Electron Spectroscopy and the Study of Chemical Reactions on the Surfaces of Metals

A.G.Akimov and L.P.Kazanskii

The experimental technique and the physical principles of the fundamental electron spectroscopic methods are examined: X-ray electron spectroscopy (XES), Auger electron spectroscopy (AES), and ultraviolet photoelectron spectroscopy (UPES). Their advantages and disadvantages are compared. The application of electron spectroscopic methods in the study of chemical reactions on the surfaces of metals is considered in relation to the investigation of the oxidation of metals and alloys in both the vapour-gas phase and in aqueous electrolytes. In addition, studies on the application of XES and AES to the investigation of corrosion processes at the metal-electrolyte interface are discussed.
The bibliography includes 76 references.

I. INTRODUCTION

The chemical reactions occurring on the surfaces of solids have been the subject of studies in many independent branches of physical chemistry† such as catalysis, electrochemistry, metal corrosion, etc. As a rule, the interaction of the surface of a solid with the components of the surrounding medium involves a chemical modification of the surface itself. Investigation of such "modification" by methods of electron spectroscopy makes it possible to obtain qualitative and quantitative information about the nature of the interactions on the surface of the solid, which range from adsorption interaction to a significant alteration of the chemical composition of a surface region with a thickness up to 10^{-5}–10^{-4} cm.

The set of methods referred to as "electron spectroscopy" includes X-ray electron spectroscopy (XES)#, Auger electron spectroscopy (AES), ultraviolet photoelectron spectroscopy (UPES), the spectroscopy of characteristic losses (SCL) (or electron energy loss spectroscopy), and many other methods.

†The techniques for the physicochemical study of chemical reactions on the surface is considered in A.Adamson's monograph "The Physical Chemistry of Surfaces" (Translated into Russian), Izd.Mir, Moscow, 1979.

#This method has been referred to as ESCA (electronic spectroscopy for chemical analysis) by the authors—a team of Swedish scientists working under the supervision of K.Siegbahn[1].

This review deals mainly with the first three methods, since they have found most extensive applications in studies on the chemical composition of the surfaces of solids. A common feature of all the methods under consideration is that the spectrum of electrons is subjected to final analysis. The physical principles of the excitation of the spectrum of electrons are described in the next section.

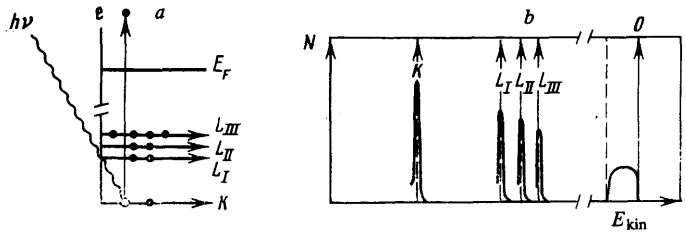

Figure 1. Schematic illustration of the electronic levels in a metal with ionisation of the K level (a) and the corresponding electron spectrum[1] (b): E_F = Fermi level; e = free electron; N = number of photoelectrons; E_b = binding energy of electrons; E_{kin} = kinetic energy of photoelectrons.

II. PHYSICAL PRINCIPLES AND ANALYTICAL POSSIBILITIES OF ELECTRON SPECTROSCOPIC METHODS

Fig. 1a [1] illustrates the diagrams of electronic levels in a metal. The action of a quantum of known energy on the K shell leads to its ionisation; if the energy of the electrons is sufficiently high, the latter leave the metal and become free. By detecting the free electrons emerging from the metal under the influence of radiation, it is possible to obtain the electron spectrum illustrated in Fig. 1b. Evidently the electron spectrum corresponds to the energy level diagram in Fig. 1a. The accuracy of the measurement of the energy of the free electron is determined by the natural width of the ionised level and the accuracy of the measurement of the wavelength of the incident radiation. The spectrum illustrated in Fig. 1b is also referred to as the photoelectron spectrum and is the main object of study in XES and UPES, in contrast to the spectra of Auger electrons obtained in AES.

The mechanism of the formation of Auger electrons can be described as follows. When a vacancy is produced in one of the inner electronic levels due to its ionisation under the influence of a particular type of radiation, there is also a possibility of another type of emergence of an electron from the solid. Such a vacancy can be filled by an electron in one of the outer levels and the energy of this transition can be evolved in the form of a quantum of electromagnetic radiation or can be transferred to one of the electrons in the outer

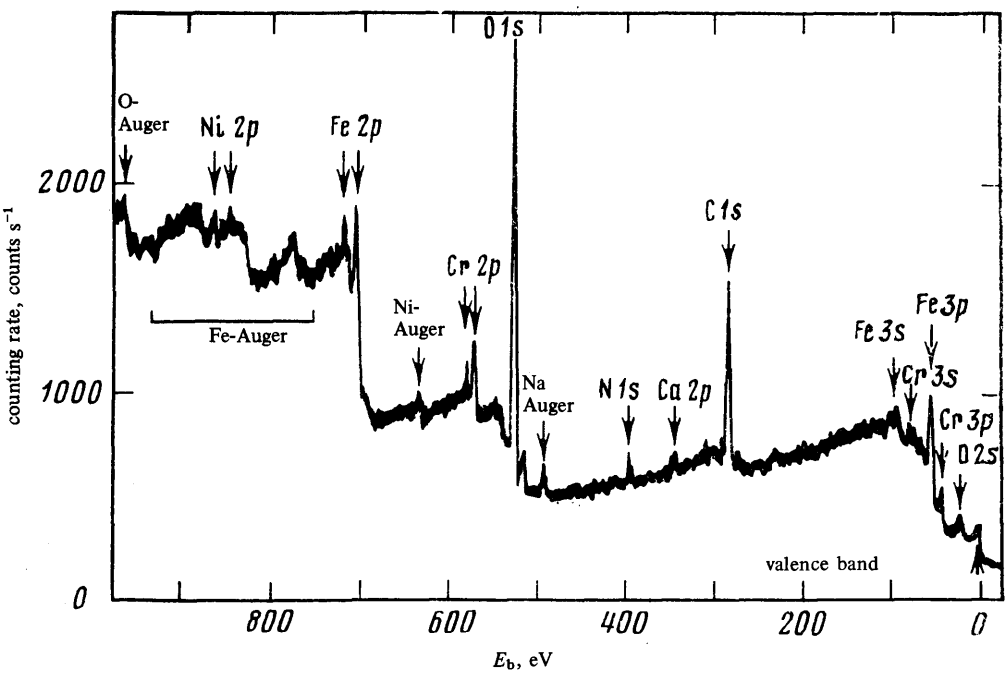

Figure 2. Electron spectrum of the surface of the Kh18N10T steel oxidised in air at 20 °C.[4]

levels, which is then ejected from the specimens. This process is referred to as the Auger effect and the ejected electrons are called Auger electrons§. The probability of the Auger process increases with decrease of the atomic number of the element, while the yield of X-ray fluorescence diminishes with decrease of the atomic number of the element. Because of this, it is possible to investigate, by analysing the spectra of Auger electrons, the surfaces of solids in order to detect light elements on the latter.

Thus, when ionising radiation acts on a metal surface, it is possible to obtain both photoelectron spectra associated with a simple one-electron process and Auger spectra associated with many-electron transitions. However, the approaches used in the analysis of the electron spectra (of both photoelectrons and Auger electrons) are very similar.

Indeed the fundamental equation of the external photoeffect is the Einstein equation:

$$h\nu = E_f - E_i + E_{kin}, \quad (1)$$

where $h\nu$ is the energy of the photons, E_f the energy of the system in the final state after the ejection of an electron from the K shell, E_i the overall initial energy of the atom or the molecule, and E_{kin} the kinetic energy of the dislodged electron. By defining the binding energy of the electrons E_b^F as the energy necessary to remove the electron from the K level to infinity (where $E_{kin} = 0$), it is possible to formulate Eqn.(1) as follows:

$$E_b^f = h\nu - E_{kin} - \varphi, \quad (2)$$

where E_b^F is the binding energy of the electrons of the metallic specimen measured relative to the Fermi level of the spectrometer and ϕ is the electron work function of the metal of the spectrometer. The equation relating the kinetic energy of the Auger electrons E'_{kin} to the energies of the levels of the given element is[2]

$$E'_{kin} = E_K - E_L - E_L^{z+1}; \quad (3)$$

where $E_{K(L)}$ is the energy of the $K(L)$ level of the element under consideration and E_L^{z+1} is the energy of the L level of the element having an atomic number one greater than the element of the specimen.

The determination of E_b permits the elemental analysis of the specimens, because there is a specific energy spectrum of electronic levels corresponding to each element. Fig.2 [4] illustrates the electronic spectrum obtained on irradiation of the surface of the Kh18N10T alloy oxidised in air at room temperature; the aluminium K_α line was used to obtain the X-radiation. It follows from Fig.2 that the electronic spectrum exhibits lines corresponding to photoelectrons and Auger electrons. Examination of the energies of the lines permits a qualitative analysis of the surface layer¶. The first studies by Siegbahn et al.[1] showed that the energies of the X-ray electron and Auger electron lines depend on the oxidation state of the atom of the test element. As a rule an increase of the degree of oxidation increases the shift of the binding energy of the electron (ΔE_b) relative to E_b in the zero oxidation state. Consequently, one can infer not only the elemental composition of the surface of metals but also the oxidation state of the elements. This can be illustrated by the data in Fig.3,[1] which illustrates the X-ray electron spectra of the beryllium 1s line. A structure consisting of two peaks corresponds to beryllium sputtered *in vacuo* (Fig.3*a*). According to the XES theory[1-3], the low-energy (relative to E_b) peak should be attributed to metallic beryllium and the high-energy peak is due to beryllium oxide BeO. Evidently the X-ray electron spectrum of beryllium oxidised at a high temperature (Fig.3*b*) contains only the high-energy peak, which confirms the validity of the assignment of this peak to beryllium in the +2 oxidation state.

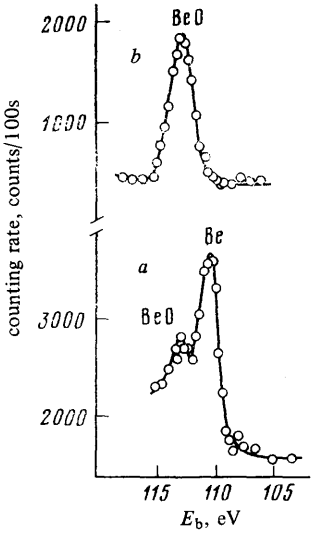

Figure 3. Electron spectra of beryllium[1] obtained by vacuum vaporisation after reduction with zirconium (*a*) and of the specimen after heat treatment in air (*b*).

It is noteworthy that the X-ray electron spectra† can carry information relating not only to the nature of the atom under investigation itself but also to its environment. A change in the charge distribution in the valence shell, occurring when the valence state of the atom is altered, influences also all the inner electrons and is therefore manifested in the electron spectra. This situation can be illustrated by the spectra of beryllium and its compounds shown in Fig.4.[1] Evidently, when beryllium is oxidised, E_b for the inner 1s electron of beryllium increases by 2.9 eV. Beryllium in BeF_2 has an even higher positive charge than in BeO [although the oxidation state is the same (+2)] as a result of the high electronegativity of fluorine, since the binding energy of the 1s electrons of beryllium in BeF_2 is greater than in BeO. In the general case the chemical shifts of the maxima in the X-ray electron spectra increase with increase of the amount of ionic character of the bond.

§For a more detailed description of the physical principles of the Auger process, see "Methods for the Analysis of Surfaces" (Edited by A.Zaderna) (Translated into Russian), Izd.Mir, Moscow, 1979.

¶Problems concerning the thickness of this layer will be considered below.

†Only the information obtained from the XES is considered, since allowance for the effects of collective interactions is extremely difficult for the two-electron Auger process.

In compounds where the test element exists in different oxidation states but is surrounded by identical atoms E_b varies approximately linearly with the degree of oxidation, which has been shown[3] in relation to nitrogen and chlorine oxides.

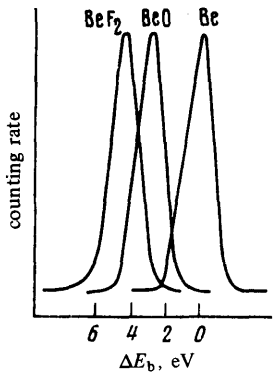

Figure 4. The positions of the lines due to metallic beryllium, beryllium oxide, and beryllium fluoride in the electron spectrum[1]; ΔE_b = change in binding energy.

For elements of a single Period, the line shift in the electron spectrum varies linearly with the total number of valence electrons and with the formal degree of oxidation[5,6].

According to the estimates of Siegbahn et al.[1], the photoelectrons abstracted from the surface carry information about a surface layer not thicker than 100 Å. Later studies showed that this layer can be even thinner. Thus the investigation of gold coated by a thin layer of graphite showed[7] that, when the electron energy changes from 1169 to 920 eV, the thickness of the layer of graphite which absorbs 95% of the electrons changes from 55 to 43 Å. By selecting the energy of the exciting radiation, E_b, and the angle of the path of the electrons between the surface and the spectrometer slit, it is possible to increase the thickness of the layer investigated to ~10 Å.[3] Fraser et al.[8] arrived at the same figure by considering the mean free path of the electron in non-elastic scattering in close-packed solids. According to Nemoshkalenko and Aleshin[2], when the energies of the primary electrons are suitably selected, AES can carry information about 2–3 monolayers of the test substance.

We shall consider the scope of the quantitative analysis by electron spectroscopy. The data given below refer to photoelectron spectra and primarily to XES, since a complete quantitative theory of analysis with the aid of AES is still being established.

Having assumed that the intensity of the beam of X-ray photons does not undergo appreciable changes in the surface region 100 Å thick, the intensity I of a stream of photo electrons with a specified energy can be expressed[2] by

$$dI = F\sigma Nk \exp(-x/\lambda)\,dx, \qquad (4)$$

where F is the intensity of the stream of X-ray photons, σ the photoionisation cross-section for the given energy of the photons and the atomic level under consideration, N the number of electrons of the given kind per unit volume of the substance, k the constant for the given spectrometer, x the distance which the electron traverses in the substance, and λ the effective depth from which electrons emerge, determined by the length of the free path of the electron in the test substance.

Using Eqn.(4), the following expression can be written for the intensity of the stream of photoelectrons which have emerged from a massive specimen:

$$I = F\sigma_1 N_1 k\lambda_1 [1 - \exp(-d/\lambda_1)], \qquad (5)$$

where d is the thickness of the layer which the photoelectrons have traversed. It follows from Eqn.(5) that the intensity is linearly related to the number of atoms in the test substance N_1 and this constitutes a basis of the quantitative analysis. Indeed, using Eqn.(5) to determine the relative increments in the concentrations of the components of the surface, the following simple expression can be obtained when the λ_i of the components are equal:

$$I_A/I_B = \sigma_A N_A (\sigma_B N_B)^{-1}. \qquad (6)$$

Here subscripts A and B refer to components A and B. The values of σ are known for virtually all chemical elements from the results of a number of studies[9,10]; although the accuracy of the tabulated σ is low (~10%), the availability of known values of σ makes it possible to employ Eqn.(6) and hence XES for quantitative analysis. One should not forget that Eqn.(6) was derived taking into account a number of simplifying postulates and therefore in each specific case one must estimate its applicability.

A more rigorous theory of photoelectron emission[11], developed taking into account the difference between the probabilities of excitation from states with different symmetries and the differences between the effects associated with the scattering of the electron wave in the crystal and on its surface, leads to much more complex expressions than Eqns.(4)–(6). However, practical experience has shown that the use of Eqns.(4)–(6) is in most cases justified.

In applying the XES method to quantitative analysis, one should remember that the existing apparatus has a maximum absolute sensitivity of ~10^{-10} g.[12,13] However, the relative sensitivity of the XES method does not exceed ~0.1% and it is therefore irrational to employ, for example, XES when the content of the given alloy component on the surface is less than 1% relative to the base.

It is of interest to compare the XES, UPES, and AES methods. The fundamental advantages of the UPES method are shown in the study of the changes of the energies of the electronic levels close to the valence band. This is due to the comparatively small range of the energies of the emitted electrons associated with the comparatively low energy of the exciting light quanta when a helium discharge lamp is used as the source of radiation. At the same time, the resolution of the UPES method can be to within 0.05 eV, which is more than an order of magnitude better than the resolution of the best X-ray electronic spectrometers. This feature of the UPES makes it possible to investigate fine effects such as the change in the structure of the valence band following a change in the concentration of one of the alloy components or the role of π,σ interactions in the adsorption of molecules, including hydrocarbons[14], on the surfaces of metals. The possibilities of UPES in the study of surfaces have been described in greater detail in another review[15].

It follows from Eqn.(3) that the measurements of the kinetic energies of the Auger electrons of atoms in different compounds should yield virtually the same information about the nature of the chemical bond as the values of E_b. In certain cases the Auger spectra have a definite advantage over the photoelectron spectra. In particular, the depth from which electrons in the substance emerge depends on the kinetic energy of the electron; therefore, knowing the distribution

of Auger electrons, it is possible to estimate the thickness of the surface layer investigated. The shift of the lines due to Auger electrons can be greater than the shift of the line due to photoelectrons[16]. Furthermore, owing to the greater efficiency of the liberation of the Auger electron and the possibility of creating fairly powerful beams of primary exciting electrons, the rate of accumulation of Auger spectra can exceed by a factor of 10^2 the rate of accumulation of X-ray electron spectra. However, a number of studies have shown that the effect of a beam of primary electrons can lead to a series of irreversible changes in the surface. These effects are associated both with the desorption of the adsorbed molecules from the surface under the influence of the electron beam[17] and with the surface dissociation and subsequent diffusion of the components of the specimen into the bulk of the specimen[18]. A recent detailed analysis of the "beam effects"[19] enabled the authors to conclude that the AES should be used as an auxiliary method in the quantitative study of the surface. AES should then naturally be regarded as an extremely effective means of the elemental analysis of the surface.

Compared with the excitation of the spectrum by a beam of electrons, used in Auger spectroscopy at the present time, the excitation by X-ray quanta is characterised by smaller cross-sections of the desorption of the adsorbed substances and a weaker secondary electron background. The relatively small intrinsic width of the lines due to the photoelectrons emitted from the inner shells greatly improves the accuracy of the measurement of the "chemical shift" of the spectral lines. The interpretation of the spectra of inner electrons is simpler than that of the results of the many-electron Auger process. The sensitivity of the photoelectron spectra excited by X-rays to substances adsorbed on the surface can be increased by selecting the corresponding angles between the ejected electrons and the surface of the specimen[20].

In many instances it is possible to achieve a sensitivity equivalent to ~0.01 of the monolayer in the study of adsorption by XES. Such sensitivity has been reached in practice in the study of the adsorption of CO, CO_2, and O_2 on platinum[13]. A direct comparison of the sensitivity of the XES (ESCA) and AES methods has been carried out in a study[21] where X-ray electronic and Auger spectra of 54 elements (ranging from lithium as the lightest element to technetium as the heaviest element) were obtained under the same conditions on the same specimens. The sensitivities of the methods were compared[21] in terms of the signal/noise ratio under the optimum conditions for the detection of the element. The results of the above study showed that the XES method is more sensitive for 10 elements (Na, Cr, Mn, Kr, Cd, Sb, Xe, W, and Th), while for the remainder the AES method is more sensitive.

Thus the XES method is at present the most universal for analytical purposes. On the other hand, in the study of each specific object one should bear in mind the advantages and disadvantages of each of the methods described and, in investigating an object which had not been studied previously, it may prove extremely useful to compare the Auger and photoelectron spectra.

III. EXPERIMENTAL TECHNIQUE

The fundamental design of the electron spectrometer used to obtain electron spectra, which is involved in virtually all modern models of electron spectrometers, combines all three methods: UPES, AES, and XES. The presence of three excitation sources makes it possible to obtain with the maximum efficiency the electron spectra considered in these methods, while a single system can be used to detect the electrons.

Ultraviolet light and X-ray generators and electron guns are used as sources of exciting radiation. Ultraviolet light is generated mainly by capillary discharge lamps filled with helium at a pressure of ~1 mmHg. The resonance line at a wavelength of 584 Å (21.21 eV) predominates in the discharge. The emission is collimated with the aid of a capillary tube. The sources of X-rays consist of both the usual X-ray tubes and of tubes with a rotating anode (to decrease the local over-heating of the anode). The material of the anode is usually aluminium and magnesium and rarely copper and chromium. The radiation is made monochromatic to increase the resolution of the spectrometers.

In modern X-ray spectrometers there are two types of analysers: magnetic and electrostatic. In magnetic spectrometers the electrons are focussed with the aid of a magnetic field. Apparatus with double magnetic focussing has been described[1]. In almost all commercial spectrometers electrostatic focussing is used nowadays; in this case the requirements for the compensation of the Earth's magnetic field are much less stringent. The scanning of the spectrum with respect to energy is achieved by a retarding electrostatic field applied as a rule between the spectrometer and the source. In the best modern electron spectrometers provision is made for highly efficient systems designed to generate an ultrahigh vacuum. The residual pressure after evacuation with heating at ~200° is $\sim 10^{-10}$ mmHg. The maximum pressure of the gas (vapour) in the specimen chamber depends on the excitation source employed but does not exceed 10^{-5} mmHg.

After passing through the analyser, the electrons are detected by a radiation receiver. In the first spectrometers of Siegbahn's group[1] photographic plates were used for detection. Nowadays electrons are counted with the aid of proportional counters or electron multipliers.

Although the fundamental design of the electron spectrometers has not changed, the measuring technique continues to improve. Thus a method has been described[22] for eliminating the interfering background signal which is superimposed on the Auger spectra in the region of low electron energies and depends strongly on the energy. The method consists in modulating the intensity of the electron beam with a continuous alteration of the modulation amplitude as the electron energy is varied, which causes a corresponding change in the sensitivity of the spectrometer as a function of the energy. This method made it possible to detect many intense closely spaced peaks for low electron energies, i.e. under conditions where the fine structure is usually lost.

One should note that in the industrial production of electron spectrometers a tendency has arisen very recently to manufacture two types of instruments. The first type consists of high-speed spectrometers designed for the rapid analysis of several specimens immersed in the vacuum chamber simultaneously (sometimes up to 20), which can consist of a combination of two complex instruments. Thus "Physical Electronics Industrials"# has manufactured an instrument which is a combination of X-ray electron and scanning Auger spectrometers; 12 specimens can be fixed simultaneously in the cassette of the apparatus. However, despite its considerable analytical possibilities, this device, designed for large series of routine measurements (necessary, for example, in the manufacture of the elements of integrated circuits), cannot replace the instruments of the second type, designed for scientific research. In these instruments (for example, in the ESCA-3 electron spectrometer)[2] the time required to obtain the spectra of a series of specimens is much longer.

#See "Handbook for Electron Spectroscopy", PEI, N.Y., 1978.

However, the instrument has a chamber for the preliminary treatment of the specimen, separated from the analyser chamber by a vacuum lock. In this device the metallic specimen can be etched by an ion beam in order to obtain a clean surface. The specimen can be heated (using an electron gun) to 1800 °C or cooled to the temperature of liquid nitrogen. In the preliminary treatment chamber the metal can be sputtered. The provision of metering taps in the chamber makes it possible to treat the specimen in a specified atmosphere. The content of the components of the atmosphere is controlled by a quadrupole mass-spectrometer, the sensor of which is mounted directly in the preliminary treatment chamber. This auxiliary equipment significantly extends the scope of the experiment.

IV. OXIDATION OF METALS

The oxidation of metals, particularly at temperatures close to 300 K, which leads to the formation of very thin oxide films, is one of the most "natural" processes investigated with the aid of electron spectroscopy. This is why the first studies on the oxide films on metals, arising when oxygen interacts with the surface, were carried out almost simultaneously with the development of the method of electron spectroscopy itself[1]. The early studies of the oxidation of metal surfaces have been briefly reviewed[3,23]. We shall examine below the fundamental results of a series of investigations which not only made it possible to understand more deeply the mechanism of the initial stages of the oxidation but also in many instances led to the discovery of hitherto unknown effects.

The considerable practical value of iron and its alloys have apparently been the cause of the extensive research carried out in different countries into oxidised surfaces of iron (and iron alloys) with the aid of XES and AES. In the first study where XES was used to investigate the oxidation of iron in atmospheres of oxygen and water vapour[24] it was shown that the shift of the Fe $2p_{3/2}$ level, observed in the oxidation of iron by oxygen, depends significantly on the duration of exposure to oxygen and the pressure of the latter. The range of oxygen pressures was 10^{-2}–10^{2} mmHg. Shifts of the binding energy (ΔE_b) of the electrons of the Fe $2p_{3/2}$ level of 3.2 and 4.2 eV corresponded to the minimum and maximum pressures respectively. These results[24] show that, depending on the oxidant pressure, the relative contents of Fe^{2+} and Fe^{3+} ions in the surface layer of the oxide can be significantly altered.

On the other hand, the presence of two states of oxygen on the iron surface has been observed[24] (the O 1*s* line consisted of two peaks); the relative contribution of each state also depends on the oxygen pressure and the duration of exposure. The authors[24] explained the existence of a doublet in the structure of the O 1*s* line by the presence on the surface of two forms of oxygen—in the chemisorbed state and the form corresponding to the oxygen in the iron oxide. The latest conclusions by the above investigators[24] are in clear conflict with the results of a study[25] where it was observed with the aid of AES that, for nearly monolayer coverages, the oxygen forms with the surface bonds analogous to those in Fe_2O_3 and the "chemisorption" component of oxygen is therefore negligibly small.

The combination of AES with mass spectrometry[26] and slow-electron diffraction[7] yields extremely important information about the interaction of the surfaces of an iron single crystal with oxygen and water vapour in the very initial stages. But it has been shown[27] that the oxidation of the (100) and (110) faces leads to an increase of the lattice parameters and to a change of symmetry from cubic to hexagonal. It has been noted[26] that, for surface coverages less than a monolayer, the adhesion coefficient is close to 0.2. This quantity persists up to the accumulation of oxygen on the surface in an amount of $\sim 1.6 \times 10^{15}$ cm^2. This quantity of oxygen corresponds satisfactorily to the surface density of the Fe atoms on the (110) face. Next the adhesion coefficient falls to less than 10^{-2}. These data are correlated with the results of a study[28] where it was shown that the oxygen adsorbed on the iron surface (the oxygen–surface bond energy is 9 kcal mol^{-1}) gives rise to a surface superstructure, which leads in its turn to a sharp decrease of the adhesion coefficient. On saturation with oxygen, this superstructure rearranges to two-dimensional FeO crystals. Further adsorption of oxygen leads to the formation of a three-dimensional oxide film. An equally detailed study of the oxidation of iron by water vapour was made by Dwyer et al.[29] In determining the kinetic parameters of the adsorption of oxidant molecules on iron, the authors of the above studies did not consider the kinetics of the growth of the three-dimensional oxide. Such a study with the aid of XES was made by Akimov et al.[30], who investigated the oxidation of polycrystalline iron in oxygen and water vapour; the range of oxidant pressures was 10^{-5}–10^{-7} mmHg. Much attention has been devoted to the purity of the initial surface and the oxidants§. The purity of the oxygen and water vapour was followed with the aid of a quadrupole mass-spectrometer combined with the preliminary treatment chamber of the X-ray electron spectrometer. A gun for the etching of the surface of the specimen with Ar^+ ions was mounted on this chamber. The surface of the specimen was regarded as "clean" when the ratio of the integral intensities of the iron and oxygen signals was ~100. Approximate calculation showed that this intensity ratio corresponds to the adsorption of ~0.1 of a monolayer of oxygen on the surface. Figs.5*a* and 5*b* [30] present the X-ray electron spectra of the Fe $2p_{3/2}$ lines for oxidation with oxygen and water vapour. Figs.5*c* and 5*d* illustrate the X-ray electron spectra of the O 1*s* line also for oxidation with oxygen and water vapour respectively. Analysis of the data presented in Fig.5 permitted the following conclusions.

1. After exposure of iron to oxygen (duration of exposure ≥ 10 *L*¶), an oxide film having the composition Fe_3O_4 is formed on its surface. This conclusion is based on the measurement of ΔE_b for the Fe $2p_{3/2}$ line in the oxidation process, which amounted to -3.6 ± 0.1 eV, and on the stoichiometric ratio Fe/O, calculated from measurements of the integral intensities of the Fe $2p_{3/2}$ and O 1*s* lines. For comparison, one should note that ΔE_b amounts to 4.2 and ~1.0 eV for Fe_2O_3 and FeO respectively. The smaller value of ΔE_b for Fe_3O_4 compared with Fe_2O_3 is associated with the presence of iron ions in the +2 oxidation state. Ertl and Wandelt arrived at the same conclusion[32].

2. The exposure of iron to water vapour does not lead to the formation of a three-dimensional oxide film on the iron surface, as shown by the comparatively small changes in the intensity of the Fe $2p_{3/2}$ line (Fig.5*b*) and the absence of the oxide component of this line.

3. The symmetry of the O 1*s* peak, its small half-width, and the value of E_b for the oxidation of iron with oxygen show that the oxygen adsorbed on the iron immediately forms bonds analogous to the Fe–O bonds in the oxide. The clear asymmetry of the O 1*s* peak in the oxidation of iron by water vapour and the results of the Fourier resolution of this peak

§It has been shown[31] that the presence of impurities on the surface can inhibit (sulphur) or significantly accelerate (carbon) the oxidation.

¶Here *L* denotes a Langmuir (10^{-6} mmHg s).

show that oxygen exists on the surface in two states: the oxygen involved in the Fe–O bond on the surface oxide and the oxygen of the hydroxide ion—the high-energy component of the O 1s doublet.

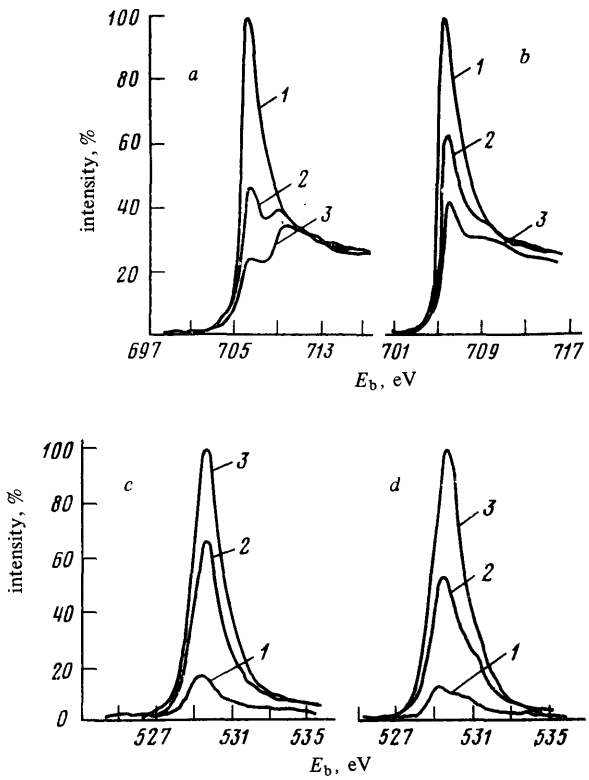

Figure 5. X-Ray electron spectra of the Fe $2p_{3/2}$ (*a* and *b*) and O 1*s* (*c* and *d*) lines for the Fe + O_2 (*a* and *c*) and Fe + H_2O (vapour) (*b* and *d*) systems; exposure (in Langmuirs): 1*a*)–1*d*) 0; 2*a*) and 2*c*) 5; 2*b*) 2.4×10^4; 2*d*) 2.4×10^3; 3*a*) and 3*c*) 10^3; 3*b*) 5×10^4; 3*d*) 5×10^3.

By analysing the dependence of the intensities of the X-ray electron lines of the elements on the duration of exposure in an atmosphere of the oxidant, it was possible to establish[30] certain kinetic relations for the initial stages of the interaction of iron with oxygen and water vapour. In the initial stage of the oxidation, where the peak in the X-ray electron spectrum of the Fe $2p_{3/2}$ line, corresponding to iron in the oxidised state, is not visible because it is overlapped by a high-intensity background caused by the scattering of the electrons dislodged from the Fe $2p_{3/2}$ level, it is difficult to infer the growth of the oxide film from the decrease of the intensity of the Fe $2p_{3/2}$ peak. Its intensity depends on the thickness of the surface film, in the given case an oxide, in the following manner[2]:

$$I=I_0\exp[-d/(\lambda\cos\alpha)], \qquad (7)$$

where α is the angle between the normal to the plane of the specimen and the spectrometer slit, I the intensity of the Fe $2p_{3/2}$ line for a given exposure, I_0 the intensity of the signal due to the clean surface, d the thickness of the film, and $\lambda = 15$ Å the depth from which electrons are emitted with a given kinetic energy[33]. Eqn.(7) is valid when the values of λ for the clean and oxidised metal surfaces are constant, which can be assumed to a first approximation.

The dependence of the thickness of the oxide film d on the duration of exposure to O_2, calculated from Eqn.(7), is illustrated in Fig.6.[30] It follows from the data in Fig.6 that, up to a thickness of ~5 Å, the oxide film grows in accordance with a linear law; for greater thicknesses, a logarithmic law governs the growth of the oxide film, corresponding formally to the model of the growth of the oxide surface put forward by Hauffe and Ilschner[23]. This shows that the transfer of charged species in the surface oxide begins to limit the rate of growth of the oxide only after the attainment of a film thickness of ~5 Å, which corresponds to two oxide monolayers.

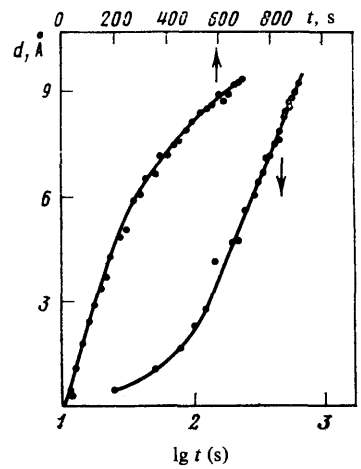

Figure 6. Dependence of the oxide film thickness (d) on the time of exposure t of iron to O_2.

The slight changes in the intensity of the Fe $2p_{3/2}$ peak following the absorption of H_2O vapour on the surface of the specimen (Fig.5*b*) suggest that this entails only the absorption of the products of the interaction between the adsorbate and the adsorbent. The degree of the adsorbent surface coverage θ can be estimated by modifying Eqn.(7) somewhat. If the thickness of the adsorbed layer does not change with θ, the modified equation relating the intensity of the Fe $2p_{3/2}$ peak to θ, can be written thus:

$$I=I_0(1-\theta)+I_0\theta\exp(-\Delta/\lambda). \qquad (8)$$

where Δ is the thickness of the adsorbed layer. On the basis of the known radii of the O^- and OH^- ions as well as the geometrical structure of the H_2O molecule, one can adopt $\Delta \cong 2.5$ Å. Having adopted, as before, $\lambda = 15$ Å, we obtain

$$I=I_0(1-\theta+0.85\theta)=I_0(1-0.15\theta), \qquad (9)$$

whence

$$\theta=6.7(1-I/I_0). \qquad (10)$$

The dependence of θ on the duration of exposure of the specimen to water vapour, calculated from Eqn.(10) for a water vapour pressure of 10^{-8} mmHg, is presented in Fig.7.[30] An estimate of the contamination of the surface by O, C, N,

and Ar atoms after bombarding it with a stream of Ar^+ ions leads to an initial surface coverage $\theta_i < 0.1$. This value of θ_i was adopted as the starting point for the θ readings in Fig.7.

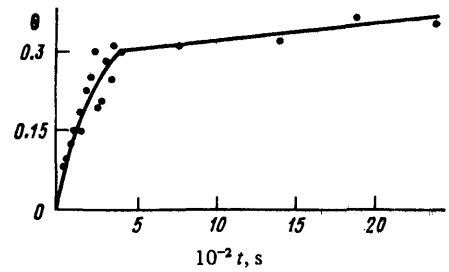

Figure 7. Dependence of the degree of surface coverage θ of iron on the exposure time t in H_2O vapour.

The data in Fig.7 show that, in the adsorption of the dissociation products of water molecules, $\theta = 0.3$ is attained fairly rapidly after which the rate of surface coverage decreases significantly and that, for an exposure of iron to water vapour $>10^4$ *L*, no growth of the oxide film is observed[30]. The low values of θ for which a significant inhibition of adsorption is attained demonstrate, in our view, a strong interaction of the adsorbed species on the surface.

Numerous studies have been made of the oxidation of nickel (and particularly of the adsorption of oxygen and other oxidants) by electron spectroscopy. In the first of these[34] the X-ray electron spectra of nickel were obtained before and after its treatment with oxygen and water vapour. It was also shown that the oxide film on nickel consists of NiO. Other workers arrived at the same conclusion[35]. The surface of nickel has been investigated[36,37] by XES for very low exposures in oxygen (exposure <2 *L*).[37] For such small exposures, a bulk-phase oxide film was not formed on the surface and the chemisorption of oxygen on the nickel surface was investigated.

The X-ray electron spectra of the nickel surface with chemisorbed oxygen served as the basis for a quantum-mechanical model of the formation of the Ni_3O cluster, put forward by Batra and Pobaux[37]. The model of the NiO_6^{10-} cluster has been calculated[38] on the basis of data obtained in the study of the interaction of the (111) face of nickel with oxygen by ultraviolet electronic spectroscopy and low energy electron diffraction.

The results of a detailed investigation of the oxidation of Ni single crystals [(111), (110), and (100) faces] and polycrystalline nickel in the range 30–70 °C with the aid of UPES and XES have been described[39]. It was observed that the initial stage of the interaction with oxygen constitutes dissociative chemisorption for all four types of surface. For a coverage equivalent to ~0.2 of a monolayer, the chemisorption structure comprises adsorbed oxygen atoms distributed on the surface of the nickel support. With increase in the degree of surface coverage to 0.8 of a monolayer, the oxygen atoms are arranged at the lattice sites between the surface nickel atoms. With increase of exposure, the oxygen atoms penetrate into the bulk of the nickel specimen and form a three-dimensional oxide with an average thickness of ~18 Å. This oxide layer is a non-stoichiometric nickel oxide NiO.

The oxidation of nickel was investigated also by the authors of the present review[40]. The results are fully correlated with the conclusion[39] that the oxidation of nickel proceeds via a chemisorption stage. Furthermore, it has been shown[40] that the chemisorbed oxygen on the surface of nickel exists together with the three-dimensional oxide. This is indicated by the data in Fig.8.[40] The figure shows that the X-ray electron spectra of the O 1s line, corresponding to oxygen on the surface of nickel (at 20 °C), undergo a significant change not only in intensity but also in form with increase of exposure. If, after etching with Ar^+ ions the surface gives rise to a low-intensity peak with a maximum at 531 eV (curve *1*) corresponding to a small amount of oxygen, then exposure to oxygen, equal to 20 *L* (curve *2*), does not increase significantly the intensity of the peak, but causes its appreciable broadening. Fourier analysis of this structure yields two peaks with $E_b = 529.5$ and 531 eV. An increase of exposure (curves *3* and *4*) leads to an increase of the intensity of the O 1*s* peak and to a change of the intensity ratio of the two peak components. According to some investigators[35,39], E_b for electrons corresponding to the O 1*s* line of NiO is 529.5 eV. On the other hand, according to Joyner and Robertson[41], the presence of adsorbed oxygen increases E_b by 1.5 eV, which yields 531 eV in our case.

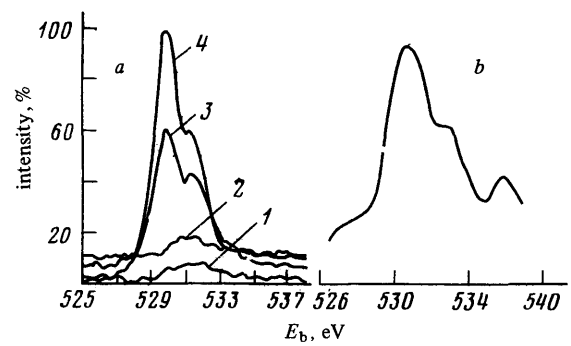

Figure 8. *a*) X-Ray electron spectra of the O 1*s* line on exposure of nickel to O_2 at 20 °C [exposure (in Langmuirs): 1) 0; 2) 2; 3) 10^3; 4) 10^5]; *b*) X-ray electron spectra of the O 1s line on heating an oxidised nickel surface in a vacuum of $\sim 10^{-10}$ mmHg at 100 °C.

Thus the change in the structure of the O 1*s* peak on interaction of nickel with oxygen indicates the existence of only adsorbed oxygen on the nickel surface in the initial stage of the interaction and the existence of oxygen in two states—adsorbed and "oxide"†—in subsequent stages of the oxidation. Heating of the oxidised nickel *in vacuo* ($\sim 10^{-10}$ mmHg) to 100 °C diminishes somewhat the oxide component and the O 1*s* doublet is better resolved (Fig.8*b*).

The oxidation of aluminium was investigated by AES and layer-by-layer etching of the oxide by a beam of Ar^+ ions in a study[42] which is largely of methodological importance. A study[43] of the kinetics of the adsorption and oxidation of aluminium, magnesium, and manganese, and chromium is of considerable interest, the oxidation of aluminium and magnesium having been investigated in greatest detail. The

†A state analogous to that of oxygen in the nickel oxide NiO.

information obtained[43] is of extreme interest also because the interactions of metals with oxygen and water vapour were studied simultaneously by two methods: XES and the method of piezoquartz weighing. The quartz resonator was mounted directly in the preliminary treatment chamber of the electron spectrometer. Data were obtained[43] for both the chemical composition of the surfaces of the oxides and for the dependence of the adhesion coefficient of the oxidant molecules on the exposure and hence on the chemical composition of the surface. The experimental demonstration of the direct proportionality between the change in the intensity of the peak of the O 1s line and the amount of adsorbed oxygen on the above metals must be regarded as an important result of the investigation[43]. The possibility of the formation of both the oxide MgO and the hydroxide $Mg(OH)_2$ on the surface of magnesium when it interacts with water vapour was demonstrated[43]. ΔE_b for these compounds amounted under these conditions to 2.5 eV according to the data of the above investigation. The oxidation of magnesium has been studied in greater detail by Akimov et al.[44], who obtained the electron spectra of the O 1s line, confirming the conclusion[43] that a mixed oxide, consisting of magnesium oxide and hydroxide, is formed on the magnesium surface on interaction with water vapour (Fig.9). This is indicated both by the values of E_b corresponding to the O 1s doublet and by the ΔE_b for these peaks. With increase of the exposure of the magnesium surface in water vapour, the relative amount of $Mg(OH)_2$ also increases. The ratio of the amount of magnesium hydroxide to that of the oxide is stabilised for an exposure of 20–30 *L* and amounts to 0.45; the overall thickness of the oxide film is then also stabilised.

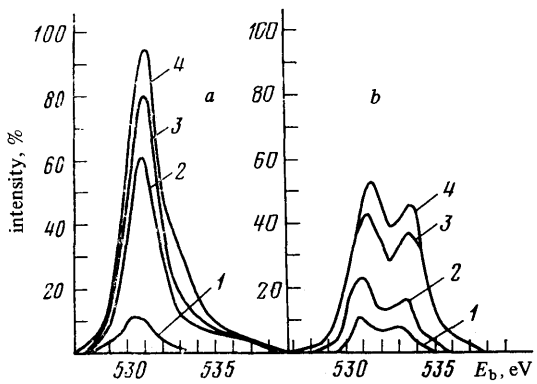

Figure 9. X-Ray electron spectra of the O 1s line on exposure of magnesium to O_2 (*a*) and to H_2O vapour (*b*); exposure (in Langmuirs): *a*: 1) 0.75; 2) 8; 3) 25; 4) 3100; *b*: 1) 5; 2) 10; 3) 25; 4) 10^4.

The oxidation of titanium has been studied by XES.[45–48] An investigation[45] of the electrons corresponding to the Ti $2p_{3/2}$ line for an oxidised titanium surface and titanium oxides showed that the ΔE_b for the Ti $2p_{3/2}$ electrons in TiO and TiO_2 amount to 1.9 and 5.4 eV respectively (relative to the same line for titanium in the zero oxidation state). These data differ from the values of ΔE_b for TiO and TiO_2 published previously[46] (1.0 and 4.9 eV). However, the results of Grant et al.[47] and additional data[48], also published by Simon et al.[45], demonstrate the validity of the values obtained by the latter workers[45]. The value of the study by Simon et al.[48] also lies in the fact that these workers elucidated the composition of the surface in the oxidation of titanium as a function of temperature at an oxygen pressure of ~10^{-5} mmHg. Furthermore, Simon et al.[48] established the values of ΔE_b for titanium compounds such as the carbide, nitride, and hydride, which are respectively 1.8 ± 0.2, 2.2 ± 0.2, and 0.6 ± 0.2 eV.

A study of the oxidation of alloys showed that certain effects can be observed only with the aid of electron spectroscopic methods. Thus a study[49] of the composition of the surface of Au–Ni alloys showed that, when oxygen was adsorbed, the concentration of gold on the surface increased by a factor of 100 compared with the bulk phase and, conversely, the adsorption of hydrogen caused an enrichment of the surface in nickel. The enrichment of the surface in indium on Au–In alloys has been observed with the aid of AES.[50]

The enrichment of the surface in tin following the oxidation of an Ag–Sn alloy has been observed[51] by XES, its extent increasing on heating the alloy. A study of the oxidation of Ni–Al alloys[52] containing between 10 and 30% of nickel, in air at temperatures in the range 20–450 °C showed that aluminium predominates on the surface and determines the behaviour of the alloy on oxidation, even after treatment with alkali, which tends to remove aluminium from the surface. A significant change in the composition of the surface of the alloy has been observed in a study[53] where the oxidation of platinum–rhodium alloys was investigated in air at temperatures up to 1000 °C with the aid of XES and the mass spectrometry of secondary ions. The authors[53] found a significant enrichment of the surface in rhodium at alloy oxidation temperatures close to 1000 °C.

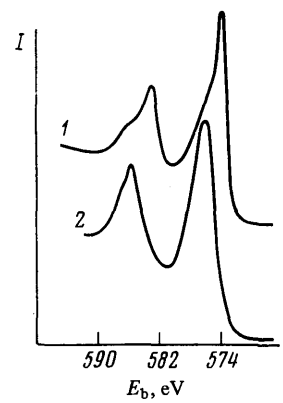

Figure 10. X-Ray electron spectra of the Cr 2p line obtained on oxidation of massive chromium (curve *1*) and the 86% Fe + 14% Cr alloy (curve *2*).

The dependence of the surface concentration of chromium in the $Fe_{0.84}Cr_{0.16}$ single crystal on the oxygen pressure has been investigated[54]. The authors concluded that the change in the ratio of the concentrations of chromium and iron on the surface is associated with the difference between the free surface energies and oxygen affinities of chromium and iron. The oxidation of Fe–Cr alloys in oxygen and water vapour has also been studied by Akimov et al.[55] at ~300 K and oxygen and water vapour pressures in the range 10^{-7}–10^{-5} mmHg.

They investigated the kinetics of the oxidation of these alloys and determined the compositions of the oxide films formed on their surfaces. It was found that the oxide films consist of a mixture of Fe_3O_4 and Cr_2O_3. Comparison of the X-ray electron spectra (Fig.10) of the Cr 2*p* line for the oxidised surface of chromium (curve *1*) and the oxidised surface of an alloy of 86% of iron and 14% of chromium (curve *2*) shows that chromium in the massive state and in the alloy is not oxidised in the same way. Indeed, the chromium in the massive state is oxidised at low oxygen pressures to give a stable oxide film with a thickness equivalent to 2–3 monolayers[10], which is manifested by a slight "bulge" on the Cr $2p_{3/2}$ peak on the high-energy side. The chromium in the alloy with iron is wholly oxidised to Cr_2O_3 for the same exposures, which follows from the shift of the E_b for the Cr $2p_{3/2}$ peak (curve *2*). This difference in the oxidation of chromium in the alloy and in the massive state can be accounted for by the absence of kinetic control in the oxidation of chromium in the alloy, which shows in its turn the absence of aggregates made up of chromium atoms from the oxide film, i.e. the oxide film consists of a solid solution of Cr_2O_3 in Fe_3O_4.

V. ELECTROCHEMICAL PROCESSES AND METAL CORROSION

The electrochemical reactions occurring at the metal–electrolyte interface can lead to a significant change of the chemical composition of the surface of the metallic electrode. These changes are very often localised in a thin surface layer ~100 Å thick. In this case a quantitative analysis of the changes in the chemical composition of the electrode surface can be performed only by electron spectroscopic methods. Here one should recall that such analysis cannot be performed *in situ* and in each specific case one must therefore estimate the possibility of undetectable changes in the chemical composition of the surface associated with the removal of the electrode from the electrochemical cell.

One of the first studies of the application of XES in the investigation of the changes in the chemical composition of the metal as a result of chemical and electrochemical reactions in a metal–electrolyte system was one[56] where the composition of the surface of the platinum electrode was determined (indicated in weight percentages in the Table below) in the course of its treatment in concentrated nitric acid and electrochemical oxidation in 1 *N* $HClO_4$.

The composition of the platinum electrode surface.

Surface compound	HNO_3	Potential in 1.0 *N* $HClO_4$		
		0.7 V	1.2 V	2.2 V
Pt	41	56	39	34
PtO (ads.)	39	39	37	24
PtO	14	5	24	22
PtO_2	6	0	0	20

The tabulated data could not be obtained by any other method and, although the absolute values obtained in the above study[56] give rise to doubts[57], the value of this investigation consists primarily in the fact that the scope of XES in the study of the metal–electrolyte interface was demonstrated.

The electrochemical oxidation of platinum and gold in sulphuric acid has been studied[57] with the aid of XES. It was shown that the oxide layers on platinum begin to be formed at potentials in the range 0.6–0.7 V# (in the same solution); PtO_2 appears at potentials of 1.2–1.3 V. The oxide film on gold consists of Au_2O_3. The thickness of the oxide layers and the true electrode surface areas have been estimated[57]. An important result is the observation[57] of the reduction of platinum and gold oxide under the influence of X-rays; this fact, which was disregarded by Kim et al.[56], can have a significant effect on the results of X-ray electron spectroscopic studies.

The modifications of a tin oxide surface of the electrode formed on adsorption of aminopropylethoxysilane $(C_2H_5O)Si.(CH_2)_3NH_2$ on the latter have been investigated[58] with the aid of XES. It was shown that the adsorption of this substance leads to the formation of covalent –Sn–O–Si– bonds on the electrode surface. The results of the analysis of the X-ray electron spectra are in good agreement with those obtained in the measurement of the impedance in the electrode–electrolyte system.

The surface films arising on a gold electrode in the electrochemical reduction of the Cr^{6+} ion have been studied in an investigation[59] where the gold electrode was polarised in 1 M chromic acid mixture and a mixture of 1 M chromic acid and 0.01 M sulphuric acid. The dependence of the chemical composition of the surface on that of the solution and the electrode potential has been investigated[59] by XES; furthermore, the changes in the thickness of the surface layer, formed on gold following the adsorption of various complexes arising as a consequence of the electrochemical reduction of Cr^{6+} ions, have been studied by analysing X-ray electron spectra.

The chemical composition of the surface of an iron electrode ("Armco") has been investigated[60] by XES in a neutral solution to which a series of oxo-anions, used as corrosion inhibitors, were added. The following salts were studied: Na_2WO_4, Na_2MoO_4, Na_3VO_4, $NaVO_3$, and Na_2CrO_4. The salt concentrations in the electrolyte corresponded to the protective concentrations found as a result of separate experiments. The results[60] permit the following conclusions.

1. All the oxo-anions investigated are strongly chemisorbed on the iron surface, behaving at the same time as acceptors, which follows from the somewhat higher values of E_b for the Fe $2p_{3/2}$ electrons compared with E_b for the Fe $2p_{3/2}$ electrons in the case of Fe_2O_3.
2. On chemisorption, the oxidation state of all the oxo-anions, except the chromate anions, remain unchanged.
3. The entire chemisorbed chromate is reduced, undergoing a transition from the +6 oxidation state to the +3 oxidation state.
4. On chemisorption of the oxo-anions (with the exception of chromate), the oxide Fe_2O_3, in which part of the oxygen has been substituted by the oxo-anions, is present on the surface.
5. The anomalously high protective capacity of chromate compared with other oxo-anions can apparently be accounted for by the existence of a stable complex, the formation of which is probably associated with the reduction of the CrO_4^{2-} anion on the surface of iron.

The study of the interaction of organic inhibitors with the surfaces of metals and alloys is of considerable interest. The interaction of metal ions with the inhibitor results in the formation of complexes whose solubility is fairly low and which are deposited on the surface of the metal. These complexes can in fact enter into the composition of the protective surface layer, which prevents the oxidation of the metal.

#Here and henceforth the potential is given relative to the normal hydrogen electrode.

Despite certain difficulties, particularly the necessity to remove the specimen from the working solution and to transfer it through the atmosphere (although the latter can be eliminated by employing a preliminary chamber filled with nitrogen or another inert gas), promising data have been recently obtained with the aid of XES.[61,62]

For example, surface layers formed as a result of the interaction of benzotriazole with copper (benzotriazole inhibits the corrosion of copper in chloride solutions) have been studied[61]. It has been shown that the protective film consists mainly of the copper(I) complex of benzotriazole. These data were compared with the results obtained with the aid of infrared reflection spectroscopy and the authors[61] were able to estimate the thickness of the surface film as a function of the method of treatment of the specimen.

In the study of the interaction of the surface of iron with organic molecules containing amino- and cyano-groups, it was shown that the interaction of iron with the amino-group results in a considerable decrease in the positive charge on the iron atom and an increase of the positive charge on the nitrogen atom as a result of the formation of the Fe ← N coordinate bond.

However, one should note that there have been as yet no studies of the interaction of the metal surfaces with inhibitors. Furthermore, studies of the interaction of metal surfaces with volatile inhibitors, in which one could carry out experiments in the spectrometer chamber without contact of the specimen with the atmosphere, are apparently of interest.

The interest in the problem of the passivity of metals led to a number of investigations involving the study by electron spectroscopic methods of passive oxide films on the surfaces of metals, in the first place iron and its alloys. The passive films on an iron electrode in neutral borate solutions have been studied[63,64]. Auger spectra have been obtained[63] with layer-by-layer etching of the passivating oxide film on iron with Ar^+ ions, which was formed in the anodic oxidation of an iron electrode in a borate buffer (pH 8.4); its thickness did not exceed 50 Å according to the authors[63], who concluded that a two-layer model is suitable for the oxide film on the iron surface, the inner and outer layers consisting of Fe_3O_4 and γ-Fe_2O_3 respectively.

Different oxide phases, formed on iron under different oxidation conditions, have been studied[64] by AES. The authors[64] were able to distinguish different oxide phases on iron: FeO, Fe_3O_4, Fe_2O_3, and FeOOH. However, the conclusions reached in the above studies[63,64] can hardly be regarded as unambiguous. Apart from the disadvantages of the AES in quantitative analysis described above, this is also indicated[65] by studies of the degradation of the passivating film on iron when the specimen is heated *in vacuo*[65]. According to Revie et al.[65] heating of the specimen leads to irreversible changes in the oxide film associated with the decomposition of OH^- ions. The exposure of the oxide film to a beam of primary electrons, used to generate Auger electrons, can lead to analogous results.

The X-ray electron spectra of chrome and chrome-nickel steels in $1N\ H_2SO_4$ have been obtained[66] and interpreted over a wide range of potentials. It was shown that, depending on the electrode potential, the surface can be enriched in iron or chromium, i.e. the possibility of the selective dissolution of chrome steels was confirmed. It was observed[66] that the surface of steel electrodes exposed at a potential of −0.4 V (the potential corresponding to the maximum rate of anodic dissolution of chromium) is significantly enriched in iron; the opposite behaviour is observed when the electrodes are maintained at −0.15 V. At this electrode potential, which corresponds to the maximum rate of the anodic dissolution of iron, the surface is enriched in chromium. The enrichment of the surface in nickel was not observed.

The influence of silicon on the electrochemical behaviour of Ni–Si alloys (silicon concentration from 0.1 to 3.3 wt.%) in $2N\ H_2SO_4$ has been studied[67]. The silicon concentration on the surface was determined by XES. It was shown[67] that the introduction of silicon into the alloy increases the repassivation currents by two orders of magnitude. Chemical analysis of the surface showed that this effect is associated with a change in the surface concentration of silicon when the electrode potential is altered. It was found that the silicon is present on the surface in two oxidation states (+2 and +4).

The states of the surface of a nickel electrode in the active and passive regions have been studied by different methods[68], including XES (the electrolyte was $1N\ H_2SO_4$). The X-ray electron spectra obtained confirmed that, at potentials more positive than 0.6 V, films of the nickel oxide Ni_2O_3 are formed on the nickel surface. The formation of this oxide terminates at potentials of ~1.0 V. At potentials more negative than 0.6 V (but corresponding to the passive region) an NiO film is present on the nickel surface.

The dependence of the composition (atomic ratio of magnesium and aluminium) of the surface of aluminium bronze in seawater on the electrode potential has been studied by XES.[69] The relation obtained is satisfactorily consistent with the electrochemical idea that the layer near the electrode becomes more alkaline in the cathodic range of potentials and more acid in the anodic range.

The joint application of the technique involving the etching of the surface with a beam of Ar^+ ion and the XES method permitted a layer-by-layer analysis of the passive films formed on chrome steels[70,71]. The surface layer formed on binary Fe–Cr alloys $\{40 \leq [Cr] \leq 30$ wt.%$\}$ following the exposure of the specimens to doubly distilled water freed from oxygen has been investigated at 25° and 70 °C.[70] It was shown that in all cases the concentration of chromium in the surface layer of the oxide increases near the oxide–medium interface; the concentration of chromium on the surface varies linearly with its volume concentration, but dc_S/dc_V increases with temperature (c_S and c_V are the surface and volume concentrations of chromium in the alloy). The passive layer consists of a two-layer film, in which the outer layer consists of chromium hydroxide $Cr(OH)_3$, while the mixed oxide $Fe_{1+x}Cr_{2-x}O_4$ is located closer to the metal. A model of the interaction of steel with water has been proposed[68].

The influence of the same medium and temperatures as in the study of Olefjord and Fischmeister[70] on a chrome-nickel steel (18/8 steel) has been investigated[63]. Castle and Clayton[71] were able to achieve a milder etching of the surface by Ar^+ ions and to obtain a larger number of points on the concentration profiles, which makes their result more reliable. The thickness of the oxide films was 15–30 Å. The composition of the surface oxide includes Cr^{3+}, Fe^{2+}, and Fe^{3+} bound to OH^- or O^{2-} ions. The authors[71] believe that the selective oxidation or dissolution of the components of the steels is ruled out.

---o0o---

The above examples of the application of the XES, AES, and UPES methods in the study of the interaction of the surfaces of metals and alloys with the external medium show that, with their aid, it is possible to obtain very valuable and sometimes unique information about the nature of the chemical interactions occurring on the surfaces and in the surface layers of solids. Application of electron spectroscopic methods in combination with mass-spectrometric and diffraction methods yields a fully quantitative picture of the complex chemical processes occurring on the surfaces of metals when the latter interact with various media and makes it possible

to identify reliably the chemical transformations already in the chemisorption stage when the degree of surface coverage is much less than a monolayer.

