect them by NMR [1-4] as species stable in solution only in isolated instances. The chemistry of vinyl cations (VC) is therefore developing at the present time mainly on the basis of the study of the characteristics of reactions occurring under conditions most favourable for the formation of cationoid intermediates of the VC type. Either the solvolysis of vinyl derivatives containing readily removable groups such as triflate [trifluoromethanesulphonate(OTf)] or nonaflate [nonafluorobutanesulphonate (ONf)] or the addition of cationoid reagents to the triple bond are usually employed. In both cases it is better to use polar and non-nucleophilic media.

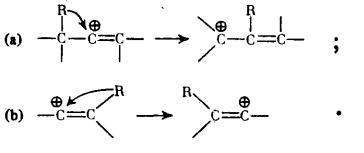


The question of the validity of the hypothesis of the intermediate formation of VC in these processes is by no means always clear, because it is sometimes difficult to exclude the possibility of alternative pathways leading to the formation of the observed products, for example, the elimination–addition or addition–elimination mechanisms in the solvolysis of vinyl derivatives or the synchronous Ad_E3 mechanism in the addition to the C≡C bond.

The choice between possible mechanisms is usually made on the basis of the study of the kinetics and stereochemistry in combination with data on the composition of the reaction products formed under various conditions. However, one of the principal criteria indicating the intermediate formation of VC is as a rule the observation of sextet rearrangements. Although, strictly speaking, this criterion does not constitute total proof, it has been used traditionally also in the more general case involving the study of the mechanisms of any reactions with possible involvement of carbonium ions as intermediates.

The characteristics of sextet rearrangements of the "usual" carbonium ions have been studied very widely and have been considered in detail in a series of monographs and reviews[5-8]. The data on the rearrangements of VC are much more scanty and limited, but in recent years numerous instances of reactions of this kind have been described and in the present review an attempt is made to survey these data†.

† Different aspects of the chemistry of VC have been examined in a series of reviews[16-23] published recently, which reflects the enhanced interest in these intermediates.



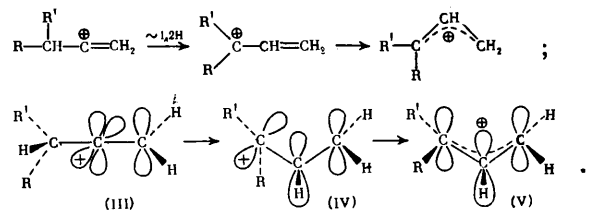
In discussing the characteristics of the rearrangements of C≡C, it is necessary to have a clear idea about their structure. At the present time this problem has still not been adequately investigated experimentally, although the available calculations in the literature[9-12] have shown that a linear structure with an *sp*-hybridised carbon atom having a positive charge is preferred for VC. This structure of VC has been confirmed[1,4] by ^{13}C and ^{1}H NMR for VC (I) and (II) in which the alkyl groups proved to be equivalent:

(I) (II)

The results of solvolytic reactions also indicate a linear structure of VC. Thus the rate of solvolysis of cycloalkenyl triflates in 50% aqueous ethanol solution at 75 °C increases with increase of ring size, while the the cyclo-octene derivative it becomes comparable to the rate solvolysis of (*E*)-1-methyl-1-propenyl triflate[13-15]. The relatively low rate of solvolysis of cyclohexenyl triflate can be explained by the impossibility of attaining a linear geometry in the vinyl-cation-like transition state in rings of this size.

The examples of rearrangements in vinyl-cationoid intermediates (VCI) available at the present time are mainly 1,2-shifts and can be divided into two large groups: (a) rearrangements with migration to the double bond leading to allyl cations and (b) rearrangements via the double bond, as a result of which one VC isomerises to another:

The less numerous rearrangements occurring as a result of higher-order shifts do not fit within the framework of this classification, because they involve simultaneously saturated and unsaturated fragments of the molecule and their usual result is the formation of a carbonium ion centre at a saturated carbon atom.



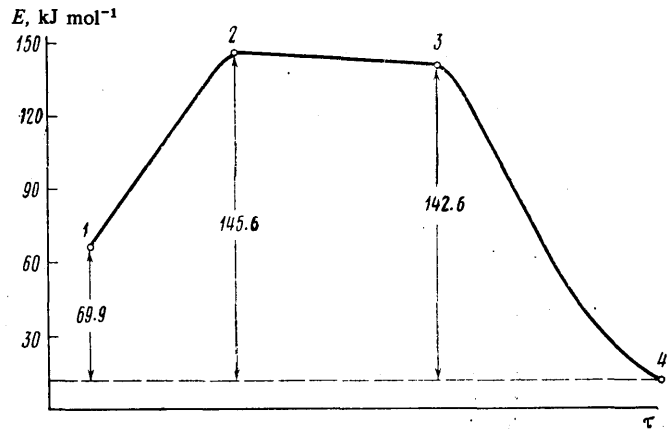
For each of the above type of rearrangements, there is a possibility of a more detailed classification based on the atoms or groups which migrate under these conditions.

II. REARRANGEMENTS WITH MIGRATION TO THE DOUBLE BOND

1. The 1,2-Hydride Shift

The hydride shifts in the chemistry of the "usual" carbonium ions are very common and usually take place extremely readily (the activation barrier to such rearrangements is frequently less than 12–16 kJ mol^{-1}). For example, the 1,2-hydride shift in the 2-butyl cation is so fast compared with the NMR time scale that even at −120 °C only a single average signal due to the CH_3 group is observed in its ^{1}H NMR spectrum[24].

The 1,2-hydride shifts in VC take place with much more difficulty and have been described for a fairly limited number of examples. This fact may appear fairly strange since this type of 1,2-shift should result in the conversion of an unstable VC to the stabilised system of the allyl cation and hence the thermodynamic driving force of such rearrangements should be fairly considerable. However, the difficulty of the 1,2-shifts in VC can be explained by considering the stereochemistry of the orbital interactions in this process. Indeed the conversion of the linear VC (III) into the planar resonance-stabilised allyl cation (V) should proceed via a non-planar transition state (or intermediate) (IV), in which resonance stabilisation is impossible and which is additionally destabilised by the presence of an orthogonal π-system:

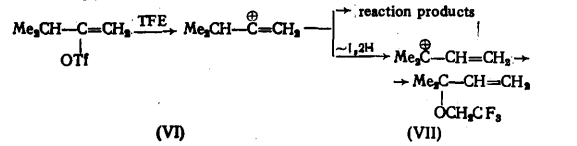


This is apparently why the activation barrier to the above process is in fact significantly higher than for the 1,2-shift in the "usual" carbonium ions.

The energetic pathway of the 1,2-hydride shift in VC, obtained[12] on the basis of the available calculations of the energies of the isomeric $C_3H_5^{\oplus}$ ions, is illustrated in the Figure.

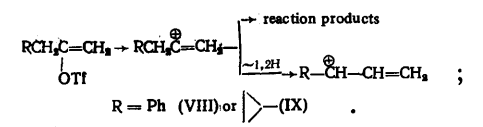
The 1,2-hydride shifts in VC have been studied in greatest detail in connection with the protonation of alkynes in "magic" acid (FSO_3H–SbF_5). It has been found that in none of the instances investigated is it possible to observe directly (by ^{1}H NMR) the formation of VC even at low temperatures (−78 °C), although these conditions have almost always proved to be suitable for the observation of carbonium ions of other types. It has been shown that the result of the protonation of the triple bond, observed with the aid of ^{1}H NMR, is the formation of the allyl cation (produced by the unimolecular 1,2-hydride shift in the VCI) or an oligomeric product (a bimolecular process). The latter pathway is usually preferred when the reaction is carried out at low temperatures (78 °C). An increase of temperature as a rule leads to a significant increase of the yield of rearrangement products, which reflects the usual kinetics of unimolecular and bimolecular reactions.

The 1,2-hydride shift takes place most readily in VC formed from alkynes, in which there are two alkyl substituents at the α-carbon atom. The rearrangements in such alkynes take place at −20 °C. The activation barrier for such systems is lower than the value indicated in Fig.1 owing to the stabilising effect of the alkyl groups. In alkynes with only one alkyl substituent at the α-carbon atom the 1,2-hydride shifts take place at higher temperatures (7–20 °C). The protonation of alkynes without branches at the α-carbon atom is more complex and in this instance it is not possible to detect the formation of allyl cations introduced by the 1,2-hydride shift in the VC formed initially.



The energetic pathway of the 1,2-hydride shift in the vinyl cation:

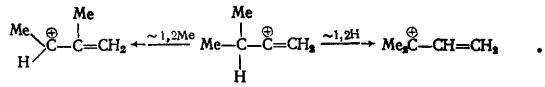
1) $Me-\overset{\oplus}{C}=CH_2$; 2) $H_2C\overset{H}{\overset{+}{\cdots}}C=CH_2$; 3) $H_2\overset{\oplus}{C}-CH=CH_2$;



4) $H_2C\overset{CH}{\overset{+}{\cdots}}CH_2$.

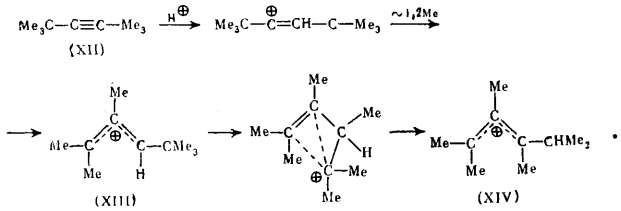
The only other example in which a 1,2-hydride shift to the double bond is observed is the solvolysis of isopropylvinyl trifluoromethanesulphonate (VI) in trifluoroethanol (TFE). The ether (VII), which is believed[26] to be formed as a result of the 1,2-hydride shift in the VCI formation stage, was isolated together with the normal solvolysis products under these conditions:

However, the authors do not consider the possibility of its formation via the elimination–addition mechanism.



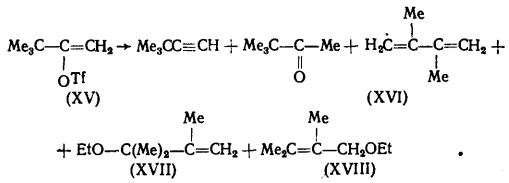
This result appears to be unexpected also because, for example, in the solvolysis of 1-benzylvinyl triflate (VIII) [27] and 1-cyclopropylmethylvinyl triflate (IX),[28] compounds which might be formed via a 1,2-hydride shift in the VCI are not detected among the products, although the presence of a stabilising substituent at the allyl carbon atom in the given systems should facilitate such a transition:

2. The 1,2-Shifts of Methyl Groups



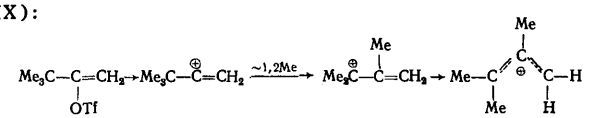
The characteristics of the 1,2-hydride shifts in VCI mentioned above, leading to an increase of the activation barrier compared with the rearrangements in the "usual" carbonium

ions, apply equally to the 1,2-shifts of methyl groups. In this instance too the number of examples is negligibly small compared with the number of studies on the 1,2-migrations in the "usual" carboniun ions. As will be seen from further exposition, the 1,2-shift of the methyl group is observed in compounds with a t-butyl substituent at the carbon atom with a positive charge. This is not surprising, since, in the presence of a hydrogen atom attached to an α-carbon atom, the hydride ion migrates, as has been observed in the protonation of alkynes[25], as a result of which the cation (X) formed is more stable than the alternative cation (XI):



(XI) (X)

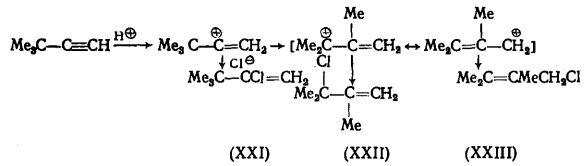
The protonation of t-butylacetylene and 2-t-butyl-1-methylacetylene at −20 °C in FSO_3H-SbF_5 leads to the formation of the corresponding allyl cations[25], which indicates the occurrence of 1,2-methyl shifts in the VCI formed initially. At a lower temperature (−78 °C) complex mixtures of oligomerisation products are formed in these reactions. However, the rearrangement involving the sterically hindered di-t-butylacetylene (XII) is observed also at −78 °C. In this instance the rearrangement is more far reaching and, instead of the signals of the allyl cation (XIII), the ^1H NMR spectrum shows signals due to the carbenium ion (XIV), which is apparently formed as a result of the rearrangement of the homoallyl cation:



(XII) (XIII) (XIV)

The solvolysis of t-butylvinyl triflate (XV) in aqueous ethanol solution yields t-butylacetylene as the main product, but this is accompanied by the formation of 10–15% of 2,3-dimethylbutadiene (XVI) and of the rearranged alcohols and ethers (XVII) and (XVIII):[29]

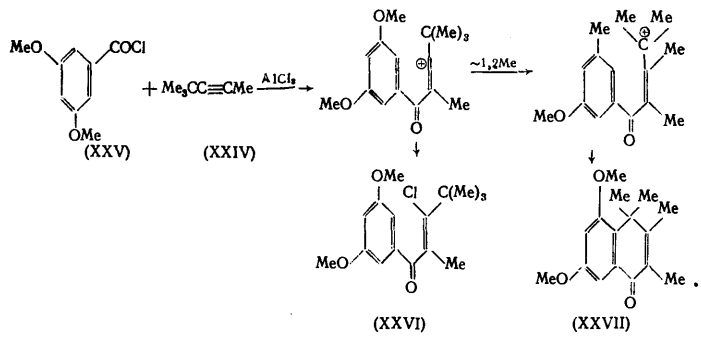
(XV) (XVI) (XVII) (XVIII)



The products (XVI)–(XVIII) were obtained as a result of the 1,2-shift of the methyl group in the VC (XIX) formed initially and further transformations of the isomeric cation (XX):

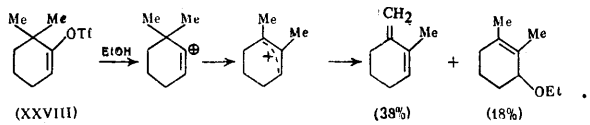
(XV) (XIX) (XX)

Analogous products are formed also in the acetolysis of compound (XV). The study of this process in CH_3COOD showed that deuterium is not incorporated in the reaction products and the alternative mechanisms of the formation of these products via addition–elimination or elimination–addition processes do not therefore occur and a rearrangement in the VCI takes place[30].



The addition of hydrogen halides to acetylenes is not usually accompanied by rearrangements[31], but in the interaction of t-butylacetylene with HCl without a solvent (the alkyne and dry HCl are mixed in a closed vessel at approximately −180 °C and the temperature is then raised to room temperature) the rearrangement products (XXII) and (XXIII) were isolated in 10–15% yield together with the normal reaction product (XXI):[32]

(XXI) (XXII) (XXIII)

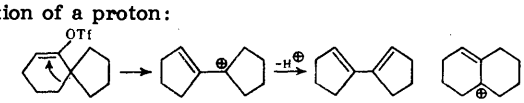


With increase of the amount of HCl to give a tenfold excess, the yield of rearranged products increases to 64%.

In the acylation of 4,4-dimethylpent-2-yne (XXIV) with 3,5-dimethoxybenzoyl chloride (XXV) in the presence of $AlCl_3$, 5–10% of the product of the 1,2-migration of the CH_3 group [compound (XXVII)] is formed together with β-chlorovinyl ketone (XXVI):[33]

(XXV) (XXIV) (XXVI) (XXVII)

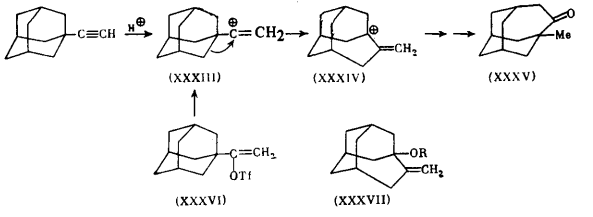
The 1,2-migration of the methyl group has also been observed in the solvolysis of the cyclohexenyl triflates (XXVIII) with two methyl groups at the α-carbon atom[34]:



(XXVIII) (38%) (18%)

3. Rearrangements Involving a Change in the Cyclic System of Alicyclic Molecules

Most of the rearrangements involving an alteration of the skeleton of alicyclic compounds should be included in the class of rearrangements via the double bond of VC and these will be considered below.

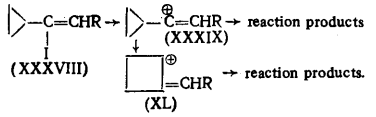


However, there are several examples which can be regarded as rearrangements with migration to the double bond. Thus the main product of the solvolysis of spiro-vinyl triflate (XXIX) in 60% aqueous ethanol or 50% aqueous TFE (in the presence of pyridine buffer) at 130 °C is the diene (XXXI). The authors[35] explain its formation by concerted ionisation and migration with the probable anchimeric participation of a bond of the cyclohexane ring in a convenient position, which leads to the formation of the carbenium ion (XXX) and the latter is converted into compound (XXXI) as a result of the elimination of a proton:

(XXIX) (XXX) (XXXI) (XXXII)

Important evidence in support of this concerted mechanism is the absence of compounds among the reaction products whose formation would have corresponded to the intermediate generation of the carbonium ion (XXXII). Its formation might have been expected by analogy with the above example of the migration of one or two geminal methyl groups in the solvolysis of compound (XXVIII). However, the virtually quantitative (>90%) yield of the diene (XXXI) shows that none of the spiroalkyl bonds of the cyclopentane ring in compound (XXIX) is involved in the migration.

Another example is the conversion of the adamantane system into the homoadamantane system. The hydration of adamantylacetylene catalyed by mercury salts takes place normally and leads to adamantyl methyl ketone[36]. However, in the protonation of adamantylacetylene with 90% H_2SO_4 in hexane at −5 °C 3-methyl-4-homoadamantanone (XXXV) is formed together with the normal product—adamantyl methyl ketone[37]:



(XXXIII) (XXXIV) (XXXV)

(XXXVI) (XXXVII)

Its formation can be explained by the rearrangement of the adamantylvinyl cation (XXXIII) to the homoadamantyl cation (XXXIV). The solvolysis of the vinyl triflate (XXXVI) confirms the proposed mechanism of the rearrangement. Depending on the conditions of the solvolysis[30], the main products are either elimination products (in 60% ethanol and acetic acid with a buffer) or rearranged products (in TFE); thus the use of a less basic solvent promotes the rearrangement, which confirms that the latter takes place via the VCI (XXXIII). It was also shown that the further transformation of the cation (XXXIV) into the final reaction products proceeds under the influence of an acid, since in the solvolysis in TFE with a buffer the main reaction products were compounds of the type of (XXXVII, R = CH_2CF_3 or H). If the CF_3SO_3H evolved in the solvolysis is not neutralised, the above compounds rearrange to compound (XXXV). It must be emphasised that the driving force of the rearrangement of the VC (XXXIII) should apparently be considerable, since the increasing strain of the system on passing from adamantane to homoadamantane does not prevent the rearrangement.

The rearrangement with participation of the bonds of a cyclic substituent is observed also in the solvolysis (noncatalysed or catalysed with silver salts) of 1-cyclopropyl-1-iodovinyl compounds of the type of (XXXVIII):[38–40]:

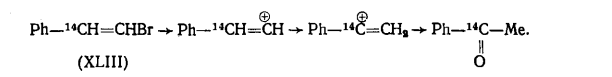
(XXXVIII) (XXXIX) (XL)

Despite the fact that the cyclopropane ring has a stabilising influence in the given systems on the VC (XXXIX) formed initially, the latter partly rearranges to the allylic cyclobutyl cation (XL) and up to 14% of cyclobutane derivatives were detected among the reaction products. Study of the temperature variation[39] showed that the yield of the rearranged products increases with temperature.

III. REARRANGEMENTS VIA THE DOUBLE BOND

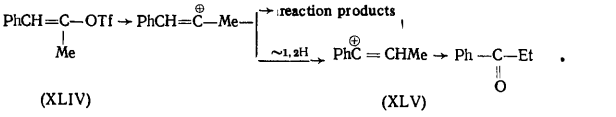
As stated above, in the 1,2-shifts via the double bond one VCI rearranges to another. Therefore the driving force of such rearrangements is the formation of a more stable VCI. Naturally the mode and extent of such rearrangements depend significantly, apart from other factors (the nature of the solvent, the nucleophiles present in the medium, etc.), on the stabilising influence of the substituents in both the initial and the rearranged VCI.

1. The 1,2-Hydride Shift



The 1,2-hydride shift of the type under consideration should take place most readily in those cases where the initial intermediate is the primary VC (XLI), since the conversion of the latter into compound (XLII) should be a thermodynamically favoured process [according to calculations for the gas phase, compound (XLII) is more stable to the extent of 67 kJ mol^{-1} than compound (XLI)]:[12]

(XLI) (XLII)

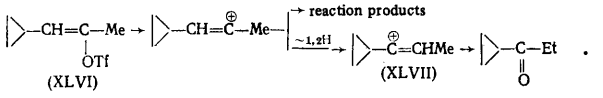


However, because of the low stability of the initial VC, the formation of this type of intermediate is unlikely and apparently occurs only in exceptional cases (see, for example, Hanack et al.[41]). Accordingly, mechanisms which do not require the intermediate formation of a primary VC are as a rule more justified in the interpretation of the results of the reactions.

For example, in the reactions of *cis*- and *trans*-β-bromostyrenes (XLIII) with $MeCO_2Ag$ in MeCOOH the formation of acetophenone as the main product (together with phenylacetylene) was observed[42]. It was also found that in the course of the reaction there is no 1,2-shift to the phenyl group and it was suggested that the hydride ion migrates in the VC:

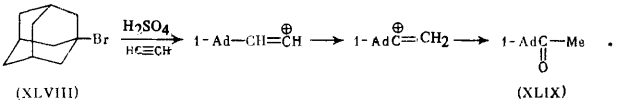
(XLIII)

However, it was later established[43] that the successive elimination–addition mechanism is more probable for the solvolysis of both β-bromostyrenes and other similar substrates[44]. There is good reason to consider mechanisms involving VC in those cases where a secondary VC is formed initially. For example, in the solvolysis of (*E*)- and (*Z*)-1-methyl-2-phenylvinyl triflates (XLIV) the main products are an alkyne and an allene. However, they are accompanied by the formation of between 3 and 17% (depending on the conditions) of ethyl phenyl ketone (XLV), produced as a result of the 1,2-hydride shift via the double bond in the VCI:[43]



(XLIV) (XLV)

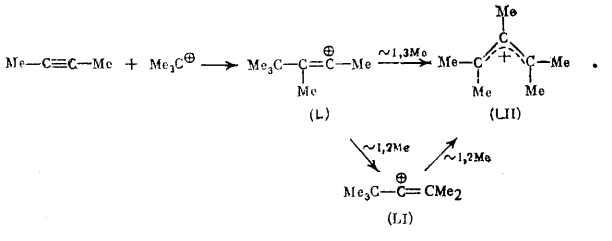
Although in the given instance synchronous elimination takes place to a considerable extent (this is manifested, in particular, by the higher rate of solvolysis of the *Z*-isomer compared with the *E*-isomer), ethyl methyl ketone (XLV) is not formed as a result of the hydration of methylphenylacetylene, since the latter is not hydrated under the reaction conditions and is isolated unchanged.



An analogous 1,2-hydride shift has been observed also in the solvolysis of (*E*)- and (*Z*)-2-cyclopropyl-1-methylvinyl triflates (XLVI).[26,45] The yield of cyclopropyl ethyl ketone

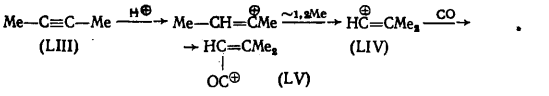
(XLVII), formed as a result of the rearrangement of the VCI, is 11–17%. In contrast to the previous case, in this instance the solvolysis via the formation of the VCI was not rigorously demonstrated, but the composition of the product and the ratio of the rates of solvolysis of the *E*- and *Z*-isomers suggest that the solvolysis does in fact proceed mainly via this mechanism:

It is of interest that, under comparable solvolysis conditions (3 : 2 or 4 : 1 TFE–H_2O mixture at 80 °C), the yield of ethyl phenyl ketone (4.7–5.9%) is smaller by a factor greater than two than the yield of cyclopropyl ethyl ketone (11.1 to 16.9%), which is associated, according to the authors[26,43], with the greater ability of the cyclopropane ring to stabilise the α-cationic centre.



A 1,2-hydride shift via the double bond has also been suggested to account for the results of the reaction of 1-adamantyl bromide (XLVIII) with acetylene in H_2SO_4,[46,47] leading to the formation of 1-adamantyl methyl ketone (XLIX) as the main product (40%):

However, a vulnerable feature of this mechanism is undoubtedly the formation of the primary VC and the reaction probably proceeds in reality via a different pathway.

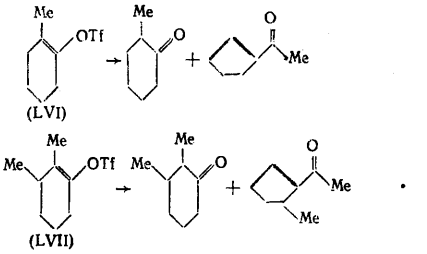


2. The 1,2-Shifts of the Methyl Groups

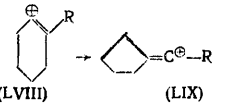
The ^1H NMR spectra of the products of the addition of the t-butyl cation (obtained via the reaction of t-C_4H_9Cl with $SbCl_5$ in SO_2) to but-2-yne showed[48] that, even at low temperatures (-75 °C), the pentamethylallyl cation (LII) is formed exclusively. It can be formed either as a result of a single 1,3-shift of the methyl group or as a result of two consecutive 1,2-shifts:

This problem was solved in the alkylation of but-2-yne by $(CD_3)_3CCl$; on the basis of the distribution of the D label, it was shown that the allyl cation (LII) is formed as a consequence of two consecutive 1,2-shifts of the CH_3 groups[48]. Thus this reaction is a unique example in which both types of rearrangements in VC are observed in succession: initially via the double bond [(L) → (LI)] and then via migration to the double bond [(LI) → (LII)]. This example also shows apparently that two consecutive 1,2-methyl shifts instead of a single 1,3-migration are preferable for VC, as for the "usual" carbonium ions.

A fairly unusual rearrangement has been observed[49] when a mixture of but-2-yne and CO was passed into the "superacid" medium ($FHSO_3$–SbF_5):



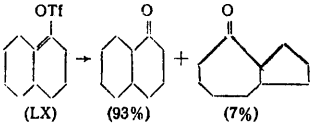
The acylium ion (LV), believed[49] to be capable of formation as a result of a 1,2-shift of the CH_3 group via the double bond, was detected (by ^1H NMR) among the reaction products. The reaction is unusual, because the VC (LIII) formed initially rearranges to a less stable VC (LIV), while in all the rearrangements described above the driving force is the formation of a thermodynamically more stable VC. It is appropriate to mention here that the carbonylation of the "usual" carbonium ions always leads to the formation of thermodynamically more stable isomers[50]. In the explanation of the course of the above reaction, the authors[49] attribute to SbF_5 a specific role in the formation of complexes with alkynes, which, however, appears to be unlikely.



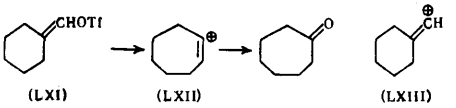
3. Rearrangements Associated with a Change in the Cyclic System of Alicyclic Molecules

The rearrangements of cyclic VC are characterised by a series of features due primarily to the fact that the mode and extent of the rearrangements are determined not only by the greater thermodynamic stability of the rearranged ion but also by the structure (ring size) of the entire alicyclic molecule.

The solvolysis of methyl-substituted cyclohexenyl triflates (LVI) and (LVII) yields a mixture of approximately equal amounts of the rearranged and non-rearranged products[13]:

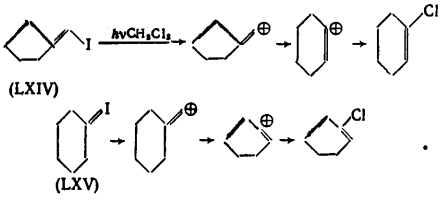


At first sight these results appear to be fairly strange, since a linear geometry is preferable for VC and the complete conversion of the VC (LVIII) into the VC (LIX) might have been expected:



However, this transition is apparently prevented by the increasing strain in the methylenecyclopentane system compared with the cyclohexenyl system. It is also possible that cyclohexanone derivatives are not formed via VC but as a result of the dissociation of the S–O bond[51].

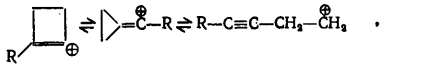
A much smaller degree of rearrangement is observed[13] in the solvolysis of the bicyclic vinyl triflate (LX):



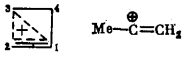
The rearrangements described above occur only in systems having a substituent at the β-carbon atom of the vinyl group. For the cations (LVIII, R=H), the rearrangement is hardly observed, because it would lead to the formation of very unstable primary VC of the type of (LIX, R=H), which, as stated above, is unlikely under the solvolysis conditions. The data on the solvolysis of the vinyl triflate (LXI), which results in the formation of 95% of cyclohexanone and 2.5% of formylcyclohexane, are consistent with these ideas:

(LXI) (LXII) (LXIII)

Cycloheptanone is probably formed via a mechanism involving concerted ionisation and the migration of an alkyl group, leading to the intermediate cycloheptenyl VC (LXII).[35] These results show that, despite the preferred linear configuration of VC, the bent secondary VC (LXII) is more stable than the linear primary VC (LXIII); hence it is clear how significantly the size of the VCI ring influences the mode and degree of the rearrangement.



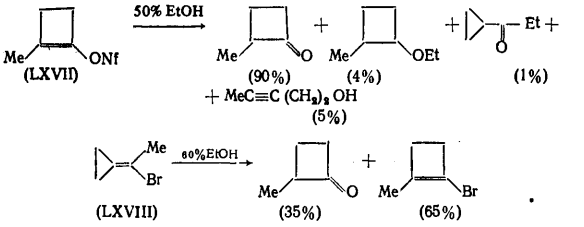
Rearrangements of a similar kind have been observed in studies of the photochemical transformations of vinyl halides which are believed to proceed via a stage involving the heterolysis of a carbon–halogen bond with formation of VC. Thus the photolysis of the vinyl iodides (LXIV) and (LXV) in methylene chloride results in the formation of considerable amounts of 1-chlorocyclohexene and 1-chlorocycloheptene respectively; this is believed[52] to occur as a result of a rearrangement via the double bond of the initial primary VC to the secondary VC, which subsequently abstract a chloride ion from the solvent molecule:



(LXIV)

(LXV)

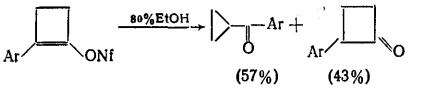
Interesting examples of reversible transformations of the VCI, occurring as 1,2-shifts via the double bond, have been described by Hanack and coworkers[41,51,53], who investigated the solvolysis of cyclobutenyl nonaflates, bromomethylenecyclopropanes, and but-3-yn-1-ol derivatives. It was found that the composition of the products obtained is very insensitive to the nature of the substrate, which is consistent with the following mechanism of the transformation of carbonium ion intermediates:



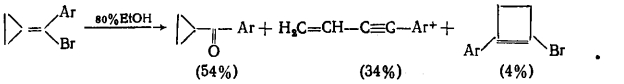
Bearing in mind that a linear geometry is preferable for the VC, the assumption that these transformations involve the cyclobutenyl cation, for which this type of geometry is impossible, appears fairly strange. However, it has been suggested[51] that the positive charge in the cyclobutenyl cation is delocalised over $C_{(2)}$ and $C_{(3)}$ as a result of the overlap of the vacant *p* orbital of the VC and the σ orbital of the $C_{(2)}$–$C_{(3)}$ bond:

(LXVI) (XLII)

The possibility of the formation of this non-classical structure (LXVI) has been confirmed by calculations[51] showing that its stability is comparable to that of the linear VC (LXII). The mode and degree of the rearrangements in the systems under consideration depend on the ability of the substituent R to stabilise the positive charge. Thus the only product of the solvolysis of cyclopropylidenemethyl bromide in the 1 : 1 water–ethanol mixture was cyclobutanone[53]. The same ketone proved to be the main product of the solvolysis of cyclobutenyl nonaflate[51]. On the basis of these data as well as calculations, the authors concluded that the cyclobutenyl cation is more stable than the cyclopropylidenemethyl cation.



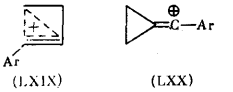
It is noteworthy that in these examples and those described above the carbonium ion mechanism has been fairly reliably demonstrated for solvolytic reactions of this kind. The absence of an addition–elimination process has been demonstrated by the independence of the solvolysis rate constant on the pH of the medium; furthermore, for certain reactions in labelled solvents, no incorporation of the isotope label was observed. In some cases[51,54] the ionic mechanism of the reactions was demonstrated by adding to the reaction mixture salts with an anion different from that of the leaving group. Under these conditions, both the initial and rearranged compounds containing the anion of the added salt were isolated; this demonstrates that the rearrangements proceed via the intermediate formation of ion pairs. The introduction of the methyl group in the 2-position of the cyclobutenyl ring exerts an additional stabilising effect on the cyclobutenyl cation formed, as shown by the considerable increase of the rate of solvolysis. The formation of cyclobutane derivatives as the main products in the solvolysis of 2-methylcyclobutenyl nonaflate (LXVII) and bromoethylidenecyclopropane (LXVIII) is believed[41,51] to show that the 2-methylcyclobutenyl cation is much more stable than the corresponding cyclopropylidene VC:



(LXVII) (90%) (4%) (1%) (5%)

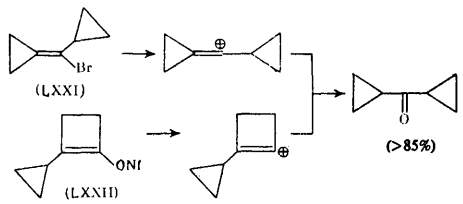
(LXVIII) (35%) (65%)

The introduction of an aromatic substituent (a phenyl or anisyl group) in compounds (LXVII) and (LXVIII) instead of the CH_3 group alters significantly the composition of the products formed (cyclopropene derivatives constitute more than 50% of the mixture[51,55]):

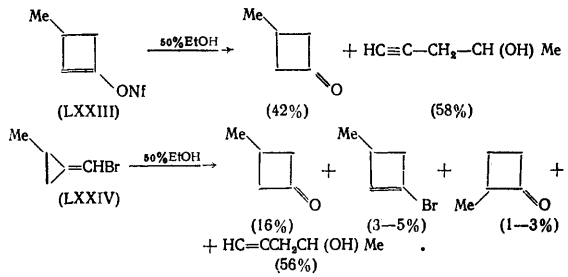


(57%) (43%)

(54%) (34%) (4%)



Thus the stabilising influence of the aromatic substituent on the cyclobutenyl cation (LXIX) is very insignificant:



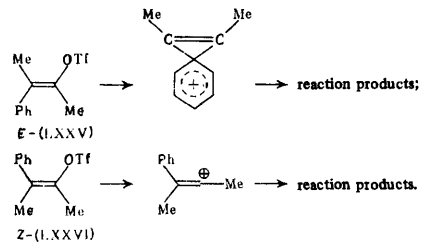
(LXIX) (LXX)

This is also indicated by the rate constants for the solvolysis of 2-arylcyclobutenyl nonaflates, which increase little compared with the rate constant for the unsubstituted derivative.

On the other hand, the VC (LXX) is stabilised significantly by an aromatic substituent. The stabilisation of this species by the cyclopropane ring is even greater, which is reflected in the composition of the solvolysis products of the cyclopropylcyclopropylidene bromide (LXXI) [41] or 2-cyclopropylcyclobutenyl nonaflate (LXXII): [51]

The main product of the solvolysis of these compounds in ethanol is dicyclopropylketone. The solvolysis of 3-methylcyclobutenyl nonaflate (LXXIII) leads to a mixture of 3-methylcyclobutanone and pent-1-yn-4-ol.[51] Derivatives of cyclobutane and the same alcohol have been isolated in the solvolysis of the *E*- and *Z*-isomers of 2-methylcyclopropylidenemethyl bromides (LXXIV),[56] both isomers giving rise to the same mixtures of products:

Thus in the given instances the 3-methylcyclobutenyl cation is more stable than the 2-methylcyclopropylidene cation.

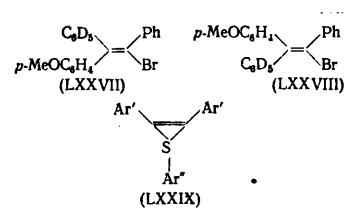


4. The 1,2-Shifts of Aryl Groups

The migration of aryl groups has been studied in greatest detail among the rearrangements of the VCI. This is quite natural because aryl-substituted VC in fact belongs to the most stable intermediates and the characteristics of the reactivity of these carbonium ions can be most conveniently studied on these models.

The usual method of synthesising VC of this type is solvolysis of various arylvinyl compounds; the study of the kinetics of this reaction and of data for the compositions of the products made it possible to elucidate a number of features relating to the migration of aryl groups via the double bond.

One of the principal problems in this connection is whether or not the migrating group is involved in the transition state of the heterolysis or whether the initial ionisation leads to a non-rearranged VC. Evidently in the general case the answer to this question depends to the greatest extent on the structure of the initial substances and particularly on their configuration. This has been studied in very great detail [57,58] in relation to the solvolysis of the *E*- and *Z*-isomers of 3-phenyl-2-but-2-enyl triflates (LXXV) and (LXXVI). The solvolysis of the *Z*-isomer in 60% aqueous ethanol gives rise to 33.5% of 3-phenyl-2-butanone and 66.5% of allene, while the *E*-isomer produces 82% of the ketone and only 18% of the allene; the rate of solvolysis of the *E*-isomer is twenty times higher than that of the *Z*-isomer.

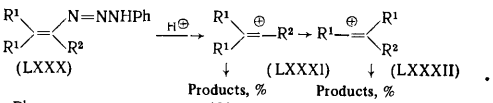


The solvolysis of these compounds in absolute TFE established the dependence of the mode of reaction on the stereochemistry of the initial compounds. To account for the different rates of reaction, the differences between the products, and their stereochemistries (the solvolysis in TFE yields the *E*-isomers in both cases), it has been suggested [57] that the *E*-isomer reacts preferentially if not exclusively with participation of the β-phenyl group and the formation of a bridged ethylidenephenonium ion as an intermediate. The *Z*-isomer yields initially a linear VC, which gives rise to a considerable amount of allene after the elimination of the proton. The formation of the *trans*-adduct in the solvolysis of the *E*-isomer in TFE confirms the formation of a bridged intermediate during the solvolysis, while it is believed [57] that in the case of the *Z*-isomer the VC forms an ion pair with the leaving group, which leads to a *trans*-adduct in the reaction with the solvent:

This mechanism was also confirmed in a study of the reactions with isotopically-labelled compounds (α- and β-CD_3 groups). The *E*-isomer then gives rise to compounds with a virtually complete redistribution of the D label, which was to be expected for the formation of an intermediate bridged carbenium ion, while in the reaction with the *Z*-isomer the degree of redistribution of the label is much smaller.

Further confirmation of the proposed mechanism was obtained in the study of the β-isotope effect (α-CD_3 group). It was found that the β-effect in the *Z*-isomer is very large (k_H/k_D = 1.47), while that for the *E*-isomer is smaller (k_H/k_D = 1.16). This shows that a linear VC with a positive charge on the α-carbon atom is formed from the *Z*-isomer, while in the case of the *E*-isomer the positive charge on the VCI is to a large extent delocalised over the benzene ring, which leads to a lower value of the isotope effect. This example clearly demonstrates that, depending on the configuration of the arylvinyl compounds, the latter can react with or without the involvement of the β-phenyl group.

On passing from the α-alkyl- to the α-aryl-vinyl systems, the stabilising effect of the α-aryl group on the vinyl cationoid centre produced exerts a significant influence on the mode of reaction; this leads to reactions in such systems via open-chain linear VC without the participation of the β-aryl groups. Thus the kinetics, stereochemistry, and degree of the rearrangement in the reactions of the vinyl bromides (LXXVII) and (LXXVIII) clearly show that the β-aryl groups are not involved in the heterolysis of the bonds [59]:



Linear VC are formed analogously from α-anisyl-substituted systems [60]. Numerous data on the solvolysis of β-arylthiovinyl derivatives have shown that the heterolysis of their

bonds proceeds with participation of the β-substituents and with the intermediate formation of thi-irenium ions of the type of (LXXIX).[61]

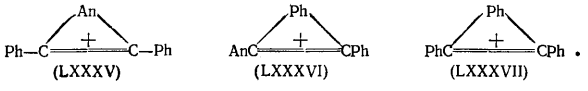
The degree of the rearrangement caused by the 1,2-shift of the aryl groups via the double bond depends on many factors: the structure of the initial vinyl compound, the method of generation of the VC, the solvents employed, and the nature of the migrating group.

The most significant properties of the solvents for the rearrangements are their nucleophilicity and ionising capacity. It has been suggested[60] that, in solvents with a high dielectric constant, the stability and lifetime of the carbonium ions increase. In highly nucleophilic solvents the rate of reaction of carbonium ions with the solvent increases and there is a corresponding decrease of the yield of rearrangement products. For all the migrations of aryl groups investigated, the best solvent promoting the rearrangements proved to be TFE, which has a high ionising capacity and a low nucleophilicity. In 60% ethanol, which has a higher dielectric constant and is more nucleophilic, the yield of rearrangement products is much lower. Acetic acid occupies an intermediate place between the above solvents. All the remaining factors influencing the degree of rearrangement are to some extent related. However, the decisive factors are of course the structure and stereochemistry of the initial vinyl derivative, because the ease of formation of the VCI in solvolysis, its stability, and hence the tendency towards rearrangements or reactions with the solvent depend on them.

The same VCI can arise in different reactions—in the solvolysis of arylvinyl bromides and arylvinyl triflates and in the interaction of arylvinyltriazenes with acids. Comparative studies[62,63] have shown that in certain cases the degree of the rearrangement depends significantly on the source of the VCI. For example, the solvolysis of the triflate $(Ph)_2C{=}C(OTf)Me$ in 80% EtOH leads to the formation of rearrangement products, while the triflate $(Ph)_2C{=}CHOTf$ is solvolysed very slowly and the rearrangement products are not formed[30]. Formally, the same VC can be generated via the reaction of arylvinyltriazenes (LXXX) with an acid; data on these reactions are compiled below[62,63] (Scheme 1)

(LXXX) → (LXXXI) ↓ (LXXXII)

	Products, %	Products, %
(a) $R^1 = R^2 = Ph$	100	0
(b) $R^1 = n\text{-}MeC_6H_4$, $R^2 = Ph$	80	20
(c) R^1 Ph, $R^2 = Me$	5	86
(d) $R^1 = Ph$, $R^2 = H$	0	90
(e) $R^1 = R^2 = p\text{-}MeOC_6H_4$	68	38



The degree of the rearrangement in symmetrically substituted triazenes (LXXX, a and e) was determined[64] in compounds labelled with ^{13}C or ^{14}C as the vinyl carbon atoms. It is seen from the results presented that the VC (LXXXIc), generated both by the solvolysis of the triflate and by the reaction of a triazene with an acid, rearranges almost wholely to the VC (LXXXIIc). In contrast to these results, the VC (LXXXId) formed in the reaction of triazene also rearranges wholely, but no rearrangement products were detected in the solvolysis of the triflate. This difference in the course of the reaction can apparently be accounted for by the impossibility of the formation of the primary VCI (LXXXId) under the conditions of the solvolysis reaction, as a result of which the solvolysis proceeds via an elimination–addition mechanism.

Other examples indicating the dependence of the degree of rearrangement on the mode of generation of the VC have been obtained in the study of degenerate rearrangements in the VC (LXXXI, a and e) (in systems with labelled vinyl carbon atoms). The reaction of the triazene (LXXXe) with acetic acid results in the formation of 38% of the rearranged acetate. The reaction of trianisylvinyl bromide with silver acetate in acetic acid leads to the formation of 20% of rearrangement products[64], i.e. the yield of the latter diminishes. In contrast to this, the triazene (LXXXa) does not give rise to rearrangement products, while the solvolysis of triphenyl triflate in acetic acid[65] or the interaction of triphenylvinyl bromide with silver acetate in acetic acid[67] lead to the formation of 7% of rearrangement products, i.e. under solvolytic conditions a higher degree of rearrangement is observed. These results can be explained by the different degrees of involvement of the ion pairs in the reaction; whereas in the first instance (the trianisylvinyl cation) the rearrangement proceeds in the VCI formation stage, the formation of rearranged products in the solvolysis of triphenylvinyl compounds takes place in the ion-pair formation stage.

The available data on the solvolysis of various triarylvinyl compounds[60] make it possible to consider the problem of the relative migratory capacities[23] of aryl groups, particularly phenyl and anisyl groups, in rearrangements via the double bond. In this respect one of the most interesting examples is the solvolysis of 2-anisyl-1,2-diphenylvinyl bromides (LXXXIII), since in the resulting VC (LXXXIV) there is a possibility of a 1,2-shift of the phenyl group and of a degenerate rearrangement associated with the migration of the anisyl group (the degree of rearrangement was determined in the solvolysis of 2-anisyl-2-pentadeuterophenyl-1-phenylvinyl bromides[67]):

$$\underset{\text{(LXXXIII)}}{Ph\,(p\text{-}MeOC_6H_4)\,C{=}C\,(Ph)\,Br} \rightarrow \underset{\text{(LXXXIV)}}{Ph\,(p\text{-}MeOC_6H_4)\,C{=}\overset{\oplus}{C}\,(Ph)} \xrightarrow{\sim 1,2\,Ph} p\text{-}MeOC_6H_4\overset{\oplus}{C}{=}C\,(Ph)_2 .$$

The migratory capacity of the anisyl group relative to that of the phenyl group, from competing migrations in the VC (LXXXIV), proved to be 76 for 60% ethanol and 120 for acetic acid. These data demonstrate the difference between the energies of the transition states for the two rearrangements, since the energies of the ground states are the same. Thus the formation of bridged structures of type (LXXXV) with the anisyl group in the transition state is preferable to the formation of structures of the type (LXXXVI):

(LXXXV) (LXXXVI) (LXXXVII)

This is also indicated by a comparison of the 1,2-shift of the anisyl group described above with the 1,2-shift of the phenyl group in the solvolysis of triphenylvinyl triflate. It has been shown[60] that the migratory capacity of the anisyl group in acetic acid is 82 times greater than that of the phenyl group, i.e. in this instance the anisyl group in the transition state (LXXXV) stabilises the positive charge more effectively than the phenyl group in compound (LXXXVII). The degree and mode of the 1,2-shifts of the aryl groups are significantly influenced also by groups not involved in the migration but are linked directly to the atom from which the migrating group departs and to the atom to which it becomes attached. Under these conditions, the stronger stabilising influence of the anisyl group, compared with the phenyl group, on the carbonium ion centre is most significant.

For all the combinations of the substitution of vinyl atoms by phenyl or anisyl groups investigated in the solvolysis of triarylvinyl derivatives, it has been found that the degree of migration to the α-phenyl-substituted centre ($Ar^3 = Ph$) in VC of the type of (LXXXVIII) is greater than the degree of migration to the α-anisyl-substituted centre ($Ar^3 = p\text{-}MeOC_6H_4$):

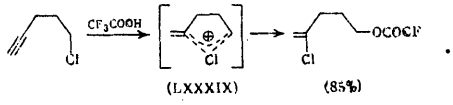
$$\underset{\text{(LXXXVIII)}}{Ar^1\,Ar^2\,C{=}\overset{\oplus}{C}Ar^3} .$$

On the other hand, the rearrangements of the α-anisyl-substituted VC with formation of an α-phenyl-substituted VC have not been observed. The rearrangements of VC with Ar^1 or Ar^2 = *p*-$MeOC_6H_4$, leading to the formation of VC in which one of the substituents is the phenyl group, are also preferable to the corresponding degenerate rearrangements. It follows from the examples considered that the following transformation is most favourable:

$$(p\text{-}MeOC_6H_4)_2C{=}\overset{\oplus}{C}Ph \xrightarrow{\sim 1,2\,An} p\text{-}MeOC_6H_4C^{\oplus}{=}C(Ph)C_6H_4OMe\text{-}p\ .$$

On the other hand, the degenerate migration of the phenyl group between two anisyl-substituted centres is least favourable:

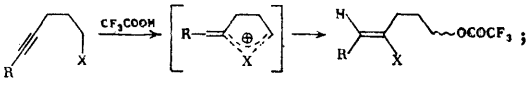
$$An^*(Ph)C{=}\overset{\oplus}{C}An \rightarrow An^*\overset{\oplus}{C}{=}C(An)Ph\ ;\quad An = p\text{-}MeOC_6H_4\ .$$



Comparison of the relative capacities for 1,2-migration of the phenyl and anisyl groups in saturated and unsaturated systems[23] shows that in both cases the anisyl group migrates more readily. The only exception has been found in the case of the deamination of 1,2,2-triarylethylamines[68], where a smaller degree of migration was observed for the β-anisyl group compared with the β-phenyl group. In the analogous transformations of phenyltriazenes in reactions with acids, the greater relative migratory capacity of the anisyl group was observed as usual.

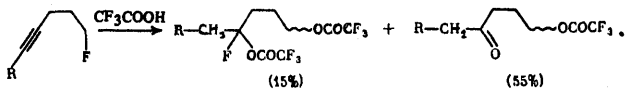
IV. HIGHER-ORDER SHIFTS IN VINYL CATIONS

An extremely limited number of examples of such transformations in VCI are available and apparently, as in the case of the "usual" carbonium ions[69], the higher-order shifts are not characteristic of the VCI. In particular, it has been observed earlier that, instead of the 1,3-shift, two consecutive 1,2-migrations of the methyl group take place in the VC (L).[48] Depending on the nature of the migrating group, all the examples of the higher-order shifts described can be divided into two groups: (1) halogen shifts and (2) hydride ion shifts.



1. The Halogen Shifts

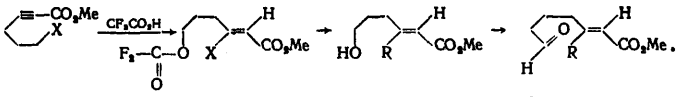
An unusal rearrangement with a 1,4-shift of chlorine in a VC was observed for the first time by Peterson and coworkers[70,71]. They obtained 2-chloropent-4-enyl trifluoroacetate by the reaction of 5-chloropentyne with trifluoroacetic acid. It is apparently formed via a mechanism involving the synchronous protonation of the triple bond and a shift of the halogen via an intermediate state of the chloronium ion type (LXXXIX) with subsequent attack by CF_3CO_2H:



(LXXXIX) (85%)

Interestingly, in contrast to the acetylene derivative, 5-chloropentene gives only 0.6% of the product involving the migration of chlorine. This can be explained by the different degrees of formation of the chloronium ions. It was shown later[72] that the interaction of other halogen-containing acetylene derivatives with analogous structures (5-bromo- and 5-iodo-pentynes, 6-chloro- and 6-iodo-hex-2-ynes) with trifluoroacetic acid also involves a 1,4-shift of the halogen atom:

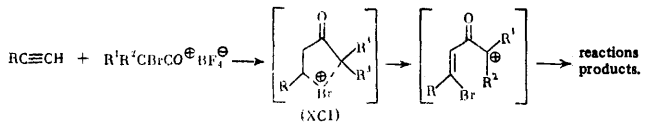
X = Cl, Br or I.



Next it was observed[72] that the interaction of γ-fluoroalkynes with trifluoroacetic acid results in the formation, together with rearranged products, of 15% of a bisadduct corresponding to the fairly unusual 1,4-shift of the fluorine in the VC (similar shifts have not been observed in the chemistry of the "usual" carbonium ions):

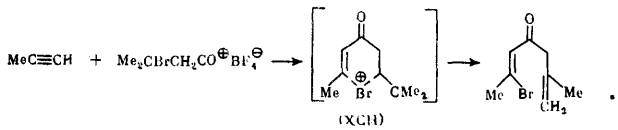
(15%) (55%)

The structure of the products obtained shows that exclusive *trans*-addition of the proton and halogen to the triple bond takes place[72].



This stereospecific mode of the rearrangement has been used[73] to obtain the aldehyde (XC), which serves as an intermediate in the synthesis of the juvenile hormone:

(XC)

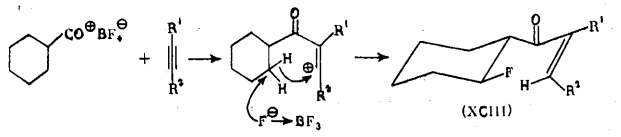


It was found that in the methyl ester of 6-iodohex-2-ynoic acid the 1,4-shift of iodine takes place quantitatively on refluxing for 50 h with trifluoroacetic acid. In contrast to this, the 6-chloroderivative rearranges much more slowly and, after heating the reaction mixture for eight days at 130 °C, only 30% of the rearranged ester and 60–65% of the initial ester were isolated. Thus the esters of acetylenecarboxylic acids rearrange at much lower rates than the alkylacetylenes described above, which is probably associated with the deactivating effect of the methoxycarbonyl group.

The migration of the bromine atom has also been observed in the acylation of alkynes by bromoacylium cationoid reagents[74,75]. In this case the reaction evidently proceeds as the coupled *cis*-addition of the acylium cation and the halide anion to the triple bond. A characteristic feature of the reaction is that the source of the bromide anion is the acylium residue and the final result of the process is a 1,4-shift of the bromine atom. The structure of the final products suggests that in these reactions there apparently arises an intermediate of the type of the five-membered bromonium ion (XCI), the opening of the ring of which actually leads to the formation of β-bromovinyl ketones with a Z-configuration of the double bond:

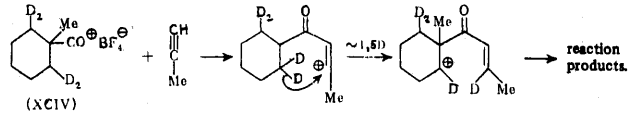
(XCI)

The interaction of alkynes with β-bromoisovaleryl tetrafluoroborate also leads to the formation of β-bromovinyl ketones[76]. Apparently in this instance a six-membered bromonium ion (XCII) is formed as an intermediate:



(XCII)

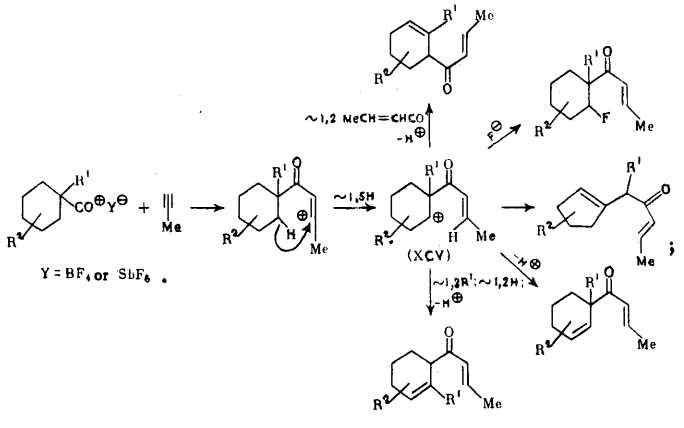
2. The Shift of the Hydride Ion



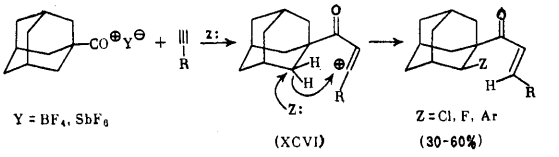
Higher-order hydride shifts constitute a fairly rare phenomenon in the thoroughly investigated chemistry of the "usual" carbonium ions, *trans*-annular reactions involving

rings of medium size constituting an exception[69]. Direct and quantitative data on the 1,3-, 1,4-, and 1,5-hydride shifts are available only for 2,4-dimethyl-2-pentyl, 2,5-dimethyl-2-hexyl-, and 2,6-dimethyl-2-heptyl cations[77]. Here it is of interest to note that the lowest activation energy (25–29 kJ mol^{-1}) is required for the 1,5-hydride shift. The recently discovered new intramolecular 1,5-hydride shift reaction involving VCI is of undoubted interest in this connection.

In the acylation of alkynes with cyclohexanoyl tetrafluoroborate[78], fluoroketones of the type of compound (XCIII) were obtained as the main products:

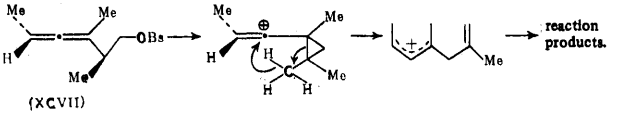


The structure of these compounds (the *E*-configuration of the double bond) suggested that they are formed via an intramolecular 1,5-hydride shift. To demonstrate this hypothesis, Kanishchev et al.[79] used as the acylating agent 1-methyl-2,2,6,6-tetradeuterocyclohexanoyl tetrafluorborate (XCIV):

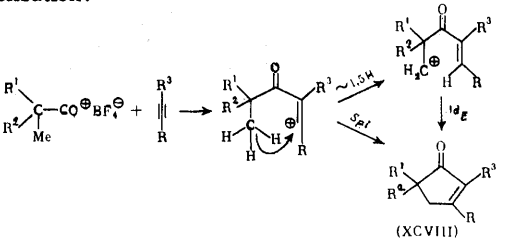


A careful study of the ^{1}H NMR and mass spectra of the reaction products showed that at the β-carbon atom of the side chain there is only a deuterium atom (>95%) and they are therefore formed exclusively via an intramolecular 1,5-hydride shift. It is of interest to note that the hydrogen atoms of the C–H σ-bond of the CH_3 group of the cyclohexane ring do not participate in this reaction; this has also been demonstrated by an experiment in which the protons of the methyl group were replaced by deuterium.

Further study of the acylation of alkynes showed[81–84] that the observed 1,5-hydride shift is a common process in these reactions when aliphatic cycloacylium salts are used as acylating agents. It has been found that this type of transformation takes place most readily for the equatorial position of the carbonyl group in the cyclohexane ring of the initial reactant. A direct result of the 1,5-hydride shift under consideration is the formation of an aliphatic cyclocarbonium ion (XCV); the nature of the final reaction products is determined by the specific features of the structure and stereochemistry of the cyclic skeleton and also by the nature of the nucleophiles present in the medium. In a general form the list of processes observed in these reactions can be represented schematically as follows:

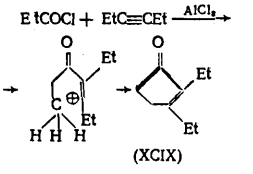


The 1,5-hydride shift takes place particularly effectively in the acylation of alkynes by acylium salts derived from adamantane-1-carboxylic acid[81–84] because in this case the VC (XCVI) formed has six equivalent C–H σ-bonds involving the β-carbon atoms:



It is readily seen that in all cases the outcome of the reaction is the introduction of a functional group into the aliphatic cyclic residue. The preparative usefulness of these reactions was demonstrated for the formation of a series of 1,2-disubstituted adamantanes, which are difficult to obtain.

Only in the examples of the 1,5-hydride shift described above were the transformations of VCI of this kind rigorously demonstrated. In all other cases the occurrence of higher-order hydride shifts is one of the postulated pathways followed in the transformations of the VC into the final reaction products. For example, in the protonation of branched alkylacetylenes[25] in superacid media the authors do not rule out the possibility of a 1,5-hydride shift in the VC formed, although there are other possible reaction pathways.



The 1,4-hydride shift has been postulated[85] to account for the formation of nonatrienes in the solvolysis of 2,2,3-trimethylhexa-3,4-dienylbromobenzenesulphonates (XCVII):

In contrast to the acylation of alkynes by aliphatic cycloacylium salts described above, the analogous reactions with cationoid reagents derived from branched aliphatic acids lead to alkylcyclopentenones (XCVII).[86] They are formed via the attack on the β-CH bond of the acylating agent by the cationoid centre, ring closure occurring either via a mechanism involving direct electrophilic substitution (S_Ei) or via a stage in which there is a 1,5-hydride shift with subsequent Ad_E cyclisation:

2,3-Diethylcyclopent-2-enone (XCIX) is apparently formed via an analogous mechanism (in small amounts) in the acylation of hex-3-yne with propionyl chloride[87]:

---oOo---

The data examined above show that sextet rearrangements are just as characteristic of VC as of carbonium ions of other types. The features of VC rearrangements have now been systematically investigated only for the 1,2-migrations of aryl groups. In the majority of cases the result of the investigation has been merely the demonstration of the occurrence of the rearrangement and the elucidation of the general structural features determining its feasibility. There are not yet experimental data characterising quantitatively VC rearrangements. At the same time, the available results show that the transformations of VC are not only of theoretical interest but can also be used for synthetic purposes. An example of useful synthetic processes of this kind is provided by cyclisation (the formation of cyclopentenones), the 1,4-shift of the halogen in the series of ω-halogenoalkynes, the 1,5-hydride shifts in the acylation of alkynes, and finally the generation of allyl cations from alkynes.

Advances in the Chemistry of α,α'-Disubstituted Pyridines

L.N.Yakhontov and D.M.Krasnokutskaya

The methods of synthesis of α,α'-disubstituted pyridines are surveyed and recent advances in this field are indicated. Various ways of constructing the α,α'-disubstituted pyridine ring and of replacing one set of α,α'-substituents by another are described. The characteristics of the chemical behaviour of α,α'-disubstituted pyridines due to the steric and inductive effects of the substituents and their influence on the reactivity of the nitrogen atom and processes involving electrophilic substitution in the pyridine ring are examined. The chemical behaviour of the various functional groups in pyridine systems with α,α'-substituents as well as the characteristic features of the tautomerism and the dual reactivity of substances of this class are discussed.
The bibliography includes 254 references.

CONTENTS

I Introduction 565
II. Methods of synthesis of α,α'-disubstituted pyridines 565
III. Chemical characteristics of α,α'-disubstituted pyridines 572

I. INTRODUCTION

The introduction of α,α'-substituents into nitrogen-containing heteroaromatic compounds alters significantly their chemical properties. Together with the usual inductive and mesomeric effects of the substituents in aromatic systems, their influence on the ring heteroatom is in this case manifested and frequently becomes of primary importance.

The mechanism of this influence has been by no means completely investigated and according to many authors is not restricted to steric and inductive factors but includes additional effects characterised by different investigators as "effects of the proximity to the heteroatom", "the effect of the mutual influence of atoms transmitted through space and not through bonds", "the field effect", etc. The physical significance of these effects is not adequately clear but in one way or another the nature of the heterocyclic nitrogen atom changes markedly under the influence of α,α'-substituents. In many cases its nucleophilic properties and its capacity for protonation, complex formation, and solvation are significantly suppressed. This frequently leads to the loss of specificity in the chemical behaviour of the compounds as nitrogen heterocycles and to the appearance of properties typical for aromatic systems without a heteroatom.

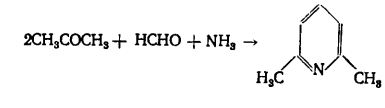
It is noteworthy that the effects of α,α'-substituents in various chemical reactions can be extremely varied. These include the destabilisation of the intermediate carbanions, the ease of chelate formation with the interacting reagents, the suppression of processes proceeding via "conjugate acids", etc. The nature of the mutual influence of the α- and α'-substituents transmitted through the ring heteroatom is complex and to a large extent still remains uninvestigated.

So far as we are aware, there are no reviews in the literature dealing with the influence of α,α'-substituents on the properties of azine systems. The aim of the present review is an attempt to fill this gap to some extent and to survey the available information for the simplest case of α,α'-disubstituted nitrogen-containing heterocycles, namely α,α'-disubstituted pyridines. The review surveys also the methods of synthesis of α,α'-disubstituted pyridines described in numerous scattered articles and reviews devoted to specific problems and the advances achieved in this field in recent years.

II. METHODS OF SYNTHESIS OF α,α'-DISUBSTITUTED PYRIDINES

α,α'-Disubstituted pyridines can be obtained by various methods:

(1) By constructing the pyridine ring from aliphatic compounds.

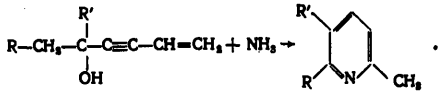


(2) By converting a wide variety of cyclic non-pyridine compounds into α,α'-disubstituted pyridines.

(3) By replacing one set of substituents in α,α'-disubstituted pyridines by another.

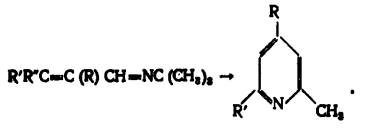
The methods of synthesis of new compounds involving a change in the nature of the substituents only in the β-, β'-, or γ-positions of the pyridine ring and not involving the α,α'-substituents constitute a special group, which will not be discussed in this review.

1. Synthesis of α,α'-Disubstituted Pyridines from Aliphatic Compounds



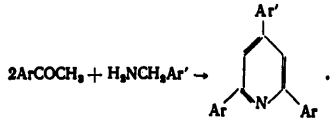
The classical method of synthesising α,α'-disubstituted pyridines with alkyl or aryl residues is the Chichibabin reaction, widely used in the pyridine chemistry and based on the condensation (usually in the gase phase) of ammonia with ketones, aldehydes, nitriles, acetylene derivatives, or their mixtures[1,2]. A series of 2,4,6-triarylpyridines have been synthesised by this method from aromatic aldehydes, aryl methyl ketones, and ammonium acetate[3]. The Chichibabin reaction is used also on an industrial scale to obtain synthetic 2,6-dimethylpyridine (2,6-lutidine) via the mechanism[4]

The synthesis of α,α'-dialkylpyridines by the interaction of aliphatic ketones with ammonia in the gas phase on a platinum catalyst has been recently reported[5].

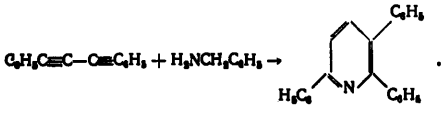


A number of 6-alkyl(aryl)-2-methylpyridines have been obtained by the condensation of vinylacetylenic alcohols

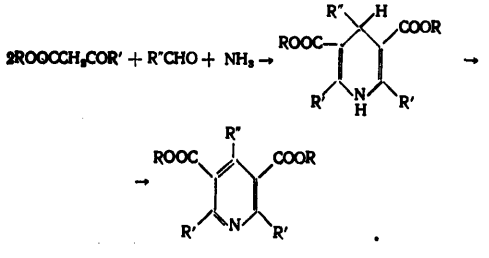
with ammonia[1]:



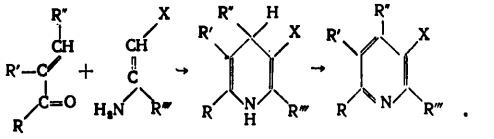
A mixture of the corresponding ketone with vinylacetylene can also be used in the reaction with ammonia.



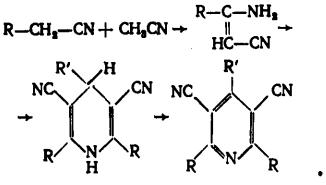
The reaction of unsaturated imino-compounds with chromium and aluminium salts has been used to obtain 4-ethyl-2,6-dimethylpyridine and its analogues via the mechanism[6]



2,4,6-Triarylpyridines are obtained by Reddelin's method involving the condensation of acetophenone with benzylamines in the presence of traces of hydrogen bromide[7,8]:

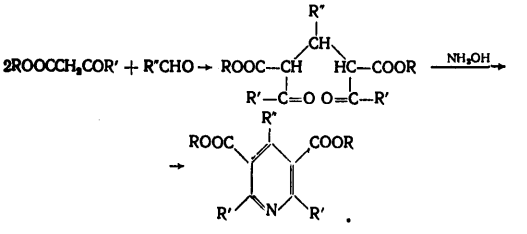


Refluxing of diphenylbutadiyne with benzylamine leads to 2,3,6-triphenylpyridine[9]:

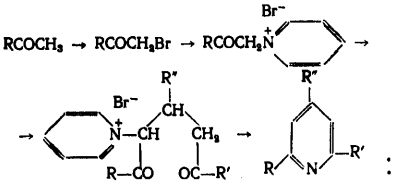


The Hantzsch reaction[10], involving the cyclocondensation of β-ketoesters with aldehydes and ammonia and subsequent oxidation of the 1,4-dihydropyridine derivatives formed, is of practical importance in the synthesis of α,α'-disubstituted pyridines:

Many modifications of Hantzsch's method are known. Instead of ammonia, ammonium acetate, formamide, urotropine, and more rarely primary amines are introduced into the reaction. Together with acetoacetic esters, the esters of cyanoacetic and malonic acids and their various derivatives are used as the carbonyl components: enol acetals, enol esters, iminoethers, etc. In many instances, particularly in the synthesis of asymmetric compounds, it is convenient to begin with α,β-unsaturated ketones, which are intermediates in the Hantzsch reaction formed on condensation of aldehydes with β-dicarbonyl compounds or from substances of analogous structure: methylene aldehydes, methylene ketimines and esters, acetylenic amidines[11], β-chlorovinyl ketones[12], etc. Another possible intermediate in the Hantzsch synthesis—β-aminocrotonic ester or substance of analogous structure (enaminoketones, enaminonitriles, etc.)—are frequently used as second components in these reactions[10,11]:

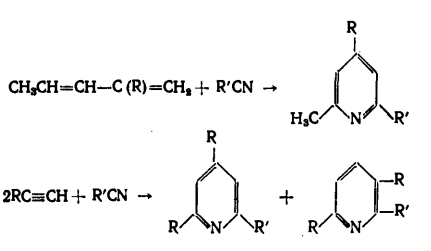


One of the variants of the Hantzsch synthesis is the Meyer–Mohr reaction[13], involving the cyclocondensation of aldehydes or ketones with enaminonitriles obtained on interaction of various nitriles with acetonitrile in the presence of strong bases:

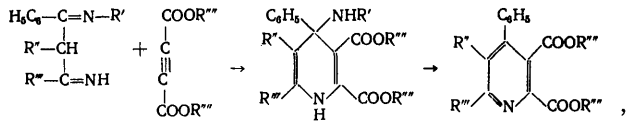


Another variant consists of the condensation of β-aminocrotonic ester with 1,3-enynylamines[14], sodioformylacetone, the acetal of ethoxycrotonaldehyde, or α-ethynylcarbonyl compounds[15].

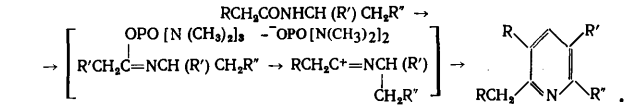
The isolation of the intermediate product of the condensation of acetoacetic ester with an aldehyde (a derivatives of a 1,5-diketone) and its treatment with hydroxylamine constitute a modification of the initial Hantzsch synthesis[253]:



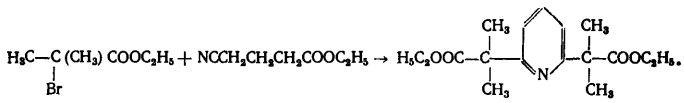
The direct cyclisation of 1,5-diketones and their oximes or imines has also been described[1,11,16].



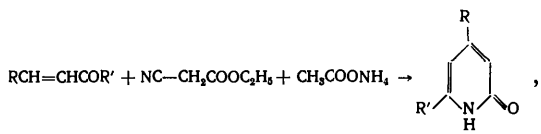
The synthesis of α,α'-disubstituted pyridines from *N*-acetonylpyridinium salts, unsaturated ketones, and ammonium acetate via 1,5-dicarbonyl compounds, proposed by Kröhnke,[17,18] is of considerable preparative interest:



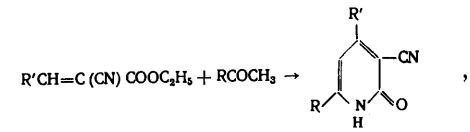
Certain α,α'-disubstituted pyridines have also been obtained by the reaction of nitriles with dienes[19] or acetylenes[20]:



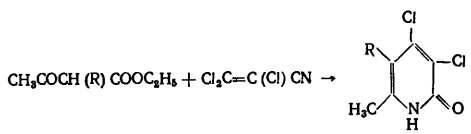
or of 1,3-di-imines with acetylenedicarboxylate esters[21]:



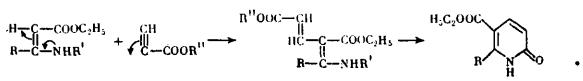
by the cyclisation of secondary carboxamides involving cautious heating in hexamethylphosphoramide[22]:



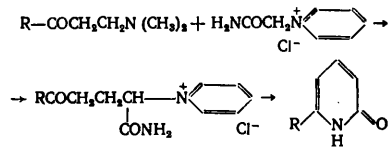
or by the condensation of α-bromoesters with γ-alkoxycarbonylnitriles under the conditions of the Reformatzky reaction[23]:



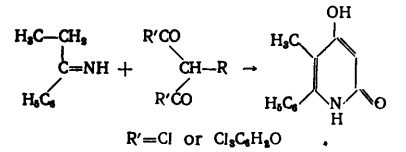
A method of synthesis of 6-substituted 2-pyridones, which follows directly from the Hantzsch reaction, is based on the condensation of the derivatives of malonic ester or malononitrile with enamines[24-28] and also of cyanoacetic ester with α,β-unsaturated ketones and aminoacetate[29]:



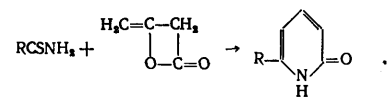
of cyanoacrylic esters with ketones[30]:



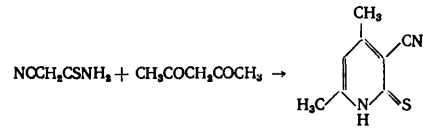
or of β-ketoesters with trichloroacrylonitrile[31]:



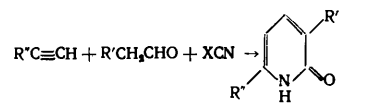
When enaminoesters react with propiolic acid esters, dienamines, which are also capable of cyclising to 6-substituted 2-pyridones, are formed readily[32]:



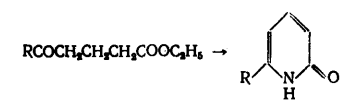
The condensation of α,β-unsaturated ketones or the corresponding products of the Mannich reaction with *N*-carbamoylmethylpyridinium salts also leads to 6-substituted 2-pyridones[33]:



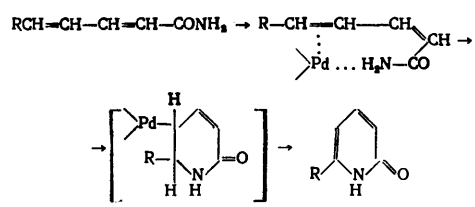
The 2-pyridones are likewise obtained when propiophenoneimine interacts with monosubstituted malonyl chlorides[34] or malonic esters[35]:



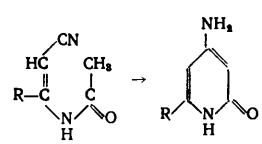
Another way of synthesising 6-substituted 2-pyridones containing in addition a hydroxy-group in the 4-position consists in the condensation of thioamides with diketen[36]:



The cyclocondensation of cyanothioacetamide with acetylacetone yielded 3-cyano-4,6-dimethyl-2-pyridinethione:

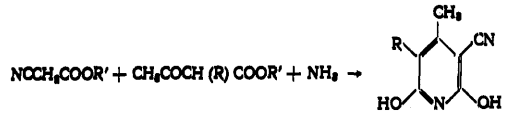


while the condensation of acetylenic compounds with aldehydes and nitriles gave rise to 3,6-disubstituted 2-pyridones[37]:

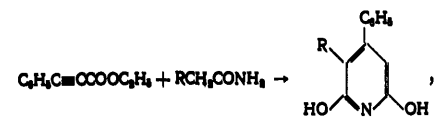


By analogy with the cyclisation of 1,5-diketones discussed above, the interaction of 5-oxoalkenecarboxylic acids or their derivatives (amines, nitriles, etc.) with ammonia or primary amines also leads to the formation of 2,6-disubstituted pyridines—in the given instance 6-substituted 2-pyridones[11]:

The methods of synthesis of 6-substituted 2-pyridones by the cyclisation of 2,4-pentadienamides with lithium chloropalladate(II) in acetonitrile in the presence of triethylamine[38], i.e.

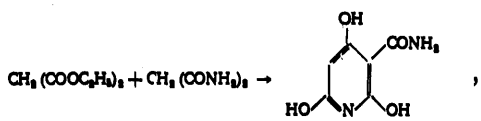


and the Dieckmann cyclisation of certain *N*-substituted amides via the mechanism[11]

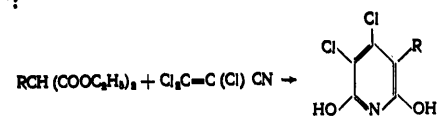


occupy a special place.

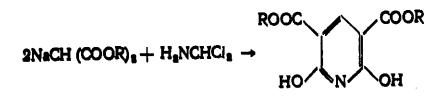
The most general and most widely used method of synthesis of α,α'-dihydroxypyridines is the Guareschi–Thorpe reaction[11,39,40], which is based on the cyclocondensation of cyanoacetic and α-alkylacetoacetic esters with ammonia:



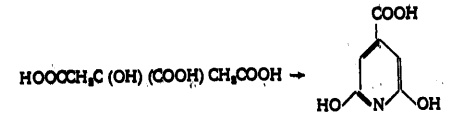
The corresponding amides are frequently used in this reaction instead of esters. The alkyl substituent R may contain different functional groups and multiple bonds. The cyclocondensation is usually carried out in water at room temperature, but reactions without a solvent or in non-aqueous media have also been described[39]. α,β-Unsaturated carbonyl compounds have been used instead of acetoacetic ester or amide[11]. Cyclocondensation with cyanoacetic ester or cyanoacetamide is carried out in this case in the presence of alkali metal alkoxides. One of the variants of the synthesis involves the interaction of cyanoacetic ester with aldehydes and ammonia, whereupon α,β-unsaturated carbonyl derivatives are formed as intermediates as a result of the reaction of the aldehydes with cyanoacetic ester.



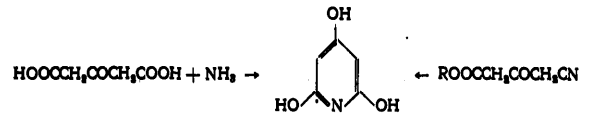
The cyclocondensation of phenylpropiolic ester with amides leads to 3,4-disubstituted 2,6-dihydroxypyridines[41,42]:



that of malonic ester with malonodiamide in the presence of sodium methoxide produces 3-carbamoyl-2,4,6-trihydroxypyridine[43]:

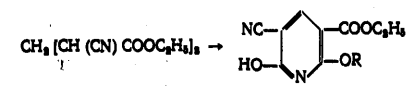


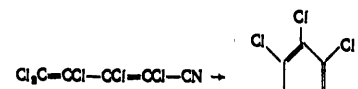
and that of substituted malonic ester with trichloroacrylonitrile under the influence of potassium t-butoxide results in the formation of 3-substituted 4,5-dichloro-2,6-dihydroxypyridines[44]:



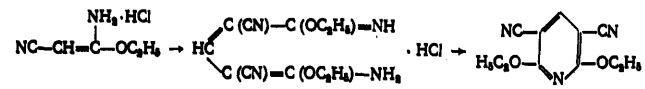
The Gattermann–Skitta reaction, involving the formation of 2,6-dihydroxypyridines by the cyclocondensation of sodiomalonic ester with dichloromethylamine, is a variant of the Hantzsch synthesis[254]:

Different variants of the cyclisation of glutaric acid and its substituted derivatives are widely used for the synthesis of α,α'-dihydroxypyridines. β-Oxo-, β-hydroxy-, and β-imino-derivatives of glutaric acid as well as substituted β-carboxy-β-hydroxyglutaric (citric) acid are most often used for this purpose[11]. An example is provided by the synthesis of 2,6-dihydroxyisonicotinic (citrazinic) acid from citric acid and its conversion into isonicotinic acid (the method has found industrial application)[45]:

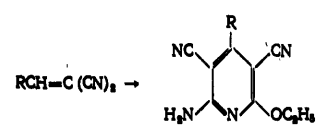




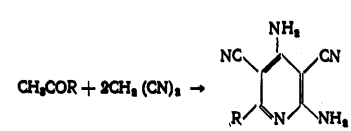
as well as the cyclisation with ammonia of β-oxoglutaric (acetonedicarboxylic) acid, its esters, or mononitrile[11]:



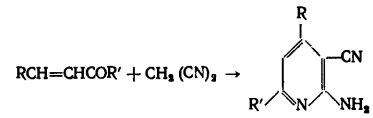
Aryl isothiocyanates or aryl isocyanates have also been used as nitrogen-containing components in these reactions[46].



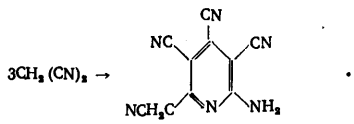
The reactions of methylenebiscyanoacetic esters[11] and pentachloropentadienonitrile[47] with alkali metal oxides as well as the interaction of acid α-methylene derivatives with symmetrical triazine[48] have been used for the closure of a pyridine ring containing 2-alkoxy-6-hydroxy(alkoxy) substituents:



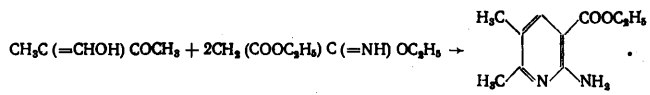
The most general method of synthesis of 2-alkoxy-6-aminopyridines, based on the closure of the pyridine ring, is the condensation of substituted methylenemalonodinitriles with alkali metal alkoxides[49–52]:



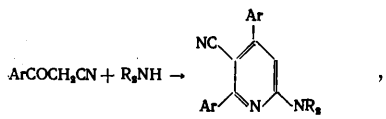
The reactions of acetoacetic or malonic esters with methylene amidines, methyleneimidates, and 5-aminopyrazolones[53], the cyclisation of acetonedicarboxylic ester with ammonia[54], and the condensation of acetylenic compounds with cyanamide[20] are used for these purposes.



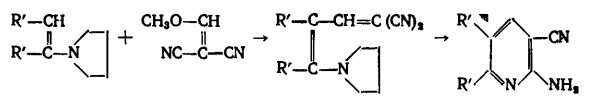
Malonodinitrile has been widely used in recent years in the synthesis of 6-substituted 2-aminopyridines[55]; the condensation of the dinitrile with methyl ketones in the presence of an excess of ammonium acetate leads to 6-alkyl-2-aminopyridines[56,57]:



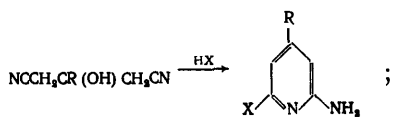
The reaction with unsaturated ketones proceeds in a somewhat different manner[56] via the mechanism



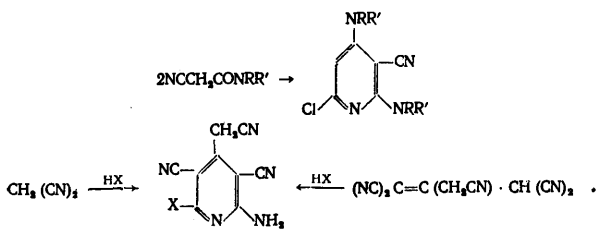
Under the influence of zinc chloride, malonodinitrile trimerises[55]:



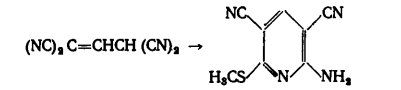
Substituted 2-amino-6-methylpyridine has been obtained by the condensation of ethyl α-hydroxymethylenemethyl ketone with monoiminomalonic ester[58]:



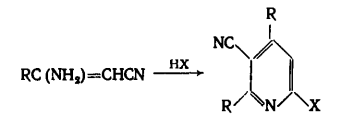
The analogous 6-aryl derivatives are formed on condensation of ω-cyanoacetophenones with secondary amines[59]:



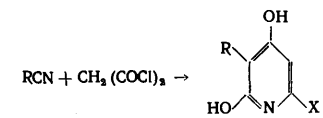
while 6-alkyl derivatives are formed when enamines interact with methoxymethylenemalonodinitrile via intermediate dienamines[60]:



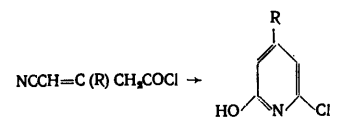
The reactions of 3-hydroxyglutarodinitrile with primary and secondary amines lead to substituted α,α'-diaminopyridines[61]. The use of anhydrous hydrogen bromide or iodide in analogous processes makes it possible to obtain high yields of 2-amino-6-halogenopyridines[62,63]:



Both possible 2,6-disubstituted isomers are obtained from asymmetric starting materials[64]. Instead of the hydroxy-derivative, the corresponding unsaturated dinitrile can be used in the reaction[65]. Substituted 2-amino-6-chloropyridines have been obtained by the interaction of cyanoacetyldialkylamines with phosphoryl chloride[66] and also by treating malonodinitrile[67], 1,1,3,3-tetracyanopropene, or 2-cyanomethyl-1,1,3,3-tetracyanopropene[63] with hydrogen halides:

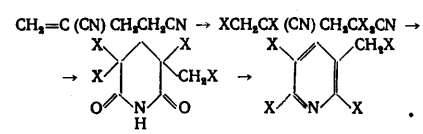


The condensation of 1,1,3,3-tetracyanopropene with methylisothiourea leads to substituted 2-amino-6-methylthiopyridine[68]:



The interaction of enamines with methoxymethylenemalonodinitrile and treatment of the intermediate dienamines with hydrogen halides instead of ammonia made it possible to obtain 6-substituted 2-halogenopyridines[60]. Analogous compounds are also formed on cyclisation of the nitriles or esters of 6-aminocinnamic and β-aminocrotonic acids in the presence of hydrogen halides[70,71]:

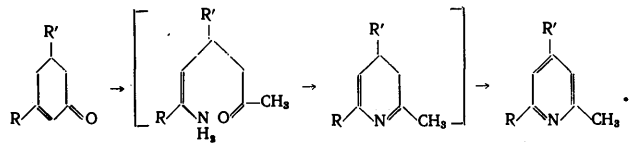
2-Halogeno-6-hydroxypyridines have been synthesised by the condensation of malonyl chloride with nitriles[71]:



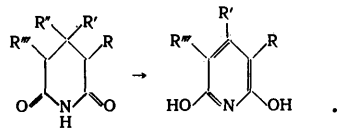
Another method of synthesising compounds of this type consists in the cyclisation of the chlorides of unsaturated γ-cyanoacids under the influence of hydrogen halides[72]:

6-Alkoxy-2-halogenopyridines are formed on cyclisation of perchloropentadienonitrile under the influence of a Grignard reagent[73].

The reaction of glutaramides and glutarimides with phosphorus halides and subsequent aromatisation of the cyclic halogeno-derivatives[74,75] as well as the dimerisation of acrylonitrile, the halogenation of the dimer, the cyclisation of the product, and treatment of the substituted glutarimide with phosphoric acid halides[76] have been used to obtain 2,6-dihalogenopyridines:

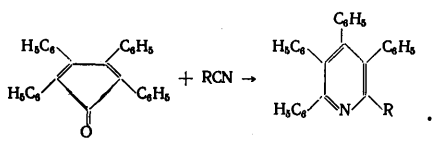


2. The Synthesis of α,α'-Disubstituted Pyridines from Other Cyclic Compounds

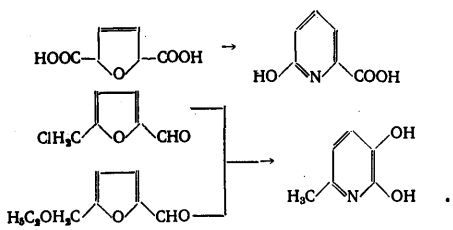


Methods based on the conversion of various non-pyridine cyclic systems into pyridine systems have played an important role in the synthesis of α,α'-disubstituted pyridines.

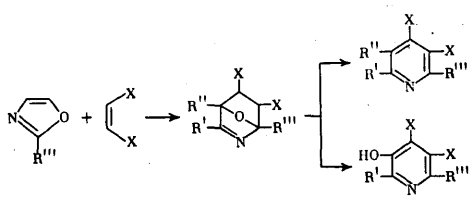
6-Substituted 2-methylpyridines have been obtained[77] in low yields by heating cyclohexanones with ammonia or ammonium chloride under pressure at 250 °C.[77] It was assumed that the process proceeds via the intermediate formation of



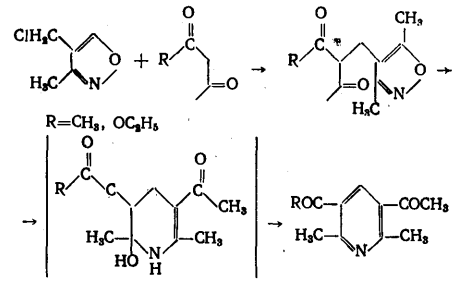
enamines derived from 1,5-dicarbonyl compounds:



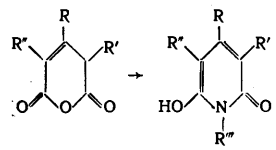
The synthesis of α,α'-dihydroxypyridines (derivatives of glutaconimide) by the oxidation of the corresponding glutarimides has been described[11]:



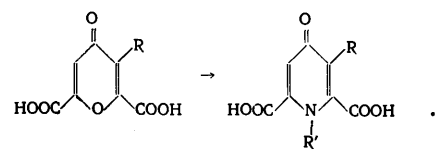
High yields have been achieved in the Diels–Alder condensation of tetraphenylcyclopentadienone with nitriles[78]:



6-Hydroxypicolinic acid has been obtained from 2,5-dicarboxy-2,5-dihydrofuran on heating to 160 °C with aqueous ammonia and ammonium bromide[79]. The reactions of 5-chloromethyl- and 5-ethoxymethyl-furfurals with aqueous ammonium chloride result in the formation under the same conditions of 2,3-dihydroxy-6-methylpyridine together with other products, while 5-substituted 2-acetylfurans are converted into 2,6-disubstituted 3-hydroxypyridines[80–82]:

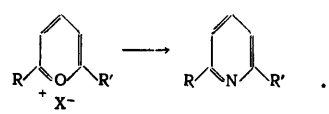


The azadiene condensation of substituted oxazoles with dienophiles (the Kondrat'eva reaction), discovered at the end of the 1950's, constitutes an interesting method of synthesis of α,α'-disubstituted pyridines[83]:

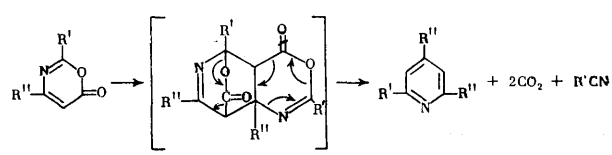


α,α'-Disubstituted pyridines have been synthesised from isoxazoles by catalytic hydrogenation via the mechanism[84,85]

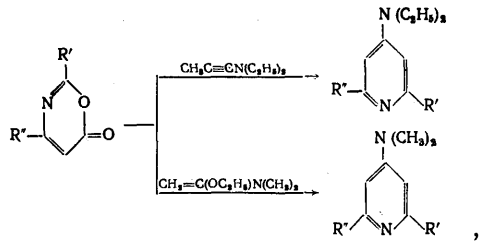
The transformations of the corresponding six-membered oxygen-containing heterocycles occupy a definite place in the synthesis of α,α'-disubstituted pyridines. For example, 6-substituted α-pyrones, obtained by the reaction of malonyl chloride with isocyanates, are converted by treatment with ammonia or amines into the corresponding 6-substituted 2-hydroxypyridines[11,86]. Reactions of this type have been examined in a review[87]:



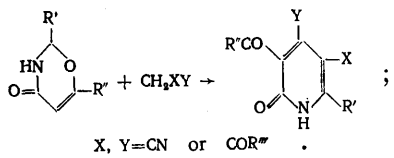
α,α'-Disubstituted γ-pyrones of the type of chelidonic acid are converted into α,α'-disubstituted γ-pyridones (derivatives of chelidamic acid) on treatment with ammonia or amines[88]:



α,α'-Dihalogeno-γ-pyrones give rise similarly to α,α'-dihalogeno-γ-pyridones[89].

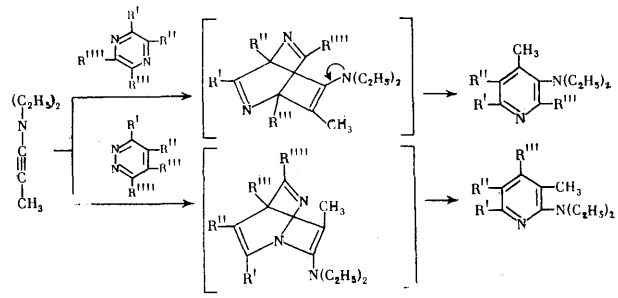


Numerous 2,6-disubstituted pyridines [including 2,6-di(t-butyl)pyridines, which are difficult to obtain by other methods[90]] have been synthesised by the reaction of 2,6-disubstituted pyrylium salts with ammonia or amines[91–93]:

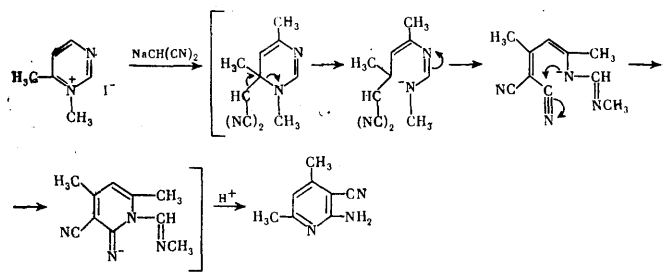


A group of methods is based on the use of oxazine and diazine derivatives as starting materials. These include the pyrolytic cleavage of 6-hydroxy-6*H*-1,3-oxazines[94]:

on interaction with ynamines and keten *O*,*N*-acetals[95]:



and also the reactions of 2-aryl(alkyl)-4-hydroxy-4*H*-1,3-oxazines with β-dicarbonyl or β-cyanocarbonyl compounds[96]:



X, Y=CN or COR''' .

The Diels–Alder condensation of 1-diethylaminopropyne with pyrazine[97] and pyridazine[98] derivatives, i.e.

and the rearrangements of 4-substituted pyrimidines and their quaternary derivatives under the influence of nucleophiles[99–101], i.e.

belong to the same group.

3. Methods of Transforming α,α′-Substituents in the Pyriding Ring

Reactions involving the classical transformation of one set of α,α′-substituents in pyridine structures into another occupy an important place in the synthesis of α,α′-disubstituted pyridines[1,11].

2,6-Dihydroxypyridines are obtained by the hydrolysis of 2,6-diamino, 2,6-dihalogeno-, or 2,6-dialkoxy-pyridines; 6-chloro-2-hydroxypyridines are synthesised by the diazotisation of 2-amino-6-chloropyridine and by the hydrolysis of 2,6-dichloro- or 2-alkoxy-6-chloro-pyridines. 2,6-Dialkoxypyridines are synthesised by the reaction of 2,6-dihalogenopyridines with alkali metal alkoxides[102] or by the alkylation of 2,6-dihydroxypyridines[103]. Under milder conditions, 2,6-dihalogenopyridines react with alkali metal alkoxides to form 6-alkoxy-2-halogenopyridines.

2,6-Dihalogenopyridines are obtained by the reaction of the corresponding 2,6-dihydroxy-derivatives with phosphoric acid halides or hydrogen halides, by the direct halogenation of pyridine bases, their *N*-oxides, or carboxylic acids[104,105], by the substitution of one halogen by another on interaction with hydrogen halides or their salts[106,107], by the arrangement of 2-chloropyridine *N*-oxide on interaction with phosphoryl chloride[108], and by the replacement of nitro-groups by a halogen in the reaction with hydrogen halides.

The reactions of various α,α′-disubstituted pyridines with hydroxy- or halogeno-groups as substituents with P_2S_5 yielded α,α′-dimercaptopyridines[109].

2-Amino-6-halogenopyridines have been synthesised from 2,6-dihalogenopyridines by the substitution of one halogen by an amino-group and from 2-amino-6-hydroxypyridine by the substitution of the hydroxy-group by a halogen; 2,6-diaminepyridines have been synthesised by the corresponding reactions of 2,6-dihalogenopyridines or 6-alkoxy-2-chloropyridines, by the direct Chichibabin amination of pyridines[110], or from dipicolinic acid via the Curtius or Hofmann reactions[111].

6-Alkoxy-2-aminopyridines are obtained by substituting the halogen by an amino-group in 6-alkoxy-2-halogenopyridines; 2-amino-6-nitropyridines are synthesised by the substitution of the bromine atom by the amino-group in 2-bromo-6-nitropyridines; 2-amino-6-hydroxypyridines are obtained by the Chichibabin reaction from α-pyridone or by the hydrolysis of 2,6-diaminopyridine. An interesting instance of the direct amination of 3-azido-2-nitropyridine with formation of a 6-amino-2-nitropyridine derivative and of 2,3,6-triaminopyridine from the latter has been described recently[112].

Direct nitration of pyridine in the α,α′-positions with formation of the 2,6-dinitro-derivatives is possible only in the presence of a strong electron-donating substituent such as an alkoxy-group in the β-position[113]. 3-Methoxy (or hydroxy)-6-methylpyridines are converted on nitration into 3-methoxy(or hydroxy)-6-methyl-2-nitropyridines[114]; the nitration of 3-hydroxy-2-nitropyridine leads to 2,6-dinitro- and 3-hydroxy-2,4,6-trinitropyridine[115]. Kinetic studies have shown that the nitration process involves in these instances the protonated form and that the partial nitration rate constants are 4×10^{-10} for the 2-position and 1×10^{-11} for the 6-position in the 3-methoxypyridinium cation[116]. The halogenation of 3-alkoxy(or hydroxy)pyridines leads similarly to 2,6-dihalogeno-derivatives[113,117], aminomethylation gives rise to 3-alkoxy(hydroxy)-2,6-di(aminomethyl)pyridines[113,118,119], and hydroxymethylation leads to 3-alkoxy-2,6-di-(hydroxymethyl)pyridines[113].

The aminomethylation of 3-hydroxypyridines containing alkyl, alkoxy-, hydroxy-, or nitro-groups in the 2-position, takes place in the 6-position[113,120–124] and the hydroxymethylation of 3-hydroxy-6-methylpyridine involves the 2-position [123,125]; 5-hydroxypicolinic acid is converted as a result of an analogous reaction into 5-hydroxy-6-hydroxymethylpicolinic acid[126]. The azo-coupling of 2,3-dihydroxy-3-ethoxy-2-methoxy-, or 2,5-dihydroxy-pyridines involves the 6-position[127].

Methods of synthesis of 2,6-di(hydroxymethyl)pyridine from 2,6-lutidine via 2,6-diformylpyridine[128-130] or its *N*-oxide[131], via 2,6-di(chloromethyl)pyridine[132] and 2,6-dicyanopyridine[133], and also on the basis of the Böckelheide reaction repeated twice[134] or the oxidation of 2,6-lutidine to dipicolinic acid with reduction of the esters of the latter by complex metal hydrides have been recommended[135].

2,6-Di(bromomethyl)pyridine has been obtained from 2,6-di(hydroxymethyl)pyridine[136] and also by the direct radical bromination of 2,6-lutidine[137]. 2,6-Diformyl pyridine has been synthesied by the catalytic oxidation of 2,6-lutidine[128, 130,138]. 6-Formylpicolinic acid has been obtained similarly from 6-methylpicolinic acid[11].

The Claisen condensation of dipicolinic ester with ethyl acetate has been used to synthesise 2,6-diacetylpyridine[139], while 2,6-dibenzoylpyridine has been obtained by the Friedel–Crafts condensation of dipicolinic acid dichloride with benzene[11]. 2,6-Diacylpyridines have been reduced by the Kishner method to 2,6-dialkylpyridines[140].

The reaction of pyridine *N*-oxide with phenylmagnesium bromide gave a low yield of 2,6-diphenylpyridine together with 2-phenylpyridine[11]. The synthesis of 2,6-dicyanopyridine from 2,6-dibromopyridine and copper cyanide has been described[141].

Potassium permanganate[142], selenium dioxide or its complexes[143], nitrogen oxides in the presence of selenium dioxide[144], sodium dichromate and chromic anhydride[145] have been used as oxidants for the conversion of 2,6-lutidine into 6-methylpicolinic and dipicolinic acids. Dipicolinic acid has also been obtained by the carboxylation of pyridine[146] or picolinic acid[147] and by the oxidative ammonolysis of 2,6-lutidine[148,149] with subsequent hydrolysis of 2,6-dicyanopyridine[150].

III. CHEMICAL CHARACTERISTICS OF α,α′-DISUBSTITUTED PYRIDINES

1. The Influence of α,α′-Substituents on the Reactivity of the Nitrogen of the Pyridine Ring

In the complex mechanism of the influence of α,α′-substituents on the pyridine nitrogen atom steric effects, which have been studied in greatest detail in relation to 2,6-dialkylpyridines, play an important role. Brown and coworkers[151-153] and then other investigators[154,155] showed that, when α,α′-methyl groups are introduced, steric hindrance to the protonation of the pyridine nitrogen is not observed. However, on passing to 2,6-di(t-butyl)pyridine, the pK_a and the heats of neutralisation with methanesulphonic acid in nitromethane (ΔH) clearly indicate a significant steric hindrance in the protonation process. In the analogous reaction with picric acid steric hindrance is manifested even in 6-(t-butyl)-2-isopropylpyridine, which, like 2,6-di(t-butyl)pyridine is incapable of forming a picrate.

On passing from protonation to complex formation involving more bulky reagents—the Lewis acids [BH_3, BF_3, and $B(CH_3)_3$]—steric hindrance becomes appreciably more significant. For example, the heats of formation of complexes with BF_3 decrease in the sequence pyridine > α-picoline > 2,6-lutidine by 9.2 and 35.6 kJ mol^{-1} respectively. In the analogous reaction in $B(CH_3)_3$ the value of $\Delta\Delta H$ is 24.7 kJ mol^{-1} even for α-picoline, while 2,6-lutidine does not form a complex with this reagent at all.

The above steric effects are not only of theoretical but also of preparative interest in a number of instances; the methods of separation of 2,6-lutidine from other components of the β-picoline fraction[156] and the methods of separation of protic and Lewis acids[157] are based on them.

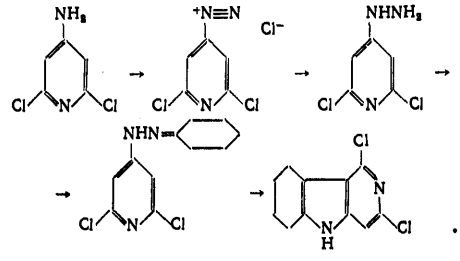
Analogous steric effects are observed also in the interaction of α,α′-disubstituted pyridines with alkyl halides. For example, 2,6-di(t-butyl)pyridine does not form a quaternary salt even with methyl iodide. 2,6-Dimethyl-, 2,6-diethyl, and 2,6-di-isopropylpyridines are converted under identical conditions into methiodides in yields of 99, 74, and 45% respectively[140].

α,α′-Functional substituents exert a more complex influence on the heterocyclic nitrogen atom. For example, in the case of 2,6-dihalogenopyridines the substituents exhibit, in addition to a definite steric effect, a much stronger inductive electron-accepting influence[158]. In contrast to compounds without halogen atoms or α-monohalogeno-derivatives[158-160], 2,6-dihalogenopyridines do not form stable salts with inorganic acids, do not give rise to picrates or complexes with Lewis acids[74,158,161], form quaternary salts with very great difficulty even after prolonged heating at high temperatures under pressure, and are virtually not oxidised to N-oxides[158].

In contrast to 6-methylpicolinic acid, dipicolinic (pyridine-2,6-dicarboxylic) acid is a very weak base and, for example, does not combine with cation-exchange resins in the H^+-form. This permits the esterification of dipicolinic acid by various alcohols in the presence of ion exchangers in high yields[135].

2. The Influence of α,α′-Substituents on the Transformations of the Functional Groups in Other Positions in the Pyridine Ring

The change in the basicity of the pyridine nitrogen under the influence of α,α′-substituents influences not only the processes involving the heteroatom but also the reactivity of the entire pyridine system.

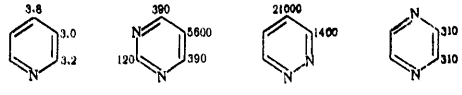


Significant differences between the reactions of pyridines and the analogous benzene derivatives are known to be related both to the change in the distribution of electron densities in the aromatic system owing to the electron-accepting influence of the pyridine nitrogen and to the fact that many electrophilic reactions do not involve the free pyridine bases but take place with participation of the corresponding "conjugate acids", which are characteristed by an even greater electron-accepting effect of the positively charged heteroatom[162,163].

The introduction of α,α′-substituents into the pyridine ring affects both the distribution of electron density in the system and the ease of formation of the corresponding "conjugate acids". The influence of the ring heteroatom is therefore to a large extent blocked in many reactions of pyridines having electron-accepting or sterically hindered substituents in the 2- and 6-positions and compounds of this type begin to behave like the analogous benzene derivatives.

Pyridines are sulphonated with fairly considerable difficulty, forming more readily complexes with SO_3 via the nitrogen atom[11]. 2,6-Di(t-butyl)pyridine, in which the nitrogen heteroatom is sterically hindered and is incapable of forming the "conjugate acid" under the reaction conditions, proved to be capable of being sulphonated in the 3-position under very mild conditions—by reaction with sulphur trioxide in liquid SO_2 below 0 °C.[151,152] In contrast to the corresponding dehalogenated compounds, the γ-methyl group in α,α′-dihalogeno-γ-methylpyridines does not condense with aldehydes and mesoxalic ester and is not oxidised by selenium dioxide even under very severe conditions[158]. The chlorides of 2,6-dihalogenopyridine carboxylic acids readily undergo the Rosenmund reaction to aldehydes[164], like the chlorides of

aromatic acids; the corresponding 2,6-dehalogenated derivatives of pyridine are not converted into aldehydes by this procedure.



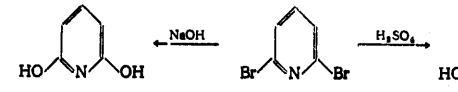
In contrast to the usual 4-aminopyridines, which do not form stable diazonium salts, 4-amino-2,6-dichloropyridine is easily converted on treatment with sodium nitrite into a fairly stable diazonium salt[165], which is reduced in a high yield by tin(II) chloride to 2,6-dichloro-4-pyridylhydrazine. The thermal conversion of the corresponding 4-pyridylhydrazones into indoles in methylene glycol, in which a positively charged pyridinium nitrogen is not formed, actually proceeds with greater difficulty and is less unambiguous for 2,6-dichloropyridines than for the analogous substances without halogen atoms[165]:

Apparently the smaller capacity of α,α'-dihalogenopyridine derivatives for solvation by ethylene glycol has an effect in this instance.

Interesting results were obtained in the study of the quantitative effects of α-substituents by the method of correlation analysis. Determination of a series of such compounds led Zuman[166] to assert that such substances exhibit the "effect of proximity to the heteroatom" with a deviation from the correlation. A study of different series showed that, in contrast to *ortho*-substituted anilines, for α-substituted pyridines the correlation is better in terms of σ_{meta} and σ_{ortho} constants; on this basis, the author[167] concluded that there is virtually no transmission of the influence of α-substituents in terms of the conjugation effect. Owing to the short distances between the α-substituent and the nitrogen, the mutual influence of these reaction centres is exerted through space and not through the bonds. The field effect is taken into account by σ' and σ* constants and less rigorously by the σ_{meta} constant. A field effect decaying rapidly with distance is virtually atypical for the analogous benzene derivatives, where the distance between the reaction centres in the *ortho*-positions is much greater.

For a quantitative estimate of the influence of α-substituents in *N*-heteroaromatic systems, measurements were made[168] of the rate of deuterium isotope exchange in an alkaline medium for different positions of the heterocycles (the rate constants for the exchange of the corresponding hydrogen atoms at 164.6 °C multiplied by a factor of 10^6 are indicated below):

It was found that the hydrogen atoms located near the carbon atoms between the two nitrogen atoms or at the carbon atoms adjoining the nitrogen atoms usually exhibit the smallest capacity for deuterium exchange under these conditions. In pyridine, for example, the base-catalysed deuterium exchange takes place most readily in the 4-position[169], although according to the calculations of charges by the Hückel method the 2-position should be the most "acid"[168].



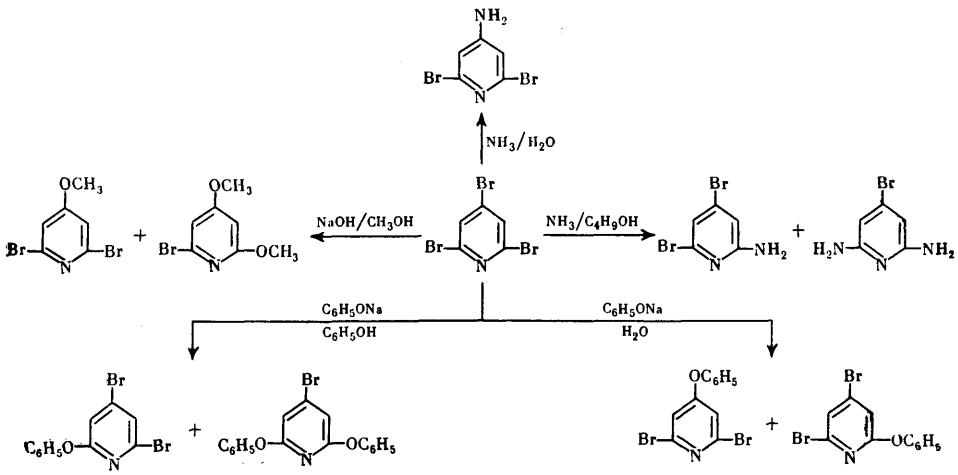
The reduced activity of the α-positions in isotope exchange reactions[170] is apparently the result of the operation of two factors: the decrease of the amount of *s* character of the hydrogen bond with the carbon adjoining the atom of the nucleophile and the repulsion between the electron pairs of the nitrogen and the carbanion being generated. These factors were studied theoretically by various investigators from the standpoint of the theory of hetarynes[171] and α-effects[168, 172].

The above effects should apparently be taken into account also in the study of the characteristics of the chemical behaviour of α,α'-disubstituted pyridines, but as yet there is no information in the literature about this subject.

3. Comparative Reactivities of α,α'- and γ-Substituents in the Pyridine Molecule

The differences between the reactivities of α- and γ-substituents in the pyridine ring, on the one hand, and β-substituents, on the other, have been studied in fair detail[11]. At the same time the comparative reactivities of α-, α'-, and γ-substituents in pyridine compounds have been little investigated. There are as yet no theoretical generalisations in this field and the problem is still mainly in the stage of the accumulation of experimental data. Unfortunately in the series of pyridines, including α,α'-disubstituted and α,α',γ-trisubstituted derivatives, a detailed analysis of the effect of specific solvation and of the influence of various solvents on the reaction mechanism, of the kind carried out, for example, for pyrimidine derivatives[173], has not been performed.

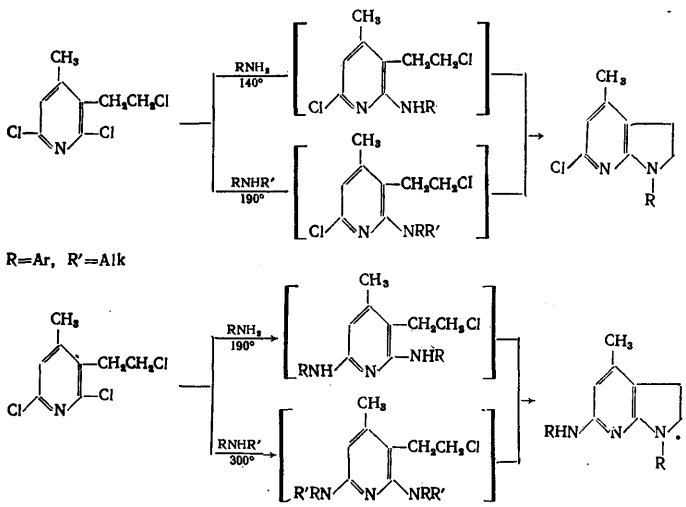
It has been established experimentally that, on heating with an aqueous solution of sodium hydroxide, 2,6-dibromopyridine is fairly smoothly converted into 2,6-dihydroxypyridine, while heating with 70% sulphuric acid even at 160 °C leads only to 6-bromo-2-hydroxypyridine[11]:



Nucleophilic substitution of 2,4,6-tribromopyridine takes place in the 4- and 2,4-positions in a methanol solution of sodium hydroxide, in the 2- and 2,6-positions in the presence of sodium phenoxide with an excess of phenol, in the 2- and 4-positions in an aqueous solution of sodium phenoxide, in the 4-position in an aqueous solution of ammonia, and in the 2- and 6-positions in a butanol solution of ammonia[11] (see scheme at the top of page 574).

Analogous effects are observed also in the reactions of polyhalogenopyridines. For example, pentachloropyridine reacts with magnesium and butyl-lithium in ether in the 4-position[174]; in methylcyclohexane the same reaction with butyl-lithium takes place only in the 2-position[175-177].

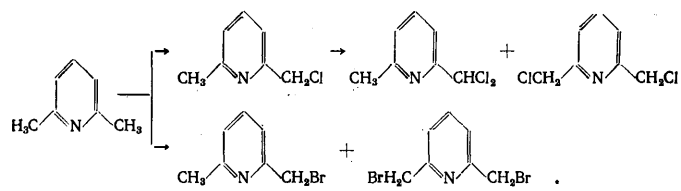
The interaction of pentachloro-,[74] pentabromo-,[178] and pentafluoropyridines[179] with a series of nucleophiles proceeds selectively at the $C_{(4)}$ atom. On the other hand, pentachloropyridine reacts with certain amines only at the $C_{(2)}$ atom[180], while in others it gives rise to a mixture of products of substitution at the $C_{(2)}$ and $C_{(4)}$ atoms[181]. It has been shown recently[182] that the reaction of pentafluoropyridine with pentafluorophenol in the presence of potassium fluoride and 18-crown-6-ether proceeds selectively with substitution of fluorine in the 2-position, although normally this mode of reaction is atypical for pentafluoropyridines[183-185].



The *N*-sodio-derivative of α-aminopyridine formed in the Chichibabin reaction as a result of the interaction of pyridine with sodium amide is again aminated with sodium amide at a

higher temperature to give 2,6-diaminopyridine. The same compound is also formed on interaction of 2-dimethylaminopyridine with sodium amide; the dimethylamino-group is split off in the form of an *N*-sodio-derivative[186].

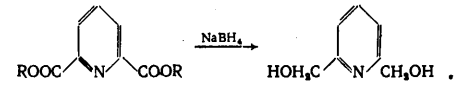
In contrast to aromatic diamines, forming 1 : 2 complexes with Lewis acids, 2,6-diaminopyridine combines with only one BF_3 molecule (like 2,4,6-triaminotriazine) to form a 1 : 1 adduct[187]. The hydrolysis of 2,6-diaminopyridine yields only 6-amino-2-hydroxypyridine[11].



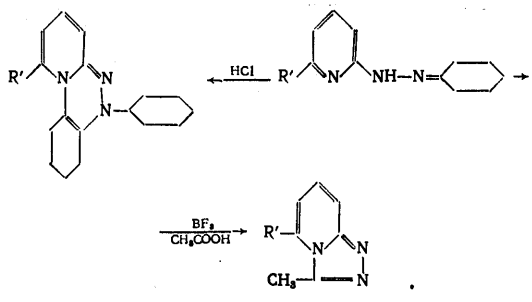
The products of the interaction of substituted 2,6-dichloropyridine (trichlorocollidine) with primary and secondary amines indicate different reactivities of the α- and α'-chlorine atoms in this compound:

The α- and α'-chlorine atoms interact with aromatic amines at 140° and 190 °C respectively[188]; the α-chlorine atom begins to interact with secondary amines of the type of *N*-alkylanilines at 190 °C, while the α'-chlorine atom does not react until 300 °C, *N*-dealkylation occurring in both cases[188-190]. The processes are very sensitive to steric hindrance and the reaction with t-butylamine does not occur at all[188]. After the substitution of the α- or α,α'-chlorine atoms in trichlorocollidine by amine residues, cyclisation involving the β-chloroethyl side chain takes place readily and 7-azaindoline derivatives are formed[189].

Kinetic studies of the oxidation of 2,6-lutidine with potassium permanganate in an aqueous medium showed that the process takes place stepwise and the products corresponding to all oxidation stages are formed even in the earliest stages: 2,6-lutidine → 6-methylpicolinic acid → dipicolinic acid → oxalates → carbonates[142].



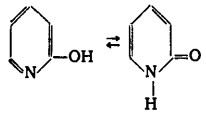
On bromination of 2,6-lutidine with *N*-bromosuccinimide, the monobromo-derivative and the symmetrical dibromo-derivative were isolated in low yields[137]. Further halogenation in CCl_4 at 60 °C in the presence of added sodium carbonate and water of 2-chloromethyl-6-methylpyridine, obtained by the chlorination of 2,6-lutidine, leads to the formation of the asymmetric dichloro-product at a rate which is 3.7 times faster than the formation of the symmetrical product[191]. The opposite results have been described for the reactions of 2,6-lutidine with organolithium compounds[192]:



Analysis of the differences between the reactivities of the α,α'- and γ-substituents in the pyridine ring has shown that in many cases the differences are caused by the formation of intermediates with participation of the α,α'-substituents and the pyridine nitrogen atom. For example, it has been established[193] that, in the reduction of isomeric bisalkoxycarbonylpyridines with di-isobutylaluminium hydride, the ester residues in the α,α'-positions of the pyridine ring are the first to be converted into aldehyde groups. This is apparently caused by the favourable energetic factors in the formation of intermediate cyclic products with participation of the complex hydride, the ester groups, and the pyridine nitrogen.

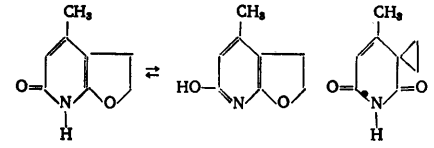
The formation of an intramolecular complex also explains the tendency of pyridine-2,6-dicarboxylate (dipicolinate) esters to be reduced by sodium tetrahydroborate, used in the large-scale industrial synthesis of the medicinal preparation paramidin[135]. Sodium tetrahydroborate does not usually interact with ester groups but dipicolinate esters are reduced by this reagent to 2,6-di(hydroxymethyl)pyridine

in high yields:



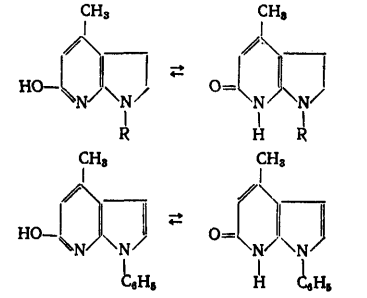
Processes in which the cyclic substances formed are the final reaction products also belong to the class of reactions involving the formation of new rings with participation of the α,α′-substituents and the pyridine nitrogen atom. For example, when 6-bromo- and particularly 6-methyl-2-pyridinylhydrazones of cyclohexanone are treated with hydrochloric acid or the etherate of boron trifluoride in acetic acid, cyclisation via the pyridine nitrogen atom takes place under the conditions of the Fischer reaction. This results in the formation of derivatives of 1*H*-benzo[1,2-*e*]pyrido[2,1-*c*]-*asymm*-triazine and triazolo[4,3-*c*]pyridine:[194–196]

4. Problems of the Tautomerism and the Dual Reactivity of α,α′-Disubstituted Pyridines



The characteristics of the distribution of electron density in α,α′-disubstituted pyridines, the nature of the protonation and solvation of these compounds have a significant influence on the lactam–lactim tautomerism of 6-substituted 2-hydroxypyridines.

It is known[197–199] that the lactam–lactim tautomeric equilibrium involving α- and γ-hydroxypyridines in aqueous solutions is greatly displaced towards lactams. The enthalpy characterising the extent to which the oxo-form is favoured by energy factors amounts to 14.2 kJ mol^{-1} for α-pyridone[200], while the tautomeric equilibrium constant is 3.0.[197]



The formation of associated species via intermolecular hydrogen bonds[201–204] and solvation effects[205,206] apparently play an important role. The decrease of the concentration of the test substance in non-polar solvents and an increase of temperature displace somewhat the tautomeric equilibrium in the direction of lactims even in more concentrated solutions [201,207]. For example, at an α-pyridone concentration in cyclohexane of 1.25×10^{-7} M, pK_T decreases to 1.6.[201] However, in this case too the oxo-tautomer predominates[201,208]. It has been established recently by ultraviolet[209] and infrared[213–217] spectroscopy and mass spectrometry[210–212] that only in the gas phase is the tautomeric equilibrium involving α-pyridone displaced towards the hydroxy-form with an equilibrium constant of ~0.4.[201,207,218]

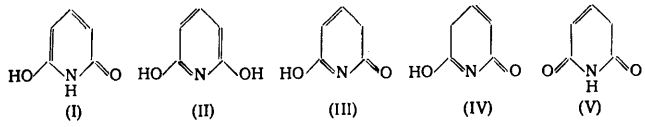
Up to 1966 very little was known about the influence of substituents in α-pyridones in the 6-position on the prototropic lactam–lactim tautomeric equilibrium. Only a report about the differences between the ultraviolet spectra of perchloro-2-pyridone and its *N*-methyl derivative, indicating different chromophoric systems in these compounds, was published[219]. Furthermore, there has been a report, which aroused a wide controversy, concerning the preparative separation of the oxo- and hydroxy-tautomers of 6-hydroxy-4-methyl-2,3-dihydrofuro[2,3-*c*]pyridine, which have different solubilities in ethyl acetate, different melting points, different ultraviolect spectra, and different colour reactions with iron(III) chloride[220]. However, further investigations [221–223] disproved the possibility of isolating individual stable hydroxy- and oxo-tautomers and showed that the second compound is an isomeric product with a spiro-structure:

It was discovered in 1966 [224] that, on passing from α-pyridone to the analogous derivatives of dihydropyrrolo-[2,3-*c*]pyridine (6-hydroxy-7-azaindolines), there is an appreciable shift of the lactam–lactim equilibrium towards lactims. Comparable amounts of both tautomeric forms have been detected in solutions of these compounds by ultraviolet and infrared spectroscopy, but, as a result of a change in the solvent polarity, the equilibrium can be displaced reversibly towards the oxo- or hydroxy-tautomer until it predominates:

On passing from 7-azaindolines to 7-azaindoles, the equilibrium is displaced still more towards the hydroxy-form[225]. For example, infrared spectroscopy failed to detect the lactam form of 6-hydroxy-4-methyl-1-phenyl-7-azaindole either in the crystalline form or in dioxan solution and a weak absorption due to the lactam carbonyl begins to be manifested at 1642 cm^{-1} only in the spectrum of a solution in a more polar solvent—carbon tetrachloride—together with the intense band due to the hydroxy-group of the lactim at 3580 cm^{-1}. Concordant results have been obtained also by ultraviolet spectroscopy using as a reference "fixed" *N*- and *O*-methyl derivatives[225]. The prototropic tautomeric equilibrium is displaced towards the lactim even more in the case of the oxygen analogues of 7-azaindolines—derivatives of 7-azabenzofuran[226].

A change in the junction between the rings, namely the transition from 6-hydroxy-7-aza-compounds to 6-hydroxy-5-azaindoles or benzofurans, causes a sharp weakening of the influence of the heteroatom of the five-membered ring on the position of the tautomeric equilibrium: the predominance of the oxo-form characteristic of α-pyridones is restored for the compounds in the crystalline state and in solutions of different polarity[226]. This permitted the conclusion that a

decisive factor in the effect of the heteroatom of the five-membered ring is its inductive influence, which rapidly decays with distance.



The study of the lactam–lactim equilibria involving monocyclic 6-substituted α-pyridones showed that the tautomeric equilibria of 6-amino- and 6-chloro-2-hydroxy-pyridines are also significantly displaced towards the lactims[227]. Quantitative analysis demonstrated[227] that the effect of the 6-amino-group is somewhat greater if the latter is incorporated in the five-membered ring condensed to pyridine and the influence of hetero-substituents increases, in conformity with their $-I$ effect, in the sequence Cl > OR > NR_2. When the 6-amino-group is acylated, its $-I$ effect diminishes and the tautomeric equilibrium is greatly displaced towards the lactam[228].

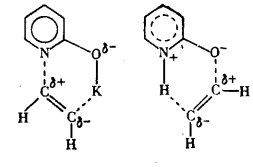
Thermodynamic studies have shown[200,229] that the conversion of the lactam into the lactim is an exothermic process for the majority of the solvents investigated. With decrease of solvent polarity, the process becomes less exothermic and in dioxan, where the lactim formed greatly predominates, the process already becomes endothermic. An increase of temperature favours a decrease of the content of the lactam forms in more polar solvents, while in solvents of low polarity the opposite behaviour is observed.

The existence in solutions of comparable amounts of the hydroxy- and oxo-tautomers of 6-chloro-2-hydroxypyridine has been demonstrated, their ratio being proportional to the solvent polarity[72,227,230,231]. The addition of an anionic surfactant (sodium lauryl sulphate) to an aqueous solution of 6-chloro-2-hydroxypyridine has little effect on the tautomeric equilibrium, while the addition of a cationic detergent (cetyltrimethylammonium bromide) shifts the equilibrium towards the lactim form[232].

The predominance of the lactim form has also been described for 5,6-dichloro-2-hydroxy-3,4-diphenylpyridine[233]. Problems concerning the protonation of 6-amino-2-hydroxy-pyridines have been examined in detail[234].

Of the five theoretically possible tautomeric forms (I)–(V) of 2,6-dihydroxypyridine,

(I) (II) (III) (IV) (V)



apparently three forms exist in aqueous solutions: (I), (II), and (V) in proportions of 60 : 25 : 15.[222,235–237] The oxolactim (I) predominates not only in water, alcohols, and dimethyl sulphoxide but also in cyclohexane with 5% of added alcohol. The tautomeric equilibrium is displaced towards the lactim to an even greater extent for 2-hydroxy-6-methoxypyridine[238]. The lactam–lactim tautomerism involving comparable amounts of the tautomeric forms has been described also for 2,3,6-dihydroxypyridines[239].

The 5,6-annelation of γ-pyridone via condensation with the dihydrofuran ring leads to a shift in the tautomeric equilibrium towards the lactim, which is greater than for the monocyclic 6-substituted α-pyridones; on the other hand, following condensation with the six-membered tetrahydropyran ring, the shift of the tautomeric equilibrium towards the lactim is smaller than for the monocyclic 6-substituted α-pyridones[240–242].

The displacement of the tautomeric equilibria of α,α′-disubstituted pyridines to the region where there are comparable amounts of the lactam and lactim tautomeric forms made it possible to investigate the more refined influence of the β- and γ-substituents in the pyridine ring on this process[238]. Usually, after the almost complete displacement of the tautomeric equilibria of α-pyridones towards lactams, such influences of the β- and γ-substituents cannot be detected[197,231,243,244]. It has been found that γ-substituents affect mainly the conjugation effect. For example, whereas the introduction of the hydroxy-group in the 6-position of the α-pyridone system displaces the tautomeric equilibrium towards the lactim owing to its $-I$ effect, the same group in the 4-position of the pyridine ring causes some displacement of the equilibrium towards the lactam by virtue of its $+M$ effect, i.e. it exerts the directly opposite effect[238,245]. Electron-accepting substituents in the β-position of the pyridine molecule shifts the tautomeric equilibrium towards the lactam in the absence of additional effects due to intramolecular hydrogen bonds, etc.[238]

It is noteworthy that the mode of the *N*- or *O*-alkylation processes involving 6-substituted 2-hydroxypyridines is not correlated with the position of the lactam–lactim tautomeric equilibrium[224–226]. α-Pyridone is alkylated at the nitrogen atom by dimethyl sulphate in an aqueous alkaline medium. The alkylation of 6-hydroxy-7-azaindolines under the conditions where the tautomeric equilibrium is displaced towards the lactim leads to high yields of the corresponding *O*-methyl derivatives. However, treatment of 6-hydroxy-7-azabenzofurans, whose tautomeric equilibrium is displaced towards the lactim to an even greater extent, with dimethyl sulphate in an aqueous alkaline medium again gives rise to high yields of *N*-methyl derivatives[227]. A similar behaviour has been observed also in the reactions with diazomethane. α-Pyridone forms virtually only the *O*-methyl derivative, 6-amino-2-hydroxypyridine gives rise to a mixture of equal amounts of the *O*- and *N*-methylated products, while 6-chloro-2-hydroxypyridine, whose tautomeric equilibrium is displaced towards the lactim to an even greater extent, is methylated predominantly at the nitrogen atom[227].

Evidently dynamic reaction factors and not the position of the tautomeric equilibrium play a decisive role in the alkylation of α-hydroxy-derivatives of *N*-heteroaromatic compounds. The view, which remained current for a long time, that the ratio of the amounts of methylation products can indicate the position of the tautomeric equilibrium in the initial compound is therefore erroneous. This claim is also supported by the formation of different proportions of *N*- and *O*-vinyl derivatives when α-pyridones react with acetylene, as a function of the catalyst employed—from 66 : 1 (in the presence of potassium hydroxide) to 23 : 75 (in the presence of cadmium acetate). Shostakovskii et al.[246] assumed that this is associated with the existence of two types of intermediate cyclic vinylation products.

Quantitative determination of the positions of alkylotropic equilibria of the type of 2-methoxypyridine–1-methyl-2-pyridone from the heats and the equilibrium constants showed that in all cases the lactam forms predominate, the enthalpy differences amounting to 50.6 ± 3.3 and 32.2 ± 9.6 kJ mol^{-1} for the liquid and gas phases respectively[247,248]. The introduction of the methyl group in the 6-position of the pyridine ring has little effect on the equilibrium position. On passing to the 6-chloro-derivative, the enthalpy difference decreases significantly owing to the electron-accepting effect of the chlorine atom: to 17.2 ± 9.2 kJ mol^{-1} for the liquid phase and to 1.3 – 15.5 kJ mol^{-1} for the gas phase.

Calculation of the aromaticity of 2-methoxypyridine and 1-methyl-2-pyridone showed that it amounts to ~20% of that of benzene[249], which is consistent with the values of the aromaticity of α-pyridone calculated previously[217,250]. Unfortunately quantum-chemical calculations based on the geometrical optimisation of the α-pyridone system did not yield results in agreement with experiment[251,252].

Thus studies on the chemistry of α,α'-disubstituted pyridines revealed in recent years new features which are of general theoretical interest. At the same time these investigations have also posed new problems associated with the mechanism of the transmission of the effects of α,α'-substituents in heteroaromatic systems, the nature of the mutual influence of the α- and α'-functional groups, etc. The solution of these problems has an importance going quite far beyond the framework of the individual types of pyridine derivatives.

Antioxidant Stabilisation of Polymers

Yu.A.Shlyapnikov

Physicochemical aspects of the stabilisation of polymers are discussed. Attention is paid mainly to the aging and stabilisation of polymers under processing conditions. Topics considered are the kinetics and mechanism of the high-temperature oxidation of polymers, critical phenomena in the inhibited oxidation of polymers, the theory of synergism and antagonism among antioxidants, the reasons for differences in efficiency of antioxidants, and certain aspects of the relation between the efficiency of antioxidants and their molecular structure. A list of 132 references is included.

CONTENTS

I. Introduction 581

V. Kinetics of the inhibited oxidation of polymers 587
VI. Some special methods for the stabilisation of polymers 597

I. INTRODUCTION

Physical and chemical processes, combined under the general term *aging*, begin immediately after formation of a polymer or a polymeric material. Oxygen and other components of the environment—ozone, water, etc.—are involved. Aging is accelerated by rise in temperature by light, by strong ionising radiations, and by mechanical stresses, being especially rapid under processing conditions for thermoplastic polymers.

We shall disregard the aging of polymers by light, one of the chief reasons for their deterioration under operating conditions, and also those types of aging that are specific to solid polymers. We shall concentrate on chemical processes occurring in polymer melts at high temperatures in the absence and in the presence of oxygen, frequently termed thermal and thermo-oxidative degradation†.

II. THERMO-OXIDATIVE DEGRADATION OF POLYMERS

If the polymer is processed in air, or if it has been stored in air before processing and contains dissolved oxygen, it will undergo thermo-oxidative degradation during processing. This type of polymer degradation has been studied the most thoroughly.

Many references have been made[1,2] to the great similarity in mechanism between the oxidation of polymers and the liquid-phase oxidation of hydrocarbons. On the other hand, little attention has been paid until recently to the differences between the oxidation of substances of low and of high molecular weight. Liquid-phase oxidation of the former is usually investigated at relatively low temperatures, not exceeding 130–150 °C, owing to their high partial vapour pressures at the experimental temperature, whereas the processing temperature of a polymer may exceed 200 °C. No information has appeared on the liquid-phase oxidation of lower hydrocarbons at such high temperatures.

† The term *degradation* frequently denotes only those processes that are accompanied by a decrease in molecular weight or degree of polymerisation.

We shall first consider those stages of oxidation that are common to compounds of low and high molecular weight. Oxidation of a hydrocarbon RH is regarded as a complicated radical chain reaction with degenerate chain branching involving the main states outlined below[3,4].

(*a*) Chain generation has been represented as either a uni-, bi-, or ter-molecular reaction:

$$RH \xrightarrow{k_0} R^{\cdot} + H^{\cdot} \qquad (1)$$

$$RH + O_2 \xrightarrow{k_0'} R^{\cdot} + HO_2^{\cdot} \qquad (2)$$

$$2RH + O_2 \xrightarrow{k_0''} 2R^{\cdot} + H_2O_2 . \qquad (3)$$

(*b*) Chain propagation (growth) occurs as follows:

$$R^{\cdot} + O_2 \xrightarrow{k_1} RO_2^{\cdot} \qquad (4)$$

$$RO_2^{\cdot} + RH \xrightarrow{k_2} ROOH + R^{\cdot} . \qquad (5)$$

(*c*) Chain branching results from unimolecular breakdown of a hydroperoxide, reaction of a hydroperoxide with the hydrocarbon (polymer), or interaction of two hydroperoxy-groups:

$$ROOH \xrightarrow{k_4} RO^{\cdot} + {}^{\cdot}OH \qquad (6)$$

$$ROOH + RH \xrightarrow{k_4'} RO^{\cdot} + R^{\cdot} + H_2O \qquad (7)$$

$$2ROOH \xrightarrow{k_4''} RO_2^{\cdot} + RO^{\cdot} + H_2O . \qquad (8)$$

The radicals RO$^{\cdot}$ and HO$^{\cdot}$ are assumed to react rapidly with the surrounding material to form alkyl radicals R$^{\cdot}$:

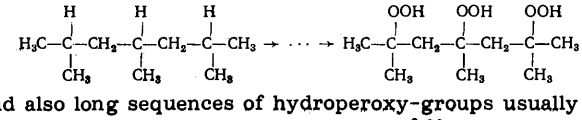
$$RO^{\cdot}({}^{\cdot}OH) + RH \rightarrow ROH(H_2O) + R^{\cdot} . \qquad (9)$$

Breakdown of the radical RO$^{\cdot}$ may yield alkyl radicals of lower molecular weight: for example[5]

$$C_6H_5-\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{C}}-O^{\cdot} \rightarrow C_6H_5-\overset{\overset{O}{\|}}{C}-CH_3 + {}^{\cdot}CH_3 . \qquad (9a)$$

(*d*) Chain termination results from the recombination or disproportionation of any two free radicals involved in the

oxidation:

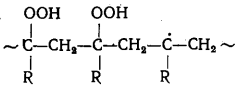


$$2R^{\cdot} \xrightarrow{k_0} R_2 \qquad (10)$$

$$R^{\cdot} + RO_2^{\cdot} \xrightarrow{k_0'} ROOR \qquad (11)$$

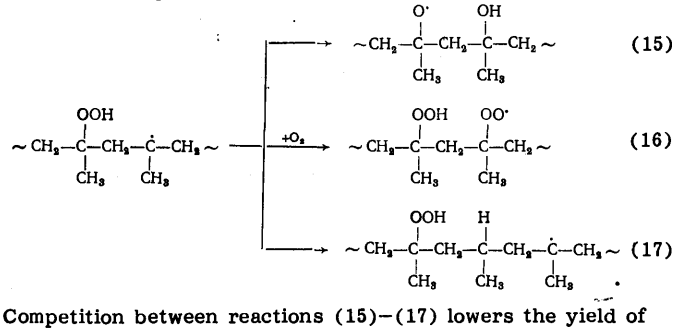
$$2RO_2^{\cdot} \xrightarrow{k_0''} ROOR + O_2 . \qquad (12)$$

Considering the individual stages in greater detail, we note that chain generation has hitherto been the last studied. It probably occurs by reaction (2), but in real polymers chains may be generated also by reactions of various impurities[6], in particular metals of variable valency (primarily iron), peroxides, and other compounds.



As to the chain-propagating reactions (4) and (5), the majority of authors hold completely identical views. In compounds of fairly high molecular weight and in polymers, however, reaction (5) can take place in two ways: the radical $RO_2^{\cdot}$ can detach a hydrogen atom either from a neighbouring molecule or from an adjacent carbon atom in its own molecule. The latter path gives di- and even tri-hydroperoxides in yields comparable with that of the monohydroperoxide[7,8]

(13)

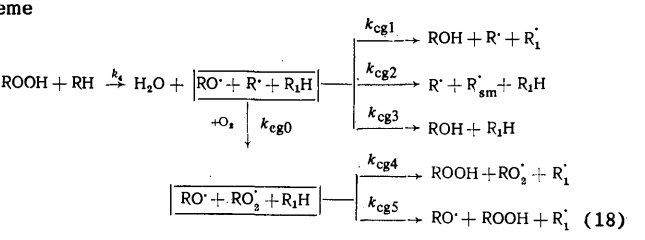


and also long sequences of hydroperoxy-groups usually occupying β positions in polyolefin molecules[9,10].