Naturally, the analytical possibilities of the above methods are not of interest solely to specialists working in the field of oxidation, corrosion, and electrochemistry, although the examples of the application of the methods refer to these particular fields. One should note that a number of reports containing extensive data on the application of XES, AES, and UPES in the study of adsorption and catalytic processes have now been published[72-75]; furthermore, a collection of reports[76], published in Russian translation in 1979, is extremely useful to investigators becoming acquainted with the applications of electron spectroscopic methods.

Internal Reflection Spectra of Surface Compounds and Adsorbed Molecules

V.M.Zolotarev, V.I.Lygin, and B.N.Tarasevich

The application of attenuated total reflection (ATR) spectroscopy in surface studies of inorganic adsorbents and catalysts, polymers, and optically transparent electrodes is discussed. The basic principles of ATR spectroscopy as applied to surface phenomena are considered, with special reference to thin films, industrial adsorbents and catalysts, and polymer degradation processes. 276 References.

I. INTRODUCTION

Since the first report (Fahrenfort, 1961) of spectral measurements on a condensed phase by attenuated total internal reflection[1] the ATR (attenuated total reflection) method has been widely used in practical spectrochemical studies[2-5].

The basic principles of attentuated total reflection spectroscopy and of its applications have already been discussed in monographs[5,6] and reviews[7-13]. The rapid development of practical applications was helped by the discovery of high refractive index materials transparent in the infra-red, by new mathematical methods of describing the ATR spectra, and by the appearance of special attachments for all types of i.r. spectrometer, allowing single (ATR) and multiple (MATR) internal reflection. The wide appeal of the method is explained also by the similarity between the ATR and the transmission spectra, both in the position of the bands and in the validity of Beer's law.

However, in spite of the outward similarity between ATR and transmission spectra, there is a fundamental difference, associated with the form of the electromagnetic field interacting with the sample. When the spectrum is recorded under ATR conditions the electric vector of the light wave near the interface between the sample and the prism retains all its three components, and as a result the ATR spectra (unlike the transmission spectra) give information on the dipoles oriented at right angles to the surface. Hence, the surface and the bulk properties of solids can be studied simultaneously by the combined use of ATR and transmission spectra.

A large amount of experimental information on surface phenomena obtained by the ATR method is now available. New variants of internal reflection spectroscopy include spectrorefractometry, Raman spectroscopy, liquid ATR spectroscopy, studies of chemical reactions and of adsorption on flat surfaces, and the use of optically transparent electrodes in electrochemistry. New develoments in methods of obtaining the ATR spectra of surfaces and in the study of surface compounds and of adsorption on sorbents, catalysts, polymer surfaces, and electrodes are reviewed in this paper.

II. BASIC PRINCIPLES OF THE ATTENUATED INTERNAL REFLECTION SPECTROSCOPY METHOD

The ATR spectra are produced by the high sensitivity of the reflection coefficient R to changes in the absorption coefficient κ and, to a smaller extent, in the refractive index n. By optimising the experimental conditions we can minimise the sensitivity of the spectra to changes in n while retaining their sensitivity to changes in κ. This is achieved by suitable choice of the angle of incidence: a few degrees greater than the critical angle ($\sin\theta_{crit} = n_2/n_1$, where n_2 is the refractive index of the unknown material and n_1 is the refractive index of the ATR attachment, with $n_1 > n_2$). The spectra recorded with $\theta > \theta_{crit}$ show very little distortion of the bands, though the intensity of the bands is greatly reduced. Stronger bands can be obtained by increasing the number of reflections: the method is then called the MATR (multiple attenuated total reflection) method. The spectra measured with $\theta \cong \theta_{crit}$ can differ very substantially from the absorption spectra, but they offer a high contrast even after a single reflection. The choice of the method of producing the spectrum (ATR or MATR) depends on the specific features of the problem.

1. Principles of Quantitative Analysis by ATR Spectroscopy

Quantiative analysis by ATR spectroscopy consists in determining the optical constants n and κ from the ATR spectra of the experimental materials by using the Fresnel formulae. The spectra obtained from multi-layer systems, or substances having a surface layer of variable concentration, can be analysed by using the generalised Fresnel formulae sometimes called the recursion formulae[14,15]. Since the calculation can be carried out on a computer the use of the recursion formulae offers a flexible method of quantitative analysis in ATR spectroscoy, because most surface concentration profiles can be modelled as multi-layer systems on a computer. Various approximations are used in analytical practice to describe the dependence of the reflectance coefficient R on the absorption (or on the concentration) by means

of simple expressions. These approximations are obtained by expanding the R coefficient in a power series of the adsorption coefficient κ.[16] The expression proposed by Harrick[5] is the simplest and the most widely used.

The reflectance coefficient R under conditions of internal reflection can be expressed as

$$R = 1 - \alpha d_{\text{eff}},$$

where $\alpha = 4\pi\kappa\nu$ is the absorption coefficient, and d_{eff} is the effective thickness. At low absorptions ($\alpha d_{\text{eff}} < 0.1$) this expression is equivalent to approximating R by a series expansion in α truncated after the first term. Hence, since the attenuation of the light intensity after a single reflection is small, the experimetnally measured reflectance coefficient can be expressed as

$$R = e^{-\alpha d_{\text{eff}}}.$$

For large samples, of thickness much greater than the wavelength of the light ($2\pi d/\lambda_1 > 1$), we have the following expressions for parallel and for perpendicular polarisation of the incident light respectively:

$$\frac{d^{\perp}_{\text{eff}}}{\lambda_1} = \frac{n_{21}\cos\theta}{\pi(1-n_{21}^2)\cdot(\sin^2\theta - n_{21}^2)^{1/2}} \qquad \frac{d^{\parallel}_{\text{eff}}}{\lambda_1} = d^{\perp}_{\text{eff}} \cdot \frac{2\sin^2\theta - n_{21}^2}{(1-n_{21}^2)\sin^2\theta - n_{21}^2},$$

where $n_{21} = n_2/n_1$ is the relative refractive index. In both cases the effective thickness decreases as θ increases, and increases with the wave length of the light in the optically denser medium ($\lambda_1 = \lambda/n_1$).

Several authors have used the Beer–Lambert law in spectro-analytical ATR work. Calibration curves (optical density against concentration) were used to analyse polyester layers[17,18], for the quantitative determination of vinyl acetate in the polyethylene copolymer[19] used as a surface-active additive to Nylon-6,[20] to monitor the extent of reaction during the synthesis of epoxy resins[21], and for the quantitative determination of carbonyl compounds in polyethylene[22].

In the case of a thin film on a transparent substrate (n_3), and assuming that the conditions $2\pi d/\lambda_1 < 0.1$ and $\kappa < 0.1$ apply, the effective thicknesses can be obtained to a good approximation from the expressions

$$d^{\perp}_{\text{eff}} = \frac{4n_{31}d\cos\theta}{1-n_{31}^2}, \qquad d^{\parallel}_{\text{eff}} = d^{\perp}_{\text{eff}} \frac{(1+n_{32}^4)\sin^2\theta - n_{31}^2}{(1+n_{31}^2)\sin^2\theta - n_{31}^2}.$$

By comparing the expressions for thick samples and for thin films we note that the ATR spectra of thin films are similar in many ways to ordinary transmission spectra. Thus, their intensity is independent of the wave length, and in the neighbourhood of the critical angle the changes in d_{eff} are gradual. In thin films $d^{\perp}_{\text{eff}}$ can be greater than or smaller than $d^{\parallel}_{\text{eff}}$, depending on the relative values of n_1 and n_2, and both these parameters can be substantially greater than the geometric thickness of the sample.

The spectral changes in the absorption coefficient α can be found by measuring R. The integral characteristics of the bands also are calculated from the ATR spectra, using the more convenient Γ-integral (related to the usual A-integral ($A = \int \alpha d\nu$) by the simple expression $\Gamma = A\nu_{\max}$)[23]. Since $\alpha = Kc$, where K is the molecular absorption coefficient and c is the concentration, we have

$$R = e^{-Kcd'_{\text{eff}}/\nu},$$

where $d'_{\text{eff}} = d_{\text{eff}}\nu \cdot n_1$. Therefore we can write

$$\Gamma = \int \alpha \frac{1}{\nu} d\nu = \frac{1}{cd'_{\text{eff}}} \int \ln\frac{1}{R} d\nu.$$

If the Γ-integral is expressed in the dimensions of cm^2 mole^{-1} the intensity of the fundamental vibrations lies in the range 10^2–10^5, and that of the overtones in the range 1–100.

In practice the Kramers–Kronig method[24] is used most often to evaluate n and κ, because it requires only half as many measurements as the two-angle method[5]. The Kramers–Kronig calculations rely on reference values ("tie-values") of n and κ, known for one or two points in the integration region:

$$\varphi(\nu_0) = -\frac{\nu_0}{\pi}\int_{\nu_{\text{init}}}^{\nu_{\text{fin}}} \frac{\ln R(\nu)}{\nu^2 - \nu_0^2} + C_1(\nu_0) + C_2(\nu_0),$$

where ν and ν_0 are the time-dependent and the fixed wave number, ν_{init} and ν_{fin} are the limits of the integration range, and C_1 and C_2 are correction terms[24]. Having calculated $\phi(\nu_0)$ we can find the "amplitude" reflection coefficient

$$\hat{r}(\nu_0) = R^{1/2} e^{i\varphi(\nu_0)},$$

which is related to n and κ (for perpendicular polarisation) by the expression

$$\hat{r}_{\perp} = \frac{(\bar{n}_2^2 - n_1^2\sin^2\theta)^{1/2} - n_1\cos\theta}{(\bar{n}_2^2 - n_1^2\sin^2\theta)^{1/2} + n_1\cos\theta},$$

where $\bar{n}_2$ is the complex refractive index of the material ($\bar{n}_2 = n_2 - i\kappa_2$). The first attempt to measure n_2 and κ_2 from ATR infrared spectra by this method[11] gave satisfactory results.

Some regions of the spectrum of fused quartz[25] are shown in Fig.1 to illustrate the comparison of bulk and surface properties in terms of measurements of optical constants by different methods. The absorption by the surface layers of SiO_2, given by the ATR measurements, is quite different from the bulk optical properties of quartz. The results shown in Fig.1 are qualitatively consistent with measurements on a quartz sample in optical contact with a Ge ATR cell, and with measurements by the liquid technique[68].

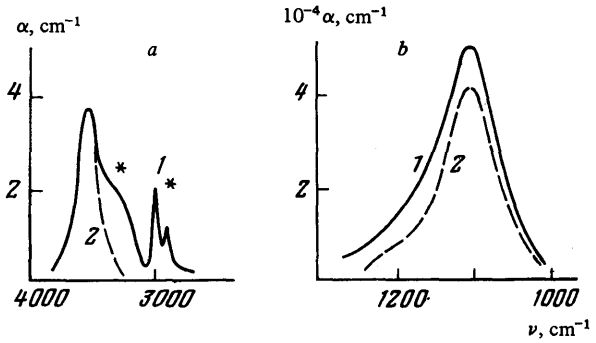

Figure 1. Optical properties of polished fused quartz, measured by different methods: (*a*) *1*) ATR method, *2*) transmission method; (*b*) *1*) ATR method, *2*) external reflection method. The asterisks denote bands due to adsorbed water and hydrocarbons.

Direct quantiative studies of substances supported on solid surfaces are complicated by the need for an ideal contact between the sample and the ATR cell (which is readily achieved in the case of liquid samples). Some workers assume that a "physical contact" is adequate for measurements of n

and κ, others make a correction for the transition layer (or gap) by using an intermediate value of the refractive index[26–28]. In some cases "optical contact" between the surfaces is successfully established, giving reliable measurements on strong bands, but is is claimed[29] that a gap of 40–100 Å is still present, though it does not substantially affect the measurements if the material which fills the gap by capillary condensation (usually water) is transparent in the chosen spectra region. In the case of measurements in the absorption band of the adsorbate (i.e. in the transmission region of the substrate material) even such a small gap can produce unexpected results, since the topography of the surface will produce a gap at the contact between the two solid surfaces, and as a result of capillary forces this gap will contain a thin layer of water and hydrocarbons. These effects are more marked when the surfaces are etched.

The possibility (in principle) of obtaining accurate values of n and κ from a solid surface can be realised in practice by using liquid ATR spectroscopy in the visible[5] or the i.r. region[30]. This variant has been used to study pentacene films adsorbed on crystalline or glassy substrates, and also the surface properties of poly(tetrafluoroethylene) (Teflon-4) in thin-film and in massive samples[30]. Immersion liquids having a specially high refractive index have proved very useful in this work.

An important practical contribution to this type of measurement was a detailed study[31] of the dependence of the results on the quality of the optical contact and on the size of the air gap beween the polymer sample and the MATR cell, with a description of an attachment for pressing the sample controllably against the cell. An apparatus including such an attachment is described also in Ref.32.

Modified variants of ATR spectroscopy have been used in recent years (in addition to the more traditional ATR methods) to study solid surfaces[33–35]. In all these variants a gap, usually air-filled, is present between the sample and the ATR cell when a spectrum is recorded from a flat surface. Under these conditions the incident light interacts with surface vibrations (polaritons) which are non-radiative, i.e. they are not detected under normal conditions such as in transmission spectra. Studies of the spectroscopic characteristics of polaritons give information on the dynamics of the crystal lattice. Experiments of this type, with alkali halide crystals, were first reported in Ref.36. The method was used also to study the surface of a series of uniaxial crystals[37], including α-quartz[38,39].

In studies of finely divided media by the ATR method surface polariton bands can appear in the spectrum close to strong bands from the crystalline powder[40]. The intensity and shape of the latter will be largely determined by the crystal habit of the particles and by the polarisation of the incident light. It has been shown[40,41] that whereas external reflectance spectra consist mainly of bands from transverse vibrations of the crystal lattice the ATR spectra tend to reveal longitudinal and surface vibrations. It should be noted that the study of adsorption on powders not previously treated (e.g. by pressing) requires a large number of reflections (50–100), as well as an expanded photometric scale.

In work with relatively coarse particles distortion of the bands (or even the appearance of new bands) is possible, and model calculations of the reflectance spectra must be carried out to avoid incorrect interpretation of the experimental results. Thus, a simple multi-layer model has been used[41] to calculate the ATR spectra of powders and fibres from the Fresnel formulae for multi-layer systems[14]. The effective reflectance coefficient R of such a system for a plane wave can be expressed as a statistical sum in the case of cylindrical fibres. It is assumed that the optical properties of each layer are equivalent to those of one fibre. If the diameter of the fibre is $d \gg \lambda$, and $\theta \gg \theta_{crit}$, the integration can be replaced by a summation with $\theta = \text{const}$.[44]

A convincing test of this model, made with fused quartz fibres 10 and 50 μm in diameter, gave excellent agreement between calculation and experiment, especially with perpendicular polarisation[42]. The advantage of using a model approach is clearly demonstrated in Refs.42 and 43, where a system of new, very strong i.r. bands at 1100–900 cm^{-1} (which are not found in transmission) is satisfactorily interpreted by using a somewhat more detailed model of close-packed quartz fibres 10 μm in diameter (see Fig.2). In the case of spherical particles the R coefficient must be calculated with allowance for the increase in the relative contribution to R with the number of steps when the sphere is divided into flat layers. These problems are highly relevant to the future application of MATR spectroscopy in studies of industrial adsorbents and catalysts, most of which are used in a powder or fibre form, and also in studies of polymer fibres.

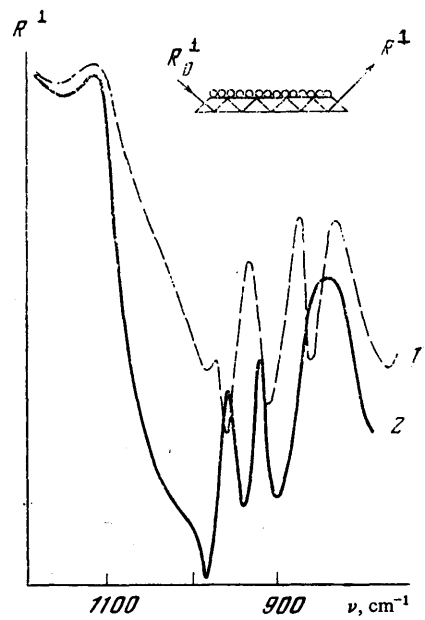

Figure 2. Comparison of experimental (*1*) and calculated (*2*) MATR spectra for close-packed quartz fibres 10 μm in diameter[43].

The roughness of surfaces with a fine finish has been studied[44] by using a model of the surface consisting of a system of intermediate layers with gradually varying values of n and κ. SiO_2 and LiF crystals were studied in the "residual ray" region. The optical properties of the transition

layer were modelled by the Lorentz–Lorenz equation in the complex form

$$\frac{\bar{n}_l^2-1}{\bar{n}_l^2+2}=\frac{\bar{n}_M^2-1}{\bar{n}_M^2+2}V+\frac{\bar{n}_s^2-1}{\bar{n}_s^2+2}(1-V),$$

where $\bar{n}_l$, $\bar{n}_s$, and $\bar{n}_M$ are the complex refractive indices of the layer of roughened surface, of the substance filling the uneven regions of the surface, and of the material M at a given depth within the sample respectively, and V is the proportion by volume of the bulk phase in the layer M. This approach has proved very successful in quantitative studies of the state of water and hydrocarbons adsorbed on micro-heterogeneous polished surfaces[29,45,46], and also in the study of microporous films[44,47–51].

2. Thin Films

Quantitative studies of thin films offer entirely new possibilities in the application of spectroscopic methods to practical problems in micro-electronics, integrated optics, and laser technology. However, allowance must be made for possible non-uniformities in very thin films, especially discontinuities in properties over the thickness of the film and roughness of the substrate surface, both of which can influence the optical properties of the film. The molecular adsorption of water on a polished fused quartz surface has been studied extensively[52–55], and the optical properties of the water film on an undulating surface with a small-scale roughness of 40–100 Å were shown to be markedly dependent on the optical characteristics of the substrate material and on the type of micro-roughness.

By allowing for these factors in the use of the Lorentz–Lorenz equation we conclude that the intrinsic spectroscopic properties of water in layers more than 10 Å thick (i.e. the shape and intensity of the stretching and bending vibration bands) are similar to those for ordinary liquid water. On the other hand, direct measurements of the refractive index of water in the very thin (~12 Å) gap between two flat surfaces in "optical contact" have revealed a clear dependence on the refractive indices of the two surfaces in contact.

A method of calculating the primary and the secondary structure of a polished surface has been developed from these these observations[45]. When the surfaces are brought in contact at a relative humidity of 50–60%, corresponding to an average thickness of 12 Å for the adsorbed water layer, the bending vibration at 1620 cm^{-1} shows a strong anomaly: its intensity is about 4 times greater than that of the corresponding band for liquid water[52]. As the relative humidity is increased the layer becomes thicker, and its optical properties become indistinguishable from those of liquid water at a thickness of 40 Å, but if the water layer is subsequently thinned the shape of the spectrum is unchanged (i.e. the spectrum does not revert to its initial state). Many hydrocarbon contaminants have been detected on these surfaces. The removal of these contaminants, which appear to be a residue from surface etching treatments, combined with special treatments to give hydrophilic surfaces, should enable thicker layers of water to be sorbed on the surface by a multimolecular mechanism. Comparison with ellipsometric measurements can be valuable, because very accurate thickness measurements on very thin films are possible by ellipsometry. The measurements suggest that the specific absorption of light by surface defects exceeds bulk absorption almost 100-fold[56].

Ellipsometry has been effectively combined with ATR spectroscopy in studies of the transition layer at the semiconductor–dielectric interface[57]. The adsorption of CO_2 on Si,[58] of H_2O on α-quartz[58], of proteins on polymers[59], and of proteins on carbon[60] have also been studied. As well as flat interfaces, layers adsorbed by porous systems have been examined by the ATR method[48–50,61].

3. Apparatus

A wide range of ATR and MATR attachments, mainly for the i.r. region, is now avaiable commercially. Apparatus for measurements in vacuum and at different temperatures is being developed[62,63], including the special MNPVO-3 MATR attachment which can be used with Soviet spectrophotometers (IKS-14, -22, -16, -29) as well as with the UR-20. This apparatus has already been used in a number of investigations, and has yielded very interesting results[29,43,45,52]. A vacuum adsorption cell is described also in Ref.64.

Attempts to develop a liquid-phase version of ATR spectroscopy resulted in the production of various attachments for the visible region[65]. Liquid MATR cells have been based on liquid chalcogenide glasses, especially As_xBr_yS, which are transparent in the i.r. region.[66–69] The standard ultra-high refractive index immersion liquids (with refractive indices up to $n = 2.1$) were shown[52] to have a set of wide transmission "windows" at 4000–750 cm^{-1}, making them suitable for use in ATR spectroscopy. Media with $n \geq 2.4$ have also been discovered.

Instrumental developments in ATR spectroscopy include, in addition to the construction of new attachments for the spectrophotometer, new designs of high-precision apparatus. These include the IRF-461 spectrophotorefractometer, developed for the simultaneous and accurate determination of both the optical constants n and κ of the complex refractive index[70]. Another recent development is the ISN-1, a multi-purpose industrial MATR spectrophotometer[71,72] which can be applied to a wide range of surface investigations.

The high sensitivity of the combination of MATR with Fourier spectrometers has allowed, for example, the measurement of MATR spectra in the i.r. region on polybutadiene filled with Aerosil and carbon black (up to 20 parts by weight per 100 parts of elastomer). The technique is particularly useful in studies of optically transparent electrodes, which attenuate the light beam up to 100-fold. Various problems in electrochemistry have been solved by using MATR cells coated with a film (up to 800 Å thick) of gold, platinum, or other conductor.

Plasma techniques have been used to clean the surface of ATR cells. Practical recommendations on the alignment of the apparatus and on corrections for a number of systematic errors (convergence of the light beam, uncertainty in the number of reflections, error in the angle of incidence) are made in Ref.11. Some of the recommended assemblies[11] have been used by other workers to determine n and κ for a number of liquids[73–79].

III. ADSORPTION

1. Surface Chemistry

The surface compounds which determine the selectivity of adsorbents and the catalytic properties of catalysts have been studied intensively by i.r. spectroscopy[80,81]. Whereas the transmission variant of i.r. spectroscopy is usually adequate for finely divided adsorbents and catalysts, having a large surface area, the MATR method has to be used to study the surface chemistry and the adsorption phenomena

of thin films supported on massive solids (silicon or germanium crystals, quartz, various glasses, crystals of halide salts, etc.)[82-84]. Special vacuum cells have been developed for MATR studies of surface compounds and adsorbed molecules[64,85].

The influence of surface treatment on the optical properties of the constituents of MATR cells has been studied in several laboratories. Surface treatment of a silicon MATR prism by hydrogen ions produces an absorption band at 2062 cm^{-1}, assigned to vibrations of the Si–H groups[86]. When silicon MATR elements are heated in water absorption bands due to amorphous silica appear at 1600–1850 cm^{-1}.[87] The MATR spectrum of thermally oxidised silicon includes absorption bands at 1870 and 1620 cm^{-1} (Si–O vibrations)[81]. Absorption bands from the OH group (3630–3650 cm^{-1}) and from the Si–H group (2250 cm^{-1}) are found in the spectrum of a silicon sample bombarded with phosphorus ions and heat treated in hydrogen[88]. Anodic oxidation of a silicon surface produces absorption bands from hydrogen-bonded hydroxyl groups in the MATR spectrum. Free hydroxyl and hydride groups have have been observed[89] on a silica surface heated at 1050° to 1200 °C in oxygen and water vapour. Molecular deposition reactions, in which the surface of a Si or Ge prism is treated with $SiCl_4$ or $GeCl_4$, produce strong bands at 1070 cm^{-1} (SiO_2) or 860 cm^{-1} (GeO_2, hexagonal) in the MATR spectrum[90-92].

MATR studies of porous silica films up to 1000 Å thick have yielded valuable information on the surface chemistry of this system. The films were prepared on the surface of MATR plates, and used as models of highly disperse adsorbates based on silica. One method of deposition used in this work was by electron-beam evaporation of crystalline silicon[47]. The initial spectrum of a film deposited on quartz by this method[85] included a broad absorption band at 3000–3700 cm^{-1}. Heating the sample to 50 °C produces bands at 3640 and 3460 cm^{-1}. When the temperature is raised to 150–200 °C the band at 3460 cm^{-1} is almost completely suppressed, and a band appears at 3670 cm^{-1}. After treating the sample in vacuum at 350–400 °C a band is observed at 3700 cm^{-1}, but the band at 3670 cm^{-1} does not disappear fully even after baking at 450 °C.[85]

Similar changes in the MATR spectrum have been reported for silica films deposited on silicon prisms[93] by the hydrolysis of $SiCl_4$ vapour at room temperature or from alcoholic solutions of $Si(OC_2H_5)_4$. Molecular water was found[93] to be almost completely removed by pumping at 35 °C. After dehydroxylation at 200 °C the spectrum shows an absorption band from hydrogen-bonded surface hydroxyl groups (at 3520 cm^{-1}) and a band from free hydroxyl groups on the micropore surfaces (at 3680 cm^{-1}). Only the absorption band for the free groups (at 3700 cm^{-1}) remains after vacuum treatment at 400 °C. The shift of this band by 50 cm^{-1} as compared with the free hydroxyl group band on Aerosil (3750 cm^{-1}) [81] is explained by perturbations of these groups through interactions with the oxygen atoms of the micropores.

A systematic study of hydrolysis reactions on the surface of quartz glass, and of their relevance to surface defects in glass and hence to the strength of glass, has been undertaken by the MATR method[94-100]. An absorption band at 3650 cm^{-1} and a weaker band at 3500–3550 cm^{-1} can be observed in the MATR spectrum of the surface layer of quartz glass. The absorption band due to adsorbed water molecules disappears after the prism is heated to 300 °C.[95] The influence of the thickness of the layer containing hydroxyl groups, and of the polarisation state of the light, on the precision with which the concentration of hydroxyl groups in quartz glass can be determined by the MATR method has been the object of a special study[96].

The hydrolysis of a quartz glass surface in a saturated aqueous solution of silica at 200–300 °C is discussed in Ref.97. The real strength of the glass (with surface defects) was found to increase with the temperature and the duration of the immersion in the aqueous solution. This effect is ascribed to preferential hydrolysis of the most highly stressed siloxane bonds on the surface of the glass. The strength of etched quartz glass has been shown to depend on the hydrolysis of a small proportion of the surface bonds[98]. The hydrolysis of quartz glass in an autoclave at 70–240 °C affects a surface layer 2–10 μm thick[99]. On the other hand, the nucleation and fast growth of all types of defect, accompanied by a large decrease in strength, occurs at the cristobalite (200–300 °C) and quartz (570–600 °C) phase transition temperatures of the crystalline modifications of silica[100].

The surface chemistry of other solids also has been studied. Thus, the MATR spectra of polished samples of gallium arsenide which had been stored in water show absorption bands at 700 cm^{-1} (Ga–O, As–O), 1550 cm^{-1} (Ga=O, As=O), and 850 cm^{-1} (Ga–OH, As–OH).[101]

MATR studies of the surface chemistry of powdered adsorbents deposited on a prism have been less successful, owing to the limited volume of material which can be irradiated. The MATR method has been used[102] to study the spectrum of surface hydroxyl groups in powdered α-quartz of 0.5 μm particle size. After heat treatment in vacuum at 200 °C the powder gave narrow symmetrical bands at 3649 and 3627 cm^{-1}, which were assigned to two different types of free hydroxyl group on the surface. The absorption bands from structural hydroxyl groups in zeolite (at 3740 cm^{-1}) were shown[103] to be much weaker in the MATR spectra than in transmission spectra.

The MATR method is very valuable in surface studies of carbon adsorbents, which end to absorb and scatter the i.r. radiation[104-107]. Thus, MATR spectroscopy has been used[104] to identify the functional groups on active carbon surfaces. The MATR spectra (at 1000–2000 cm^{-1}) of sugar charcoal activated in O_2 or $CO_2 + O_2$ atmospheres denote the presence of surface carbonyl and carboxyl groups[106]. Carbon films deposited in a vacuum on a KRS-5 element were investigated[107]: after being oxidised in a solution of $K_2S_2O_8$ these films gave absorption bands from CO groups (at 1710 and 1736 cm^{-1}) and bands from aliphatic CH groups (at 2850 and 2920 cm^{-1}).

The spectrum of a Cu film 20 Å thick deposited in a vacuum on a KRS-5 prism and subsequently exposed to the air showed absorption in the region of 700–320 cm^{-1}, consistent with the formation of Cu_2O.[107]

2. Adsorbed Molecules

MATR has been used as a very sensitive method of checking the freedom from organic contaminants of single-crystal silicon surfaces. The sensitivity of the detection of aliphatic organic compounds on the surface of a silicon element is 3×10^{-9} g cm^{-2}, and higher than the sensitivity of the methods of surface control used in the electronic components industry[108]. When the element has been washed in de-ionised water the MATR spectrum is found[109] to include absorption bands from the stretching vibrations of CH groups in aliphatic hydrocarbons present on the surface at a concentration of 3×10^{-8} g cm^{-2}. Heating the silicon plate in alcohol causes partial removal of the surface oxide layer, together with its associated organic contaminants[110,111].

The adsorption of stearic acid molecules on single-crystal surfaces has been studied in detail[112–116]. Sharke[112] examined the monolayers of stearic acid and its esters on germanium prism. The sensitivity of the detection, using the absorption bands of C–H and C=O stretching vibrations, was 2.3×10^{-7} g cm^{-2}. Dimeric molecules of the fatty acid are adsorbed preferentially from solutions of stearic acid in CCl_4 of 0.005–0.01% concentration[113]. The interaction between stearic acid molecules and a silicon surface is reported[113] to be significant only at solution concentrations >0.01%, though the effects become noticeable even at lower concentrations if the adsorbed water molecules are previously removed.

The MATR method[114] has been used to measure the adsorption isotherm of stearic acid from CCl_4 solution on the surface of a silicon prism (curve *2* of Fig.3). The result is compared with the Gibbs adsorption isotherm in curve *1* of Fig.3. The concentrations of adsorbed molecules were determined after removing the prism from the solution. The sensitivity of the detection of stearic acid on the prism from the 2920 cm^{-1} band was 3×10^{-9} g cm^{-2}. The portion of the isotherm near the first point of inflection (at low concentrations) corresponds to the surface area occupied by one molecule of stearic acid (154 Å), and is consistent with a planar orientation of the molecules along the prism surface. The region of almost constant surface concentrations, in equilibrium with concentrations of $2–3 \times 10^{-4}$ mole fraction, corresponds to a sloping portion of the Gibbs adsorption isotherm, for which the surface is covered with a monolayer of molecules oriented at an angle to the surface. The point of inflection (curve *1* of Fig.3) at an equilibrium concentration of 4×10^{-4} mole fraction corresponds to an area of 20.5 Å^2 per molecule, and therefore indicates molecular orientation at right angles to the surface in the close-packed monolayer. The MATR spectra of adsorbed stearic acid molecules measured at the points of inflection of the isotherm are consistent with a change in orientation of the molecules, from planar through sloping to vertical. These changes are accompanied by an increased contribution from the "crystalline" form of the adsorbed molecules.

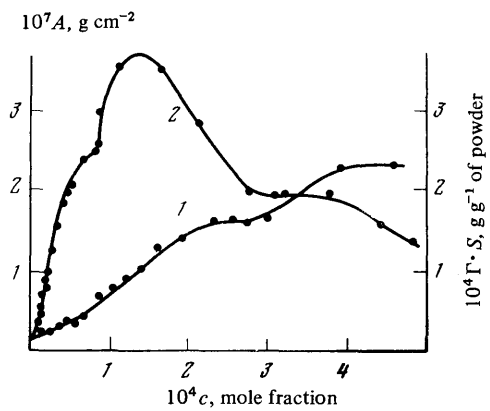

Figure 3. Adsorption isotherms for stearic acid on silicon: *1*) Gibbs adsorption (Γ) on powdered silicon from CCl_4 solutions; *2*) surface concentration of stearic acid (A) adsorbed on a silicon MATR prism from solution in CCl_4 (S is the surface area of the powder)[114].

Polarised MATR spectra give additional information on the orientation of adsorbed molecules. Takeneka and coworkers[116] studied the polarised MATR spectra of molecular layers of stearic acid deposited on the surface of a germanium prism by the Langmuir–Blodgett method. They concluded that these films consist of a system of monoclinic crystals, oriented with their C axis at an angle varying from 217° to 35° (depending on the number of layers) to the normal to the stearic acid–germanium interface. Preferential growth of these crystals takes place in the plane parallel to the stearic acid–germanium interface. The thickness of a monolayer is 23.8 Å.

The aggregation and the orientation of large flat molecules on the surface of MATR elements has been studied also by other workers[117,118].

The spectrum of a monolayer of ethyl octadecanoate molecules on the surface of a germanium prism includes an absorption band for free CO groups (1745 cm^{-1}), but not for hydrogen-bonded CO groups (1710 cm^{-1}).[103] This shows that hydrogen bonds are not formed between molecules in the adsorbed state. Reaction between the carbonyl groups and the Ge surface is observed after lengthy storage.

The polarised MATR spectra in the visible region for Methylene Blue adsorbed on a glass prism surface are discussed in Ref.117. Adsorption cuases a change in the relative intensity of the absorption from monomeric (600 nm) and dimeric (660 nm) molecules, as well as the appearance of a new absorption band at 740 nm. These spectral changes are ascribed to preferential adsorption of the dimeric form. The polarisation measurements indicate a parallel orientation of the adsorbed molecules.

Polarised MATR spectra have been used[118] to study the orientation of 1,1-diethyl-2,2-carbocyanine bromide molecules on silver chloride and glass surfaces. On a silver chloride surface these molecules are adsorbed as aggregates or micelles, in which the plane of the molecules is perpendicular to the surface. On the other hand, on a glass surface the adsorption is mainly molecular, or in small aggregates of the sandwich type. Under the latter conditions there is no preferential orientation of the molecules with respect to the surface.

Very interesting results have been obtained from MATR studies of adsorption on adsorbents and catalysts of industrial importance, and on models of these adsorbents. The state of the adsorbate has been characterised by MATR studies of these materials in the form of oxide films on the surface of the optical elements. The small thickness of the films (<1 μm) and, therefore, the low absorption and almost total lack of scattering of the i.r. radiation ensure that the adsorbate is detected with a high sensitivity[119]. The sensitivity of detection of adsorbed water by the MATR method (using the 1625 cm^{-1} band) is 0.03% of a monolayer[93].

The adsorption properties of films prepared on the surface of silicon elements by the hydrolysis of $SiCl_4$ vapour are determined by the microporous structure of the film[93]. These films can adsorb water molecules, but not ethanol molecules: in other words, their pore diameter is $<4.7 \times 10^{-4}$ μm. Silica films prepared from alcoholic solutions of $Si(OC_2H_5)_4$ have a looser structure.

The adsorption of water molecules by films which have been dehydroxylated at 400 °C causes hydroxylation of the micropore surface[93]. The absorption bands produced by the adsorption of water molecules correspond to bending vibrations of the dimeric molecules (at 1625 cm^{-1}) and to stretching vibrations of the OH group in the strong hydrogen bond region (3300 cm^{-1}, see Fig.4). This suggests the formation of two types of hydrogen bond by the adsorbed molecules: with the oxygen atoms of the surface hydroxyl groups and

with the oxygen atoms on the micropore surfaces. Heating the films in air (to 400 °C) does not lower the adsorption of water molecules, but sintering effects are produced by heating the porous films to 700 °C.[120]

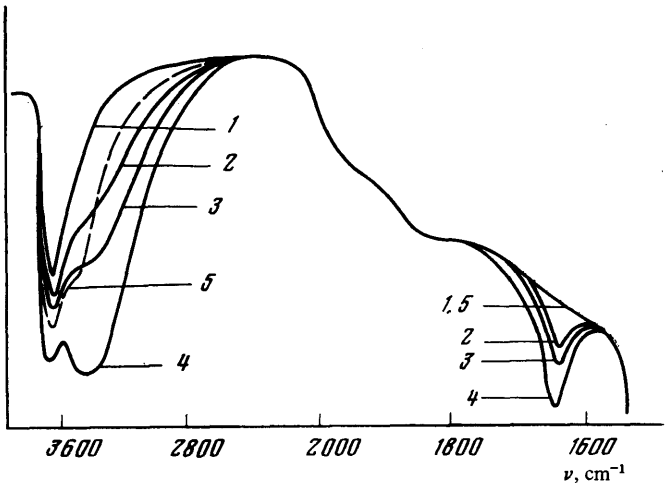

Figure 4. Infrared MATR spectra of water adsorbed on a silica film baked in vacuum at 400°: *1*) initial film, stored in vacuum at 30°, *2*) after adsorption of H_2O at 0.33 mmHg, 3) ditto at 0.8 mmHg, 4) after 4 days in contact with H_2O vapour at 0.8 mmHg, 5) after freezing out the H_2O vapour with liquid nitrogen[93].

The methods of quantitative evaluation of the MATR spectra (see II, 1) allow us to determine the amount of water adsorbed and to calculate the volume and diameter of pores in the film[47,62]. Absorption bands at 3650 and 3550 cm^{-1} were observed[47] in the MATR spectrum of SiO_2 films prepared by electron-beam evaporation in a vacuum and allowed to adsorb water from a moist atmosphere. The water content was determined from the intensity of the 3550 cm^{-1} band in films of different thickness prepared in different ways, and the pore volume was calculated in each case. An average pore diameter of 5–7 Å was obtained[47].

Changes in the MATR spectrum produced by the adsorption of $CHCl_3$ on films of this type heated to different temperatures indicate sintering effects at temperatures as low as 100 °C.[85]

MATR spectroscopy has been used[121] to determine the water content of thin films of SiO_2, MgF_2, and ZnS deposited by vacuum evaporation on Si, Ge, and KRS-5 prisms. The layers were shown to be fully saturated with water after admission of air at a relative humidity of 60–70% into the vacuum chamber. The changes in optical characteristics of the layer are throught to be due to the increased refractive index produced by the filling of the micropores by water molecules.

ZnS films prepared by laser evaporation in air have also been examined[51]. Their MATR spectra contained bands due to adsorbed water and hydrocarbon molecules.

The pore surfaces of films prepared by vacuum evaporation may contain, in addition to hydroxyl groups, other adsorption centres of the acceptor type which can induce major changes in the electronic structure of adsorbed molecules. Thus, anomalous band intensities as well as new absorption bands are observed[119] in the MATR spectra of $CHCl_3$ and CCl_4 molecules adsorbed on Ge and MgF_2 films evaporated in a vacuum by the electron beam method. Most of the water adsorbed on gallium arsenide layers was found[101] to be in a molecular form, attached to the surface by donor–acceptor bonds.

The MATR spectra of all the films obtained by vacuum deposition of SiO_2, ZrO_2, GeO_2, In_2O_3, Al_2O_3, NdO, MgF_2, SrF_2, NdF_2, CaF_2, ZnS, and Sb_2S_3 were found to contain an absorption band due to adsorbed water (3350 cm^{-1}). Various studies of the effect of deposition rate, residual gas pressure, and substrate temperature on the porosity of these films have been reported[62,122,123].

The MATR spectra of molecules adsorbed on single crystals of aluminium oxide are particularly interesting, because this compound is widely used as an adsorbent and a catalyst. The polarised MATR spectra of surface hydroxyl groups have been measured[124] on the (0001), (1123), and (4150) faces of an α-Al_2O_3 crystal. Molecular orientation in monolayers of calcium stearate and n-pentanol on the (4150) face was determined, and the adsorption isotherms were measured on all three faces at 30–120 °C. The isosteric heats of adsorption for a film 0.4 of a monolayer thick on the (0001), (1123), and (4150) faces were 13, 19, and 26 kcal $mole^{-1}$ respectively.

The MATR spectra of stearic acid molecules adsorbed from CCl_4 solutions on Ge and on Al_2O_3 (0001 face) prisms have been studied[115] with a Fourier spectrometer. The maximum detection sensitivity was 0.03 of a monolayer. The authors discuss in detail[115] the application of MATR spectroscopy to adsorption and desorption kinetics, adsorption isotherms, adsorbent–adsorbate interactions, molecular orientation, and to the structure and chemisorption of layers of adsorbed molecules.

The polarised spectra of CO molecules adsorbed on palladium salts deposited on the surface of a NaCl prism have been measured[125]. The low-frequency absorption bands (<1800 cm^{-1}) are assigned to CO molecules adsorbed with a high heat of adsorption (~40 kcal $mole^{-1}$) on Pd atoms from low-index crystallite faces, whereas the absorption bands at 1800–2000 cm^{-1} are associated with bridging structures found only on some of the faces of the Pd crystallites. Linear surface structures are found on Pd atoms of all the faces of the crystallites.

MATR spectra have been used[106,107,117] to study adsorption on opaque carbon films. The spectra of *p*-nitrophenol adsorbed on charcoal[106] and on carbon black[117] are consistent with the formation of donor–acceptor complexes with surface carbonyl groups. The spectra of albumin adsorbed on evapported carbon films have also been described[107].

The MATR method is also being applied to studies of biological materials, including bacteria[126]. A method of measuring the adsorption and desorption isotherms of water on protein films deposited from aqueous solutions on the surface of a KRS-5 prism has been described[127]. The MATR adsorption isotherms for water molecules on egg albumen and on tropomyosin were shown to be identical to those given by the MacBain balance.

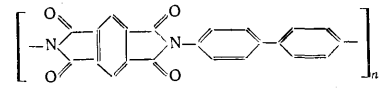
The MATR method can be used also to study molecules on powdered adsorbents. Thus, it has been applied in the identification of compounds in chromatographic spots in the

separation of mixtures of *o*- and *p*-nitrotoluenes with 2,4-dinitrotoluene and of a mixture of *o*-, *m*-, and *p*-anisidine[128], and in the separation of steroids by thin-layer chromatography[129]. The MATR spectra of the dye Crystal Violet adsorbed on silica gel[130] and of ethyl xanthogenate on the surface of copper powder particles[131] have also been reported.

We should stress the need for the utmost caution in interpreting the spectra of adsorbed molecules near strong absorption bands due to the adsorbent[132], because bands from surface polaritons can appear in the MATR spectra of powders on the high-frequency wing of the adsorbent band (see II, 1).

IV. PHYSICAL CHEMISTRY OF POLYMER SURFACES

ATR spectroscopy has been applied very effectively to studies of polymeric materials, whose physical and mechanical properties are very well adapted to the technique. The possibilities of the method in studies of the surface layers of polymers have been demonstrated in several investigations[133–141].



A series of papers[142–144] deals with the molecular mechanism of polymer degradation under mechanism load, and explains the role of surface layers in the degradation of polymers. The concentration of defects produced by the breakdown of macromolecules has been determined in low-pressure, intermediate-pressure, and high-pressure polyethylene (PE),[144] in rubbers and vulcanised products from natural and synthetic latex[142,143,145], and in poly(ethylene terephthalate) (PETP).[146] When the samples are subjected to mechanical load the concentration of end-groups in a surface layer 1 μm thick becomes 1–3 orders of magnitude greater than in the bulk (depending on conditions). Macroscopic cracks in the surface layer become saturated with decomposition products of the polymer molecules[143]. Using the shift of the vibration frequencies in the i.r. spectrum produced by mechanical loads, the stress in loaded PETP samples was shown to be as high as 700 kg mm^{-2}, i.e. close to the theoretical strength of the material[146]. The overloaded bonds are the first to break under the influence of thermal fluctuations, and therefore the enhanced concentration of these bonds in the surface layer (one order higher than in the bulk) explains the important role played by the surface layer in controlling the degradation of polymers under mechanical stress.

In ATR spectroscopy the absorption depends on the direction in which the radiation is polarised[5]. With anisotropic samples, the advantages of ATR measurements in polarised light over ordinary absorption spectroscopy include the possibility of studying strongly absorbing materials, the decoupling of the absorption coefficients for the three spatial directions (k_x, k_y, k_z),[147] and the possibility of studying the orientation of molecules on the surface independently of their orientation in the bulk.

Flournoy developed the theory of the interaction of a damped light wave under ATR conditions with an anisotropic medium[147], and he subsequently used it[148] to determine the orientation of macromolecules in uniaxially oriented films of polypropylene. Among the many investigations using polarised light one of the most noteworthy is a study[149–151] of the spontaneous orientation in planes of polypeptide and protein macromolecules in the α-form. Planar orientation was shown to occur mainly in a thin surface layer directly adjacent to the substrate, and to become gradually less pronounced with increasing distance from the substrate.

A study[52,153–156] of various polyimides has established the planar orientation of the macromolecules, brought about by cooperative effects involving the macromolecules in media bounded by a planar substrate. The techniques used in the analysis of ATR spectra of fibres (of organic or inorganic origin) are discussed in depth in Refs. 43 and 52. Polarised ATR spectroscopy and wide-angle X-ray diffraction have been used to show that the functional NH and C=O groups in aromatic polyamide fibres are oriented at right angles to the fibre drawing axis[157]. Shushkov and coworkers[158,159] studied the orientation of molecules in polyester fibres, and showed that under axial stretching PETP fibres undergo a transition from folded *gauche* conformations to stretched *trans* conformations. Oriented PETP fibres are discussed also in Refs. 160–162.

The angles between the moments for the vibrational transitions and the axis of the macromolecule have been calculated for several bands in the ATR i.r. spectra[52,154,155,162]. Satisfactory consistency between the spectroscopic results and X-ray diffraction data has been obtained by using the crystallinity bands. Oriented films of polytetrafluoroethylene have been studied by the MATR method using polarised light[163]. The more marked dichroism of the bands at 1150 and 553 cm^{-1} in the MATR spectra (as compared with the transmission spectra) was interpreted as evidence for a greater degree of orientation of the macromolecules in the surface layer than in the bulk. We have compared[164] the surface and the bulk properties of a polyimide film prepared from the dianhydride of pyromellitic acid and 4,4′-diaminophenylene:

By comparing the transmission and the MATR spectra in polarised light we also concluded that states of the macromolecules not found in the bulk are produced at the surface of samples by heat treatment.

The ATR method has been used to study the interaction between poly(dimethylsiloxane) (SKT) and a filler (Aerosil), and the observed spectral effects were explained by the formation of hydrogen bonds between the hydroxyl groups of Aerosil and the Si–O–Si groups of SKT.[165,166] At the same time the orientation of the macromolecules in a uniaxially stretched regular polymer was examined, and it was found that in *cis*-polybutadiene and polyisoprene the surface orientation of the macromolecules varies with time, the dichroic ratios of some of the bands reaching a maximum several days after mechanical treatment of the sample. The longer relaxation times of the surface layers were ascribed to the involvement of supermolecular structures in the rearrangement, in contrast to the bulk orientation effects which involve only segments of the macromolecules. The reorientation time of the supermolecular structures on the surface can be 10^4–10^5 times greater than the reorientation time of the segments in the bulk of a stretched vulcanisate[167]. The ATR method has been used to analyse artificial leather-cloth made from poly(vinyl chloride), polypropylene film, layered plastics, adhesive tapes, carbon-filled (up to 3% and 20% respectively) rubbers[20] and elastomers[168], cellulose fibres[169], and some thermally stable fibres[170].

An investigation of layers of lipids and proteins adsorbed at the water–air interface has been reported[171–173]. Monolayers and multilayers freshly deposited on a germanium MATR element by the Langmuir–Blodgett method (80 reflections) were found to have i.r. spectra similar to those of the corresponding melts. On the other hand adsorbed layers allowed to stand for 160 h on the MATR surface yield bands which are characteristic of the crystalline state. These conclusions are confirmed by electron micrographs of the layers[172]. In two-layer structures the hydrocarbon chains are oriented normal to the surface of the MATR element.

By varying the experimental conditions under which the ATR spectra are recorded (angle of incidence, relative refractive index n_{21}, state of polarisation of the light) the depth of penetration of the light and the effective sampling thickness can be varied between wide limits, thus extending the range of applications of the method to include diffusion problems. The idea was first formulated by Harrick[5], and realised experimentally by Carlsson and Wiles[174-176]. Photooxidation and treatment in a corona discharge of unstabilised polypropylene (PP) produces characteristic hydroxyl (3400 cm^{-1}) and carbonyl (1715 cm^{-1}) bands in both the transmission and the MATR spectra. Using a set of MATR elements made of germanium and of KRS-5 the authors[174-176] varied the relative depth of penetration d_p/λ from 0.066 to 0.201, and this allowed them to observe a gradual decrease in the relative optical densities D_{1715}/D_{2840} and D_{3400}/D_{2840} with increasing depth. The decrease in concentration of carbonyl and hydroxyl groups in a direction normal to the sample surface is approximately exponential.

Subsequently[177-181] the ATR method was used to study the oxidation of polyolefins by ozone by determining the concentration gradients of carbonyl oxidation products in polyethylene. Using a semi-cylindrical ATR element the effective thickness was varied over a wide range by varying the angle of incidence θ. If the sample contains a concentration gradient of more than one group the method gives the overall trend to a good approximation. Plots of $D_{C=O}/D_{C-H}$ against $d^{\perp}_{eff}$ (where $d^{\perp}_{eff}$ is the effective thickness of the layer for perpendicular polarisation of the light) are shown in Fig.5.

The following expression has been obtained[180,181] for the dependence of the concentration of carbonyl products on $d^{\perp}_{eff}$:

$$c_{C=O} = \frac{D_{C-H}}{\varepsilon_{C=O} d^{\perp}_{eff}} \cdot 10^{a/d^{\perp}_{eff}+b},$$

where D_{C-H} is the optical density of the band used as an internal standard, $\varepsilon_{C=O}$ is the molar absorption coefficient, and a and b are empirical constants. Differentiation of these curves with respect to $d^{\perp}_{eff}$ should give the concentration gradients of oxidised groups in depth. As Fig.5*b* shows, most of the carbonyl products of the oxidation of polyethylene by ozone are concentrated in a surface layer a few micrometres thick.

Quantitative tests of the validity of Fick's law in polymer diffusion are conveniently carried out by this approach. The diffusion coefficients of methanol and acetone in polyisobutylene rubber have been measured[182] by the single ATR method. Two thermal diffusion schemes, shown in Fig.6, were used in this experiment. In the scheme of Fig.6*a* the surface *AA'* of the rubber film is in intimate (adhesion) contact with the surface of the ATR element, and its other surface is in contact with the diffusant. In this case the penetration of the diffusant is monitored from the increase in the

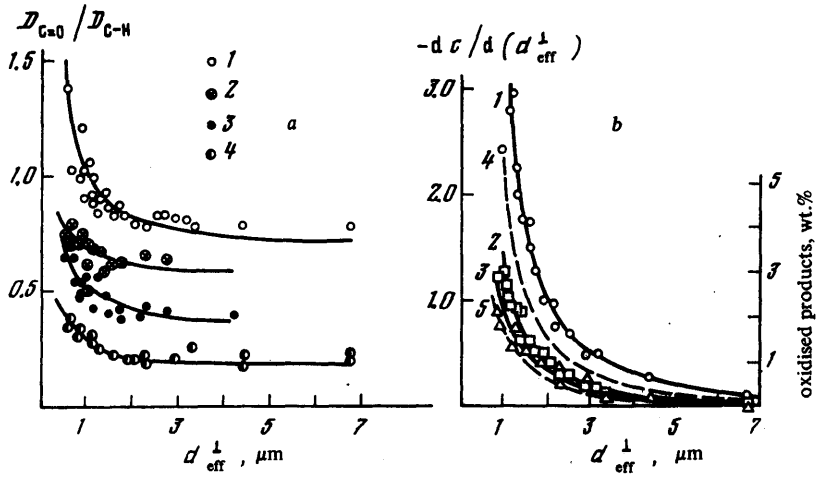


Figure 5. (*a*) Relative optical density $D_{C=O}/D_{C-H}$ against $d^{\perp}_{eff}$ for polyethylene (*1*, *2*) and polypropylene (*3*, *4*) oxidised by ozone: *1*) 170 mg $litre^{-1}$ of ozone, oxidation time 5 h; *2*) 170 mg $litre^{-1}$ of ozone, oxidation time 1 h; *3*) 130 mg $litre^{-1}$ of ozone, 5 h; *4*) 130 mg $litre^{-1}$ of ozone, 1 h. (*b*) plots of $dc/d(d^{\perp}_{eff})$ against $d^{\perp}_{eff}$ for polyethylene oxidised by ozone (170 mg $litre^{-1}$) for different times (*1*) 5, *2*) 1, *3*) 0.5 h), and variation with depth of the concentration of oxidised groups in polyethylene oxidised with ozone (170 mg $litre^{-1}$) for different times (*4*) 5, *5*) 1 h).[181]

relative optical density of the analytical band. In the second scheme (Fig.6*b*) the surface *BB'* (which had been in direct contact with the diffusant) is pressed against the ATR element. The concentration gradients of the diffusant as a function of the film thickness *l* measured in this way are shown in Fig.6*c* for different times t_n. The equation obtained [182] accurately describes the kinetics of the changes in diffusant concentration in the polymer in the direction of d_p and at time *t*.

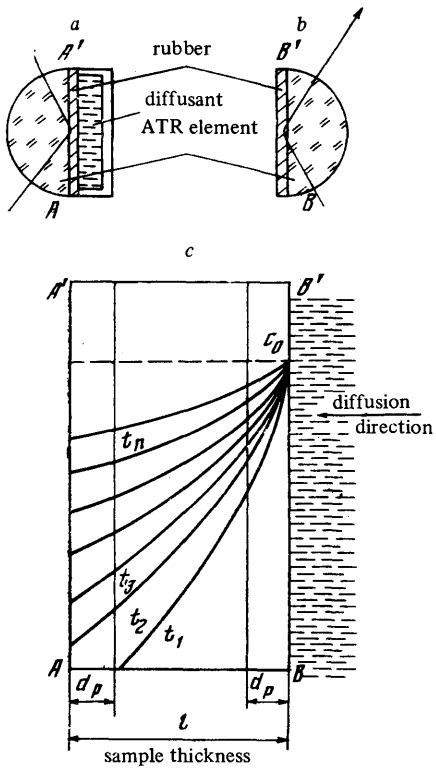

Figure 6. Two arrangements of the diffusion experiment in rubber. (*a*) diffusion monitored from the *AA'* surface; (*b*) diffusion monitored from the *BB'* surface, which had previously been in contact with the diffusant; (*c*) is a schematic presentation of the concentration profile of diffusant through the thickness of the rubber film at different times (t_1, t_2, ... t_n); c_0 is the concentration of diffusant at the surface; the depth of penetration of the radiation is given[182] as $d_p = \lambda_1/2\pi(\sin^2\theta - n_{21}^2)^{1/2}$.

A similar experimental arrangement was used[183,184] to study the diffusion kinetics of non-solvents in elastomers by the MATR method. This approach confirmed[185] the authors' previous suggestion that the surface layer of a polymer in adhesional contact with a solid surface has an abnormally high density. During diffusion, or heat treatment, the macromolecules undergo transitions into more probable conformations, giving a more uniform density distribution.

The diffusion coefficients of ethyl acetate in polyethylene and of ethanol in poly(butyl methacrylate) have been measured[186,187] by applying Fick's equation to the ATR results. By varying the reflection conditions a decrease in the concentration of epoxy resin with increasing distance from the resin–polysiloxane rubber interface was detected[188].

Since the oxidative degradation of polymers often begins at the surface, internal reflection spectroscopy can give important information on the initial steps of the processes involved.

Measurements of the optical density ratio of the bands at 720 and 730 cm^{-1} in the MATR spectra of PE which had been exposed to ozone revealed[189,190] an increase in the degree of crystallinity, arising from the preferential "combustion" of the amorphous phase[191]. By combining ATR measurements with electron microscopy and low-angle light diffraction it was established that in linear polyethylene the supermolecular formations in a surface layer ~1 μm thick are the same as those in the bulk. However, there are large differences in internal structure between the bulk and the surface: the crystallite orientations are different, and the amorphous regions of the surface layer contain an abnormally high proportion of folded molecules with a large number of defects. The main difference between the surface layer and the bulk lies in the structure of the molecules in the amorphous regions[152]. It has also been shown, by the MATR method, that previously unknown but stable hydroxy-, keto-, and alkoxy-acids with a very low content of C–H bonds can be produced by deep oxidation of PE with ozone[189].

The mechanism of the oxidative degradation of PE at the copper–PE interface is discussed in Refs.192 and 193. It is shown that the formation of carbonyl-containing products is markedly accelerated at a surface in contact with copper, and that the MATR spectrum of the copper surface contains bands suggesting the formation of carboxylic acid salts which act as catalysts for the oxidation of the PE.

Accelerated photo-oxidation of PE in the presence of titanium dioxide[194], and the effect of thermal and oxidative degradation on the adhesion of PE to aluminium[195,196], have been reported. The dependence of adhesion on the time of heat treatment goes through two maxima, which are explained by postulating simultaneous oxidation and structural rearrangement processes in the surface layer of PE. Experiments on the adhesion of PE to a quartz MATR element led to the hypothesis that hydrogen bonds can be formed between functional groups on the PE surface and the surface hydroxyl groups of the quartz[197].

Under practical conditions the surfaces of many materials are exposed to corona discharges, and therefore particular attention has been devoted to this type of interaction. For example, polytetrafluoroethylene has been exposed to air and to ammonia under corona discharge conditions[22]. In the air atmosphere volatile degradation products are formed, and desorbed from the PE surface, whereas in the ammonia atmosphere surface modification occurs to a depth of several micrometres. Extensive investigations of the effect of corona discharges on polyolefin surfaces have been reported[174–176]. The infrared ATR spectra of polyamide films which had been exposed to a glow discharge showed intensity changes in the stretching vibration bands of the C–H groups and in the Amide II bands (1550 cm^{-1}), and an increase in the concentration of carbon products[198].

In conclusion we should mention a short review of the application of ATR to studies of polymers and fibres[199], and a useful applied investigation of adhesive tapes in which the effect of the position, size, and shape of the polymer sample on the quality of the MATR i.r. spectra is clearly brought out[200].

V. ELECTROCHEMISTRY

Electrochemists have always been concerned with structural changes on electrode surfaces and in the layer of solution in contact with the electrode, but until recently direct (and non-destructive) methods of observation were not available. Adsorption and reflectance spectrophotometry and ellipsometric methods are now being applied in electrochemistry. A discussion of the whole range of optical methods lies beyond the scope of the present review, and interested readers are referred to recent publications on this topic[201-203]. Some of the most recent work has dealt with an experimental arrangement called the optically transparent electrode (OTE) in the English and American literature, which can be set up by using conventional absorption spectrophotometry[203-205] or ATR spectroscopy[206]. We shall confine our discussion to the OTE relying on internal reflection.

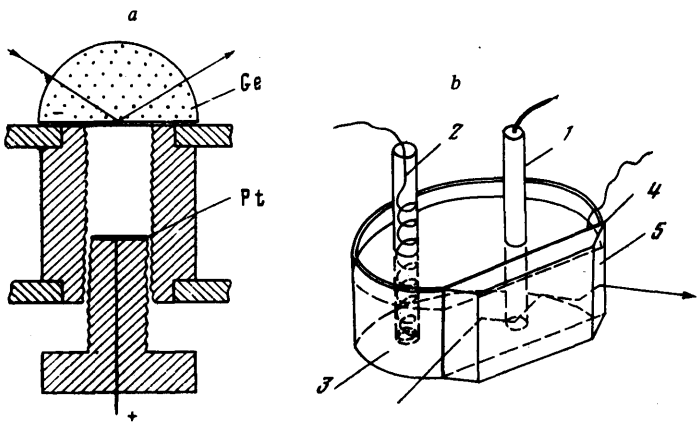

Figure 7. OTE cells based on (*a*) ATR [187] and (*b*) MATR [201] elements: *1*) calomel reference electrode, *2*) external gold electrode, *3*) electrolyte solution, *4*) gold OTE, *5*) glass MATR element.