Propagation of the kinetic oxidation chain involves the formation of peroxyalkyl radicals

(14)

within an individual macromolecule. In such radicals an unstable hydroperoxy-group is always located near the free valency. Interaction of this valency with a hydroperoxy-group that has just been formed leads to loss of the latter. Other possible conversion paths for the peroxyalkyl radical—addition of an oxygen molecule and detachment of a hydrogen atom from the next monomer unit—result in removal of the reaction centre away from the hydroperoxy-group and stabilisation of the group[11]:



(15) (16) (17)

Competition between reactions (15)–(17) lowers the yield of hydroperoxide in the oxidation of polymers below that observed with analogues of low molecular weight, and the yield becomes dependent on the oxygen pressure. Whereas the oxidation of lower compounds gives hydroperoxide yields close to 100%,[4] only 5–40% is obtained in the oxidation of polyolefins[11–15].

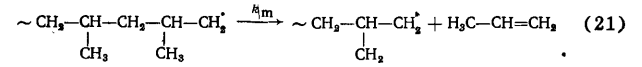
Breakdown of a hydroperoxy-group into RO$^{\cdot}$ and HO$^{\cdot}$ radicals requires the consumption of large quantities of energy (~170 kJ mole^{-1} [16]) and apparently occurs only in the gas phase. In the liquid phase and especially in the molten polymer reactions (7) and (8) are more probable[9,17].

Considering reaction (7) for definiteness, we note that interaction of a hydroperoxy-group in a polymer with a monomer unit in the same or a neighbouring macromolecule produces a pair of free valencies (usually in the form of the radicals R$^{\cdot}$ and RO$^{\cdot}$) located either on neighbouring macromolecules or on a small segment of the same molecule. In a polymer the low translational mobility of a macromolecule is combined with the relatively high vibrational mobility of its segments necessary for the recombination of radicals. For this reason the major proportion of the radicals formed from a hydroperoxide will disappear immediately after formation. In order that breakdown of the hydroperoxy-group should lead to formation of two new kinetic chains (such secondary chain generation as a result of chemical transformation of reaction products is termed *degenerate chain branching*) the free valencies should move sufficiently far apart—should escape from the "cage" formed by molecules of the surrounding material.

In a polymer direct diffusion of primary radicals plays no appreciable part in the escape of radicals from the cage. Three other possibilities remain: one of the radicals of a pair may interact with a neighbouring monomer unit in the same or another macromolecule R_1H, it may react with an oxygen molecule, or the radical RO$^{\cdot}$ may break down with formation of a mobile small radical $R_{sm}^{\cdot}$. The main stages in the breakdown of a hydroperoxide can be represented by the scheme

(18)

in which a cage containing a pair of radicals together with segments of macromolecules R_1H is enclosed in a frame. Each reaction of one of the radicals increases the distance between the free valencies, and the probability of recombination diminishes rapidly. Neglecting for simplicity the probability of recombination of the secondary radicals $R_1^{\cdot}$ and $R_{sm}^{\cdot}$, we find for the mean yield of free radicals formed on the breakdown of ROOH the formula



$$\delta = \frac{w_r}{k_4[\mathrm{ROOH}]\,[\mathrm{RH}]} = \frac{2\,(k_{cg0}[O_2] + k_{cg1} + k_{cg2})}{k_{cg0}[O_2] + k_{cg1} + k_{cg2} + k_{cg3}}, \qquad (19)$$

This expression can be expanded as a series of powers of $[O_2]$. If the oxygen concentration is not too high ($[O_2] \ll k_3/k_{cg0}$) only two terms need be retained, so that[18]

$$\delta = \delta_0 + \delta_1[O_2]. \qquad (20)$$

Existence of such a relation at oxygen pressures over the polymer up to 1 atm has been established experimentally[18–20]. One of the experimental proofs will be examined below.

Radicals R$^{\cdot}$ in a polymer may be either terminal or central depending on whether the free valency is located at or remote from the end of a macromolecule. Radicals with a free valency at the end of the chain $R_e^{\cdot}$ are able to eliminate a monomer:

(21)

Reaction (21) involves no change in the number of terminal radicals, and therefore is disregarded in their balance. Radicals $R_e^{\cdot}$ are consumed mainly by reaction with oxygen (4), and the resulting radicals ReOO$^{\cdot}$ detach hydrogen from the

next monomer unit to form not terminal but central radicals $R_c^{\cdot}$.

From the balance equation for R_e

$$d[R_e^{\cdot}]/dt = \delta k_4 [ROOH][RH] - k_1 [R_e^{\cdot}][O_2], \quad (22)$$

we find, putting $\delta = \delta_e + \delta_1[O_2]$, that the dependence on the oxygen pressure of the rate of depolymerisation accompanying decomposition of a polymer hydroperoxide is

$$w_m = \frac{k_4 k_m}{k_1}[RH][ROOH]\{\delta_1 + \delta_0/[O_2]\}. \quad (23)$$

If $\delta_1 = 0$, i.e. if the yield of free radicals on decomposition of the polymer hydroperoxide is independent of the oxygen pressure, it follows from (23) that the rate of formation of monomer will tend to zero with rise in oxygen pressure; if $\delta_1 > 0$, however, it will tend to a limit other than zero.

The initial rate of formation of propene has been measured[20] in the decomposition of two types of polypropylene hydroperoxide: the usual hydroperoxide was obtained by oxidising polypropylene with molecular oxygen at 130 °C, and a postirradation sample was formed by heating to room temperature a specimen of the polymer first saturated with oxygen and exposed to a small dose of γ-rays. The postirradiation hydroperoxide contained isolated hydroperoxy-groups surrounded by unoxidised material. Fig.1 shows that the rate of formation of propene from both hydroperoxides tended to a finite limit or remained constant: i.e. in both cases the yield of free radicals increased under the influence of oxygen.

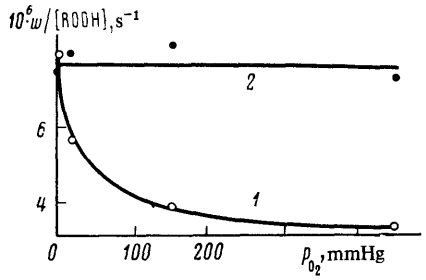


Figure 1. Dependence[20] on oxygen pressure at 130 °C of rate of formation of propene by the decomposition of polypropylene hydroperoxide prepared by: *1*) oxidation of polypropylene at 130 °C; *2*) postirradiation oxidation at room temperature.

Because of the competition between reactions (15)–(17) the sequence of hydroperoxy-groups includes unoxidised units and other functional groups, e.g. hydroxy, the proportions of which depend on the conditions of oxidation. During decomposition some of the hydroperoxy-groups break down, and new functional groups will appear on the polymer chain, not necessarily identical with those formed in the primary reactions. All this makes the concept of "polymer hydroperoxide" extraordinarily indefinite, and is the reason for the disagreement in published values of constants for "the same" hydroperoxide.

Termination of the oxidation chain can occur on the interaction of any two free radicals involved in the reaction. Not only macroradicals can take part in chain termination but also "light" radicals[21] formed by the breakdown of RO$^{\cdot}$ radicals, as in reaction (9a). The recombination of two macroradicals may lead to their cross-linking, which is accompanied by increase in the molecular weight of the linear polymer and even by formation in it of three-dimensional structures, often termed the "gel fraction" as a consequence of insolubility in substances that dissolve the unoxidised polymer[22].

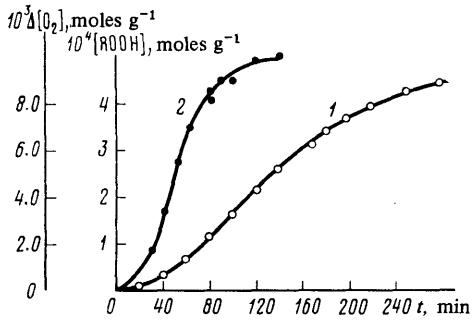

Figure 2. Oxidation of solid isotactic polypropylene[18] under an oxygen pressure of 400 mmHg at 130 °C: *1*) absorption of oxygen; *2*) accumulation of hydroperoxides.

The oxidation of polymers at not very high temperatures is autocatalytic[15–17]. This is explained by the increase rate of formation of free radicals with increase in hydroperoxide concentration, but the time of autocatalysis is of the same order of magnitude as the lifetime of the hydroperoxide, i.e. the reciprocal of its decomposition rate constant. Fig.2 shows a typical curve for the absorption of oxygen during the oxidation of a polymer (polypropylene). The curve has the sigmoid form characteristic of autocatalytic processes. Fig.2 shows that the times for attaining maximum rate of absorption of oxygen and maximum concentration of hydroperoxide are approximately the same.

The initial rate of absorption of oxygen in the oxidation is often too small to be measured, and only after some time, termed the *induction period*, does it increase sufficiently to begin to affect instruments used to observe the reaction. The dependence on the oxygen pressure p of the induction period τ in the oxidation of polymers is described in several cases by the formula[23,24]

$$\tau = a + bp^{-1}, \quad (24)$$

in which a and b are constants depending in particular on the sensitivity of the instrument recording the absorption of oxygen. The coefficients a and b vary with temperature according to the Arrhenius law, with effective activation energies calculated from their variation that are negative and usually differ from each other.

III. HIGH-TEMPERATURE OXIDATION OF POLYMERS

Long induction periods—from tens of minutes to several years—are usually observed in the oxidation of polymers (in the absence of stabilisers) at their working temperatures. With rise in temperature the induction period rapidly becomes shorter, and in the vicinity of 200 °C is already measured in

tens of seconds. At higher temperatures any induction period in oxidation becomes completely imperceptible.

The mechanism of the oxidation of polymers changes at 280–300 °C. The main stage of the chain propagation reaction (5) is replaced by breakdown of the peroxy-radical:

$$RO_2^{\cdot} \xrightarrow{k_{7a}} {}^{\cdot}OH + \text{Inactive products} \qquad RO_2^{\cdot} \xrightarrow{k_{7b}} R_1^{\cdot} + \text{Inactive products} \quad . \tag{25}$$

Such a reaction was first suggested by Enikolopyan[25] to explain the negative temperature coefficient of oxidation in the gas phase; he estimated its activation energy as ~85 kJ mole^{-1}. The isomerisation of $RO_2^{\cdot}$ radicals in polyethylene has been assumed[25] to involve the reactions

$$\sim CH(O{-}O^{\cdot})-CH_2\sim \rightarrow \sim CH(O)-CH\sim + {}^{\cdot}OH \tag{26}$$

$$\sim CH(O{-}O^{\cdot})-CH_2\sim \rightarrow \sim C(=O)-CH_2\sim + {}^{\cdot}OH \quad . \tag{27}$$

The occurrence of (26) is indicated by the formation of α-oxide groups in polyethylene that has been oxidised at temperatures above 300 °C. The carbonyl groups formed by several mechanisms are observed in polyethylene oxidised at any temperature; their content is greatest when oxidation has occurred at 300 °C. We can also complete the scheme by the reactions of HO$^{\cdot}$ radicals—chain transfer

$$RH + {}^{\cdot}OH \xrightarrow{k_8} R^{\cdot} + H_2O \tag{28}$$

and chain termination

$$R^{\cdot} + {}^{\cdot}OH \xrightarrow{k_9} ROH \quad . \tag{29}$$

If we write a set of balanced equations for the radicals R$^{\cdot}$, $RO_2^{\cdot}$, and HO$^{\cdot}$ and the hydroperoxide, and solve them by Bodenstein's method[27] on the assumption that the kinetic chains are long, i.e. that the rate of reaction (28) exceeds substantially that of (29), we obtain for the rate of high-temperature oxidation of a polymer containing aliphatic groups (RH) the formula[26]

$$w = \delta k_1 k_2 k_8 [RH]^2 [O_2]/2k_{7a}k_9. \tag{30}$$

According to (30) the rate of oxidation of a polymer, which varies little with oxygen pressure at low temperatures, becomes proportional to the concentration and hence pressure of oxygen at high temperatures. This conclusion is extremely important, since it shows that a polymer might be protected from oxidation by brief heating (e.g. during processing), by restricting the access of oxygen, or by introducing into the polymer absorbents for oxygen[28]. The last method can be used only for the short-term protection of a polymer from oxidation at high temperatures, being unsuitable for its protection under conditions of prolonged storage or operation in air. This question will be discussed in greater detail below.

In Fig.3 rate curves for the absorption of oxygen during the oxidation of polyethylene at 360 °C [? see Fig.3] under various oxygen pressures are plotted as $\lg(p_0/p)$ against time. The initial segments of these curves are straight lines. We shall show that this indicates proportionality between rate and oxygen pressure.

In a closed volume V the change in the quantity of oxygen N_{O_2} (in moles per kilogram of polymer) is related to the change in its pressure $-\Delta p$ by the formula

$$N_{O_2} = V(-\Delta p)/RTm, \tag{31}$$

in which m is the mass of the oxidisable specimen. If the rate of absorption of oxygen during the reaction is proportional to its concentration in the polymer $dN_{O_2}/dt = k_{exp}[O_2]$, while the concentration of oxygen in the polymer depends on its pressure above the polymer in conformity with Henry's law $[O_2] = \gamma p$, we can write

$$\frac{d}{dt}\left\{\frac{V(-\Delta p)}{RTm}\right\} = k_{exp}\gamma p. \tag{32}$$

Transferring p to the left-hand side, and dt to the right-hand side, and integrating the resulting equation from 0 to t and from p_0 to p, we finally obtain

$$\ln(p_0/p) = RTm\gamma k_{exp}t/V \quad . \tag{33}$$

Thus if the reaction velocity is proportional to the oxygen concentration, the kinetic curve becomes a straight line in the above coordinates, the slope of which is independent of the oxygen pressure, as is observed experimentally (Fig.3).

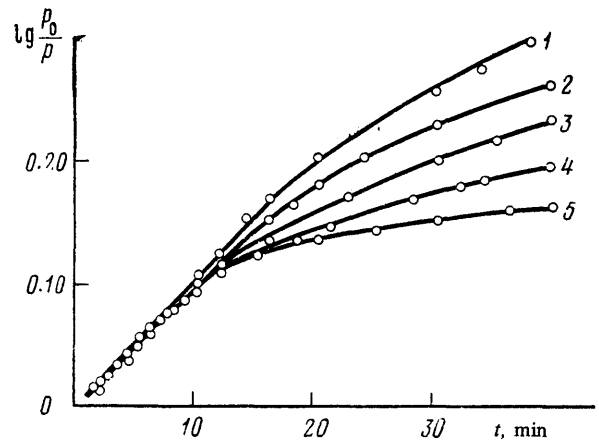

Figure 3. Absorption of oxygen in the high-temperature oxidation of polyethylene (melt)[26] at 300 °C [? see text] under different pressures (mmHg): *1*) 20; *2*) 40; *3*) 60; *4*) 80; *5*) 100.

The demoninator of formula (30) contains the quantity k_{7a}, whose temperature variation corresponds to an activation energy of ~85 kJ mole^{-1}. Rapid increase in the denominator with temperature should slow down the increase in rate (under otherwise similar conditions). Indeed, the rate of oxidation of polyethylene increases slightly with temperature above 300 °C, at which δ in the numerator of (30) reaches its stoichiometric limit ($0 \leq \delta_{max} \leq 2$). In the temperature range intermediate between low- and high-temperature oxidation a more complicated pattern is observed: the rate of absorption of oxygen diminishes with rise in temperature at low pressures (up to 60 mmHg), but at higher pressures it increases. The dependence on the oxygen pressure of the maximum rate of absorption of oxygen in the oxidation of high-density polyethylene is shown in Fig.4.

The monomer units of many thermostable polymers contain small aliphatic groups, mostly methylene or dimethylmethylene together with large aromatic or heterocyclic groups. When oxygen acts on such polymers, these aliphatic groups are the first to be oxidised. The rate is described by formula (30):

i.e. it is proportional to the oxygen pressure, and its temperature variation corresponds to low activation energies, in the range 20–80 kJ mole^{-1}. In some cases the rate of oxidation, decreasing as the aliphatic fragments are consumed, remains proportional to the square of the concentration of remaining methylene groups, as also follows from formula (30).

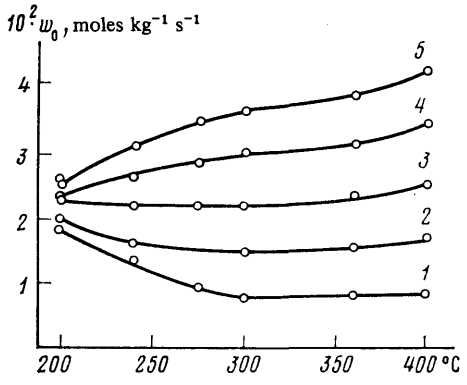

Figure 4. Temperature dependence of maximum rate of absorption of oxygen in the oxidation of polyethylene[26] under different oxygen pressures: *1*)–*5*) as in Fig. 3.

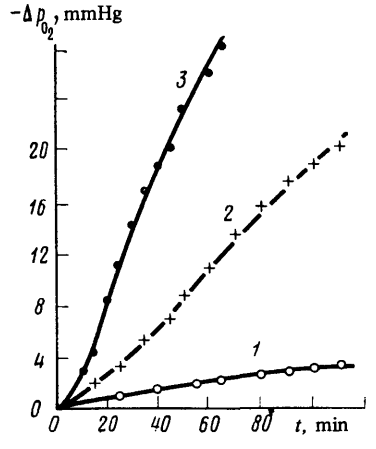

Figure 5. Absorption of oxygen during the oxidation of a polysulphone containing isopropylidene groups ~C(CH$_3$)$_2$~ in the chain[29] under an oxygen pressure of 150 mmHg at different temperatures (°C): *1*) 300; *2*) 350; *3*) 400.

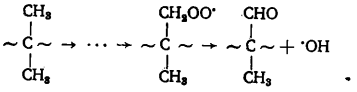
The oxidation of aliphatic groups in a macromolecule may initiate oxidative degradation of aromatic groups, which in the absence of methylene groups takes place at temperatures up to 350–400 °C with considerably smaller velocities[29]. A sharp decrease in rate is observed[30] after the exhaustion of methylene groups, and it was suggested that high-temperature oxidation converted the latter mainly into ketone groups, without degradation of the macromolecules (polybenzoxazole[30]).

Oxidation of a polymer (a polysulphone containing phenylene and isopropylidene groups) at temperatures up to 400 °C was observed[29] to follow an autocatalytic course lasting tens of minutes (Fig. 5). Such long times of autocatalysis cannot be attributed to accumulation of hydroperoxides, since the lifetimes of the latter at such high temperatures are measured in fractions of a second, whereas the period of autocatalytic progress has the same order of magnitude as the lifetime of the product Pr responsible for autocatalysis. In order to show the existence of such a relation we examine the balance equation for this product.



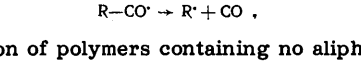
$$d[Pr]/dt = \varkappa w_{O_2} - k_{Pr}[Pr], \qquad (34)$$

in which w_{O_2} is the rate of absorption of oxygen and $\varkappa$ the yield of the product per mole of oxygen absorbed. Assuming to a first approximation that the rate w_{O_2} is constant, we find that

$$[Pr] = \frac{\varkappa w_{O_2}}{k_{Pr}}(1 - e^{-k_{Pr}t}). \qquad (35)$$

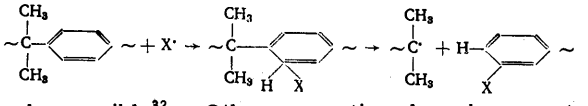
According to this formula the concentration of the product will differ from its maximum value of $\varkappa w_{O_2} k_{Pr}^{-1}$, by 10% when $\exp(-k_{Pr}t) = 0.1$ or at $t = 2.3\, k_{Pr}^{-1}$ and by 1% at $t = 4.6 k_{Pr}^{-1}$, whereas the lifetime of the product is k_{Pr}^{-1}.[27]

Autocatalysis in the high-temperature oxidation of polymers may be due to the formation of aldehyde groups[29]:

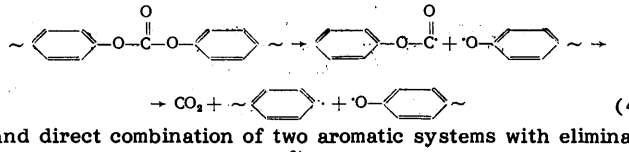


(36)

Oxidation of such groups may provide an additional source of free radicals[31]:

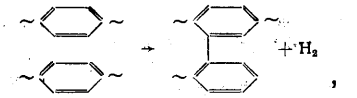


(37)



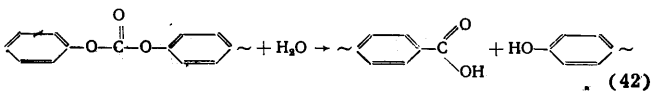
(38)

The oxidation of polymers containing no aliphatic groups is far slower. The mechanism of their interaction with oxygen has not been reliably established. Besides detachment of hydrogen atoms from aromatic systems followed by addition of oxygen to the resulting macroradicals and small radicals reactions of the type



(39)

are also possible[32]. Other suggestions have been rupture of the main chain into two macroradicals[33]



(40)

and direct combination of two aromatic systems with elimination of a hydrogen molecule[34]

(41)

Water formed at various stages in the high-temperature oxidation of heterochain polymers may be involved in reactions leading to rupture of the polymer chain[35]:

(42)

Not only HO· radicals but also other simple radicals—$CH_3^·$, $CH_3OO^·$, $C_6H_5^·$, etc.,—may be involved in the oxidation of polymers at high temperatures. The more reactive radicals take part mainly in chain-transfer reactions, and the less reactive in chain termination.

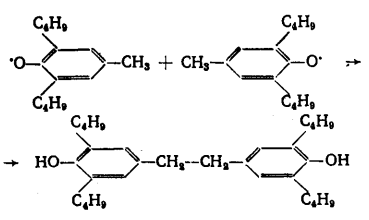
IV. CHEMICAL REACTIONS UNDERLYING THE STABILISATION OF POLYMERS

The properties of a polymeric material can be stabilised during thermo-oxidative degradation by two fundamentally different methods—by lowering the overall rate of oxidation or by eliminating individual undesirable consequences of the reaction, e.g. discoloration resulting from the accumulation of particular chromophoric groups in the polymer.

As already mentioned, the oxidation of organic compounds by molecular oxygen is a free-radical chain reaction with degenerate chain branching, i.e. with branching caused by reactions of intermediate products formed in the main chain reaction. The overall rate of the chain reaction can be diminished either by increasing the rate of chain termination or by decomposing the intermediate products involved in branching.

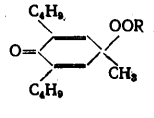
In 1947 Bolland and ten Have[36,37] suggested and substantiated a mechanism of chain termination in the oxidation of phenolic antioxidants in which a phenol molecule reacts with a peroxy-radical, donating to the latter a hydrogen atom and forming a hydroperoxide molecule and a relatively inactive free radical incapable of propagating the chain:

$$RO_2^· + ArOH \rightarrow ROOH + ArO^· . \qquad (43)$$



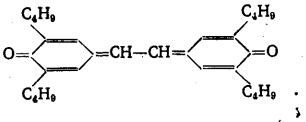
The subsequent fate of the inactive phenoxyl radical has been the subject of many investigations[36-46]. Among conversion products of the antioxidant have been found various compounds formed by dimerisation of phenoxy-radicals and also compounds of quinoid structure, which may result from oxidation and disproportionation of these radicals. Thus the antioxidant quinol is converted into the quinone, probably by interaction of the primary ArO· radical with a second peroxy-radical[37]:

(44)



Formation of a quinone may result from disproportionation of two hydroxyphenoxy-radicals[38] or their reaction with an oxygen molecule.

The widely used antioxidant 2,6-di-t-butyl-4-methylphenol (Ionol) is known to yield dimerisation products of the primary radical[39-41]



(45)

products of interaction of peroxy- and phenoxy-radicals[39]

(46)

and products of further conversion of compounds formed by dimerisation of ArO· [39,41]

(47)

However, the majority of phenoxy-radicals formed from this inhibitor under the usual conditions (non-sensitised) of the oxidation of polypropylene interacted to form intensely coloured products of high molecular weight. On further oxidation these products disappeared[42]. The radicals can also take part in chain transfer[43,44]:

$$ArO^· + RH \rightarrow ArOH + R^· . \qquad (48)$$

A scheme analogous to (43) was suggested[43,47] for chain termination by aromatic amines:

$$RO_2^· + R_1R_2NH \rightarrow ROOH + R_1R_2N^· . \qquad (49)$$

In 1954 Boozer and Hammond[48,49] proposed a different mechanism of chain termination, in which the antioxidant molecule initially adds a peroxy-radical reversibly to form a complex, which reacts with a second peroxy-radical to give an inactive product:

$$RO_2^· + A \rightleftharpoons ARO_2^· \qquad (50)$$

$$ARO_2^· + RO_2^· \rightarrow \text{Products} . \qquad (51)$$

This suggested mechanism has been criticised by many workers[46,50,51]. It was shown that "ordinary" oxidation inhibitors—phenols and aromatic amines—terminate oxidation chains in conformity with Eqn.(43) or (49). However, certain relatively ineffective antioxidants, such as anthracene and carbon black, were later shown to retard the oxidation of polyalkenes by the Boozer–Hammond mechanism of chain termination[48], i.e. by catalysing quadratic (involving the interaction of two active centres) termination of the oxidation chain[52,53].

It is interesting that phenols and amines, which react rapidly with peroxy-radicals, hardly interact if at all with alkyl radicals R·. Thus Dolgoplosk et al.[54] showed that, in the absence of oxygen, phenols and secondary aromatic amines do not retard the polymerisation of styrene and several other monomers, and only slightly retard that of allyl and vinyl acetates; in the presence of oxygen the same phenols and amines effectively inhibit the polymerisation of all these monomers. Similar observations were reported by other workers[55]. Vasil'ev showed[56] that, in the absence of oxygen, the antioxidant 2,6-di-t-butylphenol remains unconsumed in ethylbenzene containing an initiator.

According to Eqns.(43) and (49) interaction of a phenol or an amine molecule with a peroxy-radical gives a hydroperoxide molecule or a hydroperoxy-group, capable of breaking down subsequently into two free radicals. It was suggested[57] that relatively inactive free radicals could be used as antioxidants in order to eliminate this side-effect. In practice, however, such radicals proved to be relatively inactive antioxidants, since the concentration of alkyl radicals in the compound undergoing oxidation was extremely low in comparison with that of peroxy-radicals, while the "inactive" nitroxyl radicals at the high concentrations necessary for stabilisation played an appreciable part in the initiation of oxidation[58]. In those cases in which such radicals nevertheless retarded oxidation effectively it was found[59] that

they were first reduced to the corresponding aromatic amines:

$$2Ar_2NO^{\cdot} + x\,RH \rightarrow Ar_2NH + \text{Products} \ . \qquad (52)$$

In this process one amine molecule formed from two "stable" radicals; furthermore, it is accompanied by degradation of the polymer, so that it is more advantageous to introduce into the latter not the radical $Ar_2NO^{\cdot}$ but the corresponding aromatic amine.

Quinones behave similarly to "stable" radicals. Thus benzoquinone when heated in a hydrocarbon is slowly converted into a mixture of quinol and its mono- and di-ethers, which are actual inhibitors[60]. The view was also expressed[61] that quinones retard oxidation by reacting with $R^{\cdot}$ radicals.

Aromatic phosphites are also capable of terminating oxidation chains. The mechanism is apparently extremely complicated: these compounds can be hydrolysed to phenols, and can reduce peroxides and interact directly with peroxy-radicals. It was suggested[62,63] that this last reaction is represented by the equation

$$RO_2^{\cdot} + (ArO)_3P \rightarrow RO(ArO)_2PO + ArO^{\cdot} \ . \qquad (53)$$

Organic sulphides and phosphites (phosphorous esters) slow down oxidation by a mechanism involving decomposition of intermediate products. The first reports[64,65] of increase in the rate of decomposition of hydroperoxides in the presence of organic sulphides showed that purely aliphatic sulphides react most rapidly with hydroperoxides, mixed sulphides react more slowly, and aromatic sulphides hardly react at all. The antioxidant properties of these sulphides in the oxidation of white oil vary in the same sequence. Both during oxidation and on interaction with hydroperoxides the sulphides first pass into sulphoxides and then into sulphones:

$$ROOH + R_1{-}S{-}R_1 \rightarrow ROH + R_1{-}\overset{\overset{O}{\|}}{S}{-}R_1 \qquad (54)$$

$$ROOH + R_1{-}\overset{\overset{O}{\|}}{S}{-}R_1 \rightarrow ROH + R_1{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}R_1 \ . \qquad (55)$$

These observations have been confirmed many times by other workers[66,67]. The yield of free radicals in reactions between hydroperoxides and sulphides is extraordinarily low, not exceeding one radical per thousand hydroperoxide molecules that have reacted[68].

Organic phosphites react with hydroperoxides by a similar mechanism[63]:

$$ROOH + P(OR_1)_3 \rightarrow ROH + O{=}P(OR_1)_3 \ . \qquad (56)$$

Several phosphites, e.g. iso-octyl diphenyl phosphite, are considerably more efficient than organic sulphides in reducing hydroperoxides[69].

V. KINETICS OF THE INHIBITED OXIDATION OF POLYMERS

Reductants of hydroperoxides are seldom used as individual antioxidants for polymer materials[70], but are usually employed mixed with substances that terminate oxidation chains, i.e. oxidation inhibitors in the narrow sense. The latter, however, are used both as individual antioxidants and as the main components of mixed antioxidants. Both cases will be discussed below.

As mentioned above, the chief substances used as oxidation inhibitors are phenols and secondary aromatic amines, of general formula IH. Because of their great reactivity such inhibitors, when introduced into a polymer undergoing oxidation, take part in all stages of the oxidation chain—generation, propagation, branching, and termination—and react with all types of free radicals formed in the polymer. The primary products formed from the inhibitors may undergo further reactions. All this makes the mechanism of inhibited oxidation extremely complicated. Below we shall take the mechanism of inhibited oxidation to mean the minimum set of main stages necessary for a quantitative description of the observed regularities.

The main stage at which oxidation is inhibited is chain termination

$$RO_2^{\cdot} + IH \rightarrow ROOH + I^{\cdot} \ . \qquad (57)$$

The resulting $I^{\cdot}$ radicals may be involved in chain transfer by interacting with the oxidisable material:

$$I^{\cdot} + RH \rightarrow IH + R^{\cdot} \ . \qquad (58)$$

If reaction (58) were the sole means of consumption of the relatively inactive radicals $I^{\cdot}$, they would sooner or later accumulate in sufficient concentration for the rate of reaction (58) to become comparable with that of (57). For every chain terminated there would then be a chain initiated by an $I^{\cdot}$ radical: i.e. the inhibitor would cease to influence the reaction velocity.

The situation is unaffected by taking into account the reaction of $I^{\cdot}$ radicals with alkyl radicals $R^{\cdot}$, for the concentration of the latter in the polymer is negligible in comparison with that of $RO_2^{\cdot}$. Because of the great viscosity of the medium and the near immobility of the macroradicals $R^{\cdot}$ and $RO_2^{\cdot}$ the rates of their reactions with IH molecules and $I^{\cdot}$ radicals will be determined by the frequency with which the reactant species meet, so that the difference in the reactivity of different substances towards the polymer radicals becomes insignificant. For example, the rate constants of the reactions of macroradicals with inhibitor molecules and inactive radicals in polystyrene differ by the factors of at most 10–15.[71]

Let us suppose for definiteness that the rate constant of reaction (57) amounts to 10% of that of the process

$$I^{\cdot} + R^{\cdot} \rightarrow RI \qquad (59)$$

while the concentration of $R^{\cdot}$ radicals is 1% of that of $RO_2^{\cdot}$ radicals. Then the rate of consumption of inhibitor radicals $I^{\cdot}$ will become equal to the rate of their formation only when $[I^{\cdot}]/[IH] = 10$, i.e. after almost all the inhibitor has been converted into radicals. Thus reaction (59) cannot effectively remove $I^{\cdot}$ radicals from the polymer.

With the same relative rate constants and radical concentrations the reaction

$$I^{\cdot} + RO_2^{\cdot} \rightarrow ROOI \qquad (60)$$

will occur at the same rate as the formation of $I^{\cdot}$ provided that $[I^{\cdot}]/[IH] \geq 0.1$. In a medium of low molecular weight reaction (60) converts an inactive $I^{\cdot}$ radical and an active $RO_2^{\cdot}$ radical into the quinolide peroxide(46),[39,72] but in a polymer it produces a peroxy-group "grafted" to the polymer chain. Breakdown of such a peroxy-group will yield two new radicals, apparently more active than their precursors. At the fairly high temperatures at which polymers are processed the peroxy-groups will break down almost instantaneously: i.e. reaction (60) may lead to conversion of an inactive $I^{\cdot}$ radical into an active $RO^{\cdot}$ radical.

Thus for a given substance effectively to inhibit the oxidation of a polymer it is necessary not only that the chain-termination (57) rate constant should be sufficiently high but also that termination should yield an inactive radical $I^{\cdot}$ that should be sufficiently rapidly consumed in reactions not

involving the polymer, e.g. recombination—such as (45)—or disproportionation

$$2I^{\cdot} \xrightarrow{k_6} \text{Products}, \qquad (61)$$

In fact the concentrations of inhibitor radicals formed in the oxidation of polypropylene with initial inhibitor concentrations of $(7-9)\times10^{-2}$ mole kg^{-1} do not exceed 10^{16} $g^{-1} = 1.7\times10^{-5}$ mole kg^{-1}: i.e. they are <1% of the inhibitor concentration[73]. Thus such reactions do indeed play an important part in the consumption of inhibitor radicals. The concentration of the latter (measured accurate to an unknown factor) has been shown[74] to be proportional to the square root of the rate of consumption of the inhibitor:

$$[I^{\cdot}] = \text{const}\left(-\frac{d[IH]}{dt}\right)^{1/2}, \qquad (62)$$

This is consistent with a mechanism of consumption of $I^{\cdot}$ radicals by recombination or disproportionation, when

$$d[I^{\cdot}]/dt = -d[IH]/dt - k_6[I^{\cdot}]^2. \qquad (63)$$

With $d[I^{\cdot}]/dt = 0$ when a steady concentration of the radicals is reached, we obtain for $[I^{\cdot}]$ an expression of the form (62).

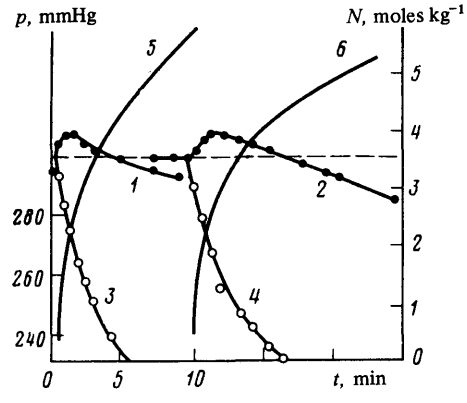


Figure 6. Effect of the inhibitor methylene-2,2′-bis-(4-methyl-6-t-butylphenol)—Antioxidant 22–46 (0.1 mole kg^{-1})—on the oxidation of polyethylene[75] under an initial pressure of 300 mmHg (broken line) at 260 °C: *1*) variation in total pressure in absence of inhibitor; *2*) as (1) in presence of inhibitor; *3*) partial oxygen pressure without inhibitor; *4*) partial oxygen pressure with inhibitor; *5*) formation of volatile products (*N*) without inhibitor; *6*) as (5) with inhibitor.

Fig. 6 illustrates the absorption of oxygen during the oxidation of polypropylene at 260 °C in the absence and in the presence of an inhibitor, the variation in total presssure in the reaction vessel, and the quantity of volatile degradation products evolved from the polymer during oxidation. It is evident that the inhibitor—in this case methylene-2,2′-bis-(4-methyl-6-t-butylphenol), known also as *Antioxidant 22–46*—merely delayed for some time the start of a rapid process characterised by a high rate of absorption of oxygen together with a high rate of formation of volatile degradation products[75]. The induction period from the start of the reaction to the rapid stage is short in the absence of an inhibitor, being measured at high temperatures in fractions of a second, but is lengthened by an inhibitor, sometimes by factors of 10^2–10^4. When oxidation passes into the rapid stage, the molecular weight and consequent properties of the polymer change rapidly, "disastrously", the material becomes unsuitable for practical use, and articles made from it disintegrate. Henceforward, therefore, we shall be interested only in processes occurring during the induction period.

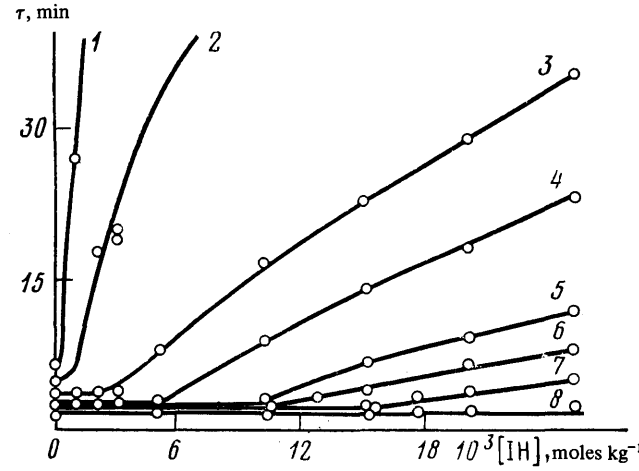

Figure 7. Dependence of induction period in the oxidation of polyethylene on concentration of Antioxidant 22–46 under 300 mmHg [76] at different temperatures (°C): *1*) 200; *2*) 220; *3*) 230; *4*) 240; *5*) 250; *6*) 260; *7*) 265; *8*) 270.

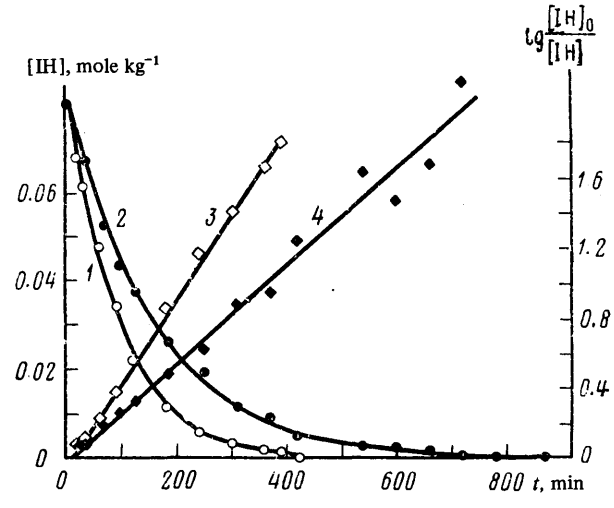

Figure 8. Effect of didecyl sulphide (0.08 mole kg^{-1}) on variation in concentration of Antioxidant 22–46 during induction period in the oxidation of polypropylene[80] under an oxygen pressure of 300 mmHg at 200 °C: *1*) sulphide absent; *2*) sulphide present; *3*) as (*1*) plotted for a first-order reaction; *4*) as (*3*) in the presence of sulphide.

Fig.7 illustrates the dependence of induction period on inhibitor concentration at various temperatures. Up to a certain critical concentration the inhibitor has hardly any effect, but beyond it the induction period increases with concentration. The critical concentration increases rapidly with temperature, while the slope of the curves diminishes. Around 280–290 °C, i.e. at temperatures at which the mechanism of oxidation changes, the "usual" antioxidants cease to retard oxidation, and their critical concentrations increase to several tenths of a mole per kilogram, i.e. 3–10 mass % and even above. Use of such high antioxidant concentrations is obviously inadmissible for the most diverse reasons, beginning with cost and ending with their marked effect on the properties of the polymer material.

The polymer does not remain unchanged during the induction period. Firstly the antioxidant (inhibitor) it contains is consumed. The corresponding curve can be linearised by plotting $\lg([IH]/[IH]_0]$ against time (Fig.8). Kinetic curves for a first-order reaction, described by formulae such as

$$-d[IH]/dt = k[IH], \quad (64)$$

$$[IH] = [IH]_0 e^{-kt} \quad (65)$$

become straight lines in such coordinates[27].

Increasing the vertical scale in Fig.8 would reveal that the slow consumption of inhibitor, which up to a certain time obeys a first-order law, accelerates sharply at the end of the induction period. This is immediately followed by a marked increase in the rate of absorption of oxygen: i.e. the induction period is complete. Consumption of the inhibitor accelerates immediately its concentration falls below this critical concentration. Denoting by τ_{cr} the portion of the induction period from attainment of the critical concentration to the start of the rapid reaction, assuming that the inhibitor concentration falls from $[IH]_0$ to $[IH]_{cr}$ during the time interval $\tau - \tau_{cr}$, substituting these values in Eqn.(65), and taking logarithms, we obtain the formula

$$\tau = \tau_{cr} + \frac{1}{k} \ln \frac{[IH]_0}{[IH]_{cr}} \quad (66)$$

relating the induction period with the concentration of inhibitor in the initial polymer[77,78]. This provides a good description of the experimental dependence of the induction period in the oxidation of polymers on the initial inhibitor concentration in all cases in which conversion products of the inhibitor have little effect on the rate of oxidation. A logarithmic dependence of induction period on inhibitor concentration was established empirically by Rosenwald[79], who studied the oxidation of petrol.

Fig.8 shows that, if a substance that reduces hydroperoxy-groups [didecyl sulphide $(C_{10}H_{21})_2S$] is introduced into a polymer containing an oxidation inhibitor, the first-order consumption of inhibitor is maintained, but the absolute value of the rate constant is lower[80].

During the induction period the molecular weight of the polymer decreases. At sufficiently high inhibitor concentrations—several times the critical value—an approximately linear relation exists between the rate of degradation of polymer chains and the inhibitor concentration, which breaks down only when the latter has fallen to roughly double the critical concentration, after which the rate of degradation increases sharply[81] (Fig.9). With few exceptions[69] reductants of hydroperoxy-groups do not lower the rate of polymer degradation. The rate of absorption of oxygen shows a similar dependence on the inhibitor concentration[82].

Volatile products, in particular monomers[74,83], are formed during the induction period in the inhibited oxidation of polyethylene and polypropylene, but their rates of formation are low ($\sim 10^{-9}$ mole kg^{-1} s^{-1} at 200 °C), and at sufficiently high inhibitor concentrations are independent both of such concentrations[74,83] and of the oxygen pressure[74].

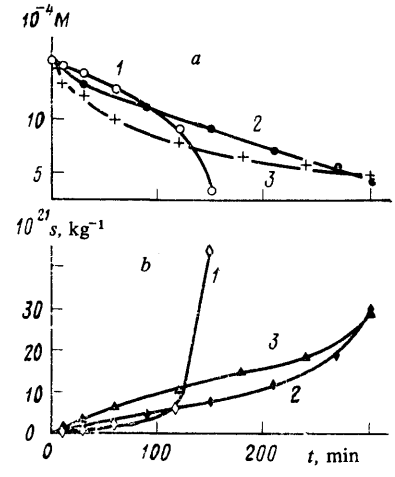

Figure 9. Variation in (*a*) molecular weight and (*b*) number of breaks in polymer chain during induction period in the inhibited oxidation of polypropylene under 300 mmHg at 200 °C in the presence of Antioxidant 22-46 at different initial concentrations (mole kg^{-1}): *1*) 0.004; *2*) 0.025; *3*) 0.0625.

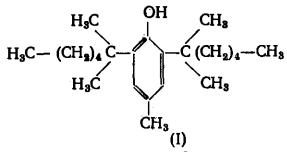
Thus, as had been pointed out in the early work on inhibited oxidation[84], antioxidants do not arrest polymer oxidation and the accompanying degradative processes but merely lower their rates considerably.

According to the original theory an inhibitor terminates the kinetic oxidation chain and is itself thereby consumed[85] at a rate

$$-d[IH]/dt = \frac{1}{j} w_n, \quad (67)$$

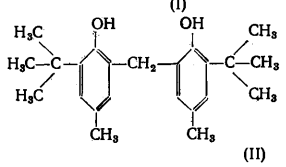
where w_n is the rate of chain generation and j the stoichiometric inhibition coefficient, i.e. the number of free radicals destroyed by one inhibitor molecule. Comparison of Eqns. (66) and (67) clearly reveals agreement between experiment and theory if $w_n = k[IH]$, i.e. if the rate of chain generation is proportional to the inhibitor concentration, which can be explained only by involvement of the inhibitor in chain generation[86,87].



The aromatic amines and alkylated phenols used as inhibitors are considerably more reactive than the polymers they protect, not only towards peroxy-radicals but also towards molecular oxygen. For this reason, even at low (subcritical) inhibitor concentrations, the reaction

$$IH + O_2 \xrightarrow{k_8} I^{\cdot} + HO_2^{\cdot} \xrightarrow{(RH)} \cdots \rightarrow R^{\cdot} \quad (68)$$

occurs at rates exceeding the rate of chain generation in the absence of an inhibitor, i.e. reactions (1)–(3),[77,78,80]



One reason for the difference in antioxidant efficiency between inhibitors belonging to the same class of compounds may be a difference in the rate constants of reaction (68). However, even compounds that are very similar in chemical

nature may differ very greatly in antioxidant efficiency. Thus the alkylphenols (I) and (II)

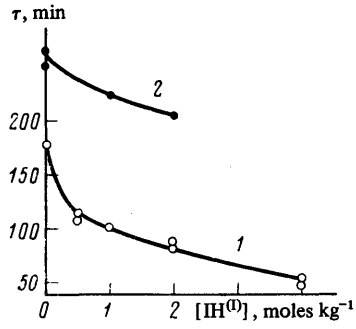
(69)

(I)

(70)

(II)

at equal concentrations of the phenolic hydroxyls give induction periods in the oxidation of polypropylene differing by factors of ten in length[77]. It might have been supposed that this was due to a difference in reactivity between the hydroxyls in (I) and (II), but experiment showed that the difference was qualitative in character: the introduction of variable concentrations of (I) into a polymer containing a constant concentration of (II) produced a greater shortening of the induction period the higher the concentration of (I), although such introduction of a second inhibitor increased the total inhibitor concentration (Fig. 10). When a reductant for hydroperoxide (didecyl sulphide) was introduced into the polymer together with the inhibitors, the qualitative difference between (I) and (II) disappeared: just as in the case illustrated in Fig. 7, the sulphide produced inflexions in the concentration dependence of the induction period, above which the length of the latter increased rapidly (Fig. 11),[80] and the consumption of the inhibitor followed a first-order curve (Fig. 12).



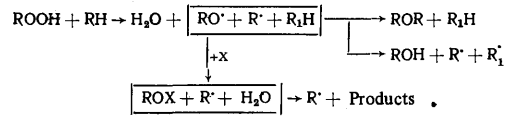


Figure 10. Dependence of induction period in the oxidation of polypropylene[77] under 300 mmHg of oxygen at 200 °C on concentration of inhibitor (I) for different contents of (II) (mole kg^{-1}): *1*) 0.01; *2*) 0.02.

In view of such behaviour of inhibitor (I) the difference could not be explained even on the assumption of a considerably greater rate of direct oxidation (68) of (I) than of (II). It was suggested that the difference between the monohydric (I) and dihydric (II) phenols was due to this difference in the number of active functional groups involved in chain termination[77,80,88].

In a substance undergoing oxidation free radicals appear and disappear in pairs. The pair formed on breakdown of a hydroperoxy-group most probably recombine, so that the yield of free radicals in this reaction is small (scheme 18). A hypothetical species X that might have destroyed only one of the radicals would have made recombination impossible for the other radical:

(71)

If in the absence of X the yield of radicals from the cage exceeds unity, the introduction of X will lower the yield of free radicals formed by decomposition of the hydroperoxy-group (and of any source of radicals in general). If, however, this yield is less than unity, X will increase the yield of free radicals.

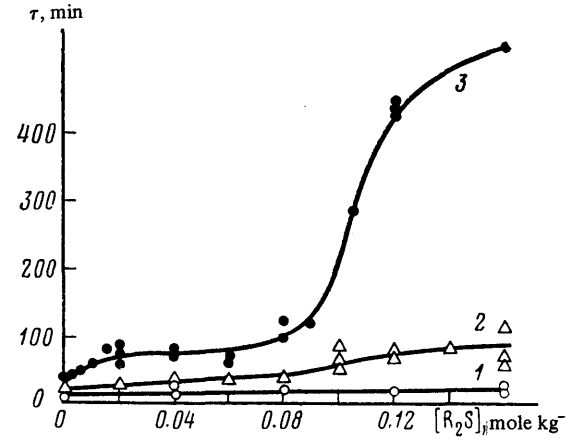

Figure 11. Dependence of induction period in the oxidation of polypropylene[80] under 300 mmHg of oxygen at 200 °C on the concentation of inhibitor (I) in the presence of different contents (mole kg^{-1}) or didecyl sulphide (R_2S): *1*) 0; *2*) 0.04; *3*) 0.08.

In order to estimate the possible effect we assume that recombination in a cage is so rapid that it can involve those X molecules that were present on formation of the cage. If the volume of the cage is taken to be $(10\ \text{Å})^3 = 10^{-24}$ litre, one litre of the polymer will contain 10^{24} cages. On introduction into the polymer of X at a concentration 0.01 M = 6×10^{21} $litre^{-1}$ only 0.6% of the cages will contain X and, if in all these cages the yield of radicals changes from the original value δ_0 to unity, the observed yield of radicals in the presence of X will be $\delta_0 + 0.006(1-\delta_0)$, which will differ appreciably from the original value δ_0 only if the latter does not exceed 0.01.

Real inhibitors will obviously differ from the above substance X. Reaction between an inhibitor and an active radical forms a relatively inactive radical I$^\cdot$ capable of recombination with the other radical of the pair; but the lower activity of I$^\cdot$ than of RO$^\cdot$ or R$^\cdot$, and also the increase in

mean distance between the radicals after each step in the reaction, will lead to a change in the yield of radicals from the cage if an inhibitor molecule enters it. Increase in the number of active functional groups in the inhibitor molecule will obviously increase the probability that the molecule will interact simultaneously with the two radicals of the pair: i.e. a phenolic diol should not increase the yield of radicals from the cage, or should increase it far less than would a monophenol.

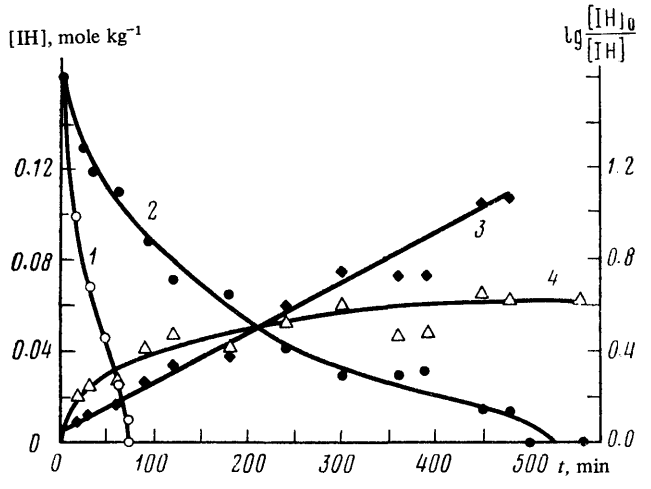

Figure 12. Consumption of inhibitor (I) during induction period in the oxidation of polypropylene[60] under 300 mmHg of oxygen at 200 °C: *1*) in absence of sulphide; *2*) in presence of didecyl sulphide (0.08 mole kg^{-1}); *3*) as (*2*) plotted as lg ($[IH]_0/[IH]$) against time; *4*) inhibitor vaporised from specimen containing sulphide.

Pudov[89,90] observed that inhibitors increased the yield of free radicals formed by the breakdown of hydroperoxy-groups in polypropylene. He showed that in the absence of an inhibitor the yield per hydroperoxy-group decomposed was ~10^{-2} radical, and the appreciable effect of the introduction of inhibitors into the polymer is consistent with the above estimates. In contrast, the yield of free radicals on the decomposition of lower peroxides or azo-compounds is 0.2–1.0, so that attempts to change this yield by means of inhibitors were unsuccessful[91].

Mono- and di-amines differ in effectiveness similarly to mono- and di-phenols: under comparable conditions diamines considerably surpass monoamines in antioxidant efficiency[92].

The presence of two hydroxy-groups in a phenol molecule is a necessary but not sufficient condition for the simultaneous entry of two phenolic hydroxyls into a cage containing a pair of radicals: it is necessary also that these groups should be located side by side in the most probable conformations of the diphenol molecule. Infrared spectra have been used[93] to determine the relative arrangement of hydroxy-groups. The close approach of two such groups leads to formation of a hydrogen bond O–H...O–H, corresponding in dilute solutions of the diphenol to an absorption band at 3440–3460 cm^{-1}. A hydrogen bond between a hydroxy-group and the π-electron system of an adjacent aromatic ring corresponds to a band at 3520–3550 cm^{-1}, and a free hydroxyl gives a band at 3630–3660 cm^{-1}.[94] The experiments show[93] that only those diphenols are effective antioxidants in whose molecules the hydroxy-groups are linked by a hydrogen bond, bond, i.e. are situated close together in the main conformation. The inhibitor 3,3',5,5'-tetra-t-butylbiphenyl-2,2'-diol, which differs from (II) in the absence of a methylene group between rings, has a unique conformation with OH...π hydrogen bonds, in which the hydroxy-groups are far apart, and is therefore an ineffective antioxidant. The effectiveness of (II) is greatly diminished also when one of its hydroxyls is replaced by an ester group[95].

Another possible mechanism by which an inhibitor can affect the yield of free radicals formed from a hydroperoxy-group is direct interaction between this group and the inhibitor molecule[96,97]:

$$ROOH + IH \rightarrow RO^{\cdot} + I^{\cdot} + H_2O \rightarrow \cdots \rightarrow \delta R^{\cdot}. \qquad (72)$$

The dependence of the yield of free radicals on the hydroperoxide concentration can be written (independently of the mechanism) as the series

$$\delta = \delta_0 + \delta_t [IH] + \delta_{tt} [IH]^2 + \ldots \qquad (73)$$

or at low inhibitor concentrations

$$\delta = \delta_0 + \delta_t [IH]. \qquad (74)$$

Thus with sufficiently high inhibitor concentratons, when the stages of chain generation (1)–(3) and quadratic chain termination (10)–(12) can be neglected, oxidation can be represented by the stages[88]

$$\begin{gathered} IH + O_2 \xrightarrow{k_0} I^{\cdot} + HO_2^{\cdot} \xrightarrow{(RH)} \cdots \rightarrow \alpha R^{\cdot} \\ R^{\cdot} + O_2 \xrightarrow{k_1} RO_2^{\cdot} \\ RO_2^{\cdot} + RH \xrightarrow{k_2} ROOH + R^{\cdot} \\ RO_2^{\cdot} + IH \xrightarrow{k_3} ROOH + I^{\cdot} \\ ROOH + RH \xrightarrow{k_4(IH,O_2)} \delta R^{\cdot} + \text{Products} \\ ROOH + R_2S \xrightarrow{k_5} \text{Products} \end{gathered} \qquad (75)$$

which give rise to the balance equations

$$d[R^{\cdot}]/\alpha\, t = d\, k_0 [IH] [O_2] + k_2 [RO_2^{\cdot}] [RH] + \delta k_4 [ROOH] [RH] - k_1 [R^{\cdot}] [O_2], \qquad (76)$$

$$d[RO_2^{\cdot}]/d\, t = k_1 [R^{\cdot}] [O_2] - k_2 [RO_2^{\cdot}] [RH] - k_3 [RO_2^{\cdot}] [IH], \qquad (77)$$

$$[OH]/d\, t = k_2 [RO_2^{\cdot}] [RH] + k_3 [RO_2^{\cdot}] [IH] - k_4 [ROOH] [RH] - k_5 [ROOH] [R_2S] \qquad (78)$$

for $R^{\cdot}$, $RO_2^{\cdot}$, and ROOH.

If the process takes place at a sufficiently high temperature, at which the lifetime of hydroperoxy-groups is short compared with the duration of the reaction, we can attempt to solve Eqns.(76)–(78) by Bodenstein's method[98], i.e. by neglecting rates of change of the instantaneous radical and hydroperoxide concentrations in comparison with their rates of formation and consumption, equating $d[R^{\cdot}]/dt$, $d[RO_2^{\cdot}]/dt$, and d[ROOH]/dt to zero. The set of differential equations (76)–(78) then becomes a set of algebraic equations, which can readily be solved by the usual methods. It then follows from Eqn.(78) that the steady-state concentrations of peroxy-radicals and hydroperoxy-groups are related by the formula

$$[ROOH] = \frac{k_2 [RH] + k_3 [IH]}{k_4 [RH] + k_5 [R_2S]} [RO_2^{\cdot}]. \qquad (79)$$

Substituting for [ROOH] in (76) and solving simultaneously the resulting equation and (77), we find for the steady-state

concentration of peroxy-radicals

$$[RO_2^{\cdot}]_{st} = \alpha k_0 [IH] [O_2] \cdot \left[k_3 [IH] - \frac{\delta k_4 [RH] (k_2 [RH] + k_3 [IH])}{k_4 [RH] + k_5 [R_2S]} \right]^{-1}. \quad (80)$$

This will be finite (i.e. inhibited oxidation of a polymer will be a steady-state process) only if the antioxidant concentration exceeds some critical value

$$[IH]_{cr} = \delta k_2 k_4 [RH]^2 \cdot \{(1-\delta) k_3 k_4 [RH] + k_3 k_5 [R_2S]\}^{-1}, \quad (81)$$

i.e. the critical inhibitor concentration. When $[IH] < [IH]_{cr}$, the rate $d[RO_2^{\cdot}]/dt$ will increase without limit: i.e. Bodenstein's method will be inapplicable[99].

The physical significance of the critical concentration is that below it the oxidation will be autocatalytic (non-stationary) until the rate is limited by quadratic chain termination (12), but above this concentration the process will be stationary and occur at a very low rate. On the curves representing the dependence of the oxidation induction period on inhibitor concentration the critical concentration corresponds to a sharp inflexion, after which the induction period begins to increase with concentration[100] (Fig.6).

Substituting in (81) for δ from (74) and putting $[R_2S] = 0$, we obtain the quadratic equation

$$\delta_i k_3 [IH]^2_{cr} + (\delta_i k_2 [RH] - (1-\delta_0) k_3) [IH]_{cr} + \delta_0 k_2 [RH] = 0 \quad (82)$$

for the critical concentration of an inhibitor that increases the probability of degenerate chain branching. When

$$0 \leqslant \delta_i < (1-\delta_0^{1/3})^2 k_3 / k_2 [RH]$$

the quadratic equation has two positive real roots: i.e. an inhibitor that branches kinetic chains has two critical concentrations, and oxidation is a steady-state process only when the inhibitor concentration lies between them. An inhibitor for which the above relation exists between the constants δ_0, δ_i, k_2, and k_3 is an antioxidant of moderate strength[101].

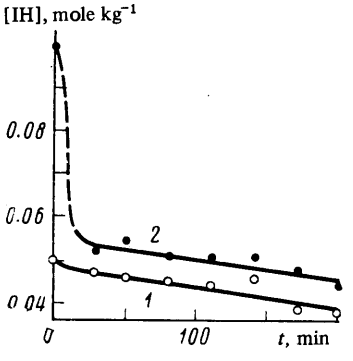

Figure 13. Variation in concentration of phenyl-2-naphthylamine in the initial stage of the induction period in the oxidation of polypropylene[104] under 300 mmHg of oxygen at 200 °C for different initial concentrations (mole kg^{-1}): *1*) 0.05; *2*) 0.10.

The lower (usual) critical concentration has been observed many times in the oxidation of simple compounds[102,103] and polymers[77,78,80,100]. The upper critical concentration appears as a sharp increase in rate of consumption of inhibitor above some concentration (Fig.13), which sometimes (not necessarily) slows down abruptly after the excess of inhibitor above the upper critical concentration has been consumed, or as a sharp "ceiling" (Fig.14) or maximum (Fig.15) in the dependence of induction period on inhibitor concentration. Whereas the rate of degradation of the polymer initially decreases and then smoothly increases with inhibitor concentrations in the range between lower and upper critical values, above the latter this rate increases sharply[104-106].

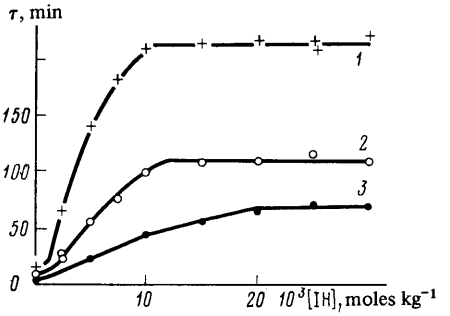

Figure 14. Dependence of induction period in the oxidation of polypropylene[105] under 300 mmHg of oxygen on concentration of methylene-2-2'-bis-(4-chloro-6-t-butylphenol) at different temperatures (°C): *1*) 180; *2*) 190; *3*) 200.

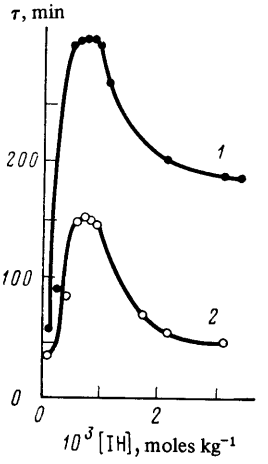

Figure 15. Dependence of induction period in the oxidation of an indene–coumaric resin[106] under 300 mmHg of oxygen on concentration of methylene-2,2'-bis-(4-methyl-6-t-butylphenol) at different temperatures (°C): *1*) 150; *2*) 180.

If in (82) we put $k_3[IH] \ll k_2[RH]$, i.e. confine our attention to low inhibitor concentrations, we find for the lower critical concentration of a moderately strong antioxidant the approximate formula[101]

$$[IH]_{cr} = \delta_0 k_2 [RH] \cdot (k_3 - \delta_i k_2 [RH])^{-1}. \quad (83)$$

The rate of consumption of the inhibitor can be written as the sum of the rates of its direct oxidation by molecular oxygen and its reaction with $RO_2^{\cdot}$ radicals:

$$-\frac{d[IH]}{dt} = k_0[IH][O_2] + \alpha k_0 k_3 [IH]^2 [O_2] \times$$
$$\times \left[k_3[IH] - \frac{\delta k_4 [RH](k_2[RH] + k_3[IH])}{k_4[RH] + k_5[R_2S]}\right]^{-1}. \quad (84)$$

When $[IH] \gg [IH]_{cr}$, the second term in the demoninator is small in comparison with $k_3[IH]$, and Eqn.(84) represents first-order consumption of the inhibitor. An inhibitor in whose presence δ remains approximately constant, and whose first-order rate of consumption is maintained even in the absence of R_2S, has been termed a *strong antioxidant*[80].

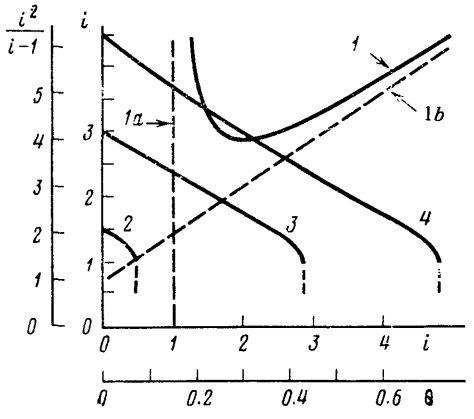

Figure 16. Calculation from Ref.101 of: *1*) dependence of dimensionless rate of consumption of an antioxidant of medium strength $w = i^2/(i-1)$ on its instantaneous concentration i; *1a,b*) asymptotes corresponding to (1); *2*)–*4*) variation in dimensionless concentration of the antioxidant with the dimensionless time θ during the oxidation induction period for different initial concentrations.

The law governing consumption of a moderately strong antioxidant can be found by substituting for δ from (74) in (84). Assuming also that $[R_2S] = 0$ with $k_3[IH] \ll k_2[RH]$ and $\delta_0 \ll 1$, we obtain

$$-\frac{d[IH]}{dt} = \left[1 + \frac{\alpha k_3}{k_6 - \delta k_2 [RH] - \delta_0 k_2 [RH]/[IH]}\right] k_0 [IH][O_2]. \quad (85)$$

This formula can be transformed into

$$-\frac{di}{d\theta} = \frac{i^2}{i-1} + \frac{k_3 - \delta_i k_2 [RH]}{k_2}, \quad (86)$$

where

$$i = [IH]/[IH]_{cr} \text{ и } \theta = \alpha k_0 k_3 [O_2] t/(k_3 - \delta_i k_2 [RH])$$

are dimensionless coordinates (of inhibitor concentration and time). If α is large, while the difference $k_3 - \delta_i k_2[RH]$ is small, the last term in (86) can be neglected, and the concentration dependence of the rate of inhibitor consumption becomes

$$-di/d\theta = i^2(i-1)^{-1}. \quad (86a)$$

Fig.16 shows that, despite the complicated concentration dependence of the rate of inhibitor consumption indicated by formula (86a), the minimum lies high above the abscissae axis, so that the rate departs little from its mean value, by not more than 20% over the range $i = 1.3$–4.7, and even 5.6% in the range 1.5–3. In conformity with this the variation in the concentration of antioxidant of moderate strength is nearly linear in the region of the critical concentration. Experimental curves for the consumption of many inhibitors, e.g. phenyl-2-naphthylamine[101] (Fig.17), are similar in form to the calculated curves in Fig.16.

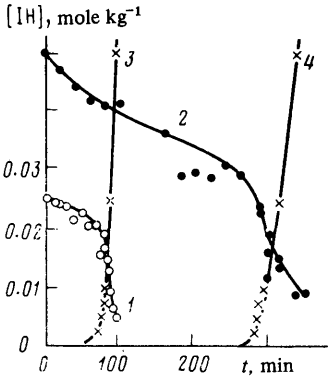

Figure 17. Inhibited oxidation of polypropylene[101] under 300 mmHg of oxygen at 200 °C: *1*) variation in concentration of phenyl-2-naphthylamine (initial concentration 0.025 mole kg^{-1}); *2*) as (*1*) but initially 0.05 mole kg^{-1}; *3*) absorption of oxygen (0.025); *4*) absorption of oxygen (0.05).

Equation (82) has no real roots, i.e. the inhibitor has no critical concentration, when

$$\delta_i > (1 - \delta_0^{1/2})^2 k_3/k_2[RH]$$

such an inhibitor cannot make oxidation a stationary process whatever its concentration: i.e. it is a weak antioxidant. Equations (75) cannot then be solved by Bodenstein's method. The autocatalysis factor for oxidation of a polymer in the presence of a weak antioxidant can be determined by means of Semenov's formula[107]

$$\varphi = (\nu\delta - 1)/\theta, \quad (87)$$

in which ν is the length of the unbranched chain, in the present case

$$\nu = 1 + k_2[RH]/k_3[IH], \quad (88)$$

and θ the lifetime of the branching product, i.e. $\theta = (k_4[RH])^{-1}$ when $[R_2S] = 0$. Substituting in (87) for δ from (74) and for ν from (88), we find that

$$\varphi = \frac{k_4[RH]}{k_2}\left\{\delta_i k_2[RH] - (1-\delta_0)k_3 + \delta_i k_3[IH] + \frac{\delta_0 k_2[RH]}{[IH]}\right\}. \quad (89)$$

The expression in braces is the left-hand side of (82) divided by [IH], and with

$$\delta_i > (1 - \delta_0^{1/2})^2 k_3/k_2[RH]$$

is positive at all values of [IH]. For certain mean values of [IH] both terms containing it in the brackets in Eqn.(89) can be neglected. Over this concentration range the rate of absorption of oxygen and of other stages in oxidation of a

polymer containing a weak antioxidant will be described by the exponential law $w = w_0 \exp(\phi t)$ with ϕ constant.

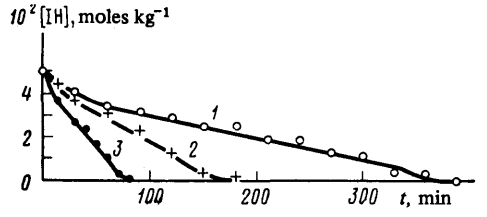

Figure 18. Variation in concentration of the weak antioxidant 2,6-di-t-butyl-4-phenylphenol during induction period in the oxidation of polypropylene under 300 mmHg of oxygen at (°C): *1*) 180; *2*) 190; *3*) 200.

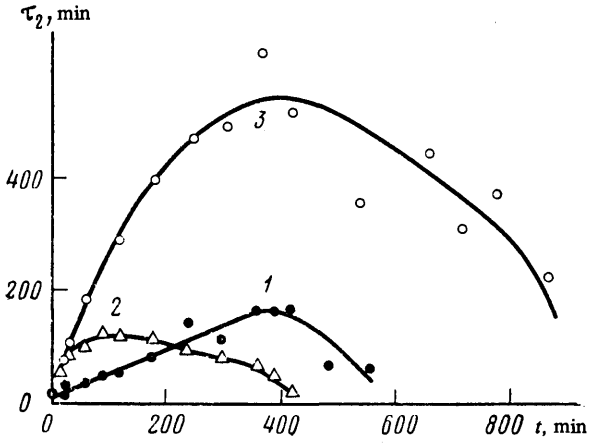

Figure 19. Dependence of induction period in the oxidation of polypropylene containing conversion products of antioxidants (unconsumed antioxidants removed by vaccum distillation at 200 °C) on duration of oxidation of initial specimens[80] under 300 mmHg of oxygen at 200 °C for additions of a mixture of inhibitor (I) (0.16 mole kg^{-1}) with: *1*) didecyl sulphide; *2*) inhibitor (II) (0.08 mole kg^{-1}); *3*) a mixture of (II) and didecyl sulphide (each 0.08 mole kg^{-1}).

The rate of consumption of inhibitors that are weak antioxidants considerably exceeds that of strong antioxidants. The proportion of direct oxidation of the inhibitor is then insignificant in comparison with its consumption in chain termination, the rate of which is given approximately by the product of the instantaneous inhibitor concentration and a quantity proportional to exp ϕt. The curves described by this law are sometimes fairly complicated, but sometimes they approximate to straight lines[108,109] (Fig.18).

So far we have been considering only the action of the initial inhibitor. However, conversion products of inhibitors are usually involved in oxidation of a polymer, and are quite often fairly effective antioxidants. The conversion products remaining in a polymer after unconsumed inhibitor has been removed from it may ensure long induction periods (Fig.19).[80] Formula (81) shows that a weak inhibitor, in whose presence the critical concentration increases right up to $\delta = 1$, may behave as a strong antioxidant in the presence of a sufficient concentration of a reductant for hydroperoxide.

When a polymer contains both a weak or moderate antioxidant and a hydroperoxide reductant at a constant total concentration $[A] = [IH] + [R_2S]$, substitution in (81) of $\delta = \delta_0 + \delta_i[IH]$ and $[R_2S] = [A] - [IH]$, with neglect of $k_3[IH]$ in comparison with $k_2[RH]$, yields for the critical inhibitor concentration

$$[IH]_{cr}^2 - \left\{\frac{k_4[RH]}{k_3 k_6}(k_3 - \delta_i k_2 [RH]) + [A]\right\}[IH]_{cr} + \frac{\delta_0 k_2 k_4}{k_3 k_5}[RH]^2 = 0. \quad (90)$$

This quadratic equation has two positive real roots provided that [A] exceeds some critical value

$$[A]_{cr} = \frac{k_4[RH]}{k_3 k_5}(\delta k_2 [RH] - k_3) + 2[RH](\delta_0 k_2 k_4 / k_3 k_5)^{1/2}. \quad (91)$$

Thus for every concentration $[A] > [A]_{cr}$ there exist two critical mixture compositions such that only between them is oxidation a stationary process, but outside this range it is autocatalytic. On plots of induction period against composition short induction periods correspond to an autocatalytic process, but long induction periods to a steady-state process. If one of the mixture components is an antioxidant of medium strength, having a critical concentration even in the absence of a reductant, the region of a steady-state process will adjoin the edge of the diagram provided that $[A] > [IH]_{cr}$.

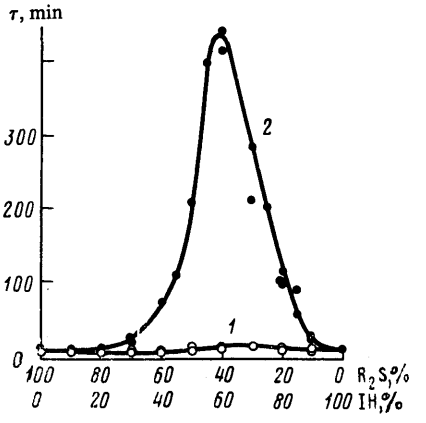

Figure 20. Dependence of induction period τ in the oxidation of polypropylene under 300 mmHg of oxygen at 200 °C on composition of a mixture of phenyl-2-naphthylamine (IH) and didodecyl thiodipropionate (R_2S) [97] at total concentrations (mole kg^{-1}): *1*) 0.005; *2*) 0.010.

Fig.20 shows such plots for two mixture concentrations lying below and above the critical total $[A]_{cr}$. It is evident that doubling the total concentration produces a sharp change in the character of the diagram, with appearance of a narrow maximum[97]. Many similar diagrams have been published[80,109,110].

The above phenomenon, consisting in the longer or more effective inhibition of oxidation by a mixture of two antioxidants than by each component at a specified total concentration, is termed *antioxidant synergism*. The only rigorous criterion of synergism may be the presence of a maximum in the composition dependence of induction period or of a minimum in that of rate of degradation. From a practical point of view it is advantageous to replace an individual antioxidant by a mixture only if the mixture at a constant total concentration (or a constant total cost) retards oxidation longer or more effectively than does each component, whence follows the above definition of synergism.

In some cases a mixture of two antioxidants is less effective than the more effective component at the same partial concentration, a phenomenon that is termed *antioxidant antagonism*. An example of such antagonism was illustrated in Fig. 10. We shall examine another example in greater detail.

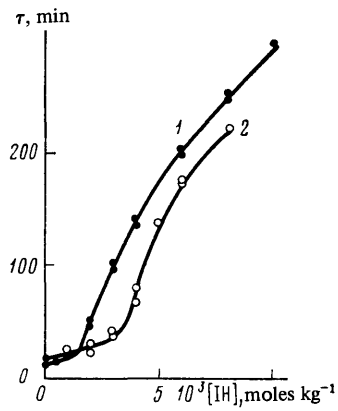

Figure 21. Effect of 2,4,6-tri-t-butylphenol (0.01 mole kg^{-1}) on dependence of induction period in the oxidation of polypropylene under 300 mmHg at 200 °C on the concentration of methylene-2,2′-bis-(4-methyl-6-t-butylphenol)[108]: *1*) second inhibitor absent; *2*) second inhibitor present.

In Fig. 21 the curve representing the dependence of the induction period in the oxidation of polypropylene, containing the weak antioxidant 2,4,6-tri-t-butylphenol at a constant concentration of 0.01 mole kg^{-1}, on the concentration of a second antioxidant (II) lies below the corresponding curve for pure polypropylene almost throughout its length[108], and the partial critical concentration of the strong antioxidant (II) is increased in the presence of weak 2,4,6-tri-t-butylphenol. Assuming that both antioxidants (IH′ and IH″) terminate chains, replacing $k_3[IH]$ in (81) by $k_{31}[IH'] + k_{32}[IH'']$, and rearranging ($[R_2S] = 0$), we obtain

$$[IH']_{cr} = \frac{\delta k_2 [RH]}{(1-\delta) k_{31}} - \frac{k_{32}}{k_{31}} [IH''] . \qquad (92)$$

Differentiating (92) with respect to [IH″], we then find that

$$\frac{\partial [IH']_{cr}}{\partial [IH'']} = \frac{k_2 [RH]}{(1-\delta)^2 k_3} \cdot \frac{\partial \delta}{\partial [IH'']} - \frac{k_{32}}{k_{31}} \qquad (93)$$

will be positive (i.e. the critical concentration of IH′ will increase in the presence of IH″) only if the second antioxidant increases the probability of degenerate chain branching sufficiently strongly, so that

$$\frac{\partial \delta}{\partial [IH'']} \cdot \frac{k_{32} (1-\delta)^2}{k_2 [RH]} > 0. \qquad (94)$$

Hence in this case the antagonism is explained by a marked increase in the probability of chain branching under the influence of the second antioxidant: mixtures of two inhibitors—one strong and the other a weak antioxidant—may in some cases be less effective than one of the components (the strong antioxidant) used separately at the same concentration as in the mixture.

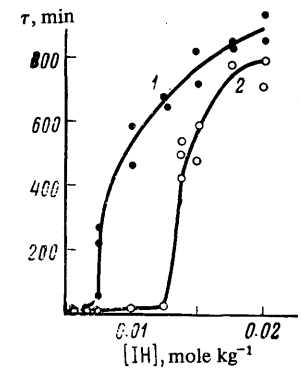

Figure 22. Effect of mixing of inhibitor with polymer on dependence of induction period in the oxidation of polypropylene under 300 mmHg at 200 °C on concentration of dimethylbis-*p*-aminophenylphenoxysilane[111]: *1*) non-uniform; *2*) uniform.

Diminished efficiency of an antioxidant may be due to insufficiently uniform admixture with the polymer. Thus a threefold increase in the "inoperative" concentration of the antioxidant dimethylbis-*p*-phenylaminophenoxysilane was observed[111] on passing from a uniform to a non-uniform distribution (polypropylene powder consisting of spherical particles of mean diameter 0.03 mm moistened with a benzene solution of the antioxidant and dried at room temperature) (Fig. 22).

A theory has been developed for the oxidation of a non-uniformly inhibited polymer[112]. Calculations were based on a simplified scheme for the progress of a branched chain reaction involving active centres of a single type. The variation in concentrations of active centres and inhibitor n and i during such reaction can be described by the equations[100]

$$dn/dt = w_0 + \varphi n - kin, \qquad (95)$$

$$-di/dt = kin, \qquad (96)$$

in which ϕ is the autocatalytic factor, w_0 the rate of chain generation, and k the rate constant of chain termination by the inhibitor. The critical inhibitor concentration in the reaction is $i_{cr} = \phi/k$. Progress of the reaction is autocatalytic or stationary according as $i < i_{cr}$ or $i > i_{cr}$.

For an extended non-uniformly inhibited specimen we must take into account the redistribution of inhibitor and active centres resulting from diffusion, for which purpose we introduce appropriate terms[113] into Eqns.(95) and (96):

$$\partial n/\partial t = D\partial^2 n/\partial x^2 + w_0 + \varphi n - kin, \qquad (95a)$$

$$\partial i/\partial t = D_i\partial^2 i/\partial x^2 - kin, \qquad (96a)$$

where D and D_i are the diffusion coefficients of active centres and of inhibitor, while x is the coordinate. In the oxidation of a long unidimensional specimen[112] part of which ($0 \leq x < x_1$) is devoid of inhibitor, while the remainder contains inhibitor at a constant concentration i_2, the initial concentration of active centres throughout the specimen equals their steady-state concentration in the inhibited portion:

$$n_0 = w_0/(ki_2 - \varphi).$$

The set of equations was integrated on a computer after transformation into

$$\partial N/\partial\tau = \gamma\partial^2 N/\partial z^2 + N(1-I) + (I_2 - 1), \qquad (97)$$

$$\partial I/\partial\tau = \partial^2 I/\partial z^2 - AIN. \qquad (98)$$

Here N and I are dimensionless concentrations corresponding to n and i, while z and τ are the dimensionless coordinate and time:

$$dz = (\varphi/D_i)^{1/2}dx;\ d\tau = \varphi dt;\ N = n/n_0;\ I = ki/\varphi = i/i_{cr}.$$

The coefficients are given by $A = kn_0/\phi$ and $\gamma = D/D_i$. Calculations were based on $A = 10^{-3}$, $\gamma = 1$, a uniform initial distribution of active centres ($N = 1$), and a non-uniform distribution of inhibitor ($I = 0$ for $0 \leq z < z_1$, and $I = I_2$ for $z \geq z_1$). Solutions of Eqns.(97) and (98) are illustrated in Fig.23.

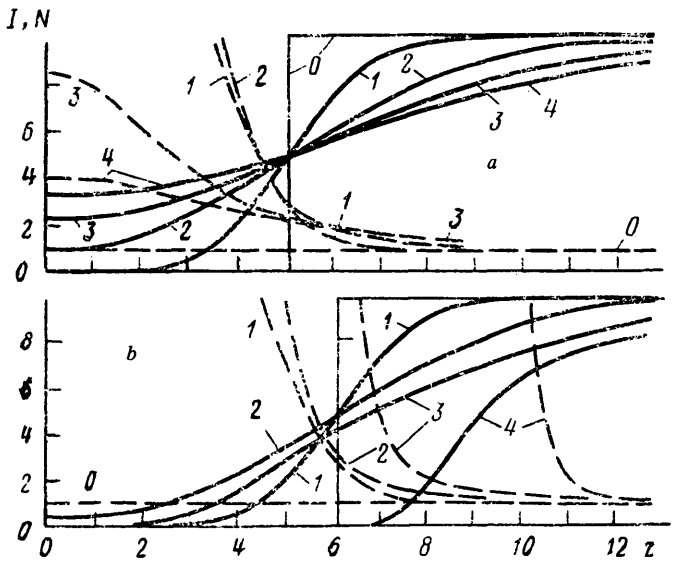

Figure 23. Distributions of dimensionless concentrations of inhibitor and active centres I and N in a unidimensional specimen[112] ($\gamma = 1$; $I_2 = 10$) for different values of z_1: *a*) 5.125; *b*) 6.15 at different times θ during the process: *0*) 0; *1*) 1; *2*) 5; *3a*) 10; *3b*) 12.5; *4a*) 15; *4b*) 17.5.

Fig.23 shows the distributions of dimensionless concentrations of inhibitor and active centres in specimens differing in the size of the initially uninhibited portion z_1. At first the process develops similarly in the two cases: both N and I increase in the originally uninhibited segment. After some time, however, a difference appears: if $z_1 = 5.125$ the concentration I increases monotonically throughout the range $0 \leq z < z_1$, but N begins to decrease: i.e. the process that began in the uninhibited portion of the specimen dies away. With $z_1 = 6.15$, on the other hand, I begins to decrease after some time, whereas N continues to increase. A reaction front appears: within a relatively narrow range of change in z the concentration I changes from approximately zero on the left to more than unity on the right, while N drops sharply in the same interval. The reaction front gradually moves to the right, towards larger z. There thus exists a limiting size of the originally uninhibited region such that, if the actual size is smaller, the process therein dies out; but if the portion free from inhibitor is larger than the critical size, a stable region of rapid oxidation arises, which spreads throughout the specimen.

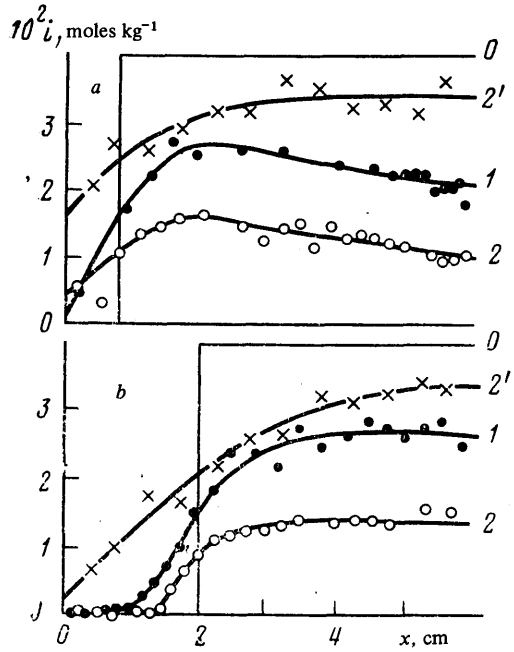

Figure 24. Concentration distribution of inhibitor methylene-2,2'-bis-(4-methyl-6-t-butylphenol) along specimen of atactic polypropylene[114] under an oxygen partial pressure of 150 mmHg (air) at 190 °C for different lengths x_1 (cm) of initially uninhibited region: *a*) 0.8; *b*) 2.0 after different periods of oxidation (min): *0*) 0; *1*) 150; *2*) 300; *2'*) 300, distribution of radioactive inhibitor and conversion products when labelled inhibitor used.

Fig.24 shows the concentration distribution of the inhibitor methylene-2,2'-bis-(4-methyl-6-t-butylphenol) (II) 150 and 300 min after the start of oxidation (in air at 190 °C) of specimens of atactic polypropylene having the non-uniform

initial inhibitor distribution shown by the broken lines 0. If the section devoid of inhibitor is 0.8 cm long, after some time inhibitor penetrates the left-hand (uninhibited) portion, suppressing oxidation. If the uninhibited portion is 2.0 cm long, inhibitor is not detected in the left-hand section, although in both cases conversion products of the inhibitor penetrate the specimen to the very edge ($z = 0$). After oxidation for 300 min the inhibitor-free portion becomes larger than it had been at 150 min. Apart from certain details, such as the maximum in the inhibitor distribution curves in Fig. 24*a* due to enhancement of its solubility in the slightly oxidised polymer and the greater rate of consumption of inhibitor in the right-hand portion (Figs. 23 and 24), calculation and experiment almost coincide[114,115].

Almost all the above experimental results relate to the oxidation of polypropylene, since systematic data have not appeared for other polymers. Passing from one polymer to another involves changes primarily in ease of detachment of the hydrogen atom from the monomer unit RH, in the distances between them, and in the solubility of oxygen: i.e. the rate constants k_0, k_1, k_2, and k_4, those of quadratic chain termination, and also the yields of hydroperoxide α and those of radicals on its breakdown δ are affected. Changes in these parameters entail changes in the rates both of uninhibited and of inhibited oxidation.

As mentioned above, inhibitors retard oxidation by interacting with peroxy-radicals $RO_2^{\cdot}$. The reactivity of such radicals is little dependent on the structure of the residue R, which is remote from the reaction centre. The rate of chain termination, i.e. the rate of interaction of $RO_2^{\cdot}$ radicals with inhibitor molecules, depends not only on the reactivity of the reactant species but also on the number of collisions between them, i.e. on concentrations and diffusion coefficients.

If a polymer contains functional groups capable of forming complexes with inhibitor molecules

$$IH + X{-}R \rightleftharpoons IH \cdot X{-}R, \qquad (99)$$

the concentration of mobile inhibitor molecules not bound in complexes will form only part its total concentration in the polymer [IH]. In the simplest case, when $[IH] \ll [IH]_p$ and $[IH]_p \ll [X{-}R]$, we obtain

$$[IH] \text{ moles kg}^{-1} = \frac{[IH \cdot XR]}{k\,[X{-}R]} = \frac{m\,[IH]_p}{1000kn}, \qquad (100)$$

where m is the equivalent weight of a monomer unit and n the number of functional groups in a unit that are involved in complex formation. Under otherwise similar conditions the effective rate constant of chain termination by an inhibitor that forms complexes with particular functional groups in the polymer will be smaller than the corresponding rate constant for an inhibitor that is incapable of complex formation. This apparently explains the relative ineffectiveness of phenolic inhibitors in polyamides[116].

Inhibitor molecules can be retained not only by polar groups but also by sites of disorder in the relative arrangement of macromolecules[117]. The sorption capacity of a polyalkene, i.e. the number of sites capable of retaining simple substances, can be increased by special treatment of the melt[118–120]. Enhancement of sorption capacity leads to some increase in the critical concentration of the inhibitor accompanied by decrease in the rate of its consumption, which at high inhibitor concentrations may lengthen the time during which it operates.

With a given polymer in the solid state the parameters k and i_{cr} in formula (66) for a particular inhibitor depend on the temperature–time conditions of preparation of the specimen[121,122]. Good compatibility of inhibitor with polymer diminishes the effectiveness of the former[123]. Compatibility was measured[123] by the rate of vaporisation of the inhibitor from the polymer, a quantity proportional to the concentration of mobile (not sorbed at any centres) inhibitor molecules.

The rate of inhibited oxidation increases[124,125] on passing from a homopolymer of ethylene to copolymers with propylene and with vinyl chloride. Both parameters in Eqn. (66), k and i_{cr}, increase, passing through maxima at certain contents of the foreign units. These parameters increase also with the γ-ray dosage of polyethylene[126]. Any breakdown in order of arrangement of macromolecules probably diminishes the stability of the polymer.

VI. SOME SPECIAL METHODS FOR THE STABILISATION OF POLYMERS

All known antioxidants rapidly become less effective with rise in temperature, and all the usual antioxidants cease to retard the oxidation of polymers between 270 and 300 °C. However, oxidation can be slowed down even at high temperatures.

A polymer can be protected from oxidation under processing conditions by conducting the operation in an inert atmosphere (nitrogen, carbon dioxide). In small-scale production an inert atmosphere can be produced in a closed space by the use of absorbents for oxygen, but these cannot protect the polymer from oxidation during storage and use[127]. To estimate the time during which such an absorbent acts we take the diffusion coefficient of molecular oxygen in the polymer at room temperature to be 10^{-6} cm^2 s^{-1},[128] and the solubility coefficient to be 0.02 mole kg^{-1} atm^{-1}. In air ($p_{O_2} = 0.2$ atm) the concentration of oxygen at the polymer surface will be 4 mmoles kg^{-1} or 4 μmoles cm^{-3}. If all the oxygen is absorbed in a layer 0.1 cm thick, its flow through 1 cm^2 of surface will be at least 40 pmoles cm^{-2} s^{-1}; and if the absorbent concentration is 0.1 mole kg^{-1} or 10 μmoles cm^{-2} in the 0.1-cm layer, the absorbent will be exhausted in 2.5×10^5 s or 3 days. This time will become shorter with rise in temperature.

One consequence of thermo-oxidative degradation is the formation of volatile products, some of which may be toxic[129]. Special absorbents are introduced into polymers to eliminate this effect. Thus barium, lead, or other salts of weak organic acids are added to absorb hydrogen chloride formed on the degradation of poly(vinyl chloride)[130]; polyamides are added to absorb formaldehyde formed in the oxidative degradation of polyoxymethylene; etc.

Discoloration during the oxidation of polymers is due to formation of a system of conjugated bonds. Substances capable of adding to such bonds will weaken the effect[130].

Every new component introduced into a polymer, either by chance or deliberately, influences the resistance of the latter to thermo-oxidative degradation. Thus metals of variable valency increase the yield of free radicals formed by the breakdown of hydroperoxides. This effect can be lessened by introducing into the polymer complexing agents, in particular ethylenediaminetetra-acetic acid and its derivatives[130].

The widely used colorant, filler, and photostabiliser—carbon black—protects a polymer from thermal oxidation at not very high temperatures, but catalyses the oxidation of many stabilisers at processing temperatures[131,132]. Polymers containing carbon black are protected by the use of thiophenols[131,132] and other sulphur derivatives[130].

At present no general methods are available for combating the harmful effects of impurities.

Thus intense research on the ageing and stabilisation of polymers has not yet eliminated the empirical selection of

stabilisers for specific polymer materials. However, from the time of the first investigations in this field the range of compounds among which effective stabilisers must be sought has been continually narrowed down, and the synthesis of novel stabilisers has become increasingly selective. In some cases the concept of critical concentrations has permitted prediction of the effects of mixing two antioxidants differing in structure. Among problems that remain unsolved in the stabilisation of polymers the first task is to develop methods for retarding oxidation at temperatures above 300 °C.

Alkaline-earth Metals and Compounds as Initiators of the Anionic Polymerisation of Unsaturated Monomers

A.A.Arest-Yakubovich

Data on the catalytic activity and stereospecificity of alkaline-earth metals in the polymerisation and copolymerisation of unsaturated monomers are summarised, and the nature of the active centres is examined togeher with the kinetics and the mechanism of these processes. The principal methods of preparing initiators for anionic polymerisation that contain compounds of these metals are outlined, and the most probable immediate prospects for practical application of the compounds in polymerisation processes are noted. A list of 175 references is included.

I. INTRODUCTION

The first publications on the ability of organolithium compounds to initiate the formation of *cis*-1,4-polyisoprene, similar in structure and properties to natural rubber[1,2], and the series of papers by Szwarc began at about the same time, which first directed attention to several unusual and interesting properties of living polymers[3-5], led to a sharp growth of interest in anionic polymerisation. During the past two decades great progress has been made both in the theory of processes initiated by alkali metals and in their practical realisation, thanks to which they now find widespread industrial application in the manufacture of various synthetic polymer materials[6]. Research on processes involving alkaline-earth metals has hitherto developed far more slowly, which is largely due to difficulties in the preparation of appropriate polymerisation initiators.

The first systematic studies in this field[7,8] were made with organocalcium compounds, which were more accessible at that time; but subsequently attention was focussed mainly on barium compounds, which exhibited interesting catalytic properties in the polymerisation and copolymerisation of diene monomers[9-12]. Sufficient information has now been obtained for the possible formulation of several general rules in this independent new field in the theory of anionic polymerisation and for identification of the most promising practical aspects.

The present Review is devoted to the polymerisation of unsaturated polymers initiated by calcium, strontium, barium, and their compounds. Magnesium compounds are included only where necessary for comparison and for citing fundamentally novel results not covered by previous reviews[13,14].

The Review begins with an outline of methods for preparing the chief polymerisation initiators containing compounds of alkaline-earth metals that are used at the present time, since most of this information has been obtained recently and has not appeared in the well known monographs on the preparation of organometallic compounds[15,16].

II. PRINCIPAL METHODS FOR THE PREPARATION OF POLYMERISATION INITIATORS BASED ON COMPOUNDS OF ALKALINE-EARTH METALS

Organometallic compounds are usually formed considerably more readily in the presence of electron-donor solvents, whereas the presence even of catalytic quantities of polar compounds is in many cases sufficient to change appreciably the character of anionic polymerisation processes and also the structure and properties of the resulting polymers[17-19]. Therefore chemists investigating polymerisation tend to prepare the initiator in the solvent in which subsequent polymerisation is to be conducted. Workers studying the polymerisation of diene monomers display a special interest in hydrocarbon solvents, which show the greatest practical promise with respect both to the properties of the resulting polymers and to technical and economic factors.

1. Electron Transfer to Hydrocarbons

Alkaline-earth metals are considerably less active than alkali metals in reactions involving electron transfer to aromatic compounds. Only in polar solvents of high solvating power such as hexamethylphosphorotriamide do they form compounds comparatively readily with biphenyl, naphthalene, anthracene, 1,1-diphenylethylene, and similar compounds[20-22]. In reactions of this type calcium is considerably less active than are magnesium and barium[22,23], which as with alkali metals[18,24] is due to competition between two main factors governing the activity of metals in these processes—the tendency to donate electrons and the gain in energy of solvation of the cation—which vary in opposite directions within a given group.

In ethereal solvents only the higher fused hydrocarbons (naphthacene, perylene), among aromatic compounds, react with alkaline-earth metals, forming sparingly soluble radical-anions and dianions that are inert towards polymerisation[23,25].

The addition of barium to non-polymerising 1,1-disubstituted vinylated aromatic compounds—1,1-diphenylethylene or α-methylstyrene—proceeds considerably more readily[10,26-28]. The products are probably metal salts of dianions—of the dimer of diphenylethylene $ba^{+-}C(C_6H_5)_2.CH_2.CH_2.C(C_6H_5)_2C^-ba^+$ (where ba is an equivalent of barium) or an oligomer of α-methylstyrene—like the well studied alkali-metal compounds[10]. Formation of the corresponding barium derivatives of oligomeric dianions of styrene (degree of polymerisation 2–5) has also been reported recently[29], but in this case special measures are necessary to prevent homopolymerisation of styrene.

Formation of all these products involves recombination of primary monomeric radical-anions[18], which is responsible for the difunctionality of the product and also increases their yield significantly, despite the relatively low electron affinity of the initial hydrocarbons.

It has recently been reported[30] that depending on the conditions the action of barium on α-methylstyrene in oxolan yields either dianions of the above type or products having only one active end. As single-ended products had never previously been observed in such systems and their formation is difficult to understand, it is not yet clear whether their appearance is a specific feature of barium or whether it is due to experimental error.

Bis-1,1,4,4-tetraphenylbutylbarium has been characterised by spectroscopic and conductivity methods[31-33]. Together with its α-methylstyrene analogue it is now probably the simplest (with regard to preparation) and most often used organobarium polymerisation initiator. Similar compounds have been obtained with strontium[34,35]; in the cases of calcium and magnesium, reaction with 1,1-diphenylethylene in ethereal media is insignificant if it occurs at all[23,26].

The reaction of alkaline-earth metals with hexa-arylethanes is apparently of the same type; it occurs readily in oxolan at room temperature and yields bistriarylmethyl derivatives of the metals[36,37]. Addition products of calcium, strontium, and barium with benzophenone (ketyls) have also been obtained in oxolan[38,39]; they initiate the polymerisation of acrylates[39], but are apparently inactive in the polymerisation of hydrocarbon monomers[40].

It has recently been shown[174] that in aromatic hydrocarbons at 50–80 °C hexaphenylethane reacts with metallic barium and strontium to form the corresponding bistriphenylmethyl derivatives, which are soluble in the reaction medium. This is the first known example of the synthesis of completely substituted compounds of alkaline-earth metals in the absence of solvating agents.

2. Reaction with Halogenohydrocarbons

Organic derivatives of alkaline-earth metals were first obtained in this way—phenylcalcium iodide in 1905,[41] phenylbarium iodide in 1927 [42]—but after it was early established that difficulties were involved in synthesis and that the products were unpromising in preparative chemistry compared with Grignard reagents, interest in this reaction died away for a long time, and was renewed only in the 1960s [43] (the history and the present-day achievements of this method have been covered quite fully in Ref. 44). Quite a number of publications have now appeared on the preparation of compounds of type RCaX (in which X is most often iodine, more rarely bromine or chlorine) in oxolan or diethyl ether[45-50]. If the metal used is especially pure, the reaction can be conducted even in a hydrocarbon medium[51] (though insoluble products are then formed, which hinders their further application). Compounds of strontium[36,52-54] and of barium[36,52,53,55] have been obtained by this method in ethereal media. With these two metals the preparation could not be effected in a hydrocarbon medium, but compounds of calcium, strontium, and barium have been obtained by cocondensation of metal and halogenoalkane vapours on a cooled surface in the absence of a solvent[53].

The substances obtained by this reaction are mixtures of completely and incompletely substituted compounds (R_2M + RMX), whose composition depends both on the nature of the alkyl halide and on the reaction conditions[9,50,56]. On the whole this method, though the principal route to lithium initiators, has not yet found appreciable extension to the synthesis of polymers in the case of alkaline-earth metals.

3. Dimetal Compounds

Alkaline-earth metals on reaction with excess of diethylzinc in benzene[57] fairly readily form dimetal complexes of general formula $MZn(C_2H_5)_4$. Such compounds were used by Furukawa et al. for the polymerisation of certain polar monomers[58,59], but they were relatively inactive owing to their insolubility and their complicated composition. At the beginning of the 1970s interest was renewed in organometallic derivatives containing both barium and zinc, as they exhibited interesting catalytic properties in the polymerisation and copolymerisation of dienes[9,11,12,60]. Methods were found for obtaining hydrocarbon-soluble initiators, which could be readily separated from excess of metal and other impurities by conducting the preparation in the presence of 1,1-diphenylethylene[61] or by replacing diethylzinc with dibutylzinc[12,62] (in the latter case there are grounds for supposing that the initiator is formed in diethyl ether[63]). Opportunities for the wider application of these compounds apparently depend on the availability of zinc alkyls.

Analogous aluminium complexes of general formula $M(AlR_4)_2$ have recently attracted attention. They are formed from the trialkylaluminium and the alkaline-earth metal[61,64] or an alkoxide thereof[65,66]. They are readily soluble in benzene and effect the polymerisation of hydrocarbon monomers, although considerably less active than zinc complexes[61].

4. Other Methods

Completely substituted organic derivatives of calcium, strontium, and barium are readily formed in oxolan from the corresponding compounds of mercury[67-70] and also (under more severe conditions) of lead[71] and tin[72]. Organomercuric synthetic reactions and the properties of the compounds isolated—including infrared, ultraviolet, and nuclear magnetic resonance spectra of several compounds—have been described most fully in patents of the Dow Chemical Co.[68]; compounds containing radicals with conjugated bonds (allyl, phenyl, benzyl, indenyl, etc.) can be obtained more readily.

Hydrocarbons containing a mobile hydrogen atom—such as fluorene, triphenylmethane, indene, cyclopentadiene, phenylacetylene—have been metallated by the action of alkaline-earth metals in strongly solvating media (liquid ammonia[73,74], hexamethylphosphorotriamide[75], 1,1-dimethyl ethylene[75], methylamine[76]). Fluorenylstrontium[77,78] and fluorenylbarium[78-81] have been obtained also by the metallation of fluorene with 1,1,4,4-tetraphenylbutyl derivatives of the metals in oxolan. However, compounds containing mobile, readily substituted hydrogen (fluorene, cyclopentadiene, etc.) form stable carbanions, which are relatively inactive in the polymerisation of hydrocarbon monomers[18,82,83].

Cumenylstrontium and cumenylbarium can be obtained[84] by cleaving cumenyl methyl ether with dispersion of the metals in oxolan.

Exchange reactions have recently been observed between barium alkoxides and organomagnesium (and organolithium) compounds[85-87], similar to those between lithium alkyls and sodium (and potassium) alkoxides[88]. The products apparently contain varying proportions of symmetrical and unsymmetrical compounds R_2Ba and RBaOR', with a significant influence on their catalytic properties[86]. Various systems of this type have been described in the patent literature[89-91]. Numerous multicomponent systems, representing various combinations of the above variants, have also been suggested (e.g. calcium–anthracene–trialkylaluminium[92], barium or strontium acetylacetonate–trialkylaluminium–alkyl–lithium[93], barium alkoxide–lithium alkoxide–trialkylaluminium[94]).

Thus the preparation of organic derivatives of alkaline-earth metals in the presence of highly polar solvents such as hexamethylphosphorotriamide presents no difficulty, but the products hardly differ in catalytic properties from the more readily available alkali-metal compounds. In ethereal solvents (oxolan, dimethyl ether) compounds having two active ends, such as bistetraphenylbutyl-barium and -strontium, are most simply obtained. The most reliable method for obtaining compounds that are completely substituted with hydrocarbon radicals having one active end is apparently reaction with mercury compounds or with hexaphenylethane.

In hydrocarbon media completely substituted compounds (bistriphenylmethyl-barium and -strontium) have been obtained only recently, as mentioned above. Several workers[9,95-97] have therefore used initiators obtained in ethereal media by removing the electron donor under more or less severe conditions. With such a method, of course, doubt always remains whether the solvent has been completely removed. The possibility of almost complete removal of oxolan has until now been confirmed analytically only for barium compounds[98].

Furthermore, as many workers have shown[51-53,68,87], the lower alkyl compounds of alkaline-earth metals are thermally unstable at room temperature, and also decompose under the influence of oxolan and other ethereal solvents. Dibenzylbarium in oxolan also undergoes gradual deactivation and isomerisation[70]. On the other hand, compounds having branched carbanions of the di- and tri-phenylmethyl type are completely stable both in hydrocarbon and in ethereal media[32]. Therefore the introduction of 1,1-diphenylethylene (sometimes α-methylstyrene) into the reaction system is often a useful method for improving the stability and the solubility of the resulting organometallic compounds[69,85,97].

III. CATALYTIC ACTIVITY AND STEREOSPECIFICITY OF ALKALINE-EARTH METALS IN POLYMERISATION PROCESSES

1. General Behaviour

The first investigations on polymerisation involving calcium, strontium, and barium used the free metals as initiators[99-105], but in most cases the results showed considerable scatter. Satisfactory reproducibility was subsequently obtained with respect to the structure of the polymers and the composition of copolymers[10,106,107], but recently almost all studies have been made under homogeneous conditions, as a consequence of the progress made in preparing compounds of these metals.

By now most monomers capable of anionic polymerisation—unsaturated compounds containing conjugated double bonds or polar substituents, such as dienes, styrene, methyl methacrylate—have been subjected to polymerisation initiated by alkaline-earth metals and their compounds. Acrylonitrile and vinyl chloride have been polymerised by the action of a dispersion of barium[100] (under homogeneous conditions, the latter could not be polymerised by an organobarium initiator[108]).

Monomers having polar side-groups are readily polymerised by the action of magnesium compounds[13,14]. Reaction of hydrocarbon monomers requires either the presence of such strong solvating agents as hexamethylphosphorotriamide[13,21,109,110] or magnesium alkoxides of certain ether–alcohols, e.g. methylcellulose or oxolan-2-ylmethanol[111,112], or (slowly) heating to 80–100 °C.[113,114]

It is interesting that metallic magnesium, which is fairly active in electron-transfer processes, reacts comparatively readily in ethereal solvents with butadiene[115-117], isoprene[118], and also with styrene and several other unsaturated compounds[119]. Since the organomagnesium compounds thus formed do not polymerise these monomers, the reaction ceases at the stage of the primary oligomeric products, and can be used to obtain concentrated solutions of double-ended organomagnesium compounds.

In the early work, concerned mainly with the polymerisation and copolymerisation of methyl methacrylate under the influence of dispersions of alkaline-earth metals, doubts were expressed concerning the mechanism of these processes: in particular it was suggested that not only an anionic but also a radical process took place[106,120-122]. The chief arguments supporting this hypothesis were the presence of a certain quantity of styrene and its copolymer with methyl methacrylate and also the difference in the general rules of stereoregulation from those found previously for reactions with alkali metals. A relevant fact here is that it has been shown many times with alkali metals that the styrene–methyl methacrylate pair cannot be used to establish the mechanism of heterogeneous processes, since in this case polymerisation is initiated predominantly on the styrene as a consequence of its considerably stronger adsorption on the metal surface[18,123]. At the present time no doubt arises about the anionic mechanism of polymerisation processes initiated by alkaline-earth metals, and the differences (sometimes very substantial) observed from processes with alkali metals reflect differences in the properties of active centres with uni- and bi-valent gegenions.

2. Stereospecificity of Alkaline-earth Metals

(a) Diene monomers

The most complete and reliable information has been obtained for the polymerisation of butadiene. The laws thus found (Table 1) differ in many respects from those established previously for alkali metals.

Hydrocarbon medium. Firstly it is evident that in hydrocarbon media metals of Group II possess a considerably greater ability than the corresponding metals of Group I to cause the 1,4-addition of butadiene units. Moreover, the total content of 1,4-units in butadiene polymers formed by the action of any alkaline-earth metal approaches those obtained in the presence of lithium, which has hitherto occupied an exceptional position among initiators of anionic polymerisation. In its ability to form a *cis*-1,4-butadiene structure barium surpasses all other initiators based on non-transition metals, including lithium (at very low concentrations of active centres ($\sim 10^{-5}$ M) the content of *cis*-1,4-units in lithium-polybutadiene obtained in an aliphatic solvent may reach 80–85%[128]). When the temperature is raised to

95 °C however, the content of *cis*-1,4-butadiene units in polymers obtained by using barium falls to 42% (with a constant content of 1,2-units[129]); for comparison the content of *cis*-1,4-units when polymerisation is effected by using lithium remains almost unchanged between −20 and 196 °C.[130]

Table 1. Structure of butadiene polymers formed at room temperature by means of initiators based on metals in Groups I and II.

The stronger coordinating power of alkaline-earth than of alkali metals is undoubtedly due to the presence of the double charge on the gegenions and hence to their increased acceptability for similar ionic radii. However, the enhanced ability of barium to form *cis*-1,4-polybutadiene, though noted some time ago[10,22] (and its ability to form isotactic poly(methyl methacrylate) was noted still earlier[120]), has not yet been rigorously explained.

Several publications (mainly patents) have recently appeared on the formation of polybutadiene in which the *trans*-1,4-structure predominates[86,89–91,125], under the influence of various initiators containing alkoxides or other oxygen-containing compounds of barium and alkyl derivatives of lithium or magnesium, between which exchange reactions undoubtedly occur. Since both lithium compounds and fully substituted barium alkyls are *cis*-regulating initiators for the polymerisation of butadiene, it is highly probable that unsymmetrical barium compounds of the type RBaOR′ are responsible for appearance of the *trans*-1,4-structure[86,87]. Investigation of such unsymmetrical compounds is of considerable general interest, since the possibility of introducing modifying groups directly into an active centre, which opens up wide prospects for controlling its catalytic properties, is evidently the most important fundamental feature of the systems that is absent in the case of univalent gegenions.

****Polymerisation in diethyl ether.

Structural data on polyisoprene (Table 2) give no clear picture owing to their great scatter, at least partly due to the complexity of analysing the structure of this polymer. Alkaline-earth metals vary little in stereospecificity towards the polymerisation of isoprene. Comparison of corresponding metals in Groups I and II definitely reveals considerably higher contents of *cis*-1,4-units for the latter, although, in contrast to the polymerisation of butadiene, none of the alkaline-earth metals reaches the high level of stereospecificity characteristic of lithium compounds.

Influence of electron donors. Increase in the atomic weight of the metal whether in Group I or II produces a regular decrease in the proportion of 1,2-units when butadiene is polymerised in oxolan (Table 1), which is fully consistent with the corresponding decrease in the tendency of the cations to undergo solvation[17,136]. Even in this case, however, heavy alkaline-earth metals (strontium and barium) differ from their neighbours in Group I in a sharp increase in the content of 1,4-units. From solvents of ethereal type only strongly solvating multidentate agents (1,1-dimethylethylene, 3,6,9-trioxaundecane) give on polymerisation with a barium gegenion

the predominance of 1,2-units characteristic of anionic polymerisation[10,32,129]. In the highly polar hexamethylphosphorotriamide all metals in Groups I and II give polymers of almost the same structure. In general the structure of polyisoprene obeys the same laws; in any case there is a clear tendency for a greater proportion of 1,4-units with alkaline-earth metals when polymerisation occurs in oxolan.

The slight tendency of alkaline-earth metal cations to be solvated is well supported by other investigations. Thus in the polymerisation of butadiene with bistetraphenylbutylbarium introduction of oxolan up to a fiftyfold excess with respect to barium has hardly any effect on the structure of the polymer[98]; with larger quantities of oxolan a gradual transition of *cis*- into *trans*-1,4-units begins, but change in the proportion of 1,2-units is observed only when the oxolan content of the solution exceeds 10 vol.%.[32,129] With lithium initiators, on the other hand, a sharp increase in the proportion of 1,2-units has already begun with equimolecular proportions of oxolan and lithium[137], and in the presence of 1 vol.% of oxolan the resulting polymer has almost the same structure as in pure oxolan[17].

Polymerisation by dimetal complexes. Mixed compounds with zinc or aluminium alkyls form butadiene and isoprene polymers in which *trans*-1,4-structures predominate, independently of the nature of the alkaline-earth metal (Tables 1 and 2). Barium–aluminium complexes are distinguished by especially high stereospecificity: with respect to the total content of 1,4-butadiene units they are comparable with the most stereospecific catalysts based on transition metals. Barium–zinc alkyls are comparable with other organobarium initiators according to the overall rate of polymerisation[61,97]. The activity of barium–aluminium initiators is low[61], but the French Michelin firm has recently proposed in a series of patents several methods for enhancing their activity (with hardly any loss of stereospecificity)—by introducing electron donors[138], lithium alkoxides[139], or lithium alkyls[140].

Table 1 clearly reveals considerable structural differences between polybutadienes formed on compounds of alkaline-earth metals and on dimetal complexes, which are especially large with barium; hence the whole of the complex is directly involved in formation of the growing chain. In this respect alkaline-earth metals differ significantly from alkali metals, for which it has definitely been established that the introduction of diethylzinc or triethylaluminium affects only the overall rate of polymerisation, not the structure of the polymers (it is assumed that in this case complexes of the type $LiZnR_3$ or $LiAlR_4$ are inactive, while polymerisation occurs only on the uncomplexed portion of the initiator[2,61,132,141,142]). Thus systems based on alkaline-earth metals are sensitive not only to electron-donor agents but also to electron acceptors. This opens up new possibilities for controlling the stereospecificity of anionic initiators that are unknown for alkali metals.

Processes initiated by metal–zinc alkyls are characterised by an appreciable dependence of polymer structure on initiator concentration. Lowering the concentration of a barium–zinc alkyl from 3–5 m*N* to 0.1 m*N* increases the content of *cis*-1,4-butadiene units from 18–21% to 55–60% with a corresponding decrease in the proportion of *trans*-1,4-units (the 1,2-structure being constant), which is due to dissociation of the complex with separation of the free barium alkyl[61]. On the other hand, the polymerisation of isoprene by means of alkylzinc complexes of calcium, strontium, and barium in benzene (though in a different concentration range, 100–1 mM) exhibited the opposite relation: decrease in initiator concentration was accompanied by transition of *cis*- into *trans*-1,4-units[132].

(b) Acrylic monomers

Considerably less attention has been paid to this group of monomers than to dienes. Tetra-alkyls of zinc with calcium, strontium, and barium cause the formation of crystalline polymers of isotactic structure from iso-, s-, and t-butyl acrylates and methacrylates in toluene or ether[59]. In the polymerisation of methyl methacrylate in toluene, as in that of dienes, the variation in the stereoregulating action differs with metals in Groups I and II: the highest contents of isotactic structure are observed with the lightest alkali metal (lithium, up to 80%[143]) and with the heaviest alkaline-earth metal (barium 71%[120]). In oxolan, polymers having a predominantly syndiotactic structure are formed with all alkaline-earth metals[120].

Polymers of methyl methacrylate obtained by the action of dispersions of alkaline-earth metals in the presence of styrene (which does not enter the polymer chain) are enriched with the isotactic structure compared with those formed from the pure monomer[106]. Thus polymerisation by means of calcium in toluene increases the content of the iso-triad from 42% to 67%. It is assumed[106] that the structure of the polymer obtained in the presence of styrene characterises the actual anionic process, whereas in its absence the polymer is enriched with the syndiotactic structure owing to partial superposition of a radical process (another possible explanation will be given in Section IV).

Table 3. Composition of copolymers and copolymerisation constants r_1, r_2 in the presence of alkaline-earth metals.

3. Copolymerisation

(a) Composition of copolymers

The copolymerisation of butadiene with styrene has been the most intensely studied, since copolymers having a random distribution of monomer units in the polymer chain provide

one of the main forms of high-volume general-purpose synthetic rubbers, and great interest has recently arisen in the search for catalysts ensuring the production of these rubbers under industrial conditions of solution polymerisation[6].

Table 3 shows that in oxolan, as with alkali metals, styrene is a considerably more reactive monomer than is butadiene. In the presence of initiators based on calcium and strontium in a hydrocarbon medium, as with lithium compounds, the copolymers are considerably enriched in butadiene. Yet butadiene–styrene copolymerisation constants are closely similar in most barium systems. It is interesting that this property is maintained in such structurally different compounds as barium alkyls and barium–zinc tetra-alkyls, despite the difference in their stereoregulating action. It is significant that the resulting copolymers contain considerably fewer 1,2-units than in radical polymerisation (10% on BaR_2 and 5% on $BaZnR_4$ compared with 20% in a radical polymer[6]) and are unlike modified lithium systems[144] in not containing microblocks.

Thus barium compounds are the only individual type effecting the formation of butadiene–styrene copolymers having a random distribution of monomer units in the chain with a low content of vinyl groups (sodium initiators also give similar copolymerisation constants, but with a content of vinyl groups exceeding 30% [17]). Depending on the type of initiator, copolymers can be obtained containing predominantly either *cis*-1,4-units (barium alkyls) or *trans*-1,4-units (barium–zinc alkyls or barium–aluminium alkyls with modifying additives). According to information in the patent literature both types of copolymers are suitable as rubbers.

Other copolymerisation systems have been investigated less thoroughly, and differences in behaviour between alkaline-earth and alkali metals are not so substantial (Table 3). Copolymerisation of styrene with methyl methacrylate on an organobarium initiator has confirmed that a homopolymer of the latter monomer is actually formed under homogeneous conditions, although with heterogeneous initiation by dispersions of alkaline-earth metals a certain quantity of styrene enters the copolymer[11,122] (the reasons for this have been discussed in detail above).

Thus in oxolan the relative reactivities of the monomers increase in the sequence

α-methylstyrene ≪ isoprene < butadiene < styrene ≪ methyl methacrylate

characteristic of anionic polymerisation. On calcium and strontium initiators in a hydrocarbon medium the activity varies in the sequence

styrene < isoprene < butadiene

as with lithium. A somewhat different dependence is observed on a barium initiator:

α-methylstyrene ≪ isoprene < butadiene ≅ styrene ≪ methyl methacrylate

(b) Structure of copolymers

It is usually supposed (explicitly or implicitly) that in anionic copolymerisation, as in the radical process, the presence of the second monomer M′ does not affect the addition of the monomer unit M, i.e. that the structure of M units is the same in the copolymer as in the homopolymer obtained under the same conditions. Only recently has it appeared that styrene influences the structure of diene units in copolymers formed by the action of lithium initiators[146,147]. However, the interaction of monomers in anionic processes has been most fully investigated on barium initiators, where it is apparently general in character (for coordination polymerisation involving transition metals this phenomenon was known considerably earlier[148]).

Table 4. Structure of butadiene part of copolymer with styrene obtained by using bis-1,1,4,4-tetraphenylbutylbarium[96,133].

Styrene in copolymer, mole %	Monomer units, %			Styrene in copolymer, mole %	Monomer units, %	
	cis-1,4	*trans*-1,4	1,2		1,2	1,4
	benzene				oxolan	
0	63	25	12	0	22	78
14	62	27	11	16	26	74
20	57	29	14	34	49	51
25	52	34	14	47	45	55
37	50	40	10	66	51	49
45	36	54	10	84	51	49
69	34	54	12	93	61	39

In the copolymerisation of butadiene with styrene by means of bistetraphenylbutylbarium in benzene (Table 4) increase in the styrene content of the copolymer is accompanied by a gradual conversion of *cis*- into *trans*-1,4-units while the content of 1,2-units remains unchanged (a high content of the *cis*-1,4-structure is maintained in the composition range of practical interest for the production of rubbers, i.e. at styrene contents up to 15 mole %). In oxolan the introduction of styrene produces a sharp increase in the content of 1,2-units (Table 4). Similarly, increase in the content of butadiene in its copolymer with isoprene (polymerisation in benzene) is accompanied by increase in the content of *trans*-1,4-units (up to 43% at a butadiene content of 69 mole %) with a corresponding decrease in the proportion of *cis*-1,4-units, the structure of the butadiene portion changing little[133]. Thus according to their influence on the structure of the diene units these monomers can be arranged in the sequence isoprene < butadiene < styrene, in which each successive member affects the structure of the preceding member, bringing it closer to that characteristic of systems with alkali metals[133].

Discussion of possible reasons for this phenomenon[32,133] shows that solvation of the gegenion by the second monomer M′ plays no decisive part. It is supposed that the main factor in copolymerisation in benzene is the decrease, with increased polarity of the bond with the terminal monomer unit in the above sequence, in the ability of the gegenion to *cis*-orient the monomer unit that is added on. (It is noteworthy that, in copolymerisation by means of a *trans*-orienting organobarium–zinc initiator, the structure of the butadiene units corresponds to that of the homopolymer throughout the composition range[145].) Thus in this process entry of M′ into the chain apparently changes the structure of the following M unit. When copolymerisation occurs in oxolan, introduction of M′ probably changes the structure of the preceding M unit (styrene adds with equal probability to α- and γ-carbon atoms of a terminal allyl unit, whereas butadiene adds predominantly to the α-atom[133]).

Thus the main features of alkaline-earth metals are higher coordinating power, lower sensitivity to electron donors, sensitivity to organometallic electron-accepting complexing agents, and the possibility of introducing modifying groups directly into the gegenion. The last two factors extend significantly the possibilities for controlling the catalytic

activity of these compounds, in definite measure assimilating them to systems based on transition metals. It is sufficient to state that barium initiators represent the first (and only) case in anionic polymerisation in which it is possible to obtain on the same metal butadiene polymers in which any of the possible structures predominates—*cis*-1,4 (BaR_2 in a hydrocarbon medium), *trans*-1,4- (barium–aluminium or barium alkoxide systems), or 1,2-structures (BaR_2 in the presence of 1,1-dimethylethylene or hexamethylphosphorotriamide).

In regard to immediate prospects for practical application a leading position is occupied without doubt by organobarium initiators for the copolymerisation of butadiene with styrene. There are grounds for supposing that, with respect both to the properties of the resulting rubbers and to the general characteristics of the industrial process, barium initiators are fully compatible with lithium initiators, while still inferior to them in economy and simplicity of production.

According to the Phillips Petroleum Col. partly crystalline *trans*-1,4-polybutadiene formed by means of barium alkoxide initiators is also an interesting material with valuable new technical properties[149].

IV. KINETICS AND MECHANISM OF POLYMERISATION IN SYSTEMS WITH BIVALENT GEGENIONS

1. Structure of Active Centres—Physicochemical Investigations

A most characteristic feature of anionic polymerisation is the existence of active centres in diverse forms—molecules having a polarised bond, their association complexes, ion-pairs varying in degree of solvation, free ions, ion-triplets, etc.—differing in their reactivity and stereospecificity[17-19]. (As a distinction from free ions the remaining forms of active centres are sometimes described in general as "combined with a gegenion".) This is fully applicable also to alkaline-earth metals, with which, however, certain complications in terminology arise (thus an electrically neutral species of type (R^-, M^{2+}, R^-) must obviously be termed an ion-pair, although it contains three ions, while the charged species (R_3^{3-}, M^{2+}) is a triplet, etc.). Furthermore, novel forms of active centres appear, that are non-existent or not specially significant in processes with alkali metals.

We must first note the peculiar structure of live polymers having carbanions at both ends of the macromolecule. Early papers on the preparation of a double-ended initiator, bis-tetraphenylbutylbarium[10,26], had already mentioned that from stoichiometric considerations this compound could not exist in a linear monomeric form. Subsequent investigation by various physicochemical methods of this initiator and the double-ended live polymers of styrene and butadiene formed in its presence showed[31,32] that in electron-donor solvents (oxoland, dimethyl ether) these compounds form macrocyclic aggregates, whose presence is responsible for several anomalies in the properties of the systems and also several peculiarities in the polymerisation processes occurring in them. In particular the electrical conductivity of the systems is significantly smaller than that of their single-ended analogues, since the primary dissociation products of macrocycles are non-conducting zwitterions, while the variation of the conductivity with concentration does not correspond to Ostwald's dilution law for weak electrolytes.

It is important to emphasise that, in contrast to other cases of the association of active centres (e.g. lithium compounds in a hydrocarbon medium), in which entry into the association complex changes significantly the character of the metal–carbon bond, in the present case the union of several species to form a single aggregate produces no appreciable change in the nature of the individual active centres in comparison with their single-ended analogues. Formation of similar cyclic aggregates has been established also for products of the action of magnesium on 2-vinylpyridine[150] and on isoprene in oxolan[118]. The latter work has confirmed the previously observed[31,32] decrease in number of fragments in the ring with increase in the length and hence flexibility of individual fragments.

A novel form of active centres, not present in alkali-metal systems, is provided also by "unsymmetrical" ion-pairs, i.e. species of the type (R^-, M^{2+}, R^{2-}), which play an important part in several processes, but as yet have hardly been studied by physicochemical methods.

Table 5. Wavelengths λ_{max} (nm) in absorption spectra of model compounds $R.C(C_6H_5)_2^-M^+$.

Barium	—	448	[33]

*Below −60 °C.
**Diphenylmethylmagnesium bromide in diethyl ether.

One of the main factors determining the reactivity and the stereospecificity of active centres is the degree of polarisation of the bond between the growing end of the chain and the gegenion. If is often estimated from the electronic absorption spectra of model compounds containing carbanions of the 1,1-diphenylalkyl type[17,151,152]. Spectral data (Table 5) together with results on the structure of butadiene polymers (Table 1) show that the correlation between λ_{max} and the character of polymerisation (the shorter the wavelength λ_{max}, i.e. the less polar the bond, the greater the proportion of the coordination process leading in particular to increase in the content of 1,4-diene structures), established for alkali-metals[17,136], is maintained for alkaline-earth metals.

According to the λ_{max} wavelength in oxolan the polarity of the metal–carbon bond in the series of alkaline-earth metals (apart from magnesium, which is inactive in polymerisation), as in the series of alkali metals[17,136], decreases as the ionic radius increases, with a corresponding diminution in the proportion of 1,2-units in the butadiene polymers, which is well explained by the weakening role of solvation effects in the same sequence. For a 1,1-diphenylalkylbarium in oxolan λ_{max} lies ar appreciably shorter wavelengths compared not only with other compounds in the same solvent but even with the diphenylalkylsodium in benzene. Hence a polybutadiene obtained by the action of barium compounds in oxolan contains more 1,4-units than do polymers obtained with alkali metals (other than lithium) in a hydrocarbon medium. This indicates unusually low polarity of the bond in a barium active centre.

In a hydrocarbon medium alkali and alkaline-earth metals show opposite variations: whereas among the alkali metals the polarity of the metal–carbon bond increases with the ionic radius of the metal, the polarity diminishes on passing from calcium to barium (the λ_{max} given in Table 5 for a 1,1-diphenylalkylstrontium in benzene may be too high[154] owing to incomplete removal of the oxolan used in the preparation). A possible explanation of such divergence is the early view[17] that the polarity of a metal–carbon bond (in a given carbanion) should increase with decrease in the electron-accepting properties of the metal. Calculation showed[156] that the electron affinity (a measure of electron-accepting properties) falls with increase in atomic number in the series of alkali metals, but increases in the alkaline-earth metals, owing to the difference in type of hybridisation of the lowest vacant orbitals—*s* in alkali metals and *sd* in alkaline-earth metals.

Table 6. Conductivity data for systems containing alkaline-earth metals in oxolan.

Barium	20	$1.65\cdot10^{-5}$	[159]
	triphenylmethyl		
Sodium	25	$7.6\cdot10^{-6}$	[160]
Barium	25	$3.6\cdot10^{-7}$	[31]
	benzyl (styryl)		
Sodium	25	$1.5\cdot10^{-7}$	[18]
Caesium	25	$2.8\cdot10^{-9}$	[18]
Barium	20	$1.1\cdot10^{-10}$	[159]
Barium	25	$4.1\cdot10^{-11}$	[161]

Valuable information on the state of active centres in solvating media is given also by conductivity measurements (Table 6). In ethereal solvents (oxolan, dimethyl ether) barium compounds at concentrations up to 10 μM undergo only the first stage of dissociation[31,32,69], without formation of free Ba^{2+} ions (the values of K_{diss} in Table 6 relate to this stage):

$$BaR_2 \overset{K_{diss}}{\rightleftarrows} [BaR]^+ + R^- \quad . \qquad (1)$$

Compounds containing a barium–carbon bond have considerably lower conductivities than those of alkali metals, in particular for the caesium analogue of the barium compound. This also indicates the low polarity of this bond.

2. Principal Kinetic Laws

The few kinetic investigations have already covered a fairly wide range of polymerisation systems. In most cases initiation stages are rapid, and termination reactions are absent. It is therefore supposed that, where not specially stipulated, the measured rate of polymerisation is the rate of chain growth, as in most research with alkali metals. Published kinetic data are summarised in Table 7.

First order of chain growth with respect to the monomer has been established in all cases without exception. Since the order of reaction with respect to the initiator differs in different systems, the reaction velocity is usually characterised by the experimental first-order rate constant

$$k' = -\frac{1}{M}\cdot\frac{dM}{dt},$$

where M is the concentration of the monomer. The growth constant k_{gr} cited in several papers is calculated: $k_{gr} = k'/c_0$, where c_0 is the concentration of growing chains. This constant acquires real meaning only when chain growth is first order with respect to active centres.

Table 7. Kinetic characteristics of chain growth in polymerisation by using compounds of alkaline-earth metals (not indicated over the concentration range of active centres c_0 = 1–10 mM).

*Difunctional initiator.

(a) Electron-donor media

Styrene. The most peculiar behaviour has been revealed in the polymerisation of styrene in oxolan. The most important feature is the existence of completely different kinetics for barium initiators of three different types.

The first type—a single-ended initiator with rapid initiation (dibenzylbarium)—has been studied simultaneously by two groups of investigators[69,159,161], who have obtained almost identical results. The measured rate of polymerisation (and hence the rate of chain growth) is independent of the concentration of active centres, so that the usual calculated quantity k_{gr} increases with dilution in inverse proportion to the initiator concentration. Such an unusual law could be explained[69,161] on the principal (established earlier for alkali metals[18]) that free carbanions play a decisive part in the anionic polymerisation of styrene, by introducing the hypothetical formation of more complicated species, "ion-triplets", by coordination of an additional styryl carbanion with the barium cation, which though weakly solvated has a

strong electrostatic field:

$$R^- + BaR_2 \overset{K_{tr}}{\rightleftarrows} [BaR_3]^- \quad (2)$$

On the postulates that equilibrium (2) is displaced to the right and that the total concentration of charged species is small (as follows from the low conductivity of the system—Table 6) calculation by means of Eqns.(1) and (2) yields the kinetic formula

$$k' = -\frac{1}{M}\cdot\frac{dM}{dt} = k_-\cdot c_- = k_-(K_{diss}/K_{tr})^{1/2} \quad (3)$$

consistent with experimental results (k_- is the growth rate constant on free anions and c_- the concentration of free styryl anions).

With the same postulates the suggested scheme predicts that the equivalent conductance of the system shall be independent of c_0. Such behaviour, which is also unusual for solutions of weak electrolytes and is due to the "asymmetry" of formation of the ion-triplets (as stated above, only the negative triplet of type BaR_3^- is formed, not the positive $Ba_2R_3^+$), has been confirmed experimentally for live barium–polystyrene[69] and for dibenzylbarium[161]). The combination of kinetic and conductivity data has permitted calculation of the dissociation constant K_{diss} (Table 6), which from the above discussion evidently cannot be obtained directly from conductivity measurements. (Ion-triplets are not formed in compounds of barium with branched carbanions such as di- and tri-phenylmethane, and the conductivity depends on the concentration[31].)

Recent preliminary reports indicate (Table 7) that this scheme is followed also by the polymerisation of styrene in oxolan under the influence of corresponding calcium and strontium initiators. The overall rate of polymerisation increases from barium through strontium to calcium (apparently owing to the accompanying increase in the dissociation constant K_{diss} and hence in the concentration of free ions[166]). This recalls the situation presented by the alkali metals, when the increase in rate of polymerisation of styrene accompanying each passage from a lower to a higher member is associated with successive increase in K_{diss}, not with change in reactivity of individual species[18].

An initiator of the second type—double-ended with rapid initiation—was historically the first organobarium subject (a barium salt of an oligomeric dianion of α-methylstyrene) of kinetic investigation[167]. Zero order with respect to the initiator was observed for the first time[167], but this was given an untenable explanation (formation of inactive association complexes of active centres), which has subsequently been criticised[69,70,150,161]. Only after the above results had been obtained for the simpler system with dibenzylbarium did it become clear that the zero order with respect to active centres has the same causes here as in the preceding case, i.e. formation of ion-triplets with free ions is kinetically decisive, and views developed subsequently by various authors[70,162] have in the main shown mutual agreement.

The most significant kinetic feature of the polymerisation of styrene with double-ended initiators, which is directly connected with the above formation of macrocyclic aggregates, is that the observed growth constant increases with length of the polymer chain, with consequent autocatalysis despite rapid completion of the initiation stage[10,161,163,168]. Thus at 20 °C the constant k' (in 10^{-3} s^{-1}) increases from 0.25 to 2.0 as the degree of polymerisation rises from 50 to 800.[162] During the polymerisation of styrene (and also of butadiene) in the presence of bistetraphenylbutylbarium the conductivity of the system increases steadily[31,32], which agrees well with the theoretically predicted increase in the constant for the dissociation of cyclic ion-pairs into free ions as the ring becomes larger[18,169]. In conformity with Eqn.(3) increase in K_{diss} leads to increase in the overall rate of polymerisation of styrene.

Only the number of growing chains in the macroring remains obscure. Viscosimetric data[31,32] show that a ring contains 5–7 polystyrene chains halfway through the process, and 3–4 chains at the end. On the other hand, closure of an intramolecular ring from one chain has been assumed, although a fall in viscosity on deactivation was also observed[162], corresponding to a mean degree of association of 1.5–4 (closure of a monomolecular ring should have led to an increase in viscosity). Apparently the most serious (and only) argument in support of a monomolecular ring is the same workers' observation[170] of non-random spontaneous deactivation of solutions of oligomeric styrylbarium dianions in oxolan on reaction with the solvent. Deactivation of one live end caused rapid deactivation of the other, which could be explained only if the two ends were attached to the same gegenion. We remark merely that actual formation of macrorings is sufficient, independently of their size, for the above interpretation of the dependence of rate of growth on chain length.

Finally, a third, completely different type of behaviour is observed on using the relatively inactive (single-ended) initiator bistriphenylmethylbarium[70,163], when the process is autocatalytic, as is usual for reactions having a slow initiation stage. The rate of chain growth (for a given concentration of growing chains) is less than one-tenth of the rate with dibenzylbarium (Table 7) and, most significantly, depends on the concentration of active centres. The non-zero reaction order is qualitatively evident from the very fact that the rate increases with number of growing chains. Mathematical treatment by several methods[70,163] has established that chain growth is first order with respect to active centres.

It is still more surprising that the resulting polymers have comparatively low molecular weight ($\bar{M}_n \cong 10000$ at 30 °C), lower by factors of 20–40 and more than the calculated value, and an extremely wide molecular-weight distribution ($\bar{M}_w/\bar{M}_n \cong 2$, whereas with live polymers slow initiation is able to raise this ratio to at most 1.3–1.4 [16]). Detailed analysis of the results indicated the occurrence of chain transfer to the monomer (probably by transfer of a hydride ion)[163]. This is perhaps the most unexpected fact, since hitherto the anionic polymerisation of styrene has been regarded as the most typical example of the formation of live polymers.

The distinguishing behavioural features of this system can be understood on the basis that, owing to the extremely low rate of initiation ($k_{in} = 2.2\times10^{-6}$ M^{-1} s^{-1} at 30 °C), most of the active centres have the structure of the unsymmetrical ion-pair ($C_6H_5.CH:CH-Ba-C(C_6H_5)_3$: i.e. they contain a triphenylmethyl group attached to the gegenion. Such active centres will dissociate preferentially at the considerably more polar $(C_6H_5)_3C-Ba$ bond (Table 6): dissociation at the $C_6H_5.CH:CH-Ba$ bond is suppressed by the presence of $[(C_6H_5)_3C-Ba]^+$ cations formed by dissociation of unchanged initiator $[(C_6H_5)_3C]_2Ba$, a strong electrolyte. As a consequence the content of $C_6H_5.CH:CH^-$ ions is much lower than in the previous cases, and the contribution by ion-pairs becomes predominant, which well explains both the general decrease in rate of chain growth and the appearance of first order with respect to active centres. Addition of styrene to a bulky active centre containing four phenyl groups around a cation apparently meets considerable difficulties, which greatly increase the probability of chain transfer but also influence significantly copolymerisation processes (for greater detail see below).

Thus in the polymerisation of styrene on barium initiators in oxolan the nature of the hydrocarbon moiety of the initiator has a significant influence on fundamental aspects of chain growth and on the nature of the resulting polymers.

Other monomers. The polymerisation of butadiene in oxolan under the influence of dibenzylbarium[161] and of dibenzylstrontium[164] is first order with respect to the initiator. Hence, as with alkali metals[171], the decisive role in steps of chain growth belongs not to free ions but to forms of active centres "combined with a gegenion". Together with the above data on the structure of the polymers and the spectra of model compounds this led to the conclusion that the active centres of chain growth in the polymerisation of butadiene by means of barium[161] and probably strontium[164] are molecules having a polarised metal–carbon bond. Live polymers of butadiene, formed under the influence of double-ended bistetraphenylbutylbarium, exhibit the same peculiarities of conductivity and viscosity behaviour, associated with the formation of macrocyclic aggregates, as do styrene systems[31]. Since free ions have no decisive role in the polymerisation of butadiene, it is clear that variation in the dissociation constant does not affect the kinetics[161]. When polymerisation occurs under the influence of bistriphenylmethylbarium an induction period is observed, as in the case of styrene, that is due to slow initiation ($k_{in} = 1.1 \times 10^{-5}$ M^{-1} s^{-1} at 30 °C)[163]. Chain growth is first order with respect to active centres, with growth constants closely similar to those obtained with dibenzylbarium (Table 7). Hence butadiene adds at about the same rate to the two types of active centres—"symmetrical" ($CH_2:CH.CH:CH-Ba-CH:CH.CH:CH_2$) and "unsymmetrical" [$CH_2:CH.CH:CH-Ba-C(C_6H_5)_3$].

Comparison of published data shows that the rate of polymerisation of butadiene in oxolan is greatest with barium, the highest alkaline-earth metal[161]; the process is slower with strontium[164], and perhaps still slower with calcium[95]. This corresponds with the variation found with alkali metals[126], but the overall rates are considerably lower than with the latter.

A pattern similar to that with butadiene is observed[165] in the polymerisation of methyl methacrylate in oxolan by means of a barium compound at −70 °C (under these conditions a live polymer is formed; at higher temperatures intramolecular chain termination takes place with involvement of ether side-groups). The reaction is first order with respect to the initiator on both single- and double-ended initiators (difluorenyl- and bistetraphenylbutyl-barium), and occurs at the same rate. Hence, as in the polymerisation of butadiene, it takes place on "combined with a gegenion" active centres (in the present case on ion-pairs[165]).

A more complicated dependence is obtained in the polymerisation of 2-vinylpyridine under the influence of a double-ended magnesium initiator[150]. The concentration dependence of the observed chain-growth constant is described by an equation of the type $k_{gr} = a + bc_0^{-1}$ (or $k' = ac_0 + b$). The same scheme is adopted as for the polymerisation of styrene with dibenzylbarium (allowing for the formation of ion-triplets), but in this case not only free ions but other species (ion-pairs or -triplets) take part in chain growth, their contribution to the total rate of polymerisation being proportional to the initiator concentration. Viscosimetric data indicate the formation of macrocyclic aggregates in the double-ended system, but polymerisation occurs[150] without autocatalysis. Unfortunately the kinetics of polymerisation with a single-ended initiator was not examined[150].

It is interesting that, when a relatively inactive initiator (dibenzylmagnesium) is used, spectral and viscosimetric data indicate formation of unsymmetrical active centres of type $NC_5H_4.CH:CH.Mg.CH_2.C_6H_5$, which differ in properties from $NC_5H_4.CH:CH.Mg.CH:CH.C_5H_4N$ centres[150].