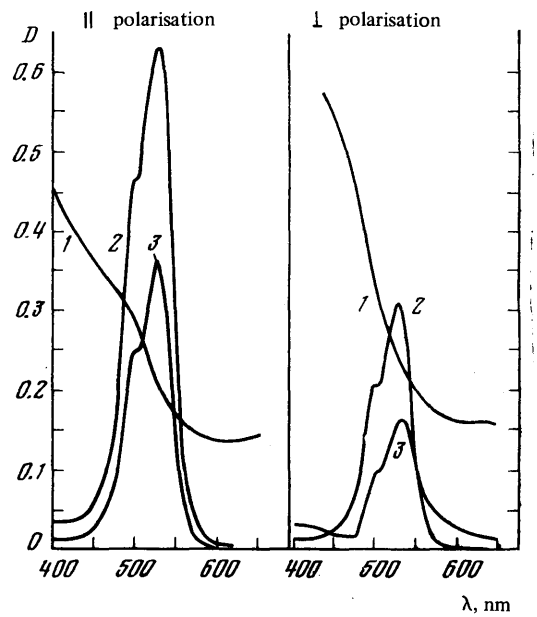
Ordinary single or multiple reflection elements are used as OTEs in the ATR mode by coating their surface with a thin (200–800 Å) conducting layer of tin oxide, gold, platinum, or carbon. Different types of OTE are described in Ref.12; two examples are shown in Fig.7. These ATR cells are placed in the cell compartment of the spectrophotometer, and the i.r. or u.v. spectra are recorded during the electrochemical experiment. The thin layer of conductor on the surface of the ATR element does not prevent the penetration of light into the electrolyte solution, but it attenuates it very strongly, and therefore the theory of ATR with allowance for thin films and multi-layer coatings must be used in the quantitative evaluation of the results[14,201]. Fig.8 shows the u.v. ATR spectra of a solution of the dye Eosin Y, obtained with an ordinary glass MATR element and with a gold-coated element respectively[201]. The enhanced intensity of the bands in the case of parallel (as opposed to perpendicular) polarisation of the light is consistent with the theory developed by Hansen[16].

The use of MATR elements coated with conducting films introduces complications into the spectral analysis owing to the possibility of resonance effects[207]. Some workers prefer to use uncoated germanium elements (for the i.r. region). Operation in the visible region of the spectrum is thought[201, 206] to offer some advantages: firstly, because electrolytes are usually transparent in this region, and secondly, because effective thicknesses are small and therefore thinner films can be studied, even in the region of light absorption by the electrolyte. The optimum film thickness can be calculated if the optical constants of the medium for the relevant spectral region are known.

In the visible region the depth of penetration of the radiation into the optically less dense medium is ~50 nm. If a compound having a diffusion coefficient of 10^{-5} cm^2 s^{-1} is formed on the OTE surface during the electrochemical process, a concentration gradient falling by 1% at a depth of 400 nm will appear within 1 s. At that depth the amplitude of oscillation of the electric vector of the electromagnetic field is damped to one thousandth of its value at the surface. Thus, rapidly plotted ATR spectra can give valuable information on surface concentration in the case of electrochemical effects on OTEs with time constants of the order of 1 s.



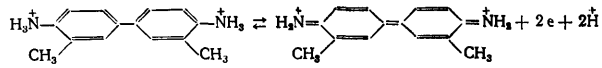


Figure 8. Internal reflection spectra of solutions of the dye Eosin Y: [201] *1*) reflectance spectrum of the gold OTE; *2*) Eosin Y on the gold OTE; *3*) Eosin Y on the glass MATR element.

As an example of this type of problem we may consider one of the earliest OTE investigations[208]: a study of the electrochemical oxidation of *o*-toluidine in hydrochloric acid. A glass plate coated with a film of SnO_2 was used as the MATR

element. The depth of penetratration was ~60 nm. The electrochemical reaction

involved the two-electron oxidation of *o*-dimethyl-*p*-phenylenediamine on the electrode surface with formation of an intermediate product with an absorption band at $\lambda_{max} = 438$ nm. From the time dependence of the optical density D_{438} and of the electrode potential the concentration and the extinction of this compound were calculated, as well as the rate constant of its disproportionation reaction.

An important experimental paper[209] suggests the use of OTEs in quantitative studies of processes as a function of distance from the electrode surface, and considers the electrochemical oxidation of *p*-anisylamine as an example.

OTEs have been used to study a wide range of electrochemical reactions, including the electrochemical behaviour of lithium perchlorate in dimethylsulphoxide on a germanium surface[210], the anodic oxidation of potassium ethyl xanthate in water (by measuring ATR spectra at different values of the anode potential)[211], and the kinetics of the disproportionation of zinc tetraphenylporphyrinate[212]. Among the most important applied investigations is a study[213] of the electrochemical corrosion of germanium in sea water.

Most of the work to which we have referred is aimed at developing applications of the method to specific problems, and it represents a considerable step forward in this direction. However, systematic studies of electrochemical problems exploiting the OTE are far less numerous. One of the best known examples is the work of Trifonov and coworkers, who in 1970 described an ATR apparatus for studying electrochemically induced polymerisation on the surface of a germanium ATR element coated with gold[214]. The apparatus was applied to an investigation of the polymerisation of acrylonitrile induced by electrochemically generated radical anions[214–218]. Most of the measurements were made on the stretching vibration band of the C≡N group. The ATR spectra recorded[215,216] at various stages during the reaction are shown in Fig. 9. Intensity changes of some other bands were also recorded.

As a result of the kinetic study the following scheme was proposed for the cathodic reaction:

$$CH_2{=}CHCN + 2e \rightarrow [CH_2{=}CHCN]^{2-}.$$

Disproportionation of the anion causes the formation of a radical anion:

$$[CH{=}CHCN]^{2-} + CH_2{=}CHCN \rightarrow 2\,[CH{=}CHCN]^{\cdot-}.$$

Recombination of the radical anion produces a di-anion with an extended carbon chain:

$$2\,[CH_2{=}CHCN]^{\cdot-} \rightarrow [CNCH(CH_2)_2CHCN]^{2-}.$$

More recently the method has been used to study the polymerisation of 1-vinylimidazole[219].

Adsorption from solutions is another area of electrochemical research in which ATR techniques are being increasingly applied. Higashigama and Takenaka[220] exposed an electrochemical cell with a germanium electrode to polarised radiation, and they showed that for certain concentrations of sodium laurate in water the adsorbed layer of lauric acid on the OTE surface consists of uniaxially oriented crystallites,

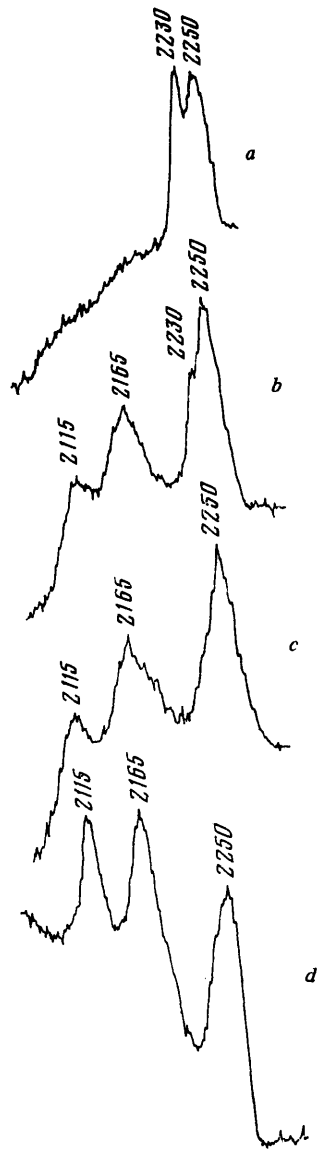

Figure 9. ATR spectra in the stretching vibration region of the C≡N group during electrolysis of acrylonitrile: (*a*) partially polymerised monomer (2230 cm^{-1}, monomer; 2250 cm^{-1}, polymer); (*b*) and (*c*) sequentially recorded spectra showing the appearance of the radical anion (2165 cm^{-1}) and of the radical dianion (2115 cm^{-1}); (*d*) spectrum for the highest achievable concentration of active particles[215].

with their crystal axis inclined at 39° to the normal to the electrode surface. When a critical concentration of sodium laurate is exceeded the adsorption becomes micellar. The effects of potential, pH, and temperature on the adsorption were also studied by the same method.

Two interesting papers[221,222] demonstrate the possibilities of modern infrared techniques. A carbon film 220–300 Å thick was evaporated on a germanium electrode. The transmission of this OTE at 1800 cm^{-1} was only 1.5%, but by using multiple scanning and scale expansion techniques it was possible to study the electrochemical adsorption of fibrinogen on the carbon electrode. The thickness of the adsorbed layer of fibrinogen was shown to be 250–350 Å. Two Amide I bands (1644 and 1614 cm^{-1}) and two Amide II bands (1553 and 1520 cm^{-1}) were observed at a surface potential of +150 mV. It was concluded that after electrochemically induced adsorption the fibrinogen molecules are present in two forms, one of which is stressed and relaxes to the normal form when the potential is removed.

The electrochemical adsorption of Methylene Blue from buffered solutions was studied in the u.v. region[223]; various examples of electrochemical reactions and adsorption on OTE surfaces are discussed in Ref.224.

Optical internal reflection spectroscopy has become one of the basic techniques of research on the physical chemistry of surfaces. The development of experimental techniques has advanced to the point where quantitative measurements can be justified. The topic most urgently in need of further theoretical development is the quantitative analysis of disperse systems by the ATR method.

The procedures so far developed can be used to analyse systems quantitatively in terms of both the optical constants over a wide region of the spectrum. This is important from the standpoint of measurement techniques, and also because it allows new problems to be formulated in surface physical chemistry. Current trends include combining the ATR method with other methods of surface investigation, such as Fourier transform spectroscopy. Internal reflection spectroscopy offers new perspectives in the study of the aggregation and orientation of molecules adsorbed on various surfaces, and important developments can be expected also in this direction.

---o0o---

Papers published while the present review was in preparation include general discussions of a number of experimental problems in ATR spectroscopy[225–230], and a discussion of a correction for the quality of the contact between the ATR element and the sample[231]. Theoretical models have been used to derive expressions for the concentration gradients in surface layers[232–234], and to compare the surface and the bulk properties of glasses[235], polymer films, and fibres[236–241]. Recently reported studies deal with the influence of surface defects on the strength of polyamide fibres[242], the influence of electrical polarisation on the spectra of polyacrylonitrile[243], and the interactions of ozone with rubber[244] and polypropylene[245] and of a glow discharge with various polymers[246]. The work on the deposition of adsorbed layers of proteins on the surface of MATR elements by the Langmuir–Blodgett method has continued[247–250]. The adsorption of proteins on polyethylene[251], the diffusion of CCl_4 in Teflon[252] and of water in lipid layers[253], processes in photographic gelatin layers[254], and the photo-oxidation of dyes on an optically transparent ZnO electrode[255] have been investigated. New optical media for ATR have been developed[256–259], and industrial spectrophotometers[260–263] and associated equipment[264–267] have been put on the market. The ATR method has been used in Raman spectral studies[268–270], and in various problems in materials science[271], in geochemistry and petroleum chemistry[272–274], and in the protection of the environment[266,275,276].

Chemical Forms of Mercury, Cadmium, and Zinc in Natural Waters

A.K.Prokof'ev

Published information on the chemical forms of mercury, cadmium, and zinc in natural wet environments (water, suspended or colloidal particles, deposits, biota) and on their toxicity and biological interconversions is generalised and critically discussed, and the mechanisms for the absorption and expulsion of these materials through the appropriate phase separation surfaces are considered. The chemical forms of these and other trace metals are shown to be the controlling factor in their geochemical cycles and their anthropogenic effects on ecological equilibria in the natural environment. 224 references.

I. INTRODUCTION

In the natural wet environment metals are found in waters, suspended or colloidal particles, the biota†, and in sludge deposits. Their distribution between these phases is controlled by complex and little understood mechanisms, involving a variety of chemical, physicochemical, biological, and physical processes which can be mutually exclusive or complementary. Existing chemical information and phenomenological models cannot adequately predict the distribution of metals between the various phases in aqueous media, which are usually very complex systems of variable composition. Though the metals are conveyed to the aqueous medium by wind erosion of dry land and by volcanic activity, a significant proportion (at least in some areas) is now contributed by man. Undesirable ecological effects can be expected as soon as the rate of supply of metals to the aqueous medium begins to exceed the rate of supply through the natural cycle: such effects have been noted in inland and coastal waters of industrially developed countries as a result of effluent disposal, of fuel combustion, and of the manufacture of cement. The atmosphere plays an important role in the transport of metals[1].

Large-scale poisoning by mercury and cadmium in Japan[2] dramatically showed that the ability of the natural environment to free itself from chemical substances of anthropogenic origin is limited, and that the chemical form of the metals (rather than, as previously assumed, their concentration) may be the controlling factor in determining the unfavourable ecological consequences. This incident also showed the need for improved methods of analysis of trace metals (TM) in natural media. A surprising trend has been recently reported in trace metal analysis: as the sensitivity and the selectivity of the analytical methods improve, the concentration of TM in the natural medium appears to decrease (by several orders of magnitude in some cases) in spite of the concurrent increase in industrial effluent levels. This observation has cast serious doubts on the validity of analytical results. Only very recently have truly reliable analytical data been obtained: these are quoted below in the appropriate sections.

The aim of this review is to generalise published information on the chemical forms of mercury, cadmium, and zinc in natural aqueous media: water (data for sea water are discussed, in part, in Refs.3 and 4), suspended and colloidal particles, sludge deposits, and the biota. Data on the toxicity and on biological conversions of trace metals are also discussed. With very few exceptions, existing analytical techniques are inadequate for the determination of the distribution of chemical forms of the TM in natural media, because the concentrations involved are exceedingly small. We shall therefore devote a special section of this review to a discussion of the chemical properties of mercury, cadmium, and zinc in aqueous solutions, in order to explain the chemical behaviour of these trace elements in nature. Many models have been proposed to account for the distribution of dissolved TMs in natural waters, but they have not been confirmed experimentally. Difficulties in interpretation arise from uncertainties in the stability constants of the complexes between the TM and some ligands, and also from the lack of reliable activity data for the reacting forms. Therefore we shall only mention the most recent models, with the most accurate values of these parameters.

To keep the length of the review within bounds the discussion of some topics (geochemistry, bio-inorganic chemistry, and hydrology) is short, or even fragmentary. For the same reason we have failed to mention many publications in spite of their direct relevance to our topic; the list of references would otherwise have been at least twice as long. Only the most recent research papers and review articles have been included.

† A historically as opposed to biologically related group of plants and animals sharing a common environment.

II. SOME CHEMICAL PROPERTIES OF MERCURY, CADMIUM, AND ZINC IN AQUEOUS SOLUTIONS

Mercury, cadmium, and zinc are typical ("non-transition") metals, because they do not show variable valency and they do not form compounds with an unfilled *d*-shell. They do not form carbonyl or olefin complexes (which are characteristic of transition metals), and they do not show the ligand field stabilisation effect. The failure to oxidise these metals to the tervalent state arises from the very high value of their third ionisation potential, and also from the high solvation energies or lattice formation energies needed to stabilise this state.

Although these metals are classified together in subgroup IIb, the chemical and physical properties of mercury (both in the elementary state and in its compounds) are markedly different from those of cadmium and zinc. Whereas the latter are electropositive metals, mercury has a high ionisation potential and a high oxidation potential, and it is chemically rather inert. The chemical properties of Hg, Cd, and Zn are discussed in detail in Refs.5 and 6. All three metals (especially, mercury) are low-melting and fairly volatile. Mercury has a vapour pressure of 1.3×10^{-3} mmHg at 20 °C, and its solubility in water is 58.8–63.9 μg litre^{-1} at 25 °C, increasing from 19.2 to 368 μg litre^{-1} between 5 and 60 °C in accordance with Henry's law (with a heat of dissolution of 5.3 kcal mole^{-1}).[7] In hydrocarbons and in ethers the solubility of mercury is over an order of magnitude greater than in water[8].

In dry air at ordinary temperature all three metals are practically unaffected (mercury reacting exceedingly slowly), but on being heated they form oxides, though at temperatures above 400 °C mercuric oxide dissociates into its elements. Cadmium and zinc do not liberate hydrogen from water, and in moist air they are quickly covered by an oxide film which protects them from further oxidation. Cadmium plating offers better corrosion protection than zinc plating or nickel plating. All these metals react with sulphur, halogens, etc.: the metallic properties become less marked on going from Zn to Hg, the heats of formation of all the compounds decreasing in that sequence[6]. Mercury reacts with many transition metals and some typical metals to form amalgams, which can have a definite composition (for example, Hg_2Na). The most typical coordination numbers of Hg, Zn, and Cd are 4, 4, and 6 respectively.

Cadmium and zinc cannot exist in aqueous solutions in the univalent state, whereas mercury forms the Hg_2^{2+} ion in which the two atoms are bivalent though the pair is electrochemically univalent and does not undergo electrolytic dissociation. The Hg_2^{2+} ion is related to other oxidation forms of mercury by the reversible disproportionation reaction $Hg_2^{2+} \rightleftharpoons Hg^0(l) + Hg^{2+}$, for which $E^0 = -1.31$ V and $K = [Hg^{2+}]/[Hg_2^{2+}] = 6.0 \times 10^{-3}$, and in which the equilibrium is strongly shifted towards the left. However, in the presence of strong complexing agents (forming strong covalent bonds), of strong oxidising agents, or in alkaline solutions, the equilibrium is shifted almost irreversibly towards the right. The Hg_2^{2+} ion has a low complexing power and it does not form covalent bonds with other elements: as a result, it cannot form metal–organic derivatives[5].

The high stability of the M^{2+} ions in aqueous solution is due to two effects. The first is their tendency to form covalent rather than ionic bonds, especially mercury, many of whose compounds are low-boiling and soluble in organic solvents more readily than in water, and differ from true salts in this respect. The second important property of these ions is their tendency to form complexes with many ligands, the Hg complexes being significantly more stable than those of Cd and Zn.[5,9] The hexa-solvates $M(H_2O)_6^{2+}$, with an octahedral structure, are formed in solution according to an X-ray diffraction study[10] of Hg^{2+}; their heats of solvation lie in the sequence Zn ≫ Cd > Hg. The enthalpy of solvation is much greater for ZnX_2 and CdX_2 (where X is a halogen) than for HgX_2, in keeping with the much stronger interaction between the water molecules and the ion in the case of cadmium and zinc. As a result, the Zn and Cd salts have a tetrahedral or octahedral structure in solution, with water molecules coordinated like those of other ligands, whereas the mercury salts have a linear structure and are very weakly solvated[11]. It is assumed that HgX_3^- ions (where X = Br, I) form a flattened pyramid in solution, whereas HgX_4^{2-} ions form a regular pyramid and CdX_4^{2-} form a regular tetrahedron (as shown by X-ray diffraction results in the case of CdI_4^{2-}).[10,12]

In aqueous solution the degree of dissociation of MX_2 (where X = halogen) falls in the series Zn > Cd ≫ Hg, the mercury halides being ~99% in the form of molecules. The form of the metal is very sensitive to concentration. Thus, $ZnCl_2$ can exist as $Zn(H_2O)_6^{2+}$, $ZnCl^+(aq)$, $ZnCl_2(aq)$, and $ZnCl_4(H_2O)^{2-}$ ions, with out any $ZnCl_3^-$ or $ZnCl_4^{2-}$ ions on the evidence of Raman spectral data[5], whereas CdX_2 exists as Cd^{2+}, CdX^+, CdX_2, CdX_3^-, and CdX_4^{2-}.[5,6] In concentrated solutions of $HgCl_2$ (with $c_{Hg} \geq 1$ *M*) containing a large excess of Cl^- corresponding to a molar ratio Cl/Hg ≥ 4.5 the predominant ion is $HgCl_4^{2-}$, but at $c_{Hg} \geq 0.5$ *M* and a molar ratio Cl/Hg ≅ 3 we find poly-nuclear complexes of the type of Hg_2Cl_4, $Hg_3Cl_{8,3}$, etc.[12] At molar ratios X/Hg < 4 (X = Br, I) HgX_3^- complexes are formed, whereas dilute solutions of HgX_2 contain HgX^+, HgX_2, HgX_3^-, and HgX_4^{2-}, but no poly-nuclear complexes (according to X-ray diffraction and Raman spectral data)[13].

It is believed that the great variety of cadmium forms (and, to some extent, of zinc and mercury forms) is due to self-complexing, for example by the reaction $3CdI_2 \rightleftharpoons Cd(CdI_3)_2$, which drastically lowers the concentration of Cd^{2+}. We note that these reactions take place even in very dilute solutions. At a 0.01 *M* concentration the relative amount of the various cadmium halide forms decreases in the series[6] $CdX^+ > Cd^{2+} \gg CdX_2 \gg CdX_3^- \gg CdX_4^{2-}$.

The ratio of the various forms depends also on pH and concentration. At pH 5 only Cd^{2+} ions are present, but at higher pH values colloidal forms are present together with their ionic and molecular hydrolysis products. In solutions of concentration $\leq 5 \times 10^{-7}$ *M* many pseudo-colloids are formed by the adsorption of $CdOH^+$ and $Cd(OH)_2$ on colloidal impurities, but at pH ≤ 7 and Cd^{2+} ion is predominant whereas at pH 8–10 the predominant species is $CdOH^+$. In solutions of 5×10^{-6} *M* concentration the hydrolysis products polymerise with formation of colloidal $Cd(OH)_2$ or of basic salts[14].

Mercury forms metal-organic compounds of the R_2Hg and RHgX type (where R is an organic radical and X is an inorganic or organic acid residue). The reactivity of these compounds is strongly dependent on the nature of R and X: they are very stable towards water and air (differing in this respect from the corresponding cadmium and zinc compounds[5,15]) because of the very low affinity of mercury for oxygen rather than because of the strength of the Hg–C bonds, which are rather weak (13–52 kcal mole^{-1}, depending on R).[5] Thus, Me^2Hg is stable for about one day in a saturated acid solution or in a 1 M solution of KOH at 85 °C, and it is resistant to photolysis with λ > 290 nm even in the presence of photosensitisers (acetone and singlet oxygen). At 10^{-4} *M* concentration MeHgX (X = Cl, OH) and $MeHg^+$ are photochemically stable for 17 h, but for X = Br, I the compounds are degraded by 10 and 90% respectively in 3.7 h (according to u.v. spectral data); at pH 5 the acidolysis half-life of Me_2Hg is 33 h.[16] Phenylmercury compounds decompose under irradiation with a quantum yield of 0.2–0.3, which is independent of pH. The

decomposition is accelerated by adding photosensitisers with a triplet state energy ≥80 kcal mole^{-1}. The photolysis half-life of these compounds and of Ph_2Hg is 17 and 8.5 h respectively[17]. Me_2Hg evaporates from aqueous solution 2.3 times more slowly than mercury vapour[16], probably because of its higher solubility (3.0 g litre^{-1} at 20 °C).[18]

After lengthy exposure to air, light, and heat the mercury-organic compounds undergo abiotic degradation, with oxygen attack by a free-radical mechanism to give both addition and degradation products[19]: $R_2Hg + O_2 \rightarrow RHgOR$ and $(C_nH_{2n+1})_2Hg + O_2 \rightarrow C_nH_{2n+1}OH + C_nH_{2n}O + Hg^0$. In u.v. light they are decomposed by the same mechanism but to free radicals and mercury: $R_2Hg \rightarrow R^{\cdot} + RHg^{\cdot} \rightarrow R^{\cdot} + Hg^0$.

An important reaction of this type of compound is the reversible symmetrisation reaction $2RHgX \leftrightharpoons R_2Hg + HgX_2$. The equilibrium is shifted towards the right by adding symmetrising agents (iodides, amides, cyanides, aluminium or magnesium oxide, etc.): this effectively removes the inorganic mercury by complex formation, precipitation, or reduction[19]. However, we should note that in aqueous solutions precipitants and sulphur compounds do not act as symmetrising agents[20]. Nevertheless organic mercury has a much lower coordinating power than inorganic mercury. Only the following complexes with simple ligands have been described: $MeHgX_2$ (where X = Br, I, Cn)[21,22], and $RHgX_3^{2-}$ (where X = I and SCN, but not Cl and Br). The $MeHg(SCN)_3^{2-}$ molecule forms a distorted tetrahedron, with two very weak Hg–SCN bonds[23]; $MeHg^+$ exists in water in the forms MeHgOH, $MeHgOH_2^+$, $(MeHg)_2OH^+$, and $(MeHg)_3O^+$, which are mutually related by reversible acid–base and self-association reactions. The last of the above forms has a low stability constant: $K = 0.3–0.7$ (according to titration curves and to PMR and Raman spectra)[21,23,24].

Alkylmercury, like inorganic mercury, forms a much stronger bond with sulphur atoms than with nitrogen, oxygen, or halogens. This effect is clearly shown by the values of log[MeHgX] in water (21.2, 9.37, 7.25, and 5.25 for $X = S^{2-}$, OH^-, NH_3, and Cl^- respectively[23]), and also by the shift of electron density from the ligands towards the mercury in complexes of the $HgY_2.XCH_2CH_2X$ type (Y = Cl, Br, I; X = OMe, SMe, NMe_2) indicated by NMR measurements on the halogen nuclei, which show a decrease in complex forming power in the series S >N >O.[25]

The very insoluble compounds HgS and $(MeHg)_2S$ give rise to the soluble species HgS_2^{2-}, $HgSH^-$, and $(MeHg)_3S^+$ in the presence of an excess or deficit of sulphide ions[26]. The latter dissociates in water by the scheme

$$(MeHg)_3S^+ \rightleftharpoons MeHg^+ + (MeHg)_2S \rightleftharpoons MeHg^+ + MeHgS^- \rightleftharpoons MeHg^+ + S^{2-}.$$

The K_{diss} values for the above steps are given[21] as 10^{-7}, 10^{-16}, and 10^{-21} respectively. In spite of the high affinity of mercury for sulphur, methylmercury is not decomposed by active thiols in water, unlike phenylmercury which undergoes the reaction[20] $Me(Ph)HgCl + RSH \rightarrow MeHgSR$ or RSHgCl: however, it is volatilised in the presence of H_2S, probably with formation of Me_2Hg.[27]

It has been shown that Hg_2^{2+} can form complexes in water with aniline (of composition Hg_2A^{2+}, where A is a monodentate ligand),[28] with organic acids (Hg_2A^+ and Hg_2A_2),[29] and with polyphosphates and dibasic acids ($Hg_2L_2^{-2q+2}$ and $Hg_2L(OH)^{-q+1}$, where L^{-q} is an anion)[30]; some of these complexes are unstable towards disproportionation. Complexes of Hg^{2+} with amines[28] (of composition HgA_2^{2+}) and with organic acids[29] (of composition HgA^+ and HgA_2) have been described, but the formation of 5-, 6-, or 7-membered chelate rings with *O*-substituted carboxylic acids could not be detected.

PMR spectra have been used to demonstrate the formation in aqueous solution of compounds of methylmercury with amines ($MeHgA^+$) and with organic acids (MeHgOCOR), stable at pH 7.5–9.5 and 0.5–13.0 respectively. A detailed description of the interaction of $MeHg^+$ with various ligands is given in Ref. 23. The existence of $[(MeHg)_2OCOMe]^+$ is also suggested[31].

Hg^{2+} is readily alkylated by organic compounds undergoing photolysis. Thus, mixtures of mercuric chloride with small amounts of acetic acid, methanol, or ethanol give MeHgCl (mixed with EtHgCl in the case of propionic acid). The same product is obtained from α-aminoacids of the alanine and leucine type, but not from RHgCl, which suggests that $Me^{\cdot}$ radicals are formed from the acids and methylate the mercury[32]. The yield of methylmercury chloride is very high during the photolysis of mercury acetate, which is reduced as far as the Hg_2^{2+} state in the presence of Cl^-.[33]

Mercury can be easily methylated also by exchange reactions with silicon-, tin-, and lead-organic compounds[34]. These reactions, described by the equation $Me_3E^+ + Hg^{2+} \rightarrow MeHg^+ + Me_2E^{2+}$, go to completion. For E = Sn, Pb the reaction rate can vary by 4–5 orders of magnitude depending on the salinity and the ionic strength of the solution. On the other hand, the arsenic analogue forms metallic mercury[35]: $Me_3As + Hg^{2+} \rightarrow Me_3As^{2+} + Hg^0$.

In the presence of the Hg^{2+} ion many aromatic compounds are easily mercurated by the reaction $Hg^{2+} + C_6H_5X \rightarrow XC_6H_4Hg^+$, accompanied by the formation of labile complexes between the reaction products and Hg^{2+}.[36]

III. CHEMICAL FORMS OF MERCURY, CADMIUM, AND ZINC IN NATURAL WATERS

Natural waters (NW) are complex solutions of different substances. Their chemical composition is extremely varied: they are conventionally classified according to mineral content into fresh waters, brackish waters, sea waters, and brines, with total ion concentrations of < 1.0, 1–25, 25–50, and >50 g kg^{-1} respectively.[37] However, this classification ignores all compositional differences.

The main types of NW are atmospheric precipitation, subterranean waters, and the waters of rivers, lakes, reservoirs, seas, and oceans. The mineralisation of atmospheric precipitation over dry land is usually 10–20 mg litre^{-1} (< 5 mg litre^{-1} for water in clouds), whereas in subterranean and in lake waters it varies from a few tens of mg litre^{-1} to 650 and 350 g kg^{-1} [mg kg^{-1}? (Ed.of Translation)]. According to chemical composition, NW can be classified into five groups: 1) the ion present at the highest concentration (Na^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, SO_4^{2-}, HCO_3^-, CO_3^{2-}); 2) dissolved gases (O_2, N_2, CO_2, H_2S, etc.); 3) biogenic materials (nitrogen, phosphorus, and silicon compounds); 4) trace elements (compounds of all the other elements); 5) organic compounds[37]. The arbitrariness of this classification is evident. For example, Na, Ca, and Fe can be assimilated by living organisms as well as the biogenic elements; also, the concentrations of the biogenic elements are often lower than those of the trace elements.

Most of the Earth's rivers show a low (< 200) or an intermediate (200–500 mg litre^{-1}) degree of mineralisation. High (500–1000) or very high (>1000 mg litre^{-1}) mineralisation of river water is seldom found. However, the chemical composition of river waters is far from uniform, especially along the length of the river (with a smaller non-uniformity across the width of the river and a negligible non-uniformity in the depth), arising from the inflow of tributaries, seepage of subsurface waters, and the uncontrolled timing of the various water flows along the length of the river[37].

Sea (and ocean) waters have a time-independent composition, uniform in different parts of the ocean as well as in depth. In the open ocean the quantitative relationship between the concentrations of the main ions is always constant, irrespective of absolute concentration. This is a fundamental rule in the chemistry of ocean waters. The constancy of the composition of oceanic waters can be perturbed only in the coastal regions, where decreasing salinity is found, and in land-locked seas, where the salinity (S) is usually low and the exchange of water with the ocean is hindered. Sea water shows another distinguishing feature as a chemical environment: a high hydrostatic pressure.

Mercury, cadmium, and zinc are present in NW at concentrations below 1 mg kg^{-1} (1 ppm), and therefore they can be classified as trace metals (TM). However, the true concentrations of TM in NW have only recently been determined[38,39], and found to be at least an order of magnitude lower than previously reported. Precise measurements of [TM] concentrations require careful attention to purity in all stages of the analysis, from sampling to end-determination, and the analytical conditions are very strict. For example, specially air-conditioned premises from which all metal surfaces are excluded are recommended[38]. Water samples for the determination of TM in hydrochemistry are usually filtered through a membrane with a pore diameter of 0.45 μm: this is done in order to compare NW having different concentrations of suspended particles (on which the TM are adsorbed, or chemically bound). These analyses yield the concentration of dissolved TM, whereas unfiltered samples give the total concentrations.

In fresh waters (Alaska snow) the concentration of Zn, Cd, and Hg was found[40] to be 1.07–1.67, 0.08–0.22, and ≤ 0.005–0.026 μg $litre^{-1}$ respectively. The concentration of Hg in ice cores was ~0.01 μg kg^{-1}, varying between 0.002 and 0.019 μg kg^{-1} in the period 1727–1971.[41] In subsurface waters the concentration of TM is strongly dependent on the location and on the sampling time within a particular month, variations as high as 10–100-fold being reported[42]. In the Mississippi estuary# the concentration of Hg was found[43] to be 0.05 μg $litre^{-1}$, and in the fresh river water 0.01–0.039 μg $litre^{-1}$.[44–46] Of the various forms of mercury, only $MeHg^+$ was determined, though it accounts for only a small part of the dissolved mercury. In the Great Lakes < 2.4×10^{-4} μg $litre^{-1}$ was found; in some other lakes of Canada 5–7×10^{-4} μg $litre^{-1}$; in the Mississippi estuary and in the Everglades less than 2 and 1% respectively[43]. The concentration of Cd in two rivers of Australia[47] was 0.02–0.30 μg $litre^{-1}$, and at the mouth of the Amazon[48] 0.067 μg kg^{-1}.

The mercury content of the surface water in the Atlantic and the Indian Ocean is 0.008–0.0335 and 0.0112–0.0201 μg $litre^{-1}$ respectively, in the China Sea 0.016–0.0284 μg $litre^{-1}$, and near the shores of Great Britain 0.0061–0.028 μg $litre^{-1}$.[49–51] The concentration in unfiltered water in the Atlantic Ocean increases with depth (0–4030 m) from 0.03–0.04 to 0.142 μg $litre^{-1}$.[52] In the Arctic Sea the concentration of Cd is 0.11 μg $litre^{-1}$,[53] in the Atlantic Ocean 0.04 μg $litre^{-1}$ [54] and 0.060 μg kg^{-1},[55] and in coastal waters < 0.05–0.8 μg $litre^{-1}$.[54] In the Pacific Ocean the concentration of Zn and Cd increases with depth (0.2–2950 and 0.3–5500 m respectively) from 0.01 to 0.6 μg $litre^{-1}$ [41] and from 0.1 to 1.1×10^{-9} mole kg^{-1},[48] indicating absorption of these metals by living organisms near the surface and regeneration at great depth from biological deposits under pressure[39,48]. The same explanation applies to the distribution of Cd (< 0.01–0.025 μg $litre^{-1}$) in the Sargasso Sea[56]. The rate of vertical transfer of Zn by biologicial means from pelagic organisms to those of the benthos§ is calculated to be much lower than the rate of transfer through excreta, and is approximately two years[57]. On the whole there is no evidence of contamination of the waters of the open oceans by Hg, Cd, and Zn.

The concentration of metals in NW is highest in a microscopic surface layer (or film) in which micro-organisms, plankton, organic compounds, and biogenic elements are also concentrated. In comparison with the underlying layers the concentration factor of the micro-layer can be as high as 100 or 1000. In these circumstances correct sampling becomes a fundamental (and so far unsolved) problem. A film 100 μm thick is usually taken, but this is too thick in comparison with a monolayer of organic and inorganic molecules (5–30 × 10^{-3} μm). Therefore the concentration factor in reality is very much greater than the measured factor. It is important to note that in surface layers from sea water the metals are bound exclusively to organic substances, the concentration of inorganic forms being the same as in the underlying layers of surface waters[58]. Since these layers can form an easily collected foam in the wind, the concentration factor for foams should be very much higher than for layers collected by submerged metal gauzes. Factors of 408 and 300 for Zn and Cd respectively were obtained for the foam from a lake in the USA.[59]

The total metal content of the ocean is believed to be held constant by the balance between the rates of addition and of removal. The mean residence time of metals in the ocean is determined from the rate of precipitation into the bottom deposits or from the rate of supply from the rivers to the ocean. These times, which are an indication of the relative reactivity of Hg, Cd, and Zn, are 26000 and 42000 years[60], 7700 and 92000 years, and 7800 and 18000 years[61] respectively.

Table 1. Estimated average concentrations of the main inorganic components dissolved in river and sea waters[62].

Component	River water		Sea water (S=35‰)	
	concn, mg $litre^{-1}$	proportion of total dissolved solids, %	concn. mg $litre^{-1}$	contribution to S, %
Na^+	6.3	5	10 770	31
K^+	2.3	2	399	1
Mg^{2+}	4.1	3.5	1 294	4
Ca^{2+}	15	12.5	412	1
Fe	0.7	<1	<0.01	—
Cl^-	7.8	6.5	19 340	55
SO_4^{2-}	11.2	9	2 712	8
HCO_3^-	58.4	49	140*	0.4
Silicon	13.1**	11	<0.1—>10***	—

* Inorganic carbon as HCO_3^-.
** As SiO_2.
*** Value depends on location and depth.

The dissolved forms of TM in NW are largely determined by the nature of the main ions and of the organic substances present. Estimates of the average concentrations of the main inorganic components of river and sea waters[62] are given in Table 1. Among the main ions of sea water, making a significant contribution to the salinity with concentrations

Funnel-shaped mouth of a river, widening out towards the sea.

§ From organisms swimming or passively drifting in the sea to those living on (or in) the bottom deposits, or moving along the sea bottom.

greater than 1 mg kg^{-1}, should be included boron compounds, Sr^{2+}, Br^-, and F^-: their concentrations are given[69] as 4.5, 7.9, 67.3, and 1.3 mg kg^{-1} at a salinity of $S = 35‰$.

Depending on the analytical method and separation technique used, several schemes have been proposed for classifying the chemical forms of metals in NW (see, for example, Ref.64). It is convenient to subdivide the forms of metals into: simple hydrated ions (M^{2+}.aq), simple compounds and complexes with inorganic (MCl_4^{2-}, MCO_3) and with organic ligands (aminoacids and citrates), stable compounds and complexes with inorganic (MS, $MSiO_3$) and with organic ligands (M-humates), and metals adsorbed by inorganic colloidal particles (M^{2+}–$Fe_2O_3.nH_2O$, M^{2+}–$MnO_2.nH_2O$, M^{2+}–clay) and by organic colloidal particles (M^{2+}–humic acids, M^{2+}–organic detritus).[65] Because of the specific chemical properties of mercury, to these forms of M^{2+} we should add $MeHg^+$ and Hg_2^{2+}, and also Hg^0 (the solubility of mercury in sea water at 30 °C obeys Henry's law and increases from 17.2 to 69.7 μg $litre^{-1}$ between 5 and 30 °C)[7] and Me_2Hg (whose solubility in sea water decreases from 2.84 to 1.88 g kg^{-1} between 0 and 26 °C).[18] The methods used to determine the forms of metals in NW are discussed in Ref.65. In particular, it is shown that Cd and Zn are present as M^{2+}.aq, as well as hydroxyl and chloride complexes (in the case of sea water).[53] We note that $^{65}Zn^{2+}$ is not transferred to the organic fraction even one year after being added to sea water[53]. No isotope exchange takes place between Hg^{2+} and MeHgCl in fresh waters[67].

NW always contain very small amounts of soluble organic compounds (SOC) consisting mainly (up to 80%) of highly oxidised and biologically stable polymeric compounds similar to the humus materials (HM) extracted from soils. The concentration of SOC in fresh waters is usually 1–10 mg $litre^{-1}$,[68] but in sea waters it is only 0.5–1.0 mg C $litre^{-1}$,[69] because of the dilution and flocculation which occurs at the boundary between fresh water and sea water[70]. The rest of the SOC consists of a mixture of polypeptides, polysaccharides, amino-acids, fatty acids, hydrocarbons, vitamins, and many other compounds. The low concentration of these materials (0.008–0.5 mg $litre^{-1}$ in the case of amino-acids[71]) is the result of bio-degradation. It makes identification very difficult: for example, in the case of sea water only ~10% of the compounds have been identified, since only a few compounds are present at a concentration $>10^{-6}$ M.[69] The problem of SOC in sea water is specially discussed in Ref.72. In polluted rivers, on the other hand, ~100 different compounds have been identified, including organic solvents and poly(ethylene glycols).[73]

Humus materials are transferred to NW through the fractional extraction of organic compounds from soils by atmospheric precipitation. They are subdivided into three components: humic acids (HA), which are soluble in basic solutions, fulvic acids (FA), which are soluble in both basic and acid solutions (and produce a yellow colour in fresh waters and subsurface waters[68]), and insoluble humus material. The distinction between these three classes is not always clear, and differences may arise from variations in elemental composition, acidity, degree of polymerisation, and molecular weight (MW).[74] In fresh waters FA and HA have MW of 300–2000 and 5000–100000 respectively[68]. The average MW of unfractioned humus from water is ~1000.[70]

The structure of humus materials is unknown. They are high-molecular poly-electrolytes of indeterminate composition. However, it is usually assumed that HA molecules consist of benzene and heterocyclic rings (probably condensed), with di- and trioxy groups, connected by CH_2-, O-, NH-, –N-, and S-groups to which are attached side chains with various functional groups. FA are believed to differ from HA by having a much greater proportion of functional (especially carboxylic acid) groups and aliphatic carbon, and a smaller proportion of aromatic carbon[68,74]. HA from soils have been shown by the NMR method (^1H and ^{13}C) to contain up to 65% of aromatic and carboxylate carbon and a large number of aliphatic OH groups: their structure is quite different from that of coal and lignin[75]. The chemical characteristics of humus from water and of sea-water FA are discussed in Refs.76 and 77.

Humus materials combine with metal ions, take part in cation exchange, contain free radicals, and adsorb metal hydroxides, proteins, insecticides, alkanes, etc. They can adsorb metal ions (up to 1–17% by weight).[68] Being stable organic free radicals[68], HA can reduce Hg^{2+} to Hg^0 in aqueous solution at pH 6.5–8.2 by a first-order reaction ($k = 0.009$ h^{-1}).[78]

The chemical nature of the combination of metal ions with HA and FA is not understood at present. It has been suggested that binding occurs through all the ion-forming functional groups, and that chelation plays an important role, as in the case of salicylic acid and pyrocatechol.[74,79] However, the analogy is not clear: for example, in HA at least 1/3 of the phenol groups has been shown not to be in the *ortho*-position with respect to the carboxyl groups[80], and the nature of the remaining phenol groups is uncertain. The metals may be combined in a tetrahedral or an octahedral coordination, in which they are fairly stable towards complex formation and reduction (as demonstrated by ESR and Raman spectra in the case of Fe^{3+}).[81] Two complex formation centres have been found in HA, with K values differing by an order of magnitude[82].

Because of the difficulty of identifying and quantitatively determining all the organic ligands dissolved in NW, the concept of the complex-forming power of the NW itself has been proposed. This quantity is a measure of the ability of the NW to form complexes with (or mask) a given metal ion. Methods of determining it are discussed in Ref.79. Values of $1–7 \times 10^{-7}$ M have been reported[83] for Cu^{2+} in fresh waters, whereas in sea water the values for Cu^{2+} and Pb^{2+} are 10^{-8}–3×10^{-7} M[53,65] and 3.2×10^{-7} M[53] respectively. Biological methods of determining complex-forming power have also been proposed[84]. These results include only a small fraction of the real complex-forming ability of the NW, since most of the reactive centres in the organic ligands are already occupied by strongly bound metals such as Fe^{3+} and Al^{3+}. For example, 7 mg $litre^{-1}$ of FA contain ~20 μmole $litre^{-1}$ of potentially reactive sites, but typical values of the measured complex-forming power[83] lie in the range 0–2 μmole $litre^{-1}$.

In NW the extent to which trace metals are combined with SOC depends on the concentration of the TM, on competition from other ions present in higher concentrations, and on pH. However, the results of the measurements can be strongly influenced by the chosen method. Thus, several workers find that most of the Zn,[85] Cd,[86,87] and Hg[44,85,87] in fresh waters is combined with SOC, whereas Florence[88] reaches the opposite conclusion for the first two of these metals. In coastal sea waters Hg[43,44,50] and Zn[53] (but not Cd) will also be found preponderantly in the organic fraction, though the effect is not observed in the open ocean[51]. FA combine with metals very strongly[43,87,89], but the complex-forming power of HA depends on their origin[90], on the pH, and on the presence of Ca^{2+} and Mg^{2+}.[91] The stability of the Zn^{2+} and Cd^{2+} complexes decreases in the sequence HA $>OH^-$, HCO_3^-, CO_3^{2-} > glycine[91]. FA from soils, with an average MW of 2775, forms Cd complexes of 1 : 1, 2 : 1, and 3 : 1 composition having stability constants $K = 10^{6.0}$, $10^{10.7}$, and $10^{15.4}$ respectively[79] at pH 7.7.

By using the gel filtration method at pH 8.0 it was found[92] that the stability of the complexes formed by HM with particular trace metals depends on the origin of the HM: $\log K = 4.83$–5.87 for Zn, 4.57–4.95 for Cd, and 18.0–21.3 for Hg. On the

whole the stability of metal–HM complexes follows the Irving–Williams stability series for metal chelates: Mg < Ca < Cd ≅ Mn < Co < Zn ≅ Ni < Cu < Hg.[92]

Because of the exceedingly low concentration of TM in NW their chemical form cannot be established by existing analytical techniques, but the effect of various equilibria on the chemical form is discussed in Refs.69 and 93. Therefore, equilibrium concentrations are calculated by using models relying on arbitrary values of the stability constants (β) of the complexes formed with inorganic ligands in conjunction with the analytically determined concentrations of the TM. However, very different β values may be used for a given complex by different workers, leading to large differences in composition and relative abundance of the various forms. For example, by inserting into the model more accurate values of β for $Zn(OH)_2$ and $ZnCO_3$ the calculated distribution of the main forms of zinc in sea water ($S = 35‰$, pH 8.1) changed from 60% $Zn(OH)_2$, 17% Zn^{2+}, 7% $ZnCl^+$, and 5% $ZnCO_3$ to 47% Zn^{2+}, 20% $ZnCl^+$, 10% $ZnCl_2$, and 10% $ZnSO_4$.[92] Other calculations suggest that in fresh waters at pH 5–9 the main forms of $MeHg^+$ are $MeHgS^-$, $(MeHg)_2S$, and MeHgSR, or (in the absence of sulphur compounds) MeHgOH and MeHgCl.[94] Sea water of salinity $S \cong 10‰$ and pH 8.2 contains 11.8% $HgCl_2$, 22.8% $HgCl_3^-$, and 64.5% $HgCl_4^{2-}$,[95,96] but under reducing conditions the main forms of zinc are $Zn(SH)_3^-$ and $Zn(SH)_2$.[97] In estuarine waters at pH 6.5–9.5 zinc and cadmium are found predominantly in the M^{2+}, MCl^+, and $M(OH)_2$ forms[98], but in fresh waters, allowing for adsorption[99], the predominant form is M^{2+}.

Using improved values of β for the complexes of metals with inorganic ligands (Table 2) in conjunction with experimental values of the stability constants of the complexes with humus materials and of the concentrations of main ions, TM, and HM, and of the total inorganic carbon and carbonate alkalinity and pH, the forms of the metals in lake waters have been calculated (Table 3). We note that >99% of the Hg and Cu is combined in the HM, whereas in the case of the other metals 70% or more is in the form of free cations. On the other hand in sea water >99% of the HM is combined with Ca and Mg, which are present at relatively high concentration, and among the TM only Cu is combined to a significant extent (~10%). The equilibrium forms of the TM have been calculated also as a function of salinity (Figs.1–3).[92] All these calculations ignore the formation of mixed or poly-nuclear complexes, and interfacial reactions.

We should stress that the formation of dissolved chemical forms of TM in NW is determined by several parameters: the pH, the redox potential, the nature and concentration of the TM, of inorganic and of organic ligands, and of colloidal particles (and the accessibility of their surface), and the possibility of interfacial reactions (precipitation, dissolution and sorption, biological and physical processes, etc.). The qualitative and quantitative effects of most of these factors on the chemical forms of dissolved metals are unknown. Therefore we cannot determine the extent to which the calculated forms of metals in NW approach the real distribution, even when very correct models are used in the calculation.

IV. FORMS IN SUSPENDED AND COLLOIDAL PARTICLES

Filtration of any NW through a membrane filter of 0.45 μm pore size produces a small residue of suspended particles (SP). The concentration of SP in the oceans is very much smaller than was previously thought: only 10 μg kg^{-1} at depths >200 m, though in surface waters the concentration varies with the season and can reach several hundred μg kg^{-1}. Most of the particles are 1–10 μm in diameter, a few are >10 μm, and the biological particles can be as large as 1 mm. The size distribution of the SP is usually independent of depth[100].

The majority of SP are particles of biological origin, found near the surface of the ocean[101]; their concentration is often greatest in regions where plankton is most abundant[102,103]. However, detritus forms are the predominant type of biological particle. In surface waters (at depths < 100 m) solid skeletal phases of marine organisms ($CaCO_3$ and SiO_2) account for 25–50% of the mass of SP, and organic substances for 30–70%.[100] The distribution and recycling of SP is particularly influenced by the presence of zooplankton[100,102]. Some of the biological particles are transferred to the sea bottom as fecal pellets[100,101], which account for 99% of the vertical transport of SP at depths >380 m (as compared with only 4% near the surface).[101]

Suspended particles are subdivided into two main groups: biogenic and non-biogenic, each of which consists of two or more subgroups. The first group includes both organic and inorganic materials ($CaCO_3$, $SrSO_4$, opal SiO_2), and the second consists mainly of alumino-silicate particles including clay and anhydrous minerals, but it includes other minerals (quartz, pyrites, dolomite, barytes, titanite, and iron and titanium oxides[103,104]). As the SP sink their inorganic content increases, mainly by the addition of sea salts in proportion to their concentration in sea water[105]. Near the sea bottom large amounts of SP are formed by the re-suspension of silt under the influence of various flows[106]. For example, a sample of SP taken at a depth >5000 m in the Sargasso Sea and consisting of 50% clay, 20% $CaCO_3$, 20% SiO_2, and 5% organic matter had originated mainly from the sea bottom[107].

Large numbers of SP are found in the surface micro-layer and in the foam of NW, producing an enhanced concentration of suspended TM.[59,108,109] For example, enrichment factors of 235 and 800 have been reported for Zn and Cd in lake foams[59]. TM are assumed to be concentrated at the water–air interface by atmospheric precipitation, and by adsorption and transport from the surface layer by air bubbles[108,109] formed by the waves, which are also the main source of aerosol particles containing sea salts[108].

Little is known about the content of TM in suspended particles. In the surface layer of the Pacific Ocean the average concentration of Zn in SP is 220 μg g^{-1};[110] in the Baltic Sea values of 0.006 and 0.99 μg $litre^{-1}$ were obtained for Cd and Zn respectively[111]. Relatively high TM concentrations are found in the fecal pellets of zooplankton, even in comparison with the amounts found in zooplankton itself: Cd (9.6 and 0.74), Zn (950 and 62), and Hg (0.34 and 0.35 μg g^{-1} respectively).[112] When the SP sink to a relatively small depth the metal content does not change significantly[111], but at greater depths there is a marked decrease (to 1.7 and 3.3% of the total concentration for Cd and Zn respectively[113]), the concentration in the case of Cd being lower by a factor of 4 at depths <400 nm.[55]

The concentration of suspended trace metals (especially Zn and Cd) in the ocean is determined by the amount of suspended organic matter[114] with which the TM are combined[103]. The composition and concentration of suspended organic matter have not been adequately studied, but proteins always appear to be present (up to 270 and 32 μg litre^{-1} have been reported for coastal and open waters respectively of the Pacific Ocean[115]). In rivers and lakes the concentration of suspended organic compounds is substantially (6–10-fold) lower than the concentration of SOC.[70] The chemistry, biology, and vertical distribution of SP in the ocean are discussed in Refs. 100–102 and 116, and their role in the detection of TM in Ref. 117.

By far the greater part of the TM transferred to the ocean from rivers is on suspended particles[118]: the proportion can be as high as ~80% (for Zn and Cu)[119] and even 90% (including Zn and Cd) in the Mississippi river[120]. The only exception is mercury, ~80% of which is transported in a soluble form while only 15–19% is found on SP.[121,122] Where fresh waters mix with sea water in estuaries, i.e. where a decrease in the flow rate is accompanied by an increase in salinity and (sometimes) in pH, two opposing processes take place[60,118,123]: 1) settling of the SP, and rapid formation and precipitation of flakes of colloidal particles containing Fe, Mn, Al, P, organic carbon, and HM,[124] accompanied by the coprecipitation of TM; 2) the release of the TM from the SP to the water. The relative importance of these two processes has not yet been determined. In some rivers of Europe[118] and of America the TM content (including Hg and Zn) of the SP decreases as the salinity increases: for example, from 403 to 240 for Zn and from 1.8 to 0.9 μg g^{-1} for Cd.[123] The influence of SP on the distribution of TM in estuaries is discussed also in Refs. 125 and 126.

Because of their rapid initial release, followed by a much slower release, the TM can be in an ionic or a complex form: this happens mainly as a result of breakdown (by oxidation) of the supporting particle[118,127], but it may be due also to desorption caused by dilution[127], stoichiometric exchange of Ca and Mg,[60] or complex formation with organic or inorganic ligands[127].

Trace metals are taken up by SP by adsorption on oxide surfaces[128]: Cd is combined only with Mn, and Zn mainly with Fe.[129] Alternatively, the TM are incorporated into the SP by complex formation, by ion exchange with clay minerals, or by reaction with humus materials[118] or with colloidal organic particles. The degree of combination is very sensitive to pH,[60,130] and can be controlled by chemical reactions at the interface through (for example) redox processes involving the substrate ($Fe^{3+} \rightarrow Fe^{2+}$) or the metal ions[131]. Humus materials can adsorb TM as well as reacting chemically with them: the adsorbed TM are held octahedrally (relatively weakly), they easily form complexes, and they are easily reduced[81].

Colloidal particles of inorganic (hydrated Fe, Mn, and Si oxides, clays, sulphides) or organic origin (HM, residues from living organisms) play an important role in controlling the degree of combination of TM in NW.[65] Inorganic colloidal particles can sorb (or chemically combine with) organic colloidal particles, and therefore they have hydrophilic properties and they oppose agglomeration.[69] It has been suggested[65] that most of the SOC in NW are in a colloidal state. Colloidal particles can combine with Cd, Pb, and Cu to the extent of 15–30, 45–70, and 40–60% respectively of their total content in sea water, but Cd and Pb are found mainly in inorganic forms, and Cu is found also in organic forms.[132] Although the colloidal fraction of TM is classified with the soluble forms the mechanisms by which the metals are combined with colloidal and with suspended particles must be similar.

V. FORMS IN SLUDGE DEPOSITS

Depending on their origin, sludge deposits consist of: 1) a lithogenous fraction (clay minerals, quartz, etc.) formed by soil erosion and usually carried by rivers into the sea; 2) particles of the hydrated Fe_2O_3 type, formed in water by inorganic reactions; 3) a biogenic fraction consisting of inorganic particles of the $CaCO_3$ type, of biological origin, and organic materials including residues from dead biota[60]. They usually have a redox potential of 100–(−400) mV, or 300–600 mV in surface waters, and pH 6.5–7.5.[133]

The upper few centimetres of bottom sludges in estuaries and coastal waters are usually in an oxidised state and are often brown, whereas the deeper layers tend to be in a reduced state, black in colour, and smelling of H_2S. Organic matter, which can account for up to 10% of the bottom sludge (or more), is decomposed by micro-organisms under both aerobic and anaerobic conditions[60]. The resulting humus material has a MW ranging from < 500 to >300000: for most of the HA the MW is >300000, but for the FA the MW is < 500 or >100000–300000 (see Ref. 74).

Sludge deposits showing different levels of contamination may contain the following metal concentrations (expressed as μg g^{-1} of dry weight): Hg from 0.01 to 14.3, Cd from 0.05 to 60, Zn from 3 to 2500.[135] In rivers the concentrations of Cd and Hg are 1.0–9.8[136] and 0.03–1.28[122] respectively, and in the Atlantic the concentrations of Cd and Zn are 0.13–0.21 and 17–134[55] respectively (μg g^{-1} of dry weight). In rivers the biota contains only 0.02% of the total mercury, and the bottom sludge contains ~97%.[122] The fractional amount of $MeHg^+$ in the bottom deposits varies from 0.1 to 2.1%, and is 100 times greater than in the biomass of the river[67]. It is important to note that only a small proportion of the metal content of the bottom sludge can be transferred to the sea by the flow of the river. In the case of mercury, for example, the proportion is ~1% of the total amount of mercury carried by the river[121,122]. However, the concentration of TM in bottom sludges is not uniform. It is highest (by a fairly large factor) in the fractions with the smallest particles[122,137] and in the fractions richest in organic matter[74,122,136,138,139]. The latter fractions are usually found downstream from regions with a highly developed heavy industry, and they are composed of settled SP.[139]

The main components of the organic fraction of free sea sludges are HM, amounting to 40% of the sludge and formed in the marine environment. Marine HA have a very high sulphur and nitrogen content.[140] They combine with TM by cation exchange and complex formation through oxy-, amino-, and thio-groups, and also by surface adsorption[140,141]. The HA are usually formed in the sludge by diagenesis¶, and they leach the TM out of the solid mineral phases[74,140] (a reaction of great importance in geochemical processes). However, the form in which the metal exists in the bottom sludge is determined by various allochthonous interactions and autochthonous processes[142]. Thus, in some sludges the Cu, Zn, and most of the Mo are combined with organic substances, and the Ni and Co with sulphides[140], whereas in others the Mn and Zn are found predominantly in the carbonate phase, the Pb in the hydroxide phase, and most of the Cd can be readily exchanged[142]: in some samples the Cd is found in the carbonate, sulphide, and organic form (80, 10, and < 5% respectively), and >90% of the Zn is in the carbonate and the organic phase in comparable amounts[143], but in other samples the Hg is accumulated in the sulphide phase[144].

¶ The totality of the natural processes by which loose deposits at the bottom of water basins are converted into sedimentary rocks.

The MS sulphides (M = Hg, Zn, etc.) are stable under anaerobic conditions, but under aerobic conditions they are oxidised in proportion to their solubility in water[145]; also, Hg^0 can be oxidised to Hg^{2+} in soils (2–27%) and it can combine with organic substances[146]. The affinity for Hg^{2+} adsorption decreases in the series RSH ≫illite >montmorillonite >RNH_2 >kaolinite >RCOOH >fine sand >medium sand > coarse sand[147]. In contaminated sludge the concentration of the Zn forms decreases in the series organically bound >carbonate >sulphide >adsorbed >exchangeable, and that of Cd in the series carbonate >sulphide >organically bound >adsorbed > exchangeable.[148]

The TM transferred to the ocean by different routes (by the rivers and from the atmosphere, through effluent waters and ship discharges, etc.) always accumulate in the bottom sludges of the coastal areas of seas and lakes. Therefore a core sample of the sludge taken without disturbing the stratification can describe the accretion of TM in a given basin over any period of time up to several centuries. The geochronology of the deposits is determined from the distribution of the radioactive isotopes ^{210}Pb, $^{239+240}Pu$, and ^{137}Cs. In the surface layers of sea and lake deposits near large industrial, mining, and urban regions the concentrations of Cd, Zn, Hg, Pb, Cu, and other TM can be 5–10 times greater than in the layers laid down 50–100 years ago, thus reflecting their anthropogenic origin.[149–153] A historical plot of the vertical Zn and Cd profiles in one of the lakes of the USA[151] is reproduced in Fig.4: we note that the anthropogenic supply of these metals began in ~1910.