(b) Hydrocarbon medium

The kinetics of the polymerisation of butadiene and styrene in benzene have been investigated[97] in the presence of bis-1,1,3-triphenylpropylbarium, which had been obtained in oxolan and then distilled with chromatographic control of completeness of removal. The order of chain growth with respect to the initiator concentration in the polymerisation of butadiene is close to one-third, which indicates the association of active centres usual in anionic polymerisation in hydrocarbon media, in this case formation of trimeric complexes. The polymerisation of styrene, on the other hand, is first order with respect to the initiator, and hence polystyrylbarium active centres are unassociated even in benzene. Association of polybutadienylbarium active centres and non-association of polystyrylbarium have been confirmed by viscosimetric data[97]. In the polymerisation of butadiene in benzene by means of double-ended bistetraphenylbutylbarium, when association should lead to the formation of a kind of three-dimensional network, "gelation" of the solution was already observed at low degrees of conversion of the monomer, but the solution again became mobile on deactivation[129].

According to the above results styrene is polymerised more rapidly than butadiene by barium compounds in benzene. In the presence of a mixed calcium initiator $R_2Ca-RCaI$, on the other hand, rates of homopolymerisation correspond to the sequence butadiene > isoprene > styrene[95] (the rates of polymerisation of both butadiene and styrene were lower here than with a barium initiator). The activation energy of the polymerisation of butadiene by means of this initiator is 87 kJ $mole^{-1}$.[8]

Overall rates of polymerisation of butadiene and styrene by means of barium compounds in benzene are closely similar to rates observed with lithium initiators[172]. Since, however, both polystyryl- and probably also polybutadienyl-lithium active centres are considerably more strongly associated than are barium centres, the relatively high rate of polymerisation on barium initiators is clearly due to a greater effective concentration of active centres, not to their reactivity.

One of the most characteristic features of anionic polymerisation with alkali metals is the sharp increase in its overall rate on passing from hydrocarbon to electron-donor solvents. With barium initiators, however, Table 7 shows that over the usual concentration range (10–1 mN) transfer from benzene to oxolan produces no appreciable increase in total rate of polymerisation. Since in the polymerisation of butadiene in benzene chain growth involves only a small fraction of unassociated active centres, whereas polymerisation of styrene in oxolan occurs predominantly on free ions with an insignificant contribution by ion-pairs, it is obvious that the reactivity of "combined with a gegenion" forms of polybutadienyl- and polystyryl-barium active centres is higher in benzene than in oxolan[97]. In the polymerisation of styrene under the influence of "butylcalcium iodide"[95], on the other hand, transfer from benzene to oxolan causes a sharp increase in total rate (by several orders of magnitude), as with alkali metals.

3. Mechanism of Copolymerisation

The influence of the hydrocarbon part of the initiator on the character of the processes initiated, which is specific to

alkaline-earth metals and has been reported in the preceding subsection, is just as clearly evident in copolymerisation. The main features of the copolymerisation of butadiene with styrene by means of bistriphenylmethylbarium in oxolan differ significantly[173] from those of copolymerisation initiated by other barium compounds (Section III). Whereas with dibenzylbarium styrene is considerably more active than butadiene (Table 3), in the presence of the former initiator the activities of the monomers level out ($r_1 = r_2 = 1.0$).

Estimation of the rates of indibidual primary steps (by comparing copolymerisation constants with homopolymerisation rate constants of the same monomers) showed that in the presence of bistriphenylmethylbarium the rates of both styrene-addition steps (to its own and to a butadiene active centre) fall by more than 90%, whereas the rates of addition of butadiene to both growing chains remain almost unchanged[173] (this work[173] was done before it became clear that transfer from one initiator to another causes a complete change in the mechanism of individual primary steps; this result can therefore be regarded merely as a qualitative indication of an appreciable decrease in reactivity of styrene as a consequence of the presence of a triphenylmethyl group in the active centre). Such presence influences also the structure of the copolymers[173]. Whereas in copolymerisation by means of "ordinary" barium initiators increase in the styrene content is accompanied by enrichment of the butadiene part with 1,2-units (Table 6), in the presence of bistriphenylmethylbarium introduction of up to 60% of styrene into the copolymer does not affect the structure of the butadiene units. (All the above applies to copolymers obtained in the initial stages: with high conversions, when "symmetrical" active centres begin to appear, a non-uniform copolymer is formed, enriched with styrene and 1,2-butadiene units[173].)

Effects due to interaction of groups in an active centre may obviously be still more widely evident in copolymerisation than in homopolymerisation, since growing chains with different kinds of terminal units can here act as "perturbing" groups. Interpretation of the results is, of course, considerably complicated thereby, but a broad field is opened up for research. Thus investigation of the influence of styrene on the structure of butadiene units in copolymers formed under the influence of barium compounds has revealed[32,96,133] that calculations based on simple models regarding growing chains as isolated will not give a quantitative description of the results. Thus the structure of the resulting monomer unit obviously depends not only on the structure of "its" growing chain but also on the nature of the terminal unit of the adjacent chain combined with the same gegenion.

Results obtained[106] on the structure of poly(methyl methacrylate) formed in the presence of styrene are relevant here. The explanation given (a competing radical process) is open to doubt (Section III). An alternative explanation of this effect may be that, as mentioned earlier, styrene is preferentially involved in initiation when a mixture with methyl methacrylate is in contact with a heterogeneous initiator[18,123], so that subsequent polymerisation of the methacrylate takes place on "unsymmetrical" centres of the type $C_6H_5.CH:CH-Ca-CH:C(CH_3).COOCH_3$.

Such effects due to interaction between two different groups attached to the same gegenion undoubtedly play an important part in homo- and co-polymerisation initiated by compounds of alkaline-earth metals (as also in the chemistry of these compounds in general). Unfortunately the almost complete absence of quantitative experimental data does not permit even qualitative prediction of the direction of this influence. As yet only the single observation can be cited[159] that the dissociation constant of the unsymmetrical styrene–phenylborate salt $C_6H_5.CH:CH.Ba.B(C_6H_5)_4 \rightleftharpoons [C_6H_5.CH:CH.Ba]^+ + B(C_6H_5)_4^-$ in oxolan is roughly double that of symmetrical barium tetraphenylborate. Thus in this case introduction of a less polar group (styryl) causes additional polarisation of the bond with the more polar group.

---o0o---

The results discussed above confirm the validity and usefulness of many fundamental principles of the theory of anionic polymerisation developed for alkali metals, but also reveal several fundamentally novel forms of behaviour not observed previously. The behavioural features of alkaline-earth metals can be divided (more or less arbitrarily) into two groups. Such phenomena as the presence of unsymmetrical active centres or the formation of live macrorings in double-ended systems are due to the actual bivalency of the gegenion; they should, of course, occur to some extent in processes with all Group II metals. Other phenomena—e.g. low polarity of the metal–carbon bond, enhanced coordinating power in the polymerisation of butadiene, low sensitivity to electron donors, less tendency to association in a hydrocarbon medium, etc.—are connected mainly with the specific electronic structure of actual gegenions, and are usually most strongly developed with the heavier metals (barium and strontium).

Discovery and investigation of all these novel phenomena will both broaden significantly our general theoretical ideas on anionic polymerisation and open up new prospects for their practical application. Although possible uses of alkaline-earth metals in polymerisation are more or less determined (conclusion to Section III), at least for the immediate future, theoretical aspects of this field are only beginning to be worked out. There is every reason to expect that further research will not only prove fruitful in developing the new field—polymerisation by means of alkaline-earth metals—but will also help to shed new light on many phenomena in the "old" field (polymerisation on alkali metals), as has already been observed more than once in the theory of anionic polymerisation, with expansion of the range of materials investigated.

Electron Transfer in Photochemical Reactions

A.K.Chibisov

Modern ideas concerning the mechanism of electron transfer in photochemical reactions in solution are discussed. The quenching of the excited state via the electron transfer mechanism, the intermediate states and the role of the medium in the formation of radical-ions, the reactivity of excited states in the electron transfer reaction, and the energetics of this reaction are examined.
The bibliography includes 203 references.

I. INTRODUCTION

Among different types of photochemical reactions, the electron transfer process is one of the most common. Electron transfer processes constitute the basis of many reactions in organic photochemistry (for example, heterolytic substitution reactions[1-4]) and the photochemistry of coordination compounds[5-8], the photochemical methods for recording information[9,10] and in the first place spectral sensitisation in photography[11-14], the photodegradation of dyes[15], and many photobiological processes, for example, photosynthesis[16,17]. Photochemical oxidation-reduction reactions with participation of aromatic, carbonyl, and heterocyclic compounds[4,18], dyes of different classes[15,19-21], pigments[22-25], and coordination compounds[5-8], and inorganic ions[26-28] are widely investigated.

Definite advances, due primarily to progress in the development of experimental technique, have been achieved in recent years in this field of photochemical reactions. The application of nano- and pico-second lasers made it possible to investigate in detail the mechanism of electron transfer and the properties of the intermediates of oxidation-reduction photoreactions. Numerous studies, whose aim was to establish a correlation between the efficiency of the electron transfer and the properties of the reacting molecules and also studies devoted to the investigation of the energetics and kinetics of the electron transfer reaction, the elucidation of the role of the medium, etc. have been published recently.

This review deals with the current ideas about the mechanisms of electron transfer in photochemical reactions in solutions. Modern views on the mechanism of oxidation-reduction photoreactions are to some extent based on the

available theories of electron transfer[29-32] and also on the characteristic features of the behaviour of excited molecules.

II. ENERGETICS OF THE ELECTRON TRANSFER REACTION

Photochemical reactions (including electron transfer reactions) begin with the absorption of light by the molecular system, which leads to the formation of electronically excited states. The properties of molecules in the excited state can differ from their properties in the ground (unexcited) state, which is manifested by changes in the dipole moment, polarisability, and geometry of the molecules, by changes in the position of the acid–basic equilibrium, and also by changes in the ionisation potential, electron affinities, etc.[1,4,21,25,33-37].

The free energy ΔG of an electron transfer reaction in the gas phase between donor (D) and acceptor (A) molecules is defined fairly accurately by the relation

$$\Delta G = I_D - E_A, \qquad (1)$$

where I_D is the ionisation potential of the donor and E_A the electron affinity of the acceptor.

On photoexcitation, the ionisation potential I_D diminishes by the excitation energy of the donor $E(^{1,3}D^*)$†, while the electron affinity E_A increases by the excitation energy of the acceptor $E(^{1,3}A^*)$.[33] Thus the free energy ΔG of the photochemical electron transfer, for example between $^{1,3}A^*$ and D, namely

$$^{1,3}A^* + D \rightarrow A^{\bar{}} + D^{\ddagger}, \qquad (I)$$

is defined by the relation

$$\Delta G = I_D - [E_A + E(^{1,3}A^*)]. \qquad (2)$$

If the photoreaction takes place between electrically neutral molecules, the electron transfer results in the formation of the radical-ion pair $A^{\bar{}}D^{\ddagger}$ stabilised by the Coulombic interaction:

$$^{1,3}A^* + D \rightarrow A^{\bar{}}D^{\ddagger}. \qquad (II)$$

In this case the free energy change is

$$\Delta G = I_D - [E_A + E(^{1,3}A^*)] - e^2/R, \qquad (3)$$

where e is the electronic charge and R the distance between the centres of the molecules A and D. Electron transfer in reactions (I) and (II) becomes possible when $\Delta G < 0$.

When the energetics of a photoreaction in solution is considered, one must take into account the energy of the transfer of the molecules $^{1,3}A^*(^{1,3}D^*)$ and A(D), the radical-ion pair $A^{\bar{}}D^{\ddagger}$, and the radical-ions $A^{\bar{}}$ and $D^{\ddagger}$ from the gas to the condensed phase. The energy of the transfer (solvation) of ions (radical-ions) from a vacuum into a medium with a dielectric constant ε is given by the following expression according to Born:

$$\Delta G(A^{\bar{}}) + \Delta G(D^{\ddagger}) = -\frac{e^2}{2}\left(\frac{1}{R_{A^{\bar{}}}} + \frac{1}{R_{D^{\ddagger}}}\right)\left(1 - \frac{1}{\varepsilon}\right), \qquad (4)$$

where $R_{A^{\bar{}}}$ and $R_{D^{\ddagger}}$ are the radii of the radical-ions $A^{\bar{}}$ and $D^{\ddagger}$ respectively. Consequently the free energy of the photochemical electron transfer reaction in solution, leading to the formation of solvated radical-ions as the final products [reaction analogous to reaction (I)] is

$$\Delta G = I_D - [E_A + E(^{1,3}A^*)] - \frac{e^2}{2}\left(\frac{1}{R_{A^{\bar{}}}} + \frac{1}{R_{D^{\ddagger}}}\right)\left(1 - \frac{1}{\varepsilon}\right). \qquad (5)$$

†The superscript 1,3 denotes the multiplicity of the state (singlet, triplet).

The energy of the transfer of an ion (radical-ion) pair, having an effective radius r and a dipole moment μ, from a vacuum into a medium with a dielectric constant ε is given by the following expression according to Kirkwood[38]:

$$\Delta G(A^{\bar{}}D^{+}) \simeq -\frac{\mu^2}{r^3}\left(\frac{\varepsilon - 1}{2\varepsilon + 1}\right). \qquad (6)$$

If the photochemical electron transfer involves the formation of a solvated radical-ion pair (exciplex) as the final product, then the free energy of the reaction, analogous to reaction (II), is

$$\Delta G = I_D - [E_A + E(^{1,3}A^*)] - \frac{e^2}{R} - \frac{\mu^2}{r^3}\left(\frac{\varepsilon - 1}{2\varepsilon + 1}\right). \qquad (7)$$

For the electron transfer reaction in solution, it is convenient to replace the values of I_D and E_A known for the gas phase by the half-wave potentials for the polarographic reduction of the donor $E_{1/2}(D/D^+)$ and the polarographic reduction of the acceptor $E_{1/2}(A^-/A)$:[39-42]

$$I_D = E_{1/2}(D/D^+) - \Delta G(D^+) + \text{const}, \qquad (8)$$

$$E_A = E_{1/2}(A^-/A^+) + \Delta G(A^-) + \text{const}. \qquad (9)$$

The half-wave potentials are known for many aromatic hydrocarbons[43-48], inorganic compounds[49-52], dyes[53,54], and pigments[25]. The free energy of electron transfer in the photochemical reaction analogous to reaction (I), formulated in terms of the $E_{1/2}$ potentials, is

$$\Delta G = E_{1/2}(D/D^+) - [E_{1/2}(A^-/A) + E(^{1,3}A^*)], \qquad (10)$$

and for a photochemical electron transfer reaction analogous to reaction (II) the free energy is

$$\Delta G = E_{1/2}(D/D^+) - [E_{1/2}(A^-/A) + E(^{1,3}A)] + \frac{e^2}{2}\left(1 - \frac{1}{\varepsilon}\right)\left(\frac{1}{R_{D^{\ddagger}}} + \frac{1}{R_{A^{\bar{}}}}\right) - \frac{e^2}{R} - \frac{\mu^2}{r^3}\left(\frac{\varepsilon - 1}{2\varepsilon + 1}\right). \qquad (11)$$

The electrochemical potentials of the molecules in the ground, excited singlet, and excited triplet states.

Note. The numbers in square brackets denote references (Ed.of Translation).

In particular, it follows from Eqn.(10) that the polarographic reduction potential increases (the polarographic oxidation potential decreases) by the electronic excitation energy.

The Table lists the values of $E_{1/2}$ and $E(^{1,3}A^*, ^{1,3}D^*)$ for a series of compounds. Thus the condition for reaction (I) in solution is the inequality

$$E_{1/2}(D/D^+) - E_{1/2}(A^-/A) - E(^{1,3}A^*) < 0. \quad (12)$$

The above relation is convenient for assessing the possibility of the electron transfer reaction in a specific system $^{1,3}A^*$–D.

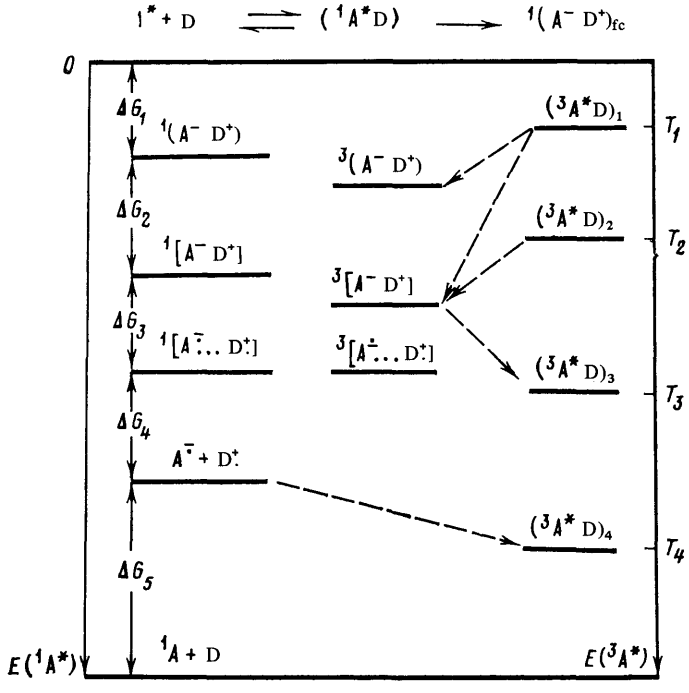

Figure 1. The energy scheme for electron transfer in a photochemical reaction between an acceptor A* and a donor D (for explanation, see text).

The efficiency of the formation of the final products of the electron transfer reaction is determined mainly by the energetics of the intermediate stages. Fig.1 presents a generalised energy scheme for electron transfer between the molecules of the acceptor $^{1,3}A^*$ and the donor D#. The electron transfer process involving the formation of solvated radical-ions includes the following sequence of stages.

1. The formation of a collision complex $^1A^*D$ between the excited singlet molecule $^1A^*$ and the molecule D in the ground state as a result of diffusional collisions between $^1A^*$ and D:

$$^1A^* + D \rightleftharpoons (^1A^*D). \quad (III)$$

Reaction (III) competes with the intersystem crossing into the triplet state $^3A^*$ and also with fluorescence and internal conversion processes. The free energy of reaction (III) is

$$\Delta G = -RT \ln \Delta V, \quad (13)$$

where ΔV is the relative change in the volume on formation of the complex[48].

#The reasoning remains the same when one considers the electron transfer reaction between $^{1,3}D^*$ and A.

2. Adiabatic electron transfer in the complex ($^1A^*D$) with formation of a vibrationally excited charge transfer state $^1(A^-D^+)_{fc}$ (the Franck–Condon state).

3. Vibrational relaxation from $^1(A^-D^+)_{fc}$ to the thermalised state $^1(A^-D^+)$ which takes place over a period of 10^{-12} s with retention of the initial orientation of the solvent molecules. The thermalised radical-ion pair in the triplet state $^3(A^-D^+)$ can be formed under the following conditions: (1) the transition to the triplet state T_1 competes effectively with the quenching of the fluorescence of $^1A^*$ by the donor molecules D; (2) the triplet level T_1 lies above the level corresponding to the charge transfer state $^3(A^-D^+)$. The free energy change ΔG_1 (Fig.1) is

$$\Delta G_1 = E_{1/2}(D/D^+) - [E_{1/2}(A^-/A) + E(^1A^*)] + \frac{e^2}{2}\left(\frac{1}{R_{D^+}} + \frac{1}{R_{A^-}}\right)\left(1 - \frac{1}{\varepsilon}\right) - \frac{e^2}{R} - \frac{\mu^2}{r^3}\left(\frac{n^2-1}{2n^2+1}\right), \quad (14)$$

where n is the refractive index of the medium. Thus a necessary condition for the quenching of the fluorescence (or the triplet state) of the acceptor by the electron donor is $\Delta G_1 < 0$.

4. The reorientation of the solvent molecules around the radical-ion pair $^1(A^-D^+)$ over a period 10^{-11}–10^{-10} s with formation of a radical-ion pair $^1[A^-D^+]$ (exciplex) stabilised by solvent molecules. The radical-ion pair $^3[A^-D^+]$ can be formed via the triplet state, pathways involving both $(^3A^*D)_1$ and $(^3A^*D)_2$ being energetically feasible under these conditions. However, electron transfer via the T_2 state is less probable, because it requires a definite orientation of the solvent molecules around the radical-ion pair $^3[A^-D^+]$. The solvation process can lead to the formation of solvate-separated radical-ion pairs $^1[A^-...D^+]$ and $^3[A^-...D^+]$ stabilised by the Coulombic interaction arising between the radical-ions A and D. The free energy changes ΔG_2 and ΔG_3 are

$$\Delta G_2 = -\frac{\mu^2}{r^3}\left(\frac{\varepsilon-1}{2\varepsilon+1} - \frac{n^2-1}{2n^2+1}\right), \quad (15)$$

$$\Delta G_3 = -\frac{e^2}{2}\left(\frac{1}{R_{D^+}} + \frac{1}{R_{A^-}}\right)\left(1 - \frac{1}{\varepsilon}\right) - \frac{e^2}{\varepsilon a} + \frac{e^2}{R} + \frac{\mu^2}{r^3}\left(\frac{\varepsilon-1}{2\varepsilon+1}\right), \quad (16)$$

where a is the distance between A^- and D^+ in the solvate-separated radical-ion pair.

5. In polar media the solvate-separated radical-ion pair dissociates into solvated radical-ions and the free energy of the reaction is

$$\Delta G_4 = e^2/\varepsilon a. \quad (17)$$

6. The formation of radical-ion pairs in the triplet state $^3[A^-D^+]$ and $^3[A^-...D^+]$ from the triplet state T_3 is energetically unlikely and requires an activation energy.

7. The recombination of radical-ions can lead to the population of the triplet level T_4 subject to the condition that

$$E_{1/2}(D/D^+) - E_{1/2}(A^-/A) > T_4. \quad (18)$$

The above relations (14)–(18) make it possible to find the free energies of the corresponding processes and hence to reach a conclusion about their feasibility.

III. THE QUENCHING OF THE EXCITED STATE AS A RESULT OF ELECTRON TRANSFER

The electron transfer in photochemical reactions between molecules, for example, those of the acceptor ($^{1,3}A^*$) and donor (D), can occur both as a result of diffusional collisions between $^{1,3}A^*$ and D and within the excited

complex formed beforehand by non-excited molecules A and D. The mechanism of the electron transfer reactions occurring as a result of the diffusional collisions between $^{1,3}A^*$ and D is considered below, it being assumed that a complex between A and D is not formed.

The electron transfer in a photochemical reaction between organic compounds can proceed both via excited singlet and the triplet state of the partners. The interaction between $^{1,3}A^*$ and D inevitably leads to the appearance of an additional pathway to the degradation of the excitation energy of the molecule $^{1,3}A^*$ and electron transfer results in a decrease of the lifetime of the excited molecules in the presence of a quenching additive. For the reaction between excited singlet acceptor molecules $^1A^*$ and non-excited donor molecules D,

$$^1A^* + D \xrightarrow{k_q^S} A^- + D^+, \qquad (IV)$$

the decrease of the lifetime of the molecules $^1A^*$ in the presence of D obeys the Stern–Volmer equation

$$\tau_S^0/\tau_S = 1 + k_q^S \tau_S^0 [D], \qquad (19)$$

where τ_S^0 and τ_S are the lifetimes of the excited singlet molecules $^1A^*$ in the absence and presence of the donor molecules respectively. For the reaction between triplet acceptor molecules $^3A^*$ and non-excited donor molecules D,

$$^3A^* + D \xrightarrow{k_q^T} A^- + D^+, \qquad (V)$$

the decrease of the lifetime of the triplet acceptor molecules in the presence of the quenching additive D is described by an equation analogous to Eqn.(19), k_q^S and k_q^T being the quenching rate constants for the corresponding states.

Thus the experimental observation of a linear relation between the relative decrease of the lifetime of excited molecules and the concentration of the quenching additive indicates directly the feasibility of the electron transfer. However one should note that not every quenching process of the excited states $^{1,3}A^*$ under the influence of the additive D, described quantitatively by Eqn.(19), is due to the electron transfer reaction (IV) or (V). A relation of the Stern–Volmer type holds also for many other processes, for example, for the triplet–triplet energy transfer between the acceptor and donor and the transfer of a hydrogen atom between $^{1,3}A^*$ and D. The electron transfer reaction is characterised, firstly, by the formation of an exciplex (in media of low polarity), secondly, by the formation of solvated radical-ions (in polar media), and, thirdly, by the existence of a correlation between the efficiency of the quenching of the excited state and the electron-donating (electron-accepting) properties of the quenching agent.

A definite relation can be established between the quenching rate constants $k_q^S(k_q^T)$ and the electron-donating properties of the quenching agent. In polar media the electron transfer in the collision complex between the excited acceptor molecule and the molecule of the donor quenching agent leads to the formation of a solvate-separated radical-ion pair and is described by the following scheme[56]:

Scheme 1

$$\begin{array}{ccccc} ^{1,3}A^* + D & \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} & (^{1,3}A^*D) & \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} & ^{1,3}[A^- \ldots D^+], \\ {\scriptstyle 1/\tau_{S,T}^0}\downarrow & & & & \downarrow{\scriptstyle k_{30}} \end{array}$$

where k_{12}, k_{21}, k_{23}, k_{32}, and k_{30} are the rate constants for the corresponding processes. It follows from Scheme 1 that

$$k_q^S \ (\text{or} \ k_q^T) = \frac{k_{12}}{1 + (1 + k_{32}/k_{30})\, k_{21}/k_{23}}. \qquad (20)$$

Eqn.(20) can be formulated in the following way:

$$k_q^S, k_q^T = k_{12}/\left[1 + \frac{k_{12}}{K_p k_{30}}\left(e^{\Delta G_{23}^{\ddagger}/RT} + e^{\Delta G_{23}/RT}\right)\right], \qquad (21)$$

where $\Delta G_{23}^{\ddagger}$ is the free energy of activation, ΔG_{23} the free energy of electron transfer in the collision complex, and $K_p = k_{12}/k_{21}$ the equilibrium constant.

$\Delta G_{23}^{\ddagger}$ and ΔG_{23} are related:

$$\Delta G_{23}^{\ddagger} = \Delta G_{23}/2 + [(\Delta G_{23}/2)^2 + (\Delta G_{23}^{\ddagger}(0))^2]^{1/2}, \qquad (22)$$

where $\Delta G_{23}^{\ddagger}(0)$ is the free energy of activation for $\Delta G_{23} = 0$.

Eqn.(21) can be simplified in the following two cases.

1. $\Delta G_{23} \ll 0$ and $\Delta G_{23}^{\ddagger} \cong 0$, whereupon

$$k_q^S \ (\text{or} \ k_q^T) = k_{12}/(1 + k_{21}/k_{30}). \qquad (23)$$

In this case the quenching rate constants k_q^S and k_q^T are invariant and independent of the nature of the donor quenching agent. It has been shown[56] that the ratio $k_{21}/k_{30} < 1$ for the electron transfer reaction between excited singlet molecules of a number of aromatic hydrocarbons (anthracene, 3,4-benzacridine, etc.) and electron donor molecules (tetramethyl-*p*-phenylenediamine, diethylaniline, methyldiphenylamine, etc.) and, in conformity with Eqn.(23), the rate constant for the quenching of the fluorescence is virtually identical with the constant k_{12} determined by the diffusion of the reacting molecules.

2. $\Delta G_{23} \gg 0$ and $\Delta G_{23}^{\ddagger} \cong \Delta G_{23}$, whereupon

$$k_q^S (\text{or} \ k_q^T) = \frac{K_p k_{30}}{2} e^{-\Delta G_{23}/RT}; \qquad (24)$$

according to Eqn.(24), there should be a linear relation between $\ln k_q^S$, $\ln k_q^T$, and ΔG_{23}. Figs.2*a* and 2*b* present the relations between k_q^S and ΔG_{23} for the reaction between aromatic hydrocarbons and electron donors[56] and between k_q^T/k_{12} and ΔG_{23} for the reaction between thionine and electron donors[57]. Fig.2 shows, firstly, that the values of k_q^S and k_q^T are constant over a wide range of values of ΔG_{23}, starting from $\Delta G_{23} < 10$ kcal mol^{-1} and, secondly, that the values of $\ln k_q^S$ and $\ln k_q^T$ are directly proportional to ΔG_{23}, starting from $\Delta G_{23} > 3$ kcal mol^{-1}. Thus Fig.2 illustrates a satisfactory agreement between the experimental data and the results of the theoretical study of Eqns.(21) to (24).

Relations similar to those presented in Fig.2 have also been obtained for the quenching of the fluorescence of pyrene and anthracene by a number of electron acceptors[58], of rubicene and acridine by certain amines[59,60], of substituted naphthalenes by dienes[61], of aromatic hydrocarbons and azastilbenes by inorganic anions[49,52,62], of bipyridyl complexes of ruthenium by nitro-compounds[63] and organic electron donors[64], of uranyl ions by metal cations[65], etc. The quenching of triplet states via the electron transfer mechanism [in conformity with Eqns.(23) and (24)] has been demonstrated for 2-naphthol[66], benzophenone[67], duroquinone[68], Methylene Blue[69,70], a number of aromatic hydrocarbons and carbonyl compounds[71], and also chlorophyll[72,73].

In non-polar media electron transfer also takes place in the collision complex between an excited molecule, for example, an acceptor molecule, and a non-excited donor molecule and

leads to the formation of a solvated radical-ion pair (exciplex). In this case the electron transfer is analogous to Scheme 1 (the difference consists in the replacement of the solvate-separated radical-ion pair by the exciplex) and the expressions for the rate constants for the quenching of the excited singlet and triplet states are analogous to Eqns.(20), (21), (23), and (24). The relations between $\ln k_q^S$ and $\ln k_q^T$, on the one hand, and ΔG_{23}, on the other ($\Delta G'_{23}$ is the free energy of the electron transfer reaction in the collision complex with formation of an exciplex), are similar to those presented in Fig.2.[73-75]

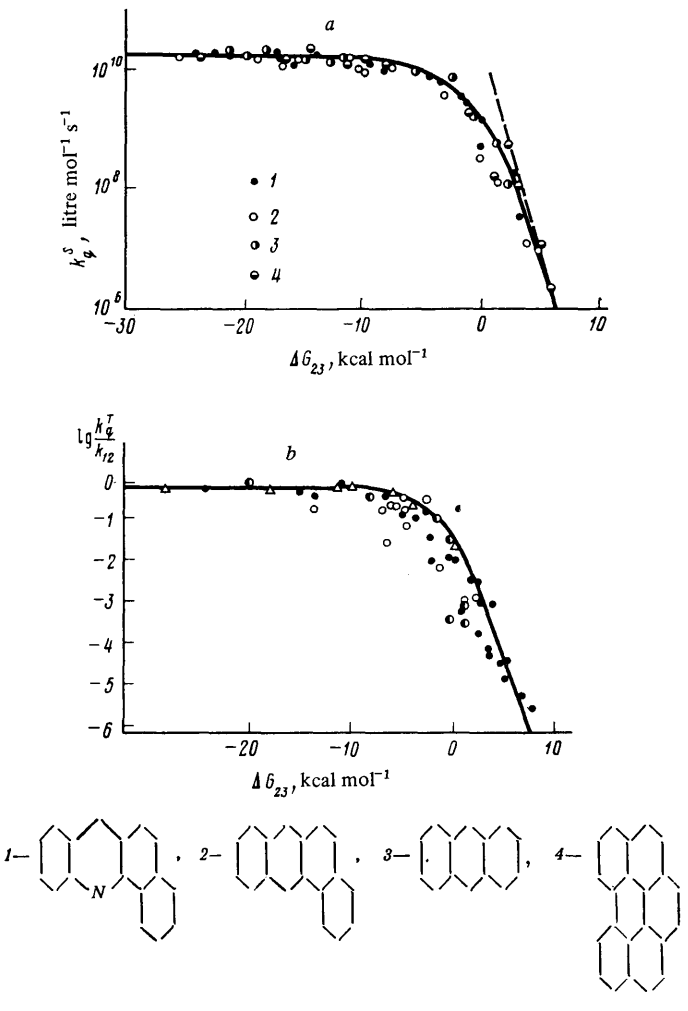

Figure 2. Dependence of the rate constants for (*a*) the quenching of the fluorescence of aromatic hydrocarbons[56] and (*b*) the quenching of the triplet state of Thionine[57] on the change in the free energy ΔG_{23}.

ΔG_{23} can be expressed in terms of the polarographic oxidation potential of the donor and the polarographic reduction potential of the acceptor:

$$\Delta G_{23} = E_{1/2}(D/D^+) - E_{1/2}(A^-/A) - E(^{1,3}A^*) - e^2/\varepsilon a. \quad (25)$$

The variation of the quenching rate constant with the donor oxidation potential (or the acceptor reduction potential for the photochemical oxidation of the donor) is analogous to that shown in Fig.2.

Two consequences which follow from an examination of Eqn.(23) and (24) must be mentioned. Firstly, according to Eqn.(23), the constants k_q^S and k_q^T can differ as a consequence of the difference between the rate constants for the destruction of the singlet and triplet radical-ion pairs (k_{30}). For the triplet pair, k_{30} should be appreciably smaller than for the singlet pair because the transition from the triplet pair to the ground state of the initial reaction products is forbidden[76-78]. Secondly, it follows from Eqn.(24) that the constants k_q^S and k_q^T must differ because of the difference between the values of ΔG_{23} for the reaction proceeding via the excited singlet and triplet states respectively:

$$\ln(k_q^S/k_q^T) = \ln(k_{30}^S/k_{30}^T) + \frac{1}{RT}[E(^1A^*) - E(^3A^*)]. \quad (26)$$

Thus the study of the kinetics and thermodynamics of the electron transfer process in photochemical reactions makes it possible to account for the quenching of the excited state by electron donors and acceptors as a consequence of electron transfer and to find the oxidation (reduction) potentials of the quenching agent molecules from the rate constant for the quenching of the excited state.

IV. THE NATURE OF THE EXCITED STATE OF THE MOLECULES INVOLVED IN THE ELECTRON TRANSFER REACTION

Electron transfer with participation of both excited singlet and triplet molecular states is energetically feasible.

1. Electron Transfer with Participation of the Triplet State

In liquid solutions electron transfer takes place as a result of diffusional collisions between the excited molecule and the other molecule involved in the reaction. The number of "acceptor" collisions is determined by the number of collisions between the reacting species during the lifetime of the excited states. The relation between the relative yield of the electron transfer reaction product, the lifetime of the excited state, and the concentration of the reactant D can be established for the reactions

$$^{1,3}A^* + D \xrightarrow{k_r} A^- + D^+, \quad (VI)$$

$$^{1,3}A^* \xrightarrow{k_0} A, \quad (VII)$$

where k_r is the effective rate constant for the electron transfer and k_0 the rate constant for the deactivation of the excited state $^{1,3}A^*$.

If the lifetime of the product exceeds significantly the duration of the electron transfer reaction, then the following relation exists between the initial concentration of the excited molecules $[^{1,3}A^*]_0$ and the maximum concentration $[A^-]_{max}$:

$$[A^-]_{max} = [^{1,3}A^*]_0(1 + k_0/k_r[D])^{-1}, \quad (27)$$

from which it follows that the maximum concentration of A^- is greatest for the condition $k_0 \ll k_r[D]$ and smallest for $k_0 \gg k_r[D]$. Typical rate constants for the excited singlet states of the molecules of many organic substances are $k_r \cong 10^9$ litre mol^{-1} s^{-1} and $k_0 \cong 2 \times 10^8$ s^{-1}. In this case the maximum yield of the electron transfer reaction products is

attained at concentrations of the quenching agent [D] > 1 M. Typical rate constants for the triplet states of molecules are $k_\gamma \cong 10^8$ litre mol^{-1} s^{-1} and $k_0 \cong 10^3$ s^{-1}; for these values, the maximum yield of $A^{\overline{\cdot}}$ (or $D^{\overset{+}{\cdot}}$) is attained at donor concentrations [D] > 10^{-4} M.[15,21]

Thus it follows from the results presented that, as a consequence of the significant difference between the lifetimes of the excited singlet and triplet molecules, the electron transfer at low concentrations of the quenching agent can proceed only via the triplet state. The proof of the involvement of the triplet state in the electron transfer reaction is based on a series of experimental data.

1. The quenching of the T state by electron acceptors (donors). To some extent, the quenching rate constant reflects the reactivity of the triplet states. The constant is found from data for the quenching of the triplet–triplet absorption.

2. Comparison of the emission times of a pulsed photoexcitation source and the time required for the accumulation of the electron transfer products. If the reaction proceeds via the triplet state and, according to the experimental conditions, the pulsed photoexcitation time τ_{pep} is significantly shorter than the lifetime of the triplet state τ_T, then the time of the attainment of the maximum concentration τ_{max} of the radical-ions at low concentrations of the quenching agent (electron acceptor or donor) must satisfy the condition

$$\tau_{pep} < \tau_{max} \leqslant \tau_T. \qquad (28)$$

If the radical-ions are formed with participation of the excited singlet state, then the maximum concentration of the radical-ions is attained during the photopulse ($\tau_{max} \cong \tau_{pep}$).

3. The competitive quenching of the triplet state. It follows from Eqns.(VI) and (VII) that, in the presence of a competitive quenching agent for the T state, the quantum yield of the radical-ions $\phi_{A^{\overline{\cdot}},D^{\overset{+}{\cdot}}}$ decreases in accordance with the equation

$$\varphi_{A^{\overline{\cdot}},D^{\overset{+}{\cdot}}} = \varphi^0_{A^{\overline{\cdot}},D^{\overset{+}{\cdot}}} (1 + k_Q \tau^0_T [Q])^{-1}, \qquad (29)$$

where $\phi^0_{A^{\overline{\cdot}},D^{\overset{+}{\cdot}}}$ and τ^0_T are quantities determined in the absence of the competitive quenching agent Q. The competitive quenching agents can be compounds with heavy atoms as well as compounds which function as acceptors of the triplet excitation energy, for example, oxygen, etc.[79].

Extensive factual data, demonstrating convincingly that the electron transfer takes place via the triplet states of the molecules of many organic compounds, have now accumulated. The involvement of triplet states has been demonstrated in the reduction of pyrene by radical-anions ($CO_2^{\overline{\cdot}}$, $CH_2O^{\overline{\cdot}}$, $CH_3CHO^{\overline{\cdot}}$),[80] of 2-naphthol and 1-anthrol by quinoline and 4-methylpyridine,[81] of 4-nitropyridine by isopropyl alcohol[82], of benzophenone and 2-naphthaldehyde by amines[83–86], and of quinones by amines and Fe^{2+},[87,88] and in the photochemical oxidation of phenothiazine by nitrobenzene[89] and Eu^{3+}.[90] The important role of the triplet state has also been demonstrated in one-electron reduction and oxidation reactions of dyes and photosynthetic pigments: Thionine[91–95], Methylene Blue[60,69,96–104], fluorescein[105–108], eosin[109–111], erythrosin[21], safranine T,[112] phenosafranine[113], oxonin[114], Acridine Orange[115], rhodamine 6G,[116–118], polymethine dyes[119,120], chlorophyll[22,121–130], phaeophytin[131], Mg-phthalocyanine[132], porphyrins[133], etc.

The above examples illustrate the electron transfer reaction occurring as a result of diffusional collisions between a triplet donor (acceptor) molecule and a non-excited molecule of the other reactant (exogenic electron acceptor or donor respectively). At the same time electron transfer can proceed with participation of molecular triplet states also in the absence of extraneous electron donor or acceptor molecules. In this case the other reactant may be a molecule in the triplet state (triplet–triplet interaction) or in a non-excited state (concentration-dependent quenching):

$$^3A^* + {}^3A^* \rightarrow A^{\overline{\cdot}} + A^{\overset{+}{\cdot}}, \qquad (VIII)$$

$$^3A^* + {}^1A \rightarrow A^{\overline{\cdot}} + A^{\overset{+}{\cdot}}. \qquad (IX)$$

Measurements of the rate of accumulation of radical-ions formed via reactions (VIII) and (IX) have shown that the rate constants for the accumulation of $A^{\overline{\cdot}}$ are always smaller than the rate constants for the quenching of the triplet state as a result of the triplet–triplet interaction and the concentration-dependent quenching[19,21,111]. Consequently the electron transfer reactions (VIII) and (IX) are accompanied by processes involving the "physical" deactivation of the triplet states:

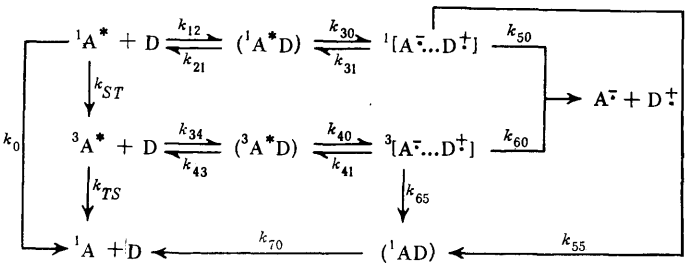
$$^3A^* + {}^3A^* \rightarrow {}^1A^* + {}^1A, \qquad (X)$$

$$^3A^* + {}^1A \rightarrow {}^1A + {}^1A. \qquad (XI)$$

The feasibility of electron transfer via reactions (VIII) and (IX) can be assessed with the aid of the relations

$$E_{1/2}(A/A^+) - E_{1/2}(\overline{A}/A) - 2E(^3A^*) < 0, \qquad (30)$$

$$E_{1/2}(A/A^+) - E_{1/2}(A^-/A) - E(^3A^*) < 0. \qquad (31)$$



For example, the polarographic oxidation and reduction potentials are respectively +0.76 and −0.99 V for chlorophyll *a* in the $^3E^* = 1.33$ eV triplet state (see Table). Thus, in conformity with Eqns.(30) and (31), the electron transfer can occur only when two triplet chlorophyll *a* molecules interact. The detection of the pigment radical-ions has been confirmed by[134] measurements of the transient conductivity arising on pulsed photoexcitation of chlorophyll solutions. The occurrence of electron transfer via reactions (VIII) and (IX) has been established for fluorescein[105], eosin[135], rhodamine 6G,[116,118] and thiazine[97,111] and polymethine dyes[120,136].

2. Kinetic Analysis of the Electron Transfer Reaction Mechanism

With increase in the concentration of the quenching additive, the number of "successful" collisions not only between triplet and quenching agent molecules but also between excited singlet and quenching agent molecules also increase. Consequently at certain concentrations of the quenching agent there is a possibility of electron transfer involving the excited singlet states of the molecules and leading to the formation of radical-ions. The formation of radical-ions as a result of electron transfer between the excited molecule of, for example, the acceptor and the non-excited molecule of the donor occurs only in polar media. The dependence of the quantum yield in the formation of radical-ions on the concentration of the quenching agent in the electron transfer reaction, proceeding through excited

singlet and triplet states of the acceptor in conformity with Scheme 2, is analysed below:

Scheme 2

It is suggested that a complex is not formed between the acceptor and donor molecules; k_0 and k_{ST} are the rate constants for the fluorescence (including internal conversion) and the intercombination conversion to the triplet state respectively and k_{TS} is the rate constant for the intercombination degradation.

For a reaction proceeding similarly via the excited singlet state, there is a linear relation between the reciprocal of the quantum yield in the formation of solvated radical-ions ($A^{\bar{\cdot}}$ or $D^{+\cdot}$) and the reciprocal of the donor concentration:

$$\frac{1}{\varphi^{S}_{A^{\bar{\cdot}},D^{+}}} = 1 + \frac{k_{55}}{k_{50}} + \left(1 + \frac{k_{55}}{k_{50}}\right)\frac{1}{k_q^S \tau_S^0 [D]}, \qquad (32)$$

where

$$k_q^S = k_{12}/\left[1 + \frac{k_{21}}{k_{30}}\left(1 + \frac{k_{31}}{k_{50} + k_{55}}\right)\right], \qquad (33)$$

$$\tau_S^0 = (k_0 + k_{ST})^{-1}. \qquad (34)$$

For a reaction proceeding solely via the triplet state (when the excited singlet state is quenched), the dependence of the quantum yield in the formation of solvated radical-ions ($A^{\bar{\cdot}}$ or $D^{+\cdot}$) on 1/[D] passes through a minimum in conformity with the relation

$$1/\varphi^{(T)}_{A^{\bar{\cdot}},D^{+}} = \left(\frac{1 + k_{65}/k_{60}}{\varphi_T}\right)\left(1 + \frac{k_q^S \tau_S^0}{k_q^T \tau_T^0} + k_q^S \tau_S^0 [D] + \frac{1}{k_q^T \tau_T^0 [D]}\right). \qquad (35)$$

where

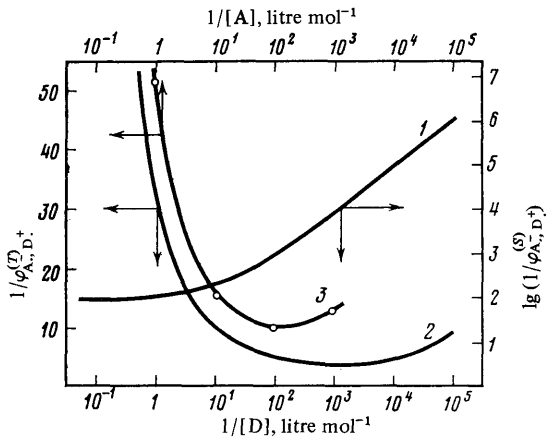
$$k_q^T = k_{34}/\left[1 + \frac{k_{43}}{k_{40}}\left(1 + \frac{k_{41}}{k_{60} + k_{65}}\right)\right], \qquad (36)$$

$$k_q^S = k_{12}/\left[1 + \frac{k_{21}}{k_{30}}\left(1 + \frac{k_{31}}{k_{55}}\right)\right], \qquad (37)$$

$$\varphi_T = \frac{k_{ST}}{k_0 + k_{ST}}, \qquad (38)$$

$$\tau_T^0 = k_{TS}^{-1}. \qquad (39)$$

Relations (32) and (35) have been obtained for the electron transfer reaction between an excited acceptor molecule and a non-excited donor molecule. Exactly the same expressions for the reciprocals of the quantum yield in the formation of the radical-ions can be obtained for the electron transfer reaction between an excited donor molecule and a non-excited acceptor molecule. Fig.3 illustrates the the relations between $1/\phi^{(S,T)}_{A^{\bar{\cdot}},D^{+\cdot}}$ and 1/[D] expected according to Eqns.(32) and (35) and corresponding to the values $\phi_T \cong 0.5$, $k_q^S \cong 10^{10}$ litre mol^{-1} s^{-1}, $k_q^T \cong 10^9$ litre mol^{-1} s^{-1} (it is suggested that $\Delta G_{30,40} \ll 0$), $\tau_S^0 \cong 10^{-9}$ s, $\tau_T^0 \cong 10^{-4}$ s, $k_{65}/k_{60} \cong 1$, and $k_{55}/k_{50} \cong 10-10^2$ typical for dyes and pigments. Fig.3 also presents experimental data obtained for the photochemical oxidation of chlorophyll *a* by nitrobenzene. Comparison of the experimental relation with relations (32) and (35) shows that radical-ions are formed solely via the triplet state.



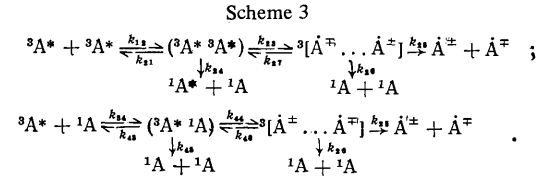


Figure 3. Dependence of the reciprocal of the quantum yield for the formation of radical-ions on the reciprocal of the concentration of the excited state quenching agent: *1*) and *2*) according to Eqns.(32) and (35); *3*) experimental data for the photochemical oxidation of chlorophyll with nitrobenzene[128].

Thus the conclusion that the triplet state plays an important role in the formation of electron transfer products is based on the kinetic analysis of the reaction mechanism postulating the quenching of both the excited singlet and triplet states. This conclusion has been confirmed in direct experiments on the electron transfer between an excited bacteriophaeophytin molecule and *p*-benzoquinone by the method of picosecond spectrophotometry[137].

As stated above, electron transfer can occur as a result of the interaction of both two triplet molecules with one another and of a triplet molecule with a non-excited molecule. The electron transfer reactions and the competing processes are presented in Scheme 3 below:

Scheme 3

Measurements of the rate constants for the quenching of the triplet state as a result of the triplet–triplet interaction [$k_q^{(T-T)}$] and the concentration-dependent quenching [$k_q^{(T-S)}$] have shown that $k_q^{(T-T)}$ exceeds $k_q^{(T-S)}$: in terms of order of magnitude, $k_q^{(T-T)} \cong 10^9$ litre

mol^{-1} s^{-1} and $k_q^{(T-S)} \cong 10^7-10^8$ litre mol^{-1} s^{-1}.[19,21,111,118,120] The difference between $k_q^{(T-T)}$ and $k_q^{(T-S)}$ can be explained in terms of Scheme 3, from which it follows that

$$k_q^{T-T} \simeq k_{12}/(1+k_{21}/k_{23}) + k_{12}/2(1+k_{23}/k_{21}). \quad (40)$$

Eqn.(40) has been obtained on the assumption that $k_{27} < (k_{25}+k_{26})$, since $\Delta G_{23} < -20$ kcal mol^{-1} [in conformity with tabulated data and Eqn.(30)] and $k_{24} < k_{23}$, k_{21}. It also follows from Scheme 3 that

$$k_q^{(T-S)} \simeq \frac{k_{34}}{2k_{43}/k_{44}} + \frac{k_{34}}{k_{43}/k_{45}}. \quad (41)$$

Eqn.(41) has been obtained on the assumption that $k_{46} \cong k_{25}+k_{26}$ [$\Delta G_{44} > 2-5$ kcal mol^{-1} in conformity with the tabulated data and Eqn.(31)], and $k_{43} > k_{45}$, k_{44}. Since $k_{12}=k_{34}$ and $k_{21}=k_{43}$, the differences between $k_q^{(T-T)}$ and $k_q^{(T-S)}$ are due to the fact that $k_{44} < k_{23}$. Measurements of the rate constants for electron transfer as a result of the triplet–triplet interaction [$k_r^{(T-T)}$] and the concentration-dependent quenching [$k_r^{(T-S)}$] have shown that $k_r^{(T-T)}$ exceeds $k_r^{(T-S)}$.[21,118,120] The explanation of this finding follows from an examination of Scheme 3.

When account is taken of the above assumptions, Scheme 3 leads to

$$k_r^{(T-T)} = \frac{k_{12}}{(1+k_{21}/k_{23})(1+k_{26}/k_{25})}, \quad (42)$$

$$k_r^{(T-S)} = \frac{k_{34}}{2(k_{43}/k_{44})(1+k_{26}/k_{25})}. \quad (43)$$

Thus the efficiency of electron transfer via the triplet–triplet interaction and concentration-dependent quenching mechanisms is determined by processes occurring in the radical-ion pairs.

Radical-ion pairs are formed in the electron transfer reaction (Scheme 2) exclusively via the triplet state. The explanation of the important role of the triplet state consists in the different rates of the recombination processes occurring in the singlet and triplet radical-ion pairs respectively. According to Scheme 2, electron transfer takes place in the collision complexes formed by the donor molecule with an excited singlet or triplet acceptor molecule. This leads to the formation of radical-pairs in the singlet and triplet states respectively. The probability of the dissociation of the radical-ion pairs into solvated radical-ions is determined by the ratios $k_{50}/(k_{31}+k_{50}+k_{55})$ (for the pair in the singlet state) and $k_{60}/(k_{41}+k_{60}+k_{65})$ (for the pair in the triplet state). For exothermic electron transfer reactions ($\Delta G < -10$ kcal mol^{-1}), the constants k_{31} and k_{41} make a small contribution to the overall rate constant for the destruction of radical-ion pairs and in addition it is evident that $k_{50} \cong k_{69}$.

Thus the ratio of the probabilities of the dissociation of the singlet and triplet radical-ion pairs into radical-ions is $(k_{60}+k_{65})/(k_{50}+k_{55})$. As a consequence of the prohibition of transitions between states of different multiplicity, it is to be expected that $k_{55} \gg k_{65}$ and in addition that $k_{50} < k_{55}$, since the dissociation of the ion pair into radical-ions involves the overcoming of Coulombic interaction forces. Consequently the recombination process, taking place effectively in the singlet pair, significantly suppresses the dissociation of the singlet pair, in contrast to the pair in the triplet state. Thus, according to Gouterman and Holten[77], radical-ions are formed in the photochemical oxidation of bacteriophaeophytin by *p*-benzoquinone exclusively via the triplet state, which has been confirmed in the study of the rate constants for the processes: $k_{55} \cong 10^{12}$, $k_{50} \cong k_{60} \cong 4 \times 10^9$, and $k_{65} \ll 4 \times 10^9$ s^{-1}.

V. THE REACTIVITY OF THE EXCITED STATE IN THE ELECTRON TRANSFER REACTION

The formation of radical-ions in the photochemical electron transfer reaction is a multistage process. The electron transfer takes place in the collision complex formed by excited molecules and a non-excited molecule of the other reactant and leads to the formation of a radical-ion pair. The rate constant k_{23} in Scheme 1 can serve as a measure of the reactivity of the excited state in the electron transfer reaction.

The reactivities of the excited singlet and triplet states are compared below. According to Scheme 2, the electron transfer rate constants can be expressed in the form

$$k_{30} \propto \exp\left(-\Delta G_{30}^{\neq}/RT\right), \quad (44)$$

$$k_{40} \propto \exp\left(-\Delta G_{40}^{\neq}/RT\right), \quad (45)$$

where $G_{30,40}^{\neq}$ is the free energy of activation for electron transfer via the excited singlet and triplet states respectively.

It follows from Eqns.(44) and (45) that the expression

$$\ln(k_{30}/k_{40}) = (\Delta G_{40} - \Delta G_{30})/RT, \quad (46)$$

is valid for endothermic reactions ($\Delta G_{30,40} \gg 0$) when account is taken of Eqn.(22), whereupon $\Delta G_{30,40}^{\neq} \cong \Delta G_{30,40}$. Since

$$(\Delta G_{40} - \Delta G_{30}) = E(^1A^*) - E(^3A^*) \equiv \Delta E, \quad (47)$$

we have

$$\ln(k_{30}/k_{40}) = \Delta E/RT. \quad (48)$$

Thus the greater energy of the excited singlet state of the molecule compared with that of the triplet state is responsible for the greater reactivity of the excited singlet molecules. For an exothermic reaction, where $\Delta G_{30,40} \ll 0$ and $\Delta G_{30,40}^{\neq} \cong 0$, the difference between k_{30} and k_{40} is significantly reduced.

1. Protonation of the Excited State and Comparative Reactivity

Electron transfer can proceed with participation of both protonated (for example, $^{1,3}A^*H^+$) and deprotonated ($^{1,3}A^*$) molecules. The rate constant for the quenching of the excited state is related to the free energy of reaction; consequently there is a relation between the free energy of the electron transfer reaction and the protolytic equilibrium constant for molecules in the excited state. The electron transfer reactions involving deprotonated and protonated excited molecules are presented in Scheme 4:

Scheme 4

$$\begin{array}{ccc} {}^{1,3}A^*H^+ + D & \rightarrow & AH + D^+ \\ \downarrow\uparrow H^+ & & \downarrow\uparrow H^+ \\ {}^{1,3}A^* + D & \rightarrow & A^- + D^+ \end{array}$$

The expressions for the free energy of the electron transfer reaction are

$$\Delta G_b = E_{1/2}(D/D^+) - [E_{1/2}(A^-/A) + E(^{1,3}A^*)], \quad (49)$$

$$\Delta G_a = E_{1/2}(D/D^+) - [E_{1/2}(AH/AH^+) + E(^{1,3}A^*H^+)]; \quad (50)$$

where subscripts a and b denote the protonated and deprotonated states of the acceptor molecules respectively. It follows from Eqns.(49) and (50) that

$$\Delta\Delta G = (\Delta G_b - \Delta G_a) = [E_{1/2}(\mathrm{AH/AH^+}) - E_{1/2}(\mathrm{A^-/A})] + [E(^{1,3}\mathrm{A^*\,H^+}) - E(^{1,3}\mathrm{A^*})]. \quad (51)$$

Scheme 5 below (the Forster cycle)

Scheme 5

$$\begin{array}{ccc} {}^{1,3}\mathrm{A^*} + \mathrm{H^+} & \overset{pK^*}{\rightleftharpoons} & {}^{1,3}\mathrm{A^*\,H^+} \\ \uparrow h\nu_1 & & \uparrow h\nu_2 \\ \mathrm{A} + \mathrm{H^+} & \overset{pK}{\rightleftharpoons} & \mathrm{AH^+} \end{array}$$

leads to the relation

$$E(^{1,3}\mathrm{A^*\,H^+}) - E(^{1,3}\mathrm{A^*}) = 2.3RT(pK - pK^*), \quad (52)$$

where pK and pK^* refer to the acid–base equilibria involving the non-excited and excited (singlet and triplet) molecules (according to Scheme 5)[15]. Scheme 6

Scheme 6

$$\begin{array}{ccc} \mathrm{A^-} + \mathrm{H^+} & \overset{pK_R}{\rightleftharpoons} & \mathrm{\dot{A}H} \\ \uparrow e & & \uparrow e \\ \mathrm{A} + \mathrm{H^+} & \overset{pK}{\rightleftharpoons} & \mathrm{AH^+} \end{array}$$

also leads to

$$E_{1/2}(\mathrm{AH/AH^+}) - E_{1/2}(\mathrm{A^-/A}) = 2.3RT(pK_R - pK); \quad (53)$$

we finally have

$$\Delta\Delta G = 2.3RT(pK_R - pK^*). \quad (54)$$

Thus it follows from Eqn.(54) that the increase of the rate constant for the quenching of the excited state of the protonated acceptor molecules by the electron donor molecules is determined by the condition $pK_R > pK^*$. For the photochemical reduction of Thionine by aromatic hydrocarbons[57], the Thionine triplet state quenching constant is higher in an acid medium, which is consistent with the conclusion which follows from Eqn.(54), since $pK_R = 10.4$ and $pK^* = 7.0$ for Thionine.

At the same time, according to Eqns.(44) and (45), the rate constant for electron transfer within the collision complex can be expressed in terms of the changes in the free energy of activation. In the case of an endothermic electron transfer reaction the ratio of the electron transfer rate constant for the reactions of protonated ($k^a_{30,40}$) and deprotonated ($k^b_{30,40}$) excited molecules can be expressed in terms of pK_R and pK^* in the following way:

$$\ln\frac{k^a_{30,40}}{k^b_{30,40}} = 2.3(pK_R - pK^*). \quad (55)$$

Consequently a conclusion concerning the comparative reactivities of the protonated and deprotonated excited molecules can be based on the values of pK_R and pK^*.

2. Relation between the Reactivity and the Nature of the Electronic Excitation

For photochemical electron transfer reactions, the excited electronic n,π^* and π,π^* states are of greater interest. The n,π^* state is populated as a result of the $n \to \pi^*$ transition in which the n electrons of the heteroatom pass to the antibonding π orbital. The maximum information about the involvement of the T_{n,π^*} states in photochemical reactions has been obtained in relation to carbonyl compounds[34,138,139]. The high reactivity of the T_{n,π^*} states in the electron transfer reaction is due to the appearance of an electron density deficit at the oxygen atom of the carbonyl group as a result of the $n \to \pi^*$ transition. Thus the photochemical reduction of benzophenone and acetophenone in aqueous solutions as a result of electron transfer from a carbonate ion has been investigated[140].

A high reactivity of triplet n,π^* states has been observed also for aromatic quinones (benzo-, naphtho-, and anthra-quinones) with the lowest T_{n,π^*} level. A number of studies have been made[140–146] in which semiquinone radicals were formed as a result of electron transfer from a series of inorganic anions (CO_3^{2-}, SO_4^{2-}, Cl^-, SCN^-, PO_4^{3-}, OH^-, etc.). Quantitative measurements of the electron transfer rate constant in photochemical reduction reactions have been made for anthraquinones in aqueous solutions[145,147,148] by the method of competition kinetics. The rate constants for electron transfer to the T_{n,π^*} state of anthraquinone-2,6-disulphonic acid are 1.8×10^6 litre $mol^{-1}\ s^{-1}$ for HCO_3^- and 7.1×10^6 litre $mol^{-1}\ s^{-1}$ for OH^-.

As shown above, the rate constant for electron transfer in the collision complex is a measure of the reactivity of the excited state, but it can be by no means always determined or estimated. The quantum yield of the electron transfer products γ can also serve as a relative measure of reactivity. Measurements have been made[140] of γ for the formation of $CO_3^{\dot{-}}$ in the photochemical oxidation of carbonate by different quinone derivatives. It follows from the results of this study that naphtho- and anthra-quinones can be separated into two groups: those which oxidise carbonate with a quantum yield γ close to unity (1,4-naphthoquinone, 8-methyl-1,4-naphthoquinone, and anthraquinonesulphonic acid) and those which do not oxidise carbonate ($\gamma < 10^{-3}$; hydroxy- and amino-derivatives of naphtho- and anthraquinones).

This difference between reactivities can be associated with the different positions of the triplet n,π^* and π,π^* levels in the anthraquinone molecules[149,150]. The much lower reactivity of the triplet π,π^* states compared with the n,π^* states of aromatic carbonyl compounds is associated with the absence of a deficiency of electron density at the oxygen atom of the carbonyl group. The lack of data for the electron transfer rate constants involving carbonyl T_{π,π^*} states hinders a quantitative estimate of the reactivity of such states. The principal conclusions on this subject have been reached by comparing the yields γ of the products of the photochemical reduction of carbonyl compounds with different positions of the triplet n,π^* and π,π^* levels.

Despite the considerable differences between the reactivities of the T_{n,π^*} and T_{π,π^*} states, it has been noted that the acetophenone derivatives, which have a lowest T_{π,π^*} level, are capable of photochemical reduction with an appreciable yield[151,152]. For the alkyl phenyl ketones investigated, it is known that (a) $\Delta E \cong 1000\ cm^{-1}$ and (b) the wave function of the T_{π,π^*} state becomes "mixed" with that of the T_{n,π^*} state. Thus the photochemical reduction of phenyl ketones proceeds via a lowest triplet π,π^* state, which has partial n,π^* character and which is responsible for the appreciable quantum yield of the reaction. The reaction can also proceed via a highest T_{n,π^*} state (with a lowest T_{π,π^*} state) populated on thermal excitation[153].

Thus, examination of the data presented reveals a significant difference between the reactivities of the molecules of carbonyl compounds and quinones in the T_{n,π^*} state (compared with T_{π,π^*}) in the electron transfer reaction.

VI. THE INTERMEDIATE STATES IN THE FORMATION OF RADICAL-IONS

As stated above, solvated radical-ions are formed in the photochemical electron transfer reaction between the donor and acceptor molecules via a series of intermediate states including the exciplex and the solvate-separated radical-ion pair. The exciplex or the complex in the excited state are formed as a result of the interaction of the excited (singlet, triplet) donor (acceptor) molecule with a non-excited acceptor (donor) molecule[154-158]. The formation of an exciplex has been observed in non-polar (weakly polar) media on the basis of the appearance of a structureless luminescence band or of a transient absorption[159,160]. The existence of singlet exciplexes has been established reliably for atomatic hydrocarbons[48,161-171], aminopyridine[172], fluorene[173], transition metal complexes[174], etc. Triplet exciplexes have been investigated in less detail, mainly due to the extremely low phosphorescence quantum yields in the liquid solutions. The existance of triplet exciplexes is therefore established on the basis of the appearance of a transient absorption. The formation of triplet exciplexes has been observed between metalloporphyrins and aromatic nitro-compounds[175-177], chlorophyll and *p*-benzoquinone[178], phaeophytin and *p*-benzoquinone[179], benzene (and its methyl derivatives) and tetracyanobenzene[180], etc. The formation of triplet exciplexes has also been postulated in a number of studies of the mechanism of the quenching of the triplet state of thiazine[94,95] and polymethine dyes[120].

Measurements of the absorption spectra of the exciplexes by the method of laser photolysis[160] showed that the exciplexes have in many instances the structure of an ion pair[164-167,181]. At the same time it also follows from spectroscopic and thermodynamic data that the triplet exciplexes of many metalloporphyrins in the chlorophyll have the structure of an ion pair with partial charge transfer[177,178]. The wave function of the exciplex can be represented by a combination of the wave functions of states with complete charge transfer and states with excitation localised at one of the components of the complex[61,182]:

$$\psi_{exc} = \alpha\psi_1(\bar{A}D^+) + \beta\psi_2(A^*D) + \gamma\psi_3(AD^*). \qquad (56)$$

For singlet exciplexes comprising aromatic hydrocarbons and amines and also heterocyclic compounds and amines, which have the ionic structure A^-D^+, measurements have been made of the dipole moments μ, the heats of formation ΔH, and the molecular volumes ΔV. Thus $\mu = 13.3 \pm 1.7$ D for the exciplex of 3,4-benzacridine and diethylaniline[170]. The heats of formation $-\Delta H$ vary from 6.6 to 10.2 kcal mol^{-1} on passing from the exciplex of biphenyl and diethylaniline to the exciplex of anthracene and diethylaniline[48]. The change in molecular volume on formation of the exciplex relative to the initial components is $-\Delta V = 15.5$ cm^3 litre mol^{-1} for the pyrene–diethylaniline pair[170].

As stated above, in contrast to charge-transfer complexes, exciplexes are formed only in the excited state and this leads to the quenching of the fluorescence of the initial molecules (for singlet exciplexes) or to the quenching of the triplet–triplet absorption (for triplet exciplexes) and is accompanied by the appearance of a new luminescence or transient absorption. The mechanism of the electron transfer reactions leading to the formation of an exciplex is in broad outline analogous to Scheme 1. The application of picosecond laser excitation made it possible to obtain a series of data on the kinetics of the formation of exciplexes[183-185]. It has been shown for the exciplex of anthracene and diethylaniline that the exciplex formation rate constant is equal to the diffusional constant $(10 \pm 1) \times 10^{10}$ litre mol^{-1} s^{-1}. The formation of an exciplex of anthracene and diethylaniline in pure diethylaniline is slower than in hexane, since the rate-limiting stage of the reaction is orientational relaxation whose period is longer in diethylaniline than in hexane.

In non-polar and weakly polar media the formation of solvated radical-ions is usually not observed and the excitation energy is degraded as a result of a set of radiative and non-radiative processes. The solvated radical-ions can be formed in non-polar media as a result of two-quantum reactions, in which the second quantum is absorbed by the exciplex[160]. The non-radiative processes occurring in singlet exciplexes can be represented by a set of the following reactions[186-188]:

$$^1A^* + D \rightleftharpoons (^1A^*D) \rightarrow {}^1(A^-D^+)_{fc}, \qquad (XII)$$

$$^1(A^-D^+)_{fc} \rightarrow {}^1(A^-D^+), \qquad (XIII)$$

$$^1(A^-D^+)_{fc} \rightarrow {}^3A^* + D, \qquad (XIV)$$

$$^1(A^-D^+) \rightarrow A + D + D)_{fl}, \qquad (XV)$$

$$^1(A^-D^+) \rightarrow {}^3A^* + D, \qquad (XVI)$$

$$^1(A^-D^+) \rightarrow {}^1[A^-D^+] \qquad (XVII)$$

$$^1[A^-D^+] \rightarrow A + D + h\nu_{fl}, \qquad (XVIII)$$

$$^1[A^-D^+) \rightarrow A + D. \qquad (XIX)$$

The electron transfer takes place in a collision complex and leads to the formation of a Franck–Condon state of the exciplex [reaction (XII)] which is followed by the vibrational relaxation process (XIII). When the exciplex passes to a thermalised state, a "fast" intercombination transition to the triplet state [reaction (XIV)] competes. The subsequent deactivation processes include fluorescence from a vibrationally relaxed state [reaction (XV)], a "slow" intercombination transition to triplet states [reaction (XVI)], and a transition to a fully relaxed state as a result of the reorientation of the solvent molecule [reaction (XVII)], which is followed by fluorescence [reaction (XVIII)] and recombination [reaction (XIX)] processes. According to a series of data[163-165,189], the ratio of the rate constant for the radiative deactivation of the exciplex to the overall rate constant for the non-radiative deactivation process is in the range 0.01 to 1.5 for the perylene–dimethylaniline, 1,12-benzoperylene–*p*-chloro-*N*,*N*-dimethylaniline, etc. complexes.

In polar media the lifetime of the exciplex is shortened and this is accompanied by a decrease of the fluorescence yield and the appearance of solvated radical-ions. It has been shown[190] for the exciplex of anthracene and diethylaniline that the solvate radical-ions can be formed via the exciplex. According to a study[191] by the method of laser photolysis, an increase in the dielectric constant of the medium alters the electronic structure of the exciplex.

In weakly polar and polar media a solvate-separated radical-ion pair is an intermediate in the formation of solvated radical-ions. The formation of a solvate-separated radical-ion pair was demonstrated[192] on the basis of absorption spectra measured 50 ns after the laser excitation of pyrene in the presence of an electron acceptor–dicyanobenzene in dichloromethane. Parallel photoconductivity measurements demonstrated the absence of solvated radical-ions in the course of 50 ns after photoexcitation.