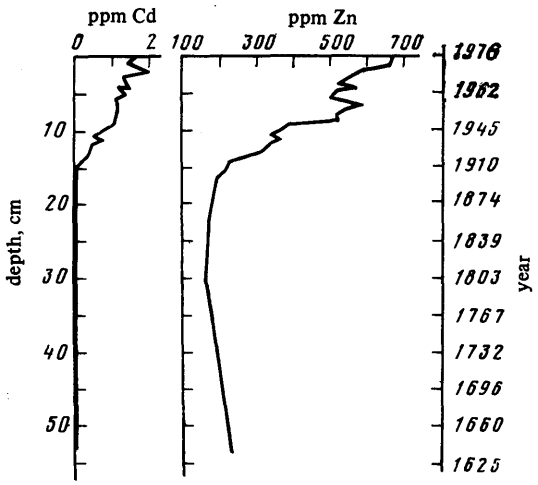

Figure 4. Concentrations of Cd and Zn as a function of depth in the bottom sludge of a lake in the USA.[151]

The sludge waters in contact with the bottom deposits always differ from the water in higher levels because of slow reactions in the sludge, which change the chemical composition of the water[154]. The composition of the sludge waters also depends on the depth of the deposits[155]; their organic content is high (30–800 mg C $litre^{-1}$ in marine sludges[69]), and in fresh water sludges the MW is >300.[74] Sulphide ions and oxygen are the most important components, because they determine the concentration of TM in sludge waters: under reducing or oxidising conditions [TM] can be 1–2 orders of magnitude lower or higher than in sea water.[154,156,157] This effect is ascribed to the formation of complexes with SOC[140] and of insoluble sulphides[60,156,157]. However, we should note that the concentrations of TM under reducing conditions are very much higher than the thermodynamic solubilities of their sulphides. This is due to the enhanced solubility of the sulphides in the presence of organic compounds, or to the formation of the more soluble polysulphides[60,158]. Under oxidising conditions most of the dissolved Hg is present as complexes with organic compounds of MW < 500 or >100000.[158] The most important dissolved forms of Zn, Cd, and Hg in marine sludge waters, calculated by combining experimental results with an equilibrium model[156], are listed in Table 4. However, the model ignores complexes formed by metals with HM, which are very important in the case of mercury.

Table 4. Main dissolved forms of mercury, cadmium, and zinc in the sludge waters of marine deposits at pH 7.5[156] (as % of total concentration).

Oxidising condition		Reducing conditions	
component	content	component	content
$HgCl_4^{2-}$	80.4	HgS_2^{2-}	98.5
$HgCl_3^-$	15.4	Hg (cysteine)	1.2
$HgCl_2$	4.1	$HgS(HS)_2^{2-}$	0.2
$Hg(OH)_2$	<0.1	$Hg(HS)_3^-$	<0.1
HgClBr	<0.1	$HgS(H_2S)_2$	<0.1
$CdCl^+$	56.5	$Cd(HS)_2$	97.2
$CdCl_2$	15.2	$Cd(HS)_3^-$	2.2
$CdCl_4^{2-}$	10.0	$Cd(HS)_4^{2-}$	0.1
$CdCl_6^{4-}$	9.1	$Cd(HS)^+$	<0.1
$CdCl_3^-$	9.0	$CdCl^+$	<0.1
Zn^{2+}	38.1	$Zn(HS)_3^-$	99.2
$Zn(OH)_2$	29.6	Zn^{2+}	0.2
$ZnCl^+$	18.0	$Zn(OH)_2$	0.1
$ZnCl_2$	6.6	$ZnCl^+$	<0.1
$ZnSO_4$	4.3	$ZnCl_2$	<0.1

The direction of the migration of TM in the water–sludge system is determined by the redox potential and by the pH,[156,159] and also by the chemical composition of the sludge waters and of the water in the higher levels[156]. Two opposite points of view on the effect of the redox potential can be defended[159]: 1) the presence of sulphides under reducing conditions will cause precipitation of the TM, but oxidation to SO_4^{2-} will make the TM mobile and transfer them to the supernatant waters; 2) the TM will be solubilised under reducing conditions because of the reduction of the Fe and Mn hydroxides on which the TM are sorbed or coprecipitated under oxidising conditions. It is experimentally found that the extent to which the Fe and Mn become mobile increases as the redox potential is displaced towards reducing conditions, and the mobility of Zn, Cd, Cu, Pb, and Ni increases in the oxidising region, whereas in the case of Hg and Cr the redox conditions appear to be irrelevant. Mobility can be produced by redox reactions, complex formation, dissolution, diffusion, desorption, biological effects, and dynamic processes[156]. For example, TM become mobile when river sludges are mixed with sea water.[160]

VI. FORMS IN THE BIOTA

Only about 20 elements of the Periodic Table contribute significantly to the maintenance of life on Earth, though up to 60 have been detected in living tissues, and all the elements found in the surrounding environment must be present in trace amounts in living tissues. In cells the elements exist as compounds and complexes of various kinds. About one-third of the enzymes known in biochemistry are active only in the presence of metal ions. Of the metals discussed in this review zinc is biologically the most important[161].

Pelagic organisms can store TM from their surroundings and adapt to changes in their natural concentrations in water and in their nutrients. Geometric mean concentrations of Hg, Cd, and Zn in different types of marine organism (excluding data from heavily polluted regions[60]) are listed in Table 5 together with their ranges (including pollution effects).[162] The TM content is not the same in different tissues of the organism: in heavily contaminated environments the concentration of TM is highest in liver and kidney tissues[60]. The take-up of TM is usually proportional to the growth and final size of the living organism.[163,164] In general the TM content is controlled by many factors which are difficult to consider jointly. For example, in fishes the concentration of mercury depends on the availability of food and on its mercury content, on the chemical form and concentration of mercury in the dissolved state, on the type of fish and its position in the food chain, and on the age, sex, and size of the fish. It is important to note that the concentrations of TM in fishes recently netted from one particular region and in fishes netted several decades ago (museum specimens) are almost identical[165]. However, concentrations can fluctuate, seasonally as well as annually[166]; a marked decrease in TM concentration has been noted[167] in starving invertebrates. The dynamics of the biological accessibility of mercury in a small estuary are discussed in Ref. 168.

Table 5. Geometric mean concentrations of mercury, cadmium, and zinc in different groups of marine organisms (over the whole organism, except shell molluscs)[60] and concentration ranges[162] in μg g^{-1} of dry weight.

Dry weight, %	Organism	Hg		Cd		Zn	
		Ref.60	Ref.162	Ref.60	Ref.162	Ref.60	Ref.162
~20	Marine algae (all types)	0.15	0,002—0.008	0.5	0.86—2.41	90	11—666
—	Phytoplankton	0.17	—	2	1.5—1.8	38	7.1—136
~11	Zooplankton (Copepoda)	0.1	—	4	1.2—2.6	113	9.9—625
~5	Tunicata (mainly Ascidia)	0.1	—	1	0.02—0.2*	200	10—14*
~20	Bivalve molluscs	0.4	—	2	—	100	—
~20	Oysters	0.4	—	10	—	1700	—
~20	Gastropoda	0.2	0.03—0.33	6	0.25—46	200	2.6—2354
22—54	Echinoderms	0.3	—	2	—	100	—
~30	Crustaceans (Decapoda)	0.4	<0.02—0.44	1	0.1—5	80	20—121
3—19	Coelenterata	0.1	—	1	—	50	—
~25	Cephalopoda	0.3	—	5		250	—
~25	Fishes	0.4	0.026—2.6	0.2	0.01—200	80	0.5—396

* per 1 g of live weight.

Organisms can accumulate relatively large amounts of metal: for example, in fishes the concentration factor (from water to fish) is 2.9×10^3 and 10.6×10^3 for open and coastal sea waters respectively[169]. Species such as swordfish and tunny, being at the apex of the food chain, usually contain large concentrations of TM (for example, mercury[170]), which are normal for these species. Some organisms (such as large sea-weeds and mussels) can accumulate TM selectively in some tissues only, and have therefore been selected as indicators of the level of contamination of the water medium.[171] The metal content of organisms can reflect fairly accurately the concentration in the water: for example, mussels have been used to determine mercury in water to a sensitivity of 0.005—0.010 μg $litre^{-1}$.[172]

Metals are absorbed by the tissues of living organisms as a result of adsorption on body surfaces, breathing organs, and alimentary canals (in the case of metals ingested with the food); adsorption is followed by diffusion through cell membranes and combination with organic ligands contained in the cells.[60] The extent of absorption depends on many factors: the chemical and physical forms of the metals, their concentration, the temperature, the presence of various organic or inorganic compounds, the state of the body surface of the organism, etc. For example, organic mercury is absorbed much more easily than inorganic mercury by fishes, crustaceans, and molluscs because of its solubility in the mucilaginous surface layer of their bodies and gills, which assists its penetration through the cell membranes[60,173]. The rate of absorption of $MeHg^+$ by fishes increases (but not in direct proportion) with concentration and temperature, is independent of the presence of organic compounds (for biochemical oxygen demand values of 8—800 mg $litre^{-1}$), and is a maximum for a Cl^- concentration of ~200 mg $litre^{-1}$.[96] The influence of natural factors on the absorption of mercury and cadmium by mussels is discussed in Refs. 174 and 175. However, great care is needed in predicting *in situ* absorption of metals by marine fauna from laboratory data[173].

After the metal has been absorbed by the organism its distribution in the various tissues can vary markedly with time. Thus, a trout exposed for one day to a solution of MeHgCl containing 10.7 μg Hg $litre^{-1}$ was found to contain ~10 times more methylmercury in its gills than in its other organs, the concentration of MeHgCl being lowest in the brain and in the skeletal muscles. However, the relative amounts changed with time, and after 6 weeks the MeHgCl level of the fish was highest in the brain, skeletal muscles, and gonads[176]. On the other hand the absorption of Cd^{2+} from sea water involves a time lag, but is then linearly related to time and to the concentration of Cd^{2+} (if not too high). The maximum concentration factor is 165 at a concentration of 0.7 μg Cd ml^{-1}. However, the complexes of cadmium with EDTA, humic and alginic acids, and even pectin are absorbed without time lag, and both the rate of accumulation and the final concentration in the tissues increase by a factor of two in the series kidneys ≫ viscera >gills ≫mantle >muscle. Cadmium is excreted 18 times more slowly than it is absorbed (mainly through the kidneys).[176]

The tendency to accumulate different chemical forms of the metals in different tissues has been demonstrated in the case of mercury. Hg^{2+} accumulates mainly in the kidneys, and its concentration in the brain tends to be low. Inhaled mercury vapour enters the blood (in small amounts) as Hg^0, which rapidly diffuses through the hematoencephalitic barrier and is oxidised to Hg^{2+} in the brain. Over 90% of the mercury in blood is found in the erythrocytes, combined with haemoglobin, the remainder being combined with proteins in the plasma. Most of the mercury found in the bile is combined with di- and tri-peptides containing cysteine. On the whole, the distribution of mercury after inhalation of mercury vapour or ingestion of phenylmercury or mercuric diuretics is similar (except for the brain) to the distribution of Hg^{2+}, because of the rapid biotransformation of these forms of mercury into Hg^{2+}. On the other hand in $MeHg^+$ and its alkyl derivatives the Hg–C bond is relatively stable in biological systems, and

therefore these compounds show a different distribution and different biological effects. The high lipid solubility of $MeHg^+$ allows it to pass through the hematoencephalitic barrier and to accumulate in the brain, where it produces irreversible poisoning of the central nervous system.[178] It has been shown that $MeHg^+$ can catalyse the hydration and hydrolysis of vinyl ether bonds in plasmogens (the main constituents of the phospholipids in the cell membrane).[179]

The relative toxicity of these metals towards many forms of marine and estuary life decreases in the sequence[60,180] Hg ≫ Cd > Zn, and the mercury compounds lie in the sequence[181] $RHg^+ > ArHg^+ > Hg^{2+}$. However, these sequences are arbitrary, since the toxicity of the metals depends on their chemical and physical forms, on the dose, on the path by which the metal enters the organism, etc.[180,181] For example, the toxicity is proportional to the concentration of free Cd^{2+} ions in water[182], and decreases in the presence of factors which tend to lower this concentration by changes in form or by complex formation (increased water hardness[183] and salinity[182], presence of organic[182] and humus substances[86]). In general, chelate formation lowers the toxicity of the metals[182], which can be correlated with parameters defining the "hardness" or "softness" of the metals[184]. Surprisingly, $MeHg^+$ and Cd^{2+} inhibit the regeneration of tail-fins in fish, but the effect disappears when these forms are mixed with Hg^{2+}.[185] A toxicological comparison of the effect of Cd, Hg, and Cu on natural and on culture populations of Copepoda has been reported[186]. The toxicology of mercury compounds has been studied in great detail, and widely reported, including biological effects[178,181,187].

Direct electron microscopic evidence has been obtained that oysters can store Cu and Zn in the form of different compounds within bubbles surrounded by membranes in the amebocytes which are present in all the soft tissues, and that these metals are combined with S and P respectively. It is suggested that this mechanism of storage and de-toxification of TM in biological systems may be wide-spread. However, there are important differences between the different metals and the different organisms. Whereas Cu and Zn are stored in amebocytes, and they accumulate mainly in the gills and in the mantle, Fe and Pb are found in bubbles of epithelium cells of the kidneys[188], and Cd becomes concentrated in the kidneys and viscera[177].

The action of many enzymes requires Zn and Cu in the ternary and quaternary protein structures. However, if these enzymes are exposed to excessive concentrations of the functional metals, or to other trace metals able to compete with them (like Hg and Cd), their normal functions may be impaired. This effect may be due to conformational changes, as a result of which the substrate molecules are unable for a long time to "adapt" themselves to the reactive centres of the enzymes. On the other hand, some toxic metals (including mercury) are able to split various enzymes into their regulating and catalytic sub-units, so that the normal regulatory function is lost. Therefore in order to ensure normal cell operation the excess of functional metals (or the toxic metals) must be removed from the biological sphere of action. This is accompanied by the formation of metal thionein (MT), which can combine with TM and biologically deactivate them.[189]

Metal thionein is the principal means of storing Zn and Cu in the liver and kidneys, where it is found in the cell walls of tissues, and it probably contributes to the control of metal adsorption in the mucous lining of the intestine. It is a protein with a MW of 10000–12000, containing an unusually high proportion of cystein (~30% of the total amino-acid residues). The presence of a large number of thiol groups gives the MT a high affinity for metals: 2–3 cystein residues are available to combine with each metal atom for a metal content of 7–10%.[190,191] In living organisms MT is always saturated with metals, and it contains Zn in approximately one-half of the reactive centres. Production of MT can be stimulated by adding Zn and Cu, and also Hg, Cd, and Ag.[190]

One of the modern theories of de-toxification is based on these properties of MT: it states that Hg and Cd are free from toxic effects as long as their concentration is insufficient to exceed the combining power of MT. Hence, when Hg and Cd are ingested into the organism they initially displace from the MT the Zn and Cu (which are much less strongly bound) and transfer them to high-MW proteins (metal-enzymes). Since the displaced metals are naturally occurring components of many of the proteins, they are relatively non-toxic. Only when the concentration of Hg and Cd exceeds the combining power of the MT are these metals transferred to the metal-enzymes, where they begin to display their toxic properties within the cell. However, this transfer depends also on the relative rates of supply of Hg (or Cd) and of MT synthesis (stimulated by the trace metal). Therefore it is suggested[191] that the critical factor determining the survival of the organism is not the concentration of Hg or Cd in the tissues (which can be quite high) but whether the trace metals are located in the MT or in the metal-enzymes.

As was stated above, some species of predatory salt-water fish may contain relatively large amounts of mercury (in some cases >2 mg g^{-1}) without any harm to themselves[170]. This was inexplicable until it was realised that in these cases the mercury is always accompanied by selenium in a 1 : 1 molar ratio (or by an excess of selenium): somehow, the selenium appears to moderate the toxicity of the mercury. It was recently shown that the selenium-containing enzyme glycine-reductase is, in effect, a selenium cysteine, and the de-toxification of mercury by selenium was ascribed to combination of the mercury with selenium-containing peptides and proteins (as in the case of MT). This hypothesis is confirmed by the observation (from PMR spectra[192]) that the affinity towards $MeHg^+$ of the various groups decreases along the series SeH > SH ≫ Se–Se > NH_2 > S–S, SeMe, SMe. In the case of Cd^{2+} the detoxification effect of selenium and the distribution in different tissues were shown[193] to be similar to those of Hg^{2+} but different from those of $MeHg^+$.

At different concentration levels, Zn and Cd in tissues may compete for combination with proteins. Thus, in liver and kidney cytoplasms the inflow of Cd can combine with high-molecular proteins until the combining power of the MT is exceeded if these proteins are not already saturated with Zn. If they are, the excess of Zn and the Cd are taken up by the MT.[189] Even in poisoned molluscs the Zn, Cd, and Cu are combined with low-molecular proteins if the concentration factor is high but not if the concentration factor is low.[194] In water organisms Cd may be found also in the free state[195]. The degree to which Hg is combined with low-molecular proteins can differ in different organs (as was found in oysters)[196].

In spite of the important role of TM in the life processes of various organisms, very little was known until recently of their chemical behaviour in metabolism, their toxicology, and their bio-transformations. The earliest systematic studies concerned their interaction with sulphur-containing amino-acids. It was shown that all the ligand atoms of these amino-acids (sulphur, nitrogen, and oxygen) can combine with the metals, though the type of bond formed depends on the nature of the metal (even for metals from the same sub-group). In aqueous solutions the resulting compounds and complexes are very labile, and the interaction of a given metal ion with the ligand atoms is a function of pH. Therefore a given metal may be bound to different ligands in the crystalline and in the dissolved state. The same is true of the complexes formed with homologous amino-acids, due to differences in packing of the crystal lattice and to differences in conformational and configurational stability.

This effect is easily demonstrated by considering the interaction of M^{2+} with S-methylcysteine (mcyst) and methionine (met). Whereas in an acid solution Zn^{2+} and Cd^{2+} do not react, and Hg^{2+} forms 1 : 2 complexes with an Hg–S bond, in an alkaline solution the M^{2+} ions form chelates of 1 : 2 composition with M–N,O bonds, and in the case of mercury and mcyst with Hg–S,N bonds (according to the PMR spectra). Hence, in the case of mercury complexes in alkaline solutions the strength of individual bonds is less important than the very high stability of the 5-membered Hg–N,O ring as compared with the 6-membered Hg–S,N ring.[197] On the other hand, in the crystalline state the Zn and Cd in 1 : 2 complexes are combined with N and O atoms[198–200], but the Hg in the complexes with mcyst and met is combined with S[201] and with S and O[202] respectively. However, Cd forms 1 : 1 complexes with penicillamine (pen) containing Cd–S,N,O[203] and Cd–S,O[202] bonds, whereas mercury forms only Hg–S bonds[202] (according to X-ray diffraction analysis). In the complexes of Zn^{2+} and Cd^{2+} with histidine (1 : 2 composition) the metals are bound to N (both amino and imidazole) and to O.[204] Measurements of K have shown that the complex-forming power of M^{2+} towards five octadentate ligands containing sulphur and nitrogen atoms decreases in the series Hg > Zn > Cd > Mg > Ca.[205]

The change in the bonding centre with pH (due to competing reactions) has been studied most thoroughly for the $MeHg^+$ complexes of 1 : 1 composition. With simple amino-acids of the glycine type and at low pH the $MeHg^+$ is attached to the carboxylic acid group, and at high pH it is attached to the amino group[23]. With sulphur-containing amino-acids (for example, met) at pH 2 the $MeHg^+$ ion is combined with the thioether group, but as the pH is increased it begins to "float" along the met molecule and appears to form complexes with the carboxylic acid group (though this has not been proved), and at pH 8–9 it forms complexes with the amino group. As the pH is increased still further the complex begins to dissociate, and at pH 13.5 it is fully decomposed[206]. Bonding with cyst and met has been studied in a similar way[23], and the K values of the corresponding complexes have been determined. On the whole, the apparent stability of the complexes of methylmercury with various ligands depends on pH, and at pH 7–9 it decreases in the sequence thiol > amino > OH^- > carboxylic acid > thioether ligand.[206] The way in which $MeHg^+$ is combined in biologically important compounds is discussed in more detail in Ref. 23.

$MeHg^+$ and $PhHg^+$ have been shown[207] to form 1 : 1 complexes with ligands which coordinate through SNO and SSO (pen, cyst, 2,3-dimercaptopropan-1-ol), and 2 : 1 complexes when the ligands are in excess, with Hg–S, Hg–S,N, and Hg–S,S bonds, whereas with SO and NO ligands (N-acetylcysteine, glycine) only 1 : 1 complexes with Hg–S and Hg–N bonds respectively are formed. The K values for these complexes decrease in the series MeHgS > PhHgN ≳ PhHgS > MeHgN ≫ PhHgO, MeHgO and S > N > O (according to i.r. and PMR spectral data, and potentiometric titrations). The latter method also showed the formation of $MeHgL_2^-$ complexes[31] with simple amino-acids, but chelation in these compounds is still uncertain. The 1 : 1 compounds of $PhHg^+$ with cyst and pen are not very stable, and they undergo spontaneous symmetrisation[208]. Lastly, X-ray structural analysis has shown that Hg–S and Hg–S,N bonds are present in MeHg·pen and $(MeHg)_2$.pen complexes[209], Hg–S bonds in the MeHg.cyst complex[210], and Hg–N bonds in the MeHg.met complex[211], the mercury being also weakly coordinated to oxygen in the latter two complexes.

As in the amino-acids, the metal combination centres in peptides depend on pH. Thus, Zn^{2+} and Cd^{2+} in leucylglycine complexes of 1 : 1 composition at pH < 5 are combined with the carboxylic acid group of the glycine residue to form linear structures, whereas at pH > 5 they are combined with the amino and carbonyl groups of the leucine (according to the ^1H and ^{13}C NMR spectra)[212]. Under similar conditions di-, tri-. and pentapeptides form $[Zn_2L_2]^{2+}$ complexes whose K values have been determined by potentiometric titration[213]. In crystalline compounds, on the other hand, Cd and Zn combine with peptides through N (amino) and O (carboxylate and peptide) to give chelate compounds as a rule[199,204]. In the 2 : 1 complexes of $MeHg^+$ with glutathione at pH < 4 both cations are combined with thiol groups, but at pH 4–8 one of the cations is transferred to the amino group and at pH > 10 it dissociates to MeHgOH.[23]

However, the reactions of the metal ions with proteins differ from those with amino-acids and peptides, because in proteins the α-NH_2 and α-COOH groups of long polypeptide chains are separated by the covalent bonds of several residues. This interaction is affected also by the conformation of the peptide chain, which can block a potential attachment point while a remote side chain is in the correct position for the formation of a chelate ring. An example is provided by the metal-enzymes and metal-proteins, in which the strong interaction between the metal and the protein part plays a decisive and biologically specific role[204,214]. Depending on the type of protein, a given metal ion can fulfil various functions, determined by the limitations imposed by the protein environment. Hence the biologic specificity of the metal function probably has a stereochemical origin[161,204]. Information on the complexes of TM with proteins in the crystalline and the dissolved state is given in Ref. 215 with a statement of the amino-acid residue combined with the metal.

The chemical form of the metals undergoes substantial changes during absorption, transport, and storage in biological tissues and liquids. At physiological pH values they are usually combined with peptides, proteins, and other ligands, but in the acid regions of the digestive tract they can exist in uncomplexed forms[190]. The reactive centres of proteins and enzymes for the attachment of all forms of mercury[187] (and probably also of cadmium[216]) are almost exclusively thiol groups.

It has been suggested that the whole of the $MeHg^+$ present in tissues is combined with cystein-containing peptides and proteins, containing thiol groups. However, in spite of the high thermodynamic stability of these compounds, they can easily exchange with other thiol groups as a result of bimolecular nucleophilic substitution by the reaction $MeHgSR + R'S^- \rightleftharpoons MeHgSR' + RS^-$. This fast exchange, which takes place at physiological pH values, is accompanied by redistribution of the $MeHg^+$ between these groups, which makes the identification of the initial compounds extremely difficult. Conversely, in the stomach (at pH 1.5–2.5 and high concentrations of Cl^-) exchange occurs by the reaction $MeHgSR + H^+ \rightleftharpoons MeHg^+ + RSH$, and most of the methylmercury is in the form of fat-soluble MeHgCl.[178,217]

Metal ions are necessary also for the biologic functions of nucleic acids, and they play an important part in many metabolic processes involving nucleotides as monomers. However, Hg^{2+} compounds can denature native DNA, sometimes reversibly, and $MeHg^+$ causes chromosome disturbance and therefore acts as a mutagen[181]. Furthermore, mercurated nucleotides hinder the synthesis of RNA in the nucleus (by 30–40%).[218] Hence, the interaction of Hg^{2+} (and especially of $MeHg^+$) with the components of nucleic acids has been studied in detail, whereas data for other metals tend to be fragmentary. In general metal ions can be combined with various reactive centres of purine and pyrimidine bases in nucleotides and nucleosides, with formation of both mono- and poly-nuclear complexes and compounds, depending on the base, the pH,

the metal, and the concentration. Thus, in solid complexes of Hg^{2+}, Cd^{2+}, and Zn^{2+} with ATP the metals are combined with N(7) of adenine and with phosphate[219], and Cd^{2+} with uridine (C=O(4)) and ribose, whereas with thymine only the deoxyribose group is involved (according to i.r. spectra).[220] The stereoselectivity of the attachment of the metals to the nucleic acid components is discussed in Ref. 221.

Hg^{2+} and $MeHg^+$ are usually attached to N(1) in purine nucleosides and to N(3) in pyrimidine nucleosides. With bases, $MeHg^+$ forms its strongest bonds with uracil and thymine. It is thought[181,222] that the denaturing of native DNA by Hg^{2+} and $MeHg^+$ involves initially the deprotonation of N(3) in thymidine, and then of N(1) in guanosine (according to Raman spectra). $MeHg^+$ may additionally be combined with ribose and (very weakly) with phosphate[181].

Relatively little is known about the action of TM on marine flora. The highest concentrations of individual TM (Hg, Cd, Zn, As, etc.) which are harmless to marine fauna are also non-toxic to fresh-water phytoplankton, but mixtures are extremely toxic, and can inhibit ~70% of the primary productivity. Cadmium can have both synergic (with Cu and Zn) and antagonistic effects (with Se).[223] At a cadmium concentration of 2 μg $litre^{-1}$ the growth rate of diatomaceous algae decreases by an order of magnitude[224], and at 5–10 μg $litre^{-1}$ the microbial colonisation and decomposition of foliated material is inhibited[225]. However, only a few of the 99 species of phytoplankton examined were found to absorb Hg^{2+}, Cd^{2+}, Pb^{2+}, and Cu^{2+} *in situ*, and these account for only a very small part of the bio-mass.[226] The effect of TM on the Laminariaceae is described in Ref. 227.

In an experiment lasting 72 days, carried out in a reservoir of 1300 m^3 capacity covered with a plastic sheet, the productivity of phytoplankton was found[228] to decrease after 12 days in the presence of 5 μg $litre^{-1}$ of mercury, and zooplankton could not be detected after 34 days. The concentration of dissolved mercury was less than 50% of the total mercury content, which fell by 3% per day. At the end of the experiment >90% of the mercury was found in the bottom sludge[228].

VII. BIOLOGICAL CONVERSION OF THE FORMS

Among the metals under discussion, only mercury can exist in nature in different states of oxidation and form stable mercury-organic compounds. Therefore, biological conversion of the forms (especially methylation and demethylation) has been studied mainly with mercury derivatives. In biological systems three coenzymes can act as methylating agents: S-adenosylmethionine, N^5-methyltetrahydrofolates ($Me-N^5$), and vitamin B_{12} derivatives (methyl corrinoids). All these substances can transfer a methyl group as the Me^+ cation, but only the methyl corrinoids can generate it also in the form of the Me^- anion and the Me· radical, which enables them to methylate Hg^{2+} salts and Hg^0 respectively. Methyl cobalamin $Me-B_{12}$ (one of the methyl corrinoids) is found in microorganisms and in warm-blooded animals: it produces $MeHg^+$ and Me_2Hg by enzymic and non-enzymic paths in relative amounts depending on the concentration of mercury.

The mechanism of non-enzymic methylation of $Hg(OAc)_2$ by methyl cobalamin in aqueous solution is believed to involve heterolytic breaking of the Co–Me bond without change in valency of the Co^{3+}, followed by transfer of Me^- to the Hg to give $MeHg^+$ and aquocobalamin as the end-products. Being highly electrophilic, Hg^{2+} can also coordinate with the $Me-B_{12}$ base through 5,6-dimethylbenzimidazole (DMBI) to give a mixture of $Me-B_{12}$ complexes both with and without breaking of the Co–DMBI bond. The first complex reacts with Hg^{2+} at least 1000 times faster than the second, because of the greater electron density in the Co–C bond resulting from coordination to the DMBI. Me_2Hg is formed in a similar way, but only from $MeHg^+$, and at a rate 6000 times smaller[229].

However, the demethylation of $Me-B_{12}$ induced by Hg^{2+} in chloride or acetate solutions was found[230] to occur in a single step, without breaking of the Co–DMBI bond, whereas Hg^{2+} in aqueous solutions can break this bond reversibly as a result of complex formation with DMBI by the reaction $Me-B_{12}+Hg^{2+} \rightleftharpoons Me-B_{12}-Hg^{2+}$. In the latter case the methylation kinetics are complex, and depend on the concentration of Hg^{2+}.

The reaction rate is very sensitive to the degree of dissociation of the mercury salts, and for the synthesis of $MeHg^+$ it decreases in the sequence[231] $OAc^- > Cl^- > Br^-$ (the rate constant of the reaction for mercuric acetate and cyanide respectively being 260×10^{-4} and $< 0.01 \times 10^{-4}$ s^{-1}).[229] In the case of Me_2Hg the corresponding series is[187,229] $Cl^- > OH^-$. This reaction is inhibited by phosphates and thiols. Non-enzymic electrophilic methylation of mercury is found in aerobic organisms, which contain methyl corrinoids as metabolic intermediates.

The free radical mechanism for the methylation of mercury by $Me-B_{12}$ has not been investigated, but in the case of other metals and metalloids (for example, for Cr^{2+}) it has been shown to involve homolytic breaking by these elements of the Co–C bond of methyl cobalamin to give Co^{2+}–cobalamin and the corresponding methyl derivative. The reaction takes place only in the presence of oxygen (which is needed to generate the radicals[229]).

It has been suggested that the mechanism of the methylation of elements by $Me-B_{12}$ depends on the standard reduction potential E^0 of the element. For $E^0 > 0.8$ V an electrophilic mechanism is predicted for the most highly oxidised members of redox couples (for example, Pb^{4+}/Pb^{2+}, Pd^{2+}/Pd^0, and Hg^{2+}/Hg^0), and for $E^0 < 0.154$ V a radical mechanism for the least oxidised members of redox couples (for example, Sn^{4+}/Sn^{2+} and Cr^{3+}/Cr^{2+}). The range $0.154 \text{ V} < E^0 < 0.8$ V includes the elements for which both members of the couple can be methylated. It is important to note that for some elements (e.g. Se) the methylation mechanism can vary with pH.[229]

Methyl corrinoids also take part in the enzymic synthesis of $MeHg^+$ in the presence of the enzyme methionine synthetase, found in various aerobic and anaerobic micro-organisms and in the liver of mammals, which slowly catalyses the reaction. The suggested mechanism includes the transfer of Me^- from the $Me-B_{12}$ co-enzyme to the enzyme in the presence of catalytically active amounts of S-adenosylmethionine. The enzyme–co-enzyme complex is re-methylated by Me^+ provided by $Me-N^5$. This complex can nucleophilically methylate Hg^{2+}, forming $MeHg^+$ and an aquocobalamin–enzyme complex which can be reconverted into the original complex by the action of flavin adenine dinucleotide (which reduces Co^{3+} to Co^+), followed by methylation of the complex by $Me-N^5$. In the presence of cysteine $MeHg^+$ forms methylmercury cysteine, which can give MeHgSMe in the presence of an excess of Me^+.[187]

The microbiological methylation of Hg^{2+} was first demonstrated *in vitro* with lake sludges[232], but it was subsequently found *in vivo* in marine[233] and river deposits[234]. With $PhHg^+$ the process occurs even more readily, and it seems likely that any form of mercury is converted (at least, partly) into $MeHg^+$ in a water environment. Bio-methylation by bacteria and molds is possible under both aerobic and anaerobic conditions[233,235,236]: in this case the main reaction product is $MeHg^+$ under aerobic conditions, and under anaerobic conditions (in the absence of S^{2-}) the main product is Me_2Hg[235] and methylation proceeds more easily[233]. The rate of the reaction is proportional to the metabolic activity of the microorganisms, to the total concentration of Hg^{2+} ions and their

availability, and to temperature[98,234-236]. Methylation is assisted by the presence of organic substances[96,233,234]; it depends on the salinity, and the process is most effective at a Cl^- concentration of ~200 mg litre^{-1}.[96] The optimum pH value for the synthesis of $MeHg^+$ is 4.5.[237] At pH 7 the rate of methylation is highest[96], and the main product is $MeHg^+$, but small amounts of Me_2Hg are also formed[236]. Early studies of methylation are reviewed in Refs.235 and 238.

We should note that bio-methylation of mercury has not been observed in plants and soils[235]: in these systems $MeHg^+$ can be formed by a non-biological path. The methylating factor can be extracted by alkali, and is decomposed by radiation. It is thought to consist of fulvic rather than humic acids, since solutions of the latter do not methylate mercury[239].

Bio-methylation under natural conditions is always accompanied by bio-demethylation to inorganic mercury, leading to an equilibrium concentration of $MeHg^+$ (or, more exactly, an equilibrium ratio of $MeHg^+$ to total mercury). This conclusion was reached from studies of river[240] and marine[241] sludges *in vitro*. Bio-degradation is probably faster under aerobic than under anaerobic conditions[233], though similar rates have been reported[240].

Experiments with isotopically labelled mercury have shown that in river sludges the *in vitro* mineralisation of $MeHg^+$ and methylation of Hg^{2+} depends on the type of deposit, and that the two processes are favoured by low and by high concentrations of organic matter respectively. Equilibrium concentrations of $MeHg^+$ of 0.2 and 12% were obtained, the equilibration times being 3 and 6 months respectively[67].

Many organic derivatives of mercury are decomposed by bacteria to Hg^0.[187,238] The same end product can be obtained by reducing Hg^{2+} with an enzyme found in various bacteria, which requires reduced nicotinamide adenine dinucleotide as a co-enzyme (NADH):[237]

$$Hg^{2+} + NADH + H^+ \rightleftharpoons Hg^0 + 2H^+ + NAD^+ \ .$$

Aerobic micro-organisms bring Hg^{2+} into solution from HgS as a result of the oxidation of sulphide to sulphate ions.

Bacteria and their metabolites play an important role in the transport of Zn^{2+} and Cd^{2+} from sea water to the bottom deposits. Because of the large quantities of H_2S produced by bacteria it is assumed that the metals are precipitated as MS or coprecipitated with FeS, since only ~20% of the deposited Zn^{2+} and a negligible proportion of the Cd^{2+} are found within the bacterial cells.[242]

Very little work has been done on the biological conversions of mercury compounds in living marine organisms. Thus, $HgCl_2$ introduced in various ways into a rainbow trout is not methylated[243], whereas MeHgCl is partly decomposed after being absorbed by the trout[176] (*in vivo* experiments). However, these conclusions may be erroneous because of the inadequate experimental conditions. Published data on the ratio of $MeHg^+$ to total mercury in fishes tend to be inconsistent[244].

---o0o---

We may conclude from this review that the penetration of chemical and physicochemical concepts and methods into our understanding of the role of the chemical forms of mercury, cadmium, and zinc in natural water environments is still inadequate. However, owing to the increasing impact of chemicals of anthropogenic origin on the ecological equilibrium, a more active participation in these studies from chemists of different specialisations is highly desirable.

The Use of Taft Relations for the Correlation of the Properties of Organosilicon Compounds. The Role of Substituent Effects

V.P.Mileshkevich and N.F.Novikova

Data for the correlations between the properties of organosilicon compounds on the basis of Taft equations are surveyed for the first time. The results for 140 relations involving reactivities, capacities for complex formation, and spectroscopic characteristics are examined. The specific features of the influence of individual effects of substituents at the silicon atom and the ability of the silicon atom and silicon-containing groups to transmit effects are discussed.
The bibliography includes 149 references.

III. Specific features of the effects of substituents at the silicon atom 53
IV. The ability of the silicon atom and of silicon-containing groups to transmit effects 59

I. INTRODUCTION

The only common and practically feasible approach to a quantitative description of the relations between the properties of organic compounds and their structure available at present is the Hammett–Taft theory. The fundamental postulate of the theory, based on the thermodynamic principle of linear free energy relations (LFE), presupposes that, to a first approximation, the influence of individual effects of substituents (inductive, resonance, etc.) on the given property of the molecule is additive[1–3].

Since the LFE principle is general, analogous relations are observed also for compounds where the indicator centre does not consist of carbon but of other elements. Among these, organic derivatives of phosphorus and silicon have been most widely investigated. An extremely significant feature of the electronic structures of these (and other) elements of the Third Period, responsible for their difference from carbon, is the possibility of p_π–d_π interaction via the d orbitals energetically available for combining with other reactants, which have an excess p- or π-electron density†. Quantum-chemical calculations on the p_π–d_π interaction predicted its intensification with increase of the positive charge of the atom of the Third Period on σ-bonding to electronegative substituents[6]. A pronounced pair interaction between the inductive and resonance effects of the substituents was therefore to be expected in this instance. Nevertheless, in organic derivatives of phosphorus, for which experimental data concerning relations of the Hammett–Taft type have already been reliably surveyed, systematic deviations from the additivity have not been observed[7].

In this review the first attempt is made to survey the available literature data concerning the application of various modifications of the Taft equation to aliphatic organosilicon compounds. As regards the structure-property correlations for aryl derivatives of silicon, we shall only mention that the Hammett equation in its traditional form is applicable to almost all cases.

†It is noteworthy that the p_π–d_π interaction constitutes the most widely accepted hypothesis used to account for a number of anomalies in the properties of elements with vacant d orbitals. Other views have also been described[4,5].

II. EXPERIMENTAL RESULTS

The available data on the structure–property correlations for organosilicon compounds are presented in Tables 1–3. The following numbering of the equations has been adopted:

$$A_i = A_0 + \rho^* \sum \sigma_i^*; \quad (1)$$

$$A_i = A_0 + \rho^* \sum \sigma_i^* + \delta \sum E_{s_i} \quad (2)$$

where A_i are numerical characteristics of the given property, σ_i^* are the Taft constants of the substituents, E_{s_i} are the steric constants of the substituents, and ρ^* and δ are the corresponding slopes.

The deviations from these equations are noted separately. The following notation is used in Tables 1–3: r and R are the coefficients of pair and multiple correlation respectively, n is the number of compounds the values of A_i for which were used in the correlation (the number of points), and s is the standard error of the correlation. It is also indicated which particular steric constants (E_S, E_S^C, and E_S^0) or non-Taft inductive constants [σ_i and σ(Si)] of the substituents were used in the original studies. In those cases where an independent and non-contradictory interpretation of the results exists for similar reaction series based on the same property, Tables 1–3 list only the data based on more extensive experimental results (the corresponding literature references are underlined). Certain relations (designated by an asterisk opposite the reference) were found by ourselves from literature data either for the first time or from an equation other than that given in the original communication.

Apart from the reports listed in Tables 1–3, there have been a number of publications in which the dependence of the given property on the constants of the substituents at the silicon atom was illustrated only in graphical terms. The relations between the logarithms of the rate constants and the Taft constants for the acid solvolysis of dimethylorganylsilanes[93], the cleavage of the Si–O bond in Me_3SiOR

***Eqn.(2) was used.

****Relative to trimethylsilane; the values of $\Delta\delta$ are expressed in Hz.

*****Relative to Me_2O.

with the aid of butyl-lithium[94], the solvolysis of bis(trialkylsilyl) sulphides[95], the thermal decomposition of triorganyl(t-butylperoxy)silanes[96], the anionic polymerisation of cyclotetrasiloxanes $(Me_2SiO)_n[Me(CF_3CH_2CH_2)SiO]_{4-n}$, where $n = 0-3$ [97], and the dependence on the Taft constants of the constants for chain transfer by triorganylsilanes in the radical polymerisation of olefins[98], of the relative acidities of alkyl(triorganylsilyl)amines and hexaorganyldisilazanes calculated from the values of $\Delta\nu$(NH) in the infrared spectra of mixtures of the above compounds with a ligand [tetrahydrofuran (THF) and dioxan] [99], of the relative basicities of methyl(triorganylsilyl)amines determined by ^{1}H NMR from the change in the chemical shift $\Delta\delta$ of the proton in chloroform in equilibrium with a mixture of the above compounds[100], of the stretching vibration frequencies of the Si–Ci bond in the infrared spectra of triorganylchlorosilanes[101], of the stretching vibration frequencies $\Delta\nu$(OH) and the corresponding values of $A^{0.5}$ in the infrared spectra of triorganylsilanols[102], of the chemical shifts $\tau(H_3-CSi)$ [but not τ(H–Si)] of methyldiorganylsilanes MeRR'SiH, of the shifts $\tau(-CH_2)$ [but not $\tau(-CH_3)$] of the protons in the ethyl groups of the compounds EtRR'SiH [103], EtRR'SiVin [104] [here and subsequently Vin stands for vinyl – $CH=CH_2$ (Ed.of Translation)], and Et_nSiX_{4-n} (X = halogen) [105], of the chemical shifts of the H(1) protons [but not H(3)] of the vinyl group

in the ^{1}H NMR spectra of all the compounds R_3SiVin [104], of the frequencies ν_m[77] (^{35}Cl) in the NQR spectra of the compounds Me_nSiCl_{4-n} ($n=1-4$), $(EtO)_{4-n}SiCl_n$ ($n=1-4$), and $(MeO)_{4-n}SiCl_n$ ($n=1-3$) [106], and of the dipole moments of vinylorganyldimethoxysilanes[107] were described in this way. There is a relation between the dipole moments of phenyltrialkoxysilanes ($r=0.91$) and the E_S^0 of the alkyls in the alkoxy-groups but not the σ^* of these substituents ($r=0.55$).[108] The dependence of the logarithm of the rate constant for the addition of the trichloromethyl group in chlorobenzene to triorganylvinylsilanes $Me_2RSiVin$ (R = n-, iso-, or t-alkyl) at 80 °C on the steric constants of the substituents R has been demonstrated graphically[109].

We shall now consider the principal features of the influence of the substituents which are of general importance for the structure–property relations involving organosilicon compounds.

The following equations have been used respectively:

*$\nu_i = \nu_0 + \rho^* \sum\sigma^* + a \sum(n_H + 0.4n_C)$;

**$\nu_i = \nu_0 + \rho^* \sum\sigma^* + aq$, where $q = 0-3$ is the number of silicon hydride bonds combined with the "indicator" Si–H bond;

***$J = J_0 + \rho^* \sum\sigma^* + \rho_1^* (\sigma_1^*\sigma_2^* + \sigma_2^*\sigma_3^* + \sigma_1^*\sigma_3^*)$.

III. SPECIFIC FEATURES OF THE EFFECTS OF SUBSTITUENTS AT THE SILICON ATOM

1. The Inductive Effect

The vast majority of the relations presented in Tables 1–3 demonstrate the exclusive influence of the inductive effect of the substituents. In this respect organosilicon compounds exhibit a much greater similarity to normal organic compounds than to organic derivatives of phosphorus. Indeed, the inductive Taft σ^* constants cannot be used for the ρ,σ analysis of organophosphorus compounds owing to the considerable resonance influence of many substituted alkyl groups. As a result, whereas the Kabachnik constants σ^f for unsubstituted alkyl groups are proportional to their σ^* constants, for substituted alkyls (and substituents capable of p_π–d_π conjugation with phosphorus), the constant σ^f reflects both the inductive (σ^f_I) and resonance (σ^r_R) influence of the substituent:

$$\sigma^f = \sigma^f_I + \sigma^f_R .$$

The resonance effect of the substituted alkyls in organophosphorus compounds (and in derivatives of other elements having d orbitals available for bonding[110]) has been explained by an intramolecular interaction, for example, of the following type[7]:

Such bonding is possible, in principle, also in silicon compounds; nevertheless its manifestation is not typical in this instance, which has been confirmed by numerous relations involving only the Taft σ^* constants for a wide variety of unsubstituted and substituted alkyl groups. The data for the "α-effect", which will be examined below, constitute an exception.

On the other hand, the relations for compounds with substituents capable of p_π–d_π interaction deviate as a rule from the relations based on the σ^* constants of other substituents (for further details, see below). At the same time, examples (Table 3, Nos.16, 20, and 21) of the dependence of certain properties solely on the inductive effect have been described in the literature for compounds with any substituents at the silicon atom. Relations Nos.20 and 21 have been most completely confirmed experimentally for the spin–spin coupling constants $J(^{29}SiH)$ for molecules of silicon hydrides on the basis of ^1H NMR data. These data are also consistent with theoretical ideas, according to which the extent of the short-range spin–spin interaction is determined mainly by the amount of s character of the corresponding bond[111]. The above relations are therefore suitable for the estimation of the inductive constants of any non-trivial substituents at the silicon atom, for which the literature values of the Taft constant are not available[77,112].

2. The Influence of the Steric Effect

The extreme rarity of the manifestation of the steric effect in reactions of organophosphorus compounds is most likely to be due to the fact that the most readily available derivatives containing the compact phosphoryl groups were used in most of the investigations. However, if the compound has three organic substituents at the phosphorus atom, their steric influence on the reactivity is in some cases fairly appreciable[7].

In contrast to organophosphorus compounds, compounds with three or even four organic substituents at the silicon atom have been frequently synthesised even more readily than their organic analogues. Therefore the majority of the reactions of organosilicon compounds investigated at the level of ρ,σ analysis have been carried out using derivatives with a strongly shielded silicon atom. The influence of the steric effect of substituents at the silicon atom on the reactivity of a wide variety of organosilicon compounds has been discussed very widely in the literature at a qualitative level. Certain generalisations in this field are described in Sommer's monograph[17].

The quantitative data presented in Table 1 demonstrate a significant manifestation of the steric influence of substituents in many reactions of compounds of the type R_3SiX and even R_2SiX_2 (R = organic substituent and X = functional group). Not a single case of correlations which do not take into account the steric effect has been described for compounds with tertiary substituents at the silicon atom. There are a few instances of such relations describing compounds with substituents having the isostructure (Table 1, Nos.6, 7, 16, 29, and 33). On the other hand, the data for some reactions of compounds with substituents having the normal structure were interpreted successfully solely in terms of an equation taking into account the steric effect (Table 1, Nos.5, 26 and 28).

The role of the steric effect diminishes as bulky substituents move further away from the reaction centre. Thus the logarithms of the equilibrium constants for the alcoholysis of trimethylacyloxysilanes $Me_3SiOCOR$, in which the substituent R is separated from the silicon atom by the group OC(O), are linearly related to the $\sigma^*_{R_i}$ for any R, including R = t-Bu (Table 1, No.20). In the remaining cases the correlations for reactions of triorganylsilanes with functional groups, which do not take into account the steric factor, are most likely to be because compounds with substituents whose steric effects differed little were used in the investigations rather than to the low value of the steric factor. This hypothesis is supported by the finding that the majority of the reactions in Table 1 are characterised by a weak inductive effect of the substituents (low values of the reaction constant ρ^* in the Taft equation), which is the reason for the increased importance of other effects, including the steric effects, taken into account by any multiple correlation.

As for a number of organic compounds, the reactions of organosilicon derivatives involving acid catalysis are characterised by a much weaker influence of the inductive effect and a much stronger influence of the steric effect of the substituents than the analogous processes under the influence of a basic catalyst. Thus, although the values of $\lg k_{rel}$ for the triethylamine-catalysed condensation of diorganylsilanediols in methanol are related to the values of $\sum \sigma^*$ of the diorganyl groups by a single-parameter equation with the reaction constant $\rho^* = 4.7$ (Table 1, No.25),[32] the equation proved to be unsuitable for the analogous reaction in the presence of HCl.[33]

The result of our treatment of the data of Dejak et al.[33] in terms of an equation taking into account both $\sum \sigma^*$ and $\sum E^c_s$ (Table 1, No.26) confirmed the hypothesis of Dejak et al.[33] concerning the decisive role of the steric factor in this reaction. The results of studies[8,10] of the kinetics of the acid and alkaline solvolysis respectively of triorganylsilanes with n-alkyl, fluoroalkyl, and cyanoalkyl substituents

were evaluated from the relation between $\lg k_i$ and $\sum \sigma_i^*$ (Table 1, Nos.1 and 4). The value of ρ^* for alkaline solvolysis (4.42) proved to be much higher than for acid solvolysis (0.77). However, in both cases there were appreciable deviations of the points corresponding to compounds with more bulky substituents. The experimental data[9] for the reactions indicated (without the corresponding results for compounds with fluoro- and cyano-alkyl groups, for which literature values of the steric constants are not available) were interpreted in terms of Eqn.(2), which takes into account both the inductive and steric effects of the substituents. As a result, the two-parameter correlation for the basic solvolysis made it possible to describe by a single relation a series of points differing appreciably from the theoretical values obtained with the aid of their inductive effects of the substituents alone (Table 1, No.5). Statistical treatment of the experimental data for the analogous acid solvolysis reaction showed that the rate of the process is almost wholly determined by the steric effect of the substituents (Table 1, No.2).[9]#

An analogous conclusion has been reached[20] for the hydrosilylation of hex-1-yne by triorganylsilanes (Table 1, No.14). However, in this study too a very narrow statistical selection was made (only six points were chosen for the calculation) and there are deviations of the points for Et_3SiH, Pr_3SiH, and $Me_2(Me_3CCH_2)SiH$ which cannot be accounted for by the proposed relation. Since instances of the dependence of the reaction rate exclusively on the steric effect of the substituents are extremely rare in correlation analysis, the above examples merit additional investigation.

3. The Influence of the Hyperconjugation Effect

Apparently owing to the abundance of different substituents containing C–H bonds at the silicon atom, many more data which can be interpreted as due to the manifestation of the hyperconjugation effect (in the given case σ,d conjugation) have been obtained for organosilicon compounds than for phosphorus derivatives. In particular, it is believed that, precisely because of the displacement of the electrons of the C–H bonds to the d orbitals of the silicon atom, the C–Si bond is unusually weakly polarised and is chemically inert[114]. The stabilisation of the C–Si bond by σ,d hyperconjugation has been confirmed by theoretical calculations[115,116].

Quantitative allowance for the hyperconjugation effect in the determination of the reactivity of organosilicon compounds has been based solely on kinetic data for the reactions of organylsilanes with methylphosphonic acid (Table 1, No.15). In order to establish a correlation, use was made of points for eight compounds having the general formula RMe_2SiH with n-, iso-, and s-substituents as well as R = cyclohexyl. The deviation of the point for the t-butyl derivative was explained by the "saturation of hyperconjugation", i.e. by a decrease of the sensitivity of the rate of reaction to a change in the number of α-C–H bonds with increase of the latter[21].

The authors[21] (Table 1, No.9) found that the points for the compounds R_3SiH (R = $PhCH_2$ or n-alkyl but not Me) and MeR_2SiH form two parallel lines on the $\lg k_i - \sum \sigma_i^*$ diagram. Their relative positions suggested an increased influence of the hyperconjugation effect for methyl derivatives. The facts that the Me_3SiCH_2 group ($\sigma^0 = -0.20$) is significantly more electropositive than the Me_2Si group ($\sigma^0 = 0.04$) [117] and that the Et_3SiCH_2 group is less electropositive than the Me_2SiCH_2 group ($\sigma^* = -0.13$ and -0.26 respectively) constitute very important arguments in support of the occurrence of hyperconjugation[118].

The interpretation of certain spectroscopic properties of organosilicon compounds also supports the hyperconjugation effect. Infrared spectroscopic data for organylsilicon hydrides are particularly characteristic. The values of ν_i(SiH) for compounds in the R_3SiH, R_2SiH_2, and $RSiH_3$ series (R = alkyl or substituted alkyl) form three parallel lines on the correlation diagram in terms of $\sum \sigma^*(R)$.[63,64] The authors explained this finding by the different contributions of the hyperconjugation effect depending on the number of alkyl substituents at the silicon atom. The individual correlations for a series of compounds with n- or iso-groups can apparently also be accounted for by the differences between the hyperconjugation components[65]. It has been shown[62] (Table 3, No.3) that the data for all the above organylsilicon hydrides can be described by a general relation taking into account the effect of hyperconjugation. However, we should note that, when there are substituents capable of $p_\pi - d_\pi$ interaction at the silicon atom ($R_nX_{3-n}SiH$, R = H, alkyl, or substituted alkyl, X = Cl, Ph, or Vin, and $n = 1$ or 2), the hyperconjugation effect is not exhibited (Table 3, Nos.6–10). This finding was explained by competition between the substituents R and X for the *d* orbitals of the silicon atom, as a result of which the stronger $p_\pi - d_\pi$ conjugation predominates[68].

There are also certain differences between the parameters of the correlations of the integral intensities of the Si–H bond absorption bands and the Taft constants for a series of compounds differing in the structure of the alkyl substituents at the silicon atom[65] or the number of Si–H bond in the molecule[69] (Table 3, Nos.14 and 15). Plots of $\Delta A_i^{0.5}$ against $\sum \sigma_p$ for the organylsilicon hydrides $R_nX_{3-n}SiH$ (R = alkyl, X = Cl, Ph, or XC_6H_4, and $n = 0$, 1, or 2) give rise to three lines with identical slopes for a series of compounds differing in the values of *n*. It is believed[65] that the distances between the lines for the X_3SiH series and the lines for RX_2SiH or R_2XSiH characterise the magnitude of the effect of the σ,d conjugation of one or two alkyl groups respectively with the silicon atom[71].

4. The Influence of the α-Effect

We shall now consider recent data concerning the α-effect in certain α-substituted alkylsilanes, mainly chloromethyl derivatives. In the majority of correlations of the properties of organosilicon compounds the influence of substituents of the type CH_nCl_{3-n} as well as other substituted alkyls is successfully taken into account by the usual σ^* constant. This applies to the reactivities[30,32–37,42] and ^1H NMR data for organylethoxysilanes[81] and organylmethylsilanes[79], the relative basicities of hexaorganyldisiloxanes, triorganylethoxysilanes[45], organyltriethoxysilanes, and organyltrimethoxysilanes[46], the infrared spectra (position[62] and intensity[69] of the absorption band due to the Si–H bond) of organylsilicon hydrides, and the NQR spectra of many organylchlorosilanes[88,91].

Later this relation was used to estimate the steric effects of certain non-trivial substituents at the silicon atom[113].

Furthermore, for a number of existing examples the apparent "anomaly" of the properties of compounds with α-chloroalkyl substituents, which has been usually attributed to the α-effect, has been either inadequately rigorously demonstrated or an alternative explanation is possible. Thus the unduly low reactivity, from the standpoint of relation No.1 (Table 1), of chloromethyldimethylsilane has been explained in a study of the acid hydrolysis of organylsilicon hydrides[8] by the presence of the resonance structure $^{+}ClCH_2=Si^{-}\leftrightharpoons$. However, it was found later[9] that the point for this compound does not deviate from the general relation taking into account the steric constants of the substituents (Table 1, No.2).

The relations between $\lg k_i$ and $\sum \sigma_i^*$ proposed[13,15] for the ozonisation and bromination reactions respectively do not describe a greater number of points than the number of points which deviate appreciably from them (the latter include the points for compounds with α-chloroalkyl substituents). The use of these relations for the construction of mathematical models of the corresponding processes is therefore problematical. Consequently the authors' conclusions[13,15] concerning the manifestation of the α-effect are not sufficiently well founded.

In the infrared spectra of organylsilicon hydrides with a chloromethyl group the absorption band due to the Si–H bond is frequently an unresolved doublet. The average value of ν(SiH) fits on the existing relations without deviations (Table 3, Nos.2–4). The presence of the doublet has been explained[119,120] by the equilibrium between the inner-complex (α-effect) and the usual forms of the molecules of the compounds indicated. However, this view has been criticised[121] and the phenomenon has been attributed to the presence of conformational isomers.

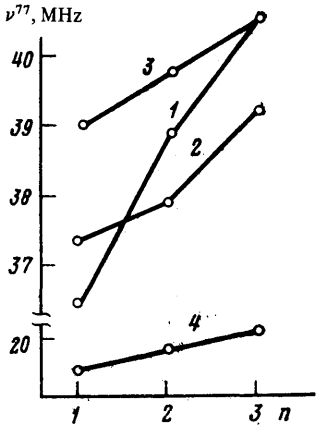

Figure 1. Relation between the ^{35}Cl NQR frequency (ν^{77}) for the molecules of the $ECl_3CCl_nH_{3-n}$ series (E = C or Si) and the number of chlorine atoms n: *1*) in the CCl_nH_{3-n} group with E = C; *2*) ditto with E = Si; *3*) in the CCl_3 group; *4*) in the $SiCl_3$ group[123].

The most extensive data on the properties of chloromethyl derivatives of silicon, attributed to the influence of the α-effect, have been obtained by NQR. As already mentioned above, the points for compounds with such substituents fit without deviations on the correlations between the values of ν_m^{77} and $\sum\sigma^*$ for the series of compounds RR'R"SiCl, where R is an organic substituent and R' and R" are organic substituents or Cl (Table 3, Nos.43–45), and for compounds $RR'R''SiCH_nCl_{3-n}$, where R, R', and R" are organic substituents, halogens, and alkoxy or siloxy-groups, and $n = 0$, 1, or 2 (Table 3, Nos.46–48). The following facts have been attributed to the manifestations of the α-effect. Despite the lower electronegativity of the silicon atom compared with the carbon atom, which presupposes lower Taft constants for substituents in compounds involving silicon, in the $R_3ECH_nCl_{3-n}$ series, where E = Si or C, the quantity ν_m^{77} for compounds with E = Si and low values of $\sum\sigma^*(R_3)$ is greater than in the case where M = C.[91,122–124]. Accordingly, of one begins with the relation between ν_m^{77} and σ* for the RCl series ($\nu_0 = 33.2$ and $\rho^* = 2.7$) [125], it is found that unusually high values of the σ* constant for the R_3SiCH_2 groups correspond to the experimental values of ν_m^{77} for the compounds R_3SiCH_2Cl. For example, $\sigma^* = 0.4$ has been calculated for the Me_3SiCH_2 group, in contrast to $\sigma^* = -0.26$ in handbooks. This phenomenon is characteristic precisely of α-derivatives, since the values of ν_m^{77} for the $R_3E(CH_2)_nCl$ series are higher in the case where E = Si only when $n = 1$ but not when $n = 0$, 2, or 3.[122]

The specific features of the NQR of chlorine in the Si–C–Cl group are clearly shown when the frequencies ν_m^{77} for compounds in the $CCl_3CCl_nH_{3-n}$ and $Cl_3SiCCl_nH_{3-n}$ series are compared (Fig.1). Whereas the frequencies for the chlorine atoms attached to the silicon in the $SiCl_3$ group are significantly lower than the corresponding frequencies $\nu_m^{77}(CCl_3)$ in the $CCl_3CCl_nH_{3-n}$ series (as might have been expected in view of the influence of the electropositive silicon), the frequencies for the groups $ECCl_nH_{3-n}$ with E = Si or C differ much less, which indicates the operation of the α-effect in the silicon-containing fragment[123]. The authors[123] also see the manifestation of the α-effect in the observation that the slope ρ* in the Taft equation for compounds of the R_3CCl series without silicon (1.02) is significantly higher than for the organosilicon series $RR'(X_3Si)CCl$ (0.42). However, this view can be contrasted with the finding that the values of ρ* found from the analogous relation for organic derivatives are higher than for organosilicon derivatives also in the R_3ECl series (E = C or Si) where the conditions for the manifestation of the α-effect do not exist.