The processes occurring in the singlet radical-ion pairs can be represented by the following reactions:

$$^1A^* + D \rightleftharpoons (^1A^*D) \rightarrow {}^1(A^{\ddagger} \ldots D^{\ddagger}), \qquad (XX)$$

$$^1(A^{\ddagger} \ldots D^{\ddagger}) \rightarrow A + D, \qquad (XXI)$$

$$^1(A^{\ddagger} \ldots D^{\ddagger}) \rightarrow {}^3(A^{\ddagger} \ldots D^{\ddagger}), \qquad (XXII)$$

$$^1(A^{\ddagger} \ldots D^{\ddagger}) \rightarrow {}^1[A^{\ddagger} \ldots D^{\ddagger}], \qquad (XXIII)$$

$$^1[A^{\ddagger} \ldots D^{\ddagger}] \rightleftharpoons A^{\ddagger} + D^{\ddagger}. \qquad (XXIV)$$

The electron transfer takes place in the collision complex and leads to the formation of a "primary" radical-ion pair $^1(A^{\bar{\cdot}}...D^{+\cdot})$ [reaction (XX)], which is apparently similar to the Franck–Condon state of the exciplex[193]. The dissociation of the solvate-separated radical-ion pair $^1[A^{\bar{\cdot}}...D^{+\cdot}]$ into solvated radical-ions [reaction (XXIV)] precedes the recombination [reaction (XXI)] and intercombination conversion [reaction (XXII)] processes and the orientational relaxation of the solvent [reaction (XXIII)] in the pair $^1(A^{\bar{\cdot}}...D^{+\cdot})$.[193–195]. According to a number of studies[195–197], the recombination process takes place over a period of ~10 ns. The intercombination transition can be extremely effective as a consequence of the interaction between the electron spins and nuclei and can take place over a period of several nanoseconds[197–199].

The processes in triplet radical-ion pairs are fundamentally analogous to the processes in the singlet pairs. The main difference consists in the times of the recombination processes. Thus according to Gouterman and Holten[77], the recombination time in the singlet radical-ion pair formed by bacteriophaeophytin and *p*-benzoquinone is 5 ps, while the recombination time in the triplet pair is significantly greater than 230 ps. The difference between the recombination times is responsible for the difference between the quantum yields in the formation of solvated radical-ions via the excited singlet and triplet states.

VII. THE ROLE OF THE MEDIUM IN ELECTRON TRANSFER PROCESSES

As mentioned above, solvated radical-ions are formed as the final electron transfer products in photochemical reactions only in polar media, which has been manifested experimentally by the transient absorption of the radical-ions or the transient conductivity of the solution. In non-polar media there is no photoinduced absorption or photoinduced conductivity. Studies of the electron transfer mechanism[25,69–71] in media of different polarity have demonstrated the relation between the intermediate states in electron transfer. Scheme 7 presents the fundamental processes in the photochemical oxidation of a donor $^{1,3}D^*$:

Scheme 7

$$^{1,3}D^* + A \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} (^{1,3}D^*A) \begin{cases} \overset{k_{23}}{\underset{k_{32}}{\rightleftharpoons}} {}^{1,3}[D^+A^-] \\ \overset{k_{34}}{\underset{k_{43}}{\rightleftharpoons}} {}^{1,3}[D^{+\cdot}...A^{\bar{\cdot}}] \overset{k_{56}}{\underset{k_{65}}{\rightleftharpoons}} D^{+\cdot} + A^{\bar{\cdot}} \end{cases} \qquad k_{45} \downarrow \uparrow k_{54}$$

The pathway followed in the electron transfer reaction can be traced from the changes in free energy as a function of the dielectric constant of the medium[200]. The change in the free energy of formation of the exciplex ΔG_{23} (notation of Scheme 7) is given by the following expression according to Eqns.(14) and (15) and Knibbe[48]:

$$\Delta G_{23} = \Delta G_{23}(\text{hexane}) - \frac{\mu^2}{r^3}\left(\frac{\varepsilon - 1}{2\varepsilon + 1} - 0.186\right). \qquad (57)$$

The change in the free energy of formation of the solvate-separated radical-ion pair ΔG_{34} is given by the following equation according to Eqns.(14)–(16):

$$\Delta G_{34} = [E_{1/2}(D/D^+) - E_{1/2}(A^-/A)]_{\varepsilon_0} - \frac{e^2}{\varepsilon a} + \Delta G_{\text{solv}} - E(^1,^3D^*), \qquad (58)$$

where

$$\Delta G_{\text{solv}} = \frac{e^2}{2}\left(\frac{1}{R_{D^+}} + \frac{1}{R_{A^-}}\right)\left(\frac{1}{\varepsilon} - \frac{1}{\varepsilon_0}\right) \qquad (59)$$

is the change in the free energy of solvation on passing from a medium with a dielectric constant ε_0 (in which the polarographic oxidation-reduction potentials are measured) to a medium with a dielectric constant ε. The change in the free energy of formation of solvated radical-ions $\Delta G_{34} + \Delta G_{56}$ is described by an expression analogous to Eqn.(10).

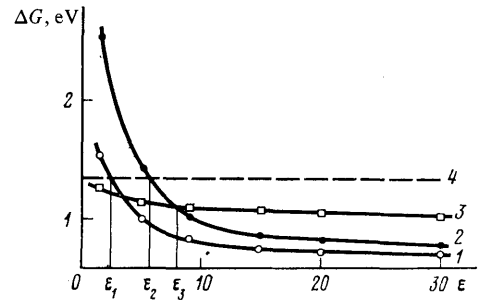

Figure 4. Dependence of the change in the free energy ΔG of formation of a solvate-separated radical-ion pair (curve *1*), solvated radical-ions (curve *2*), and the exciplex (curve *3*) for the chlorophyll *a*–*p*-benzoquinone system on the dielectric constant of the medium ε; curve *4* represents the position of the triplet level of chlorophyll *a*.[201]

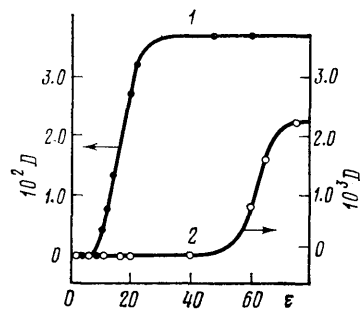

Figure 5. Dependence of the optical density *D* of the chlorophyll *a* radical-cation on the dielectric constant of the medium in the presence of *p*-benzoquinone (curve *1*) and nitrobenzene (curve *2*).[202]

Fig.4 presents the variation of the changes in the free energies of formation of the exciplex, the radical-ion pair, and solvated radical-ions based on the data of Andreeva and Chibisov[201]. Examination of the relations in Fig.4 shows, firstly, that in non-polar media the values of ΔG_{34} and $\Delta G_{34} + \Delta G_{56}$ are significantly positive in relation to the donor excitation energy, while ΔG_{23} is negative. This explains the possibility of the formation of the exciplex alone and hence the absence of solvated radical-ions. Secondly, with increase of ε for the medium, both ΔG_{34} and $\Delta G_{34} + \Delta G_{56}$ decrease, changing sign at dielectric constants ε_1 and ε_2 respectively. Consequently radical-ions are formed when $\varepsilon > \varepsilon_2$. Thirdly, ΔG_{34} becomes more negative than ΔG_{23} when $\varepsilon > \varepsilon_3$, as a consequence of which the radical-ion pair is formed effectively directly via the collision complex.

The results of the study of the dependence of the yield of the radical-ions on ε for the medium have shown that it is described by an S-shaped curve[202,203]. This type of relation can be understood by referring to Figs.5 and 6. At low dielectric constants of the medium the yield of radical-ions is virtually zero owing to the energetically unfavourable electron transfer process in the collision complex and also the necessity to overcome the Coulombic interaction forces in the radical-ion pair when the latter dissociates into radical-ions. With increase in the dielectric constant of the medium, a monotonic increase of the concentration of radical-ions to a maximum is observed. For higher values of ε, the free energies $\Delta G'$ and $\Delta G''$ become significantly negative; furthermore, the energy of the Coulombic interaction in the ion pair diminishes, which significantly facilitates its dissociation into solvated radical-ions.

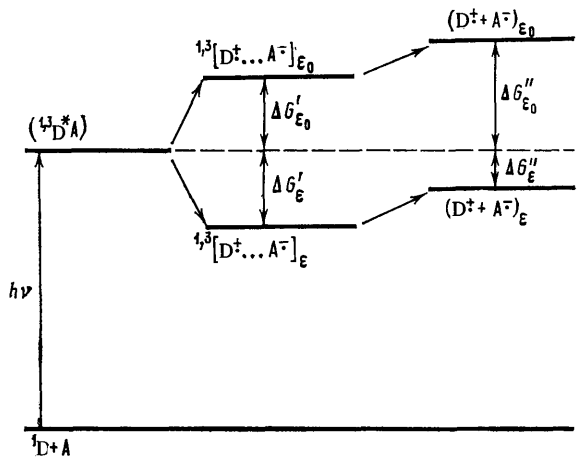

Figure 6. Schematic illustration of the arrangement of the energy levels of the intermediate states for low (ε_0) and high (ε) dielectric constants of the medium.

A quantitative expression for the dependence of the quantum yield in the formation of radical-ions on the dielectric constant of the medium can be obtained as follows. It is assumed that the quenching of the fluorescence of the acceptor by the electron donor can be neglected. It then follows from Eqn.(35) that

$$\varphi_{A^{\mp},D^{\pm}} = \varphi_T\left(\frac{k_{60}}{k_{60}+k_{65}}\right)\left(\frac{k_q^T\tau_T^0[D]}{1+k_q^T\tau_T^0[D]}\right). \qquad (60)$$

The dependence of $\phi_{A^{\mp},D^{\pm}}$ on ε is determined by the relations $k_{60}(\varepsilon)$ and $k_q^T(\varepsilon)$. The expression for $k_{60}(\varepsilon)$ assumes the form[203]

$$k_{60}(\varepsilon) = \frac{\text{const}}{\eta\varepsilon^{3/2}}\exp\left(-\frac{e^2}{\varepsilon aRT}\right), \qquad (61)$$

where η is the solvent viscosity.

The dependence of k_q^T on ε is determined, according to Eqn.(36), by the quantities $k_{40}(\varepsilon)$, $k_{41}(\varepsilon)$, and $k_{60}(\varepsilon)$. In the case where $\Delta G_{40} \ll 0$ (Scheme 2) the quenching rate constant $k_q^T(\varepsilon)$ can be expressed in a form analogous to that of Eqn.(23):

$$k_q^T(\varepsilon) = k_{34}/[1 + k_{43}/(k_{65} + k_{60}(\varepsilon))]. \qquad (62)$$

In the case where $\Delta G_{40} > 0$ the expression for $k_q^T(\varepsilon)$ is analogous to Eqn.(24):

$$k_q^T(\varepsilon) = \frac{k_{34}(k_{65}+k_{60}(\varepsilon))}{2k_{43}}\exp\left(-\frac{\Delta G_{40}(\varepsilon)}{RT}\right), \qquad (63)$$

while the expression for $\Delta G_{40}(\varepsilon)$ is analogous to Eqn.(58).

The formation of intermediates in electron transfer and their subsequent transformations depend significantly on the ratios of the excitation energies of one of the reactants, the electrochemical oxidation-reduction potentials, and the dielectric constant of the medium. By varying these parameters, it is possible to alter the efficiency of the formation of intermediates in the electron transfer reaction.

Thermal Decomposition of Lanthanide, Yttrium, and Scandium Oxalates and Carbonates

V.A.Sharov and G.V.Bezdenezhnykh

Data concerning the thermal decomposition of lanthanide, yttrium, and scandium oxalates and carbonates are surveyed. The complexity of the process, the large number of stages involved, and the dependence of the composition of the intermediates in the thermal transformations on the experimental conditions is noted. Certain process characteristics have been discovered and it is concluded that the decomposition process depends on the ionic radius of the metal. The bibliography includes 83 references.

I. INTRODUCTION

In the review an attempt is made to survey the existing data on the thermal decomposition of lanthanide, yttrium, and scandium oxalates and carbonates. The principal studies in this field have been carried out in the last 2–3 decades.

In the thermal decomposition of hydrated lanthanide oxalates it is possible to distinguish two stages: dehydration and decomposition of anhydrous oxalates. The available literature data for each stage are not unambiguous due to the dependence of the results on the experimental conditions (the rate of heating, the size of the specimen sample, the sensitivity of the apparatus, etc.). From a critical examination of the available data, we have attempted to reach certain conclusions about the compositions of the intermediate hydrates and about the changes in the nature and strength of the bonds in the series of compounds considered.

II. DEHYDRATION OF OXALATES

The dehydration of lanthanide oxalates proceeds with formation of intermediate hydrates. The dehydration process has been investigated by derivatographic methods in various media (air, argon, and CO_2) and *in vacuo* and also by infrared spectrophotometry and diffractometry.

In the first studies[1,2] of the dehydration of lanthanide oxalates at heating rates of 6, 2.5, and 0.33 K min^{-1} it was already observed that the composition and the region of stability of the intermediate hydrates depend on the heating rate of the specimen, the size of the sample, and the sensitivity of the apparatus. Systematic treatment of the result of subsequent studies confirmed this conclusion[3–27]. In this connection studies of the dehydration of all the lanthanide oxalates under the same conditions are of greatest interest for the elucidation of the characteristics of the dehydration process.

The first attempt to subdivide all the lanthanide oxalates into groups based on their ability to form intermediate hydrates of definite composition was made by Wendlandt[4,28]. He assigned to the first group lanthanum, praseodymium, and neodymium oxalates, for which the formation of intermediate hydrates has not been observed: the decahydrates decompose to the anhydrous compounds. For the oxalates of the second group (Sm–Dy) for formation of various hydrates and anhydrous oxalates has been observed. The oxalates of the third group (Y, Sc, Ho–Lu) give rise to stable dihydrates. Cerium oxalate does not belong to any of these groups.

Möbius and Matthes[7,8] divided the hydrated oxalates into three groups on the basis of very careful investigations. The thermogravimetric (TGA) and differential thermographic (DTA) curves for the decomposition of the oxalates of the first group (La, Ce, Pr) do not indicate the formation of lower hydrates. The oxalates of the second group (Sm–Tb) split off water in three stages, forming hexahydrates, 3,5-water oxalates, and anhydrous oxalates. Water is given up by the oxalates of the third group (Y, Er, Lu) in two stages with formation of trihydrates and dihydrates without any sign of the formation of anhydrous oxalates. Neodymium and holmium oxalates constitute transitions between two groups, while dysprosium oxalate does not form part of any of the above groups. The authors carried out their investigations at heating rates of 2, 1.1, 0.7, and 0.48 K min^{-1} and also by the isothermal heating method. In all cases decrease of the heating rate made it possible to discover the intermediates more effectively. For example, decrease of the rate of heating of the oxalate nonahydrate from 2 to 0.6 K min^{-1} showed that a relatively unstable trihydrate is formed in addition to the stable dihydrate.

The dependence of the dehydration process on the specimen sample size at a heating rate of 5 K min^{-1} has been investigated[24] for the yttrium compound. For a 500 mg sample, the curve describing the dehydration of yttrium oxalate has a single maximum, for a 318 mg sample it has three maxima, and for a 13.3 mg sample it has five maxima; the compositions of the intermediates are also correspondingly different.

Thus the temperatures of the formation and the temperature ranges corresponding to the existence of the hydrates cannot be regarded as definite constant quantities.

Data concerning the possibility of obtaining anhydrous oxalates in air are also contradictory[7,11,12,16,18,19]. On the other hand, investigators agree unanimously that *in vacuo* complete dehydration of the oxalate hydrates is attained[13,29–31].

Whereas much attention has been devoted in the literature to the composition of the intermediate hydrates of rare earth oxalates, no conclusions have been reached on the basis of the stepwise elimination of water. For example, it has been

shown clearly[2,4] that the number of dehydration stages increases in the oxalates of the elements ranging from lanthanum to dysprosium. According to these authors, this is because with increase of the atomic number of the element, the strength of the hydrogen and coordinate bonds involving the water molecules in the rare earth oxalate hydrates changes. In other words the activation energies for the elimination of water molecules linked by hydrogen (E_h^a) and coordinate (E_c^a) bonds are approximately the same for hydrated lanthanum oxalate, while $E_h^a < E_c^a$ for dysprosium oxalate.

It is also known[7,8,25,32-35] that the oxalate decahydrates of the elements located at the beginning of the series (La–Nd) lose the entire outer-sphere water and most of the coordinate water in a single stage, while closer to the centre of the series (Sm–Tb) only the outer-sphere water is lost and at the end of the series the outer-sphere and approximately half of the inner-sphere water is lost (in a single stage) (Fig.1).

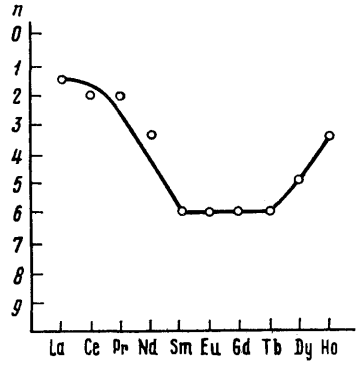

Figure 1. The first stage of the transition $Ln_2(C_2O_4)_3 \cdot 10H_2O \rightarrow Ln_2(C_2O_4)_3 \cdot nH_2O$ on heating. The curve has been plotted on the basis of the data of Bezdenezhnykh et al.[24,32]

It follows from Fig.1 that, on passing from La and Ce to Sm in the series of lanthanide oxalates, the strength of the bond between the lanthanide and the coordinated water increases; on passing from Sm to Tb, the bond strength hardly changes and subsequently weakens. There is not yet a molecular orbital scheme for the σ-bonds of complexes with a central ion having a coordination number of eight or nine. It is known only that the covalent bond between the rare earth ions and ligands is formed mainly as a result of the mixing of the occupied ligand orbitals with the partly filled 4*f* orbitals and the vacant 6*s*, 6*p*, and 5*d* orbitals of the rare earth ions[36]. An admixture of covalent character in an ionic bond should favour the formation of coordination polyhedra with vertices pointing in the directions of the maxima of the hybrid sp^3d^n orbital. This requirement is satisfied in the first place by the 9-coordination polyhedron with D_{3h} symmetry. For polyhedra with a coordination number of 8, the dodecahedron with D_{2d} symmetry is most preferred. However, the ionic contribution is greater than the covalent contribution[37].

It is interesting that the nature of the variation of the Ln-coordinated water bond strength in the rare earth oxalate decahydrates is the same as that of the variation of the stability of the octahedral complexes in the series of rare earths[38]. This justifies the hypothesis that the arrangement of the molecular orbitals (bonding, non-bonding, and the first antibonding) in polyhedra with coordination numbers of 6 and 9 is the same, the difference consisting in the number of lowest bonding orbitals (6 for an octahedron and 9 for a 9-coordination polyhedron), which are localised mainly at the ligands[38,39].

Using this orbital scheme, it is possible to explain the variation of the lanthanide-coordinated water bond strength in the series of lanthanide oxalate decahydrates (Fig.1). The increase in the strength of the Ln–H_2O bond on passing from Pm to Ce, Pr, Nd, and Sm is due to the enhancement of the bonding effect, which is determined by the possible increase of the overlap integrals (decrease of the Ln–H_2O distance) and the increase of the ionisation potential. On passing from Pm to Sm–Gd, the increase of the stability of the compounds slows down (or even ceases) because electrons appear in the antibonding t_{1u}^* orbital[38]. Beyond Tb, the Ln–H_2O bond weakens, since electrons fill the t_{1u}^* orbital.

The coordinated water in Nd–Er oxalates is split off stepwise. Its elimination temperature increases up to Tb–Dy and then falls (Fig.2), which is consistent with the above considerations concerning the nature of the variation of the Ln–H_2O (coordinated) bond strength.

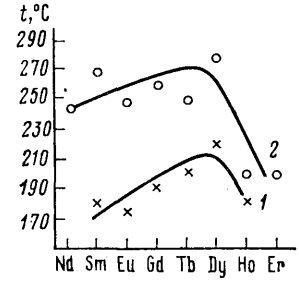

Figure 2. The minima on the DTA curves for the decomposition of the lanthanide oxalates corresponding to the loss of coordinated water: 1) first stage; 2) second stage[28].

The dehydration of terbium, ytterbium, and lutetium oxalate hexahydrates proceeds isotypically in two stages with formation of the relatively unstable trihydrate and the dihydrate, which is stable in the temperature range 200° to 350 °C.[7,8,24] It is therefore difficult to discover how the Ln–H_2O (coordinated) bond strength varies from Tm to Lu. Theoretically it should decrease, since the filling of antibonding orbitals with electrons is characteristic of Tm, Yb, and Lu.[38,39]

III. DECOMPOSITION OF OXALATES AFTER DEHYDRATION

In the study of the decomposition of rare earth, yttrium, and scandium oxalates in air, different workers obtained compounds having the following compositions:

$Ln_2(C_2O_4)_3$ 2, 11, 17, 23, 40 — 42 ; $Ln_2(C_2O_4)_2O$ 29 ;
LnC_2O_4 42 ; $Ln_2O_2(C_2O_4)_2$ 9,18 ; $Ln_2O_2OCOCO_2$ 23 ;
$Ln(CO_3)_2C_2O_4$ 22, 43 ; $Ln(CO_3)_2O$ 29 ; $(LnCO_3)_2O$ 22, 42 ;
$Ln_2(CO_3)_2$ 2, 17, 41, 44 ; $Ln_2O_3 \cdot 2CO_2$ 2, 14, 39, 41
$Ln_2O_3 \cdot CO_2$ 1, 2, 4, 9 — 12, 14,24, 40 — 42 ; $(LnO_2)CO_3$ 14, 15, 18, 22, 23, 29 ;
$2Ln_2O_3 \cdot CO_2$ 2, 17, 18 .

Apart from the products quoted, CO, CO_2, and free carbon are liberated in the thermolytic process. The formation of carbon was noted for lanthanum[5,9,14,15,42], cerium[14], praseodymium[9,45], neodymium[2,9,45,46], samarium, gadolinium[45], terbium[24], dysprosium, erbium[45], and yttrium[2,24] oxalates. Carbon was not found in the decomposition of cerium, scandium[2], erbium, thulium, ytterbium, and lutetium[24] oxalates.

The most stable intermediate proved to be the basic carbonate $Ln_2O_3.CO_2$. It has been established in recent years by X-ray diffraction[45,57] that the composition of this compound is $Ln_2O_2.CO_3$ and that it should be most correctly referred to as the dioxomonocarbonate. In the thermolysis of thulium, ytterbium, and lutetium oxalates, $Ln_2O_2.xCO_3$ ($x < 1$), which is a mixture of the dioxomonocarbonate and the oxide Ln_2O_3, was found as an intermediate[47].

The presence of three polymorphic forms of the dioxomonocarbonates $Ln_2O_2.CO_3$, namely (I), (Ia), and (II), has been demonstrated[45] on the basis of high-temperature X-ray diffraction and density data, TGA curves, and infrared spectra. They were obtained in the decomposition of the following oxalates:

La	Pr	Nd	Sm	Eu	Gd	Structure
(I)	(I)	(I)	(I)	(I)	(I)	tetragonal
	(Ia)	(Ia)				monoclinic
(II)	(II)	(II)	(II)		(II)	hexagonal

These are layer type structures made up of planar $(Ln_2O_2)_n^{+}$ polymers and CO_3^{2+} groups. Form (I) has square layers, as in LnOCl and related compounds, while form (II) is characterised by hexagonal $(Ln_2O_2)_n^{2+}$ layers, as in the A-forms of sesquioxides.

In all cases form (I) is formed in the first place from $Ln_2(CO_3)_3$. The transformation of form (I) into form (II) is observed above 400 °C without weight loss. There is no definite evidence for the formation of form (II) for heavy lanthanides. It is interesting that an analogous behaviour has been observed for the oxides of light lanthanides; the conversion of the C form (cubic) into the A form (hexagonal) requires an increase of temperature, while for the heavy lanthanides only the C form has been discovered. Since the carbonate of form (II) can be regarded as layers of the A form of Ln_2O_3 separated by C–O layers, the tendency towards the transition form (I) (tetragonal) → form (II) (hexagonal) as a function of temperature and the probable absence of form (II) for the heavy lanthanides are apparently caused directly by the known tendency towards the existence of polymorphic regions in Ln_2O_3.

By analogy with the irreversible transformation of the C form of the oxide into the A form, the transformation of form (I) into form (II) is not reversible. Nevertheless the rate of this transformation is evidently greatly influenced by the presence of carbon and (or) the particle size. The data presented by the authors[11,18,20,26,47,62,63] suggest that form (I) is characteristic of all the lanthanides: the corresponding compounds of the heavy lanthanides decompose at temperatures only slightly above the temperatures at which they are obtained from $Ln_2(CO_3)_3$.[45]

On the basis of their own studies, the authors[47] explained the available TGA curves in the literature for the decomposition of lanthanide oxalates and carbonates. Depending on which lanthanide is investigated, three types of generalised curves are obtained. For La and Pr at a heating rate of 0.6 K h^{-1}, there is a phase change to $Ln_2O_2.CO_3$ (II). The latter is formed before the dissociation temperature is attained. For Nd and Sm–Gd at a heating rate of 0.6 K h^{-1}, the phase transition from $Ln_2O_2.CO_3$ (I) or (Ia) to $Ln_2O_2.CO_3$ (II) does not reach completion, because the thermal decomposition of phases (I) and (Ia) to Ln_2O_3 begins. The length of the plateau on the TGA curves depends on the heating rate.

It is known[47] that the $Ln_2O_2.CO_3$ (II) phase is not encountered when the ionic radius of Ln^{3+} is smaller than for Gd^{3+}. The formation of the $Ln_2O_2.CO_3$ (I) or (Ia) phase is characteristic on heating Tb–Lu oxalates or carbonates. The $Tb_2O_2.CO_3$ (I) and (Ia) forms have a high thermal stability, while $Yb_2O_2.CO_3$ (I) and (Ia) begin to decompose immediately after formation.

The decomposition temperatures of $Ln_2O_2.CO_3$ have been published[45,48–50]. The Dy, Ho, Er, and Y dioxomonocarbonates have been obtained by a hydrothermal method and their X-ray diffraction patterns (the values of *h*, *k*, *l*, *d*, *I*) have been published[51].

The thermolysis has been studied by the DTA method[10,12,14,15,22,42,52,53], which is more sensitive to phase transitions than the TGA method. The decomposition of the hydrated La,[10,14,15,42,52] Nd, Sm–Gd,[52] Tb–Lu[24,54], Y,[10,24,52,54] and Sc [10] oxalates in the range 300–600 °C is accompanied by complex exothermic processes, which are a consequence of the decomposition of the oxalates and demonstrate the simultaneous occurrence of two reactions: the endothermic decomposition of the oxalate or carbonates of various compositions and an exothermic reaction involving the interaction of CO and O_2 with formation of CO_2 and the oxidation of free carbon[14,42,43,55]. This has been confirmed, firstly, by the fact that the total amount of the evolved gases is greater than the weight loss by the sample[10] and, secondly, by the observation that the decomposition of, for example, yttrium oxalate in a helium atmosphere[10] or of lanthanum oxalate in an argon atmosphere[23] is accompanied by endothermic effects. Above 600–700 °C, exothermic processes associated with the crystallisation of cryptocrystalline oxides[52] and the conversion of the metastable C form of the oxide into the B form[53] are observed for all the oxalates.

Since the decomposition temperatures of the anhydrous oxalates increase in the La–Lu series[28], an impression has been created that the Ln–C_2O_4 bond strength increases in this series. However, one should bear in mind here that the increase of the Ln–C_2O_4 bond strength entails a decrease of the thermal stability of the oxygen-containing salts[57,58]. Hence it follows that the Ln–C_2O_4 bond strength should be weakened in the La–Lu series, which is consistent with the weakening of the basic properties in the same series. This weakening occurs monotonically from La to Tb, but subsequently, from Tb to Lu, the Ln–C_2O_4 bond strength hardly changes. Thus the nature of the variation of the Ln–C_2O_4 bond strength in the series of lanthanide oxalates differs from that for the Ln–H_2O bond strength. To a first approximation, this can be explained by the fact that, in contrast to the water molecules, the C_2O_4 groups can be linked to the central ion via not only σ-bonds but also via π-bonds.[59]

The final products of the decomposition of the oxalates are the oxides CeO_2, Pr_6O_{11}, Ln_2O_3 (Ln = La, Nd, Sm, Eu, Gd, Dy, or Ho), and Tb_6O_{11} (converted into $TbO_{1.714}$ with an endothermic effect at 865 °C).

The thermal dissociation reactions of the lanthanide oxalates *in vacuo* and in inert media proceed differently. The vacuum thermal decomposition of the La–Eu oxalates[44,60] takes place with formation of the intermediates $Ln_2(C_2O_4)(CO_3)_2$, $Ln_2(CO_3)_3$, $Ln_2O_{0.6}(CO_3)_{2.4}$, and $Ln_2O(CO_3)_2$, the evolution of CO and CO_2, and the formation of free carbon. All the oxides formed are black due to the presence of free carbon. Studies have been made of the oxalates of Ce,[9,13] La,[61] Nd–Sm, Gd–Dy, and Er,[20] Eu,[22,23,29,30] Yb,[27,29,43] Y,[26,62,63] and Sc.[3]

An attempt has been made[62] at a qualitative explanation of the formation of intermediates in the decomposition of *s*, *p*, and *d* metals as a result of the combination of various radicals formed on dissociation of $-M-C_2O_4-M-$ linkages, where M is a metal. Free carbon is obtained as a result of the disproportionation of CO or the decomposition of the carbon–oxygen polymers C_4O_3, C_8O_3, and $C_{12}O_9$, which have been described in the literature. These polymers can be obtained as a consequence of the combination of carbon–oxygen radicals formed on dissociation of the bonds in the C_2O_4 groups.

An attempt may be made to reach a series of conclusions from the data presented above.

1. Since the basic properties of the lanthanide ions weaken with increasing atomic number (with decreasing ionic radius), the strength of the bond formed between Ln^{3+} and the oxalato- or carbonato-group should decrease. This has been confirmed by the majority of investigations[2,11,31,45,48,61], with the exception of that of Palei et al.[17]

2. The weakening of the $Ln-CO_3$ bond with increasing atomic number of the lanthanide explains the preferential formation of the normal carbonates and compounds of the type $Ln_2O(CO_3)_2$ by the light lanthanides[2,14,15,41,60]. The carbonates of the heavy lanthanides are unstable and rapidly decompose to the oxides[31,45].

3. The mechanism of the thermal decomposition of light lanthanide oxalates should have the following general form:

$$\underset{\text{(III)}}{Ln_2(C_2O_4)_3} \rightarrow \underset{\text{(IV)}}{Ln_2(C_2O_4)_x(CO_3)_y} \rightarrow \underset{\text{(V)}}{Ln_2(CO_3)_3} \rightarrow \underset{\text{(VI)}}{Ln_2O(CO_3)_2} \rightarrow \underset{\text{(VII)}}{Ln_2O_2CO_3} \rightarrow \underset{\text{(VIII)}}{Ln_2O_3}$$

It is difficult to establish from available literature data how the values of x and y vary throughout the lanthanide series. According to general considerations, an increase of the atomic number of the lanthanide should entail an increase of x and a decrease of y. This has been confirmed by the finding that the degree of disproportionation of CO diminishes from Ce to Lu. However, the opposite conclusion can also be reached, because the relative amount of CO increases in the same direction.

As a consequence of the proximity of the decomposition temperatures of compounds (III)–(VI), it has not been possible to detect all five stages in the case of the heavy lanthanides *in vacuo*, in air, and in CO_2 and N_2 atmospheres. Here the mechanism is usually restricted to compounds (III), (VII), and (VIII). This is evidently also true of scandium and ytterbium oxalates.

4. The formation of $Ln_2O_2CO_3$ has been demonstrated by hydrothermal synthesis, X-ray diffraction analysis, infrared spectroscopy, and the discovery of three polymorphic forms. In order to confirm the variation of the above compounds in the series of lanthanides, additional studies are evidently necessary, because contradictory data have been published[47,48,51].

5. The decomposition of the lanthanide, yttrium, and scandium oxalates *in vacuo* and sometimes in air results in the formation of free carbon due to the disproportionation of CO or the decomposition of carbon–oxygen polymers[2,5,9,14,15,24,42,45,46]. The latter are obtained via the combination of the oxygen-carbon radicals arising after the dissociation of the bonds with the C_2O_4 group. According to various sources, carbon burns in air at a temperature in the range 460–680 °C.

6. In an inert atmosphere the thermal decomposition of the dehydrated oxalate is accompanied by endothermic effects. In air the exothermic effects associated with the oxidation of CO and C are superimposed on them.

7. Recently the majority of investigators have used the following terminology for the intermediates in the decomposition of the oxalates and carbonates; in $Ln_2O(CO_3)_2$—monoxodicarbonate; $Ln_2O_2.CO_3$ dioxomonocarbonate. The composition $Ln_2O_2.CO_3$ (and not $Ln_2O_3.CO_2$) has been confirmed by X-ray diffraction studies[45].

IV. THERMAL DECOMPOSITION OF CARBONATES

Data on the thermal decomposition of lanthanide carbonates represent additional information about the compositions and properties of lanthanide oxide carbonates. The decomposition of lanthanide and yttrium carbonates has been investigated[1,2,18,40,49,57,64–82].

The thermal stability of lanthanide carbonates increases with increasing atomic number of the metal[71]. Thus lanthanum carbonate begins to decompose at 495 °C, while erbium carbonate begins to decompose at 770 °C. In contrast to the oxalates, the decomposition of the carbonates of the light lanthanides[18] takes place only with formation of $Ln_2O_2.CO_3$; compounds of the type $2Ln_2O_3.CO_2$ are not formed. The decomposition of the carbonates of heavy lanthanides and yttrium[73] is accompanied by the formation of $Ln_2O_3.2CO_2$ and $Ln_2O_2.CO_3$. At temperatures of approximately 900 °C and above all the carbonates are converted into the oxides[75].

On the basis of literature data and the results of their own investigations, Kokhanovskii and Pavlyuchenko[82] concluded that the decomposition of lanthanide carbonates proceeds in accordance with the mechanism $Ln_2(CO_3)_3 \rightarrow Ln_2O_2.CO_3 \rightarrow Ln_2O_3$ and is accompanied by the formation of only one intermediate. At the same time, according to their data[82], it is possible to obtain the monoxodicarbonates $Ln_2O(CO_3)_2$. The latter was established from the slight inflections in the TGA and DTA curves. The existence of $Ln_2O(CO_3)_2$ could not be confirmed either by X-ray diffraction or by infrared spectroscopy. The thermal decomposition of dioxomonocarbonates should be an endothermic process. However, bearing in mind the crystallisation of both dioxomonocarbonates and oxides, it is to be expected that the endothermic effects will be significantly distorted by the superposition of the exothermic effects. In this respect the decomposition of yttrium and gadolinium carbonates is extremely characteristic, their thermograms showing only exothermic effects in the region of the decomposition of the dioxomonocarbonates[82].

The data presented on the thermal decomposition of lanthanide carbonates confirm the conclusions reached in the previous Section concerning the thermal stability and composition of and the sign of the thermal effect associated with the intermediates formed on heating anhydrous lanthanide oxalates (carbonates, dioxomonocarbonates). The individuality of $Ln_2O(CO_3)_2$ has not so far been confirmed experimentally.

V. KINETICS OF THE DEHYDRATION AND DECOMPOSITION OF LANTHANIDE OXALATES

There are literature data on the activation energies for the thermal decomposition of lanthanum[9,12,44,83], cerium[9,22], praseodymium[9], neodymium[9], and yttrium[22] oxalates. The enthalpies of the reaction $Ln_2O_3.CO_2 \rightarrow Ln_2O_3 + CO_2$ (where Ln = La, Nd, Sm, Gd, Dy, or Lu) have been calculated from DTA curves[65].

Evidently the kinetics of the dehydration of lanthanide oxalates and of the decomposition of the intermediates formed on heating the oxalates and carbonates have been very little investigated. The number of such studies is small and none

has dealt with the compounds of all the lanthanides. In the main there are data on the oxalates of the first half of the lanthanide group. However, despite the fact that the kinetic data are widely scattered, they permit certain conclusions: (1) the water in the hydrated oxalates is retained less strongly than the oxalato-group. In the range from lanthanum to neodymium the strength of the bond between the water molecules and the lanthanide ion increases[9]. (2) The strength of the bond formed by the carbonato-group in lanthanide dioxomonocarbonates diminishes in the sequence from lanthanum to lutetium[65].

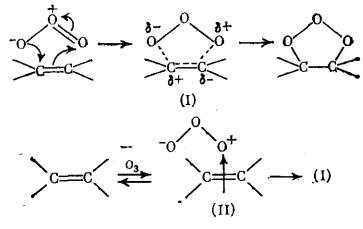
Ozonolysis—A Modern Method in the Chemistry of Olefins

V.N.Odinokov and G.A.Tolstikov

The review is devoted to the advances in the last ten years in the development of the ozonolysis of olefins as a synthetic method, in the study of the structures of peroxy-products of the azonolysis, and in the study of the stereochemistry of ozonides, which have in many respects determined the progress in our ideas concerning the mechanism of the ozonolysis of olefins.
The bibliography includes 351 references.

CONTENTS



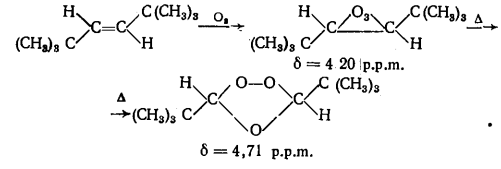
I. Introduction 636
II. Peroxy-products of ozonolysis and the mechanism of the ozonisation of olefins 636
III. The influence of the structure of olefins and the ozonisation conditions on the structure of peroxy-products of ozonolysis 640
IV. Reactions of peroxy-products of ozonolysis 644

I. INTRODUCTION

The ozonolysis† of olefins has become not only a recognised analytical method for the determination of the structures of unsaturated compounds, but also a method for the highly selective introduction of oxygen-containing functional groups into the organic molecule at the site of the double bond. The development of the ozone generation technique and of the ozonolysis process itself has attained a level such that this reaction has acquired increasing importance for technology[1]. In recent years the study of the structures of peroxy-products of ozonolysis and of the stereochemistry of ozonides, which has in many respects promoted progress in our ideas concerning the mechanism of the ozonisation of olefins, has been prosecuted particularly vigorously in recent years.

II. PEROXY-PRODUCTS OF OZONOLYSIS AND THE MECHANISM OF THE OZONISATION OF OLEFINS

It has now been established that the ozonolysis of olefins begins with the addition of an ozone molecule to the double bond. The adduct, in which the carbon–carbon bond still persists, has been called the primary ozonide[2] (in this review it is henceforth referred to as the primary ozonide). It is formed via a mechanism involving electrophilic 1,3-dipolar cycloaddition[3] via transition state (I) in which the electrophilic oxygen of the ozone molecule is bound to the carbon atom of the double bond more strongly than the nucleophilic oxygen atom. The interacting ozone and olefin molecules can attain the semipolar transition state (I) either via a single-step concerted cycloaddition[3] or via an additional reversible stage in which the π-complex (II) is formed[4-6]:



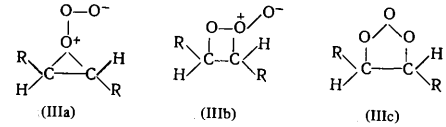
(I)

(II)

†The term "ozonolysis" is used in this review for the entire process involving the cleavage of the double bond by ozone, leading to the final peroxy- or non-peroxy-products. The term "ozonisation" refers only to the action of ozone on an unsaturated compound.

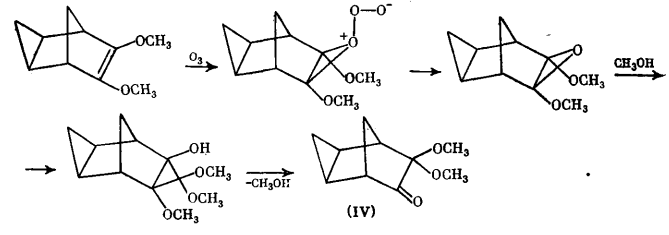
π-Complexes of ozone with aromatic compounds and arylethylenes have been detected by spectrophotometry and ^{1}H NMR at temperatures between −150 and −155 °C.[7,8] Similar complexes have also been observed for the usual olefins[9,10].

The formation of the primary ozonide is an irreversible process occurring with liberation of 37–39 kcal mol^{-1} of heat[11]. The primary ozonide derived from *trans*-1,2-di-t-butylethylene has been detected by ^{1}H NMR at −110 °C and its conversion into the normal ozonide with increase of temperature has been observed[12]:



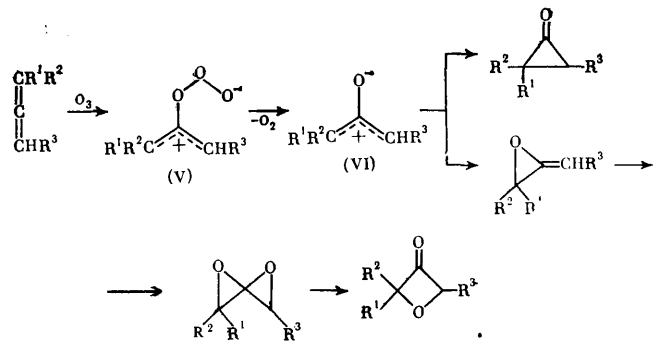
δ = 4.20 p.p.m.

δ = 4,71 p.p.m.



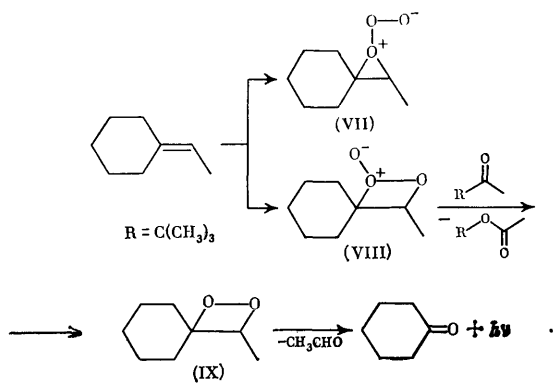
The primary ozonides of other olefins are less stable. The ^{1}H NMR spectra of the primary ozonides of *cis*-olefins recorded at −130 °C contain a broad and poorly resolved signal due to the ring protons in the range 4.35–4.40 p.p.m.[12,13] The greater stability of the primary ozonides derived from *trans*-olefins has been confirmed by quantum-mechanical calculations[14] and microwave spectroscopy[15].

Three probable structures of the primary ozonides have been discussed:



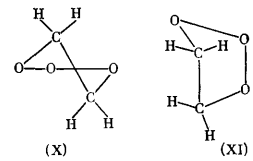
(IIIa) (IIIb) (IIIc)

The formation of the peroxyepoxide (IIIa) or the σ-complex can occur in the ozonisation of sterically hindered olefins, where the reaction products are epoxides[16-18]. The formation of the "anomalous" ozonolysis product (IV) has also been attributed to the formation of the σ-complex[19]:



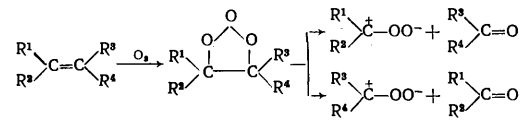
(IV)

In the case of hindered allenes the formation of the initial intermediate (V) as a consequence of the electrophilic attack by ozone has been postulated[20]. The elimination of oxygen leads to the stabilised zwitter-ion (VI), which is converted into the final ozonolysis products:



In conformity with the "unifying concept"[21], it has been suggested that the addition of ozone to the double bond of a compound, for example, ethylidenecyclohexane, gives rise to a peroxyepoxide or the σ-complex (VII), which is then converted into the Staudinger four-membered molozonide (VIII), capable of oxidising the excess aldehyde or ketone via a reaction of the Baeyer–Villiger type. The molozonide (VIII) is then converted into the dioxetan (IX) and then into cyclohexanone and acetaldehyde[22,23]:

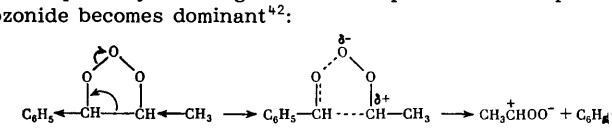
However, these results were not subsequently confirmed[24–28].



A decisive argument in support of the 1,2,3-trioxolan structure of the primary ozonide (IIIc) rather than that of the molozonide (IIIb) has come from ^{1}H NMR spectra[13,24]. Only one signal due to the methylidyne ring protons has been observed in the spectra of the primary ozonides of symmetrically disubstituted olefins, while in the case of structure (IIIb) these protons would not have been equivalent. Although in the peroxyepoxide (IIIa) both ring protons may also give rise to the same chemical shift, the signal would be significantly displaced downfield as a consequence of the deshielding influence of the positive charge on the neighbouring oxygen atom.

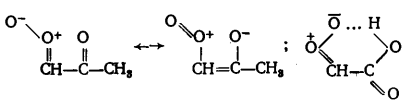
It has been suggested that the carbon–carbon bond in the 1,2,3-trioxolan ring has partial double bond character[29]. Indeed X-ray diffraction yielded a bond length of 1.44 Å, which is the mean of the lengths of single (1.54 Å) and double (1.34 Å) bonds[30]. The low stability of the primary ozonides hinders the study of their conformations by the usual methods. The quantum-chemical calculation, which permitted a choice between the possible half-chair (X) and envelope (XI) conformations of the primary ozonides of lower olefins in favour of the latter as the more stable, proved extremely effective[31]:

Thus electrophilic 1,3-dipolar cycloaddition of ozone to a carbon–carbon double bond results in the formation of a primary ozonide, which in most cases has the structure of a 1,2,3-trioxolan.

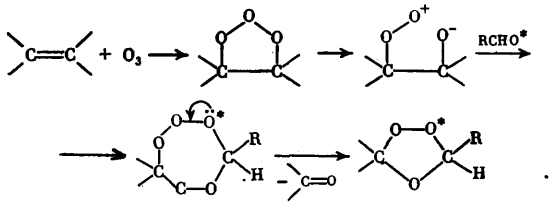


The energy-rich O–O–O linkage and the appreciable ring strain caused by the steric hindrance due to the three neighbouring oxygen atoms are responsible for the low stability of 1,2,3-trioxolan and the ease of its conversion into 1,2,4-trioxolan or the normal ozonide[32]. The mechanism of the conversion of the primary ozonide into 1,2,4-trioxolan has been widely discussed in the last ten years. Up to the middle of the 1960s, Criegee's mechanism[33], which provides a satisfactory explanation of the formation of normal and "cross" ozonides (both monomeric and oligomeric), cyclic dimeric and linear oligomeric peroxides, and "anomalous" ozonolysis products in ozonisation in inert solvents, as well as the formation of α-substituted hydroperoxides in ozonisation in a "participitating" proton-donating solvent of the type HX (X = OH, OR, OCOR, NH_2, NHR, NR_2 or CN), was generally accepted[16,34,35]. A fundamental feature of this mechanism is the formation of a zwitter-ion and of a carbonyl compound as a result of the heterolytic cleavage of the O–O and C–C bonds in the 1,2,3-trioxolan ring of the primary ozonide. For an asymmetric olefin, there is a possibility of two pathways leading to the cleavage of the primary ozonide with formation of different zwitter-ions:

It has been shown in many instances[11,36] that the mode of decomposition of the primary ozonide is determined mainly by the inductive effect of the substituents, while the mesomeric effect plays a secondary role[37]. The mode of the cleavage of primary ozonides can be conveniently investigated by analysing the products of the reaction of the zwitter-ions with methanol, which takes place quantitatively. The α-methoxyhydroperoxides formed correspond to the initial zwitter-ions[38–40]:

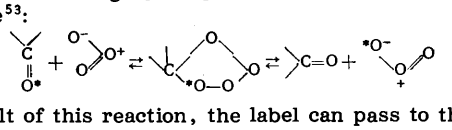


It has been established that electron-donating groups at the double bond promote the formation of a zwitter-ion with the neighbouring carbon atom as a consequence of the decrease of the local positive charge on the latter; correspondingly electron-accepting substituents destabilise the zwitter-ion and facilitate the formation of a carbonyl compound[39,41]. If the substituents exert the same influence, one of the pathways leading to the decomposition of the primary ozonide becomes dominant[42]:

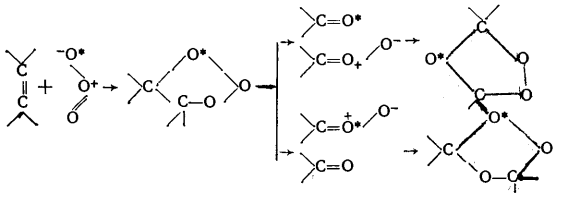


The groups stabilising the zwitter-ion can be arranged in the sequence $CH_3CO > CH_3COOH > C_6H_5 > H > CH_2OH > COOCH_3$. The stabilising influence of the keto-group can be accounted for by the possibility of its participation in the delocalisation

of the charge. The carboxy-group stabilises the zwitter-ion as a result of the formation of a hydrogen bond:

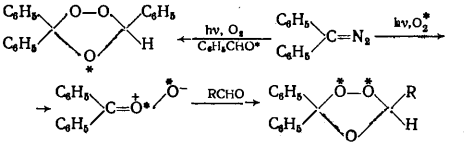


A pathway to the ozonide via a seven-membered cyclic intermediate (XII)—the product of the attack on the primary ozonide by an aldehyde molecule—which constitutes an alternative to the Criegee mechanism, has been proposed[43-46]. The main evidence in support of the new mechanism is the significant incorporation of the ^{18}O label into the peroxide bridge of the ozonide, which has been observed in the ozonisation of *trans*-1,2-di-isopropylethylene and ethylidenecyclohexane with participation of labelled acetaldehyde and propionaldehyde respectively[43,44]:

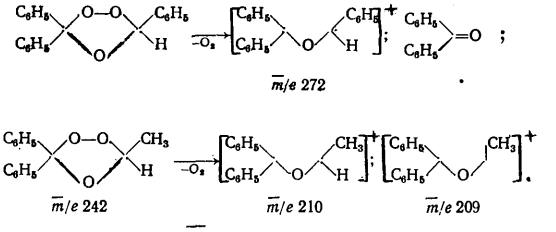


(XII)

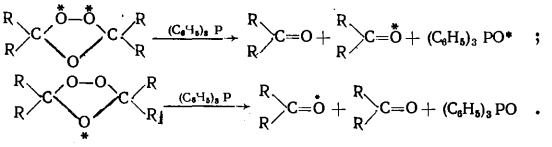
The results of the ozonolysis of *cis*- and *trans*-di-isopropylethylenes in the presence of [^{18}O] isobutyraldehyde confirmed the preferential incorporation of the label in the peroxide bridge[47]. However, in the ozonisation of phenylethylenes in the presence of [^{18}O] benzaldehyde[42,48,49] and subsequently also of lower olefins (ethylene, propene, and *cis*- and *trans*-but-2-enes) in the presence of [^{18}O]formaldehyde or [^{18}O]acetaldehyde[50] the label was found exclusively in the ether position in the ozonides. Furthermore, the joint ozonolysis of *cis*- and *trans*-di-isopropylethylene in the presence of [^{18}O]acetaldehyde even at a very low temperature (−110 °C), i.e. under the most favourable conditions for the exchange reaction between the aldehyde and the primary ozonide[52] led to the incorporation of the label in the ether bridge to the extent of 90%. An attempt was made to explain the slight (approximately 10%) incorporation of the ^{18}O label in the peroxide bridge of the ozonide by postulating a reversible exchange [2 + 3] reaction between the aldehyde and ozone[53]:



As a result of this reaction, the label can pass to the ozone molecule and with it into any position in the ozonide:



Although the possibility of such an exchange reaction of ozone with the aldehyde cannot be ruled out, under ozonisation conditions it can hardly compete appreciably with the very rapid reaction of ozone with the olefin.

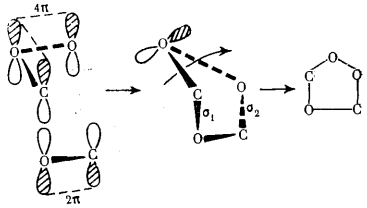


The conflict in the results for the distribution of the ^{18}O label in the ozonide can apparently be accounted for by differences in the methods of analysis. In some investigations[22,45,54] the ozonide was reduced with lithium tetrahydroaluminate with subsequent mass-spectrometric analysis of the resulting alcohols. In other investigations[42,47-49,51] the ozonides were subjected to a direct mass-spectrometric analysis. The method of microwave spectroscopy[15,50] is less susceptible to errors in interpretation, but it is applicable only to the ozonides of lower olefins. For ozonides known to contain the isotope label in the ether or peroxide position, it has been established that the M-32$^+$ fragment ion is formed as a result of the elimination of oxygen from the peroxide bridge of the ozonide. Such ozonides have been synthesised by the photoxidation of diphenyldiazomethane in the presence of benzaldehyde or acetaldehyde[55-58]:

The distribution of the label in ozonides is analysed by employing the molecular ion and the M-32$^+$ fragment[42,48,58]:

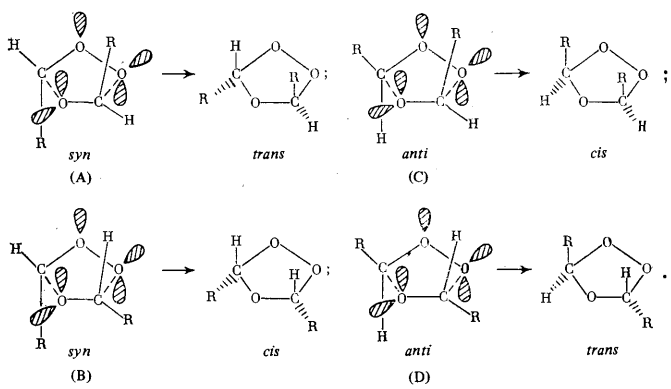
Labelled ozonides have been reduced with triphenylphosphine. Mass-spectrometric analysis of the resulting triphenylphosphine oxide showed that the attack is directed exclusively to the peroxide oxygen atom of the ozonide[58,59]:

This indirect method of determining the position of the ^{18}O label in ozonides proved to be the most reliable and convenient. With its aid it has been shown[58] that in the case of di-isopropyl ozonide—the product of the joint ozonolysis of di-isopropylethylene and ^{18}O-isobutyraldehyde—the label is located solely in the ether position, as shown by the absence of ^{18}O from triphenylphosphine oxide.



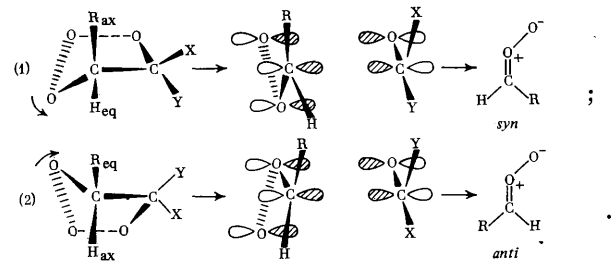
Thus the mechanism of the conversion of the primary ozonide into 1,2,4-trioxolan via the zwitter-ion must be recognised as the only correct one. The Criegee mechanism has been confirmed experimentally by the incorporation of the ^{18}O isotope label exclusively in the ether bridge of the ozonide in the joint ozonolysis of an olefin and the labelled aldehyde.

At the same time the initial Criegee mechanism[4] could not explain the dependence of the ratio of the ozonolysis products (ozonides, aldehydes, and peroxides) on the stereochemistry of the initial olefins[60]. According to Criegee's theory, the geometry of the initial olefin should not have influenced the composition of the ozonolysis product, because the same intermediate is formed from both isomers. Subsequent studies showed that ozonides can exist in the *cis*- and *trans*-forms and that the ratio of both "intrinsic" and "cross" isomers depends on the configuration of the initial olefin[61,62].

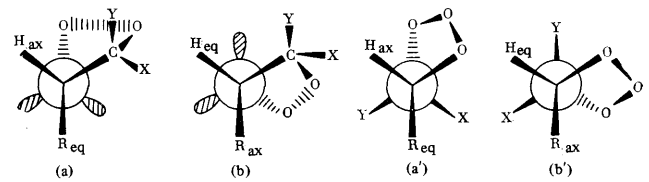


The configuration of a symmetrical disubstituted ozonide is determined by resolving it into its enantiomers. By obtaining one of the optically active forms of one of the isomers

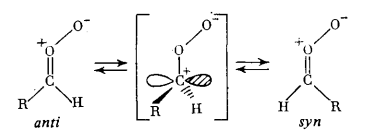
of 3,5-di-isopropyl-1,2,4-trioxolan, it was possible to conclude, for example, that the given isomer has the *trans*-configuration[63], because the *cis*-isomer is a *meso*-form and cannot be resolved into enantiomers. The configurations of a series of isomeric oxonides have been established by their chromatographic separation on acetylcellulose[64,65]. The ratio of the *cis*- and *trans*-ozonides can be determined from ^{1}H NMR spectra, provided that the spectrum of each configuration is known.



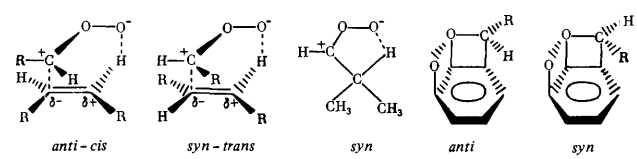
In order to explain the stereospecificity of the formation of ozonides, the existence of the zwitter-ion in the *syn*- and *anti*-configurations has been postulated[66], which was also assumed much earlier by Criegee[67]. Developing this theory, Lattimer et al.[15] considered the cyclodecomposition reactions of the primary ozonide and the cycloaddition of the zwitter-ion to the carbonyl group from the standpoint of the Woodward–Hoffmann theory, according to which ozone and the zwitter-ion are isoelectronic and have a π-system comprising four electrons. Correspondingly the π-systems of the alkene and the carbonyl compound have two electrons. Consequently the reactions involving the formation of the primary and final ozonides can be classified as supra,supra-addition of the 4π- and 2π-systems, which obeys the symmetry laws:



At the instant when the carbonyl group approaches the *syn*-zwitter-ion, the substituents R in the transition state can be oriented in two ways—(A) and (B). The transition state (A) is converted into the *trans*-ozonide and the transition state (B) is converted into the *cis*-ozonide. For the *anti*-zwitter-ion, the transition state model (C) gives rise to the *cis*-configuration of the ozonide and model (D) gives rise to the *trans*-configuration. Evidently models (A) and (C) should be preferable, because the bulky groups of the aldehyde in this case interact less strongly with the free electron pair at the terminal oxygen atom of the zwitter-ion. As a consequence of this, the *syn*-zwitter-ion is converted preferentially into the *trans*-ozonide, while the *anti*-zwitter-ion is converted into the *cis*-ozonide:



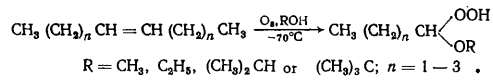
For the decomposition of the primary ozonide into the zwitter-ion and the carbonyl group, it is necessary that the oxygen adjoining the carbon atom converted into the zwitter-ion should be displaced from the "plane" of the ring of the primary ozonide. This transition state has the envelope conformation with axial (pathway 1, leading to the *syn*-zwitter-ion) or equatorial orientation of the substituent R (pathway 2, leading to the *anti*-zwitter-ion):



In order to determine which pathway is preferred for a specific olefin, it is sufficient to know the relative stabilities of the two possible transition states. In an estimate of this kind one must take into account the interactions of the substituent with the ring and with another substituent at the neighbouring carbon atom. These interactions are clearly seen in Newman's projection formulae with C–O (formulae a and b) and C–C (formulae a′ and b′) axes:

The zwitter-ion formed can isomerise to a zwitter-ion with the opposite configuration despite its short lifetime[68]:

It is known that specific solvation plays a significant role in the oxidation reactions of organic compounds[69]. It has been noted that the solvent and the olefin can stabilise the zwitter-ion by forming hydrogen bonds[70]. This effect is suppressed by an aromatic hydrocarbon[68], which can form a complex with the zwitter-ion, preventing or retarding its isomerisation:

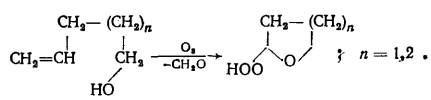


The detection of complex formation and the reversible interconversion of stereoisomeric carbonyl oxides is important for the understanding of the fine structure of the zwitter-ion. Recent calculations[31] showed that both ozone and the carbonyl oxide are singlet biradicals in their ground states. However, there is no experimental evidence for the formation of products of the reactions of the singlet biradical carbonyl oxide. For example, in the decomposition of *trans*-di-t-butyl-1,2,3-trioxolan in cumene or oct-4-ene, which are sensitive to radicals, no radical reaction products were detected[71]. Nor was it possible to detect radicals when the thermal decomposition of the same primary ozonide was followed with the aid of EPR.

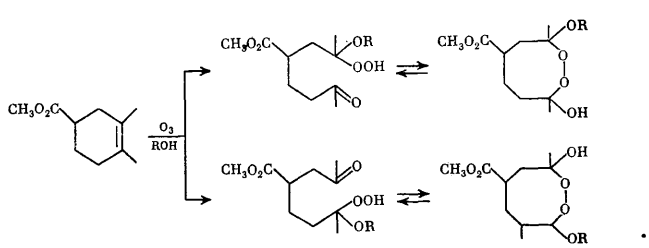
Thus the hypothesis of the existence of the zwitter-ion in the *syn*- and *anti*-configurations explains satisfactorily the experimental facts obtained hitherto, including the stereochemical features of the formation of ozonides. The attempt to show that the main intermediate in the ozonisation of olefi is a singlet biradical have not been supported by rigorous experimental data.

III. THE INFLUENCE OF THE STRUCTURE OF OLEFINS AND OZONIZATION CONDITIONS ON THE STRUCTURE OF PEROXY-PRODUCTS OF OZONOLYSIS

The solvent has a decisive influence on the structure of the peroxy-product of ozonolysis. In the ozonisation of olefins in proton-donating solvents (alcohols, carboxylic acids, and water) the zwitter-ion is as a rule stabilised by the addition of a solvent molecule, giving rise to α-substituted hydroperoxides[11,16,72].

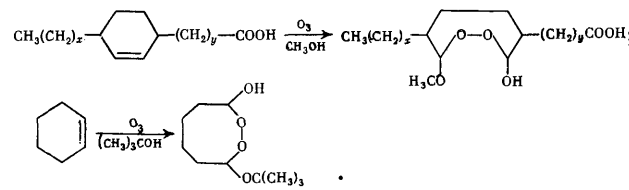


Individual alkoxyhydroperoxides have been isolated from the peroxy-products of the ozonolysis of symmetrical olefins[73]:

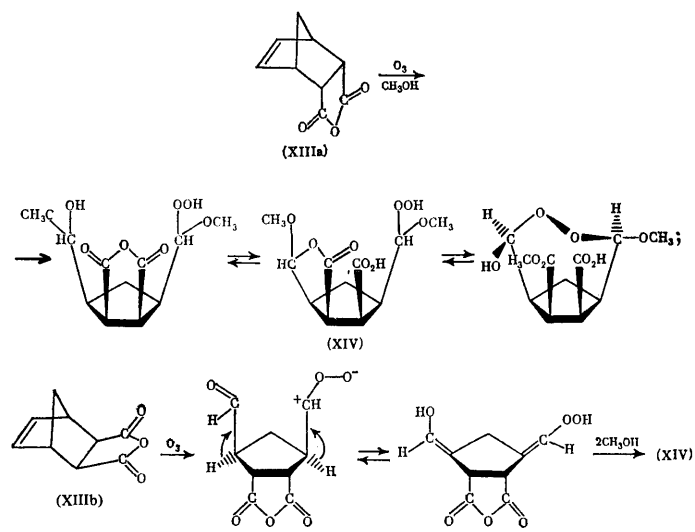


$R = CH_3$, C_2H_5, $(CH_3)_2CH$ or $(CH_3)_3C$; $n = 1-3$.

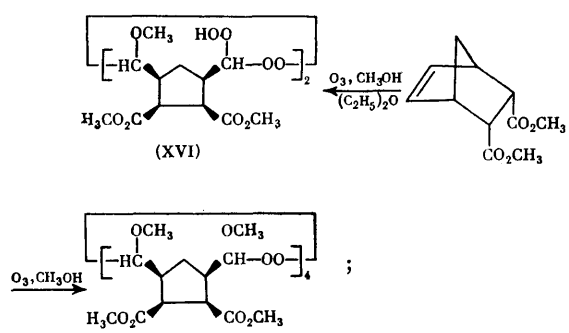
In the ozonisation of *cis*-octadec-9-ene in various alcohols (C_1–C_{16}) and monocarboxylic acids (C_2–C_{18}) or in an inert solvent containing the same alcohols or carboxylic acids in equimolar proportions, the products are the corresponding α-alkoxy- and α-acyloxy-hydroperoxides[74]. Symmetrical di-(α-hydroxyalkyl) peroxides have been obtained by the ozonisation of α-olefins in aqueous acetone[75].



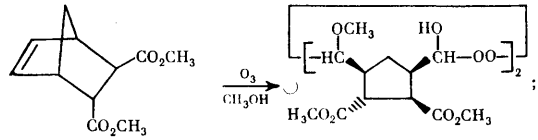
If the proton-donating group is present in the olefin molecule itself, it is involved in the stabilisation of the zwitter-ion[76]. When its position is favourable for the formation of five- or six-membered rings, such stabilisation becomes preferential[77]:

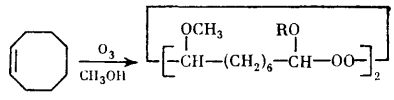


The interaction of the hydroperoxy- and formyl groups leads to the formation of α,α′-disubstituted peroxides. Depending on the nature of the olefin, the products of this reaction can have different structures. Whereas monomeric compounds are formed preferentially from linear olefins[78], in the case of cyclohexene derivatives the main products are oligomeric hemiperacetals[79,80]. However, monomeric cyclic peroxides are formed from cyclohexenes with bulky substituents[81,82]:



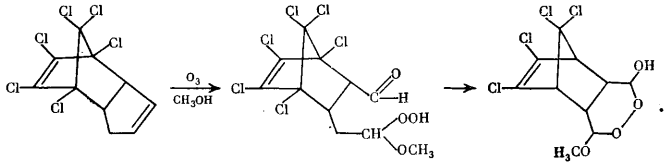
Monomeric α-methoxyhydroperoxides are obtained in the ozonisation of alkylidene- and benzylidene-adamantanes in methanol[83]. The mode of the intramolecular interaction of the hydroperoxy- and formyl groups can be regulated by the presence of bulky substituents next to the double bond[84] or by alcoholic groups[81]:

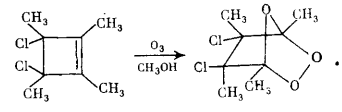




If the formyl and hydroperoxy groups are close together, as, for example, in the ozonolysis product of norbornene[85], then the monomeric hemiperacetal is the main reaction product, while in the ozonisation of carboxy-derivatives of norbornene one obtains exclusively monomeric peroxy-compounds as a consequence of the involvement of the carboxy-groups in the intramolecular interaction[86]. The formation of the same peroxy-product from the *endo*-, *cis*-, and *exo*, *cis*-anhydrides (XIIIa) and (XIIIb) is evidence for the isomerisation of the formyl groups:

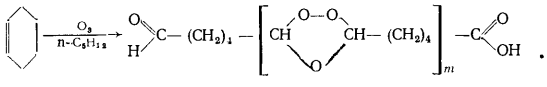
On the other hand, in the ozonisation of the dimethyl esters of the stereoisomeric bicyclo[2,2,1]hept-5-ene-2,3-dicarboxylic acids the products are exclusively oligomeric peroxides, the degree of oligomerisation being influenced by the stereochemistry of the methoxycarbonyl groups[87]. The reaction involving cyclo-octene yielded a cyclic bishemiperacetal (XV).[88] If the ozonisation of olefins is carried out in an ethereal solvent, the peroxide ozonolysis products (XVI) and (XVII), with an enhanced content of active oxygen, are formed[87,88]:



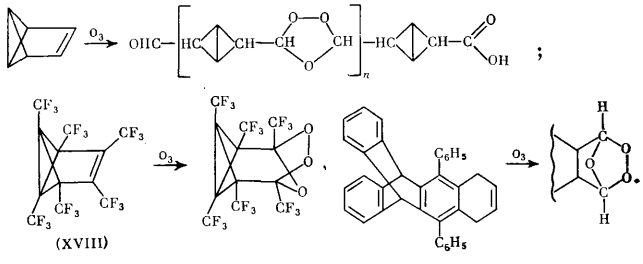


R = H (XV) or OH (XVII).

As a consequence of the deactivation of one of the double bonds by chlorine atoms, hexachlorobicyclopentadiene[89] and hexachlorobicycloheptadiene are attacked by ozone only at the unsubstituted double bond[90]:

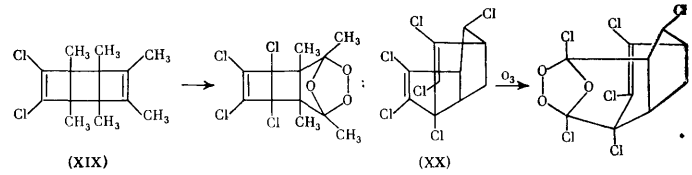


The steric influence can be so great that in the ozonisation of, for example, a substituted cyclobutene in methanol the attack on the zwitter-ion by the solvent is ruled out and the corresponding ozonide is formed[91]:



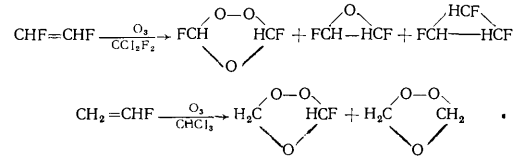
When tetraphenylethylene is ozonised in a mixture of chloroform and methanol, the product is the bishydroperoxide of diphenylmethane instead of the expected methoxyhydroperoxide[92].

The main products of the ozonisation of acyclic olefins in inert solvents are monomeric ozonides[34,93], but oligomeric ozonides are also formed. The yield of the latter depends on the solvent polarity and the structure of the olefin[34,94]. Oligomeric products are obtained almost exclusively from sterically unhindered six-membered olefins[95]:



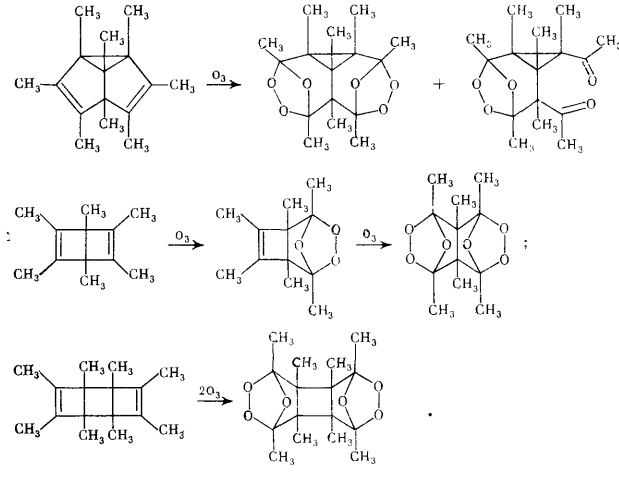
The ozonisation of cyclopentene and cyclobutene gives rise to monomeric ozonides[18,96-98], although the formation of oligomers in this case too has been noted[95].

Oligomeric ozonides are obtained from hexachlorobicyclo-[2,2,1]hepta-2,5-diene[90] and benzvalene[99]. However, the hexakis(trifluoromethyl) derivative (XVIII) gives a high yield of the monomeric ozonide[100]. For steric reasons, monomeric ozonides are also formed from polynuclear hydroaromatic hydrocarbons[101]:

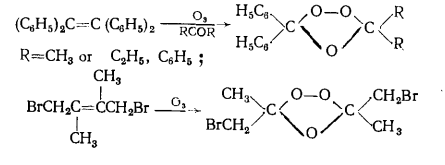


(XVIII)

In the presence of double bonds with electron-donating and electron-accepting substituents [for example, in compound (XIX)] the bond with the higher electron density is attacked[89]. In the polycyclic compound (XX) one of the chloro-substituted double bonds was ozonised[102]:

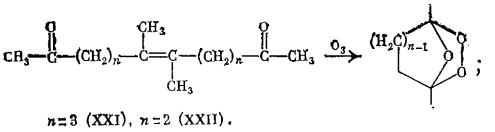


(XIX) (XX)

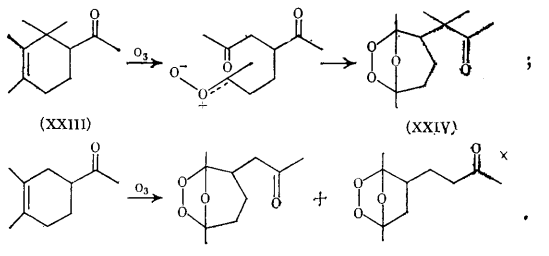


The ozonisation of *cis*- and *trans*-1,2-difluoroethylenes gives rise to a mixture of the ozonide (30%), the epoxide (15%), and trifluorocyclopropane (0.4%),[103] while fluoroethylene yields a mixture of ozonides[104]:

The corresponding diozonides are formed in the ozonisation of octamethylsemibullvalene[96,105], hexamethylbicyclo[2,2,0]-hexa-2,5-diene[106], and octamethyltricyclo-octadiene[107]:

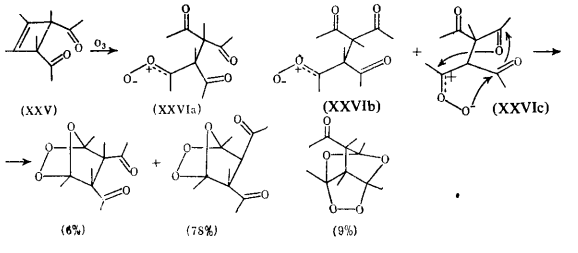


Trisubstituted[108] and tetrasubstituted[109] "cross" ozonides have been synthesised by the ozonisation of appropriately substituted olefins in the presence of an excess of the ketone. If the keto-group, arising on cleavage of the olefin, is activated by an electronegative substituent, then "intrinsic" ozonides are formed in a high yield[110]:



When a keto-group is present in the olefin molecule, there is competition between intramolecular and intermolecular reactions. Thus, in the ozonisation of the diketoalkenes (XXI) and (XXII), the intramolecular reaction of the zwitter-ion

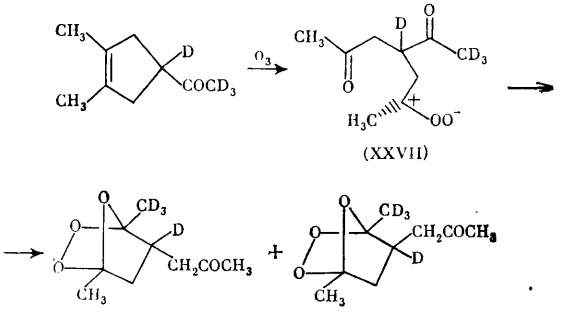
predominates and the ozonides of dimethylcyclopentene and dimethylcyclobutene respectively are formed in high yields[111]:



$n=3$ (XXI), $n=2$ (XXII).

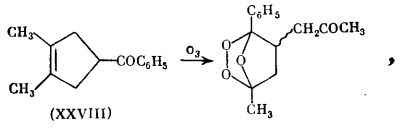
In the ozonisation of ketocyclo-olefins intramolecular competition of the two carbonyl groups is observed. Owing to the steric hindrance by the geminal methyl groups in "Dallacker's" ketone (XXIII) only the ozonide of the substituted cyclopentene (XXIV) is formed; in the absence of these methyl groups, the corresponding ozonides of both cyclopentene and cyclobutene are obtained[112]:

(XXIII) (XXIV)



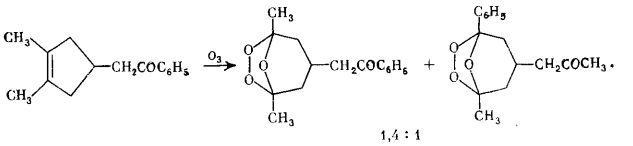
The zwitter-ion formed in the ozonisation of the symmetrically substituted cyclobutene (XXV) can have different conformations (XXVI, a–c), which lead to three products respectively[113]:

(XXV) (XXVIa) (XXVIb) (XXVIc)



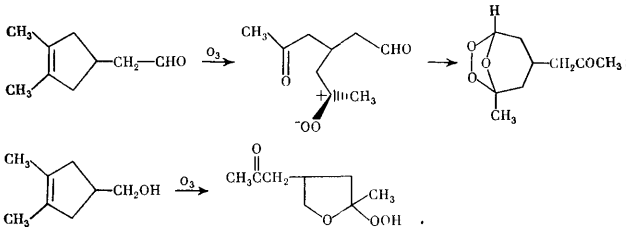
(6%) (78%) (9%)

In the zwitter-ion (XXVII), which contains two acetyl groups, there is interaction with the nearest acetyl group, because this leads to the more stable ozonide of cyclobutene[26]:

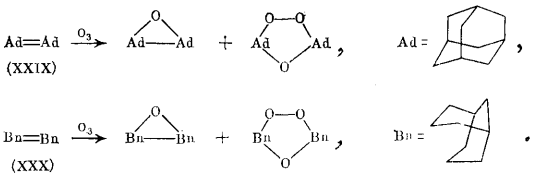


(XXVII)

For the same reason, in the ozonisation of compound (XXVIII) the reaction of the zwitter-ion with the benzoyl group and not with the more reactive acetyl group takes place preferentially. If the carbonyl groups are located in equivalent positions, the acetyl group is the more reactive[26]:

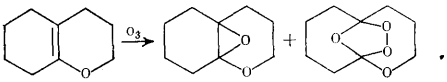


(XXVIII)

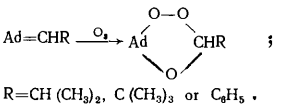


1,4 : 1

If a formyl or hydroxy-group is present, the zwitter-ion reacts with them and not with the acetyl group[26]:

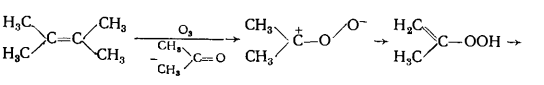


Sterically hindered olefins give rise to epoxides as well as ozonides. In the ozonisation of the alkenes (XXIX) and (XXX) the corresponding epoxides are formed preferentially instead of the expected methoxyhydroperoxides even in the presence of methanol[114]:

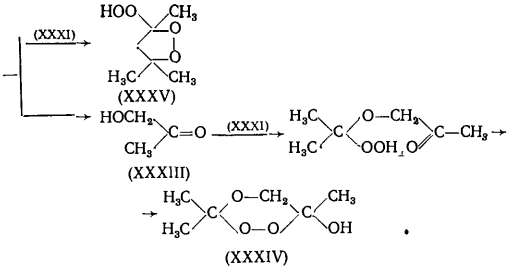


(XXIX) (XXX)

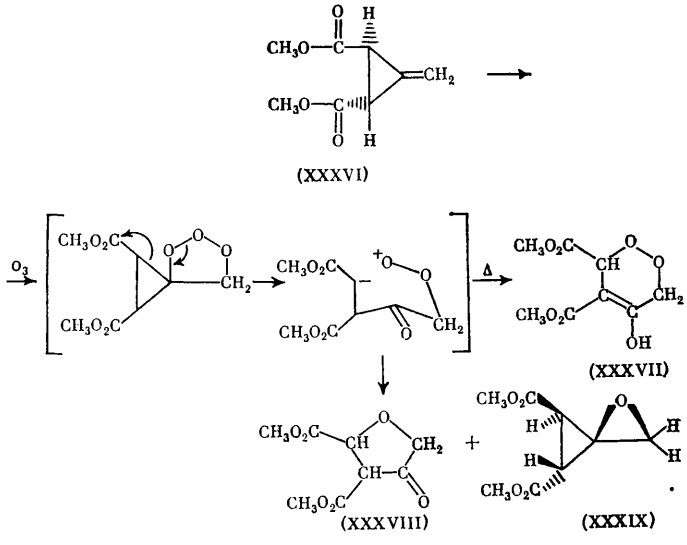
An analogous behaviour has been observed in the ozonisation of tetrahydrochromone[115]:



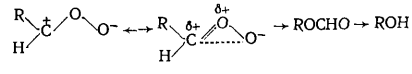
The steric hindrance may be so great that the double bond becomes inert towards ozone. Thus, whereas isopropyl-, t-butyl-, and phenyl-methyleneadamantanes normally give rise to ozonides, the replacement of the vinyl hydrogen atom by the t-butyl or phenyl group makes these compounds resistant to ozone[114]:



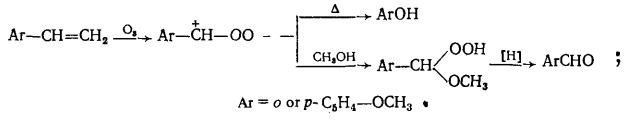
R=CH $(CH_3)_2$, C $(CH_3)_3$ or C_6H_5.



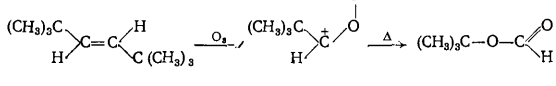
Certain zwitter-ions can be stabilised by isomerisation or rearrangement, which leads to anomalous peroxide or non-peroxide ozonolysis products. Thus the zwitter-ion (XXXI), formed in the ozonisation of tetramethylethylene, isomerises to the α-hydroxyketone (XXXIII) via the vinyl hydroperoxide (XXXII). This results in the formation of the six-membered trioxan (XXXIV) [109] or the cyclic hydroperoxide (XXXV):[116]



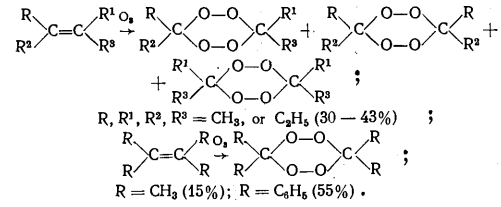
(XXXI) (XXXII)



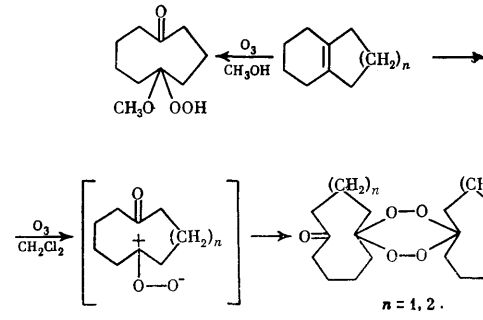
The ester of Feist's acid (XXXVI) is ozonised anomalously, being converted into a mixture of compounds (XXXVII)–(XXXIX). Evidently the peroxide (XXXVII) is the isomerisation product of the zwitter-ion[117]:



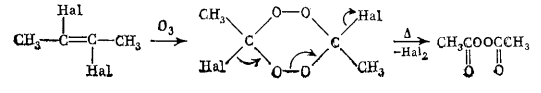
Anomalous ozonolysis products are usually observed when the zwitter-ion contains a group with a tendency towards migration[16]:



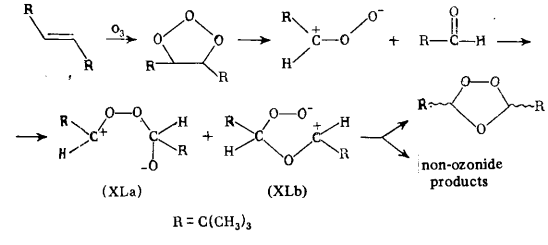
Such rearrangements are characteristic of zwitter-ions generated from substituted styrenes[118]. On the other hand, if the zwitter-ion is bound by methanol, anomalous products are not formed[119]:



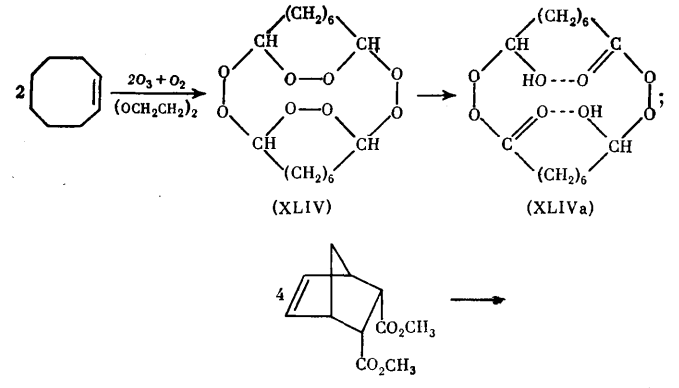
Alkyl groups show a much smaller tendency towards migration. In the ozonisation of even *trans*-di-t-butylethylene only 5% of t-butyl formate is formed[118]:



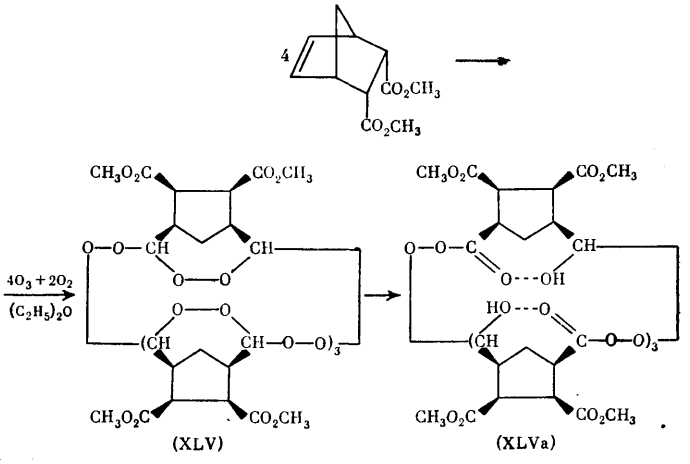
When the reaction is carried out in inert solvents, the formation of dimeric and oligomeric peroxides together with ozonides is frequently noted[32,110,120]. The yield of these compounds depends greatly on the structure of the olefin. Thus, whereas in the ozonisation of α-olefins only traces of dimeric peroxides are formed[11,16], dimeric normal and cross peroxides are obtained from tetrasubstituted ethylenes in yields ranging from 15 to 55%.[121]



The dimerisation of the zwitter-ion derived from 4,5,6,7-tetrahydroindan[122] and 9,10-octalin[123] leads to the corresponding cyclic diperoxides. The dimerisation does not occur when the ozonisation is carried out in methanol[122]:



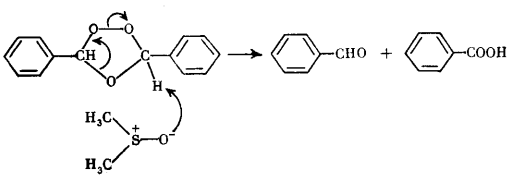
Diacetyl peroxide is obtained from *trans*-2,3-dibromobut-2-ene, probably via an intermediate cyclic diperoxide[124]. The crystalline dimeric α-chloroperoxide has been isolated in the reaction of the dichloro-derivative[125]:



The influence of the solvent on the formation of ozonides has been studied in detail in relation to *trans*-di-t-butylethylene[71]. It has been shown that the ozonide is formed only in non-polar solvents (hydrocarbons), while in methylene chloride, trichlorofluoromethane, acetone, and ethyl acetate it is not formed at all. Ozonisation in diethyl ether at −75 °C does not give rise to the ozonide, but at a lower temperature (−90 °C) it is possible to obtain the ozonide in 25% yield. The addition of an extraneous aldehyde reduces the yield of both the normal and "cross" ozonides. These results have been explained by the stepwise recombination of the zwitter-ion and the aldehyde. In a non-polar solvent the intermediate (XLa) [71] or (XLb) [126] cyclises to the ozonide, while a polar solvent solvates it, increasing the lifetime and probability of side reactions (reactions with the carbonyl oxide and aldehyde as well as polymerisation)[71]:

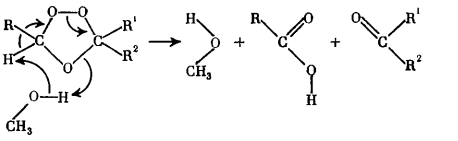
An oligomeric intermediate of type (XLa) or (XLb) solvated by a polar ethereal solvent can undergo further oxidation, which in the ozonisation of cyclic olefins leads to the peroxide ozonolysis products (XLIV) and (XLV),[88,127] which isomerise to the α-hydroxyperesters (XLIVa) and (XLVa):

(XLIV) (XLIVa)



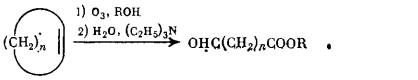
(XLV) (XLVa)

IV. REACTIONS OF PEROXY-PRODUCTS OF OZONOLYSIS

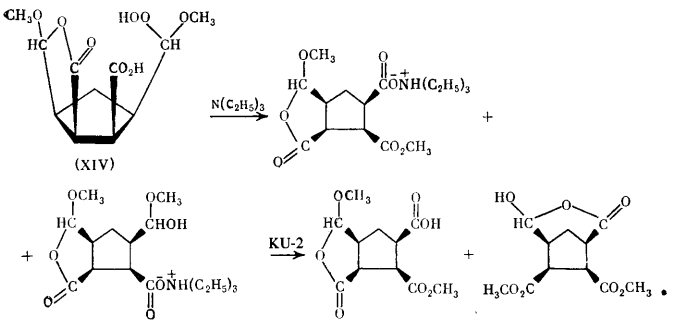


In the ozonisation of olefins a degree of oxidation intermediate between an aldehyde and carboxylic acid is attained. The reactions of ozonides and other peroxy-products of ozonolysis can be divided into two types: those occurring without a change in the degree of oxidation attained (cleavage reactions) and those with a change in the degree of oxidation (oxidation and reduction reactions).

The mode of decomposition of peroxy-compounds depends significantly on the nature of the solvent[69]. The acidity of the medium also influences hydrolysis, solvolysis, alcoholysis, and acidolysis.

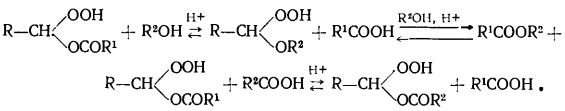


The usual products of the cleavage of ozonides are the corresponding aldehydes and carboxylic acids[16,34]. In an aqueous medium ozonides are cleaved with difficulty[16], but under the influence of strongly solvating solvents (dimethyl sulphoxide, dimethylformamide, and amines) the fragmentation of stilbene ozonide proceeds rapidly and quantitatively[128]:

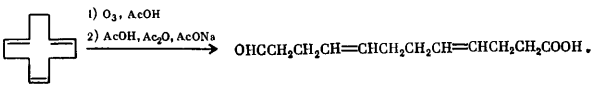


In methanol and benzyl alcohol the rate of fragmentation of ozonides is significantly higher than in benzene, di-isopropyl ether, dioxan, and tetrahydrofuran[65,129]. The solvolysis of ozonides proceeds at identical rates in neutral and weakly acid media, while in an alkaline solution the process is accelerated. The isotope effect observed in the methanolysis of deuterated ozonides[65] shows that the stage involving the elimination of a proton from the trioxolan ring is rate-determining. The exceptional role of the alcohol in the fragmentation of ozonides can be explained by the fact that it behaves simultaneously as a "base" and an "acid"[65]:

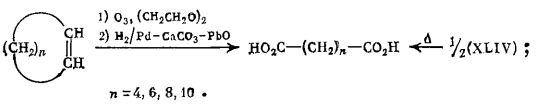
α-Substituted hydroperoxides are cleaved more readily than ozonides[130]. Thus the hydrolysis of alkoxyhydroxyperoxides derived from cyclic olefins gives rise to the esters of the corresponding ω-formylcarboxylic acids in 85% yield[131]:



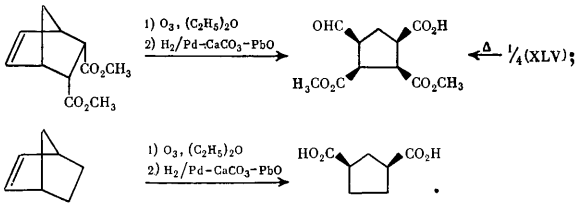
The isomerisation of the hydroperoxy-group to the carboxylate group has been observed in the interaction of the peroxide (XIV) with triethylamine[86]:



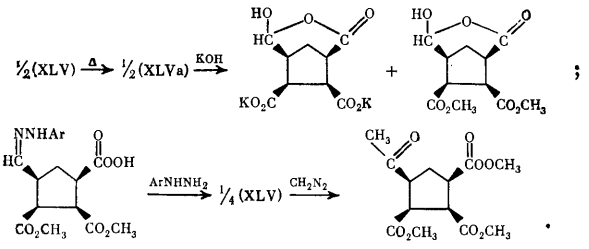
(XIV)



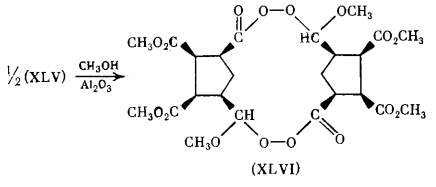
α-Acyloxyhydroperoxides undergo transesterification[132]:



The acidolysis of the product of the controlled ozonolysis of cyclic polyolefins in acetic acid leads to unsaturated ω-formylcarboxylic acids[133]:

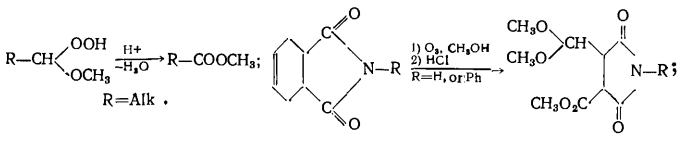


The isomerisation and cleavage of peroxides with a high content of active oxygen, which are formed in the ozonisation of cyclo-olefins in ethereal solvents[88], leads to the corresponding α,ω-dicarboxylic acids, which constitutes a new method of synthesising carboxylic acids without the need for an additional oxidation stage after ozonisation[134-136]:

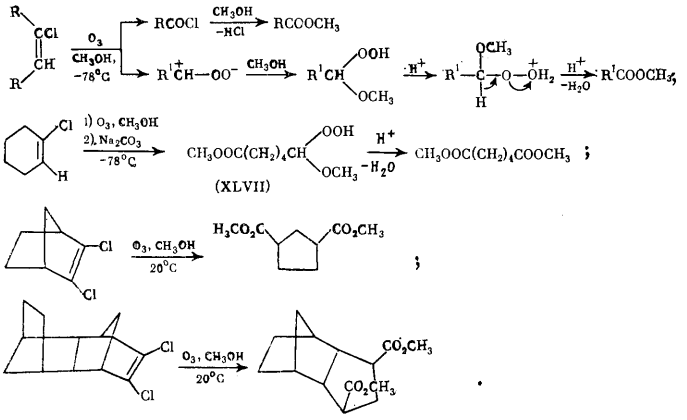


The fragmentation of the peroxide (XLV) yields the corresponding formylcarboxylic acid, while the ozonolysis of 2-norbornene in an ethereal solvent results in the formation of *cis*-cyclopentane-1,3-dicarboxylic acid[127]:

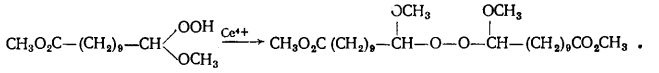
The fragmentation of the peroxide (XLV) also takes place in an alkaline solution and its interaction with diazomethane or 2,4-dinitrophenylhydrazine leads to the formation of peracid groups[127]:



On being eluted with methanol from alumina, the tetrameric peroxide (XLV) is converted[127] into the dimeric α-methoxyperester (XLVI):

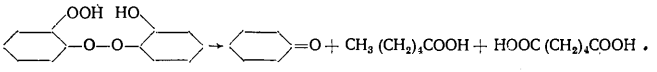


(XLVI)

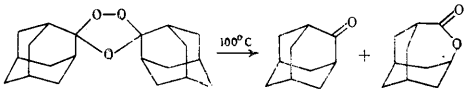


Alkoxyhydroperoxides derived from trisubstituted and asymmetrically disubstituted olefins hydrolyse rapidly to the corresponding ketones and alcohols[137]. Peroxides obtained from symmetrically disubstituted olefins do not give high yields of aldehydes under these conditions. Treatment with hydrogen chloride converts methoxyhydroperoxides quantitatively into the methyl esters of the corresponding carboxylic acids[138]. Derivatives of ω-formylcarboxylic acids have been obtained under these conditions from certain cyclic olefins[139]:

The peroxides formed in the ozonisation of chloro-olefins in methanol readily decompose into the corresponding methyl carboxylates. By neutralising the hydrogen chloride evolved, it is possible to isolate the methoxyhydroperoxide (XLVII):[138,140]

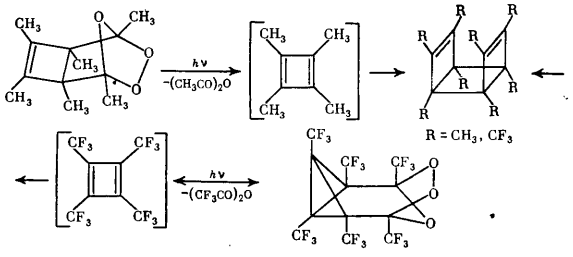


Oxidation of α-alkoxyhydroperoxides with cerium ammonium nitrate leads to the crystalline dialkoxyperoxides[129]:

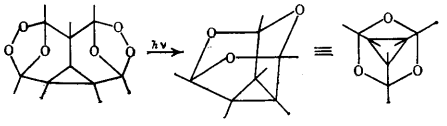


As in hydrolysis, the main products of the thermal decomposition of ozonides are the corresponding aldehydes and carboxylic acids[1,11,141].

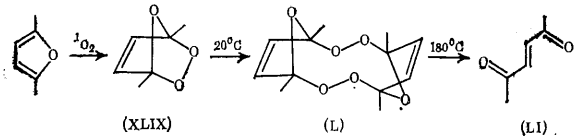
When α-hydroperoxy-α-hydroxydicyclohexyl peroxide is heated in boiling toluene, cyclohexanone is formed preferentially (25%) and there are lower yields of caproic (8%) and adipic (4%) acids[28]:



Thermal, and recently also photochemical, cleavage of ozonides has become a promising trend in organic synthesis[142]. Thus the thermolysis[96,142] of bisadamantylidene ozonide leads to the formation of adamantanone and the lactone (XLVIII):[114]

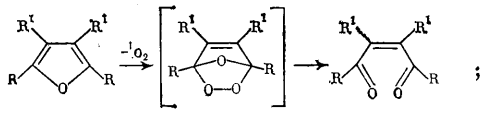


(XLVIII)

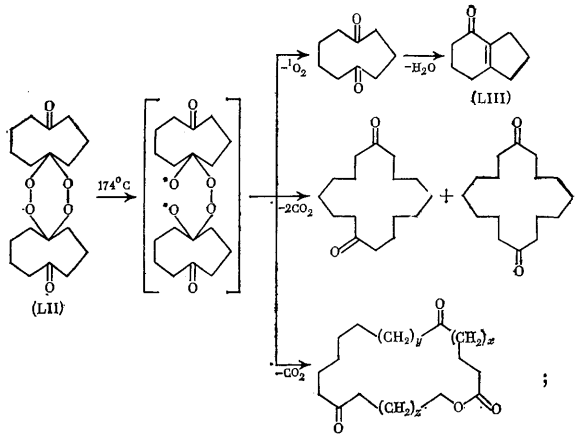


The photolysis of the mono-ozonides of Dewar hexamethylbenzene[143] and hexakis(trifluoromethyl)benzvalene[100] leads to the *syn*-dimers of tetramethyl- and tetrakis(trifluoromethyl)-cyclobutadiene:

The photolysis of the diozonide of octamethylsemibullvalene results in the formation of a triketal of a new type[103]:



Ozonides can be synthesised by methods other than the ozonisation of olefins[120]. The method involving the oxidation of furan derivatives with singlet oxygen[144], which can be readily obtained, for example, from the adduct of ozone with triphenyl phosphite[145,146] or with certain other compounds[147], is of special interest. The [4 + 2] cycloaddition results in the formation of the mono-ozonides of substituted cyclobutadienes[142]. Thus the photoxidation of 2,5-dimethylfuran yields the ozonide (XLIX), which is converted at room temperature into the stable dimer (L), the latter decomposing into the dione (LI) only at a high temperature[144]:



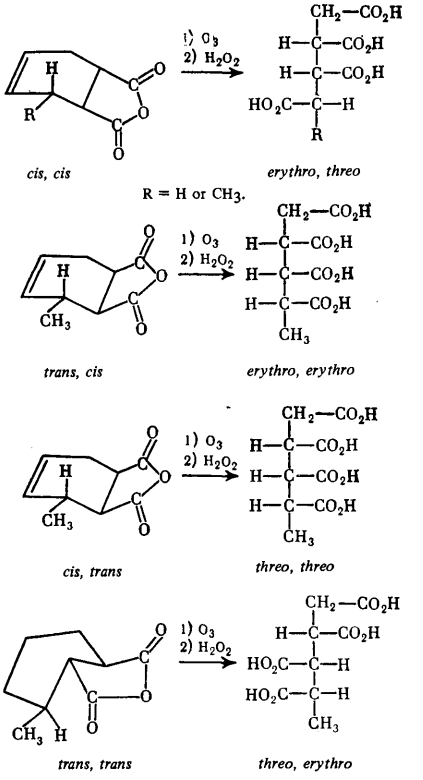
(XLIX) (L) (LI)

The photoxidation of substituted furans can be regarded as a general method of synthesis of *cis*-diacylolefins[142]:

R = R¹ = H; R = R¹ = C_6H_5; R = CH_3, R¹ = H; R = C_6H_5, R¹ = H .

The thermolysis and photolysis of cyclic di- and tri-peroxides have been considered in reviews[142,148]. Such peroxides are usually synthesised by the reaction of cycloalkanones with hydrogen peroxide[149]. In the ozonolysis of certain olefins they are formed as a consequence of the dimerisation of the zwitter-ion. The thermal or photochemical fragmentation of cyclic diperoxides leads to carbocyclenes, lactones, and cyclic ketones[142]. Thus the diperoxide (LII), obtained by the ozonolysis of 4,5,6,7-tetrahydroindan, is converted on heating in boiling decane into cyclononane-1,5-dione (18%), [cyclising to compound (LIII) during isolation], a mixture of cyclohexadecane-1,8-dione and cyclohexadecane-1,9-dione (50%), and four isomeric dioxoheptadecanolides (16%):[122]

(LII) (LIII)



x = 1, y = 3, z = 1; x = 1, y = 2, z = 2; x = 2, y = 2, z = 1; x = 2, y = 1, z = 2 .

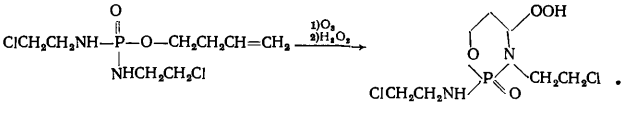
The reactions of ozonolysis peroxy-products under the influence of oxidants or reductants are widely used in preparative organic synthesis[16,34,150] and have already found application in industrial technology[1,151]. The oxidative decomposition of peroxy-products of ozonolysis takes place in two stages: the oxidation proper and thermal decomposition of peroxides. In the synthesis of carboxylic acids the two stages are combined or are arbitrarily divided in terms of temperature conditions#.

Oxidative decomposition occurs under the influence of oxygen at an elevated temperature. In this case oxidation initiators or catalysts (ozone, variable-valence metal compounds[1,16,153–159], inorganic salts in polar aprotic solvents[160], and aminoacids[161]) are used. The oxidants consist of a suspension of silver oxide in an alkaline solution[1,34,35], potassium permanganate[162], chromic acid[163], and nitric acid[164]. However, hydrogen peroxide usually employed as a mixture with formic or acetic acid, is the most convenient and most widely used reagent[1,35,150,165–167]. Investigators have paid particular attention to the synthesis of aliphatic α,ω-dicarboxylic acids[168,169], which are of greatest practical interest[1,170,171]. Methods combining the ozonisation and oxidation stages have been developed[1,35,172].

The ozonolytic synthesis of polycarboxylic acids and other polyfunctional compounds has been studied to a lesser degree. When the molecule contains several functional groups, they interact and complicate the oxidative decomposition. In the ozonolysis of cyclic polyenes or cyclo-olefins containing functional groups, catalysts increasing the process selectivity are therefore used.

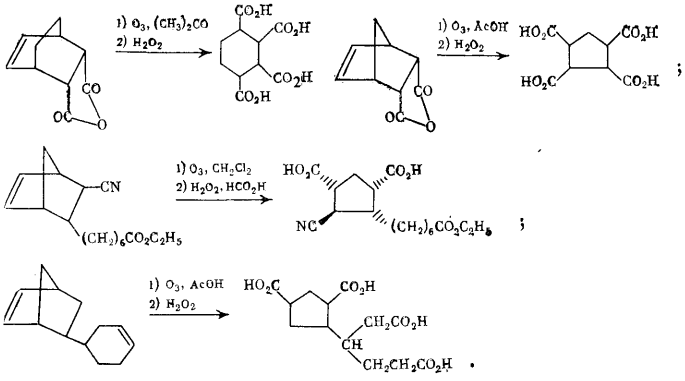
The isomeric butane-1,2,3,4-tetracarboxylic[174–176] and pentane-1,2,3,4-tetracarboxylic[177,178] acids have been synthesised by the ozonolysis of the stereoisomeric Δ^4-tetrahydro- and 3-methyl-Δ^4-tetrahydro-phthalic acids[173]:

cis, cis — *erythro, threo*



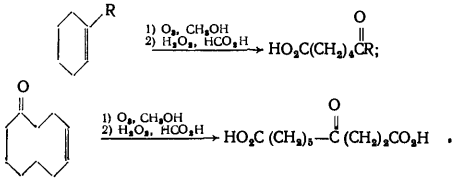
R = H or CH_3.

trans, cis — *erythro, erythro*

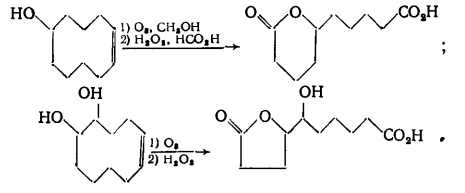


cis, trans — *threo, threo*

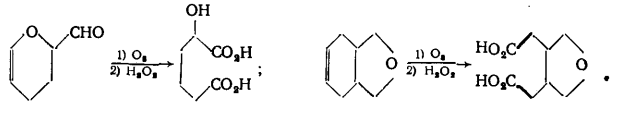
trans, trans — *threo, erythro*



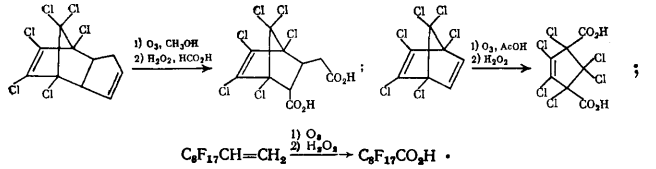
#In the ozonolysis of the alkenyl esters of phosphorodiamidic acids, peroxy-compounds were isolated after the first oxidative decomposition stage[152]:



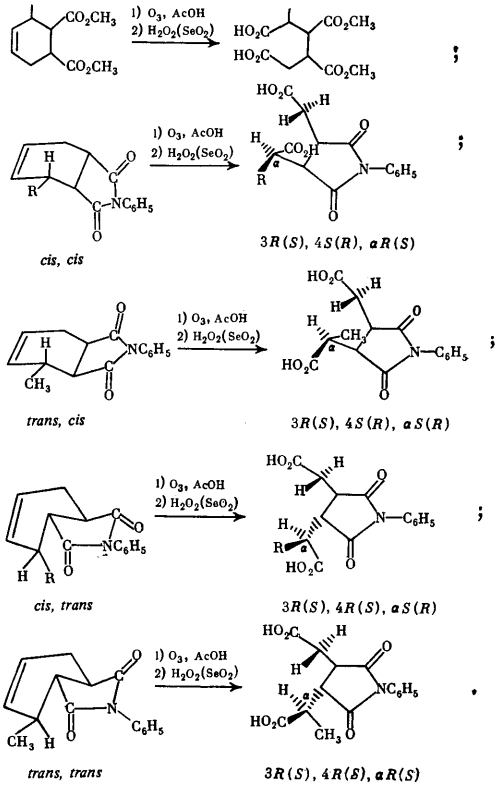
Cyclic polycarboxylic acids have been obtained from derivatives of bicyclic olefins[179–181] and tricarboxylic acids have been synthesised from alkenylcyclohexenes[182]:



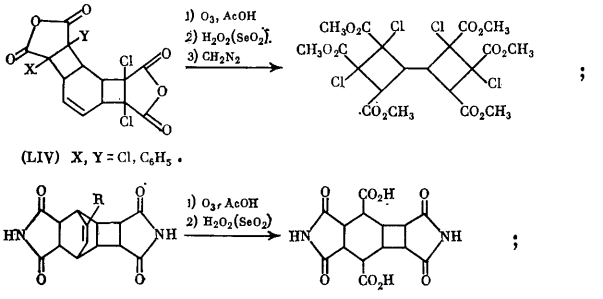
Ketocarboxylic and ketodicarboxylic acids have been obtained by the oxidative ozonolysis of 1-alkylcycloalkenes[183] and cycloalkenones[184] respectively:



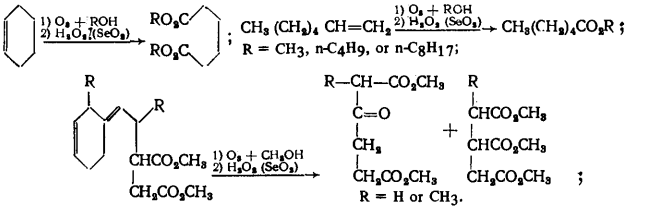
The ozonolysis of cyclo-olefins containing a hydroxy-group led to lactones whose hydrolysis constitutes a pathway to hydroxydicarboxylic acids[185,186]:



An α-hydroxydicarboxylic acid has been obtained from the acrolein dimer[187], while tetrahydrofuran derivatives have been synthesised from a cycloalkene condensed with a heterocycle[188]:

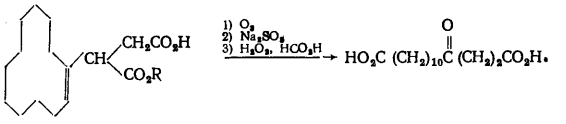


In order to synthesise polychloro-[89,90,189] and polyfluoro-derivatives[190] of di- and mono-carboxylic acids, the corresponding halogeno-derivatives of olefins have been ozonised:

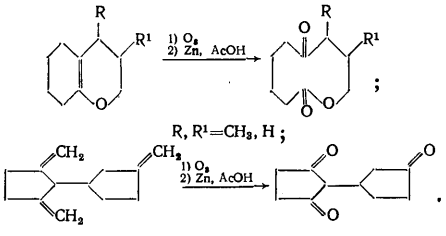


The oxidative decomposition of peroxy-products of ozonolysis, carried out by treatment with hydrogen peroxide, can be accelerated with the aid of selenium dioxide[191–193], in the presence of which the process proceeds under milder conditions with a higher selectivity. This makes it possible to increase the yield by 10–30% as well as the purity of the aliphatic polycarboxylic acids. Thus the 2,3-dimethyl ester of pentane-1,2,3,4-tetracarboxylic acid[191–193] and the corresponding stereoisomeric 3,4-disubstituted *N*-phenylpyrrolidine-2,5-diones[194–196] have been synthesised from the dimethyl ester and the stereoisomeric *N*-phenylimides of Δ^4-tetrahydrophthalic acid and its 3-methyl derivative:

The use of selenium dioxide permitted the successful ozonolysis of the polycyclic compounds (LIV) and (LV):[197,198]

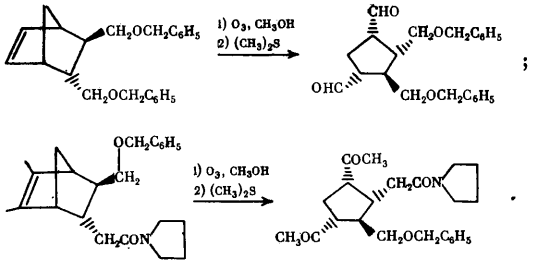


The oxidative decomposition of the peroxy-products of the ozonolysis of olefins in the corresponding alcohols led to the formation of carboxylic acid esters[193,199,200]:

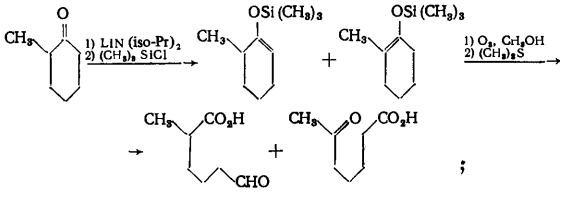


The copolymers of butadiene with isobutene[150,201,202] and styrene[203] have been converted by oxidative ozonolysis with participation of pyridine into the corresponding oligomers with terminal carboxy-groups. 3-Phenyladipic acid has been synthesised by the selenium dioxide-catalysed oxidative decomposition of the peroxy-product of the ozonolysis of regular butadiene–styrene rubber[204,205].

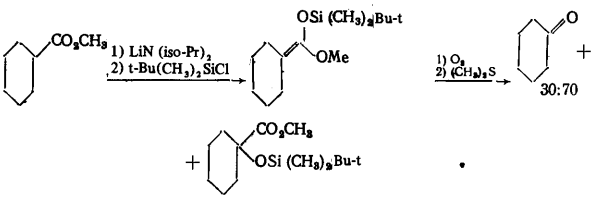
The peroxy-products of ozonolysis are sometimes subjected to preliminary reduction in order to facilitate the oxidative decomposition[206]:



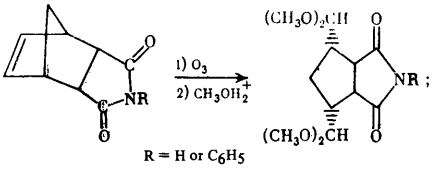
Various reductants, used to convert the peroxy-products of ozonolysis into aldehydes and ketones, have been listed in a number of reviews[16,34,207]. Among traditional reagents, sodium bisulphite[208], the lower-valence metal salts[209–211], alkali metal iodides[212], and sodium thiosulphate[213,214] have been used in recent years. Among inorganic reductants, zinc dust has been most often employed[215–219], for example, in the reductive ozonolysis of tetrahydrochromone derivatives[220] and the cyclo-oligomers of allene[221]:

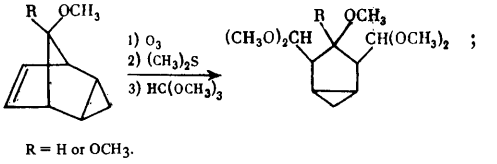


Organic reductants have been used on an increasingly wide scale in recent years. Dimethyl sulphide[222–224] and sometimes other dialkyl sulphides or thiacyclanes[225,226] have been used to synthesise alkoxyhydroperoxides:

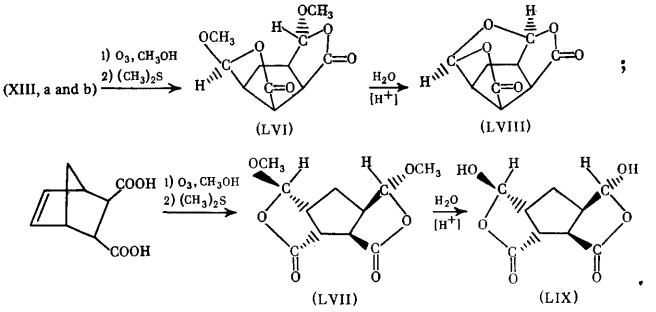


Dimethyl sulphide has been introduced into practical fine organic synthesis[227–230], for example, the synthesis of the intermediates for prostaglandins[231,232]:

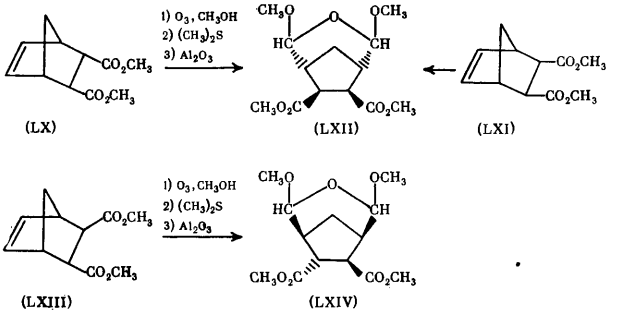


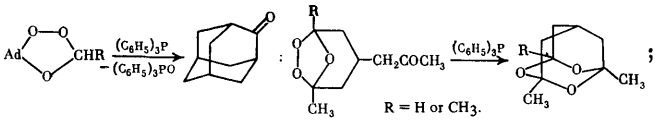


Ozonolysis has found an interesting application for the cleavage of ketones and carboxylic acids via the trimethylsilyl ethers of their enolic forms[233]:



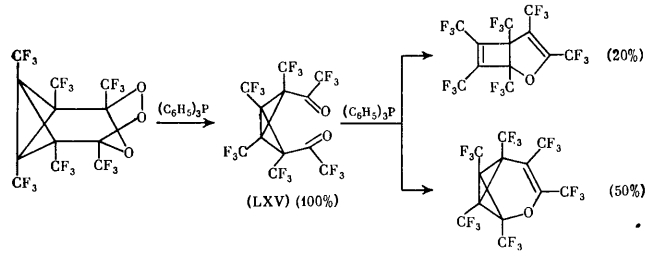
Aldehydes can sometimes be more conveniently isolated in the form of acetals[139,234–236]:



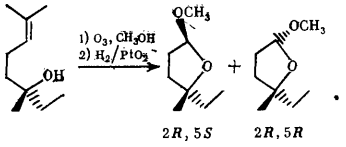


Under the influence of dimethyl sulphide, the peroxy-products of the ozonolysis of the *endo*-, *cis*- and *exo,cis*-anhydrides (XIII, a and b) give rise to the same *syn*-3,5-bis-(methoxymethyl)dilactone (LVI), while the *endo,exo*-diacid gives rise to the *anti*-isomer (LVII) under analogous conditions[237]. In the presence of water both the ozonolysis peroxy-products and the dilactones (LVI) and (LVII) are converted into oxygen-containing polyheterocyclic compounds (LVIII) and (LIX) respectively[86,237]:

The peroxy-products of the ozonolysis of the *endo,cis*- and *exo,cis*-diesters (LX) and (LXI) are converted on treatment with dimethyl sulphide into the same product (LXII), while the isomeric compound (LXIV) is formed under analogous conditions from the *endo,exo*-isomer (LXIII):[87,127]

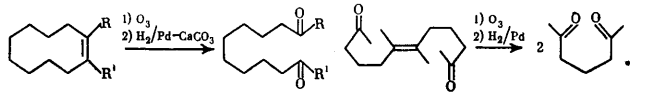


Glyoxylic acid has been used as the reductant in acetic acid[238]. Triphenylphosphine has been employed for the reduction of ozonides[239–241]. Thus the ozonides of substituted methyleneadamantantanes were converted quantitatively into adamananone after being refluxed with triphenylphosphine in hexane for 2 h.[83] The reduction of the ozonides of substituted cyclopentenes led to cyclic triacetals with the adamantane structure[26]:



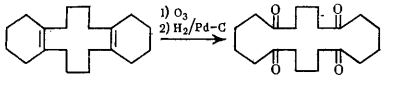
R = H or CH_3.

The ozonide of hexakis(trifluoromethyl)benzvalene has been reduced with an equimolar amount of triphenylphosphine to the diketone (LXV), which underwent further transformations in the presence of an excess of the reagent[242]:

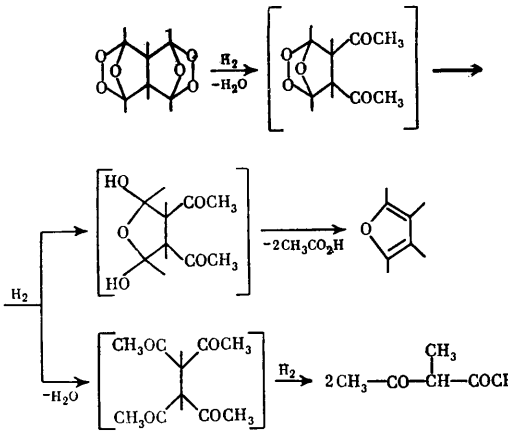


(LXV) (100%)

Methoxyhydroperoxides have been reduced electrolytically to aldehydes[243]. Selective hydrogenation on platinum group metals is a modern method[1,16,34,244–246]. Under these conditions, the product of the ozonolysis of dihydrolinalol in methanol gives rise to enantiomeric cyclic acetals, which have been separated by preparative gas–liquid chromatography[247]:

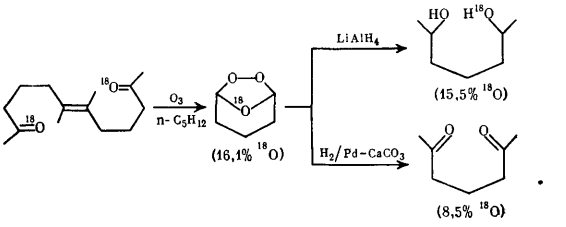


2R, 5S 2R, 5R

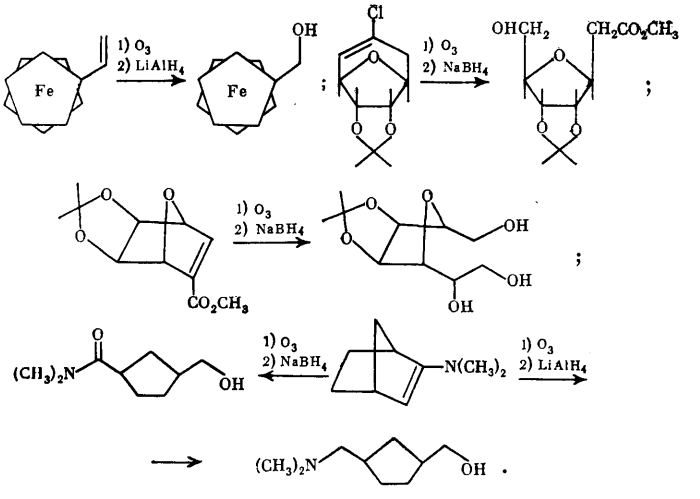


The hydrogenation of ozonides yields mainly the corresponding aldehydes, but the formation of carboxylic acids (up to 18%) as a consequence of disproportionation has also been noted[248]. If cyclohexene is ozonised in the absence of oxygen and then hydrogenated (Pd/C), then 66% of adipic dialdehyde and 24% of 5-formylvaleric acid are obtained[249]. The hydrogenation of the ozonides of substituted methyleneadamantanes results in the formation of adamantanone and the lactone (XLVIII).[83] Diketones have been obtained from cyclic[250] and linear[251] olefins with a substituted double bond:

Reductive ozonolysis has been used to synthesise macrocyclic ketones[149]:

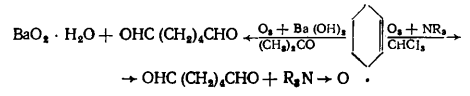


The hydrogenation of the diozonide of Dewar hexamethylbenzene led[106] to tetramethylfuran, which was identified in the form of the adduct with maleic anhydride, and to 3-methylpentane-2,4-dione:



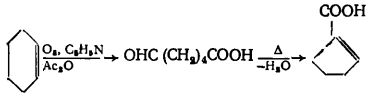
If the catalytic hydrogenation of ozonides is carried out under more severe conditions, the corresponding alcohols and glycols are obtained[252]. In the presence of amines the products are aliphatic amines[253], while diamines have been obtained from the cross-products of the ozonolysis of cycloolefins[254–256].

Complex alkali metal hydrides[1,257], boron[258], and organoaluminium compounds[259] are convenient reagents for the conversion of ozonides into alcohols. The complexes of lithium tetrahydroaluminate with chiral alcohols have reduced ozonides to optically active compounds[260]. The reaction with lithium tetrahydroaluminate takes place quantitatively with selective loss of the oxygen atom from the peroxide bridge, while in the hydrogenation over a palladium catalyst an oxygen atom is split off from both the peroxide and ether bridges[54]:

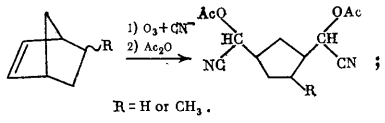


(16,1% ^{18}O) (15,5% ^{18}O) (8,5% ^{18}O)

Reductive cleavage with complex alkali metal hydrides has been used in the ozonolysis of olefinic ferrocenes[261] and in the synthesis of intermediates for nucleosides[262] and other physiologically active compounds[263]:

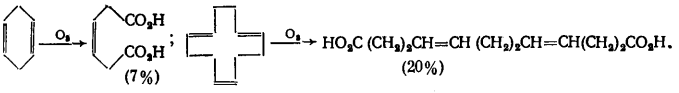


The "non-peroxide" reductive ozonolysis, carried out in the presence of compounds which take up peroxide oxygen, is of practical interest. One of the first versions was ozonolysis in the presence of tetracyanoethylene[65,264,265].

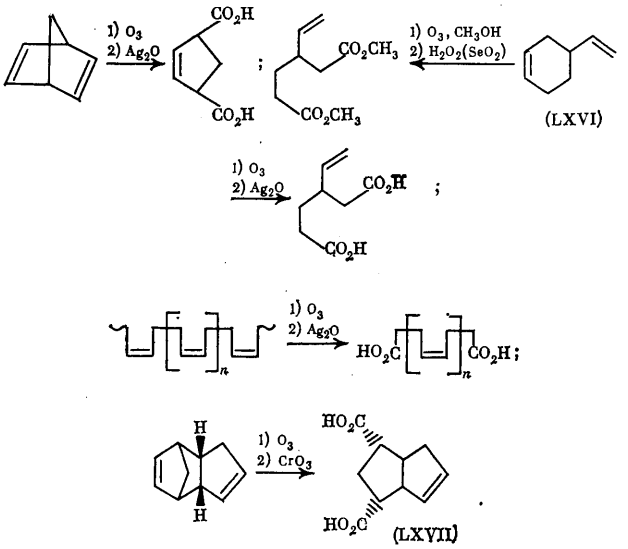


The ability of alkoxyhydroperoxides to epoxidise the double bond has been reported[266]. The reductive ozonolysis of olefins in the presence of "Baeyer–Villiger solvents" (pinacoline, cyclohexanone, and propionaldehyde)[22,23,267] was not confirmed in subsequent studies[24,27,268]. Carbonyl compounds are obtained in a single stage in ozonisation in the presence of pyridine[150], tertiary aliphatic amines[269,290], and alkaline earth metal hydroxides[271,272]:

When cyclohexene is ozonised in the presence of pyridine and acetic anhydride, then, apart from adipic acid (30%), 5-formylvaleric acid is formed (in 35–40% yield) and cyclises at an elevated temperature[273]:



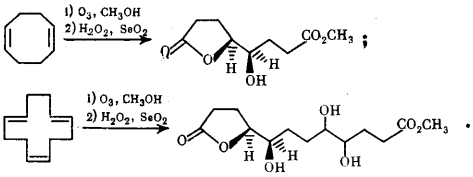
Emulsion ozonisation in the presence of reactive nucleophiles leads to non-peroxide ozonolysis products[35,274–278]. Cyano-ozonolysis has been applied to bicyclic olefins[279]:



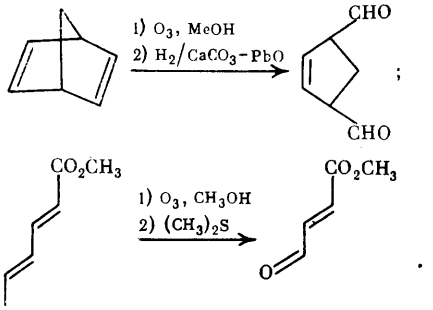
R = H or CH_3.

Methods have been developed for the determination of the positions of the double bonds in alkenes by ozonolysis and oxidation (with silver azide[280]) or reduction (with dimethyl sulphide[40,281] and triphenylphosphine[282]) and subsequent GLC analysis of the methyl esters of carboxylic acids or carbonyl compounds. The oxidative and reductive ozonolytic analytical methods have been compared[283,284]. Oxidative ozonolysis has been applied to natural rubber[285], butyl-rubber[286,287], 3-methylheptatriene–methacrylic acid copolymer[288], a mixture of isomeric bicyclic olefins[289], and natural unsaturated aliphatic acids[290]. The structures of polypiperylene[291] and isobutene oligomers[292] have been established by the ozonolysis of olefins in ethereal solvents. Reductive ozonolysis has been used to determine the structures of rubbers[293–297], poly(vinyl chloride)[298–300] and other polymers[301–303], oligomers[304], cellulose[305], and aliphatic acids[306]. The optical purities of *cis*- and *trans*-olefins have been determined with its aid[307].

Recently increasing attention has been devoted to the problem of the selectivity of chemical reactions[308,309]. In relation to the ozonolysis reaction, this problem has acquired particular importance for the specific cleavage of one of the multiple bonds in polyunsaturated compounds. Until recently, such compounds have been subjected merely to complete ozonisation in order to establish their structures. It was assumed that partial ozonolysis can be successfully achieved only when the double bonds are conjugated, whereupon the ozonide group formed exerts a significant influence on the remaining double bond, as, for example, in cyclohexa-1,3-diene[310] and *p*-divinylbenzene[11]. If the double bonds were separated by one or two carbon atoms, the unsaturated dicarboxylic acid could be obtained only in a low yield[310]:

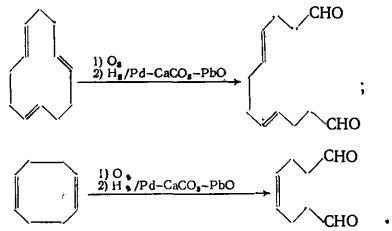


The yields of unsaturated α,ω-dicarboxylic acids increase to 50–60% in emulsion ozonisation in aqueous alkaline hydrogen peroxide[311,312]. The Asinger oxidation of the peroxy-products of the controlled ozonolysis of norbornadiene[313], 4-vinylcyclohexene (LXVI), [314–316] and poly-*cis*-buta-1,4-diene[317] led to the synthesis of the corresponding unsaturated dicarboxylic acids. The diester of 3-vinyladipic acid has been obtained by the selenium dioxide-catalysed decomposition of the peroxy-product of the partial ozonolysis of the diene (LXVI) in methanol[193,199]. Treatment of the product of the controlled ozonolysis of *endo*-dicyclopentadiene[318] with Jones' reagent yielded the acid (LXVII):

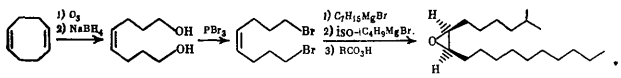


(LXVI)

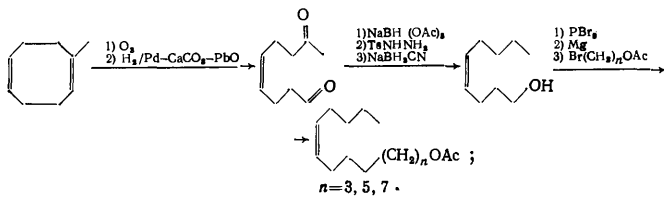
(LXVII)



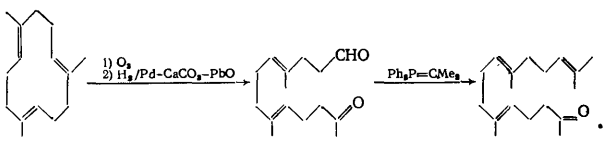
When hydrogen peroxide is used for the decomposition of the ozonides of polybutadiene[205,319,320] and polyisoprene[205,320], the hydroxylation of the double bonds results in the formation of the γ- and δ-lactones[205]. It has been shown in relation to the partial ozonolysis of the cyclic oligomers of 1,3-dienes[321,322] that this reaction is stereospecific in the presence of selenium dioxide[323]:



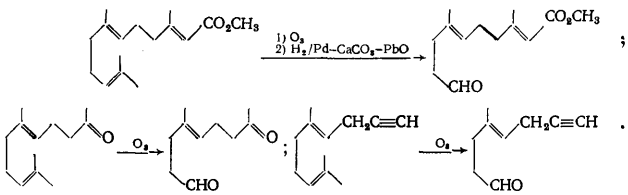
Considerable synthetic possibilities are inherent in partial reductive ozonolysis[313,324–326]:



The synthesis of substances regulating the populations of insects[327–332] requires unsaturated aldehydes and ketone with a specific configuration. As a result of the selective ozonolysis of cyclic oligomers of 1,3-dienes[333], such carbonyl compounds have become available:

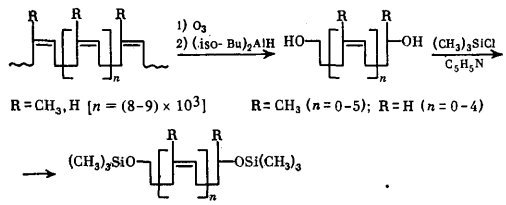


The synthesis of disparlure—the sexual attractant of the silkworm moth—has been developed on the basis of the product of selective ozonolysis of *cis,cis*-cyclo-octa-1,5-diene[334,335]:

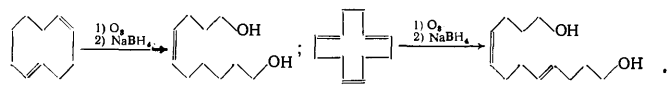


The selective cleavage of the trisubstituted double bond in 1-methyl-*cis,cis*-cyclo-octa-1,5-diene[336] constituted the basis of a new approach to the synthesis of the sexual attractants of coleoptera. These compounds have the structure of *cis*-enol acetates[330,331]:

A new stereospecific synthesis of terpenoid 1,5-polyenes involves the selective ozonolysis of cyclic isoprene oligomers[337,338]:



The selective ozonolysis of the isopropylidene group in linear isoprenoid compounds[339] constitutes a convenient method of synthesising regular isoprenoid blocks with terminal functional groups and double bonds having a specified configuration, which are necessary for the construction of polypropenols[340,341]:



Oligomeric blocks with terminal hydroxy-groups, which have found applications as monomers, plasticisers, adhesives, coatings, and binders for rocket fuel[348], are obtained by the controlled ozonolysis of *cis*-1,4-polybutadiene[259,342,343], *cis*-1,4-polyisoprene[344,345], and copolymers of 1,3-dienes[346,347] with subsequent reduction of the ozonides.

A new approach to the synthesis of bifunctional *cis*-1,5-polyprenols[349] (from natural rubber or its synthetic analogues) and *cis*-1,5-polyenes[350] (from SKD-*cis*-1,4-polybutadiene rubber) has been developed on the basis of the selective ozonolysis of polyunsaturated rubbers with a regular structure. Individual polyenes have been isolated in the form of bis(trimethylsilyl) ethers:

When the cyclic hydrocarbon contains several double bonds of different geometry, the transoid bond is attacked preferentially[351]:

---o0o---

Thus the advances achieved in the last decade have led to the inclusion of ozonolysis among the modern methods in the chemistry of olefins. There are considerable prospects for the selective ozonolysis of cyclic and linear oligomers and co-oligomers of 1,3-dienes, which have become extremely readily available in recent years as a result of the vigorous development of the chemistry of metal complex catalysis.

The Synthesis of Heterocycles from Vinylacetylenes or Diacetylenes and Nitrogen-containing Dinucleophiles

I.A.Maretina, A.E.Tsil'ko, and Yu.A.Zaichenko

Data on the reactivities of acetylenes substituted by conjugated electron donors or acceptors in heterocyclisation reactions with nitrogen-containing dinucleophiles are surveyed, the influence of the structure of the acetylenic component on the nature of the interaction is analysed, and the characteristics of the mode of intramolecular and intermolecular nucleophilic attack are discussed.
The bibliography includes 96 references.

CONTENTS

I. Introduction 657
II. Cyclisation in acid media with participation of conjugated acetylenes 657
III. The heterocyclisation of acetylenes substituted by conjugated electron donors under the conditions of direct nucleophilic attack 660
IV. The reactions of acetylenes substituted by conjugated electron acceptors in reactions with mono- and di-nucleophiles 661

I. INTRODUCTION

Acetylenic compounds are being increasingly used in reactions leading to heterocycles. Processes such as the 1,3-dipolar cycloaddition, intramolecular cyclisation, cyclisation via a double attack on the acetylenic bond, and others have come to be widely used in the chemistry of acetylenes[1]. The vigorous development of this field can be explained by the extensive possibilities, discovered in the course of research, associated with the specific reactivity of the triple bond in nucleophilic addition reactions.

The synthesis of five- and six-membered heterocycles from 1,3-bifunctional compounds containing carbonyl groups is generally known. These data have been surveyed in a series of monographs[2-4] and also in a series of reviews (see, for example, Coispeau and Elguero[5]).

Numerous studies demonstrating that in the construction of heterocyclic compounds three carbon fragments can be formed by the reactions of conjugated alkenynes or alkadiynes with dinucleophiles have been published in recent years. The mode of the intermolecular nucleophilic attack on substituted acetylenes involving mononucleophiles has been discussed in a number of monographs[1,6] and reviews[7-9].

In the present review it is shown that the participation of conjugated systems in the construction of heterocycles is a general process, but the pathways leading to the formation of rings are different when unsaturated conjugated systems and 1,3-difunctional compounds containing carbonyl groups are used. In the first place the review deals with the acid-catalysed reactions of acetylenes, substituted by conjugated electron donors, with hydrazine, hydroxylamine, and guanidine derivatives, leading to the synthesis of pyrazoles, isoxazoles, and pyrimidines. Next, the available information about the reactions of the same acetylenes under the conditions of direct nucleophilic attack, leading to pyrimidines and pyridines, is surveyed. Finally, data are presented on the reactions of dinucleophiles with acetylenes substituted by electron acceptors—ethynyl residues.

II. CYCLISATION IN ACID MEDIA WITH PARTICIPATION OF CONJUGATED ACETYLENES

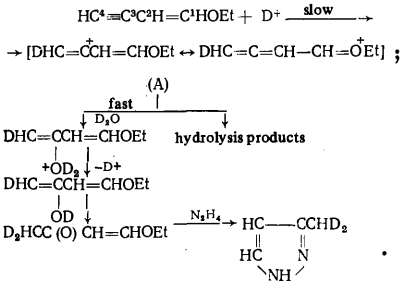
The reactions of dinucleophiles with acetylenes containing conjugated donors—1-heteroalk-1-ene-3-ynes (I)—in acid media via a mechanism different from that of the cyclisation of 1,3-dicarbonyl compounds are of greatest importance in the synthesis of heterocycles. This mechanism is based on the reactions of the protonated form of the acetylenic compound.