Thus examination of all the data for the "unusual" properties of compounds with the Si–C–Cl group shows that the most convincing evidence has been obtained with the aid of NQR–in the form of increased NQR frequencies for organosilicon compounds compared with their carbon analogues. However, the interpretation of the findings as a manifestation of intramolecular coordination has aroused objections by Mel'nikova et al.[126] in this case also, although they do not propose any alternatives. They believe[126] that the interaction in the Si–C–Cl group within the complex can be exhibited only when other highly electronegative substituents are present at the silicon atom, while according to NQR data the greatest anomaly is shown for the region of low values of σ*.

In the study of correlations for other carbon-functional organosilicon compounds with Si–C–X groups, where X is an atom with an unshared electron pair, instances of deviations due to intramolecular coordination were still more infrequent.

Thus the "unusually" large value of $\Delta\nu(OH) = 318$ cm^{-1} in the infrared spectrum of a mixture of phenol with $(Me_3SiCH_2)_2O$, initially attributed to the influence of the α-effect[127], was later shown to be satisfactorily accounted for by the relation $\Delta\nu_i = 263 - 90\ \sum\sigma_i^*$ for ethers[44] using $\sigma^*\ (Me_3SiCH_2) = -0.26$.

The higher reactivity of $Me_3SiCH_2OSiMe_3$ ($k_{rel} = 0.15$) compared with $Me_3CCH_2OSiMe_3$ ($k_{rel} = 0.049$) in the ethylamine-catalysed methanolysis of compounds in the series $R(CH_2)_nOSiMe_3$ has been explained by the intramolecular interaction between the Si and O atoms in the Si–C–O group[24]. For analogous compounds with $n = 2$, 3, or 4, the reaction rates are approximately the same. However, since the rate of this reaction is influenced appreciably by the steric effect of the substituents R (Table 1, No.19), a final conclusion concerning the causes of the feature noted above can be reached only after taking into account the steric hindrance due to the Me_3SiCH_2 group, the steric constant of which has not been determined so far.

The dependence of the values of $\Delta\nu(OH)$ in the infrared spectra of complexes of phenol with trimethylalkoxysilanes on the inductive constants has been described[50] by a quadratic equation (Table 2, No.9). The points for compounds with bulky substituents (Me_3C and Me_3CCH_2) and also CH_2Cl deviate from this relation. The electronegativity of the chloromethyl group, which is apparently unusually low from the standpoint of this relation, has been explained by a "specific" redistribution of electron density in the Si–O–C–Cl group. However, if the interpretation is based on the usual linear relation (Table 2, No.10), which is statistically quite reliable ($r = 0.94$ when the point for the compound with the sterically bulky group CH_2CCl_3 is disregarded), then the result for Me_3SiOCH_2Cl no longer appears to be anomalous.

We shall consider finally the data for the characteristic features of the properties of compounds with the Si–C–N group. The basicity constants of *N*-substituted cyclic amines having the general formula $R\overline{N(CH_2)_{m-2}CH_2}$, where $m = 6$ [129,130], 5, or 7 [118], and R = organic substituent, or $R'_3Si(CH_2)_n$ ($n = 1$, 2, or 3 and R′ = alkyl) have been determined. Individual correlations $(pK_a)_i = (pK_a)_0 + \rho^*\sigma_i^*$ have been found for each heterocycle from data for organic derivatives (except for $R = Me_3CCH_2$, which deviates). The values $\sigma^*(Me_3SiCH_2) = -0.17 - -0.18$ calculated from these relations differ appreciably from the literature value $\sigma^* = -0.26$. The difference (which, however, is significantly smaller than that obtained on the basis of NQR data for the chloromethyl substituent—see above) was explained[130] by the manifestation of the α-effect in the Si–C–N group. This difference is not associated with the steric effect of the Me_3SiCH_2 group, because it is independent of the size of the heteroring of the amine, while the analogous difference for the neopentyl group increases with *m* and hence with enhancement of the steric hindrance in the molecule.

In contrast to these data, the basicity of $Me_3SiCH_2NR_2$ (R is an organic group) hardly differs from that calculated from the relation for organic amines R_3N, namely $(pK_a)_i = 7.86 + 2.7\ \sum\sigma^*$ using the usual value $\sigma^*(Me_3SiCH_2) = -0.26$.[57]

The data considered here show that the anomalies for compounds with the Si–C–X group, which have been reliably established from the standpoint of ρ,σ analysis and which can be attributed to the α-effect, have been observed only for a very small number of compounds, so that further studies in this field are of interest. Furthermore, the question why the resonance interaction is shown much more weakly and rarely for a series of substituted silicon alkyls than for the corresponding phosphorus derivatives still awaits an answer.

5. The Influence of the p_π–d_π Effect

Although the problem of the p_π–d_π interaction in organosilicon compounds has been actively discussed already for several decades[114,131–133], no general solution whereby a quantitative account could be taken of this effect have so far been proposed.

In organophosphorus compounds, the effect of the p_π–d_π interaction can be taken into account for a wide range of substituents with the aid of the resonance constants σ_R^f.[7] The method used by Mastryukova and Kabachnik[7] to find these constants is of general validity for the estimation of resonance contributions[1–3] and consists in the determination of the difference between the real value of the measured quantity and the value calculated on the assumption that only the inductive effect of the substituent operates. This approach involves a series of assumptions. In particular, it is assumed that the resonance effect is additive and the influence of other substituent effects (steric, hyperconjugation, etc.) is neglected. The corresponding correlation equation using the Taft constants and the resonance constants σ_R is

$$A = A_0 + \rho^*\sigma^* + \rho_R\sigma_R, \qquad (3)$$

where ρ_R is a proportionality coefficient taking into account the sensitivity of the given property to the resonance effect of the substituents; for the standard series, it is assumed that $\rho_R = 1$.

It is noteworthy that attempts have been frequently made to isolate by an analogous procedure the contribution of the resonance effect (due to the p_π–d_π interaction) of individual substituents in organosilicon compounds[13,36,41,134–136], but the results obtained did not lead to the derivation of universal organosilicon resonance constants. A critical analysis of these attempts is described below: at present we shall consider the problem of the applicability of the traditional approach to the estimation of the resonance effects of substituents at the silicon atom.

In the first place we shall attempt to test the validity of the additive rule. For this purpose, it is in principle sufficient to analyse data for the properties of a series of compounds with a variable number of certain identical substituents capable of p_π–d_π interaction, for example, a series of the type $Me_{3-n}X_nSiY$, where X is a substituent, Y is a functional group, and $n = 0$–3. For this series, the dependence of the property on the number *n* of substituents X is expressed by the equation

$$A_n = n\rho_n(\sigma^* + \sigma_R^{Si}), \qquad (4)$$

where σ_R^{Si} are the resonance constants of the substituents in the organosilicon compounds. Here the values of σ_R^{Si} were taken without correction for the slope ρ_R, because each of these microseries can be regarded as standard. Under the condition where the given property is not influenced by the effects of the substituent X and the CH_3 group, which were not taken into account in Eqn.(4), a linear relation between A_n and $_n$ implies that σ_R^{Si} remains constant regardless of the number of substituents X in the molecule.

Such linear relations have been obtained for the compounds $Me_{3-n}X_nSiH$ ($n = 0$–3, X = Ph, Cl, Br, NMe_2, C ≡ CH [137], or Vin [137,138]) from the values of ν(SiH) in the infrared spectra, for $Et_{3-n}X_nSiH$ ($n = 0$–3) with X = Ph from the relative ozonolysis rate constants[12] or with X = Vin from the solvolysis rate constants (95% EtOH) [138], for $Me_{3-n}Cl_n$·.SiOR ($n = 0$–3, R = Et or iso-Pr) [51] and $Me_{4-n}Si(OR)_n$ ($n = 1$–4, R = Me, Et, Pr, or iso-Pr) [139] from the Δν(OH) in

the infrared spectra of the complexes of these compounds with phenol, for $Me_{3-n}Cl_nSiVin$ ($n = 0-3$) from the relative rate constants for the addition of the $Cl_3C^\bullet$ radical [109], for $Me_{3-n}Cl_nSiCH_2C_6H_5$ ($n = 0-3$) from the relative chlorination rate constants[140], for $Et_{4-n}X_nSi$ ($n = 0-3$) with X = Cl [80,105] or Br [105] and for $Me_{3-n}Cl_nSiOEt$ ($n = 0-3$) [81] from the values of $\tau(CH_2)$ in ^1H NMR spectra, and for $Me_{3-n}X_nSiVin$ ($n = 0-3$, X = Cl, MeO, or Me_3SiO; $n = 0$, 1, or 2, X = Ph; $n = 0$, 2, or 3, X = OEt) from the relative rate constants for their reactions with thioacetic acid[42].

At the same time it has been found that there is no linear relation for compounds in the series $Me_{4-n}Si(OPh)_n$ ($n = 1-4$) on the basis of the $\Delta\nu$(OH) in the infrared spectra of their complexes with phenol[141], for $Me_{4-n}Si(OEt)_n$ ($n = 1-4$) on the basis of the values of $\tau(CH_2)$ and $\tau(CH_3)$ in the ^1H NMR spectra[81], for $Me_{3-n}F_nCH_2Ph$ ($n = 0-3$) on the basis of the relative rate constants for their chlorination[142], for $Et_{3-n}Cl_nSiH$ ($n = 0-3$) and $Pr_{3-n}(OEt)_nSiH$ ($n = 0-3$) on the basis of the rate constants for their addition to hex-1-ene[143], for $Me_{3-n}(Me_3SiO)_nSiH$ ($n = 0-3$) and $Pr_{3-n}\cdot(EtO)_nSiH$ ($n = 0-3$) on the basis of their solvolysis rate constants (95% EtOH) [144], and for $Me_{3-n}X_nSiH$ (X = F, MeO, or EtO), $Ph_{3-n}F_nSiH$, F_nSiH_{4-n} [137], and $Pr_{3-n}(EtO)_n\cdot SiH$ [143,144] ($n = 0-3$ throughout) on the basis of ν(SiH) in the infrared spectra.

The above list shows that almost all the substituents are capable of influencing additively the properties of the corresponding compounds. As regards the instances of a non-additive influence, one should bear in mind that the reactivity data did not take into account the steric influence of the substituents, which can distort the linear relation. In the remaining instances the absence of a linear relation is apparently caused by the non-additive influence of the electronic effects of the corresponding substituents (F and RO) when the latter accumulate in the molecule.

It would seem that these data permit the conclusion that Eqn.(3) is applicable at least to compounds with substituents which usually have an additive effect (Ph, Vin, Cl, and Br). However, there is an unexpected obstacle, which in fact has no analogies for compounds of other elements: in numerous instances the values of ρ^* in analogous correlations change on passing from the R_3SiY series to the $R_{3-n}X_nSiY$ series (X are substituents capable of p_π–d_π conjugation and R are other substituents). These cases are presented in Tables 2 and 3 (see Nos.2–4, 10–12, and 13–15 in Table 2 and 6–13 and 25–30 in Table 3). In view of the fundamental importance of this process, we shall consider the most typical results in greater detail.

Fig.2 presents the dependence of the chemical shifts of the methylene protons of the ethoxy-group on the values of $\sum\sigma^*$ for the remaining three substituents at the silicon atom in the molecules of organylethoxysilanes $R_{4-n}Si(OEt)_n$ (Table 3, Nos.28–30); the points for the $Me_{4-n}Si(OEt)_n$ series are indicated separately. Evidently the linear relation (4) for this series includes only points corresponding to $n = 2$, 3, or 4, but not $n = 1$. It is also seen that, owing to the difference between the slopes of the lines for the $R_{4-n}Si(OEt)_n$ series with $n = 1$, on the one hand, and for the series with $n = 2$ and 3, on the other, the distances between them are not constant. From the standpoint of the relation for the series of compounds with $n = 1$ (Table 3, No.28), the second and third ethoxy-groups therefore influence the chemical shift via the inductive effect, which formally diminishes on passing to the region of higher values of $\sum\sigma^*$. For example, the deviation calculated in terms of the σ^* scale from the above relation, caused by the influence of the excess ethoxy-group, is −0.43 for $Me_2Si(OEt)_2$ ($\sum\sigma^* = 1.37$) and −1.81 for $(Cl_3C)_2Si(OEt)_2$ ($\sum\sigma^* = 6.67$). Evidently, the difference between these values, each of which corresponds to the resonance effect of the ethoxy-group from the standpoint of Eqn.(3) is very considerable.

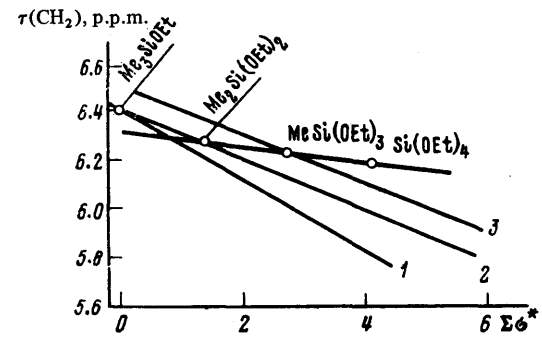

Figure 2. Dependence of the chemical shifts of the methylene protons of the ethoxy-group on the $\sum\sigma_i^*$ for the remaining three substituents at the silicon atom in the $R_{4-n}Si(OEt)_n$ molecules[81]: *1*) $n = 1$; *2*) $n = 2$; *3*) $n = 3$.

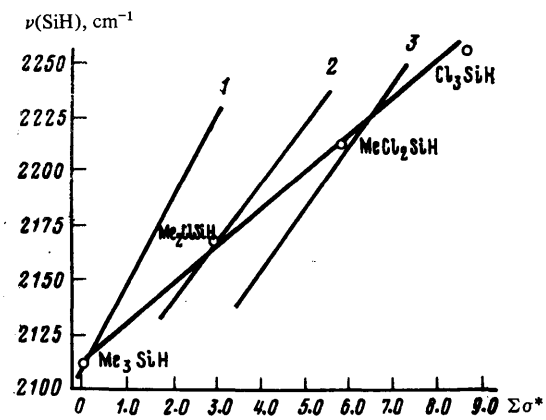

Figure 3. Dependence of ν(SiH) on σ_i^* for the substituents R_3 or $R_{3-n}Cl_n$ in the R_3SiH and $R_{3-n}Cl_nSiH$ molecules[68]: *1*) R_3SiH; *2*) R_2ClSiH; *3*) RCl_2SiH.

The individuality of the slopes of the straight lines corresponding to correlations for the series of compounds $R_{3-n}X_nSiH$ (Table 3, Nos.6–13), which differ in the type of substituent (X = Cl, Ph, or Vin), has been demonstrated[68] in relation to the dependence of the stretching vibration frequencies of the silicon hydride bond on the $\sum\sigma^*$ for the substituents at the silicon atom. An example of such relations for the case where X = Cl and their position on the graph relative to the regression line for the R_3SiH series (Table 3, No.2) are presented in Fig.3. Fig.3 also demonstrates the validity of Eqn.(4) for the $Me_nCl_{3-n}SiH$ microseries (when X = Ph or Vin, this relation also holds).

As in the previous instance, owing to the difference between the slopes of lines corresponding to the relations for R_3SiH and R_2XSiH, here the distances between the lines, caused by the influence of the substituent X, are not the same for the entire range of values of $\sum \sigma^*$.

Since the above study[68] is the only example hitherto where series of compounds with different substituents X have been investigated by a single method, it is of particular interest to analyse the nature of the variation of the slope of the relation between ρ^* and σ^* as a function of the nature of the substituent X. The data in Table 3 show that, when X = Ph or Vin, the quantity ρ^* is greater and, when X = Cl, it is smaller than in the correlation for the R_3SiH series. This corresponds formally to a decrease of the resonance influence of the substituents for X = Ph or Vin on ν(SiH) (i.e. the experimental values of ν_i approach those calculated from the relation for R_3SiH) and to an increase of the resonance influence of chlorine with increase of the values of $\sum\sigma^*(R_2X)$. Even if it is assumed that the change in the values of ρ^* is caused by the mutual influence of the inductive and resonance effects of the substituents in the molecules of R_2XSiH, it cannot therefore be taken into account by adding an additional term to the right-hand side of Eqn.(3). This is particularly true in view of the fact that, on further increase of the number of substituents X in the molecule, the slope no longer changes. Thus, so far one can only conclude that the coefficient ρ^* is specific to each substituent X; there are as yet insufficient data to formalise this phenomenon by a general correlation.

The results lead to the conclusion that in the general case the calculation of the constant σ_R^{Si} by Eqn.(3) is erroneous, because the calculated quantities are not constant for a specific substituent X and apparently do not reflect the true resonance contribution of the latter. A comparative estimate of random deviations (for different substituents X), corresponding to the quantity $\rho_R\sigma_R$ in Eqn.(3) [44,63,73,134–136,145–148], does not therefore appear to be sufficiently fruitful.

On the grounds that the values of ρ^* for the series of compounds $R_{3-n}X_nSiH$ with $n = 1$ or 2 and a constant X are virtually the same, the relations for the R_2XSiH series have been used as a basis for the estimation of the σ_R^{Si} and the deviations $\Delta\nu_i$ from these relations for compounds in the series RX_2SiH were attributed to the resonance influence of the second substituent X:

$$(\sigma_R^{Si}) = \Delta\nu_i/\rho_i^*.$$

The values of the resonance constant σ_R^{Si} found for the substituents X = Cl, Ph, and Vin were respectively −1.23, −0.51, and −0.50. The constants σ(Si), characterising the overall (effective) inductive effect of the substituents, were also calculated with the aid of the equation $\sigma^* + \sigma_R^{Si}$. Using the values of σ(Si) obtained [for substituents R which do not exhibit the resonance effect, $\sigma(Si) = \sigma^*$], the correlation parameters were calculated for the series of compounds $R_{3-n}X_nSiH$ with $n = 1$, 2, or 3 (Table 3, Nos. 11–13). The high accuracy of the correlations confirm the additivity of the resonance contribution of the substituents X independently of their number in the molecule. $\sigma_R^{Si}(OEt) = -1.06$ can be found analogously from the ^1H NMR data for the $R_2Si(OEt)_2$ and $RSi(OEt)_3$ series discussed above; $\sigma_R^{Si}(OMe) = -0.59 \pm 0.07$ has been found from data[11] for the methanolysis of the compounds $RSiH_2(OMe)$ and $RSiH(OMe)_2$. Other results suitable for estimates of this kind are so far not available in the literature.

It is seen from the preceding discussion that a fairly rigorous allowance for the p_π–d_π effect of the substituents at the silicon atom requires the use of extensive experimental data and is therefore difficult. Hence it is still useful to investigate the possibility of employing Eqn.(3), ignoring the possibility of a difference between the values of ρ^* for the R_3SiY and $R_{3-n}X_nSiY$ series, at least for an approximate comparative estimate of the extent of the p_π–d_π effects of different substituents. The only condition which ensures the possibility of applying the scale of approximate values of σ_R^{Si} obtained in this way is mutual proportionality of the influences of the p_π–d_π effect on any of the properties investigated. The validity of this condition makes it possible to use the slope ρ_R^* in Eqn.(3).

To test this claim, we shall consider the approximations obtained for the relative values of σ_R^{Si} [having assumed that $\sigma_R^{Si}(Cl) = 1$] in the case of the substituents Ph, Cl, or OEt, for which the greatest amount of factual data is available (Table 4). Table 4 shows that different research techniques manifest, as it were, a selective sensitivity to the influence of individual substituents, as a result of which a mutual proportionality of the changes in the resonance contribution does not obtain. Consequently the simplified approach to the establishment of a general relation proposed above is inapplicable. Hence it becomes clear why the values of σ_R^{Si} (or analogous quantities), frequently calculated in this way, have not been widely accepted.

Table 4. The relative values of σ_R^{Si} calculated by Eqn.(3) (for $\rho_R = 1$).

**Here R = OMe.

Thus, although the very fact of the deviation from the relation for the R_3SiY series caused by the introduction of the substituent X in $R_{3-n}X_nSiY$ can serve as an indication of the manifestation of the p_π–d_π effect of the above substituent, the magnitude of the deviation is an extremely arbitrary characteristic of the magnitude of this effect. Furthermore, the same characteristic is not constant owing to the lack of proportionality in terms of the scales of the deviations obtained by different methods and for different models. The causes of such a significant difference in the manifestations of the resonance effects of the substituents in silicon and phosphorus compounds still remain obscure.

IV. THE ABILITY OF THE SILICON ATOM AND OF SILICON-CONTAINING ATOMIC GROUPS TO TRANSMIT EFFECTS

The transmission coefficient z_N of a structural unit N is defined[1-3] as the decrease of the inductive influence of the substituents R when the latter move away from the indicator centre Y as a result of the introduction of this particular structural unit. The values of z_N are determined from the ratios of the corresponding slopes or Taft constants:

$$z_N = \rho^*_{R-N-Y}/\rho^*_{R-Y} = \sigma^*_{R-N}/\sigma^*_R .$$

The few literature values of the transmission coefficients of organosilicon structural units as well as the values which we calculated from the literature data (with the aid of the $\rho^*-\rho^*$ method) are presented in Table 5. Evidently the transmission capacity of the silicon atom (Table 5, Nos.1–3) is not constant for different compounds, in contrast to the transmission capacity of organic structural units. This indicates differences between the mechanisms of the transmission of the inductive influence of substituents via a silicon atom. Presumably this is caused by the different extents of the $p_\pi-d_\pi$ interaction in different series. The unusually high transmission coefficient of the $SiCH_2$ group (Table 5, No.4) has been attributed[57] to an additional (apart from the σ-bond) interaction of the silicon and nitrogen atom. The coefficient $z_{OSi(Me_2)} = 0.15-0.26$ (Table 5, Nos.5 and 6) is entirely comparable to the transmission coefficient of the C–O bond ($z_{C-O} = 0.26-0.34$);[1] thus the abilities of the Si–O and C–O bonds to transmit the inductive effects of substituents are approximately the same.

Table 5. The transmission coefficients of the silicon atom and silicon-containing structural units.

**The data for the RCl and R_3CCl series ($\rho^* = 1.02$) yielded $z_C = 0.37$, which is consistent with the literature value $z_{CH_2} = 0.36$.[125]

It is of interest to estimate the transmission capacity of the silicon atom compared with those of other elements in isostructural compounds. If the ρ^*/ρ^* method is used in this instance, it is possible to obtain a quantitative expression for the above estimate in the form of an "isostructural" transmission coefficient, which we shall designate by z':

$$z' = \rho^*(Si)/\rho^*(E),$$

where $\rho^*(Si)$ is the slope for the organosilicon series and $\rho^*(E)$ is the corresponding slope for the isostructural series in which silicon has been substituted by the element E. The values of z' calculated from the literature data are listed in Table 6.

Since the silicon atom is less electronegative than the carbon atom, its isostructural substituents should have a smaller inductive effect, which is reflected also in the values of z' for the silicon–carbon pair, the latter being always less than unity. However, a universal value of z' is also not observed, as for the coefficient $z(Si)$ discussed above. The inconstancy of the z' for compounds in which silicon is linked to a substituent capable of $p_\pi-d_\pi$ interaction (Table 6, Nos.1–3 and 7–9) apparently reflects the different degrees of manifestation of the resonance effect and for the series of compounds Nos.4–6 the different influences of the α-effect. It is of interest that a value $z' < 1$ has been obtained also for the Si/Ge pair (No.10), in which the germanium atom is less capable of $p_\pi-d_\pi$ bonding than the silicon atom despite being still less electronegative.

**The constants σ_i were used by Knižek et al.[74] to calculate ρ^* (M, Si).

We may note finally the instances of the changes in the transition capacity of the silicon atom on passing from compounds R_3SiY to compounds $R_{3-n}X_nSiY$, partly discussed above. As already mentioned, the slope ρ^*, characterising the relative ability of the silicon atom to transmit the inductive effect of the substituents to the indicator centre, can both decrease and increase after the introduction of different substituents. However, for highly electronegative substituents (RO, Cl), capable of effective $p_\pi-d_\pi$ conjugation with the silicon atom, the values of ρ^* for the compounds $R_{3-n}X_nSiY$ are as a rule smaller than for R_3SiX and tend to decrease further with increase of n (Nos.2–4 and 13–15 in Table 2, and 2, 6, 9, and 25–30 in Table 3). It has been suggested[45] that the decrease of the sensitivity of the indicator centre to the influence of the inductive effect of substituents with increase of the number of substituents X in the molecule is caused by the increase of the degree of $p_\pi-d_\pi$ bonding under these conditions.

* * *

Thus the results of the application of the Taft relations in order to establish correlations between the properties of organosilicon compounds and their structure demonstrates the applicability of the usual inductive (for alkyl and substituted alkyl groups) and steric constants of the substituents. In contrast to organophosphorus compounds,

substituted alkyl groups at the silicon atom do not exhibit a resonance effect with the exception of individual instances in α-substituted derivatives. The role of the hyperconjugation effect in silicon compounds has been only slightly investigated. The most specific feature of organosilicon compounds is p_π–d_π conjugation, the extent of which cannot in general be estimated with the aid of procedures usually employed in the calculation of resonance contributions. A preliminary estimate of the transmission coefficient of the silicon atom and silicon-containing groups showed that their ability to transmit the inductive effect of substituents is reduced compared with carbon (and germanium).

Organic Syntheses Based on Carbon Dioxide

A.L.Lapidus and Yang Yung Ping

Organic syntheses based on carbon dioxide are examined. Together with syntheses of organic compounds, certain aspects of the mechanism of the coordination of CO_2 to transition metal complexes are considered. The review includes studies published up to 1977.
The bibliography includes 171 references.

CONTENTS

I. Introduction 63
II. Some aspects of the mechanism of the fixation of CO_2 by transition metal complexes 63
III. The reactions of CO_2 with organic compounds 66
IV. Industrial processes with participation of CO_2 73

I. INTRODUCTION

The use of carbon dioxide as the starting material for organic syntheses constitutes one of the most important problems of modern organic chemistry. There has been a recent growth of interest in the chemistry of carbon dioxide, the reserves of which in nature are practically inexhaustible. The most promising of the natural sources of carbon dioxide are coal and carbonates. The interest in the chemistry of carbon dioxide is to a large extent associated with the latest advances in metal complex catalysis, which permits the activation of the CO_2 molecule. The advances in this field permit the hope for a successful achievement of catalytic syntheses on the basis of CO_2.

In recent years there has been a sharp increase of the amount of CO_2 released into the atmosphere by engines, industry, and electric power stations. The average increase of the CO_2 content in the Earth's atmosphere as a result of the combustion of fuels is 0.2% per annum, which is extremely undesirable from the ecological point of view[1].

In view of the rapid depletion of the reserves of petroleum and the development of coal-chemical industries, the synthesis of compounds of practical importance based on CO_2 has also become important. On the basis of carbon dioxide derived from coal, it is possible to synthesise products which are nowadays manufactured using petroleum as the raw material; this makes it timely to develop effective methods for the synthesis of important organic compounds from CO_2.

This review deals with the principal literature data published in 1971–1977 and concerning the syntheses of organic compounds with participation of CO_2 (electrochemical and photochemical processes are not included).

II. SOME ASPECTS OF THE MECHANISM OF THE FIXATION OF CO_2 BY TRANSITION METAL COMPLEXES

1. Coordination to Transition Metal Complexes

Carbon dioxide is the highest oxide of carbon, which is much more reactive than nitrogen. The CO_2 molecule has a linear structure with an ionisation potential of 13.7 eV and an electron affinity of 3.8 eV.

The bond between CO_2 and the metal in complexes can be formed in principle via the following mechanisms:

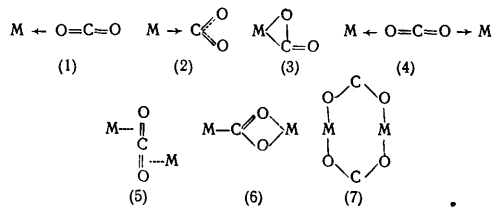

Table 1. Parameters of the infrared spectra of transition metal complexes of CO_2.

Complex	ν_{CO_2}, cm^{-1}	References
$Rh_2(CO_2)(CO)_2(PPh_3)_3$	1498,1368,813	2,3

Evidently CO_2 interacts with the metal as an electron acceptor or as a powerful nucleophile via the carbon atom. The M–O bond formed via schemes (1) and (4) is less likely; the bond is most probably formed either via the carbon atom with transfer to the latter of electrons from the metal and the formation of organometallic compounds—derivatives of metal-carboxylates [scheme (2)]—or via a mechanism involving the formation of a π-complex with participation of the C=O double bond [schemes (5), (6), and (7)]. There are at present no data confirming unambiguously a particular structure. Some information is provided by the infrared spectra of transition metal complexes of CO_2, which are presented in Table 1. With

the exception of the complex $Rh_2(CO_2)(CO)(PPh_3)_3$, synthesised by oxidising with oxygen the compound $Rh_2(CO)_4(PPh_3)_3$, and also $Cu(CO_3)(PPh_3)_4$, all the complexes presented in Table 1 have been obtained by the direct interaction of the metal compounds with CO_2.

The presence of CO_2 in the rhodium complex obtained by passing CO_2 into a solution of triphenylphosphinerhodium chloride and containing one CO_2 molecule for two rhodium atoms has been confirmed by the isolation of carbon dioxide on heating, on reduction with $LiAlH_4$ with formation of methanol, and on quantitative substitution of CO_2 by carbon monoxide[17,18]. The alkylation reaction was used to detect the metal–carbon bond in this complex. If the complex contains only the metal–oxygen bond, alkylation should lead to the formation of a carbonate ester. On the other hand, if the complex is constructed in such a way that it contains a CO_2 fragment linked to the metal via the carbon atom, alkylation may be expected to lead to the formation of a derivative of an alkanecarboxylic acid. It was found that, when the rhodium complex is acted upon by methyl iodide, methyl acetate is formed. These data are satisfactorily consistent with structure (6) containing the fragment Rh–COO–Rh.

Pure gaseous carbon dioxide gives rise to two characteristic absorption bands in the infrared spectrum in the region of 2349 and 667 cm^{-1}. The appearance of three new absorption bands in the spectrum of the complex $Rh_2(CO_2)(CO)_2 \cdot (PPh_3)_3$ in the region of 1498, 1368, and 813 cm^{-1} is treated as a result of the coordination of CO_2 to the central metal atom and of the simultaneous formation of a bent configuration of the CO_2 molecule of type (II) and (III). Such a complex has also been obtained by the interaction of $Rh_2(CO)_4 \cdot (PPh_3)_4$ with $^{18}O_2$.[2] A polynuclear complex containing CO_2 gives rise to a single absorption band in the region of 1735 cm^{-1}, corresponding to the CO_2 group. This group is capable of coordinating with two nickel atoms with formation of a π-bond in a type (5) structure[9]. However, structure (6) has been attributed to the polynuclear rhodium complex of CO_2, which has a characteristic absorption band in the region of 1630 cm^{-1}; on interaction with methyl iodide, it gives rise to methyl acetate[4].

X-Ray diffraction analysis of the complex $Ni(CO_2)(PPh_3)_2$ confirmed the planar structure corresponding to the type (3) bond with the bent configuration of the CO_2 coordinated to the nickel atom[10]:

These data concerning the formation and properties of transition metal complexes containing CO_2 lead to ways of seeking new synthetic and catalytic reactions. The presence of CO_2 in the complexes as a ligand can be inferred from the evolution of CO_2 on heating the complexes or on treating them with acids and also from the displacement of CO_2 by carbon monoxide. The complex $Pt(CO_2)(PPh_3)_2$ has been obtained[4] from $Pt(PPh_3)_3$ and CO_2. In the presence of oxygen this reaction proceeds with formation of a platinum carbonate complex[19]:

$$Pt(PPh_3)_3 + O_2 + CO_2 \rightarrow Pt(CO_3)(PPh_3)_2 + PhPO \ .$$

Subsequently the platinum carbonate complex was obtained[19] by the reaction of $PtO_2(PPh_3)_2$, synthesised beforehand, with CO_2; in this case the CO_2 molecule is inserted in the metal–oxygen bond. The fixation of CO_2 in the complex $Mo(C_2H_4) \cdot (dpe)_2$ (where dpe = $Ph_2PCH_2CH_2PPh_2$) was achieved at room temperature[20] under the influence of u.v. radiation with formation of the molybdenum complex *cis*-$Mo(CO_2)(dpe)_2$ in boiling toluene. The authors explained the formation of the molybdenum carbonyl complex by the rupture of one C–O bond with the simultaneous oxidation of diphenylethane. The complex $Mo(CO_2)_2(PMe_2Ph)_2$ is unstable and, when an attempt is made to recrystallise it from tetrahydrofuran (THF), it is readily converted into the dinuclear complex $(PMe_2Ph)_3(CO) \cdot Mo(CO_3)_2Mo(CO)(PMe_2Ph)_3$. It has been suggested[15] that CO_2 is then reduced to CO_3^{2-} via the mechanism

$$2CO_2 + 2e \rightarrow CO_3^{2-} \ .$$

The analogous reactions involving the formation of carbonyl complexes from CO_2 and transition metal complexes have been described[20–23]. The following four most characteristic types of reaction can be distinguished among them:

$$(C_5H_5)(PPh_3)NiBr + Mg \rightarrow (C_5H_5)(PPh_3)NiMgBr \xrightarrow[MgBr_2]{CO_2} [(C_5H_5)(PPh_3)NiCOOMgBr] \rightarrow$$
$$\rightarrow [(C_5H_5)(PPh_3)NiCOOMgBr] \rightarrow [(C_5H_5)(PPh_3)NiCO^+] \rightarrow (PPh_3)_2Ni(CO)_2 \ ;$$

$$(C_5H_5)_2MoH_2 + AlMe_3 \rightarrow [Mo_2{-}Al_3 \text{ polynuclear complex }] \xrightarrow{CO_2+H_2O} [(C_5H_5)_2Mo(CO)Br]^+ \ ;$$

$$RhCl(PPh_3)_3 + CO_2 \xrightarrow{HSi(OEt)_3} [RhH\{Si(OEt)_3\}Cl(PPh_3)_2] \rightarrow RhCl(CO)(PPh_3)_2 \ ;$$

$$RuCl_2(PPh_3)_3 + CO_2 \xrightarrow{HSi(OEt)_3} RuCl_2(CO_2)(PPh_3)_2 \ .$$

The opposite case, involving the interaction of CO_2 with the triphenylphosphine complex of copper and formation of the copper carbonate complex, has also been described in the literature[16]:

$$iso\text{-}BuCu(PPh_3)_2 + 2CO_2 \xrightarrow[0.5\ h;\ -40\ ^\circ C]{THF}$$
$$iso\text{-}BuCCu(CO_2)(PPh_3)_2 \xrightarrow[6\ h;\ 0\ ^\circ C]{CO_2} Cu_2(CO_3)(PPh_3)_4 \ .$$
$$\|O$$

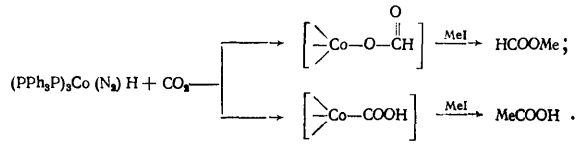
The reaction proceeds via a stage in which an acyl complex is formed and, when carbon dioxide is passed into its solution for a long time, is converted into a crystalline copper carbonate complex. When this complex interacts with hydrochloric or sulphuric acid solutions, CO_2 is evolved in molar proportions of 1 : 2 in relation to copper.

2. CO_2 Insertion Reactions

In order to synthesise various organic compounds, it is necessary that the carbon dioxide activated by coordination to transition metal complexes should form a new substrate via insertion in the M–H, M–C, M–O, or M–N bonds. Such insertion can be regarded as nucleophilic attack on the carbon atom in the CO_2 molecule which proceeds via two possible pathways:

(1) normal insertion with formation of the M–O bond and the formate:

$$M^{\delta+}-L^{\delta-} + O^{\delta-}\equiv C^{\delta+}=O \rightarrow M-O-\overset{O}{\overset{\|}{C}}-L \ ;$$

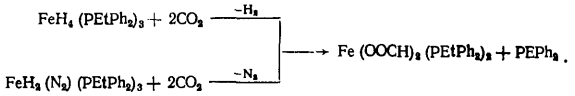


(2) anomalous insertion with formation of compounds with a metal–carbon bond—metal-carboxylates:

$$M^{\delta-}-L^{\delta+} + O^{\delta-}\equiv C^{\delta+}=\dot{O} \rightarrow M-\overset{O}{\overset{\|}{C}}-O-L;$$
$$L=H,\ C,\ O,\ N \quad etc.$$

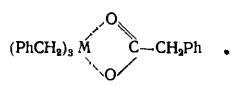
The anomalous insertion of CO_2 in the M–L bond is encountered extremely rarely.

Reactions involving insertion in the M–H and M–C bonds have been examined in detail in another review[17] and we shall therefore deal with them extremely briefly.



(a) *The insertion of CO_2 in the M–H bond.* The reaction of CO_2 with a nitrogen-containing cobalt hydride complex and subsequent methylation of the reaction products by methyl iodide lead to both methyl formate—the product of the normal insertion of CO_2 in the M–H bond[24,25]—and to acetic acid and methyl acetate—the products of the anomalous insertion of CO_2:[18]

The reaction proceeds via a stage in which a cobalt formate complex is formed, which also happens when CO_2 interacts with $CoH_3(PPh_3)_3$.



On interaction with CO_2 at room temperature, ruthenium and rhodium hydride complexes[26–28] give rise to a formate complex with a single hydride atom, in contrast to the formate complex, formed on pyrolysis or on interaction with PPh_3, N_2, H_2, CO, CS_2, HHal, and RHal, which readily splits off CO_2.

Iron hydride complexes in the crystalline state or in solution readily interact with CO_2 under the influence of light to form an iron diformate complex[29]:

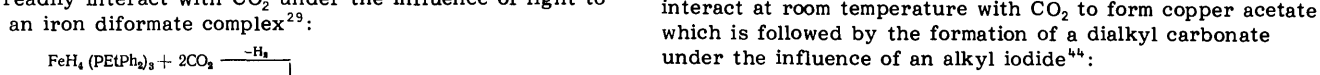
In contrast to the insertion of CO_2 in the Ru–H bond, this reaction is irreversible; when the resulting complex interacts with methyl iodide, ethyl formate is formed.

(b) *The insertion of CO_2 in the M–C bond.* Various organic compounds with functional groups can be obtained by the insertion of CO_2 in the M–C bond. Organometallic complexes having the general formula $M(CH_2Ph)_4$ (where M = Ti or Zn) effectively absorb CO_2 in solution in the molar proportions 1 : 2 and subsequent hydrolysis of the resulting substrate leads to the formation of phenylacetic acid and triphenylmethanol[30], which indicates a normal mechanism of the insertion of CO_2 in the M–C bond with formation of a cyclic complex:

Similarly, the interaction of dimethyltitanocene with CO_2 results in the formation of a stable titanocenium acetate, the reaction of which with methanol yields methyl acetate[31]. The formation of the above cyclic metal-containing structure has been confirmed spectroscopically[32].

The reaction of CO_2 with an organometallic cobalt compound containing the ethyl group proceeds via both pathways with formation of cobalt propionate (normal insertion) and a metal-carboxylate ester (anomalous insertion) as insertion products[18,33]. A carboxylate complex of cobalt is formed when propionic acid acts on the complex $LCO(CO_3)COOEt$. When the carbonate complex is treated with methyl iodide, methyl propionate and a small amount of methyl formate are formed[18].

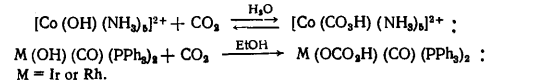
The intermediate complex containing the COOEt group [ν(CO) = 1713 cm^{-1}] is formed from the iridium[34], cobalt[35], ruthenium, and osmium complexes in the presence of alcohol and carbon monoxide[36]. The insertion of CO_2 in the Rh–C bond in a phenylrhodium complex proceeds via the normal pathway[37]:



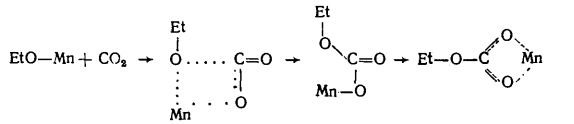
A triphenylphosphinealkylcopper complex readily interacts with CO_2 at room temperature via the anomalous insertion pathway (involving the Cu–C bond) to form unstable metal carboxylate complexes and copper carbonates[13,14,38]:

The initial alkyl complex of copper is used as the catalyst in the synthesis of nitroalkanecarboxylic acid from CO_2 and a nitroalkane[38]. The reaction with the cyanomethyl complex of copper proceeds via the normal pathway involving the insertion of CO_2 in the Cu–C bond with formation of a copper cyanoacetate complex[39], which can be used to synthesise carboxylic acids from acetylenic hydrocarbons at atmospheric pressure[40]. There are data concerning the insertion of carbon dioxide in benzyl–titanium or benzyl–zirconium[41], methyl–titanium[7,42], and Pd–C [43] bonds.

(2) *The insertion of CO_2 in the M–O bond.* Transition metal alkoxides and hydroxides interact with CO_2 via insertion in the M–O bond (normal insertion). Copper alkoxides interact at room temperature with CO_2 to form copper acetate, which is followed by the formation of a dialkyl carbonate under the influence of an alkyl iodide[44]:



The presence of absorption bands in the region of 1665 and 1305 cm^{-1} in the infrared spectrum of the copper acetate complex and the formation of an asymmetric dialkyl carbonate on interaction with RI confirm the normal insertion of CO_2 in the Cu–O bond[44]. In benzene solution the analogous copper compound reacts with CO_2 to form an alkyl carbonate complex[45]:



The normal insertion of CO_2 in the M–C bonds is observed also for $Ti(OBu)_4$, $Zr(OBu)_4$, $Fe(OEt)_3$, $Nb(OEt)_3$, and $Zr(OEt)_4$.[46] All these reactions proceed via the mechanism

The reactions with zinc[47], mercury[48], and tin[49,50] compounds proceed via an analogous mechanism involving the insertion of CO_2 in the M–O bond. The hydroxo-complexes of cobalt and other transition metals also react with insertion of CO_2 in the M–O bond and the formation of carbonate complexes[51,52]:

The reaction with the hydroxocobalt complex proceeds in an aqueous medium and the reactions with the hydroxo-complexes of iridium and rhodium take place in alcohol. In the presence of alcohol *in vacuo* alkoxomanganese reacts with CO_2 in the vapour phase to form a complex with an Mn–O bond[53]:

(d) *The insertion of CO_2 in the M–N bond.* Reactions involving the insertion of CO_2 in the M–N bond also proceed via the normal pathway in accordance with the mechanism[54–60]

$$M(NMe_2)_n + n\,CO_2 \rightarrow M(O_2CNMe_2)_n;$$
$$M = Ti, Zr, V, \text{or } Mo\ (n=4);\ Nb \text{ or } Ta\ (n=5);\ Mo \text{ or } W\ (n=3).$$

The group $\rangle C{=}O$, of a metal carbamate complex, readily exchanges for $^{13}CO_2$, forming a labelled compound detectable by NMR:[58]

$$ML_n^* + x^{12}CO_2 \rightleftarrows ML_mL^*_{n-m} + m^{12}CO_2 + (x-m)^{13}CO_2;$$
$$L = O_2^{12}CNMe;\ L^* = O_2^{13}CNMe.$$

The activation energy for the exchange reaction of the zirconium complex is 44 ± 8 kJ mol^{-1} and that for the tungsten complex is about 96 kJ mol^{-1}. When the *N,N'*-ethylenebis-(salicylideneiminato)cobalt(II) complex is reduced with sodium, the product is a mixed $NaCo^I$ complex, which readily reacts with CO_2 to form Co–C(O)–ONa.[61] The use of the latter as the catalyst can lead to new possibilities for the synthesis of different functional compounds. Aluminium[62], boron[63], silicon[64], germanium[6], tin[65,68], phosphorus[65], arsenic[67], and zinc[69] amide compounds also react with CO_2, forming carbamide complexes (via the normal insertion pathway).

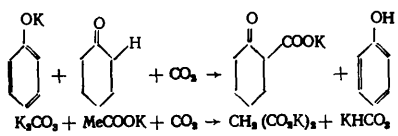
III. THE REACTIONS OF CO_2 WITH ORGANIC COMPOUNDS

1. The Addition of CO_2 to Carbanions

It is known that, when organomagnesium compounds are acted upon by CO_2, carboxylic acids are formed[70]:

$$RMgX + CO_2 \rightarrow RCOOMgX \xrightarrow{H_2O} RCOOH.$$

However, the reaction of CO_2 with dimethoxymagnesium proceeds with formation of methanol[73]:

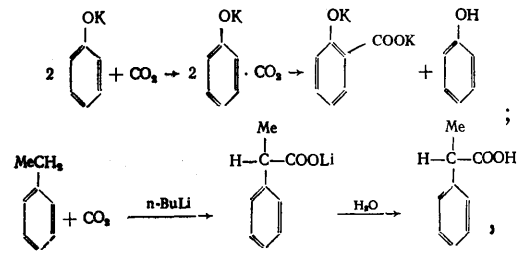


$$Mg(OMe)_2 + NO_2Me + CO_2 \rightarrow NO_2CHCOOMg + 2MeOH$$

or

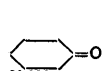
$$Mg(OMe)_2 + CO_2 \rightleftarrows MeOMgOCOOMe;$$
$$MeOMgOCOOMe + NO_2Me \rightleftarrows NO_2CHMg + 2MeOH.$$

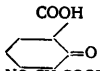
Ethylene and propene react with CO_2 in the presence of EtMgBr [71] and $Sn(OCH_2CH_2NMe_2)_2$ to form ethylene and propylene carbonates respectively in quantitative yields at 100 °C and a CO_2 pressure of 5–9 atm.

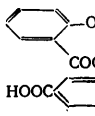


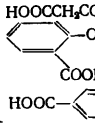
The carboxylation of cyclohexanone[74] and an acetate salt[75] proceeds differently—via the substitution of mobile hydrogen atoms in the molecule:

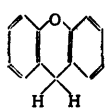
$$K_2CO_3 + MeCOOK + CO_2 \rightarrow CH_2(CO_2K)_2 + KHCO_3.$$











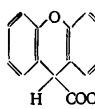


Table 2 presents data for the carboxylation of various organic compounds with a mobile hydrogen atom in the α-position in the presence of potassium carbonate and THF.[76] The data presented show that the yields of the reaction products per unit time depend on the basicity of the initial reactant.

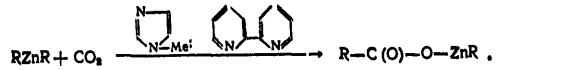
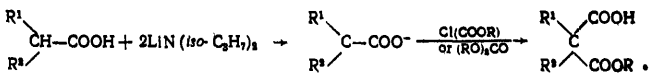
The Kolbe–Schmidt reaction, occurring as a consequence of π-electron transfer from the aromatic ring to CO_2,[77] which has found industrial applications, and the carboxylation of ethylbenzene[78],



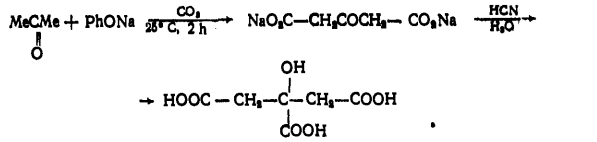
constitute prototypes of the reactions presented above. They can be regarded as nucleophilic interaction of a carbanion, with a characteristic relation between the reactivity and electronegativity of the initial reactants.

Table 2. Carboxylation of organic compounds in the presence of K_2CO_3.[76]

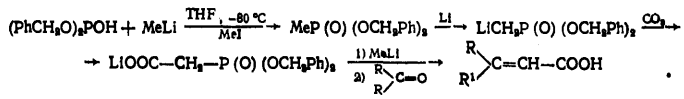


Initial reactant	pK_a	t, °C	p_{CO_2}, atm	τ, h	Reaction products	Yield, %
	<15	room	1	2		40
$MeNO_2$	11	room	1	2	NO_2CH_2COOH	25
$EtNO_2$	9	room	1	2	$NO_2C(COOH)HMe$	15
$PrNO_2$	—	room	1	2	$NO_2C(COOH)HEt$	10
$MeC(NO_2)HMe$	9	room	1	2	$MeC(COOH)(NO_2)Me$	0
MeCN	25	70	2	45	$CNCH_2COOH$	1
	—	70	2	—		0.3 0.3
MeCOMe	20	room	1	11	$MeCOCH_2COOH$ $HOOCCH_2COCH_2COOH$	7 7
MeCOOMe	24	70	2	72	$HOOCCH_2COOMe$ 	10 1 1
	29	95	1	4		10 20
MeCOCOOMe	0	—	1	1	$(CH_2COCOOMe)_2$ $C(COOH)H_2COCOOMe$	33 15

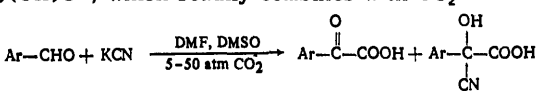
According to Pauling's data[1], alkyl derivatives of metals (R_xM) with an electronegativity less than 1.5 interact with carbon dioxide, but when the electronegativity is greater than 1.5, they do not react. Thus trialkylaluminium (the electronegativity of aluminium is 1.5) readily interacts with CO_2, while dialkylzinc (the electronegativity of zinc is 1.6)



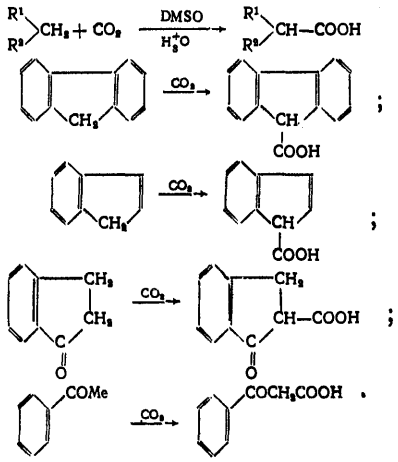
does not react with CO_2 at room temperature at atmospheric temperature[79,80]. Only the introduction of tertiary amines of the type of methylimidazole or pyridine into the reaction medium increases the reactivity of the initial reactant[81]:



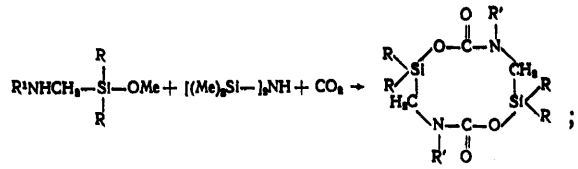
The synthesis of acids with the iso-structure, which are derivatives of malonic acid (yield 46–80%), proceeds via a carbanionic mechanism[82]:



Citric acid has been obtained from acetone and CO_2 in solution in diglyme[83]:



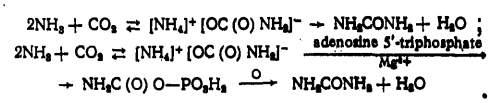
Butadiene reacts with CO_2 in a solution of sodium phenoxide in dimethylformamide (DMF) at 50 °C with formation of muconic acid (yield 81%).[84] By analogy with the Wittig–Horner vinylcarboxylation reaction, α,β-unsaturated carboxylic acids have been obtained from dibenzyl phosphate and CO_2 in the presence of Me_3Li and MeI at −80 °C:[85]



When an aldehyde reacts with potassium cyanide in DMF or dimethyl sulphoxide (DMSO), the product is the carbanion $R(CN)(OH)C^-$, which readily combines with CO_2:[86]

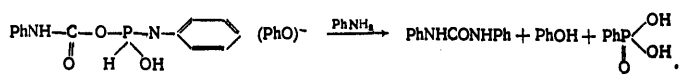
The possibility of synthesising carboxylic acids and their derivatives in yields of 30–80% by the carboxylation of a ketone and hydrocarbons with a mobile hydrogen atom had been demonstrated[86,87]:

The carboxylation of organosilicon compounds proceeds via a carbanionic mechanism[88]:



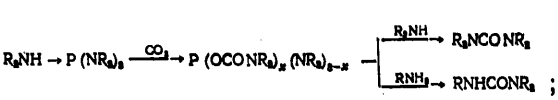
R=Me; MeO; R'=H, CH_2=$CHCH_2^-$, Me_2CH–CH_2^-, or n-Bu.

Organic compounds with a weak acidity and tending to be metallated with subsequent formation of a carbanion enter into the above reactions; the nucleophilic attack by this carbanion on CO_2 leads to the formation of carboxylic acids or their derivatives via the mechanism



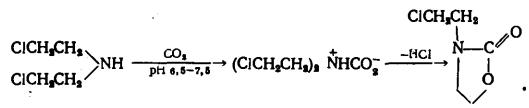
2. Reactions of CO_2 with Nitrogen-Containing Compounds

Urea, which is of practical importance, is obtained by the reaction of carbon dioxide with ammonia at 200–300 °C under pressure[89–91]:



We may note that in the living organism urea is continuously biosynthesised, leading to the fixation of ammonia, which is harmful to the organism.

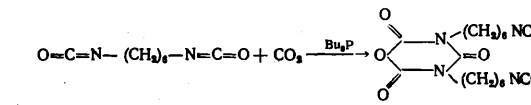
The synthesis of urea derivatives from an amine and CO_2 at atmospheric pressure in a quantitative yield was achieved for the first time by Yamazaki[92]. When CO_2 was passed into a solution of $(PhO)_2POH$ and $PhNH_2$ in pyridine for 4 h (at 40 °C), *N,N'*-diphenylurea was formed in 85% yield, while in THF the yield was 93%:



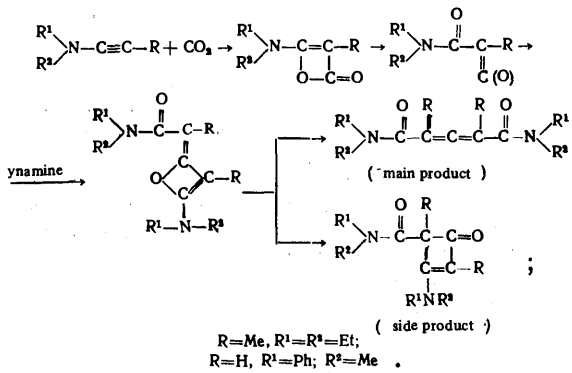
When carbon dioxide is replaced in this reaction by carbon disulphide, the product is PhNHCSNHPh (yiled 100%). These reactions can be used to synthesise polyureas or polythioureas[93].

Primary or secondary amines react with CO_2 in the presence of PCl_3 and pyridine at 60 °C with formation of symmetrical disubstituted ureas[94]:

Under analogous conditions, aromatic amines react with CO_2 in the presence of $PhOPCl_2$ in pyridine to form polyureas[95].



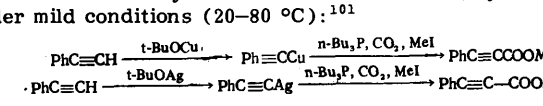
3-(2-Chloroethyl)-2-oxazolidinone has been obtained from CO_2 and di(2-chloroethyl)amine in the presence of 0.6 mole of sodium bicarbonate at 31 °C:[96,97]



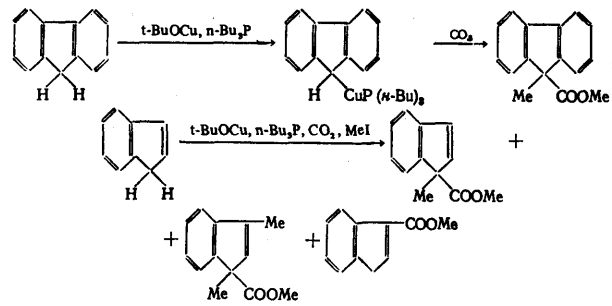
Dialkyl-substituted formaldehydes have been obtained from primary and secondary amines, CO_2, and H_2 at pressures up to 30 atm in the presence of phosphine complexes of ruthenium of the type $(PPh_3)_4RuH_2$, $(PPh_3)_4RuCl_2$, $Ph_2PCH_2CH_2PPh_2$–$RuCl_3$–EtAl, or $(PhO)_3P$–$RuCl_3$–EtAl at 130 °C (yield 60%).[98] The reaction can proceed catalytically in the presence of cobalt, rhodium, iridium, palladium, platinum, and copper complexes under analogous conditions[98]:

$$R_2NH + CO_2 + H_2 \rightarrow HC(O)NR_2 + H_2O\ .$$

In the presence of Bu_3P diisocyanates react with CO_2 to form oxadiazinone compounds[99]:



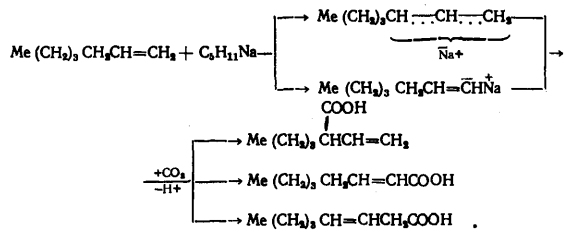
Unsaturated compounds with a high electron density of the type of ynamine readily react with CO_2 at 20 °C to form allenedicarboxamide derivatives in 100% yield[100]:



R=Me, R^1=R^2=Et;
R=H, R^1=Ph; R^2=Me .

3. Reactions of CO_2 with Unsaturated Hydrocarbons and Their Derivatives

As already mentioned above, the insertion of CO_2 in the M–C bond can serve as the basis of the synthesis of various compounds with functional groups from unsaturated hydrocarbons and their derivatives. Thus the insertion of CO_2 in the Cu–C and Ag–C bonds, depending on the σ-donor ligand (whose presence is essential), constitutes the basis of the synthesis of carboxylic acids from unsaturated hydrocarbons under mild conditions (20–80 °C):[101]



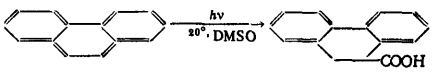
The yield of phenylacetylenecarboxylic acids from phenylacetylene and CO_2 in the presence of ligands of the type of n-Bu_3P and t-BuNC or t-BuOCu and t-BuOAg was 70%. Fluorene[101] and indene[45] are carboxylated under analogous conditions in the presence of methyl iodide with formation of methyl esters of methylfluorenecarboxylic and methyl- and dimethyl-indenecarboxylic acids respectively:

Methyl- and butyl-acetylenes react with CO_2 in the presence of vinylcopper and triethoxyphosphine $P(OEt)_3$ in hexamethylphosphoramide at −30 °C with formation of stereospecific β,β′-unsaturated carboxylic acids (yield 96%):[102]

When α-olefins are metallated by pentylsodium or alkyllithium in aprotic solvents at room temperature a hydrogen atom attached to a carbon atom in the allyl or vinyl position is substituted with formation of organometallic compounds. Carboxylation of the latter yields unsaturated acids[103,104]:

The reactivity of α-olefins in the metallation reaction is usually attributed to the ability of the hydrogen atom to be converted into a proton under the influence of bases of appropriate strength[103]. The use of complex-forming solvents in metallation reactions involving alkyl-lithium[105–109] as well as alkylmagnesium[110,111] leads to the coordination of the electron-donating groups of the solvent to the metal cation, which tends to increase the polarity of the metal–carbon bond. The most effective solvent in the metallation reaction proved to be triethylamine, in the presence of which the overall yield of carboxylic acids reached 97.7%.[112].

Indene, fluorene, acetophenone, and benzyl thioacetate are carboxylated at the active CH_2 group in triethylamine or triethylenediamine in the presence of $MgCl_2$ at p_{CO_2} = 5 atm at room temperature with a yield of the required product up to 80%.[113] Indene-3-carboxylic acid, fluorene-9-carboxylic acid, phenylacetic acid, and benzylthiocarboxylic acid were obtained from indene, fluorene, acetophenone, and benzyl thioacetate respectively. The reaction conditions were as follows: an equimolar amount of $MgCl_2$ in relation to the carboxylated reagent and duration of experiment from 17 to 72 h.



Diene hydrocarbons with conjugated double bonds (butadiene, isoprene, 2,3-dimethylbutadiene, and penta-1,3-diene) are readily carboxylated with formation of dicarboxylic acids under mild conditions with participation of an alkali metal phenoxide[114]. Thus at atmospheric pressure in THF and in the presence of an equimolar amount of sodium phenoxide, butadiene is carboxylated at 50 °C to muconic acid in 81% yield:

$$CH_2{=}CH-CH{=}CH_2 + 2CO_2 \xrightarrow[50^\circ C]{PhONa,\ THF} HOOC-CH{=}CH-CH{=}CH-COOH.$$

The reactions considered are characteristic of unsaturated hydrocarbons and their derivatives capable of forming an M–C bond in which CO_2 can be inserted via the anomalous pathway with formation of compounds of the metal-carboxylate type.

4. Reactions Involving the Addition of CO_2 to a Radical-Anion

It has been shown that CO_2 can readily add to a radical-anion with formation of a charge-transfer complex between a donor base and an acceptor. Thus, the carboxylation of phenanthrene in a solution of $PhN(CH_3)_2$ in DMSO at p_{CO_2} = 4 atm and room temperature under the influence of u.v. for 17 h yielded 9,10-dihydrophenanthrenecarboxylic acid (yield 41%):[115]

The reaction proceeds analogous with anthracene, naphthalene, pyrene, and biphenyl in a tertiary amine and dimethylaniline[1]. The mechanism of these reactions has been treated in terms of the intermediate formation of a charge-transfer complex under the influence of ultraviolet light between a strong electron donor (an amine) and aromatic hydrocarbons of the type $\overline{ArH}\cdot R_3\overset{+}{N}$. CO_2 then attacks the complex with formation of the radical-anion $(ArH)^{\cdot}-COO^-$, which readily combines with a hydride hydrogen atom from the solvent:

$$(ArH)\begin{matrix}H\\ \diagdown\\ COO^-\end{matrix} \rightarrow (ArH)\begin{matrix}H\\ \diagdown\\ COOH\end{matrix}.$$

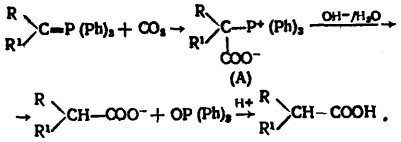
In the presence of acetonitrile and p-NCC_4H_4NC, p-methoxystyrene gives rise, under the influence of ultraviolet light to a radical-cation, which interacts with CO_2.[116]

The free radicals formed in the homolytic dissociation of the C–C bond under the conditions of the cracking of alkanes proved to be extremely reactive in relation to CO_2. Thus the vapour-phase cracking of the higher C_{17}–C_{19} paraffins and C_{20}–C_{40} paraffin wax in CO_2 at 500–700 °C yielded a mixture of saturated carboxylic acids (contact time 0.1–10 s):[117]

$$R-CH_2-Me \rightarrow R^{\cdot} + \dot{C}H_2Me;$$
$$R^{\cdot} + CO_2 + RCH_2Me \rightarrow RCOOH + R\dot{C}HMe;$$
$$\dot{C}H_2Me + CO_2 + RCH_2Me \rightarrow MeCH_2COOH + R\dot{C}HMe.$$

5. Reactions Involving the Addition of CO_2 to Ylid Compounds of Phosphorus

Ylid compounds of phosphorus readily interact with CO_2 at room temperature and atmospheric pressure with formation of betaine compounds (A), capable of being converted into carboxylic acid on hydrolysis in an alkaline medium[118]:



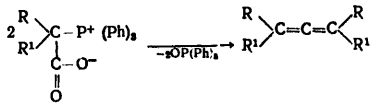


Table 3 presents data for the synthesis of carboxylic acids from various P-ylids and CO_2.

Allene has been obtained in yields up to 36% by the pyrolysis of such a betaine at 200 °C:[118]

It has been suggested[118] that the reaction proceeds via a stage in which a keten is formed. On subsequent decarboxylation, the allene is formed from two molecules. This hypothesis is confirmed by the mechanism of the synthesis of an isocyanate by the reaction of CO_2 with the dialkyl N-alkylphosphoramidate anion via a stage involving the formation of carbamate at room temperature[119]:

$$(EtO)_2P(O)-NHR \xrightarrow{OH^-} (EtO)_2P(O)-\overline{N}R \xrightarrow[25^\circ C]{CO_2} (EtO)_2P(O)-NR \rightarrow$$
$$\rightarrow (EtO)_2P(O)-O^- + R-N{=}C{=}O.$$

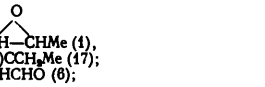
The yield of isocyanates is 73% for R = iso-C_4H_9, 80% for R = C_6H_{11}, and 88% for R = t-C_4H_9. We may note that the dialkyl N-alkylphosphoramidate anion reacts with carbon disulphide to form an isothiocyanate under analogous conditions[119].

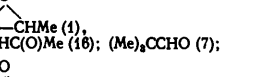
Table 3. Carboxylation of P-ylids[118].

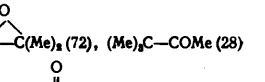
R	R¹	Yield of betaine (A), %	Yield of carboxylic acids, %
$-(CH_2)_2-$		94	90
$-(CH_2)_3-$		91	89
$-(CH_2)_5-$		98	86
$-(CH_2)_6-$		82	85
Me	Me	99	85
Ph	H	68	80

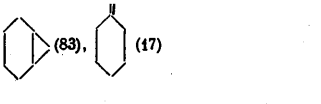
6. Organic Syntheses Based on CO_2 Under the Influence of Radiation

Alcohols, amines, carboxylic acids, and saturated and unsaturated hydrocarbons can be carboxylated with the aid of ionising radiation under the influence of free radicals, radical-ions, free atoms, and biradicals[120]. The chemical processes induced by the ionising radiation are analogous to photochemical reactions. However, whereas photochemical reactions proceed selectively, under the influence of ionising radiation the molecules are supplied with such a large amount of energy that they are involved in a wide variety of chemical processes, occurring simultaneously, which leads to a decrease of selectivity.



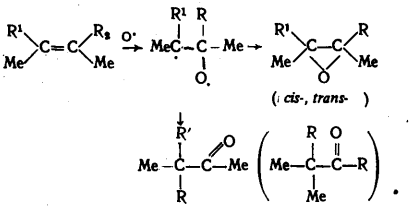






The yield of products (G) of the reaction occurring under the influence of radiation is usually calculated from the number of molecules formed following the absorption of 100 eV of energy. The reaction is performed in an aqueous solution of HCOOH or HCOONa. Thus, irradiation of a mixture of solid carbon dioxide and ethanol with γ-rays having an energy of 2 MeV yielded lactic acid ($G = 0.06$), while the use of cyclohexane, cyclohexene, and ethylamine instead of ethanol resulted in the formation of cyclohexanecarboxylic acid ($G = 0.07$),[120] a mixture of cyclohexenecarboxylic acids ($G = 0.11$), and α-alanine ($G = 0.17$).[121] Furthermore, acetic acid had been obtained from CH_4 and CO_2 by a gas-phase reaction. The replacement of CO_2 by formic acid does not affect the composition of the reaction products. Hummel and Barzynski[122] obtained carboxylic acids with a number of carbon atoms greater by unity than in the initial compound in yields of 0.15, 2.12, 2.16, 2.24, 0.33, and 0.37 by the reaction of CO_2 with cyclohexane, n-hexane, n-heptane, cyclo-octane, benzene, and toluene respectively under the influence of γ-radiation.

Ethylene reacts with CO_2 at 100 °C under the influence of γ-radiation with formation of a mixture of linear carboxylic acids having a molecular weight of 670.[123] It has been suggested that these acids are formed as a result of the addition of CO_2 to a polyethylene radical via a stabilised resonance radical, which is energetically unsuitable for further chain growth:



When an aqueous solution of CO_2 from which oxygen has been removed is γ-irradiated, formaldehyde and acetaldehyde are formed; the yields depend on the pH of the medium[124–126]. The addition of an insignificant amount of $FeSO_4$ (10^{-3} M) in an alkaline medium leads to a sharp increase of the yield of aldehydes. When the reaction is carried out in an acid medium, carboxylic acids are formed preferentially: HCOOH, $(COOH)_2$, CHOCOOH, and glyoxal[127].

Table 4. Radiolysis of olefins and CO_2 at room temperature.

Olefin	Relative velocity k_1/k_2	Reaction products (yield, %)
cis- Me—CH=CH—Me	1.0	 Me—CH—CHMe (1), MeC(O)CH$_2$Me (17); (Me)$_2$CHCHO (6);
$(Me)_2C$=CHMe	1.3	 $(Me)_2$C—CHMe (1), $(Me)_2$CHC(O)Me (16); $(Me)_2$CCHO (7);
$(Me)_2C$=C$(Me)_2$	1.7	 $(Me)_2$C—C$(Me)_2$ (72), $(Me)_2$C—COMe (28)
	1.3	 (83), (17)

Alicyclic and cyclic olefins mixed with H_2CO_3 in a steel autoclave (molar ratio olefin : CO_2 = 1 : 100) are converted into epoxy- and carbonyl compounds at room temperature or at 0 °C under the influence of γ-radiation (see Tables 4 and 5).

The formation of *cis*- and *trans*-2,3-epoxybutanes is treated as a result of stereoisomeric transformations of the adduct resulting from the radical addition of an oxygen atom to *cis*-but-2-ene:

The data in Table 5 show that the reactions of aromatic olefins proceed with formation of a mixture of epoxy- and carbonyl compounds with the exception of 1,1-diphenylethylene, which does not form epoxy-compounds but is converted into carbonyl compounds and oligomers (degree of conversion 97%).

Table 5. Radiolysis of aromatic olefins and CO_2 at 0 °C.

Olefin	Conversion, %	Reaction products (yield, %)
Ph—CH=CH$_2$	—	 PhCHO (4), PhCH—CH$_2$ (74) PhCH$_2$CHO (22)
PhC(Me)=CH$_2$	—	 PhC(O)Me (35), PhC(Me)—CH$_2$ (31), PhC(Me)HCHO (34)
cis- PhCH=CHPh	75	 PhCHO (21), PhCH—CHPh (*cis*-21, *trans*-53), (Ph)$_2$CHCHO (3), PhCH=CHPh (*trans*-2)
trans- PhCH=CHPh	52	 PhCHO (37), PhCH—CHPh (*cis*-1, *trans*-56) (Ph)$_2$CHCHO (2), PhCH=CHPh (*cis*-4)
$(Ph)_2C$=CH$_2$	97	PhC(O)Ph (13), (Ph$_2$)CHCHO (13), oligomer (74)

Under a CO_2 pressure up to 1 atm or in the presence of an equimolar amount of Na_2CO_3, ethanol gives rise to lactic acid under the influence of γ-radiation,[129,130] whose yields depend on the pH of the medium. $G = 1$ in an acid medium and reaches 2 in an alkaline medium. At pH 4–6 methanol reacts with CO_2 to form glycolic acid with $G = 1$–2.3.[130,131] The reaction proceeds via the mechanism

$$H_2O \rightarrow e^-_{aq},\ H_3O^+,\ H^+,\ OH^-,\ H_2,\ H_2O_2$$
$$MeOH + H^+ \text{ (or; } OH^-) \rightarrow \dot{C}H_2OH + H_2 \text{ (or } H_2O)$$
$$CO_2 + H^+ \rightarrow COOH \quad (k \leqslant 8 \cdot 10^6 \text{ mol}^{-1}\text{ s}^{-1}),$$
$$CO_2 + e^-_{aq} \rightarrow CO_2^- + n\,H_2O \quad (k = 7.67 \cdot 10^9 \text{ mol}^{-1}\text{ s}^{-1});$$
$$\dot{C}H_2OH + COOH \rightarrow CH_2(OH)\,COOH;$$
$$\dot{C}H_2OH + CO_2 \rightarrow CH_2(OH)\,COO^-;$$
$$CH_2(OH)\,COO^- + H_3O^+ \rightarrow CH_2(OH)\,COOH + H_2O.$$

In order to suppress the formation of CO_2^-, the reaction is carried out with methanol freed from oxygen.

The radiation-induced carboxylation of aliphatic amines under conditions analogous to those in the carboxylation of

alcohols, gives rise to aminoacids[132,133]. Thus, when a solution of methylamine saturated with CO_2 is irradiated with γ-rays, glycine is formed with a yield $G = 0.8$ at pH 9:

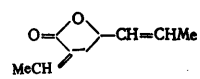
$$MeNH_2 + H^+ \rightarrow \dot{C}H_2NH_2 + H_2;$$
$$MeNH_2 + OH^- \rightarrow \dot{C}H_2NH_2 + H_2O;$$
$$\dot{C}H_2NH_2 + CO_2 \rightarrow CH_2NH_2COO^-;$$
$$\dot{C}H_2NH_2 + \dot{C}OOH \rightarrow CH_2NH_2COOH;$$
$$CH_2NH_2COO^- + H_3O^+ \rightarrow CH_2NH_2COOH + H_2O.$$

At pH > 9 the yield of glycine falls sharply, owing to the decrease of the amount of CO_2 and the occurrence of side reactions. An analogous behaviour has been observed also in the carboxylation of ethylamine[133].

The radiation-induced carboxylation of formic acid with the aid of $^{14}CO_2$ at pH 3.5 leads to the formation of labelled oxalic acid ($^{14}COOH.COOH$) with $G = 1.2$.[129,130] An increase of the pH of the medium from 5 to 6 leads to an increase of the yield of oxalic acid to $G = 7.2$ and $G = 7.6$ respectively[134,135]:

$$CO_2^- + HCOO^- \rightarrow (CO_2^- \cdot HCOO^-);$$
$$(CO_2^- \cdot HCOO^-) + CO_2 \rightarrow CO_2^- + (COO \cdot COOH^-).$$

In neutral and alkaline media the reaction proceeds with the preferential formation of oxalic acid, which is suppressed in an acid medium as a consequence of the reaction $COOH \rightarrow HCOO$.[136]



The effect of γ-radiation on aromatic hydrocarbons of the type of benzene, toluene, and xylene in a mixture with CO_2 at 0 °C leads to the formation of substituted phenols[137]. Since the addition of SF_6, which is a powerful electron acceptor, in the reaction between CO_2 and toluene did not result in the formation of cresol and only lines corresponding to O^- and CO_3^- were noted in the mass-spectrum of CO_2, the following reaction mechanisms were proposed:

$$MePh \rightarrow MePh + e;$$
$$CO_2 \rightarrow CO_2^+ + e \text{ (were } CO + O);$$
$$O + e \rightarrow O^-;$$
$$MePh + O^- \rightarrow MePhO^-;$$
$$O^- + CO_2 \rightarrow CO_3^-;$$
$$MePh + CO_3^- \rightarrow MePhO^- + CO_2;$$
$$MePhO^- + M^+ \rightarrow MePhOH + M.$$

7. Catalytic Syntheses Based on CO_2

Catalytic reactions based on CO_2 constitute a relatively little investigated field of organic chemistry. It was noted above that the insertion of CO_2 in molecules of complex compounds can serve as a basis of catalytic processes designed to obtain different functional compounds. Thus the reaction of a cobalt carboxylate complex containing an ethyl group with MeI or H^+ yields respectively ethyl acetate or ethyl formate[18,33]. The anomalous pathway in the insertion of CO_2 in the M–L bond with formation of compounds containing a metal–carbon bond (metal-carboxylic acids) suggests the possibility of the synthesis of unsaturated carboxylic acids.

The triphenylphosphine complex of palladium in an active catalyst of the carboxylation of ethylene with formation of propionic acid. In the presence of $(PPh_3)_2PhCl_2$ and H_2O at an overall C_2H_4 and CO_2 pressure of 350 atm ethylene is carboxylated at 165 °C with formation of propionic acid, the yield being up to 400 moles per mole of the catalyst introduced[138]. Propene reacts with CO_2 and H_2 only under more severe conditions (300 °C, $p_{CO_2} = 1000$ atm) in the presence of cobalt carbonyl modified with trialkylphosphine and a condensed system incorporating a carboxylic acid and a nitrogen-containing Lewis base; the reaction leads to the formation of 2-ethylhexanal or 2-ethylhexanol[139]. The reaction of CO_2 and H_2 with butadiene in the presence of $Pd[Ph_2P(CH_2)_2PPh_2]_2$ in DMF at 84–120 °C results in the formation of 12.3% of 2-ethylidenehept-5-ene-4-olide:

The reaction is accompanied by the formation of up to 53.3% of polyene-hydrocarbons[140].

Carbon dioxide can also be inserted in the Co–H bond with formation of a formate fragment, which is converted by an alkyl halide into a formate ester. This reaction is also catalysed by the complexes $L_3OS(CO)HCl$, L_3IrHCl, and L_2PtHCl (where $L = PPh_3$).[31] Using as an alkylating agent a solution of BF_3 in CH_3OH, Hashimoto and Inoue[141] synthesised a formate ester via the mechanism

$$L_nMX + H_2 + L_nMH \xrightarrow{CO_2} L_nMOC(O)H + HCOOMe \xrightarrow{MeOH} L_nM(OH) \xrightarrow[-H_2O]{H_2} L_nMH.$$

The reaction proceeds at atmospheric pressure at a temperature of 20–100 °C. The results obtained are presented in Table 6. Group VIII metal (iron, cobalt, nickel, and platinum) hydride complexes catalyse this reaction, which takes place in tertiary amines with a yield of methyl formate up to 23.4 moles per mole of complex[142]. Sodium formate has been obtained in 73.1% yield by the reaction of sodium carbonate or CO_2 with H_2 at a pressure of 108 atm and a temperature of 280 °C. $PtCl_2.H_2O$ was used as the catalyst[143].

Table 6. The synthesis of methyl formate from CO_2 and H_2.[144]

Complex	t, °C	Yield of HCOOCH*	Complex	t, °C	Yield of HCOOCH*
$(PPh_3)_4RuCl_2$	100	9.0	$(PPh_3)_3IrH_3$	100	38.2
$(PPh_3)_4RuCl_2$	20	1.0	$(PPh_3)_3IrH_3$	20	0.9
$(PPh_3)_4RuH_4$	100	4.2	$(PPh_3)_3IrHCl_2$	100	0.2
$(PPh_3)_4RuH_2$	20	0.6	$(PPh_3)_2Ir(CO)Cl$	100	0.2
$(PPh_3)_3RuHCl$	100	17.0	$(PPh_3)_3Os(CO)HCl$	100	0.6
$(PPh_3)_3RuCl_2$	100	9.0	$(Et_3P)_2PtCl_2$	100	0.1

*The yield is given in moles of HCOOMe per mole of the catalytic complex.

In the presence of Group VIII metal complexes secondary amines react with CO_2 and H_2 at 50–60 atm and 100–125 °C with formation of dialkylformamides and equimolar amounts of water[98,144]:

$$CO_2 + H_2 + R_2NH \xrightarrow{\text{catalyst}} HCONR_2 + H_2O$$

The catalysts $CoH(dpe)_2$, $CuCl(PPh_3)_3$, and $IrCl(CO)(PPh_3)_2$, in the presence of which the yield of DMF from dimethylamine reached 1200 moles per mole of catalyst in benzene, showed the highest activity. When n-hexane is used as the solvent, the phosphine complex of ruthenium catalyses this reaction under the same conditions (the yield of DMF is 57.4% [144]— Table 7).

Table 7. The synthesis of dimethyl formamide from CO_2 and an amine[144].

Catalyst	Amount of catalyst, mmoles	Me_2NH, mmoles	t, °C	Yield of DMF*
$(PPh_2CH_2CH_2PPh_2)_2CoH$	1.08	138	100	5
$(PPh_2CH_2CH_2PPh_2)_2CoH$	0.05	131	125	1000
$(PPh_3)_3RhCl$	0.3	122	100	43
$(PPh_3)_3RhCl$	0.02	138	125	170
$(PPh_3)_2(CO)RhCl$	0.38	144	100	1
$(PPh_3)_2(CO)IrCl$	0.35	133	100	28
$(PPh_3)_2(CO)IrCl$	0.2	138	125	1200
$(PPh_3)_2(CO_3)Pd$	0.79	159	100	120
$(PPh_3)_2(CO_3)Pd$	0.7	155	125	104
$(PPh_3)_2Pt$	0.56	155	125	19
$(PPh_3)_3RuCl_2$	0.39	132	125	8
$(PPh_3)_3CuCl$	0.63	133	100	8
$(PPh_3)_3CuCl$	0.03	142	125	900
$H_2PtCl_4 \cdot 6H_2O$	0.56	124	125	11

*The yield is given in moles of DMF per mole of catalyst.

Catalysts based on ruthenium, rhodium, palladium, and platinum are active in the synthesis of urea from NH_3 and CO_2 at temperatures betwen 0° and 300 °C, the presence of small amounts of H_2 and O_2 in the initial CO_2 not influencing the yields of the required product[145].

In solution in a mixture of acetonitrile and ether saturated with CO_2, diethylaminopropyne is converted in 1 h at -60 °C (or at room temperature under CO_2 pressure) into the *N*-methyl-*N*-phenyldiamide of allene-1,3-dicarboxylic acid, the hydrogenation of which on a platinum catalyst gave rise to the *N*-methyl-*N*-phenyldiamide of glutaric acid in up to 85% yield[146]. The continuous synthesis of aminoacids from CO_2 and amines at atmospheric pressure and in the presence of ion-exchange resins is extremely interesting and promising from the practical point of view[146]. Primary and secondary C_1–C_{16} amines, C_1–C_{15} di- and tri-amines, aminoalcohols, and alkyl aminocarbonates readily react with CO_2 at 20–80 °C in the presence of ion-exchange resins of the type Amberlite-45, A-400, 410, IR-45, and Dowex-3 as well as $CuCl_2$ or $Cu(OAc)_2$, forming the corresponding α-aminoacids in up to 85% yield.

Since nitro-groups are powerful electron acceptors, nitroalkanes exhibit in many reactions the properties of a weak acid and are capable of splitting off a proton with formation of a carbanion, which undergoes nucleophilic addition to CO_2 in the presence of alkylcopper complexes[101]:

$$MeNO_2 + RCu(PPh_3)_3 \xrightarrow{-RH} O_2N{-}CH_2{-}Cu(PPh_3)_3 \xrightarrow{CO_2} \rightarrow O_2NCH_2COOCu(PPh_3)_3 \xrightarrow{H_2O} O_2NCH_2COOH .$$

The reaction proceeds via a stage involving the formation of a nitroalkylcopper complex with insertion of CO_2 in the M–C bond and the formation of a carboxylic nitroacid on subsequent hydrolysis with water. This reaction is used nowadays as a model for the investigation of the chemical properties of biotin (vitamin H).[76]

Extremely interesting results have been obtained using sodium phenoxide as a catalyst in the carboxylation of methyl esters of alkanecarboxylic acids with carbon dioxide. The reaction proceeds via a carbanion formation stage. In the presence of sodium phenoxide in DMF at atmospheric pressure and a temperature of 50–70 °C methyl acetate is readily carboxylated with formation of malonate esters (yield 70 to 90%):[147–151]

$$MeCOOMe + CO_2 \xrightarrow[DMF]{PhONa,CH_2N_2} MeCOOCH_2COOMe .$$

Instead of PhONa, it is possible to use the sodium derivatives of *p*-cresol, 3,5-xylenol, and resorcinol[150].

Below 25 °C, sodium phenoxide catalyses the carboxylation of dialkyl ketone to oxoglutaric acid and its derivatives (yield 47–75%):[152–154]

$$MeCMe + 2CO_2 \xrightarrow[DMF]{PhONa} HOOCCH_2C(O)CH_2COOH .$$
$$\quad\quad\quad

IV. INDUSTRIAL PROCESSES WITH PARTICIPATION OF CO_2

In the form of liquid carbonic acid and dry ice, carbon dioxide is used as a cooling agent and a solvent, in the casting industry, and in the synthesis of urea, sodium carbonate, and ammonium carbonate.

Large-scale industrial syntheses based on CO_2 have not so far been achieved with the exception of the industrial method for the synthesis of salicylic and hydroxybenzoic acids by the Kolbe–Schmidt reaction[168]. The *p*-hydroxybenzoid acid and its derivatives obtained by this procedure are widely used in the food, light, and polymer industries.

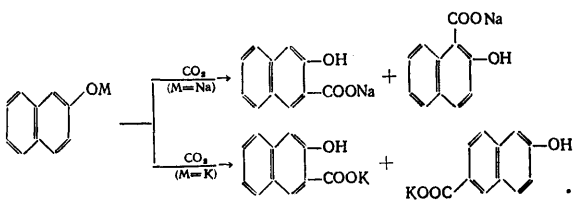


Table 8 presents the results of the carboxylation of sodium phenoxide in a homogeneous system in an aprotic solvent. The reaction proceeds with preferential carboxylation in the *para*-position, while carboxylation in a heterogeneous system takes place with the preferential formation of salicylic acid, i.e. with carboxylation in the *meta*-position. The introduction of potassium into the reaction zone and an increase of temperature to 220 °C tend to increase the yield of the required product above 80%.[169–171]

Table 8. Carboxylation of alkali metal phenoxides (PhOM) in aprotic solvents. ($\tau = 30$ min).[171]

M	Solvent	P_{CO_2}, atm	t, °C	Yield*, %	Compn. of reaction product, %		
					p-hydroxybenzoic acid	salicylic acid	4-hydroxyisopthahlic acid
K	DMF	bubbling	100	24.2	88	12	0
K	DMF	bubbling	150	30.8	83	16	1
K	DMSO	bubbling	100	22.0	94	2	4
K	DMF	5	140	33.5	88	9	3
K	DMF	5	180	41.5	83	13	4
K	DMSO	5	100	23.9	94	2	4
Na	DMF	bubbling	100	10.0	66	32	2
Na	DMF	bubbling	140	22.0	63	36	1
Na	DMSO	bubbling	100	16.5	83	11	6
Na	DMF	5	140	36.1	70	27	3
Na	DMF	5	180	45.4	53	35	12
Na	DMSO	5	140	41.1	81	13	6

*The overall yield of hydroxybenzoic acid and its derivatives is given.

The nature of the alkali metal cation influences markedly the composition of the reaction product. Thus, whereas sodium phenoxide gives rise to salicylic acid, carboxylation of potassium phenoxide under the same conditions leads to a mixture of salicylic and *p*-hydroxybenzoic acids. The influence of the cation on the mode of the reaction involving a series of naphthalene and quinoline derivatives is striking[168]:

The reaction is carried out either by treating the corresponding dry alkali metal phenoxides with CO_2 at 120–130 °C or by heating a mixture of the phenol with an excess of K_2CO_3.

The Kolbe–Schmidt reaction constitutes the main industrial method for the synthesis of salicylic acid from phenol, of aminosalicylic acid from *m*-aminophenol, and of β-hydroxynaphthoic acid from β-naphthol.

---o0o---

Thus syntheses based on CO_2 make it possible to obtain a wide range of organic compounds of practical importance. At the same time, very few reactions based on CO_2 have been utilised in industry, which is due primarily to the lack of effective carboxylation catalysts[171]. Advances in the field of metal complex catalysis in recent years as well as in the field of the activation of small molecules suggest that active and selective catalytic systems will be developed, on the basis of which the problem of the wide-scale employment of CO_2 will be resolved.

Changes in Rheological Properties during Formation and Transformation of of Polymers

A.Ya.Malkin

Published information on the changes in rheological properties of polymer melts and solutions accompanying various chemical processes—polymerisation, vulcanisation, hardening, gelation—is examined, and experimental methods for the rheological investigation of chemically unstable polymer systems are discussed in detail. Changes in rheological properties should be considered in relation to the chemical kinetics of the processes involved. Technical aspects of the problem are indicated. A list of 133 references is included.

I. INTRODUCTION

Polymers and compositions based on them provide a most interesting subject for the application of diverse physicochemical methods of investigation, largely because in this class of materials property indices can easily be changed by many powers of ten. Hence the measurement of particular characteristics is a sensitive method of physicochemical analysis of the material. A clear example is given by the rheological properties of polymers, which are highly sensitive to the length of the polymer chain, its structure, the molecular-mass distribution, and the content of the polymer in the system (solution or filled composition).

The general laws of the development of rheological properties by polymer systems as functions of the main determining factors have now been studied in some detail and have been summarised in several monographs[1-3]. Important achievements of the past decade have been measurements on specially synthesised series of monodisperse polymers and their model mixtures[4-10], and also the correlation of numerous and multifarious experimental results on the rheological properties of solutions of various polymers in different solvents throughout the possible composition range[11-18].

The many studies of the past decade have provided a reliable basis for a general quantitative description of the rheology of polymers. They had the common aim of investigating materials that were as pure as possible. Although such an approach is methodologically difficult, it is justified by the comparative ease and unambiguity with which experimental results can be interpreted. Yet this approach ignores several important classes of polymeric materials, among which polymers or polymer systems whose properties vary continuously with time should be specially distinguished. Two significant aspects are firstly that the time taken by these changes is comparable with the duration of observation and secondly that they are functionally inherent in certain polymeric materials, being responsible for their technical value. A fairly large number of cases correspond to these conditions, for time-variable systems are met in various branches of the chemical technology of polymers.

In principle two mechanisms—chemical reactions and physical phenomena—may cause the rheological properties of a material to vary with time. Below we shall consider only the occurrence on an experimental time scale of chemical reactions leading either to the formation of linear polymers or to the conversion of linear polymers (or oligomers) into three-dimensional networks. The process related to the latter case is gelation (gel formation), in which physical changes (primarily crystallisation) may be combined with chemical reactions.

II. METHODS OF INVESTIGATION AND THEIR RANGE OF APPLICATION

Study of the rheological properties of chemically unstable systems during the formation and transformation of polymers is a fairly new field of investigation, which has developed from the traditional rheology of polymers. It is therefore natural that this development has involved the widespread use of customary rheological methods with their appropriate experimental techniques and treatment of the results. However, the need for continuous monitoring of the state of the system has caused a gradual modification of the existing experimental apparatus.

The methodology of the rheology of polymers is based on steady-state and non-stationary measurements. The principles and experimental procedures related to non-stationary methods have been described in detail[19]. Among them only dynamic methods have been widely used for the study of rheologically unstable systems. They consist essentially in subjecting the test specimen to harmonic deformation of specified frequency ω and studying the response of the material in terms of the shear modulus of elasticity G and the mechanical loss angle $\tan\delta$, which depend on ω and, in the case of unstable systems, on the time t.

Relaxation methods have also found an extremely unusual application: it was proposed[20] to use them to monitor the

course of chemical reactions in rubbers subjected to an applied stress. However, this type of approach did not become widespread. Other non-stationary methods for studying viscoelastic properties of polymers were not applied to chemically unstable systems, apparently because of the fundamental difficulty of separating time effects due to relaxation phenomena from those due to chemical changes.

Non-stationary (dynamic) methods for studying chemical changes are used in the following cases—(i) to monitor the initial stage of polymerisation, primarily by means of vibration viscosimeters and procedures identical with those usual in viscosimetry[21]; (ii) to investigate the initial stages of the vulcanisation of rubber mixtures, usually by forced low-frequency vibrations, whose development led to commercial instruments and standardised methods; (iii) to study the hardening of thermosetting plastics and oligomers, especially in practical scientific research using the whole set of modern dynamic methods of measurement; and (iv) to assess the thermal stability of various polymers and to investigate high-temperature processes yielding infusible and insoluble resins.

A fair number of designs and measuring schemes are known that use various instruments operating under dynamic loading at the most diverse frequencies—from infrasonic to ultrasonic—for the above cases. Although various known designs can in principle be used for this purpose[19], the practical importance of thermostable polymers and the difficulties of preparing specimens for investigation led to the establishment of a special method—torsional braid analysis (the TBA method).[22-25]

In the TBA method a bundle of fibres (filaments) is impregnated with a solution of the test polymer. The solvent is then removed, and the usual measurements of modulus or elasticity and mechanical losses are made both on the filament with the deposited polymer and for comparison on a blank filament either under isothermal conditions or with temperature scanning. The properties of the polymer are found by difference, while the observed changes in measured indices enable the variation in state of the test material to be reliably monitored. The convenience of depositing the polymer, the small amount of polymer required, the ease of replacing the fibre braid, and the reliability with which specified temperature conditions are maintained, combined with the proposed[24] automated methods for processing the experimental data, constitute important advantages of this method in comparison with traditional dynamic methods of investigating polymers and give it promise in laboratory practice, especially for investigating newly synthesised polymers.

Steady-state methods of measurement are essentially viscosimetry[21,26] complicated by the fact that polymer systems are not viscous liquids but viscoelastic media[1]. Viscosimetric methods may be used when the test material is able to flow, and their application to the study of chemical processes is possible when the transition period preceding the establishment of steady-state flow and due both to viscoelastic and to thixotropic phenomena[27-31] is significantly shorter than the characteristic time of chemical reaction. In such case many traditional viscosimetric methods prove useful. However, the following substantial difficulties then arise: the deformation produced in any type of viscosimeter can itself have a definite effect on the course of a chemical reaction, and its intensity will depend on the rate of deformation; if the reaction is accompanied by considerable evolution of heat, special attention must be paid to maintaining controllable (e.g. isothermal) conditions of measurement; and in many cases chemical changes in polymers are accompanied by hundredfold and thousandfold changes in viscosity, so that the instrument should be able to measure viscosities of the test medium over a very wide range.

Viscosimetric methods are used industrially for two purposes—(i) to estimate the duration of retention of the fluid state by rubber mixtures (various types of Mooney viscosimeters are used[32]; certain methods of applying them have been standardised in several countries, in particular in the USA as ASTM D-1246, etc. and in the USSR we also have GOST 10 722 as a "method of determining the viscosity and the capacity for premature vulcanisation" of rubber mixtures), and (ii) to measure the "viability" of thermosetting plastics (the rotation viscosimeter developed in the USSR is used for this purpose[33,34]; an instrument of the same type is manufactured also in the Federal Republic of Germany by Gevaert; other suitable experimental methods have been reviewed[35]).

Viscosimetric methods have found very restricted use in the industrial production of polymers (isolated examples can be found[36,37]), despite the exceptionally high sensitivity of rheological indices to the composition of the polymer system and the structure of the macromolecular chain. Polymerisation processes are usually monitored by traditional viscosimetric methods and instruments. However, the problem of studying rapid polymerisation reactions, in particular of assessing the induction period and the intial stages in general, may require the development of scanning methods for monitoring viscosity[38].

The use of instruments combining viscosimetric and dynamic methods of measurement is extremely promising for the investigation of processes starting with a low-viscosity liquid and ending in separation of a solid product, for the whole process of hardening can be examined on a single small specimen. Instruments of this type are now manufactured in Great Britain (the Weissenberg rheogoniometer produced in several modifications by Sangamo Weston Ltd.), the USA (the dynamic spectrometer made by Rheometrix), and in the USSR.[39] An analogous instrument has been developed also for rubber mixtures[40].

III. POLYMERISATION AND POLYCONDENSATION

The change in viscosity and in the whole set of viscoelastic properties of a polymer system during chain growth is extremely striking, as a consequence of the very strong dependence of their governing parameters on the molecular mass and the concentration of the polymer in the solution[1-3], as well as the existence of critical points at which even the character of these relations changes[1,18,41,42]. Indeed, published qualitative results have shown that in actual cases the viscosity of the reaction mass changes by many powers of ten during polymerisation.

Measurements of the viscosity of polymers in the actual monomer are very significant in this connection. The proposed experimental technique makes it possible to follow the course of polymerisation by a dilatometric method with simultaneous measurement of viscosity[43,44]. Results for methyl methacrylate show[45] that the viscosity η is related to the extent of conversion β by the power formula

$$\eta = K\beta^n, \qquad (1)$$

where the constants K and n are determined by the composition of the reaction mass (the concentration of the initiator and the content of the molecular-weight regulator), but all cases show very high values of $n \cong 10$. The polymerisation of butyl methacrylate exhibits a similar $\eta-\beta$ relation, although the region of transition to concentrated solutions of macromolecular products at some critical value of β may be more sharply defined than with methyl methacrylate[46].

An extraordinarily rapid increase in viscosity has been observed also in the copolymerisation of butyl methacrylate with methacrylic acid, although for this sytem the effect is very strongly dependent on the composition of the copolymerising system, and an induction period of almost unchanged viscosity it observed intially[47]. However, evidence of an induction period depends to some extent on the way in which experimental results are presented, which is clearly shown by a comparison of the same data plotted on linear[48] and logarithmic[45] scales. Yet in all the above cases of radical polymerisation the $\eta-\beta$ relation, like the usual dependence of the viscosity of polymer solutions on molecular mass and concentration, undoubtedly consists of two parts—an initial segment with a relatively weak dependence of η on β, and the main segment, when at a considerable degree of conversion the dependence is extremely sharp, and the exponent n reaches very high values.

Extremely interesting experimental results illustrating the way in which viscosity changes during the polymerisation of acrylic monomers in the presence of fillers[49-53] also show change in the rate of increase of viscosity when a certain degree of conversion is reached. It was shown at the same time that the increase is accompanied by a sharp change in the whole complex of rheological properties of the polymerising system, with strengthening viscoelasticity of the solution, evidence of intense structure formation at a certain degree of conversion.

An initially slow and then extraordinarily rapid increase in viscosity of the reaction mass has been observed in the polymerisation of styrene in the actual monomer, which also has a radical mechanism[54] (it is especially interesting to compare these results with an investigation of the rheological properties of the model system formed by solutions of polystyrene of varying molecular mass in styrene[55], which will provide a physical basis for assessing the nature of the rheological transitions accompanying polymerisation). These experimental results[54] were represented by an exponential dependence of viscosity on extent of conversion, but the rheological results for solutions of polystyrene by power functions[55].

It is important to emphasise for the purposes of the present discussion that use of a single variable—extent of conversion—to describe the type of variation in viscosity has proved entirely valid for radical polymerisation under homogeneous conditions.

Unfortunately the above very interesting and significant results were not compared with the kinetics or the mechanism of polymerisation, which would have enabled sound judgments to be made on the relative roles of the main determining parameters—concentration of catalytic system, temperature, and change in the molecular mass of the product and its content in the reaction mass at various stages of polymerisation.

The monotonic character of the variation in viscosity during polymerisation is characteristic only of homogeneous processes. Various physicochemical effects, such as phase separation or inversion at a certain degree of conversion, formation of a heterogeneous system, substantially complicate the pattern of change in rheological properties. A very pertinent example is the formation of shock-resistant polystyrene. An important stage in this process is phase reversal, when at a certain degree of conversion of styrene in the polymer a transition takes place from a system in which the continuous phase is a solution of rubber in styrene to a system in which rubber is dispersed in another, newly formed continuous phase—a solution of polystyrene in styrene—the conditions at this point influencing significantly if not decisively the physicomechanical properties, i.e. the quality of the product.

A fundamental aspect of these problems is that phase reversal is accompanied by a jump in viscosity: the effective viscosity falls very rapidly at the instant of phase reversal (Fig.1 [56]). The drop in viscosity is very clearly evident, since until the critical moment the viscosity has been increasing owing to the polymerisation of styrene (but the polymer remains the dispersed component). The change in character of the variation in viscosity (from increase to decrease) is so marked that it may become an extremely reliable method for the technical monitoring of polymerisation. It should be noted that the viscoelastic properties of the composition change just as sharply at the point of phase reversal, which is evident e.g. in a decrease in the Weissenberg effect.

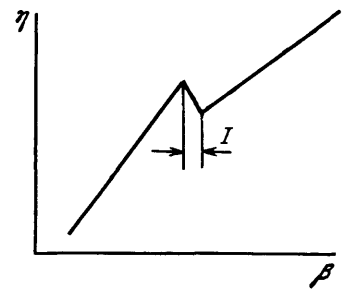

Figure 1. Variation in viscosity during polymerisation accompanied by phase reversal (in the range *I*).

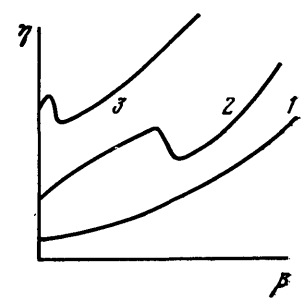

Figure 2. Variation in viscosity during: *1*) homogeneous polymerisation; *2*) phase transition during polymerisation; *3*) heterogeneous polymerisation.

The above example of an extremal change in viscosity at an instant of phase transition during polymerisation is apparently general in character. In this respect special interest attaches to viscosity measurements on methyl methacrylate polymerising in a solvent—precipitant mixture[57]. The composition of the medium was chosen to ensure that polymerisation took place under either homogeneous or transition conditions. Sharp differences were observed in the variation of viscosity (Fig.2 [57])—comparatively slow increase during homogeneous polymerisation (curve *1*), an extremal curve with change in phase state of the system (curve *2*), and a very sharp increase during heterogeneous polymerisation (curve *3*)—the continuance[57] of the relatively slow increase up to extremely high degrees of conversion being due to occurrence of the reaction in solution—not in the mass—so that the polymerising system was a not very concentrated solution.

Isolated qualitative observations show that the moment of phase reversal on formation of an insoluble polymer depends on the rate of mixing of the reaction mass. This is due to both physical causes (since the instant of phase separation depends on the rate of deformation[58,59]) and apparently to the influence of deformation on the rate of polymerisation. The latter is one of the most obscure and little studied aspects of the rheology of polymerising systems. Individual views on this aspect are extremely unconvincing, and there are hardly any "pure" researches in which this question would be studied.

The few investigations in which dependence of rate of polymerisation on deformation of the reaction mass has actually been observed include the discovery of the influence of rate of shear on rate of change of viscosity during the cross-linking of oligourethane[60]. However, the complexity of interpreting the results, consequent on the extremely specific character of the dependence of the effective viscosity of an oligomer on rate of shear, prevents their extension to other polymerising systems in general. Thus a region of dilatant behaviour—increase in effective viscosity with rate of shear—is often observed[60,61] with oligomers at low rates of shear. Significantly different flow curves are observed for concentrated solutions[1,6,13,18]. Therefore the type of dependence of viscosity on rate of shear changes as polymerisation proceeds, so that viscosity measurements with a constant rate of shear (as in Ref.60) may give points corresponding to different regions of the flow curve of the reaction mass, which makes their comparison ambiguous.

The character of the variation in viscosity depends on the mechanism of polymerisation, since the variation of the two principal factors—the mean molecular mass of the product and the polymer content of the reaction mass—is determined by this mechanism. The physical state of the specimen—whether it remains a solution during polymerisation or whether the system becomes heterogeneous, which very strongly influences the rheological properties—also depends on the nature of the reaction medium. Unfortunately, very little attention has been paid to these question: the few experimental results are qualitative in character and are in no way linked with the mechanism or the kinetics of polymerisation, although simple semi-quantitative considerations clearly indicate that the kinetics of polymerisation play a decisive part in the variation of the viscosity[62].

If polymerisation has a radical mechanism, the initial mean degree of polymerisation remains constant during a fairly lengthy initial stage[63], while the yield of polymer increases linearly with time. In terms of the governing parameters this implies that the initial stage consists in a temporally linear increase in concentration of polymer in solution. Hence the expected character of the variation in viscosity can be indicated, provided that the concentration dependence of the viscosity of solutions of specific composition is known. Experimental results make possible such an analysis, which has recently been made and has confirmed the validity of the suggested theoretical approach[64]. A more complete scheme of radical polymerisation must take into account the time variation of the mean molecular mass, which depends on the relation between reactions of chain growth and transfer. In any case, however, a detailed kinetic scheme of a specific radical polymerisation together with the constants of the elementary reactions provides sufficient basis for assessing the way in which the viscosity changes during polymerisation. Nevertheless, such an approach is valid as far as the gel point, which also can be detected by rheological methods and is associated with certain peculiarities in the viscosity properties of the reaction mass[65] or with change in the free volume as a factor determining the rheological properties of the polymerising system[66].

Another kinetic scheme, involving an ionic mechanism of polymerisation[67-69], is most simply represented by chain growth at a certain number of active centres, whose concentration A remains unchanged during the reaction, while chain termination is excluded. If the degree of conversion determined from the change in concentration of functional groups is β, the mean molecular mass of the resulting polymer is at some time proportional to the ratio β/A, while the concentration of polymer in solution is proportional to β. Thus both the molecular mass and the polymer content of the solution change, in contrast to the preceding case. This situation becomes substantially more complicated if the polymer separates from solution, which, of course, affects the rate of increase of viscosity[69].

Finally, in a specific kinetic scheme based on chain growth by a polycondensation mechanism all molecules are simultaneously involved in the increase in molecular mass, and the degree of conversion β corresponds to the mean degree of polymerisation $(1-\beta)^{-1}$, but the polymer concentration in solution during polycondensation is constant at unity. This implies that the course of changes in the governing parameters is significantly different during polycondensation than during radical or ionic polymerisation.

Dependence	Radical mechanism	Ionic mechanism	Polycondensation
$\bar{P}(\beta)$	1	β	$(1-\beta)^{-1}$
$c(\beta)$	β	β	1
$\eta(\beta)$	β^b	β^{a+b}	$(1-\beta)^a$

Thus the effects on variation in viscosity η of different types of dependence of mean degree of polymerisation $\bar{P}$ and concentration c on degree of conversion β is determined by the type of function $\eta(c,\bar{P})$. If it is assumed for illustration[1,18] that $\eta \propto \bar{P}^a c^b$ (where a and b are constants), the above effects of the mechanism of polymerisation on variation in viscosity can be summarised as in the Table. Although the degree of conversion β is the sole governing parameter in all cases, the character of the function $\eta(\beta)$ varies substantially depending on the mechanisms of formation of the polymer.

The above simple schemes of growth in viscosity during polymerisation apply to isothermal conditions. Non-isothermal phenomena during polymerisation exert a significant influence on changes in rheological properties, and may lead to completely novel non-trivial effects (a detailed survey of related problems has appeared[70,71]). Some of these cases, e.g. the changes in viscosity during adiabatic polymerisation, can be described quantitatively[62]. To obtain a more general description requires a very large body of calculations, which can be justified by the fundamental interest of the problem and for applied purposes. However, it is important that in all cases such calculations should be based on detailed knowledge of the kinetics of polymerisation, and also on establishment of the way in which viscosity depends on the molecular mass of the polymer and the content in the solution, for specific cases of theoretical or technical interest.

IV. VULCANISATION OF ELASTOMERS AND HARDENING OF THERMOSETTING PLASTICS

Elastomers and thermosetting plastics are both able to react to form a three-dimensional network of chemical bonds, with conversion from a liquid to a non-fluid and infusible material. It is this transition, in which all the rheological properties change within wide limits, that we shall discuss here. The most characteristic changes consist in an increase in viscosity to "infinitely" high values, an extremal change in hyperelastic properties at a stage preceding formation of a continuous three-dimensional network of chemical bonds[72,73], and ultimately the appearance of an equilibrium modulus characteristic of non-fluid systems. The components of the dynamic modulus of elasticity also change. Such changes are strongest at low frequencies, since the development of properties then involves movement of the macromolecular chain as a whole or of quite long segments. Formation of cross-links, however, hinders movement of the chain more strongly the larger the portion of it is involved in the elementary act of relaxation.

The great changes in rheological properties of oligomers during hardening or of rubbers during vulcanisation have formed the basis of various industrial methods for monitoring structural transformations by measuring the rheological (or mechanical) characteristics of the material. Among them the best known and quite widely used are methods for monitoring the vulcanisation of rubber mixtures using various designs of Vulcameter, Curometer, etc., as well as dozens of industrially produced and standardised, and also home-made, devices employing the most diverse types of loading. The initial stages of vulcanisation are usually monitored viscosimetrically, but the continuation of vulcanisation (hardening) after formation of the three-dimensional network of chemical bonds is recorded by dynamic methods. The chief experimental methods and modes of treatment of the results applied to rubbers and rubber mixtures for this purpose were summarised in a monograph[32].

The further efforts of investigators in this field are now directed at standardising test conditions and procedures as strictly as possible, achieving reproducible comparative results, and establishing correlations between characteristic points in relations obtained in different types of apparatus and technical indices of the moulded articles. In the immediate future we must even expect strengthening of the requirements for the standardisation of conditions of measurement together with automation of instruments used in industrial practice.

Study of the rheological changes accompanying the hardening of oligomers is in a somewhat different position. The specific nature of problems arising here is most conveniently illustrated by the example of epoxy-resins, whose hardening has been studied by means of the whole set of existing rheological methods. Hardeners of amine type have been used in most of this work.

Investigation of the initial stages of this process requires primarily the determination of viscosity—temperature—time ($\eta-T-t$) characteristics for multicomponent materials having various compositions[74-81]. A constant-temperature cross-section of such a characteristic can be represented schematically by the graph in Fig.3. The greatest interest attaches to assessment of the positions of two points: the time t_0 defines the "viability" of the oligomer, i.e. the duration of the low-viscosity liquid state; and the time t^* corresponds to the attainment of a certain high viscosity, which in practice is defined as "gelation", i.e. the point at which fluidity is lost, although the polymer actually remains fluid for some time longer. The gelation point is determined by the accepted arbitrary technical methods and corresponds[74] to a very narrow viscosity range (~1200–1400 P). This result gives a quantitative basis for the technical estimates of t^* adopted in practice, which is important when considering non-isothermal hardening schedules for thermosetting resins. Nevertheless, this viscosity criterion is fairly arbitrary, for the mouldability of compositions based on epoxy resins is determined[75] by a viscosity of only 500 P, as was demonstrated for many systems differing in composition.

It is important to observe that in general there is no correlation between t_0 and t^*. Consequently the "viability" of a material is still an inadequate indication of its technical possibilities, and the ability to be moulded may be retained for a long time (between t_0 and t^*) if the increase in viscosity during this period is not very rapid. Therefore the complete time dependence of viscosity $\eta(t)$ must be used to assess the technical properties of compositions.

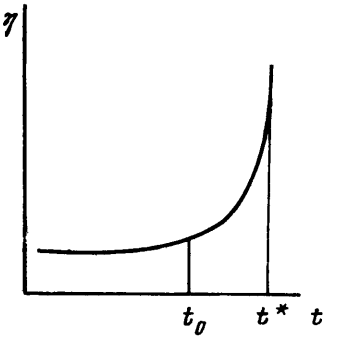

Figure 3. Assessment of critical points—"viability" and "gelation" times—in the hardening of oligomers.

The graph in Fig.3 can be expressed analytically in various ways depending on the specific hardening reactions of actual oligomers. Often this relation is clearly described by means of an exponential function:

$$\eta=\eta_0\exp(kt), \qquad (2)$$

where η_0 is the initial viscosity and k the kinetic parameter of hardening, both of which depend on the temperature. An exponential time variation of viscosity usually "works" quite well in the initial range, but not as far as the gelation point, for the increase in viscosity accelerates as this point is approached. More complicated $\eta-t$ relations have also been suggested[78,79] which take into account the very sharp increase in viscosity in the hardening of epoxy resins.

The hardening of oligomers often takes place under non-isothermal conditions. It is therefore important to generalise formula (2), so that complete $\eta-T-t$ hardening characteristics can be obtained. For this purpose the temperature dependence of η_0 is expressed in the usual way:

$$\eta_0=\eta_\infty\exp(E_\eta/RT), \qquad (3)$$

where E_η is the activation energy of viscous flow and η_∞ a constant. The temperature dependence of the rate constant

k is described similarly, but with a different activation energy E_k, of hardening:

$$k=k_\infty \exp(E_k/RT). \quad (4)$$

Then

$$\ln\eta=\ln\eta_\infty+E_\eta/RT+tk_\infty\exp(E_k/RT). \quad (5)$$

Direct measurements have shown[74] that $E_k \approx 200$ kcal mole^{-1} for the hardening of epoxy resins with amine hardeners, while E_η varies with the composition of the materials from 22 to 41 kcal mole^{-1}. Both η_∞ and k_∞ are also strongly dependent on composition.

Formula (5) can be used to estimate the gelation time t^* under non-isothermal conditions. This is important technically, since actual hardening processes almost always take place under non-isothermal conditions and go to completion fairly rapidly, so that their direct observation is difficult. The appropriate generalisation is made by replacing kt in Eqn.(2) by the expression

$$\int_0^t k(T)\,dt = k_\infty \int_0^\infty \exp[E_k/RT(t)]\,dt. \quad (6)$$

Then

$$\ln\eta = \ln\eta_\infty + E_\eta/RT + k_\infty \int_0^t \exp[E_k/RT(t)]\,dt. \quad (7)$$

The integral on the right-hand side of (7) is evaluated (for a specified programme of temperature variation) by any numerical method†.

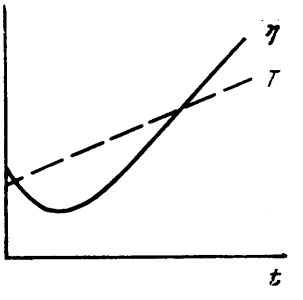

Figure 4. Variation in viscosity during non-isothermal hardening (linear time variation of temperature).

In practice a linear (or almost linear) time variation of temperature of a composition is often achieved. This gives a characteristic extremal variation in viscosity (Fig.4), due to competition, with rise in temperature, between softening (lowering of viscosity) and acceleration of the chemical reaction. Use of the generalised $\eta-T-t$ characteristic in formula (7) enables a correct estimate of the gelation time t^* to be made in this case, and an optimum hardening schedule to be selected by varying the rate of heating.

One factor restricting the possibility of increasing the rate of rise in temperature and thereby accelerating the technical process is the requirement that the temperature gradient across the mass must be lowered in the moulding of large or thick-walled articles. With external heating a uniform temperature field throughout the article cannot be guaranteed, so that hardening takes place non-uniformly, which leads to the appearance of considerable (or even unacceptably high) internal stresses. Therefore the choice of optimum rate of rise in temperature during the hardening of oligomers must take into account the heat-transfer conditions in an article of specific dimensions and the estimated internal stresses arising during heating, chemical reaction, and cooling.

The construction of $\eta-T-t$ characteristics has general value for analysing the non-isothermal hardening of thermosetting resins, compositions based on them, and other rheologically unstable materials undergoing particular chemical changes when heated. The fairly large number of studies of the changes occurring in the rheological properties of oligomers during hardening suggest a single type of behaviour governed by two characteristic indices—the duration of the initial ("induction") perod of slight increase in viscosity and the gelation time.

The possibility of the temperature—time superposition of chemorheological characteristics of polymer materials also has general value. It implies that the generalised time characteristic of the variation in viscosity can be constructed as a function of the product ta_T, where a_T is the temperature dependence of the rate of hardening. Direct measurements have shown[80] that a_T is described in terms of the same activation energy as that characterising the temperature dependence of the viscosity of the oligomer in the initial state. Apparently, however, this is not a universal rule, as has been emphasised above (the dependence of the activation energy of viscous flow on the composition of the hardened material with E_k unchanged during the hardening of epoxy resins by an amine type of hardener). Nevertheless, the possibility of applying temperature—time superposition in those specific cases in which it applies in practice provides an important method for constructing $\eta-T-t$ characteristics and enables technical parameters of a composition to be estimated at temperatures at which direct measurements cannot be made because of the high rates of hardening.

The relation between the activation energies of viscous flow and chemical reaction E_η and E_k is important in the consideration of changes in viscosity during non-isothermal hardening. In general these constants can be regarded as independent, and the general $\eta-T-t$ characteristic described by formula (7) can be used. The postulate that the change in viscosity due to hardening and the role of temperature as a factor controlling the rate of chemical reaction are far stronger than the actual temperature dependence of viscosity at a certain stage of structure formation is apparently legitimate and extremely useful in virtue of the equations it gives[81].

In essence this hypothesis is sufficient for the temperature—time superposition of $\eta-t$ relations obtained at different hardening temperatures. Hence follows in particular the possibility of estimating the activation energy (or the temperature dependence of the rate of chemical reaction in general) from the temperature dependence of the duration of reaction necessary to achieve a specified viscosity. Application of this approach to various thermosetting resins gave positive results. Thus the activation energy of the process characterised by the time variation of the viscosity of a resol agreed with the value found by an independent chemical method[82]. It was shown for epoxy resins that the activation energy of the process leading to the increase in viscosity was independent of the actual viscosity at which the corresponding duration of reaction was compared. The activation energy thus obtained from viscosimetric data was almost identical with the value found from a chemical study of the kinetics of hardening[81].

† The possibility of such an approach has recently been extended also to non-isothermal increase in viscosity of a polyester binder[113].

However, such a simple approach is restricted to the state of viscous flow: on the formation of non-fluid materials the possibility of temperature—time superposition becomes debatable. This is indicated by the differences observed between activation energies calculated from the induction period and from the gelation time[81]. Nevertheless, such differences may be fortuitous, in view of the ambiguity in the assessment of the instant at which fluidity is lost, since this point is actually determined from arbitrary indices.

The complexity involved in characterising the rheological properties of hardening polymer materials is due not only to the need to estimate changes in behaviour of the specimen with time but also to the fact that the test materials (except perhaps during the initial state) exhibit an anomalous viscosity effect, with the departure from Newtonian flow changing with the degree of structure formation. Therefore the problem of describing the flow of hardening polymers is of intrinsic value. The early papers[83,84] used the Bingham model of a viscoplastic medium to represent the viscosity properties of compositions based on phenol—formaldehyde resins. Actually, however, a true fluidity limit is most likely absent from such compositions until a three-dimensional network is formed[85,86], although a definite part may be played by the nature of the filler used, interaction of whose particles may lead to the appearance of solid properties in the compositions[87,88]. In such cases the appearance of a fluidity limit is not directly due to hardening of the oligomer, in contrast to what occurs during structure formation causing the gelation of polymer solutions[89]. Nevertheless, it is not always possible to draw a sharp boundary between these two phenomena.

A high filler content in hardening oligomers, even if it does not tend to form a stable structural network, leads to the boundary-layer slippage characteristic of highly filled compositions when they are forced through moulding channels[90,91]. In actual technical situations and in the laboratory investigations simulating them the dominant role in the hydrodynamic resistance of the channels is played by boundary-layer slippage until high degrees of structure formation are reached. The role of the filler is especially important in the flow of hardening compositions in the region of sharp changes in cross-section of the channel, e.g. in the entry portion of moulding channels[92], where a decisive part is played by the presence of the filler, not by hardening of the oligomer[92,93]. Boundary-layer slippage or rupture of the deformed composition occurs with various flows of highly filled oligomers[94], but this effect is not specific to hardening materials, since completely analogous phenomena are observed in the flow of various polymer materials[4,5,90,91].

The reliability of viscosimetric analysis for kinetic study of the hardening of oligomers largely depends on how far the change in properties of the specimen can be separated from thermal effects due to the exothermic character of hardening. The importance of this factor is clearly indicated by kinetic results for phenol—formaldehyde resins, which enabled their viscosity to be related to the extent of conversion[95,96]. Extrapolation of the results to "zero" specimen thickness proved that the induction period always observed in practice is not a true kinetic effect but is due to delay in the spread of temperature throughout the specimen. It has already been suggested above that the inevitable non-uniformity of the temperature field (and hence degree of conversion throughout the specimen) is a cause of internal stresses. Here another aspect of non-isothermal hardening is emphasised—as a factor complicating kinetic interpretation of the results—so that correct allowance for non-isothermal effects achieved by different methods[97-99] has general value for a whole range of problems associated with the changes in rheological properties of polymer materials undergoing structure formation.