Compounds of type (I) can undergo hydrolysis and (or) hydration in an acid medium[10-12]:

$$\underset{(I)}{RXCH{=}CHC{\equiv}CH} \rightarrow \begin{cases} \rightarrow \underset{(II)}{CHOCH_2C{\equiv}CH} \\ \rightarrow \underset{(III)}{RXCH{=}CHCOMe} \end{cases} \rightarrow \underset{(IV)}{MeCOCH_2CHO}$$

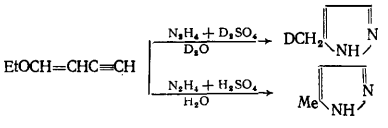
Heterocyclic systems can therefore arise in principle as a result of the interaction of the nitrogen-containing base with both the protonated form of the initial compound and with its hydrolysis or hydration products.

1. Protonation of Acetylenes Substituted by Conjugated Electron Donors



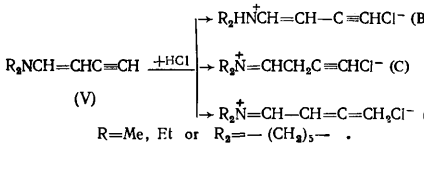
It has been shown[10,12] that the acid hydrolysis of 1-alkoxyalk-1-en-3-ynes leads to the formation of β-acetylenic aldehydes, but the authors do not present evidence for the structure of the hydrolysis products. The acid hydrolysis of the "usual" vinyl ethers[13-16] is faster by five orders of magnitude than the hydrolysis of 1-alkoxybut-1-en-3-ynes[17-19]. This fact is treated as evidence for a change in the reaction mechanism[17], total hydrolysis being preceded by the hydration of the triple bond and subsequent cleavage to acetoacetaldehyde. The mode of protonation of the conjugated system in hydrolytic reactions has been demonstrated by ^{1}H NMR [20,21] for substituted enyne ethers.

The study of the kinetics of the hydration of 1-alkoxybut-1-en-3-ynes has shown[22] that the rate of the reaction is determined by the protonation of the $C_{(4)}$ atom with formation of a conjugated carbonium ion (A), which is attacked by water molecules in the subsequent rapid stages. This is supported by the value of the isotope effect (k_{H_2O}/k_{D_2O} = 2.9); furthermore, the low entropy of activation for the hydration process (ΔS = 6.72 J mol^{-1} K^{-1} [18]) shows that in the transition state of the rate-determining stage of the process water is not firmly bound (Taft's concept[23,24]).



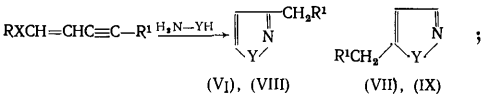
The common stage in the hydrolysis[20,21] and hydration[22] of the compounds RO–CH=CH–CH≡CR is apparently the protonation of the system at the $C_{(4)}$ atom and the formation of a mesomeric cation of type (A); the subsequent pathways in

the reaction of the cation are determined by the interaction with the electrophilic $C_{(1)}$ (hydrolysis) or $C_{(3)}$ (hydration) centre:



Scheme 1

When a nitrogen-containing base (hydrazine) was introduced into the reaction medium, the product of the direct interaction with the conjugated carbonium ion was isolated[22], which demonstrated the possibility of the direct cyclisation via the attack on the electrophilic centre $C_{(1)}$ or $C_{(3)}$ by a stronger nucleophile:



Alkynylenamines exhibit a higher reactivity in heterocyclisation reactions than the sulphur- and oxygen-containing analogues. The increased activity of the electrophilic centre at $C_{(1)}$ can be explained in this instance by the structure and properties of the protonated form produced under the cyclisation conditions[25]. Of the three possible types of salts, salt (B), which is rapidly converted via a protropic rearrangement into salt (D), is formed initially in the protonation of tertiary amines (V):

The allene structure of the immonium salts (D) has been confirmed in infrared and ultraviolet spectroscopic studies of the products of the mercuration of these amines[25]. Data[26,27] for the protonation and mercuration of enamines confirmed the immonium structure of the protonation products of amines of the vinylacetylene series. When the salt is attacked by a nucleophile, the $C_{(1)}$ reaction centre, activated by nitrogen, reacts preferentially.

2. The Reactions of the Protonated Forms of Acetylenes with Hydrazine, Hydroxylamine, and Guanidine Derivatives

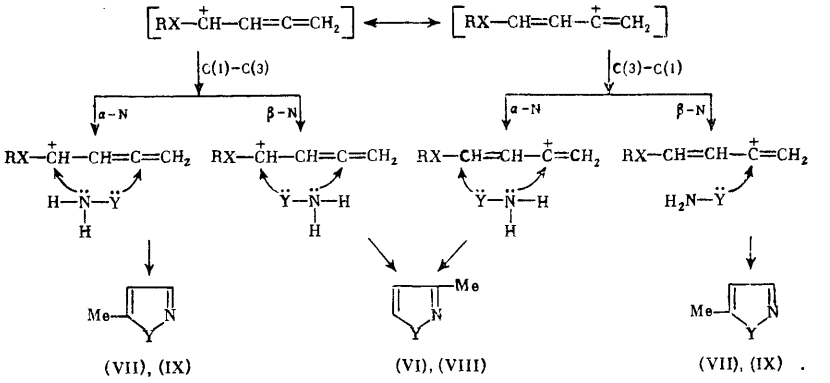
The interaction of the conjugated carbonium ions examined above with bifunctional nucleophiles can take place with participation of the $C_{(1)}$ or $C_{(3)}$ reaction centre, i.e. with formation of heterocycles substituted in different ways; both possibilities are actually realised. The reactions of heteroenyne compounds with hydrazine, substituted hydrazines, and hydroxylamine, which permit inferences to be drawn concerning the reaction pathways of the conjugated carbonium ion, lead to the formation of two pyrazole isomers (VI) and (VII) or isoxazole isomers (VIII) and (IX):[28-33]

(VI), (VIII) (VII), (IX)

R^1=H, Me, Et, n-Bu, or t-Bu; Y=NR^2 (VI, VII); Y=O (VIII, IX).

The nature of the substituent X (for R^1 = H) exerts the most significant influence on the relative activities of the two reaction centres. If RX is an electron-donating substituent (an amino-,[29] an alkoxy-,[30] or an alkylthio-group[31]), for which the mesomeric effect predominates over the inductive effect at the instant of the reaction, then the reactivity is correlated with the positive mesomeric effect of the heterogroup and varies in the sequence R_2N > RO > RS.

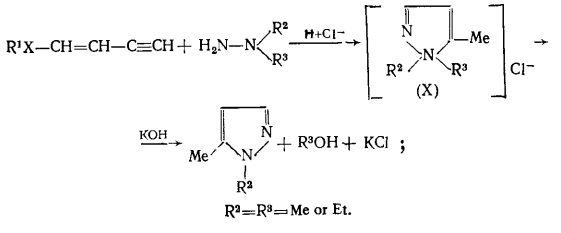
Since in an aqueous acid medium the stage completing cyclisation is the reaction of the carbonium ion with the nucleophile[22], the structure of the final product is to a large extent determined by the activity of the $C_{(1)}$ and $C_{(3)}$ electrophilic centres in the conjugated carbonium ion. For X = NR, the electrophilic $C_{(1)}$ centre exerts the greatest influence and the main products are the isomers (VII) and (IX).[29] For X=O, there is competition between the electrophilic $C_{(1)}$ and $C_{(3)}$ centres, the role of the latter centre increasing on passing from oxygen to sulphur-containing derivatives in conformity with the decrease of the +*M* effect in this sequence[30].



The influence of the nature of the substituents at the acetylenic linkage (R^1) is not manifested to quite such an extent. Substitution reduces the activity of the $C_{(3)}$ centre as a result of polarisation effects and steric factors; this increases the amount of 5-substituted pyrazoles or isoxazoles[33]. The influence of substitution at the acetylenic bond can be analysed from data for the synthesis of isoxazoles by the interaction of the homologues of 1-methoxybut-1-en-3-yne with hydroxylamine[30]. The amount of isomer (IX) increases in the homologous series.

On the other hand, the nitrogen-containing dinucleophiles H_2N=YH (Y = O, NH, NA, or NMe) can react with the $C_{(1)}$ electrophilic centre of the carbonium ion via two alternative pathways: (1) attack on the α-nitrogen atom [the formation of isomers (VII) and (IX)]; (2) attack on the β-atom (oxygen or nitrogen) [the formation of isomers (VI) and (VIII); see Scheme 2].

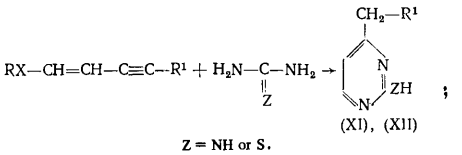
For H_2NOH, the sharp difference between the nucleophilic properties of the two centres of the base (nitrogen and oxygen) improves the picture—the primary amino-group reacts with the $C_{(1)}$ centre of the carbonium ion [$C_{(1)}$–$C_{(3)}$ α-N-attack, isomer (IX)]. Such data have been obtained for X = NR; the reaction of 1-dialkylaminoalk-1-en-3-ynes with hydroxylamine leads to the specific synthesis of 5-alkylisoxazoles[29]. In view of the foregoing, one must emphasise the comparative value of the method, because the use of dicarbonyl compounds as starting materials results in a mixture of 3- and 5-alkylisoxazoles[3].



A comparative estimate has been made of the reactivities of the two-centres (α- and β-) of asymmetric hydrazines[33]. In monoalkylhydrazines the substituted nitrogen atom is more nucleophilic and it is therefore logical to postulate the possibility of β-N-attack on the electrophilic $C_{(1)}$ centre. However, in the reaction of 1-dialkylaminobut-1-en-3-ynes with methylhydrazine only between 5 and 15% of isomer (VI) is formed as a result of an attack of this type ($C_{(1)}$–$C_{(3)}$),

Scheme 2

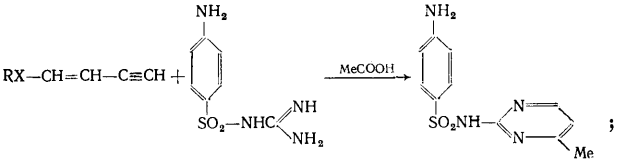
β-N).[29] In $H_2N-NHAr$ the nucleophilic activity of α-N is higher than that of β-N, so that attack on the electrophilic $C_{(1)}$ and $C_{(3)}$ centres by the α-nitrogen atom of phenylhydrazine predominates for X = NR, O, or S.



Asymmetric dialkylhydrazines $H_2NNR^2R^3$ reacted anomalously with enyne amines, ethers, and sulphides (X = NR, O, or S)[33]—the $C_{(1)}$ centre was attacked exclusively by the less nucleophilic α-nitrogen atom. The cause of the anomaly is apparently steric hindrance. Cyclisation led to the formation of quaternary pyrazolinium salts (X), which underwent the Hofmann degradation under the influence of concentrated alkali with formation of 1,5-dialkylpyrazoles (20%) and also the aminonitrile rearrangement[34]:

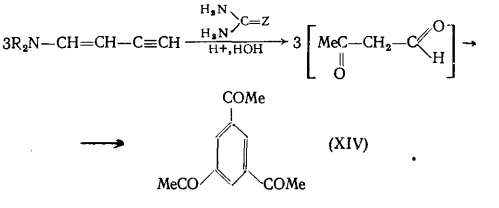
$R^3 = R^3 = Me$ or Et.

With the exception of asymmetric dialkylhalides, the nitrogen-containing bases examined exhibit the α-effect in nucleophilic addition reactions involving the carbonyl group and in nucleophilic substitution reactions[36].



The reaction of a carbonium ion with nucleophiles such as guanidine and its derivatives leads to the formation of pyrimidine bases. Alk-1-en-3-ynyl ethers and sulphides react with guanidine or thiourea in an acid medium to give 4-alkyl-2-aminopyrimidines or 4-alkyl-2-mercaptopyrimidines [compounds (XI) and (XII)]:[37-39]

Z = NH or S.

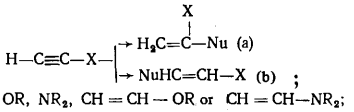


2-Amino-4-methylpyrimidine is used in the synthesis of pharmaceutical preparations[41]. Pyrimidinethiols accelerate the vulcanisation of rubbers[40].

The synthesis of sulfamerazine [2-(*p*-aminobenzenesulphonamido)-4-methylpyrimidine (XIII)], a long-action sulphonamide preparation, by the reaction of 1-heterobut-1-en-3-yne with 2-*p*-aminobenzenesulphonylguanidine is also of practical interest[42]:

RX = Et_2N, EtS, or EtO.

When 1-dialkylaminobut-1-en-3-yne is condensed with guanidine or thiourea in an acid medium, pyrimidine derivatives are not formed[37]. Only triacetylbenzene (XIV)—the product of the trimerisation of acetoacetaldehyde—was isolated from the reaction mixture. Thus, the reactions of a carbonium ion with water (hydrolysis, hydration, and trimerisation) are faster than the interaction with the nitrogen-containing base, which leads to pyrimidines:

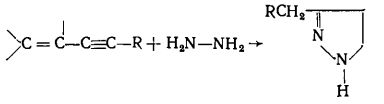


The results show that, among the three parameters (basicity, polarisability, and α-effect) characterising the reactivity of the nitrogen-containing base, the last factor apparently plays a significant role.

Evidently in an aqueous acid medium hydrolysis and hydration are not obligatory intermediate stages in the reaction with nitrogen-containing dinucleophiles. This view is based on the experiments, discussed above, using labelled atoms as well as data for the reactions of 1-dialkylaminobut-1-en-3-ynes with guanidine in an acid medium, which show that in the course of the reaction the hydrolysis and hydration products do not interact with nitrogen-containing dinucleophiles.

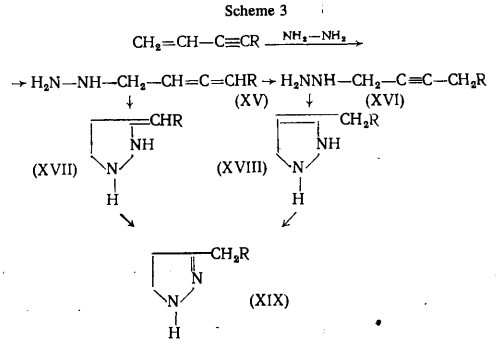
III. THE HETEROCYCLISATION OF ACETYLENES SUBSTITUTED BY CONJUGATED ELECTRON DONORS UNDER THE CONDITIONS OF DIRECT NUCLEOPHILIC ATTACK

The mode of intermolecular addition of nucleophiles to acetylenes of the type H–C≡C–X is determined by the nature of the donor X:



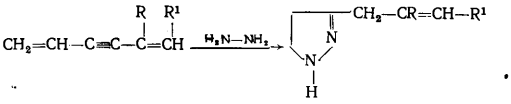
(a) X = OR, NR_2, CH = CH – OR or CH = CH–NR_2;
(b) X = SR or CH = CH – SR .

Thus, under the conditions of intermolecular attack, the nucleophile enters the α-position in alkynyl ethers (X = OR), enynyl ether (X = CH=CH–OR), and their nitrogen-containing analogues (X = NR_2 or CH=CH–NR_2) and the β-position in ethynyl sulphide (X = SR) or enynyl sulphide (X = CH=CH–SR).[45] This difference in the mode of addition is associated with the nature of the donor. The main factor responsible for the difference between the chemistry of sulphur, on the one hand, and that of oxygen and nitrogen, on the other, is the presence of *d* orbitals and the capacity for π–*d* interaction. These features are responsible for the attack on the β-carbon atom[46].

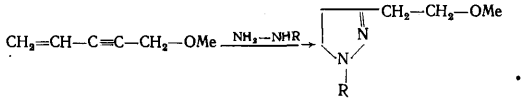


In cyclisation reactions the configuration of heterosubstituted enynes of all three types is the same ($C_{(1)}$–$C_{(3)}$ or $C_{(3)}$–$C_{(1)}$). The most varied heterocyclic compounds can be obtained from acetylene derivatives substituted by conjugated electron donors or nucleophiles capable of adding to a triple bond.

The only instance of the interaction of vinylacetylenic systems with hydrazine known in the literature refers to the synthesis of pyrazolines[47]:

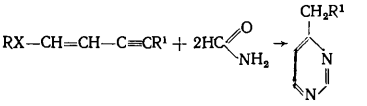


The authors[47] suggest that hydrazine adds in the 4,1-positions with subsequent cyclisation of the intermediate allene derivatives (XV) and the acetylene derivatives of hydrazines (XVI) to the unstable heterocycles (XVII) and (XVIII), which isomerise irreversibly to stable final 2-pyrazolines (XIX):[48]

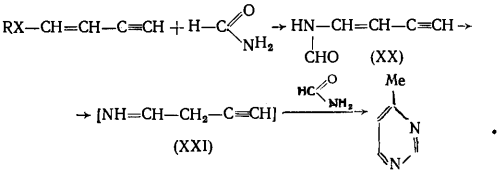


Scheme 3

In the reactions with mono- and di-substituted homologues of divinylacetylene hydrazine adds to the 4,6-positions with formation of 3-allylpyrazolines:

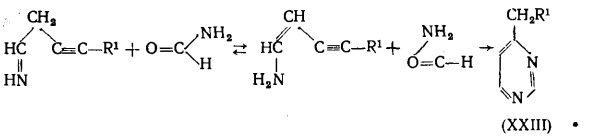


Hydrazine adds to the triple bond of isopropenylethynylmethanol[49]. Enynyl ethers with a non-conjugated alkoxy-group combine with monosubstituted hydrazines in the 1,3-positions[50]:

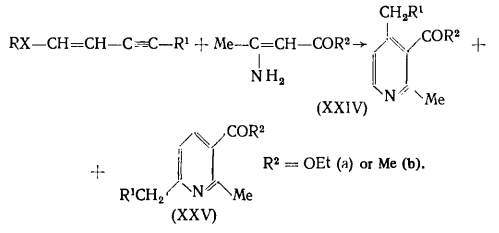


If the three-carbon fragment consists of a 1,3-conjugated enyne system, while the nitrogen-containing fragment is an amidine, thiourea, urea, guanidine, or formamide, the reaction products are pyrimidine derivatives.

4-Alkylpyrimidines have been obtained by the reaction of 1-heteroalk-1-en-3-ynes with formamide:[39, 51]

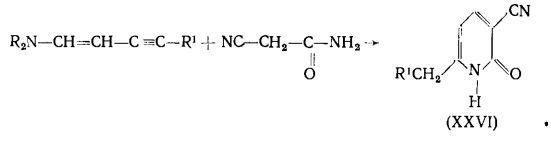


The reaction of alk-1-en-3-ynes probably proceeds via the nucleophilic substitution of the hetero-group by the amino-group of formamide with formation of the formamido-compound (XX) and the imine (XXI):



Such transamination has been proved by the isolation of dialkylformamides in the reaction with 1-dialkylaminobut-1-en-3-ynes[39]. The substitution of the stronger nucleophile (the dialkylamino-group) by the amino-group of formamide is possible according to the Law of Mass Action—when a tenfold excess of formamide is introduced into the reaction.

The formamido-compound (XX) is decarbonylated to the imine (XXI). Although the latter could not be detected, examples of stable compounds (XXII) of this kind have been described in the literature; they have been obtained by the reaction of formamide with benzoylacetone and were subsequently converted into pyrimidines at 220 °C.[52] The iminoketone is a proven intermediate in Bredereck's pyrimidine syntheses[53–56]. The imine (XXII) reacts with a second formamide molecule to form the pyrimidine ring (XXIII):



In the synthesis of pyridine systems, 1-dialkylamino(1-alkoxy)alk-1-en-3-ynes can be used as the three-carbon donors[57,58]. The two-carbon fragment can be supplied by enamines (for example, ethyl β-aminocrotonate), acetylacetone imine[57,58], and cyanoacetamide[29]. The main reaction

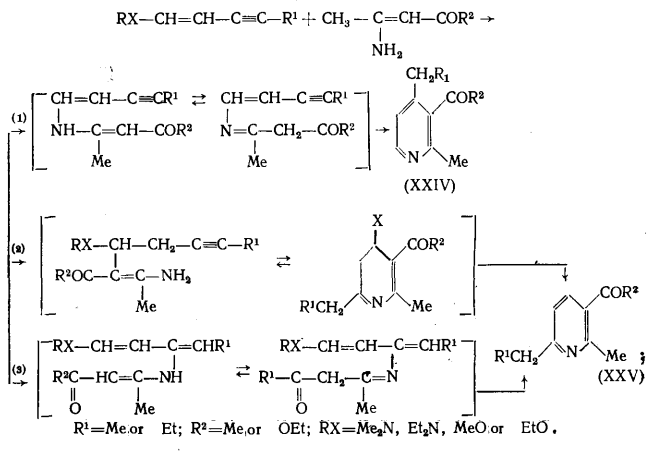
products are respectively ethyl 4-alkyl-2-methylnicotinate (XXIVa) and 3-acetyl-4-alkyl-2-methylpyrimidines (XXIVb) (90%, gas–liquid chromatographic method):

The proportions of the isomeric esters of 2,4-dimethyl- and 2,6-dimethylnicotinic acids (XXIVa) and (XXVa) have been determined chromatographically and by ^{1}H NMR, the two methods yielding satisfactorily concordant results[58].

Alk-1-en-3-ynylamines[29] condense with cyanoacetamide to form 6-alkyl-3-cyano-2-pyridones (XXVI):

The reactions described above are of interest in the sense that the involvement of the medium is ruled out—the interaction occurs on direct mixing of the reactants.

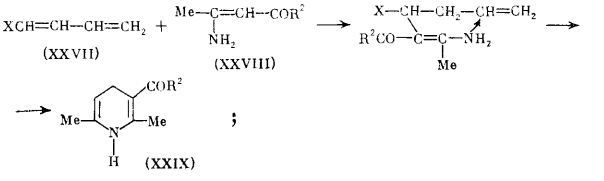
The formation of two isomers in the reactions of alk-1-en-3-ynes and alka-1,3-dienes with enamines (ethyl β-aminocrotonate or acetylacetone imine) can be accounted for by the ability of the two electrophilic centres of the initial 1,3-bifunctional compound and the two nucleophilic centres of the imine to compete.



The above systems can interact with enamines in three ways.

1. Via the transamination of the hetero-group with participation of the $C_{(1)}$ reaction centre and intramolecular cyclisation involving the active methylene group and the C≡C triple bond: this results in the formation of the 2,4-isomer (XXIV).

2. By the Michael addition of the active methylene group to the C=C double bond and subsequent intramolecular cyclisation via NH attack [the formation of the 2,6-isomer (XXV)].



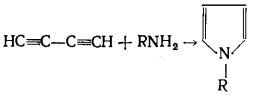
3. Via the nucleophilic attack by the primary amino-group on the $C_{(3)}$ reaction centre of the 1,3-enyne and cyclisation via the Michael addition involving the electrophilic $C_{(1)}$ centre of the conjugated system [the formation of the 2,6-isomer (XXV); see Scheme 4].

Scheme 4

Pathway (1) involves the initial addition of the primary amino-group to the electrophilic $C_{(1)}$ centre, which has a reduced electron density. This nature of the reaction presupposes the involvement of the free amino-group. Indeed, the stable *cis*-enamine structure of enaminoketones and enaminoethers unsubstituted at the nitrogen atom, stabilised by a hydrogen bond between the amino-nitrogen and the carbonyl oxygen, has been demonstrated in a number of studies[59–61].

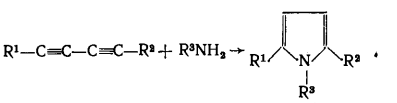
Pathway (2) operates in the interaction of dienylamines with enaminoketones and enaminoethers with formation of isomers (XXIX) [58] (yield 10%):

Pathway (3) can apparently occur only for 1,3-substituted enynes, because there are data indicating the nucleophilic attack on the triple bond of hetero-substituted 1,3-enynes by primary amines[45]. The reactivities of the electrophilic $C_{(1)}$ and $C_{(3)}$ centres in alkoxyenynes in a neutral medium are comparable, which can account for the formation of up to 50% of the product resulting from the attack by the amino-group on the triple bond.



IV. THE REACTIONS OF ACETYLENES SUBSTITUTED BY CONJUGATED ELECTRON ACCEPTORS IN REACTIONS WITH MONO- AND DI-NUCLEOPHILES

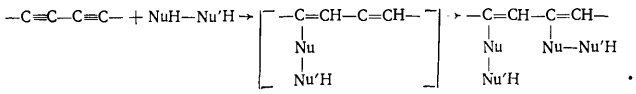
Reactions involving the addition of primary and secondary amines of all types to triple bonds conjugated with activating groups of different kinds have been described in the literature[6,62].



Thus the addition of primary amines to a diacetylene leads immediately to a 1 : 2 adduct[63], which undergoes the enamine—imine prototropic rearrangement[45,64]. Methyldiacetylene reacts with primary amines only at the unsubstituted acetylenic bond[65].

Secondary amines add to the 1,2-positions contrary to the Markovnikov rule[66–69]. Monoalkyldiacetylenes combine with secondary amines only at the terminal acetylenic bond[70]. Secondary amines add in the same manner to diacetylenic alcohols[71].

If the reaction of diacetylene with ammonia and primary amines is carried out in the presence of copper chloride, the products are pyrrole and its derivatives[72]:

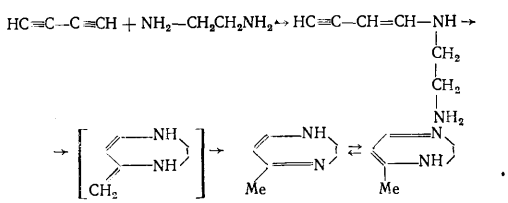


The reaction involving disubstituted symmetrical diacetylenes yielded 1,2,5-tri-substituted pyrroles[73,74]:

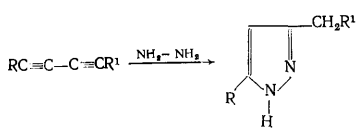
In this reaction the role of the catalyst consists in the formation of a non-polar π-complex with the triple bond, in which the electron density is uniformly distributed over both carbon atoms[75], which facilitates the closure of the pyrrole ring on interaction of the nucleophilic nitrogen with the fourth atom of the conjugated system.

The interaction of nitrogen-containing dinucleophiles with alka-1,3-diynes can proceed via two pathways—with formation of linear or cyclic structures. The mode of reactions of the first type resembles that of the reaction of diacetylene with mononucleophiles:

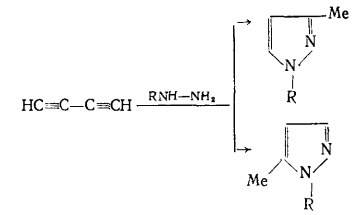
When there are two reaction centres of different strengths in the nucleophile, the centre with the maximum electron density reacts.



Thus, monoethanolamine adds to diacetylene as a primary amine, forming an adduct with a linear structure[76], which undergoes a prototropic transformation with fixation of the aminovinyl ketimine structure:

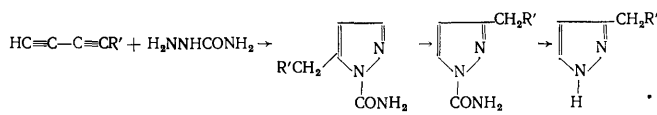


Aminoalcohols containing a disubstituted amino-group react with diacetylene to form adducts with a linear structure[77,78];

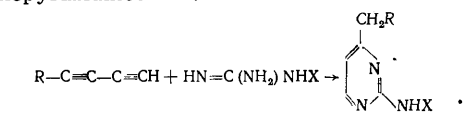


Aliphatic and aromatic diamines readily react with diacetylene, forming cyclic monoadducts. A seven-membered ring, corresponding to 1,3-addition, has been obtained from ethylenediamine[79]. Propylene-1,2-diamine adds to diacetylene in the same way[80].

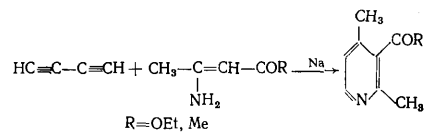
Three groups of workers published comparatively recently [45,81,82] data concerning the possibility of synthesising pyrazole derivatives from diacetylene and its mono- and di-substituted homologues:



The remarks of different investigators concerning the mode of addition are inconsistent. Thus, when methyldiacetylene $HC^1{\equiv}C^2{-}C^3{\equiv}C^4{-}Me$ condenses with hydrazine hydrate[49], 3,5-dimethylpyrazole is formed together with 3(4)-ethylpyrazole, which confirms the possibility of a mixed attack on the conjugated diyne system in both the 1,3-positions and the 4,2-positions in proportions of 6 : 1. Furthermore, a study of the reaction of diacetylene with monosubstituted hydrazines[47] showed that in the absence of water the reaction leads to the formation of the 1,3-isomer, while in the presence of water the 1,5-disubstituted pyrazoles are obtained:[47,83]



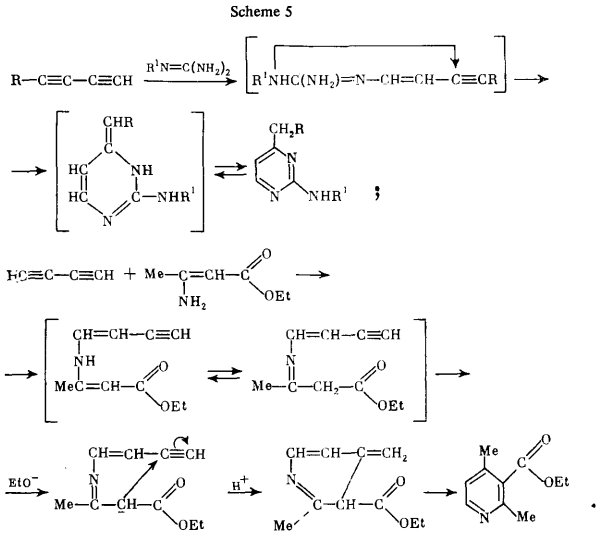
According to other data[84], the reaction of diacetylene with methylhydrazine in an alcoholic medium in the presence of sodium alkoxide leads to the formation of a mixture of isomeric 1,5- and 1,3-dimethylpyrazoles in proportions of 4 : 1.



The amides of 5-alkylpyrazole-1-carboxylic acids, corresponding to the 1,3-mode of attack on the conjugated diyne system, have been obtained by the reaction of buta-1,3-diene and its asymmetric homologues (penta-1,3-diyne and hexa-1,3-diyne) with semicarbazide[85]; under the reaction conditions, the amides isomerise irreversibly to the amides of 3-alkylpyrazole-1-carboxylic acids according to literature data:

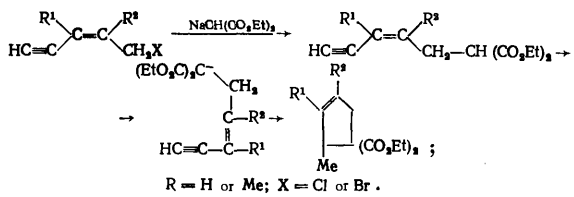
It has been established that diacetylene and its monosubstituted homologues react with guanidine or dicyanodiamide in the presence of equimolar amounts of sodium methoxide with formation of 4-alkyl-2-aminopyrimidines or 4-alkyl-2-cyanaminopyrimidines[86,87]:

The condensation of diacetylene with ethyl β-aminocrotonate or acetylacetone imine in the presence of equimolar amounts of metallic sodium results in the formation of ethyl 2,4-dimethylnicotinate or 3-acetyl-2,4-dimethylpyrimidine[88]:



It is known that acetylenic residues have an electronegativity of the same order of magnitude as cyano-groups and a higher electronegativity than the carboxy- or carbonyl group[89]. In systems where the triple bond is conjugated with electron-accepting groups, which enhance the electron deficiency at the $C_{(4)}$ atom, the attack by the nucleophile is therefore directed to the terminal carbon atom of the triple bond.

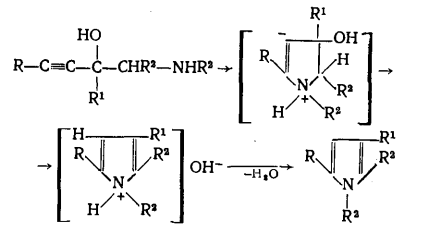
In the $C{\equiv}C{-}C{=}O$ system, which has two electrophilic centres of different hardness, one-centre nucleophiles (alcohols, amines, CH-acids) add in the 4,3-positions. Two-centre nucleophiles such as hydrazine and semicarbazide (much stronger bases) add in the 1,2-positions, i.e. they attack the electrophilic carbon atom of the carbonyl group. Hydroxylamine (a weaker nucleophile than semicarbazide) reacts via both centres[90]. If the electron acceptor at the $C_{(1)}$ atom is "strengthened", the reaction of the system with hydrazine proceeds via the same mechanism as with amines. For example, the esters of ethyleneglyoxalic acid react with alkylhydrazines[90] via the triple bond (4,3-order of addition). The reaction of the nitriles of acids of the enyne series with hydrazine takes place in the $C_{(2)}{-}C_{(4)}$ positions. Hydrazine,



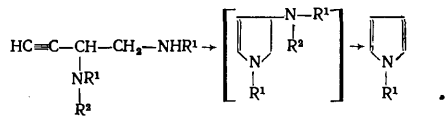
alkylhydrazines, and phenylhydrazine[91] add to these nitriles at the triple bond with subsequent cyclisation via the double bond and the formation of pyrazolines with a non-conjugated cyano-group in the side chain.

In the formation of six-membered rings, cyclisation takes place via the NH attack (pyrimidines) or CH attack (pyridines):

Scheme 5

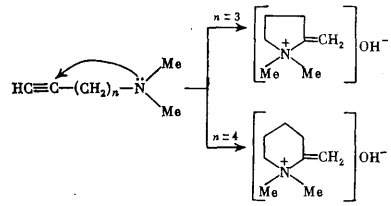


An example of the intramolecular CH attack on the acetylenic bond has been published[92]. The condensation of *cis*-1-chloropent-2-en-4-yne with sodiomalonic ester results in the formation of the diester of substituted 2-methyl-3-cyclopentene-1,1-dicarboxylic acid; the cyclisation takes place as the result of the interaction of the carbanion with the electrophilic centre of the triple bond:



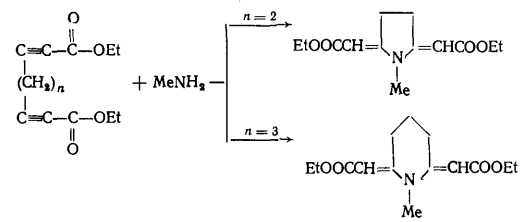
R = H or Me; X = Cl or Br.

Numerous examples of the intramolecular N–H addition to acetylenic bonds, leading to the formation of cyclic compounds, have been described in the literature. A thorough review[91] devoted to the intramolecular cyclisation of various types of acetylenic amines has been published recently. A significant factor in the formation of pyridine and pyrimidine derivatives is the tendency towards the formation of an energetically stable aromatic system. Thus the addition of primary amines to acetylene homologues[65] requires high temperatures and proceeds with much more difficulty than the reactions of the same homologues with guanidine and dicyanodiamide.

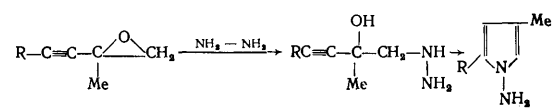


The nature of the reactions of acetylene derivatives containing the amino-group in a position non-conjugated with the multiple bond differs from that of the reactions just examined. α-Hydroxyethynyl alcohols react with primary amines to form β-aminoethynyl alcohols, which are converted into pyrroles on heating; the electron pair of the nitrogen atom then attacks the electrophilic centre of the triple bond and the resulting dipolar ion is stabilised by the simultaneous liberation of water and the migration of hydrogen[91]:

The intramolecular cyclisation of acetylenic diamines proceeds via the same mechanism but under more severe conditions, as a consequence of the reduced electrophilic properties of the triple bond[93]:

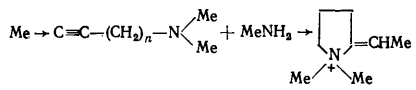


The tendency towards aromatisation apparently promotes the occurrence of these reactions, because tertiary acetylenic amines[94] cyclise at the second carbon atom. For $n = 2$, the reaction does not occur and for $n = 3$ or 4 quaternary ammonium bases derived from α-methylenepyrrolidine or α-methylenepiperidine are formed:



Here the nature of the attack on the acetylenic bond is different than in the examples quoted above[91,93] and corresponds to the polarisation of the acetylenic bond.

The double addition of primary amines to a non-conjugated diacetylenic system in the reaction of methylamine with esters of hexa-1,5-diyne-1,5-dicarboxylic or hepta-1,6-diyne-1,6-dicarboxylic acid is of interest[95]:



When hydrazine reacts with acetylenic epoxides, the resulting hydrazinoalcohols cyclise to five-membered heterocycles with elimination of the functional group and aromatisation of the system[96]:

In this case there is a possibility, in principle, of the formation of both five-membered and six-membered rings. However, only a five membered ring is obtained, because in the

transition state the reaction centres are in closer proximity on formation of five-membered rings.

The influence of the nature of substituents at the triple bond is pronounced in the absence of a conjugated bond system. Thus, in the series of tertiary acetylenic amines the replacement of hydrogen by an alkyl group makes the formation of five-membered rings difficult and six-membered rings are not formed at all:

The replacement of hydrogen by an alkyl group lowers the rate of the reaction but does not alter its general character.

---o0o---

The data presented in this review show that electronic factors exert a decisive influence on the reactivity of the acetylenic bond in the reactions of the types considered. If the triple bond is conjugated with an electron donor, the attack by the nucleophile is directed to the α-carbon atom, while in conjugation to an electron acceptor the β-carbon atom is attacked.

The pathways leading to the formation of rings—the usual pathway (based on 1,3-dicarbonyl compounds) and the pathway described here (based on 1,3-conjugated systems)—have different mechanisms. In the first instance there is a two-stage process (for example, pyrazoles and pyrazolines are formed by hydrazones), while in the second instance both centres participate in the reaction, apparently synchronously, via a many-centre mechanism. The reactions described, based on unsaturated conjugated systems or bifunctional compounds, differ also in their results—isomers of different structures are formed; whereas the reactions with β-dicarbonyl compounds give rise to mixtures of isomers, in the second case there is a specific synthesis of only one of the two possible products.

The heterofunctional derivatives of vinylacetylene investigated do not enter into intermolecular reactions with many nucleophiles and do not combine with weak CH acids, while the cyclisation with participation of such substances takes place readily. Thus transformations which do not occur in intermolecular reactions do take place in cyclisation, the decisive factor being the tendency of the system towards aromatisation.

The 1,5-Shift Reaction

V.A.Mironov, A.D.Fedorovich, and A.A.Akhrem

Data on the reaction involving the 1,5-shift of hydrogen and substituents in cyclic and acyclic dienes and trienes as well as homodienyl systems published up to June 1979 are considered and treated systematically.
The bibliography includes 197 references.

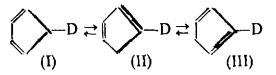
I. INTRODUCTION

Since the discovery in 1961 of the 1,5-hydrogen shift reaction[1], isomeric transformations of diene and polyene hydrocarbons have attracted much attention by investigators. Without exaggerating, one may say that studies in this field as well as investigation of other types of thermal intramolecular rearrangements have now become an independent and vigorously developing branch of organic chemistry. Studies in this field are important for the understanding of the general problem of valence tautomerism and valence isomerisation.

In the series of the so-called sigmatropic rearrangements the 1,5-shift of hydrogen and substituents is now the most thoroughly investigated reaction, but there is no review literature of any kind on this problem. The aim of the present review is to fill this gap. The available literature data are classified in terms of different types of hydrocarbon systems; the arrangement of the material corresponds approximately to the chronology of its publication.

The series of cyclopentadienes is historically the first and most thoroughly investigated system in which the 1,5-shift of both hydrogen and substituents has been observed.

II. CYCLOPENTADIENES

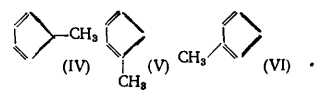


1. The Hydrogen 1,5-Shift

Inspection of early literature data shows that in many instances where the structure of the substituted cyclopentadiene had been sufficiently reliably established the distribution of double bonds in the substance was inconsistent with the expectation based on the synthetic scheme. Thus the decarboxylation of 2,4-diphenylcyclopenta-1,3-diene-1-carboxylic acid[2] yielded 1,4-diphenylcyclopentadiene instead of the expected 1,3-isomer. The cyclopentadienecarboxylic acid formed when cyclopentadienylpotassium is treated with carbon dioxide is the 1-isomer[3] and not the 5-isomer postulated previously. The dehydration of 2,3,4-trimethylcyclopent-2-en-1-ol leads to 1,2,3-trimethylcyclopentadiene instead of the 1,2,5-substituted compound[4]. Methyl cyclopenta-1,3-diene-1-carboxylate reacts partly in the form of the 2-isomer on dimerisation[5-7]. The pyrolysis of 3,3-dichlorocyclopent-1-ene leads to 2-chlorocyclopentadiene and not to the corresponding 1-isomer[8]. Finally, the dehydration of 1-phenylcyclopenta-2-en-1-ol yielded 1-phenylcyclopentadiene instead of 2-phenylcyclopentadiene[9]. Anomalous phenomena have also been observed in the alkylation of sodium, lithium, and magnesium derivatives of the cyclopentadienyl anion. Examination of the mechanism of the above reactions shows that the addition of a substituent to any of the equivalent carbon atoms of the cyclopentadienyl anion should result in the formation of 5-substituted cyclopentadiene. However, in reality the reaction usually gave rise to a mixture of the 1- and 2-isomers,[10-13] while under milder conditions the main products were the 1-isomers[12,14,15].

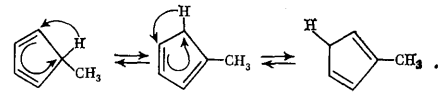
The independence of the structure of the substituted cyclopentadiene of the method of synthesis has been demonstrated by Mironov and coworkers[16,17], who established that five different synthetic pathways, formally designed to produce 1,4- or 2,5-dimethylcyclopentadienes, in all cases yield only 1,3-dimethylcyclopentadiene. The authors, who had previously observed the above anomalies, either did not attempt to explain them or explained them by the irreversible isomerisation of the substituted cyclopentadiene, formed initially, to the energetically more favourable isomer. The majority of investigators were convinced that the endocyclic double bonds in the cyclopentadiene ring are rigorously fixed; furthermore, the absence of isomerisation of cyclopentadienes was believed to have been proved[18,19].

In 1961 Mironov and coworkers[20-26] demonstrated that the system of double bonds in the cyclopentadiene ring exhibits an exceptionally high mobility. Special low-temperature methods of synthesis of cyclopentadienes were developed, which made it possible to obtain the individual isomers and



to investigate their thermal transformations. Direct interconversions of the isomeric cyclopentadienes were observed for the first time[20] in relation to 5-deuterocyclopentadiene (I) synthesised by treating cyclopentadienylmagnesium bromide with deuterium oxide at −5 °C. In the course of 1 h at 60 °C the diene (I) was converted into a mixture of equal amounts of 5-, 1-, and 2-deuterocyclopentadienes (I), (II), and (III), the transformation not being accompanied by hydrogen exchange between the molecules[20,26]:

(I) (II) (III)



Mironov and coworkers[20,26] explained this process by the irreversible migration of the double bond system with a simultaneous shift of the hydrogen atom from the 5-position of the cyclopentadiene ring, which leads to the establishment of thermodynamic equilibrium involving isomers (I)–(III). In structure (I) a shift of the double bonds is also possible as a result of the analogous migration of the deuterium atom, although such rearrangement is degenerate, since it does not alter the structure of the substance. The measurement of the infrared spectra of diene (I) at successive time intervals during the attainment of the given equilibrium showed[26,27] that the deuterocyclopentadienes isomerise in the following sequence (I) ⇌ (II) ⇌ (III).

Low-temperature methods of synthesis of all three possible isomers of methylcyclopentadiene, namely (IV), (V), and (VI), have been described[22,23]:

(IV) (V) (VI)

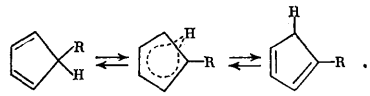
It has been established[22,23,26] that at 298 K in the liquid and gas phases 5-methylcyclopentadiene (IV) isomerises to the 1-substituted diene (V). The reaction is virtually completed after 3 h in the liquid phase and after 4 h in the gas phase; 2-methylcyclopentadiene (VI) is then formed only in insignificant amounts (<5%). It has been noted that the concentration of isomer (IV) decreases by a factor of two after equal time intervals (the reaction half-life is constant). The diene (V) isomerises much more slowly but after 2–3 days at 25 °C in the liquid phase (and even more slowly in the gas phase) the substance is transformed into a mixture of approximately equal amounts of the 1-substituted isomer (V) and the 2-substituted isomer (VI) containing <3% of isomer (IV); subsequently the mixture composition no longer changes. Distillation of dienes (IV), (V), or (VI) at atmospheric pressure[22,23,26] (b.p. ~72 °C) leads to the formation of the same mixture of dienes (V) and (VI). The formation on thermal isomerisation of each methylcyclopentadiene of the same mixture, which subsequently does not change, enabled the authors[22,23,26] to conclude that thermodynamic equilibrium is established between the dienes. The formation of homogeneous 1-methylcyclopentadiene (V) at intermediate stages of the transformation of 5-methylcyclopentadiene into a mixture of dienes (V) and (VI) shows that, in the course of equilibration and evidently also in the state of equilibrium, the double bonds migrate selectively via a mechanism corresponding to the migration of hydrogen from the 5-position of the cyclopentadiene ring to a neighbouring carbon atom or via a 1,5-hydrogen shift mechanism†:

(IV) (V) (VI).

Analogous series of experiments were carried out by the same workers in relation to 1,2-dimethyl-,[25] 1,2,3-trimethyl-,[24] and 1,2,3,4-tetramethyl-substituted[21] cyclopentadienes. In each of the instances mentioned above the dienes were found to isomerise readily, the process being completed by the attainment of thermodynamic equilibrium between isomers differing in the position of the system of endocyclic double bonds. The sequence of the interconversions of the isomers, corresponding to the 1,5-hydrogen shift mechanism, has also been observed[24].

The experimental data described enabled the authors[26] to reach the following conclusions. At a relatively low temperature (20–80 °C) the system of endocyclic double bonds in the cyclopentadiene ring migrates and the reaction results in the formation of equilibrium mixtures of isomers. The interconversions of the isomeric cyclopentadienes take place rigorously selectively as a result of the migration of hydrogen from the 5-position in the cyclopentadiene ring to a neighbouring carbon atom (in the 1-position), which is consistent with the 1,5-hydrogen shift mechanism. The reaction proceeds via an intermolecular mechanism, since it is not accompanied by hydrogen exchange between the molecules and is of first order (the half-life of the reaction is constant and the rates of isomerisation in the liquid and gas phases are comparable).

By using procedures analogous to those of Mironov and coworkers[20,26], Roth[28] synthesised in 1964 1,2,3,4,5-pentadeuterocyclopentadiene and established that, when it is heated to 45–65 °C, the hydrogen atoms are distributed uniformly among the 1-, 2-, and 5-positions of the cyclopentadiene ring and the reaction is not accompanied by hydrogen exchange. This confirmed the conclusions of Mironov et al.[20,26] Roth[28] obtained the kinetic parameters of the isomerisation of pentadeuterocyclopenadiene: $\Delta G^{\neq} = 24.3$ kcal mol^{-1}# and $\lg A = 12.06$.



The experiments of Mironov and coworkers[22,23,26] on the synthesis and isomeric transformations of diene (IV) were reproduced[29–31], the first order of the reaction was confirmed, and $\Delta H^{\neq} = 20.4$ kcal mol^{-1} and $\Delta S^{\neq} = -10$ e.u. were found for the transformation (IV) → (V). It has been established[29] that the rate of reaction does not change when the sample of the given substance is diluted with carbon tetrachloride or when the reaction is carried out in a platinum vessel. The data of Mironov and coworkers[16,22,25,26] concerning the composition of the equilibrium mixtures of mono- and di-methylcyclopentadienes were also confirmed[29,30]. The same workers[31] reproduced the earlier experiments[20,26] on the synthesis of isomerisation of 5-deuterocyclopentadiene.

Using a method similar to that described by Mironov and coworkers[22,23,26], McLean et al.[32] synthesised in 1969 2-methylpentadeuterocyclopentadiene, compared the kinetic parameters of its conversion into the 1-isomer ($\Delta H^{\neq} = 22.35$ kcal mol^{-1}, $\Delta S^{\neq} = -6.2$ e.u.) with the corresponding values for 2-methylcyclopentadiene ($\Delta H^{\neq} = 19.9$ kcal mol^{-1}, $\Delta S^{\neq} = -10.8$ e.u.), and calculated the isotope effect $k_H/k_D = 6$. The measured quantity represents the sum of the primary kinetic isotope effect and the secondary effect generated by the four D atoms attached to the double bonds, but the latter hardly constitutes 10% of the value quoted. Thus the

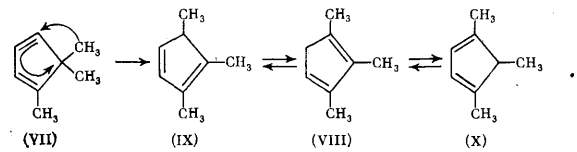
† The non-traditional designation of electron transfer in this review (and in the papers quoted) is used in order to emphasise that the essential feature of the 1,5-shift is the migration of precisely the system of two double bonds.

Here and henceforth, the conversion of the values of $\Delta G^{\neq}$, $\Delta H^{\neq}$, and $\Delta S^{\neq}$ quoted in this review to the SI system requires their multiplication by 4.18.

primary kinetic isotope effect of the 1,5-hydrogen shift in the series of cyclopentadienes greatly exceeds the value which might have been expected from the difference between the dissociation energies of the C–D and C–H bonds. This shows that in the transition state the migrating hydrogen (deuterium) atom is equidistant from the initial ($C_{(5)}$) and final ($C_{(1)}$) migration centres:

This mechanism has also been confirmed by the high negative entropy of activation for the reaction $\Delta S^{\neq} = -8$–10 e.u., corresponding to a rigorously ordered transition state, which also explains satisfactorily the rigorous sequence of the interconversions of the isomers.

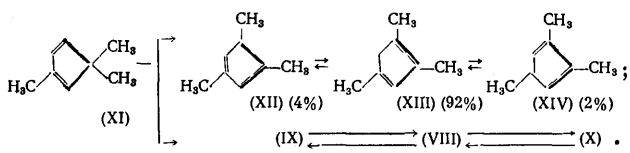
Virtunlly all subsequent studies[33–50] on cyclopentadiene derivatives were carried out taking into account the high rate of their isomerisation. The rate of the isomeric transformations of cyclopentadienes depends significantly on the nature of the substitution. Thus in 5-substituted cyclopentadienes the 1,5-shift of hydrogen takes place at a rate much higher than in their isomers with a free methylene group[22,23]. The accumulation of alkyl groups in the cyclopentadiene ring lowers the rate of reaction appreciably[26,30]. Electron-accepting substituents apparently exert the opposite effect[5].



The kinetic measurements described above were performed for the virtually irreversible reaction (IV) → (V). Recently a study has been made[51] of the kinetics of the reversible isomerisation of thermodynamically stable cyclopentadienes, namely (V) ⇌ (VI), starting with the pure diene, at 50–80 °C. The values obtained were $\Delta H^{\neq} = 20.5$ kcal mol^{-1} and $\Delta S^{\neq} = -15.7$ e.u. for the reaction (VI) → (V) and $\Delta H^{\neq} = 20.6$ kcal mol^{-1} and $\Delta S^{\neq} = -15.1$ e.u. for the reaction (V) → (VI). It is striking that, within the limits of the accuracy of the measurements, the enthalpies of activation for the reactions (IV) → (V) [29,32] and (V) → (VI) [51] are the same. This permitted the conclusion[51] that the sharp difference between the rates of the above processes is virtually caused solely by the entropy factor. In other words, the difference between the rates of the 1,5-shift of hydrogen in cyclopentadienes which are isomeric as regards the position of the system of endocyclic double bonds is determined mainly by the entropy of activation. Hence the relative thermodynamic stability of isomers and correspondingly their concentrations in the equilibrium mixture should depend to a large extent on their entropies.

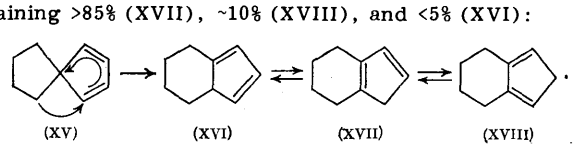
The compositions of the equilibrium mixtures of substituted cyclopentadienes have now been fairly thoroughly investigated and the general trend is known—5-substituted cyclopentadienes are energetically less favourable than their isomers with a free methylene group[26]. The change in the nature of the alkyl group in monoalkylcyclopentadienes is not reflected in the composition of the equilibrium mixture (1- and 2-alkylcyclopentadienes in proportions of 44 : 56).[52] As a result of the presence in the cyclopentadiene ring of substituents lengthening the conjugation chain, the dominant isomer (not lets than 95%) in the mixture has the structure of the 1-isomer (phenylcyclopentadiene[9], cyclopentadienecarboxylic acid[3,7,53], its methyl ester[3,7], and chloride[54]). However, the introduction of the same groups in the side chain of an alkylcyclopentadiene, even in the α-position, hardly affects the composition of the equilibrium mixture compared with alkylcyclopentadienes[55].

It is known[31,56] that the migration of the system of double bonds in cyclopentadienes is accelerated by strong bases. Thus, in the presence of sodium amide in liquid ammonia, the alkylation of the cyclopentadienyl anion leads directly to equilibrium mixtures of alkylcylopentadienes even at 240 K.[52,56,57] Sodium hydroxide in methanol also catalyses the isomeric transformations of cyclopentadienes[31]. However, under the conditions of alkaline catalysis hydrogen exchange takes place in cyclopentadienes[31]; presumably in this instance the reaction proceeds via a mechanism different from that indicated above, namely via the heterolytic dissociation of the C–H bond in the 5-position in the cyclopentadiene ring with subsequent protonation of the resulting cyclopentadienyl anion.



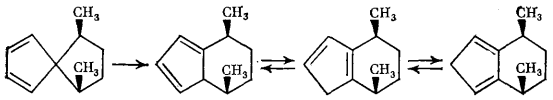
2. The 1,5-Shift of the Alkyl Group

The irreversible thermal isomerisation of 1,5,5-trimethylcyclopentadiene (VII) to 1,2,3-trimethylcyclopentadiene (VIII) in the gas phase at 623 K has been observed[4]. It was subsequently established[56,58–61] that this reaction leads to an equilibrium mixture of vicinally substituted trimethylcyclopentadienes, in which isomer (VIII) predominates[24]:



The following kinetic parameters have been obtained for this reaction: $\Delta H^{\neq} = 40.3$ kcal mol^{-1} and $\Delta S^{\neq} = -1$ e.u. (350° to 400 °C) according to the data of de Haan and Kloosterzieb[58,59] and $\Delta H^{\neq} = 43.8$ kcal mol^{-1} and $\Delta S^{\neq} = 0.7$ e.u. (328–430 °C) according to the data of Herndon and Manion[60,61].

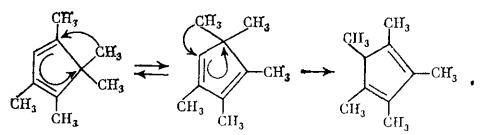
Isomerisation of the same type has been observed[59] in relation to 2,5,5-trimethylcyclopentadiene [$\Delta H^{\neq} = 44.2$ kcal mol^{-1} and $\Delta S^{\neq} = 6$ e.u. for the reaction (XI) → (VIII) + (IX) + (X) and $\Delta H^{\neq} = 44.4$ kcal mol^{-1} and $\Delta S^{\neq} = 3$ e.u. for the reaction (XI) → (XII) + (XIII) + (XIV)]:



Like compound (XI), 5,5-dimethylcyclopentadiene[56,62] is converted at 220–330 °C into a mixture of 1,2- and 2,3-dimethylcyclopentadienes ($\Delta H^{\neq} = 43.3$ kcal mol^{-1} and $\Delta S^{\neq} = 3$ e.u.[62]).

Isomerisation involving spiran cyclopentadienes can proceed via the same mechanism; thus spiro[4,4]nona-2,4-diene (XV) is smoothly converted at 503–593 K in the gas phase[63,64] into an equilibrium mixture of compounds of the tetrahydroindene series—bicyclo[4,3,0]nonadienes (XVI), (XVII), and (XVIII), containing >85% (XVII), ~10% (XVIII), and <5% (XVI):

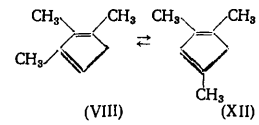
The results of Mironov and coworkers[63,64] were subsequently confirmed[65]; the following kinetic parameters were obtained for the reaction (XV) → (XVI) + (XVII) + (XVIII): $\Delta H^{\neq} = 34.6$ kcal mol^{-1} and $\Delta S^{\neq} = -1$ e.u. The study of the same reaction in relation to the *cis*- and *trans*-6,9-dimethylspiro[4,4]nona-2,4-dienes showed[66] that the isomerisation



takes place rigorously stereospecifically with retention of the configuration of the initial compound, for example:

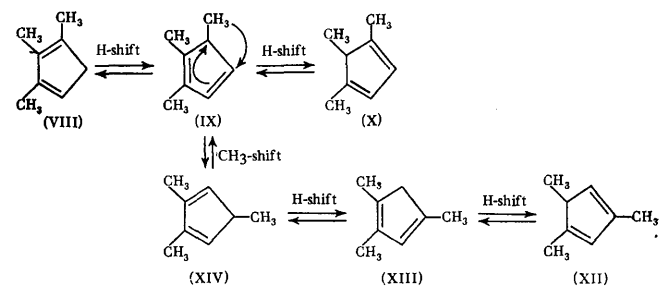
An analogous isomerisation has been observed for spiro-[4,5]deca-2,4-diene[65] ($\Delta H^{\neq} = 45.5$ kcal mol^{-1} and $\Delta S^{\neq} = 6$ e.u.). The composition of the equilibrium mixture of bicyclo[5,3,0]decadienes formed [90% of the 1(5),2-isomer] is extremely close to that mentioned above for the analogue with a six-membered ring. It is of interest that the isomerisation of spiro[4,3]octa-2,4-diene to a mixture of bicyclo-[3,3,0]octadienes [the 1,4- and 1(5),2-isomers in proportions of 1 : 1.3], with conversion of the four-membered ring into a five-membered ring[67], takes place already at 100 °C, i.e. much more readily than for the analogues described above ($\Delta G^{\neq} = 29.2$ kcal mol^{-1}, $\lg A = 13.8$)§. This reaction is virtually irreversible, because the isomers of cyclopentadienes containing two alkyl groups in the 5-position are thermodynamically unstable (cf. the 5-substituted cyclopentadienes described above).

In all the cases mentioned above the isomerisation of 5,5-disubstituted cyclopentadienes takes place selectively via the intramolecular migration of the alkyl group from the 5-position to a neighbouring carbon atom (via the 1,5-shift mechanism), since the reaction results in the elimination of the geminal substitution and the formation of 1,3-shift products has not been observed in any instance. In the concluding stage of the process equilibrium is established between isomers which differ by the positions of the endocyclic double bonds as a result of the 1,5-shift of hydrogen at a higher rate than the shift of the substituent.



The thermal transformations of a series of 5,5-disubstituted cyclopentadienes, in which the 1,5-shift of the alkyl group should not lead to the elimination of geminal substitution, i.e. to cyclopentadienes with substituted 1- and 4-positions, have been investigated. It has been established[69–71] that 1,2,4,5,5-pentamethylcyclopentadiene (XIX) is converted at 400–500 °C (contact time ~8 s) into 1,2,3,4,5-pentamethylcyclopentadiene (XX) with 1,2,3,4,5-pentamethylcyclopentadiene (XXI) as the intermediate:

(XIX) (XXI) (XX)



The formation of a *gem*-substituted diene (XXI) at intermediate stages shows that the reaction is a combination of two consecutive 1,5-shifts of the methyl group. The first, rate-limiting stage is the reversible isomerisation (XIX) ⇌ (XXI), which does not affect the geminal substitution; the second, irreversible stage (XXI) → (XX) leads to a thermodynamically stable diene, in which there is a possibility of a 1,5-shift of hydrogen. An analogous transformation at a somewhat lower temperature (330–460 °C) has been observed for 1,4,5,5-tetramethylcyclopentadiene[56,72].

In thermodynamically stable cyclopentadienes (with a free methylene group) reversible skeletal isomerisation, which leads to equilibrium mixtures of dienes differing in the nature of substitution, is observed at 400–500 °C (contact time ~8 s). An isomerisation of this type was observed for the first time in 1968 by Mironov and coworkers[73–75], who showed that at 400–500 °C 1,2,3- and 1,2,4-trimethylcyclopentadienes (VIII) and (XIII)¶ form an equilibrium mixture containing 55% of the "1,2,3-isomers" (VIII)–(X) and 45% of the "1,2,4-isomers" (XII)–(XIV):

(VIII) (XII)

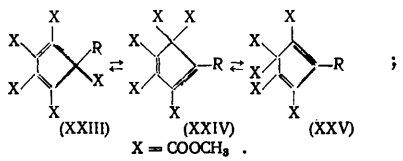
The recorded rate of isomerisation (VIII) → (XII) is appreciably higher than that of the reverse reaction (XII) → (VIII), while the ratio of the concentrations of the groups of isomers [(VIII)–(X)] : [(XII)–(XIV)] in the state of equilibrium is 1.22 : 1. Hence it was concluded[73–75] that structures (VIII) and (XII) are not directly responsible for the transformation under discussion and that the intermediates are 5-substituted cyclopentadienes. Bearing in mind that the rate of reaction is satisfactorily correlated with the content of isomers (IX) and (XIV) in the corresponding initial equilibrium mixtures, the following scheme was considered as the reaction mechanism:

The initial stage of the process is migration of hydrogen leading to an unstable isomer containing the migrating substituent in the 5-position. The rate-limiting stage of the isomerisation is the reversible intramolecular 1,5-shift of the methyl group (IX) ⇌ (XIV). In the concluding stage of the reaction equilibrium with respect to the positions of the double bonds is established for an isomer with another type of substitution.

Under similar conditions, reversible skeletal isomerisation of 1,2- and 1,3-dimethyl-substituted[76] and also of 1,2- and 1,3-di-s-butyl-substituted cyclopentadienes[57] has been observed. In both cases equilibrium mixtures of isomers, differing in the relative positions of the substituents, were obtained. It was noted[57] that the rate of migration of the s-butyl group is higher than that of the methyl group.

1,2,3,4-Tetramethylcyclopentadiene, containing a [^{14}C]-labelled methyl group in the 1(4)-position, has been synthesised and its thermal transformations have been investigated[77]. It has been established that at 400–500 °C the label is uniformly distributed between the methyl groups in the 1(4)- and 2(3)-positions; the appearance of a labelled carbon atom in the ring was not noted. This result agrees well with the mechanism of the isomerisation of thermodynamically stable cyclopentadienes described above, in which the main stage is the reversible thermal intramolecular 1,5-shift of the alkyl group and it makes it possible to rule out unambiguously the

§ The thermal transformations of spiro[4,2]hepta-2,4-diene takes place in a different way, leading to a complex mixture of hydrocarbons containing 6-methylfulvene, allylcyclopentadienes, and 1,2-dimethylcyclopent-3-ene[63,68].



¶ More precisely the corresponding equilibrium mixtures of isomers with respect to positions of the double bonds in which the given dienes predominate.

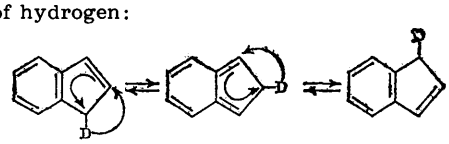
alternative mechanism involving the rupture of the cyclopentadiene ring at the $C_{(1)}$–$C_{(5)}$ bond and subsequent recyclisation in the direction of CH_3 at $C_{(1)}$–$C_{(4)}$ (with transfer of the reaction centre and the shift of a hydrogen atom—cf. Section IV).

Thus in the series of substituted cyclopentadienes four types of migration of the alkyl group at 200–450 °C, leading to a change in the nature of the substitution, have been observed: (1) reversible thermal isomerisation of 5,5-disubstituted cyclopentadienes, which does not affect the geminal substitution; (2) irreversible thermal isomerisation of 5,5-disubstituted cyclopentadienes to dienes with a free methylene group; (3) irreversible thermal isomerisation of 5,5-disubstituted cyclopentadienes containing substituents in the 1- and 4-positions to dienes with a free methylene group, which constitutes a combination of the two types of isomerisation specified above; (4) reversible thermal isomerisation of cyclopentadienes with a free methylene group, which leads to the formation of equilibrium mixtures of dienes differing in the nature of the substitution.

The 1,5-shift of the alkyl group is independent of the type of substitution and constitutes a general feature of the series of cyclopentadienes. One must note that in each case the 1,5-shift of the alkyl substitutent is accompanied by the migration of the system of endocyclic double bonds, which indicates the similarity of the phenomena under discussion to the 1,5-shift of hydrogen. The transition state in reactions involving the 1,5-shift of an alkyl group is apparently also close to that described for the hydrogen shift. This is confirmed by the rigorously consecutive sequence of transformations and their stereospecificity.

The substitutents in the cyclopentadiene ring other than alkyl groups are also capable of migrating. Thus it has been observed[78–80] that the group $COOCH_3$ can migrate via the 1,5-shift mechanism, for example, in compounds (XXIII)–(XXV):

(XXIII) (XXIV) (XXV)



X = $COOCH_3$.

At 100–150 °C the transformation (XXIII) → (XXIV) takes place and at higher temperatures transformation (XXIV) → (XXV) occurs. The results of kinetic measurements for isomerisation of the type (XXIII) → (XXIV) are presented in Table 1. The reaction is of first order and the entropy of activation is typical for a 1,5-shift. It is striking that the migration of the methoxycarbonyl group takes place much more readily than that of an alkyl group but with much more difficulty than the 1,5-shift of hydrogen. It is noteworthy that the rate of isomerisation (XXIII) → (XXIV) depends significantly on the nature of the ring substituent (Table 1).

On the basis of the data of Bladon et al.[81], it can be postulated that the phenyl group in cyclopentadienes migrates under less severe conditions than the methyl group: according to Bladon et al.[81], the reduction–dehydration of 3,4-diphenylcyclopent-3-en-1-one (with distillation of the reaction product at 250 °C) leads to the formation of 1,4-diphenylcyclopentadiene and not the 1,2-isomer, the former being evidently the product of the skeletal isomerisation of the 1,2-isomer formed initially via the mechanism described above. Thus in the cyclopentadiene series there is a possibility of both the 1,5-shift of hydrogen (20–80 °C) and the 1,5-shift of substituents (100–400 °C). The latter takes place under much more severe conditions and is accompanied by the 1,5-shift of hydrogen in the final and sometimes also the initial dienes.

III. INDENES

It was shown in 1964 [28] that heating of 1-deuteroindene (XXVI) at 200 °C leads to a uniform distribution of deuterium between the three non-aromatic carbon atoms in the absence of hydrogen exchange between the molecules. Hence, by analogy with cyclopentadienes[26], it was concluded[28] that in compounds of the indene series there is a possibility of a 1,5-shift of hydrogen:

(XXVI) (XXVII) (XXVIII)

Despite the fact that the reaction proceeds in the given instance via a stage involving the formation of the energetically unfavourable isoindene (XXVII), it always involves a 1,5-shift and not a 1,3-shift, in which the above stage is missing.

Table 1. Kinetic parameters of the 1,5-shift of the $COOCH_3$ group in 5-R-pentamethoxycarbonylcyclopentadienes (XXIII) → (XXIV)*.

The isomerisation of indenes is known to be catalysed by bases, including amines[82,83]. However, a feature of such catalytic reactions, which has not so far been explained, is their stereoselectivity[84,85] and the virtual absence of hydrogen exchange[85].

The migration of a substituent in the indene series has been known for a relatively long time. In an early study Ziegler and Crössman (1929) observed[86] the irreversible isomerisation of 1,3,3-triphenylindene to 1,2,3-triphenylindene at 400 °C (the reaction mechanism was not discussed). At 450 °C thermodynamic equilibrium is established between the isomeric 1,3-, 1,2-, and 2,3-diphenylindenes[87]. Under the same conditions, the isomerisation of 1-methyl-1,3-diphenylindene to a mixture of 1-methyl-2,3-diphenyl- and 3-methyl-1,2-diphenyl-indenes has been observed[87]. The experimental data described can now be readily interpreted by a combination of consecutive 1,5-shifts of the substituent and hydrogen, by analogy with that described in the preceding Section. The 1,5-shift of substituents in indenes has

been observed directly in a study[88] devoted to the thermal transformations of 1-methyl-1-phenylindene (XXIX):