Successive separation of thermal effects from the change in degree of hardening has shown that the increase in viscosity in the initial stages of structure formation in phenol—formaldehyde resins is described by the formula[90,91]

$$\eta=\eta_0(\beta)\exp(E/RT), \tag{8}$$

in which the pre-exponential factor $\eta_0(\beta)$ represents the effect of degree of conversion β on viscosity, while the activation energy $E = 8.22$ kcal mole^{-1} is almost independent of β until a considerable degree of conversion is attained. The maintenance of an unambiguous relation between degree of conversion and viscosity whatever the thermal history of the material is very important, since it enables a single main reaction to be regarded as causing the increase in viscosity. It is also responsible for the possibility of finding generalised $\eta-T-t$ characteristics in the form (7).

A similar approach to describing the degree of conversion attained as the sum of changes occurring with different laws of variation in the temperature of the material is valid also for rubber mixtures[100].

Another important aspect of the rheology of hardening compositions related to the non-isothermal character of flow is the influence of rate of deformation on kinetics of hardening. This problem has been very little studied, and existing data are unreliable just because effects due to the actual increase in rate of deformation and to the consequent evolution of heat (corresponding to the rise in temperature and in the rate of hardening) were not separated. Therefore the shortening of the time during which an oligomeric composition remains plastic, with increase in the flow rate of shear[101-103], may actually be due to non-equivalence of the temperature conditions of deformation. This is indicated also by the marked effect of initial temperature on the development of the effect, which may be associated with the viscosity of the oligomer: the higher the temperature the lower the initial viscosity of the reaction mass, and hence the smaller the evolution of heat at comparable rates of deformation and the weaker the influence of flow on the reaction kinetics. Therefore the influence of deformation on the course of the hardening of oligomers remains an open question.

It is very tempting to simplify the description of processes occurring in the initial stages of the hardening of oligomers by using a single parameter, e.g. the degree of conversion. This is possible if any leading mechanism of chemical changes in the reaction mass can be distinguished. Viscosity measurements during the formation of polyurethane are significant in this respect, when the precise meaning of the reaction mechanisms enabled the viscosity to be related to the molecular characteristics of the product at various stages of polycondensation[104].

Kinetic study of the hardening of oligomers by viscosimetry is mainly of value for the initial stages, which in practice correspond to preparation of the composition or decomposition of a hardening layer on a reinforcing material. Subsequent stages extending as far as the final article can conveniently and fruitfully be observed by a dynamic method, by measuring the time variation of the modulus of elasticity G and the mechanical loss angle $\tan\delta$.[105]

The most general picture of the variation in dynamic characteristics during hardening has been obtained with epoxy resins. It is shown diagrammatically in Fig. 5,[106] where the upper continuous curves represent the variation in the glass

point T_{gl} during vitrification, and t_{gl} is the length of the hardening period necessary to reach the region of vitrification. Analogous results (but not so complete) conforming to this pattern have been obtained by other workers[107,108]. In order to understand the results of rheological investigations on this process it is fundamentally important that we establish the relationship between three temperatures—that of the experiment T, the glass point of the unhardened composition T_{gl}, and the glass point of the final product $T_{gl,\infty}$—bearing in mind that achievement of maximum loss than δ corresponds to the relaxation transition point.

We may suppose, for example, that condtions of vitrification are attained before the gelation point (i.e. at $T < T_{gl}$). Maximum tan δ then corresponds to some degree of structure formation, and an already vitrified polymer will undergo only a slight decrease in tan δ as the process continues. Another case corresponds to the condition $T_{gl} < T < T_{gl,\infty}$, when two loss maxima are observed: the first occurs at the gelation point, i.e. on transtion from a fluid to a hyperelastic state, and the second at the glass point, i.e. the main relaxation transition. Finally, in the third case, with $T > T_{gl,\infty}$, gelation conditions are reached very rapidly (because of the high temperature), but vitrification does not take place: i.e. the material is in a hyperelastic state the whole time. This extremely informative view of the changes in dynamic properties of a composition is generally valid for the hardening of oligomeric resins. Important technical recommendations for two parameters—gelation time t_0 and vitrification time t_{gl}, the latter close to the time at which hardening is complete—can be obtained from this scheme. Taking Fig.5 to represent a model of the process, we can analyse the specific features of the hardening of various materials.

The fertility of applying a dynamic method to analyse the concluding stages in the formation of a rigid polymer has been demonstrated in estimating the degree of cyclisation when a polyester–amide film is heated to give a polyimide[109]. Measurements of the time dependence of the dynamic modulus of elasticity can usefully be employed for studying the induction period, the duration, and the completion of the linear and three-dimensional copolymerisation of organosiloxane monomers[110]. Interest attaches also to a recently developed method for analysing chemical changes in solid polymers by introducing a reactive component into the matrix of a heat-resistant rigid polymer: occurrence of a chemical reaction in the material, including intrachain processes, can be assessed from the variation in dynamic mechanical properties (loss angle and elastic modulus)[111,112].

The above results clearly show the possibility and the value of a dynamic method for investigating chemical processes in structure-forming oligomers and monomers. Therefore this method is readily used to monitor various real technical processes: for example, it has been proposed[113] to employ measurements of dynamic properties in the acoustic frequency range to monitor the completion of hardening in articles made from thermosetting resins and glassfibre-reinforced laminates based on them. A qualitative similarity was found[113] in the changes in acoustic (i.e. ultimately elastic) properties of binder and laminate. Although the type of time dependence of the measured signal varies, the positions of characteristic points corresponding to formation of a three-dimensional structure in the polymer and to completion of hardening almost coincide for polymer and composition based on it. Therefore use of a dynamic (e.g. acoustic) method will permit non-destructive monitoring of the concluding stage in the hardening of the polymeric binder in glass laminates. Such a method has been successfully used also to monitor foaming and subsequent hardening of polyurethane foam plastics[114].

A dynamic (or vibrational) method can also be used to monitor the vulcanisation of rubber mixtures, especially the hardening of liquid rubbers[115], when a complete change in modulus of elasticity can be observed, from low values corresponding to the liquid state right up to values in the region of the hyperelasticity plateau. However, a dynamic method will give entirely reliable results even for ordinary highly viscous rubber mixtures. This has permitted standardisation of a dynamic method for monitoring the vulcanisation of rubber mixtures (ASTM 2704–2706 in the USA), and a good correlation was shown[116] between values obtained by this method and by the customary but more inconvenient and less sensitive and reliable Mooney measurement of coefficients of viscosity.

Dynamic effects on the test material involved in non-destructive monitoring methods do not themselves in any way affect the kinetics. However, this does not limit the possibilities and prospects of applying dynamic (or vibrational) effects on structure-forming compositions, in particular thermosetting plastics. In fact, with increase in amplitude of deformation and transition to so called "large" amplitudes

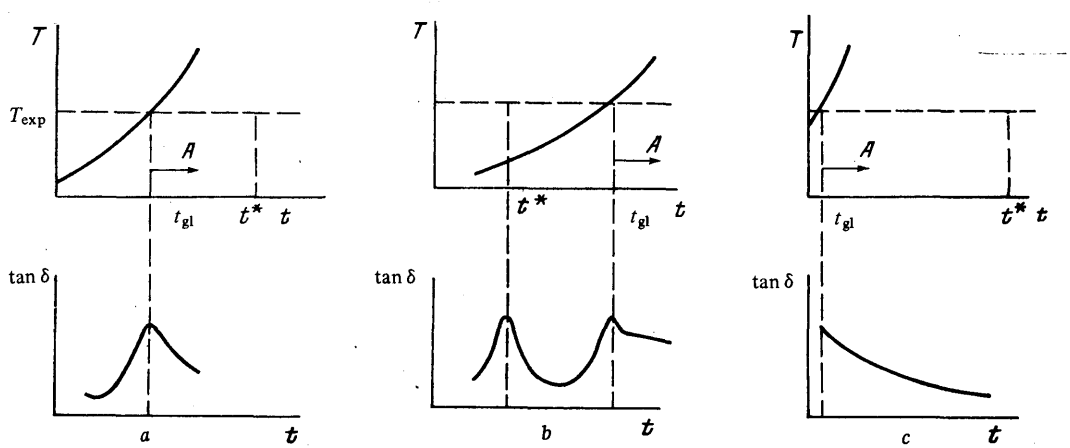

Figure 5. Variation in dynamic properties during hardening for different relations between experimental temperature and glass point: *a*) $T_{exp} < T_{gl}$; *b*) $T_{gl} < T_{exp} < T_{gl,\infty}$; *c*) $T_{exp} > T_{gl,\infty}$; *A*) the arrow indicates the region of the vitreous state of the material.

(in contrast to the "infinitesimal" amplitudes used for non-destructive measurements) vibrational effects become an efficient means of influencing the kinetics of chemical processes. This has been clearly demonstrated on the same epoxy resin[117]: increasing the amplitude of deformation led to a sharp fall in elastic modulus and to a delay in hardening, but the final state of the polymer subjected to vibration was characterised by a higher modulus. Cyclic deformation with large amplitudes presumably delays formation of a three-dimensional network of chemical bonds and intensified hardening.

Unfortunately the paper[117] gives only limited information on this interesting and promising aspect of the reality of structure-forming polymer systems. There is thus no basis at present for discussing how general is the significance of these facts. Undoubtedly, however, the use of large-amplitude dynamic effects can give important new information on the behaviour of polymer compositions during hardening and is of definite technical interest for controlling the rate of hardening and the properties of the end-products.

V. GELATION

Gelation is intermediate between polymerisation in solution and vulcanisation with respect to the accompanying change in rheological properties. The initial stages actually involve an increase in viscosity owing to chemical interactions of a limited number of macromolecules, which results in an increase in molecular mass of individual chain structures. Then a single three-dimensional network appears, which contains a considerable proportion of the initial chains, while the remaining solvent acts as a plasticiser of the rubberlike structure[118,119]. In the light of the above rheological approach, therefore, gelation involves conversion of a relatively low-viscosity liquid into a viscoelastic medium incapable of flow, regardless of the actual mechanism of gelation, which may be associated not only with chemical reactions but also with physical transitions (e.g. formation of microcrystalline regions).

The variation in viscosity during gelation has quite long been regarded as an extremely sensitive indication of the course of the process. Moreover, a rapid increase in viscosity with time has been interpreted as a criterion of conversion of the solution into a gel. Quite frequently, indeed, e.g. for ethanolic solutions the cellulose nitrate[120] or for aqueous polyacrylic acid[121], the variation in viscosity is extremely simple: a prolonged stable state or slight growth in viscosity is replaced by a very rapid fall in fluidity. The length of the induction period depends on the temperature, but the whole observed pattern of change in viscosity resembles so strikingly the kinetics of crystallisation of a polymer from solution that it can be regarded as indirect evidence of gel formation by a mechanism of crystallisation. More complicated cases of growth in viscosity with time are known, when the rate of change decreases[122].

However, known examples of increase in viscosity during gelation are partial in character, while possible ambiguity of results and interpretations based on viscosity measurements is due to ambiguity in the very concept of "viscosity" for non-Newtonian polymer solutions. The actual pattern of variation of viscosity properties during transition of a solution into a gel is substantially more complicated. As has been shown for gelling solutions of a polysulphonamide in dimethylacetamide[89], the way in which viscosity varies with time depends markedly on the conditions under which the measurements are made (Fig. 6): at high rates of shear the viscosity increases only slightly for a long time, and gives hardly any indication of the occurrence of gelation. Yet the possibility of gel formation may already have been established, if the clearest criterion of gelation—a yield point in a homogeneous system—has appeared. And then, if measurements are made at low rates of shear, a clear structure-formation effect is observed.

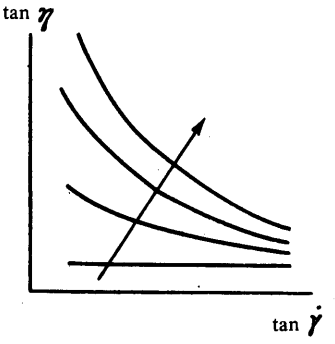

Figure 6. Variation in dependence of viscosity on rate of shear $\dot{\gamma}$ during gelation. The arrow shows the direction of increase in duration of the process.

Here we must emphasise the difference between the "state" and the "behaviour" of a material. In general this difference is well known for polymers: thus a polymer in a hyperelastic state may behave as a glass, but a melt as a rubber[2], which is a direct consequence of the relaxation mechanism of polymer deformation. The same applies to the solution—gel case. The existence of a yield point should in general be regarded as a criterion of a gel[89,119]. However, the appearance of a yield point (or a limiting shear stress) can have various causes. Thus in dispersions with a polymeric binder a solid filler may form a structure that undergoes brittle fracture at some critical stress[123]. A still closer approach to gels is made by liquid-crystalline polymer solutions, in which a well defined though not very high yield point is observed[124-126].

The borderline between jellies and other systems having a yield point is fairly arbitrary. But in any case the states of a system below and above the yield point must be distinguished. In this sense it is more correct to speak, not of the "state" of solution or gel, but of behaviour equivalent to "solution" or "gel" behaviour. However, even the transition between "fluid" and "non-fluid" states may be blurred if breakdown of the structural network formed by macromolecules takes time, i.e. if this network possesses durability[127].

From the rheological point of view transition to the gelatinous state is complete when the yield point, which increases during gelation, becomes equal to the tensile strength of the material, so that the possibility of transition to a fluid state has completely disappeared[89].

Gelation is characterised by the appearance not only of a yield point but also of a set of thixotropic properties, which in the early stages of gel formation are studied by the same rheological methods of rotational rheometry[128] as are thixotropic changes in polymer melts and solutions[129]. At the stage of formation of a three-dimensional structure the thixotropic properties of gels are observed by dynamic methods—from the time variation of the modulus of elasticity[130].

Furthermore, deformation may itself affect the rate of gelation[131], so that the introduction of shear in the measurement of viscosity is an active factor influencing the kinetics. Therefore viscosity measurements, especially if they are approached without sufficiently thorough analysis, are insufficient to assess the changes accompanying gelation. Additional information may, of course, be obtained by measuring the hyperelasticity or the viscoelastic properties of the material, which also change on formation of a jelly. But it is also relevant that in some cases rheological methods may be relatively insensitive to structural changes.

An investigation of gelation in gelatin solutions[132] has given results that are significant in this connection. Spectroscopic observation showed that, in the initial stage of structure formation, changes in intensity of several bands occured for ~6 h, indicating the occurrence of chemical reactions. These changes are entirely susceptible to the usual kinetic interpretation: they are described by a first-order equation with rate constant 0.01 min^{-1}. The viscosity, however, remains almost unchanged during this period, and increases significantly only after 9—10 h, a considerable time after completion of the chemical changes observed spectroscopically. Thus macroscopic changes (apparent in an increase in viscosity) do not necessarily follow all the microscopic processes. In the present case spectroscopic observations enable nucleation within individual molecules to be followed, whereas the viscosimetric method indicates the combined effects of intermolecular interactions—the formation of spiral multimolecular structures.

In concluding this discussion of jellies as systems undergoing changes in rheological properties during formation it must be emphasised that, despite the huge literature (a 1974 review[104] contains 399 references), very few systematic quantitative investigations of rheological changes in a system during gelation have been made, and available information is restricted to a number of particular examples.

---oOo---

This Review of published experimental facts and theoretical aspects of the changes in rheological properties accompanying polymerisation and the reactions of polymers and compositions based on them shows that the variation in all the rheological indices is regularly linked with the molecular characteristics of the polymer. This opens up wide possibilities for the use of rheological measurements for monitoring and controlling technical processes in the production of polymer materials and chemical stages in the moulding of articles (hardening, vulcanisation, etc.).

Until now this important and promising field has not received due development. The reasons are inadequate study of the relations between rheological characteristics and molecular parameters of specific and diverse materials, little attention paid to several fundamental problems, in particular the influence of rate of deformation on the kinetics of chemical processes, the absence or inadequacy of experimental technique, especially in controlling the technical process, and the absence of a general theoretical approach to the design of reaction vessels in which properties of the medium change significantly (in many cases even radically). Solving these problems will permit effective utilisation of rheological methods in the production and processing of polymer materials.

Surface Electrical Characteristics of Disperse Systems Containing Polymers

A.A.Baran and B.E.Platonov

Studies of the effect of the adsorption of non-ionogenic polymers from aqueous solution on the surface charge density, electrokinetic potential, and surface conductance of dispersed particles are summarised, and theoretical ideas on the mechanism of the effect are examined. Methods for calculating the parameters of adsorbed layers of polymers from surface electrical measurements are described and analysed. A list of 84 references is included.

I. INTRODUCTION

The interest in disperse systems containing polymers, displayed during recent years by research workers in various countries, is due to the important part played by such systems in various branches of modern industry. Water-soluble polymers are finding ever wider application as effective flocculants and stabilisers, binders and plasticisers, structure-regulating agents. Yet the mechanism of the influence of macromolecular compounds on various properties of disperse systems has been by no means fully studied, while theoretical principles for the selection and application of polymers for the above purposes are at an early stage of development.

It is generally known that the fundamental process largely determining the behaviour of disperse systems containing additions of polymers is adsorption interaction of macromolecules with the particle surface of the dispersed phase. Therefore investigation of the adsorption and the structure of adsorbed layers of polymers will help to reveal the mechanisms of the influence of macromolecular substances on various properties of dispersions, in particular the stability of their state of aggregation.

At least three main parameters—(*a*) the total adsorption, (*b*) the number or proportion of chain units in contact with the adsorbent surface, and (*c*) the density distribution of units normal to the surface or, as a first approximation, the thickness of the adsorbed layer—must be known for a description of the structure of an adsorbed layer of a macromolecular compound[1]. Usually no difficulty arises in determining the first of these parameters, but special methods are required to find the other two.

Macromolecules adsorbed on a heteropolar surface may influence substantially the structure of the electrical double layer; and potentials and charges on the latter in turn affect the conformational state of the macromolecules. Lyklema[2] has postulated that modification of the dense region of the double layer is due to the adsorption only of monomer units in direct contact with the surface, whereas changes in the diffuse region are caused by segments of adsorbed macromolecules extending into the solution as loops and spikes. Fig.1 gives a schematic picture of the adsorption of polymer macromolecules on a heteropolar interface[2]. It undoubtedly represents only a first, extremely crude approximation, but nevertheless enables the position to be understood. Lyklema's division of "spheres of influence" is also arbitrary, since changes in structure of the two regions of the double layer are interrelated.

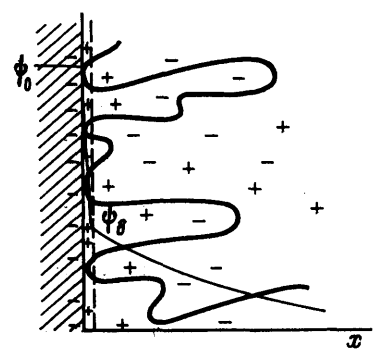

Figure 1. Diagrammatic representation of macromolecule adsorbed on a heteropolar interface, together with the variation in the ψ_0 and ψ_δ potentials with distance x from surface[2,12].

The fact that the adsorption of polymers affects the structure of the electrical double layer makes it theoretically possible to study the structure of adsorbed polymer layers by a combined investigation of the surface electrical characteristics of dispersed particles. Such investigations have been made by electrochemists at a mercury electrode, and a bibliography on this topic can be found in Ref.2,

but for disperse systems this method is novel and promising. Formation of an adsorbed layer of a macromolecular compound leads to a change in several surface electrical characteristics—surface potential and differential capacitance of the double layer, potential of the Stern layer, and the dielectric constant of the surface layer of solution—but the influence of the adsorption of polymers is usually studied on those parameters of the double layer that are susceptible to experimental determination, i.e. the surface charge density σ, the electrokinetic potential (ζ-potential), and recently the conductivity of dispersions. The present Review summarises results largely of studies on systems containing non-ionogenic water-soluble polymers. The general laws of the adsorption of polymers and the structure of the electrical double layer have been discussed in greater detail in monographs[3-5] and in textbooks of colloid chemistry.

II. EFFECT OF ADSORPTION OF POLYMERS ON SURFACE CHARGE DENSITY

The surface charge density of dispersed particles is often determined by potentiometric titration or radiometry (by means of radioactive tracers), which have been described in detail[6-9]. In the case of polymer-containing disperse systems determinations have several peculiarities, which must be taken into account in the interpretation of the effect on surface charge density of the adsorption of macromolecular compounds[1,2].

If polymer macromolecules are adsorbed on particles of a suspension or a sol, there are grounds for supposing that the surface of the dispersed phase accessible to adsorption of macromolecules will differ from the surface available for the adsorption of potential-determining ions. Quantitative aspects of this effect depend on the nature of the dispersed phase and the added polymer, and perhaps on the sequence in which the components are mixed, the concentration of the dispersed particles, and their size. However, in most cases it must be expected that a smaller surface will be accessible to macromolecules than to ions, because the internal surface of narrow pores cannot be reached by macromolecules, and also because of aggregation of particles. The latter factor is responsible for the well known decrease in adsorption of polymers with increase in concentration of the dispersed phase[10,11]. Investigations of the adsorption of polyvinyl alcohol, potential-determining ions, and dyes on particle surfaces in suspensions and sols of silver iodide have shown[1,2,12] that, under otherwise similar conditions, particles of a suspension adsorb a smaller quantity of polymer than do those of a sol, and that in suspensions 35% of the surface is unavailable for polymer adsorption.

It follows from the above that, for dispersions containing added polymers, the observed surface charge density is a composite, "mixed" quantity, somewhere between the value in the absence of an adsorbed layer and the value for portions of the surface modified by adsorption of the polymer. On the assumption that covered and uncovered parts of the surface are independent, we can write[2]

$$\sigma_{av} = f\sigma(\theta) + (1-f)\sigma_0, \qquad (1)$$

where f is the portion of the surface of charge density $\sigma(\theta)$ modified by adsorption, $1-f$ is the portion of unmodified charge density σ_0 and θ is the coverage of the surface by monomer units of adsorbed macromolecules. If f and σ_0 are known, relation (1) can be used to determine $\sigma(\theta)$. Lack of information on the accessibility of the surface to macromolecules may be a source of error in calculations of the parameters of adsorbed layers. Up to the present an aqueous dispersion of silver iodide containing polyvinyl chloride is the only system for which such information has been obtained from systematic investigations[1,2,12].

Another peculiarity is that the observed value σ_{av} is an average parameter, since the adsorption properties are different at different sites on the surface, which leads to inhomogeneity of the adsorbed layer. Combined surface electrical measurements do not yet allow more detailed information to be obtained, but this defect is inherent in most other methods of studying the adsorption of polymers.

The third feature is that the adsorption of compounds of high molecular weight, in contrast to that of the lower surface-active compounds, is in many cases irreversible. Yet the thermodynamics of surface phenomena, which is usually employed for the quantitative interpretation of surface electrical measurements, is applicable only to equilibrium reversible processes. Since the adsorption of polymers at the interface between a solid and a liquid solution depends both on the concentration of the polymer and on the parameters of the electrical double layer, two types of reversibility must be distinguished here—with respect to the concentrations of adsorbate and of potential-determining ions (e.g. pAg for silver iodide and pH for oxides).

The adsorption of macromolecular compounds from solution on colloidal particles is usually irreversible with respect to the adsorbate concentration[2], but it may be reversible (to a considerable degree, if not completely) with respect to the concentration of potential-determining ions, and then the dependence of the parameters of the adsorbed layer on the latter concentration can be subjected to thermodynamic analysis[2]. The degree of reversibility can be inferred from special adsorption experiments and also from certain indirect criteria, e.g. the appearance of hysteresis between σ—pAg or σ—pH curves obtained in the presence of the polymer with increasing and with decreasing concentration of potential-determining ions, and from the presence of a common point of intersection of these curves for different polymer concentrations, which will be discussed below. The actual degree of reversibility depends also on the time factor—on the rate of variation of pAg or pH during the experiment.

Before analysing the experimental results, we shall briefly examine theoretical views on the mechanism by which the adsorption of non-ionogenic water-soluble polymers affects the surface charge density of dispersed particles. This effect is usually due to the combined action of several factors (below).

(*a*) *Variation of χ-potential*[13]. The interphase potential difference $\Delta\phi$ established on contact between particles of a dispersed phase and a liquid solution comprises in general[13] two components: the ionic $\Delta\phi_i$ is due to the presence of an ionic double layer at the interface; and the dipolar χ is caused by the orientation of solvent (water) molecular dipoles in the vicinity of the interface. If adsorption of a polymer is accompanied by orientation of dipolar units of the macromolecules near the adsorbent surface, such orientation will lead to an additional interphase potential difference $\Delta\phi_a$, depending in magnitude and sign on the number and polarity of the monomer units, on the character and the degree of their orientation, and also on the degree of displacement of water molecules from the layer adjacent to the surface. Since for a reversible interface the interphase potential difference is determined unambiguously by the activity of potential-determining ions in the solution[14],

the appearance of $\Delta\phi_a$ will be accompanied by a change in the ionic component $\Delta\phi_i$ and hence† by a change in surface charge density, which may either increase or decrease depending on the relation between the signs of $\Delta\phi_i$ and $\Delta\phi_a$. The change in χ due to $\Delta\phi_a$ has been termed the "adsorption potential difference" and has been successfully invoked to explain several colloid-chemical phenomena[1,2,7,15–20] (see below).

(*b*) *Competition with potential-determining ions.* In each of the above cases the surface charge density varies owing to adsorption (desorption) of some of the potential-determining ions. The displacement of their adsorption equilibrium should be especially marked if they and the adsorbate are adsorbed on the same adsorption centres. The effect is not identical with the "adsorption potential difference", since it is purely statistical and is due to the fact that some of the surface centres suitable for adsorption of the ions are occupied by the adsorbate. Thus, if adsorption of the polymer is due to formation of hydrogen bonds with surface acid-base centres (e.g. hydroxy-groups), the adsorbate may compete with other hydrogen or hydroxide ions depending on the zero-charge point of the oxide and the pH of the solution. At sufficiently low pH, at which a considerable proportion of surface hydroxyls are attached to protons, formation of an adsorption bond is difficult and would be accompanied by displacement of some of the hydrogen ions from the surface. With rise in pH the number of free surface hydroxyls will increase, and competition with hydrogen ions weaken; in this pH range the formation of adsorption bonds with polymer macromolecules is facilitated. Finally, at still higher pH decrease in the total number of undissociated surface hydroxyls will lead to competition with hydroxide ions and will hinder adsorption of the polymer; as a result of competition with potential-determining ions the surface charge density diminishes.

(*c*) *Competition with gegenions in the Stern layer.* If the energies of adsorption of units of a polymer chain and of gegenions in the Stern layer are comparable, adsorption of the polymer may involve displacement of gegenions from this layer into the diffuse region of the double layer. This is equivalent to an increase in thickness of the double layer and, provided that the interphase potential difference is constant, should lead to a decrease in surface charge density, i.e. to desorption of some of the potential-determining ions. This mechanism was suggested[21] to explain the decrease in surface charge density on silver iodide as a result of the adsorption of lower aliphatic alcohols, and then was transferred to the adsorption of polymers[1,16]. The influence of competition in the Stern layer on surface charge density may be expected to depend on the density of charges in this layer and hence on the ionic strength of the solution. Yet good agreement has been observed[1] between results obtained in solutions of high and low ionic strength. On the other hand, the adsorption of heptan-1-ol on silver iodide is accompanied by desorption of potential-determining (and silver and iodide) ions only in the presence of a supporting electrolyte[22]. This suggests that the observed effect is a consequence of competition in the Stern layer, not of competition between alcohol molecules and potential-determining ions, as has been assumed[22]. Furthermore, it is difficult to imagine competition between neutral molecules and these ions, especially for adsorption centres on the surface of an ionic crystal.

(*d*) *Variation in distribution of gegenions in diffuse region of double layer.* Although several investigators of polymer-containing disperse systems have suggested that adsorption of the polymer does not affect the distribution of gegenions in the diffuse region of the double layer[6,17,20,23–25], it can reasonably be assumed that this does not apply at sufficiently high surface coverage. For the adsorption of flexible macromolecules on a surface of constant charge density Brooks[26] suggested a model in which the distribution of gegenions was affected by the excluded volume (this model will be examined in greater detail in Section III,1). Provided that the interphase potential difference is constant, the excluded-volume effect should be accompanied by a decrease in surface charge density.

(*e*) *Variation in dielectric constant of surface layer of liquid.* If the dielectric constants of the adsorbate and of water are different, that of the layer adjacent to the surface will change as it becomes enriched with adsorbed macromolecules, with consequent changes in capacitance of the double layer and, the interphase potential difference remaining constant, in surface charge density (for the diffuse ionic double layer $\sigma \propto \varepsilon^{\frac{1}{2}}$).

The relative contribution by each of the above factors to the total change in surface charge density depends on the nature of adsorbate and adsorbent, on the surface coverage and structure of the adsorbed layer, and also on the concentration of potential-determining ions, the composition, and the ionic strength of the solution. At the zero-charge point, of course, where the ionic double layer is absent, factors (*b*)–(*d*) are inoperative, for they are associated with the effect of the polymer on the structure of this layer. With increase in the ionic strength of the solution factor (*c*) should become stronger, and (*d*) weaker. In addition to the above factors we must consider the possibility that the activity coefficients of the ions may vary in polymer solutions, and also that the adsorption of macroions of pseudopolyelectrolytes, whose formation has been suggested by several workers[27,28] for non-ionogenic polymers in concentrated solutions of salts.

The displacement of the adsorption equilibrium of potential-determining ions on the adsorption of a polymer will lead to a more or less considerable change in their activity in solution, so that a cautious approach must be made to the principle of constancy of the interphase potential difference. Furthermore, the above theoretical analysis suggests that the adsorption of polymers and that of simple surface-active compounds have largely similar effects on the surface charge density.

Most of the experimental work on the effect of the adsorption of polymers on surface charge density has been done on classical hydrophobic dispersions of silver iodide or of metal sulphides, as well as on dispersions of oxides.

Silver iodide

The interface between silver iodide and an aqueous solution is one of the most thoroughly studied by colloid-chemical methods, so that it is not surprising that the effect of the

†It is assumed that, with the exception of the cases specially mentioned, the potential difference between the surface and a point inside a solid phase is constant. Variations in $\Delta\phi_i$ may then be identified with those in the surface potential ψ_0.

adsorption of non-ionogenic water-soluble polymers on the surface charge density of colloidal particles was first investigated precisely on aqueous dispersions of silver iodide. Lyklema and his coworkers[1,2,6,12,29] have used potentiometric titration to study the effect of the adsorption from aqueous solution of several specimens of polyvinyl alcohol, differing in molecular mass and in acetate-group content, on the surface charge density of silver iodide particles. The typical σ–pAg relations illustrated in Fig. 2 show that (i) the adsorption of polyvinyl alcohol diminishes the slope of the curves, (ii) the zero-charge point is displaced to more positive values, and (iii) all the curves pass through a common point of intersection. The effect produced depends on the characteristics of the specimen of polyvinyl alcohol used: it is stronger for a polymer containing 12% of acetate groups than for one containing 2%.

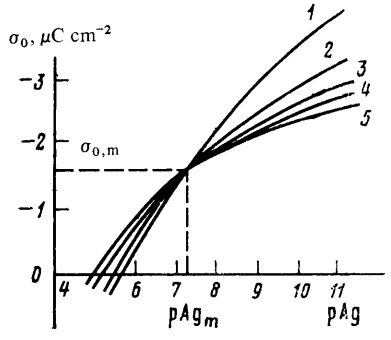

Figure 2. Surface charge density of silver iodide particles in presence of adsorbed pva of mol.wt.106500 in 0.1 M KNO_3 for various quantities of polymer adsorbed[2,12] (mg m^{-2}): *1*) 0; *2*) 0.05; *3*) 0.18; *4*) 0.38; *5*) 0.4.

The decrease in slope of the σ–pAg curves is equivalent to a decrease in the differential capacitance of the double layer, and should be attributed[1] to two main factors—displacement of the originally specifically adsorbed gegenions by monomer units of the polymer, and decrease in the dielectric constant of the layer adjacent to the surface by replacement of water molecules by units of the polymer chain, i.e. the above factors (*c*) and (*e*).

The shift in the zero-charge point may be due to change in the specific adsorption of ions, the activity coefficient of potential-determining ions, or the electrokinetic potential when water dipoles in the surface layer are replaced by the dipoles of polymer units. The last factor probably predominates, since the change in the activity coefficient appears[1] to be negligible, while the specific adsorption of nitrate ions is insignificant at the zero-charge point. The observed shift was explained[1,2,12] in terms of ideas developed earlier[7,15,30] in relation to the adsorption of simple compounds on silver and mercury iodides. The important conclusion was reached that electrochemically the adsorption of polyvinyl alcohol has much in common with that of simple compounds, and that a layer of the polymer adsorbed on the surface of silver iodide can be regarded as comprising 50% of butanol and 50% of ethylene glycol molecules. Such an approach enabled the proportion of occupied sites in the first dense layer of adsorbate to be calculated (see below for greater detail).

A common point of intersection has been observed also in the adsorption of substances of low molecular weight on silver and mercury iodides[7,30]. Examination of the Gibbs adsorption equation shows that the point of intersection then corresponded to the surface charge density at which maximum surface excess of adsorbate relative to water occurred[2,7]. The existence of a common point of intersection of σ–pAg curves in the adsorption of a polymer suggests that the adsorption of monomer units directly in contact with the surface is reversible with respect to pAg, at least if changes in pAg are not too large. At σ_m the maximum number of units are in contact with the surface, and the θ–σ relation, in effect the θ–pAg relation, can be subjected to thermodynamic analysis, even if the total polymer adsorption is irreversible with respect to concentration[2]. The position of σ_m depends on the nature of adsorbate and absorbent and on the composition of the solution[1,2,12]; it is characteristic of the system, independently of the total polymer adsorption. For silver iodide $\sigma_m = -1.6$ and -2.2 μC cm^{-2} in aqueous solutions of polyvinyl alcohols pva-2 and pva-12 with potassium nitrate as inert electrolyte (here and subsequently the numerals denote the contents (%) of unsaponified acetate groups in the polymer)[1,12]. The value obtained for the "50% butanol + 50% ethylene glycol" model was $\sigma_m = -1.7$ μC cm^{-2}, in good agreement with the experimental value for pva-2.[1] The differences observed in the electrochemical behaviour of pva-2 and pva-12 were not explained[1].

The effect of the adsorption of polyvinyl alcohol and another non-ionogenic polymer—polyethylene oxide (peo)—from aqueous solution on the surface charge density of silver iodide has been investigated by a radioactive tracer method[17–19,24,31]. The silver iodide surface was labelled with radioactive iodine-131 by isotopic exchange, and the variation in the adsorption of potential-determining iodide ions was assessed from the radioactivity of the liquid after 24-h contact of the radioactive precipitate with solutions of the polymers varying in molecular mass. The results indicate that under the experimental conditions adsorption of the polymers on a negatively charged precipitate of silver iodide is not accompanied (as in the case of non-ionogenic surface-active agents[32]) by desorption of potential-determining iodide ions.

Ideas on the "adsorption potential difference" were successively applied to explain the influence of the adsorption of polyethylene oxide on the surface charge density and the electrokinetic potential of colloidal precipitates[16–20,33]. It was concluded that, during adsorption on silver iodide particles, $\Delta\phi_a$ and $\Delta\phi_i$ are opposite in sign at negative surface charge densities, and of the same sign at positive values of the latter. Hence dipolar units of adsorbed macromolecules in contact with the surface are oriented with the negative pole (i.e. the oxygen atom) towards the liquid phase, independently of the sign of the surface charge, in agreement with other results[34]. The positive shift in the surface potential of a mercury electrode in solutions of polyethylene oxide has also been explained[35] by the adsorption of oriented dipoles. However, without additional information on the degree of displacement of water from the layer adjacent to the surface and on the polarity of the adsorbate, or on the character of the bond between polymer and surface, the sign of $\Delta\phi_a$ cannot be regarded as evidence of a particular orientation of the adsorbed units.

Antimony sulphide

Results have been published also on the influence of polyvinyl alcohol and polyethylene oxide on the surface charge density of antimony sesquisulphide[17-19,23,24]. Variation in the latter was assessed from that of the total absorption of calcium gegenions from solutions of the chloride or nitrate labelled with calcium-45, at electrolyte concentrations ensuring that the adsorption isotherms of the gegenions reached saturation.

The results of radiometric and adsorption measurements in Table 1 indicate a significant difference between antimony sulphide and silver iodide particles in their surface interaction with polyethylene oxide. With increase in adsorption of the polymer the surface charge density of the sulphide falls to a certain level, after which it remains unchanged. It is significant that this decrease, for a given quantity adsorbed, is independent of the molecular mass of the polymer.

Table 1. Adsorption of peo and Ca^{2+} from aqueous solution on Sb_2S_3 particles[19].

[peo], g litre^{-1}	$M_{peo} = 6000$		$M_{peo} = 1\,300\,000$	
	[peo], mg g^{-1}	[Ca^{2+}], μg-equiv. g^{-1}	[peo], mg g^{-1}	[Ca^{2+}], μg-equiv. g^{-1}
0	0	42.0	0	42.0
0.1	5	38.9	5	38.5
0.3	15	35.8	15	36.4
1.0	—	35.2	38	36.4
2.5	37	35.2	55	36.4

The decrease in the surface charge density of the sulphide accompanying adsorption of polyethylene oxide was regarded[17-19] as indicating that $\Delta\phi_a$ and $\Delta\phi_i$ had the same sign. Since the sulphide surface is negatively charged in water, $\Delta\phi_a$ must have a minus sign. This suggests that the orientation of monomer units is opposite to that on silver iodide, and has the oxygen atom towards the surface[19]. Such orientation may result from hydrogen bonding between oxyethylene oxygen and hydrogen of acidic groups on the sulphide surface, as infrared spectroscopy has established[36] for the aqueous silica-polyethylene oxide system. The decrease in negative values of $\Delta\phi_i$ (and ψ_0) due to such orientation should be accompanied by a decrease in the surface charge density of the antimony sulphide particles, as has been observed. Hence the statement[32] that the orientation of dipolar molecules adsorbed from aqueous solution is independent of the nature of the surface is hardly applicable to the specific interaction of adsorbate molecules with the surface of dispersed particles.

In contrast to polyethylene oxide, pva-2 and pva-12 added to an electrolyte solution up to a polymer concentration of 0.75 g litre^{-1} hardly affect the absorption of calcium genenions[23]: i.e. the surface charge density of antimony sulphide remains unchanged in the presence of adsorbed polyvinyl alcohol. This makes it highly probable that the number of monomer units of adsorbed macromolecules in contact with the sulphide surface is small: i.e. certain qualitative deductions can be made concerning the structure of an adsorbed polymer layer.

Oxides

Though polymer-containing dispersions of inorganic oxides have the greatest practical value among all the systems examined, their study began only during recent years and has been predominantly incidental. The hydrophilic character of oxide surfaces, the presence on them of functional hydroxy-groups, and characteristic structural features of the electrical double layer (the existence of a porous gel-like layer, permeable to potential-determining ions and gegenions, on the surface of certain oxides[37-40]) distinguish oxide dispersions as a special independent group of systems, whose study is of both theoretical and practical interest.

All results published at the present time have been obtained by potentiometric titration of polyvinyl alcohol–oxide systems. Adsorption of the polymer affects neither the position of the zero-charge point nor the surface charge density of haematite[2], gibbsite[41], and amorphous silica (Aerosil)[42]. The explanation for iron(III) and aluminium oxide was[2] that their surface charge was not concentrated at the surface but spread inside the superficial (gel-like) layer of solid, and this region of the electrical double layer was "invisible" to the polymer. In the Reviewers' opinion the reason may be "spreading" of the Stern layer owing to diffusion of gegenions inside the gel, which under the conditions of a potentiometric titration (solution of high ionic strength) should diminish the influence on surface charge density of competition in this layer. Furthermore, the effects of polymer adsorption on surface charge density outlined above may in considerable measure all be levelled off by the redistribution of charges and potentials in the gel-like layer, so that the change in surface charge density represents only an insignificant part, difficult to detect experimentally, of the total change in space charge.

Potentiometric titration of suspensions of Aerosil in the presence of polyvinyl alcohol has been undertaken at both high and low ionic strengths[42,43]. Since a gel-like layer is not present at the surface of Aerosil particles[44], the insensitivity of surface charge density to polymer adsorption is obviously due in this case to the insignificant number of contacts between adsorbed macromolecules and adsorbent surface.

Although potentiometric titration has not given positive results in relation to the adsorption of polyvinyl alcohol on iron(III) and aluminium oxides, the view[2] that this method is inapplicable to polymer-containing oxide dispersions can be accepted only for oxides whose surface is coated with a gel-like layer. But even in this case we cannot speak in advance of the inapplicability of potentiometric titration, since, with adsorbed macromolecules having a sufficiently strong influence on the structure of the electrical double layer, a change in surface charge density might nevertheless be detected. Finally, the surface charge density of zinc oxide is affected significantly by the adsorption of polyvinyl alcohol[45], with displacement of the zero-charge point of the oxide to higher pH. This should be regarded as indirect evidence of absence of a gel-like layer from the surface of zinc oxide, but the results[45] indicate a considerable number of polymer chain units in contact with the surface.

Thus even with dispersions of oxides study of the influence of the adsorption of polymers on surface charge density can give valuable information. Nevertheless, the above survey shows that the range of systems studied by this method is narrow, and further research on these lines is extremely desirable.

III. ADSORPTION OF POLYMERS AND ELECTROKINETIC POTENTIAL OF DISPERSED PARTICLES

The adsorption of polymers may lead to changes not only in surface charge density but also in magnitude and sometimes even sign of the electrokinetic potential. Results obtained in the study of these properties of disperse systems supplement each other.

The combined action of three factors—change in potential of the outer Helmholtz plane ψ_δ, displacement of the plane (more precisely region) of slippage within the liquid phase as a consequence of the formation of a sufficiently thick adsorbed layer on the adsorbent surface, and change in the distribution of gegenions in the diffuse region of the electrical double layer—is able to explain the influence of adsorption of a non-ionogenic polymer on the electrokinetic potential. The first of these obviously predominates at low surface coverage, and the second when adsorption is sufficiently great; the only attempt to use the third factor to explain experimental results is the Brooks model discussed below.

Changes in ψ_δ are in most cases due to corresponding changes in $\Delta\phi_i$, ψ_0, and σ (see footnote in Section II), so that a theoretical interpretation of the influence of polymer adsorption on electrokinetic potential involves discussion of its above effects on surface charge density. This potential may either increase, decrease, or change sign as a consequence of changes in ψ_δ. Displacement of the slippage plane into the solution is accompanied solely by a decrease in the electrokinetic potential and depends on the thickness of the adsorbed layer and the degree of immobilisation of liquid in it. The relative contributions by each of these factors to the resultant change in potential depends on the same characteristics of the system as does the change in surface charge density (Section II), in particular on the quantity of polymer adsorbed, and the structure and thickness of the adsorbed layer. With the exception of quantity adsorbed, direct experimental determination of these characteristics is not possible. Since they are related to such parameters of the system as the concentrations of polymer and potential-determining ions, and the composition and ionic strength of the solution, the immediate task of experimental study of the electrokinetic behaviour of polymer-containing disperse systems is to establish the dependence of the electrokinetic potential on these parameters.

1. Dependence on Polymer Concentration

Electrokinetic results are most often presented as ζ–c curves, where c is the equilibrium or initial polymer concentration. Fig. 3 shows the dependence of the electrokinetic potential of the particles in silver iodide and antimony sulphide sols on the concentrations of added polyvinyl alcohol and polyethylene oxide solutions[24]. Increase in the polymer content of the system is accompanied by a continuous

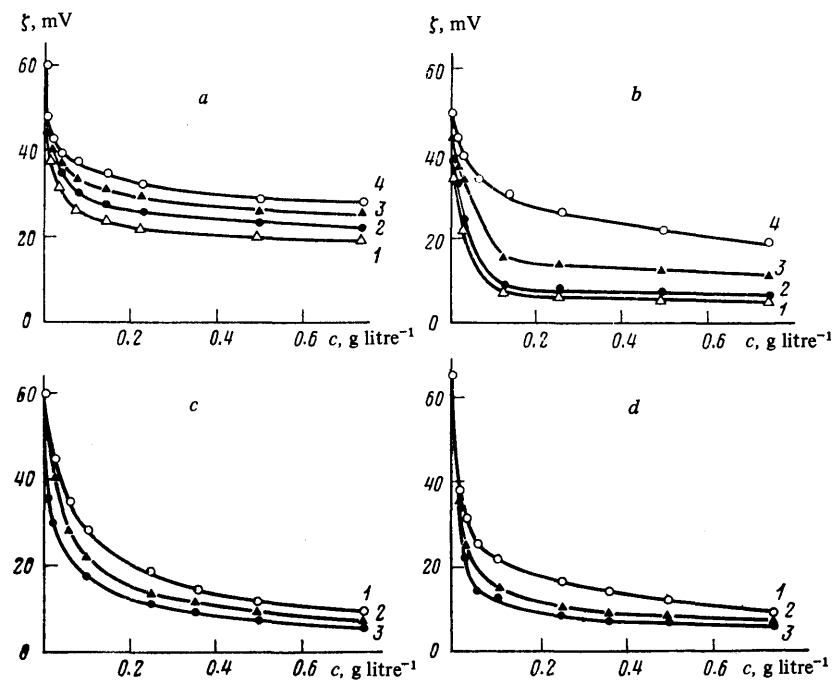

Figure 3. Effects on the electrokinetic potential of sol particles of (*a*) AgI and (*b*) Sb_2S_3 of the addition[24] of polyvinyl alcohols varying in molecular mass (10^{-4} *M*): *1*) pva-12 (2.2); *2*) pva-2 (4.1); *3*) pva-12 (5.9); *4*) pva-18 (6.5); and for (*c*) AgI and (*d*) Sb_2S_3 of the addition of polyethylene oxides (10^{-6} *M*): *1'*) 0.23; *2'*) 1.3; *3'*) 2.6.

decrease in the potential. The main fall usually occurs with small additions of polymer, after which the curves become more gently sloping, with a tendency to emerge on a plateau. Similar curves have been observed in the adsorption of these polymers on silica[16,42], negatively charged precipitates of silver iodide and antimony(III) sulphide[20,24,33], and aluminium oxide[41].

Such variation in the electrokinetic potential indicates the dominant effect of displacement of the slippage plane, some decrease in ψ_δ, or parallel action of the two factors. Since the adsorption of polyethylene oxide and polyvinyl alcohol on silver iodide and of the latter on antimony(III) sulphide particles is not accompanied by decrease in the negative surface charge density (above), the decrease in the negative electrokinetic potentials is due to the dominant effect of displacement of the slippage plane inside the solution. The fall in potential in the antimony sulphide–polyethylene oxide system is due to the combined action of the two factors, since adsorption of this polymer on the sulphide surface leads to some decrease in surface charge density. Finally, the latter remains unchanged during the adsorption of polyvinyl alcohol on silica[42] and gibbsite[41], so that the fall in potential can be attributed solely to the formation of quite thick adsorbed polymer films on these precipitates.

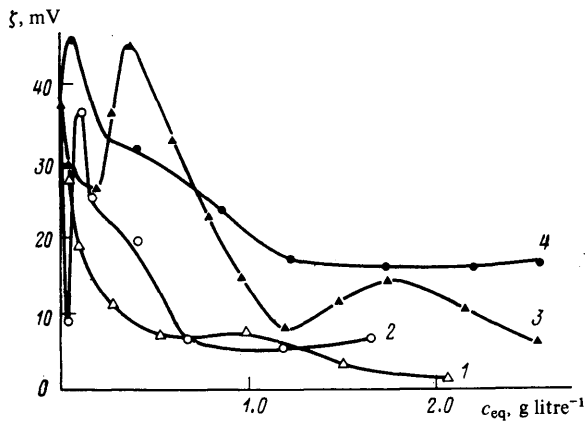

Figure 4. Dependence of electrokinetic potential of zinc oxide particles on equilibrium solution concentration[46] of polyvinyl alcohols (10^{-4} *M*): *1*) pva-12 (5.0); *2*) pva-2 (5.6); *3*) pva-18 (5.9); *4*) pva-18 (9.8).

If the above two factors have opposite effects, while the increase in ψ_δ predominates in a certain polymer concentration range, extrema appear on the ζ–*c* curves. Fig. 4 illustrates this relationship for zinc oxide in aqueous solutions of four specimens of polyvinyl alcohol[46] having different contents of acetate groups. The surface charge density of the oxide becomes more positive in solutions of pva-2 ($M = 56000$),[45] which is equivalent to increases in $\Delta\phi_i$ and ψ_δ for a positively charged surface, and should tend to raise a positive electrokinetic potential. Quantitatively this effect and also the thickness of the adsorbed polymer layer depend on the specimen of polyvinyl alcohol used.

When the increase in ψ_δ is sufficiently large, a maximum appears on the ζ–*c* curves in the corresponding concentration range (curves *2*–*4*). Among all the specimens studied[46] pva-12 gives the greatest adsorption, and forms a thick adsorbed layer even at low concentrations, which leads to a sharp drop in potential (curve *1*) and "masks" the effect of the increase in ψ_δ. Analogous ζ–*c* relations are observed on silica[42], although adsorption of polyvinyl alcohol does not affect the surface charge density[42]. Thus the presence of extrema in the curves should not by itself be regarded as evidence of change in σ, $\Delta\phi_i$, or ψ_0.

The form of the curves depends substantially on the magnitude and sign of the surface charge, i.e. on the concentration of potential-determining ions. Fig. 5 shows ζ–*c* curves for a precipitate of silver iodide in polyethylene oxide solutions with different contents of non-inert electrolytes[18,20,31]. At low polymer concentrations some increase is observed in the electrokinetic potential of a negatively charged surface and a sharp drop in potential of a positively charged precipitate (to zero), change in sign of charge, and rise in potential of opposite sign.

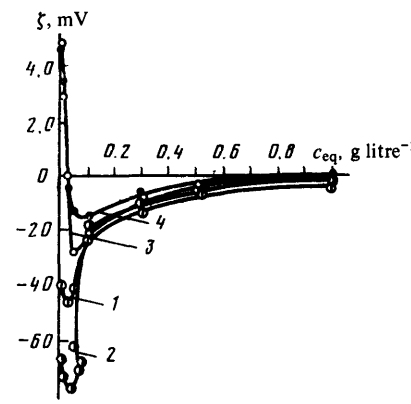

Figure 5. Dependence[17,20] of electrokinetic potential of silver iodide particles on concentration of polyethylene oxide (molecular mass 1.05×10^6) in: *1*) water; *2*) 0.1mM KI; *3*) 0.5mM $AgNO_3$; *4*) 1mM $AgNO_3$.

Change in sign on a positively charged surface of silver iodide in solutions of polyethylene oxide, observed also[34] in the coagulation by electrolytes of silver iodide sols stabilised by this polymer, has been explained[18,20,31] by the establishment of a considerable "adsorption potential difference" when the polymer is adsorbed on silver iodide particles. As noted above, with $\Delta\phi_a$ and $\Delta\phi$ having the same sign, $\Delta\phi_i$ should decrease when $\Delta\phi$ is constant. If the difference $\Delta\phi_a$ is sufficiently large ($\Delta\phi_a > \Delta\phi_i$), its compensation may require change not only in the absolute magnitude but also in the sign of $\Delta\phi_i$, which is evident in electrokinetic measurements as a change in sign of the ζ-potential.

If it is assumed, as for the interface between mercury and aqueous polyethylene oxide[35], that dipolar units of the polymer chain are oriented with their positive poles towards

the hydrophobic surface of silver iodide (independently of the sign of its charge), the sign of $\Delta\phi_a$ will be the same as or opposite to that of $\Delta\phi$ according as the silver iodide particles are positive or negative. This should lead to an increase in negative values of $\Delta\phi_i$, ψ_δ, and hence the electrokinetic potential, as well as a decrease and change in sign of positive $\Delta\phi_i$ and ζ, as is observed experimentally. With increase in concentration of polyethylene oxide the ζ-potential falls, independently of the sign of the particle charge, as a result of formation of a thick adsorbed polymer film and displacement of the slippage plane deep into the solution.

As already noted, we have explained the changes in the electrokinetic potential of hydrophobic silver iodide and antimony sulphide surfaces in aqueous solutions of polyethylene oxide and polyvinyl alcohol mainly[16-18,20,33] in terms of an "adsorption potential difference", since this is the only factor explaining the change in sign of the surface charge accompanying polymer adsorption. Yet changes in ψ_δ and hence the ζ-potential may be due also to competition between dipolar units of adsorbed macromolecules and gegenions in the dense region of the electrical double layer. Since such competition leads to a decrease in surface charge density (above), it may cause decreases in ψ_0, ψ_δ, and ζ. On the other hand, diminution in the charge density of gegenions in the dense region may be accompanied by increases in ψ_δ- and ζ-potentials, even with a general decrease in surface charge density. These ideas have been used to explain the influence of added alcohols on the stability of aqueous dispersions of silver iodide[21], but in published studies of adsorbed layers of macromolecular compounds they receive only casual mention[2].

Although most authors, when analysing electrokinetic measurements regard the interphase potential difference as unchanged for a given activity of potential-determining ions in the solution, attempts have also been made to use a constant-charge model. When studying the electrokinetic potentials of erythrocytes, quartz, and latices in aqueous salt solutions of dextran and polyethylene glycol, Brooks[47,48] observed a rise in this potential with increase in the polymer concentration. He explained and gave a quantitative basis to these results on the hypothesis that the excluded-volume effect arising within the electrical double layer on adsorption of a polymer leads to expansion of the diffuse region of the layer and a rise in the surface potential with the surface charge density unchanged[26]. If the displacement of the slippage plane is not too great, the electrokinetic potential rises also, and this plane may even lie within the adsorbed polymers layer[26]. This model is obviously not generally applicable, since the adsorption of non-ionogenic polymers may be accompanied not only by a rise but also by a sharp drop in the electrokinetic potential, even with little adsorption, when it is difficult to expect significant movement of the slippage plane. Furthermore, other reasons for a rise in electrokinetic potential are possible, although the excluded-volume effect probably also makes a definite contribution. The Brooks theory has been subjected to critical analysis[2].

2. Dependence on Adsorbed Quantity of Polymer

Adsorption and electrokinetic measurements on the same systems will give the dependence of ζ-potential on polymer adsorption, which Fig. 6 illustrates for particles of silver iodide and antimony(III) sulphide sols coated with adsorbed polyvinyl alcohol or polyethylene oxide[24]. In general these

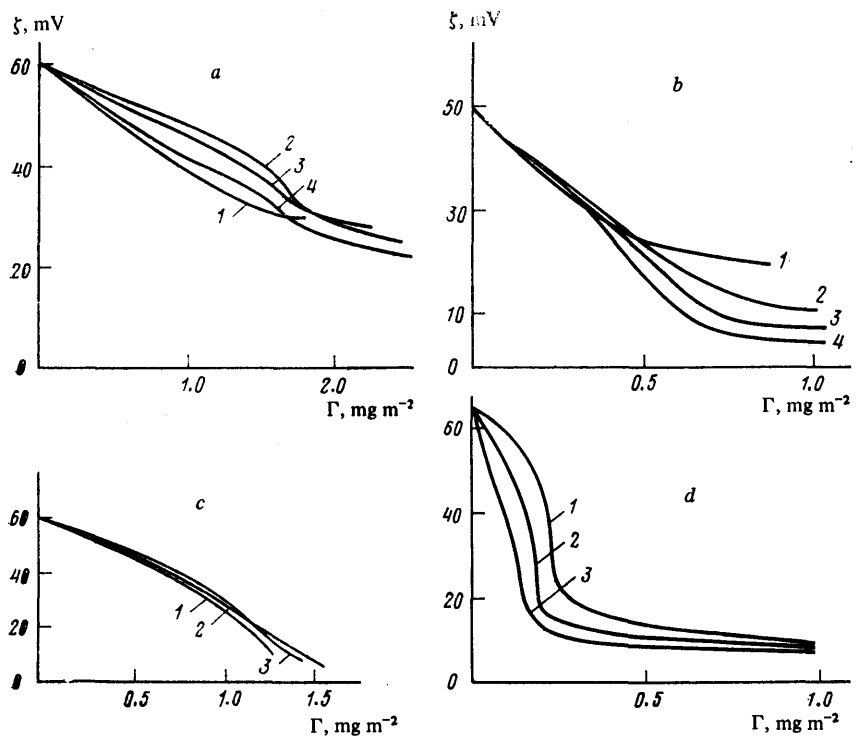

Figure 6. Variation[24] of ζ-potential of sol particles with quantity of adsorbed polymer: *a*) pva on AgI; *b*) pva on Sb_2S_3; *c*) peo on AgI; *d*) peo on Sb_2S_3. Numbering of curves as in Fig. 3.

curves resemble those for the dependence of the potential on the quantity of added polymer (Fig.3), but with the difference that increase in polymer adsorption is accompanied by an initial slow fall in electrokinetic potential followed by a more rapid drop, which is replaced by another gradual decrease, after which in many cases a plateau ensues. Since the fall in ζ-potential on the adsorption of polyvinyl alcohol on silver iodide and antimony sulphide surfaces, and of polyethylene oxide on the former, is due to displacement of the slippage plane from its original position, a ready explanation for the initial slow decrease is that the early portions of the polymer, which form a thin adsorbed layer comparable in thickness with the Stern layer, are unable to produce a significant drop in potential by this mechanism. After the first (dense) layer has been formed, further accumulation of macromolecular compound at the surface of the dispersed phase is due to lengthening of loops and spikes of adsorbed macromolecules, i.e. to thickening of the layer.

If the slippage plane is assumed to have moved to or at least near the boundary of the polymer envelope, the observed sharp drop in electrokinetic potential can reasonably be attributed to formation of the adsorbed layer, a process whose termination is indicated by emergence of the curves on a plateau (Fig.6). The sharper drop in the potential at low surface coverage of the antimony sulphide precipitate with polyethylene oxide[17,18,31] is due to the accompanying decrease in surface charge density. Good correlation has been noted[16] also in the influence of the molecular mass of polyethylene oxide on the electrokinetic potential of quartz immersed in its solutions and on the limiting adsorption of the polymer on Aerosil.

3. Dependence on Concentration of Potential-determining Ions

The influence of the concentration of potential-determining ions on the electrokinetic potential of polymer-containing disperse systems has been studied[1,2,6,12,49], and results obtained for quartz in aqueous solutions of polyethylene oxide are illustrated in Fig.7.[49] This polymer lowers substantially the ζ-potential of quartz in acid and weakly alkaline pH ranges, the decrease at constant pH being little dependent on the polymer concentration, for adsorption saturation of the quartz surface is already reached at low concentrations. With rise in pH above 9.5 the effect of the polymer on the potential diminishes, which is consistent with the decrease in adsorption of the polymer on amorphous silica (Aerosil) with rise in pH.

Such diminished effect suggests competition between hydroxide ions and polyethylene oxide for acidic adsorption centres on the surface, as well as certain conclusions on the nature of the bond between polymer and adsorbent surface. These deductions are supported by infrared spectral results[36], indicating hydrogen bonding between oxygen atoms in the polymer chain and undissociated silanol groups of the silica surface. As a consequence of this competition the pH values of maximum electrokinetic potential shift to a more alkaline range. It is significant that this maximum is about the same for all the curves and is independent of the presence of polyethylene oxide. This was regarded[49] as unambiguous evidence that at pH ≥ 11 the number of vacant undissociated adsorption centres is too small to ensure adsorption of the polymer.

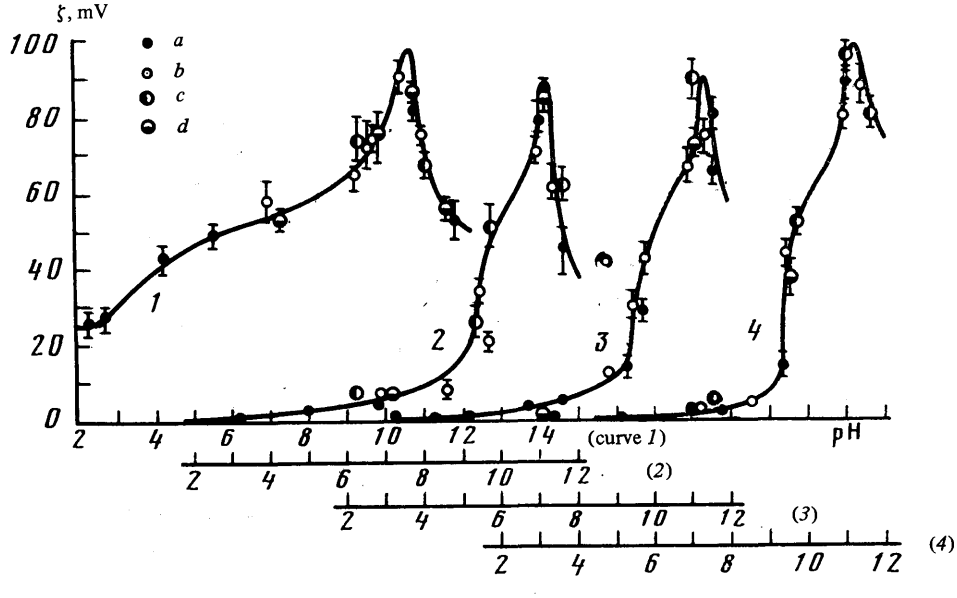

Figure 7. Dependence[49] of ζ-potential of quartz on pH for different concentrations of polyethylene oxide (g litre^{-1}); *1*) 0; *2*) 0.1; *3*) 0.3; *4*) 0.5 in: *a*) HCl; *b*) LiOH; *c*) NaOH; *d*) KOH.

The electrophoretic particle mobility of silver iodide sols in the presence of polyvinyl alcohol has been measured[1,2,6,12] as a function of pAg (Fig.8). Adsorption of the polymer is accompanied by a shift in the isoelectric point to more positive values, decrease in mobility in the region of a plateau, and diminished slope of the curves at this point. The shift in the point has been attributed[1,2,12] to displacement of dipolar water molecules from the surface layer by units of adsorbed macromolecules. The most marked shift in isoelectric point occurs with the initial portions of adsorbed polymer, which complete mainly a compact layer in contact with the particle surface. Subsequent portions are adsorbed predominantly by the lengthening of loops and spikes of adsorbed macromolecules, and the shift gradually reaches saturation. The lowering of the electrokinetic potential in the region of the "plateau" (Fig.8) and the decrease in slope of the curves at the isoelectric point are explained by movement of the slippage plane deep inside the solution on adsorption of the polymer. The shift in the isoelectric point and the diminution in slope have been used[1,2,12] to calculate certain parameters of adsorbed layers of polyvinyl alcohol on the surface of silver iodide particles (Section IV).

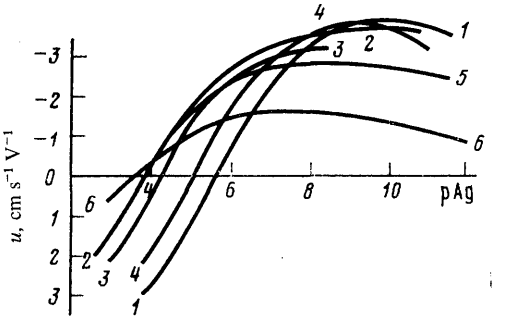

Figure 8. Dependence of electrophoretic mobility of particles of AgI sol in lmM KNO_3 on pAg in presence of different quantities (mg m^{-2}) of adsorbed pva-2 ($M = 106500$): *1*) 0; *2*) 0.12; *3*) 0.37; *4*) 0.50; *5*) 0.75; *6*) 1.00.

4. Dependence on Ionic Strength of Solution

Published information on the influence of ionic strength on the electrokinetic potential of particles in polymer-containing dispersions is extremely limited. Research[43,46,50] has actually been devoted to the effect of added inert electrolytes on the ζ–c relation. The changes observed with increase in ionic strength are explained by the effect of the added electrolyte on the thermodynamic character of the solvent, the quantity of polymer adsorbed, and the structure of adsorbed and electrical double layers. The adsorbed polymer sheath is regarded[51] as becoming increasingly permeable hydrodynamically with increase in the ionic strength of sufficiently concentrated electrolyte solutions, with a consequent displacement of the slippage plane into the adsorbed layer, approaching ever closer to the solid surface.

IV. EFFECT OF ADSORPTION OF POLYMERS ON CONDUCTIVITY OF DISPERSIONS

The electrokinetic charge σ_s usually constitutes only a small fraction of the charge in the outer part of the double layer of colloidal particles. The surface charge is in general balanced not only by the electrokinetic charge but also by gegenions present in the Stern layer and also—in the presence of a hydrodynamically stationary boundary liquid layer[52–54] or a gel-like layer (as on oxide surfaces[37–40])—by a mobile charge located in them. Fridrikhsberg et al.[55,56] showed that the mobility of ions in the stationary liquid boundary layer is closely similar to mobilities in bulk. Hence measurements of surface conductance or dielectric constant at low frequencies, which are sensitive to the ionic concentration throughout the diffuse region of the double layer, may give information on the potential ψ_δ at the boundary of the Stern layer. A quantitative theory of such an approach taking into account polarisation of the double layer has been developed by Dukhin et al.[3,4].

Calculation from measured specific surface conductances κ^σ of ψ_δ-potentials in the presence of adsorbed macromolecules is of interest from several points of view. Firstly such results supplement information, obtained from electrokinetic measurements, on the influence of the adsorption on the structure of the electrical double layer of particles. Secondly they help to reveal the mechanism of the stabilising effect of macromolecular compounds on colloidal solutions, whose stability may be determined under certain conditions, even in the presence of an adsorbed polymer layer, by the repulsion of electrical double layers[57,58]. Thirdly the possibilities of investigating the three-dimensional structure of adsorbed layers of non-ionic macromolecules are considerably increased if study of the electrokinetic potential is paralleled by that of the effect of polymer adsorption on specific surface conductance.

Whereas dozens of studies have been published on the surface conductance of dispersed particles (and have been reviewed[3]), the problem of the effect of adsorbed macromolecules on specific surface conductance has merely been posed. One of the Reviewers[59] has examined the influence of the adsorption of polyethylene oxide and polyvinyl alcohol on the conductivity of suspensions of spherical particles of antimony sulphide and polystyrene latex, as well as rod-shaped particles of the mineral palygorskite. The relative conductivity $\bar{K}/K$ of the suspensions ($\bar{K}$ being the conductivity of the suspension and K that of the dispersion medium) varied linearly with volume fraction p of the solid phase in all cases, the slopes of the straight lines diminishing as the electrolyte concentration in the system increased (Fig.9). This is explained by gradual diminution in the contribution to conductivity of surface conductance owing to the increase in conductivity of the dispersion medium and compression of the electrical double layer. With polarisation of the double layer taken into account the dependence of $\bar{K}/K$ on p for spherical and needle-shaped particles is described[3] by the equations

$$\frac{\bar{K}}{K} = 1 + 3p\left[-\frac{1}{2} + \frac{3}{2}\frac{\mathrm{Rel}}{(1+2\mathrm{Rel})}\right], \qquad (2)$$

$$\frac{\bar{K}}{K} = 1 + p\left[-\frac{5}{3} + \frac{2}{3}\mathrm{Rel}\left(1 + \frac{2}{1+2\mathrm{Rel}}\right)\right], \qquad (3)$$

where

$$\mathrm{Rel} = \varkappa^\sigma / Ka, \qquad (4)$$

is a dimensionless parameter[3,60] representing the contribution

by such polarisation to surface electrical phenomena and a is the particle radius. With high electrolyte concentrations, ensuring a negligible contribution by specific surface conductance, the theoretical limiting negative slopes of the dependence of $\overline{K}/K$ on p are realised experimentally, respectively $-\frac{3}{2}$ and $-\frac{5}{3}$ for spherical and needle-shaped particles—formulae (2) and (3).

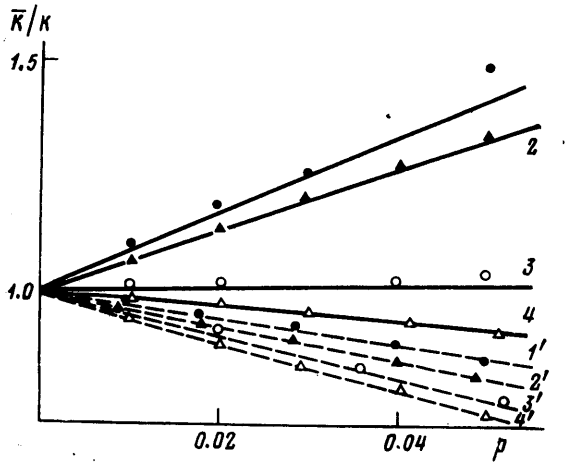

Figure 9. Dependence[59] of relative conductivity of palygorskite suspensions on proportion by volume of solid phase in sodium nitrate solutions of different concentrations (nM): *1*) 0.02; *2*) 0.1; *3*) 0.5; *4*) 5. The primes denote the presence of adsorbed pva-2 of molecular mass 48000.

Adsorption on charged particles of non-ionic polymers leads in all cases (with the electrolyte concentration unchanged) to a diminution in the slope of the relative-conductivity lines, i.e. to a decrease in the conductivity of the dispersion, the effect being larger the greater the quantity of macromolecular compound adsorbed per unit surface (Fig.9). Polymer adsorption may even change the sign of the slope. For example, addition of polyvinyl alcohol (1 mg m^{-2}) to a suspension of antimony(III) sulphide or palygorskite containing 0.01–0.1 M sodium nitrate changes the slope of the dependence of $\overline{K}/K$ on p from positive to negative (Fig.9). Furthermore, adsorption of non-ionogenic polymers gives negative slopes of the straight lines greater in absolute magnitude than would correspond to the limiting theoretical value.

Adsorption measurements[23,61] have shown that under the above experimental conditions all the macromolecular compound introduced into the system is entirely absorbed by the dispersed phase. Therefore surface effects—decrease in cross-section for passage of current in surface layer (which leads to a decrease in κ^σ) and increase in effective particle thickness owing to formation of a thick adsorbed layer—are solely responsible for the observed decrease in $\overline{K}/K$. Both effects cause the parameter Rel to decrease, which theoretically—formulae (2)–(4)—should produce the observed smaller slope of the straight lines. It must be borne in mind that the movement of ions in the adsorbed layer may be hindered not only by monomer units of the macromolecule but also by the few layers of water firmly bound to hydrophilic groups of the polymer, which have lost their solvent power. This view is supported in particular by an investigation by nuclear magnetic resonance of the hydration of polyethylene oxide and polyvinyl alcohol[62,63].

Application of Eqns.(2)–(4) to the results permitted calculation of the specific surface conductance κ^σ and ionic mobility u# within the double layer, as well as their variation in the presence of adsorbed polymer. The calculated values given as example in Table 2 show that increase in polymer adsorption is accompanied by a gradual decrease in κ^σ and u in the double layer, in full agreement with the above qualitative considerations.

Table 2. Effect of adsorption of non-ionic polymers on κ^σ and u of dispersions of palygorskite in 0.1mM $NaNO_3$.[59]

Polymer	10^{-4} M	Γ, mg m^{-2}	$10^9\kappa^\sigma$, ohm^{-1}	u, cm^2 ohm^{-1} g-equiv.$^{-1}$
		—	3.0	5.5
pva-2	4.8	0.3	2.8	5.1
peo	130	0.6	2.2	4.0
pva-23	6.4	0.9	0.9	1.7

The influence of the adsorption of macromolecules on the surface conductance of dispersions has recently been examined theoretically by Dukhin[64] on the view that the structure of the adsorption sheath, like that of a gel[65], can be described by a model of randomly oriented cylinders forming an obstacle to the passage of current. The decrease in the conductivity of a gel K_g relative to that of the electrolyte K is represented[64] by a linear dependence on the volume fraction P_p of the gel (in the present case adsorbed segments of the macromolecule):

$$K_g = K(1 - BP_p). \tag{5}$$

For strongly charged particles ($\tilde{\psi}_\delta = \psi_\delta / kT > 3$–4), provided that change in dielectric constant has little effect on the structure of the double layer, the adsorption P_p of segments diminishes the surface conductance by the factor

$$\beta = \kappa^\sigma(P_p)/\kappa^\sigma(0). \tag{6}$$

The term BP_p can be evaluated from the simplified relation[64]

$$\beta = (1 - BP_p)(1 + 3m)^{-1}, \tag{7}$$

which is valid at high electrolyte concentrations, i.e. when $\kappa h \gg 1$. Here m is a dimensionless parameter representing the contribution to κ^σ by the transport of charges by electro-osmotic flow of the liquid, which can be calculated theoretically, h is the thickness of the adsorbed polymer layer, and κ is the reciprocal of the Debye radius. Thus, by measuring the specific surface conductance in the presence and in the absence of an adsorbed polymer sheath $\kappa^\sigma(p)$ and $\kappa^\sigma(0)$, we can calculate BP_p and then[64] make a choice in favour of a particular dependence of density of adsorbed segments on distance from surface.

More detailed information on the calculation of u will be found in Ref.3.

V. DETERMINATION OF PARAMETERS OF ADSORBED LAYERS OF POLYMERS FROM SURFACE ELECTRICAL MEASUREMENTS

Information on the most important parameters of adsorbed polymer layers—the proportion ν of monomer units in direct contact with the surface, the surface coverage θ by adsorbed units, and the effective thickness h of the adsorbed layer—can be obtained from measurements of surface charge, electrokinetic potential, and surface conductance of particles in the presence of adsorbed macromolecular compounds. Comparison of these parameters with the dimensions of macromolecular coils in solution and with adsorption measurements also leads to definite conclusions on the degree of deformation of macromolecules when adsorbed and on the density distribution of segments along the normal to the surface $\rho(x)$.

Determination of the above characteristics is based on an assumed analogy in structure between the electrical double layer and a surface polymer sheath[1,2,12]. Like the former, which is arbitrarily divided into a dense region (or Stern layer), in which specific interaction takes place between ions and surface, and a diffuse region (Gouy layer) with an exponential fall in concentration of gegenions with distance from the surface, an adsorbed polymer film can be divided into a first (dense) layer of monomer units in direct contact with the surface and a loose layer of spikes and loops directed towards the solution, in which the density of segments gradually diminishes with distance[1]. Many factors—quantity of polymer adsorbed, energy of adsorption of a monomer unit, nature of solvent, flexibility of polymer chain, etc.—determine the nature of the function $\rho(x)$.[5,66-69] The Stern layer and a dense layer of adsorbed units are similar in thickness (~0.4–0.5 nm). Therefore investigation of the former (which is possible in concentrated electrolyte solutions, in which the electrical double layer is strongly compressed) may give information on the parameters of the first layer of units of adsorbed macromolecules, directly attached to the surface. Measurement of the characteristics of the diffuse ionic layer (in dilute electrolyte solutions) gives indications of spikes and loops located beyond the dense layer, the thickness of the adsorbed film, etc.

Determination of Surface Coverage θ

The surface coverage with adsorbed monomer units can be calculated[1,2,6,12,29] from data on the displacement of the zero-charge or isoelectric point as a consequence of adsorption. The basis of the first method, originally developed for the adsorption of organic molecules on a mercury electrode, is that, in the absence of specific adsorption of ions, the shift in the zero-charge point is proportional to the number of adsorbed molecules per unit area[7]:

$$\Delta_{zcp} = \text{const} \cdot n_a. \tag{8}$$

The shift is attributed in this case to displacement of water dipoles from the surface layer by adsorbed molecules of a surface-active substance. Transfer of these ideas to the adsorption of macromolecular compounds encounters several difficulties, which have been analysed in detail by Lyklema et al.[1,2,12] for the example of silver iodide and polyvinyl alcohol solution. The first difficulty is that the thermodynamics of surface phenomena, used to analyse the electrical double layer in the presence of organic compounds, is applicable only to reversible adsorption processes. Although the adsorption of polymers is irreversible with respect to change in their concentration in solution, it may be reversible with respect to change in concentration of potential-determining ions. Furthermore, the requirement of reversibility concerns only a small proportion of the total quantity of monomer per units adsorbed (those in direct contact with the surface), which is apparent on the measurement of surface charge. The second difficulty is the difference in surface area accessible to macromolecules and to potential-determining ions. Therefore an "average" charge σ_{av} (Eqn.1) is normally used in the calculation of surface coverage.

According to Frumkin[70] the charge $\sigma(\theta)$ on a surface partly covered with surface-active molecules can be written as a linear combination of the charge σ_0 on an uncovered surface and the charge $\sigma(\theta=1)$ on the surface completely (100%) covered with adsorbate:

$$\sigma(\theta) = (1-\theta)\sigma_0 + \theta\sigma(\theta=1). \tag{9}$$

This relation has been used[1,2,12] to calculate the surface coverage of silver iodide with adsorbed polyvinyl alcohol $[CH_2.CH(OH)]_n$ on the basis that the adsorption of monomer units directly attached to the surface is a reversible function of pAg. Here the Stern layer can be regarded as comprising $\frac{1}{2}\theta$ $CH_2 + \frac{1}{2}\theta$ $CH(OH) + 1 - \theta$ vacancies. The symbols $\sigma(\theta)$ and σ_0 denote the measured surface charge densities in the presence and in the absence of adsorbed polyvinyl alcohol, while $\sigma(\theta=1)$ is found indirectly by regarding the Stern layer at maximum surface coverage as a hypothetical layer 50% covered with CH_3 (as in the case of butanol) and 50% with CH(OH) groups (as for ethylene glycol). Thus at a given ψ_0-potential

$$\sigma_{pva} = (1-\theta)\sigma_0 + \frac{1}{2}\theta[\sigma(\theta=1)_{BuOH} + \sigma(\theta=1)_{egl}], \tag{10}$$

or for the shift in the zero-charge point

$$\Delta_{zcp,\,pva} = \frac{1}{2}\theta[\Delta_{zcp.}(\theta=1)_{BuOH} + \Delta_{zcp.}(\theta=1)_{egl}]. \tag{11}$$

The surface coverage in the first (dense) layer of units is clearly $\theta = n_a(\theta)/n_a(\theta=1)$, or from Eqn.(8) [29]

$$\theta = \frac{\Delta_{zcp.}(\theta)_{pva}}{\Delta_{zcp.}(\theta=1)_{pva}} = \frac{2\Delta_{zcp.}(\theta)_{pva}}{\Delta_{zcp}(\theta=1)_{BuOH} + \Delta_{zcp.}(\theta=1)_{egl}}, \tag{12}$$

where n_a is the number of adsorbed units per unit surface area. The calculation was based[1,2,6,12] on published values of the shift in the zero-charge point of silver iodide on the adsorption of butanol and ethylene glycol[7,30] and measured values of $\Delta_{zcp}(\theta)_{pva}$. The maximum surface coverage was found to be $\theta = 0.85$: i.e. even with complete surface coverage of silver iodide with polyvinyl alcohol 15% of the Stern layer is "vacant" for the polymer.

Surface coverage can be calculated also[1,2,12] from electrophoretic data—from the change in the isoelectric point of particles in the presence of adsorbed polymer—which has the advantage that the isoelectric point can be measured more accurately than the zero-charge point. Moreover, the former measurements can be made on particles of a sol, whose surface, in contrast to the suspensions on which surface charge density is measured, are completely accessible to adsorbed macromolecules.

The fact that the initial portions of polyvinyl alcohol adsorbed on silver iodide produce the largest shifts in the isoelectric point, after which the latter reach saturation, has enabled[1,2] surface coverage to be calculated from the relation

$$\theta = \frac{\Delta_{iep.}(\theta)}{\Delta_{iep}(\theta=1)}\theta_{max}. \tag{13}$$

where $\theta_{max} = 0.85$. Fig.10 shows that, with increase in adsorption, surface coverage of silver iodide by monomer units increases rapidly to ~0.7 mg m^{-2}, which indicates that the greater part of the polymer has been adsorbed as a flat layer having many contacts with the surface. Further adsorption is accompanied by a slow increase in coverage, the excess of polymer accumulating as spikes and loops.

Determination of surface coverage by the two methods gives closely similar results. It is significant that the coverage is determined mainly by the quantity of polyvinyl alcohol adsorbed, and is little dependent on the molecular mass or the content of acetate groups.

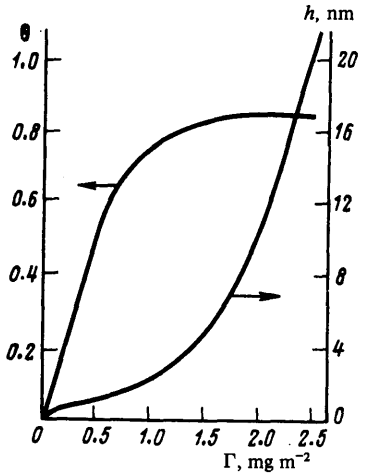

Figure 10. Effects[2,112] of quantity of polyvinyl alcohol adsorbed on surface coverage θ of silver iodide particles and on thickness *h* of adsorbed layer.

Determination of Proportion of Monomer Units in Direct Contact with Surface ν

From data on surface coverage for various quantities of polymer adsorbed Γ (in mg m^{-2}) we can calculate also an important parameter of the adsorbed layer—the proportion of monomer units in a macromolecule that are in direct contact with the surface[12]:

$$\nu = [M_{mu}/N_A a_0]\theta/\Gamma, \qquad (14)$$

where N_A is Avogadro's number, M_{mu} the molecular mass of a monomer unit, and a_0 (nm^2) the area occupied by one unit. This area can be calculated from the density of the dry polymer and its molecular mass as the projected area of the effective hydrodynamic sphere. Monomer units of water-soluble polymers can be assumed[23,29,61] to be adsorbed with the whole firmly bound hydration sphere, which e.g. for polyvinyl alcohol and polyethylene oxide comprises two water molecules per monomer unit[62,63]. Therefore the calculation of a_0 must take account also of coordinated water. This gives values of 0.30 and 0.28 nm^2 respectively for $[CH_2.CH_2.O].2H_2O$ and $[CH_2.CH(OH)].2H_2O$. Fig.11 illustrates the ν(Γ) dependence calculated from Eqn.(14) for the adsorption of polyvinyl alcohol on silver iodide. Even at low surface coverage with the polymer ν ≠ 0.4–0.5, while the proportion of units attached to the surface diminishes with increase in polymer adsorption, in good agreement with other measurements[5,71,72].

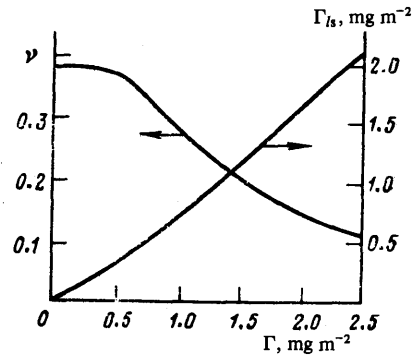

Figure 11. Dependence[12] of proportion ν of monomer units directly in contact with surface and of quantity Γ_{ls} of polymer present as spikes and loops on quantity of polyvinyl alcohol adsorbed on silver iodide particles.

The Reviewers evaluated ν from data on the number of contacts of an adsorbed macromolecular chain with the surface calculated from values of $\Delta\sigma_i$ for the surface of antimony sulphide particles during the adsorption of polyethylene oxide[19]. The total potential difference between the phases consists of ionic and dipolar components[13] (Section I), and the proposed method is based on the view that, in solutions of moderate ionic strength, the major part of the potential difference occurs in the dense region of the double layer, whose thickness is comparable with the length of a monomer unit in polyethylene oxide(0.4–0.5 nm). With an insignificant change in capacitance of the double layer in the presence of the polymer the condition of constant surface potential can then be replaced by constancy of the surface charge: $\sigma = \sigma_i + \sigma_d = \text{const}$, where σ_i is the ionic component of the surface charge, and σ_d the total charge of the ends of adsorbed dipoles oriented along the normal to the surface. By equating the observed value of $\Delta\sigma_i$ to σ_d we can calculate the number *n* of ends of dipoles oriented in the adsorbed polymer layer from the relation $\Delta\sigma_i = \sigma_d = Dn/l$, where *D* (in D) is the dipolar moment of a monomer unit and *l* the length of a dipole.

The results[19] indicate that (i) for a given quantity of polyethylene oxide adsorbed the number of contacts between polymer and surface is independent of molecular mass, (ii) with increase in surface coverage the proportion per adsorbed molecule of units in contact with the surface diminishes, and (iii) even with small amounts adsorbed the proportion of units directly attached to the surface does not exceed one-third of the total number of adsorbed units, in good agreement with published values for other polymer–solid systems[5,71–74].

Calculation of Quantity of Polymer in Loops and Spikes Γ_{ls}

From data on the area a_0 occupied by a monomer unit and the surface coverage θ it is easy to calculate the quantity of polymer Γ_1 in direct contact with the surface, i.e. in the first (dense) part of the adsorbed film. Subtraction from the total quantity adsorbed Γ will then give the quantity of polymer Γ_{ls} present on the surface as loops and spikes. Fig.11 illustrates the variation in Γ_{ls} with increase in the adsorption of polyvinyl alcohol on silver iodide particles[12].

Determination of Thickness of Adsorbed Film *h*

The adsorption of macromolecular compounds usually lowers the electrokinetic potential of particles (above). If the surface charge of the latter is not significantly changed[19, 23,50], it can reasonably be assumed that the observed decrease in potential is due primarily to displacement of the slippage plane into the liquid phase as a result of surface formation of adsorbed films of increasing thickness. In such case, even if adsorption leads to a change in surface charge density, it is usually observed at low surface coverage, and can be allowed for in the calculation of electrokinetic potential.

Film thickness can be calculated from $\zeta-\Gamma$ relations plotted from a comparison of adsorption and electrokinetic measurements on the same system. The method involves calculating the shift in the slippage plane, which is identified with the effective thickness of the polymer sheath relative to the boundary of the Stern layer. It is assumed that the adsorbed polymer does not affect the distribution of potential in the double layer and that the polymer sheath is hydrodynamically impermeable. From the equilibrium distribution of potential in the vicinity of the particles we can then calculate for each measured ζ-potential the coordinates of the slippage plane, by means of the well known theoretical formula of the diffuse double layer[13]

$$\tanh\left(\frac{ze\zeta}{4kT}\right) = \tanh\left(\frac{ze\psi_\delta}{4kT}\right) e^{-\varkappa x}, \quad h = x + \delta, \qquad (15)$$

in which $\varkappa^{-1}$ is the Debye shielding radius, z the valency of the gegenions, e the elementary charge, δ the thickness of the Stern layer, and x the distance from the slippage plane to the boundary of this layer, the ψ_δ-potential usually being equated to the ζ-potential in the absence of polymer. This method has been used to calculate film thickness h for the adsorption of polyethylene oxide and polyvinyl alcohol on particles of silver iodide and antimony sulphide[23,24,50,61,75] as well as on latices[76].

The results show that the adsorbed layers increase in thickness to several tens of nanometres with increase in polymer adsorption (Fig.12). It is significant that at a given adsorption the thickness varies little with molecular mass, and for polyvinyl alcohol with the content of acetate groups[23,24,50,61]. This implies that the mean length of adsorbed loops and spikes is also little affected by molecular mass. The values found for the film thickness agree to within 20–50% with those obtained by other methods—for polyvinyl alcohol on silver iodide viscosimetrically[6,29], for polyethylene oxide on the same surface by electron microscopy[77], and for polyvinyl alcohol on latex particles by measurement of precipitate volume, ultracentrifugation, and diffusion[76].

The present method has been criticised[2] on the grounds firstly that difficulties are involved in calculating electrokinetic potentials from electrophoretic mobility data owing to polarisation of the double layer, and secondly that the true potential at the boundary of the Stern layer is usually unknown and its replacement by ζ_0 is an approximation. It must be borne in mind also[50,51,76] that formula (15) gives the potential distribution in a planar double layer, and its

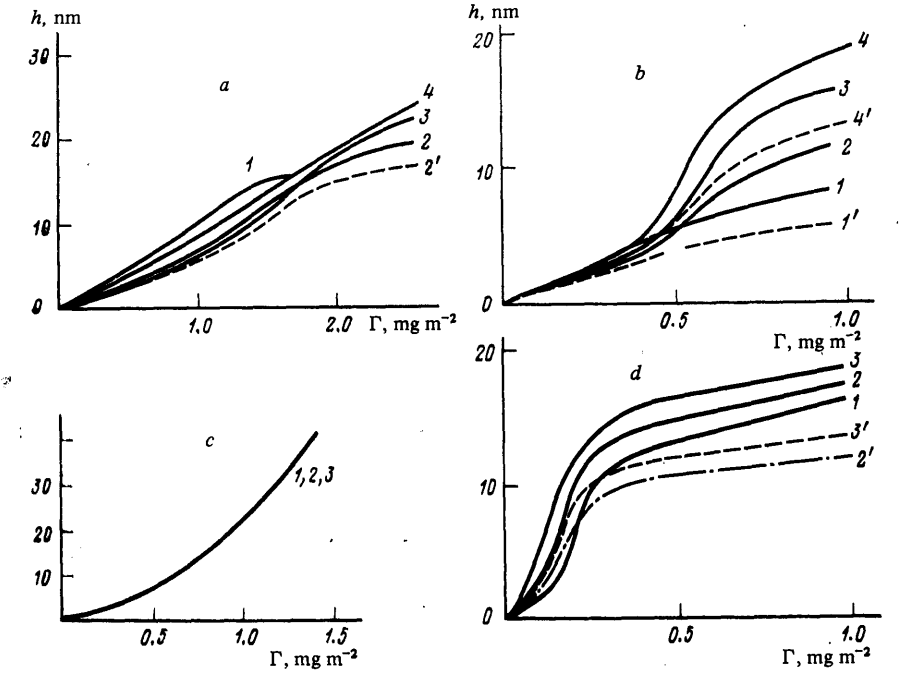

Figure 12. Variation, calculated from electrophoretic measurements[24], of thickness of polymer sheath on sol particles with quantity of polymer adsorbed. Lettering of diagrams and numbering of curves as in Figs.3 and 6 [sic].

application is valid only provided that $\kappa a \gg 1$. Furthermore, the condition of hydrodynamic impermeability of the adsorbed polymer layer may break down in solutions of high electrolyte concentrations[51].

One of us[51] used the adsorption of polyethylene oxide on fine particles ($a \approx 11$ nm) of antimony sulphide as example to make a detailed analysis of the influence of various complicating factors—polarisation of the double layer, curvature of the surface, presence of electrolytes—on the calculation of film thickness from electrophoretic data. With κ, a, and Rel having the respective values 1, 3, and 2 (the parameter $\mathrm{Rel} = e^{\frac{1}{2}\psi\delta - 1}/\kappa a$ represents the contribution by polarisation of the double layer to surface electrical phenomena; this polarisation can be neglected when $\mathrm{Rel} \ll 1$ [60,78]), i.e. when polarisation of the double layer must be taken into account, film thicknesses found from electrokinetic potentials calculated with and without allowance for such polarisation ζ_W§ and ζ_S differ by at most 10%. Such a small difference in thickness with a substantial difference in electrokinetic potentials ($\zeta_W \cong 2\zeta_S$) is due firstly to the occurrence of the distance of the slippage plane from the surface in the exponent in Eqn.(15), so that the thickness is insensitive to the ζ-potential, and secondly to the dependence of h not on absolute values of ζ but on the ratio of their hyperbolic tangents. A more substantial error in the thickness is due to disregard of surface curvature: values of h calculated from formulae for a spherical double layer are usually smaller than those calculated for a planar surface[50]. From results obtained[79] with the condition $\kappa h < 1$ a first correction for surface curvature will yield for spherical particles the formula[51]

$$\kappa h = \left[\left\{\tanh\left(\frac{ze\zeta_0}{4kT}\right)\Big/\tanh\left(\frac{ze\zeta}{4kT}\right)\right\} - 1\right]\left[1 - \left\{1/\kappa a \cosh^2\left(\frac{ze\zeta_0}{4kT}\right)\frac{\mathrm{th}\,(ze\zeta_0/4kT)}{\mathrm{th}\,(ze\zeta/4kT)}\right\}\right]. \quad (16)$$

This shows that the error when h is determined without any correction for curvature increases as ζ and κa decrease: whereas with $\kappa a = 5$ and $\zeta_0 = 100$ mV the error is only 2–3%, when $\kappa a \approx 1$ the formula from which (16) was obtained itself gives an error already exceeding 10%.[79] In general, when both surface curvature and concentration polarisation of the double layer are taken into account, the use of formula (15) with ζ-potentials determined by Smolukhovskii's method with $\kappa a \leq 1$ may produce significant distortion of the results. Thus comparison of h calculated by means of Eqn.(15) with thicknesses determined from results[81] for ζ_0 values of 50, 100, and 150 mV gives differences of 49%, 73%, and 65% respectively[51].

It was shown[51] also that the increase in effective particle radius due to polymer adsorption must also be taken into account in the calculation of thickness, i.e. that it is more correct to use $\kappa(a+h)$ instead of κa, but then the parameter h itself must be determined. This requires a set of equations to be solved, one of which defines the dependence of the equilibrium potential on the distance from the particle surface with a known potential ζ_0, while the second is obtained from the dependence of the observed electrophoretic mobility on the ζ-potential and the corresponding quantity $\kappa(a+h)$. Analytical solution of such a problem is quite laborious, even when a computer is used, so that one of us has suggested a graphical method (see Ref.51 for details). Thicknesses obtained in this way will be the most accurate, since polarisation of the double layer, curvature of the surface, and variation in effective particle radius during coating with thickening adsorbed polymer films have all been taken into account.

§The ζ_W potential is calculated in this case from Wiersema's tables[80].

It was shown also[51] that thicknesses of polyethylene oxide on antimony sulphide particles calculated from electrokinetic potentials in relatively concentrated (>0.01 M) electrolyte solutions are improbably small (≤3 nm). This may be due to enhancement of permeability of the adsorption sheath with increase in ionic strength of the solution. In such case the slippage boundary, from which the layer thickness h is assessed, will pass into this layer and move nearer the surface of the dispersed phase. Under these conditions the determination of thickness from electrophoretic data on the basis of the above simple ideas is incorrect. New possibilities for calculating h in the case of permeable adsorbed layers are revealed by a theory developed recently[64].

In view of the above limitations and difficulties involved in calculating thickness from the fall in the electrokinetic potential, Lyklema[2] suggested calculating h on silver iodide particles from the slope of the experimental variation in ζ as a function of pAg at or near the isoelectric point. The basis of the proposed method was the decrease in slope with increase in h. For a planar double layer in a uni-univalent electrolyte the equation

$$\left(\frac{d\zeta}{dpAg}\right)_{\sigma\to 0} = 58.16\,\frac{\mathrm{sech}^2(e\psi_\delta/4kT)}{\mathrm{sech}^2\,(e\zeta/4kT)}\,\frac{C}{C_d}\exp(-\kappa h), \quad (17)$$

was derived, and use of the Debye–Hückel approximation gave

$$\left(\frac{d\zeta}{dpAg}\right)_{\sigma\to 0} = 58.16\,\frac{C\exp(-\kappa h)}{C_d(a+h)} \quad (18)$$

for a spherical double layer[2,12]. In these equations C is the total capacitance of the double layer, which can be found from potentiometric data, while the capacitance C_d of the diffuse ionic layer can be obtained from the theoretical relation $C^{-1} = C_m^{-1} + C_d^{-1}$ provided that the surface potential and the electrolyte concentration are low (C_m is the capacitance of the molecular capacitor, which is usually 20 $\mu F/cm^{-2}$). The value of ψ_δ in Eqn.(17) is calculated from data on surface charge density determined by titration. Thus the only unknown in Eqns.(17) and (18) is h. The variation in the thickness of the polymer sheath calculated in this way for the adsorption of polyvinyl alcohol or particles of silver iodide is shown in Fig.10. The results are somewhat smaller than viscosimetric values for the same system and thicknesses of this polymer on latex particles measured by hydrodynamic methods[6,26,76]. Nevertheless, the course of the $h-\Gamma$ dependence and the absolute thicknesses are closely similar to those found from the fall in the electrokinetic potential (above).

Our discovery of a decrease in the relative conductivity of dispersions having a polymer sheath for values below those predicted theoretically suggests a new method for estimating film thickness. Its basis is that appearance of a "hypertheoretical" slope in the plots of $\bar{K}/K$ against p during adsorption is associated with an increase in relative particle volume due to formation of an adsorbed polymer layer within which water is immobilised. The difference Δp corresponding to points of intersection of a straight line parallel to the abscissae axis with the $\bar{K}K^{-1}-p$ straight lines for suspensions with and without added macromolecular compounds gives the increase in relative volume due to polymer adsorption. From this difference and the corresponding volumes it is easy to calculate h. For the adsorption of polyvinyl alcohol on palygorskite particles, for example, the resulting thickness (~15 nm) is extremely plausible.

Knowing the film thickness for various adsorbed quantities and parameters of macromolecular coils in solution found by viscosimetric or optical (light-scattering) methods, we can define a probable model for the adsorption of non-ionic polymers on colloidal particles. The Reviewers' calculations for the adsorption of polyvinyl alcohol and polyethylene oxide on silver iodide and antimony sulphide particles[50,82] enabled them to eliminate for these systems a model of monomer units arranged flat on the surface in the form of similar (equal-sized) loops with a regular alternation of units attached to the surface along the macromolecular chain, and also as undeformed random coils. Calculated values of h were appreciably less than double the radius of inertia of a polymer coil in solution $2\langle s^2\rangle^{\frac{1}{2}}$ (thus for polyethylene oxide of molecular mass 2.3×10^5 on antimony sulphide with $\Gamma = 1.0$ mg m^{-2} we have $h = 20$ nm, whereas $2\langle s^2\rangle^{\frac{1}{2}} \approx 50$ nm [82]), the difference between $2\langle s^2\rangle^{\frac{1}{2}}$ and h increasing rapidly with increase in molecular mass[50,83]. These facts indicate appreciable deformation of the macromolecular coils of these polymers when adsorbed on the above inorganic surfaces.

The experimental results can be explained satisfactorily by the Bulas–Hoeve–Hesselink model of an adsorbed film[60–69,83], according to which the polymer sheath on the surface consists of a denser first layer and a layer of dissimilar loops and spikes pointing towards the liquid, with an exponential size distribution. At the boundary of the first layer the density of segments changes abruptly, while beyond this layer the variation $\rho(x)$ along the normal to the surface is described for homopolymers by the exponential relation[68]

$$\rho(x) = 12\frac{x}{il_{st}^2}\exp\left(-6x^2/il_{st}^2\right), \qquad (19)$$

in which l_{st} is the length of a statistical chain unit (segment) and i the number of segments in a loop. It can be shown for such a model that the mean number of segments in a loop $\bar{i}$ and the length l_{st} are interrelated[6,29]:

$$\bar{i} = 2b\sqrt{6}/l_{st}\,p_H, \qquad (20)$$

where b is a numerical constant approximating to 0.7 [6,29] and the parameter p_H is a function of the proportion ν of units attached to the surface (it is calculated as the ratio of the number n_1 of units in the first layer to their total number n per unit surface; n_1 has been calculated from the area occupied by a unit together with the surface coverage θ found by the above method) and the dimensionless constant $K_H < 1$ determined by the flexibility of the polymer chain. This constant is evaluated by calculating from the relation[6,29]

$$h - \delta' = \frac{n-n_1}{K_H\rho_0}\ln\left(\frac{K_H\rho_0}{\rho_{eff}}\right) \qquad (21)$$

(which holds for $\Gamma \geq 0.5$ mg m^{-2}) the theoretical dependence of layer thickness h on quantity of polymer adsorbed that best coincides with the experimental curve. Here δ' is the thickness of units in the first layer, $\rho_0\delta' = n_1$, and the effective density of the adsorbed film ρ_{eff} is calculated from the theory of polymer solutions as the density of a statistical coil of radius equal to the thickness of the polymer sheath. Thus the same variation of density of segments with distance is assumed in the adsorbed film (from the surface) and in the statistical coil (from its centre of gravity): i.e. $\rho_c(i) = \rho_{eff}$ and $\bar{i} = h$. This, of course, is only an approximation, but is fairly accurate, since the thickness found from formula (21) is not very sensitive to the effective density[6,29]. For example, with $K_H = 0.8$ and $10^4\rho_0 = 70$ Å^{-3} the value of h decreases by only 17% for an increase in ρ_{eff} of 50%.[29]

The Reviewers' experimental results[23,25] on the adsorption of polyvinyl alcohol on silver iodide and on antimony sulphide corresponded most closely to the values 0.3 and 0.25 respectively for K_H; for polyethylene oxide on silver iodide K_H varied from 0.07 to 0.1 depending on the molecular mass of the specimen. From values of $\bar{i}$ calculated in this way it is easy to find the number of groups adsorbed by unit surface as $N_1 = n_1/\bar{i}$, where n_1 is the number of units attached as loops to the surface, calculated as the difference between n and n_1.

Table 3. Parameters of macromolecular chains of polyvinyl alcohol and polyethylene oxide in surface layer of silver iodide particles[23,50].

Polymer	10^{-4} M	Γ_1, mg m^{-2}	$\bar{i}$ with Γ (mg m^{-2})			$10^{-16}N_1$, m^{-2}
			0,4	0,7	1,0	
pva-12	2.2	0.17	3.8	6.6	13	11.6
peo-1	23	0.15	21	50	78	6.6
peo-2	130	0.15	23	55	87	5.9
peo-3	260	0.15	32	76	120	4.3

Thus combined adsorption, electrokinetic, and viscosimetric measurements open up a path to determination of the most important parameters of adsorbed polymer films—the number and length of loops N_1 and $\bar{i}$ adsorbed by unit area—which are required for theoretical calculation of the energy of repulsion V_R of colloidal particles covered with a polymer sheath. Table 3 lists several parameters of macromolecular chains of polyethylene oxide and polyvinyl alcohol on the surface of silver iodide and antimony sulphide particles found by the above method. The Reviewers have used them to calculate the polymer component of the energy of repulsion of the particles and for a theoretical interpretation of the stabilisation of the sols by additions of these polymers[57,58,84].

The Introduction of Tritium into Biologically Active Compounds with the Aid of Exchange Methods

L.A.Neiman

Different versions of the homogeneous and heterogeneous catalytic isotope exchange as well as catalytic substitution of a halogen by tritium are examined from the standpoint of their use for the introduction of a tritium label into compounds of biological interest (aminoacids, peptides, proteins, nucleotides, carbohydrates, steroids, medicinal agents, etc.). The bibliography includes 214 references.

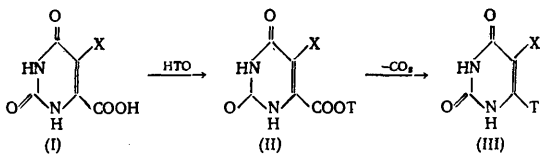
I. INTRODUCTION

Biology and related disciplines—biochemistry, molecular biology, and bio-organic chemistry—are fields of study where the use of isotope exchange has proved most fruitful. The present development of a whole series of branches of these sciences could not be imagined without the utilisation of radioactive isotopes and some branches (for example, the study of metabolism or biogenesis) have been placed on a genuine scientific basis solely as a result of the application of the isotope method. Isotope exchange has now come to be widely used in biochemistry and bio-organic chemistry as a method for the qualitative and quantitative analysis of substances. The reason for this is that isotope exchange is more sensitive by 4–6 orders of magnitude than spectroscopic methods and moreover in most instances does not require careful purification of the substances to be determined. It is frequently actually unnecessary to isolate them or to comminute the sample in which they are contained. The high sensitivity of the isotope method is particularly important for biological disciplines, because it permits a reliable determination of the substances at concentrations close to those at which their biological activity is shown.

Since the sensitivity of the method is unambiguously related to the specific radioactivity a of the labelled compound, there has arisen in recent years a clear tendency to use tritium-containing organic compounds instead of their analogues labelled with ^{14}C. Indeed, when a single T atom is introduced into a molecule, a ~30 c mmol^{-1} should be attained theoretically, while the introduction of a single ^{14}C atom yields only 64 μc mmol^{-1}. Since the molecules of organic compounds contain in many instances tens of hydrogen atoms, it is in principle possible to obtain tritiated compounds with a amounting to several hundreds and more of c mmol^{-1}. However, in practice preparations with $a > 50$–100 c mmol^{-1} are rarely used, because under the conditions of high values of a autoradiolysis is accelerated. Other advantages of tritium are the possibility of introducing it by exchange methods (i.e. into a "finished" molecule) and a much lower cost of tritium-containing compounds compared with those labelled with ^{14}C. As regards other radioactive isotopes employed (^{32}P, ^{33}P, ^{35}S, ^{125}I, etc.), the region of their applicability is naturally much narrower.

Thus tritium is nowadays the most important and most common radioactive isotope used in biology and related disciplines and the problem of methods of synthesising tritium-labelled biologically active substances (BAS)† has become extremely urgent. These methods include chemical synthesis, biosynthesis, synthesis with the aid of hot atoms, and exchange methods (catalytic isotope exchange, the Wilzbach method and its modifications, etc.), the exchange methods having a number of advantages particularly in the preparation of labelled BAS of complex structure—these are primarily single-stage synthesis ("rapidity" of synthesis), universality, comparative simplicity, and the possibility of obtaining high values of a.

This review is devoted to exchange methods for the preparation of tritium-containing BAS; the exchange of labile hydrogen atoms and homogeneous and heterogeneous catalysis of the hydrogen–tritium exchange are considered in detail. Furthermore, the review includes the method of catalytic dehalogenation, which is strictly speaking one of the synthetic methods. This is because of, firstly, its similarity (both from the standpoint of the mechanism and from the standpoint of the purely preparative aspect) to the heterogeneous catalysis of isotope exchange and, secondly, because of the extremely great importance which the method has assumed (particularly in recent years) for the preparation of virtually all classes of labelled BAS, in the first place peptides, proteins, and nucleotides. The Wilzbach method and its modifications are not considered in this review. Attention has been concentrated on studies published in the last ten years; a compilation of earlier literature can be found in Evans's monograph published in Russian translation[1] in 1970. Studies on deuterium are quoted only in those cases where it is of interest to compare them with the corresponding results for tritium or when such results for tritium are not available at all but the latter could be obtained (judging from the studies using deuterium).



II. EXCHANGE OF LABILE HYDROGEN ATOMS

On dissolution, compounds containing the >NH, –OH, and –SH groups in protic tritium-containing solvents (HTO, MeOT, EtOT, AcOT, etc.) are known to exchange rapidly the H

† In the present review biologically active substances (BAS) are understood to be both products of natural origin (proteins, peptides, aminoacids, carbohydrates, nucleotides, steroids, etc.) and synthetic preparations (medicinal agents, pesticides, carcinogens, etc.).

atoms of these groups (labile hydrogen atoms) for T even under the usual conditions. If the solute is capable of undergoing tautomeric transformations (for example keto–enol or imine–enamine tautomerism), the H atoms linked to the C atoms can also exchange with the tritium-containing solvent under conditions (frequently fairly mild) under which a tautomeric equilibrium is established (i.e. the stable H atoms become labile).

The introduction of tritium in a labile position takes place readily and reversibly, so that the reaction is as a rule of no preparative value, since the labelled BAS obtained by this method lose tritium completely on dissolution in the usual solvents or on being employed in biological studies. However, in certain cases tritium can be fairly simply transferred from a labile to a stable position. An excellent example is provided by the synthesis of 5-fluorouracil-6-*t* [2–5] and 5-bromouracil-6-*t* [6] from the corresponding orotic acids (I), which readily exchange their carboxyl hydrogen on heating with HTO or (the preferred method) [4,5] with a solution of T_2O in dioxan or dimethylformamide (DMF) (100 °C, 1 h). Such solutions are obtained as a result of passing T_2 through a suspension of PtO_2 in dioxan or DMF. Labelled orotic acids (II) are then decarboxylated at 250–300 °C with formation of the corresponding tritiated nucleic bases (III) having $\alpha \cong 1$–2 c mmol^{-1}. It has been shown[7] that thymine-6-*t* can be obtained similarly:

(I) (II) (III)

X = Br, F, or Me.

The same principle constitutes the basis of a method for the specific introduction of D or T into the α-position in α-aminoacids (alanine, phenylalanine, glutamic acid, and aspartic acid)[8]. The method involves the isotope exchange of the carboxyl hydrogen in the corresponding *N*-acylaminomalonic acid (IV) with D_2O or HTO and subsequent hydrolysis and decarboxylation. All three stages can be carried out in a single experiment:

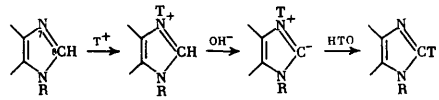
$$\underset{(IV)}{RCONHCR'(COOH)_2} \xrightarrow{HTO} RCONHCR'(COOT)_2 \xrightarrow[HTO]{\Delta} RCOOH + H_2NCT(R')COOH.$$

III. HOMOGENEOUS CATALYSIS OF HYDROGEN ISOTOPE EXCHANGE

Both base and acid catalysis as well as catalysis in the presence of soluble transition metal salts have been used to introduce tritium into BAS.

1. Base Catalysis

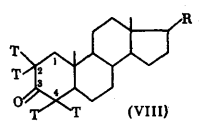
In base catalysis the isotope exchange process is initiated as a result of attack by a B^- anion, which abstracts a proton from the compound involved in exchange with formation of a carbanion, which then combines with T^+. If the intermediate carbanion is an ambident species [for example, (V)], i.e. can be protonated at two (or more) centres, the conditions for isotope exchange are the same as the conditions for tautomeric transformations and the latter can be frequently identified from the occurrence of isotope exchange:



$$R_2CH{-}C(R')=X \xrightarrow{B^-} [R_2C\cdots C(R')\cdots X]^- \xrightarrow{T^+} R_2CT{-}C(R')=X +$$
(V)

$$+ R_2C=C(R'){-}XT \quad ;$$

X=O, N–, C< .

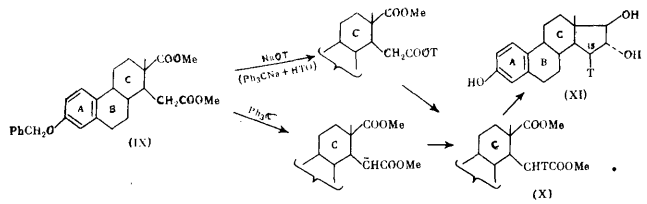


In certain cases the deprotonation proceeds very readily. Thus purine bases, nucleosides, and nucleotides exchange hydrogen, albeit slowly, at $C_{(8)}$ even at pH 8 and room temperature[9,10]. In the preparative synthesis of labelled purines it is necessary to heat the latter with HTO at 85–100 °C; the reaction time varies from 20 min (for DNA and nucleoside triphosphates, which undergo hydrolysis under these conditions) to several hours[11–13]. The rate of exchange is determined by both electronic and steric factors. The presence of a ribofuranosyl residue facilitates the exchange: at 85 °C adenosine exchanges at $C_{(8)}$ twice as fast as adenine which, however, exchanges hydrogen at $C_{(2)}$ 2000 times faster than at $C_{(8)}$.[14]

The conformation of the macromolecule and the microstructure of the helix which determine the accessibility of a particular section of the nucleic acid molecule to water, exert a significant influence[15–18]: the exchange of H at $C_{(8)}$ with HTO in the purine residues of a natural double helix DNA is almost three times slower than for a mixture of the corresponding polynucleotides; the double helix RNA exchanges even more slowly (by a factor of 30–40). Studies of the kinetics of the exchange at different pH have shown[19–22] that in reality the $N_{(7)}$-protonated form (VI) and not the purine molecule itself is deprotonated. The former is formed very rapidly, while its conversion into the ylid (VII) is the rate-limiting stage in the entire process:

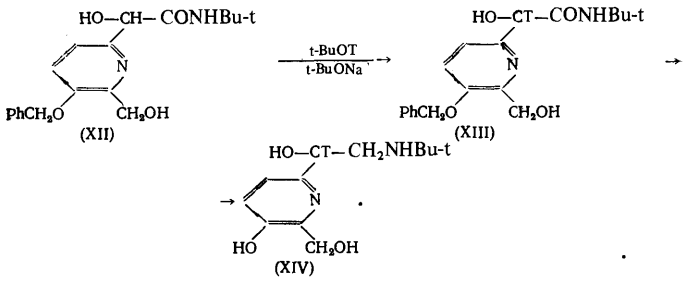
(VI) (VII)

Methylene groups activated by neighbouring electron-accepting groups (>CO, –COOR, –CN, etc.) exchange with HTO at alkaline pH, usually with heating. For ketones, for example camphor[23], the exchange proceeds under conditions identical with those for enolisation, and the isotope exchange mechanism is in this case identical with the mechanism of tautomeric keto–enol transformations. In order to introduce T into the α-position relative to the oxo-group in testosterone, progesterone, and other 3-oxosteroids, a convenient preparative method has been proposed[24,25]. It consists in passing a solution of the test substance in an organic solvent through a column filled with basic alumina subjected to a preliminary treatment with HTO. Tritium has been introduced into the 2- and 4-positions of 3-oxo-5α-cholestan-26-yl acetate (VIII) by a similar procedure—isotope exchange with iso-PrOT in the presence of aqueous NaOH:[26]



(VIII)

The tritium atoms introduced by these procedures into the steroid molecule are entirely stable in acid and neutral media, but at pH > 10 they exchange for H to the extent of 80–95% even at the usual temperature over a period of 24 h.

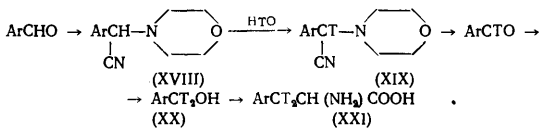


Isotope exchange involving the hydrogen in a methylene group activated by neighbouring carbonyl groups proceeds readily in an alkaline medium also in aminosugars (pH 11–11.5; 20 °C; 48 h), as shown for example, for 2-acetamido-2-deoxy-D-glucose[27], where deuterium can be introduced in the 2-position by this procedure with a high yield. Since alkaline epimerisation also takes place under these conditions 2-acetamido-2-deoxy-D-mannose-2-C-*d* is formed as a side product.

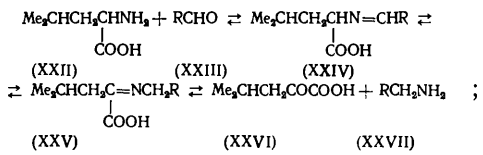
Steroid lactones—cardiac glycosides of the digitoxin series and their aglycones—exchange with HTO in DMF in the presence of Et_3N (30–80 °C, 2–8 h), more than 95% of tritium being incorporated in the lactone ring. Tritium-labelled digitoxin, digitoxigenin, digoxin, gitoxigenin, and uabain with $a \cong 0.4$–0.7 c mmol^{-1} have been obtained by this method[28].

Homogeneous base catalysis has also been used in the synthesis of triol-15-*t* (XI).[29] The 3-benzilate of the dimethyl ester of marianoleic acid (IX) is tritiated in the α-position relative to the methoxycarbonyl group on successive treatment with triphenylmethylsodium and HTO and the resulting labelled ester (X) was converted by acyloin condensation and subsequent reduction into 15-tritioestriol (XI); this compound contains a tritium atom in a position within the molecule from which it cannot be removed by the water present in living organisms:

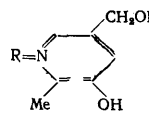
The isotope exchange between the *N*-t-butylamide of 2-(5-benzyloxy-6-hydroxymethyl-2-pyridyl)-2-hydroxyacetic acid (XII) and t-BuOT in the presence of t-BuONa takes place readily (20 °C; 16 h). The resulting amide-α-*t* (XIII) serves as the starting material for the synthesis (reduction with B_2H_6 and subsequent catalytic debenzylation) of the labelled medicinal preparation pirbuterol (XIV):[30]



The hydrogen atoms of the α-methylene group are mobile not only in lactones, esters, and acid amides (as can be seen from the examples quoted above) but also in the carboxylic acids themselves. The sodium or potassium salts of aliphatic acids (ranging from butyric to stearic) are converted in high yields into salts of α-labelled acids (XVI) and (XVII) on heating with NaOH and D_2O or HTO under severe conditions (autoclave; 200 °C; 1–3 days) with intermediate formation of the corresponding carbanions (XV):[31]



$$RCH_2COOK \rightarrow \underset{(XV)}{R\bar{C}HCOOK} \rightarrow \underset{(XVI)}{RCHTCOOK} \rightarrow \underset{(XVII)}{RCT_2COOK} .$$



The α-hydrogen atoms in lactic[32], chrysanthemic[33], and abscisic[34] acids exchange for *D* or *T* under similar conditions and in the last case tritium also enters the 4-position and the methyl group linked to $C_{(5)}$; the preparation obtained has a high activity $a \cong 6.5$ c mmol^{-1}.

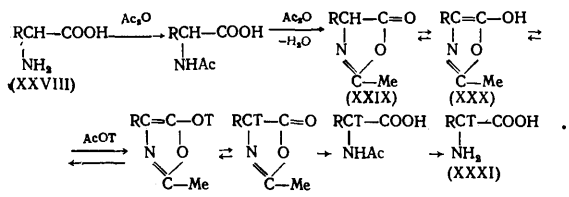
The isotope exchange involving aminoacids is unsatisfactory under these conditions. Labelled aminoacids are therefore prepared by other, more complex methods; some of these also involve isotope exchange catalysed by bases. For example, under the influence of morpholine and an aqueous NaCN solution, aromatic aldehydes are readily converted into morpholinoacetonitriles (XVIII), which exchange hydrogen in the α-position relative to the cyano-group on heating with D_2O or HTO (DMF or sulpholan; 100 °C; ~5 h).[35] Hydrolysis of the labelled nitriles (XIX) leads to aldehydes containing tritium in the formyl group; on disproportionation of these aldehydes via the Cannizzaro reaction, the corresponding benzyl-α,α-t_2 alcohols (XX) are formed and are then converted by familiar synthetic methods into aromatic aminoacids (phenylalanine, tyrosine, and dihydroxyphenylalanine) labelled with tritium in the β-position [compound (XXI)]:

A novel possibility for hydrogen isotope exchange in aminoacids under the conditions of base catalysis was demonstrated with deuterium for leucine (XXII),[36] which is converted into leucine-α,β,β-d_3 on boiling in D_2O in the presence of pyridoxal (XXIII) and potassium alum. Under these conditions, an equilibrium is established between leucine and pyridoxal, on the one hand, and the ketoacid (XXVI) and pyridoxamine (XXVII), on the other, with intermediate formation of the corresponding Schiff bases (XXIV) and (XXV). The tautomerism of these bases (XXIV) ⇌ (XXV) in D_2O is in fact responsible for the hydrogen exchange in the α-position of leucine, while the exchange in the β-position is in all probability a consequence of the keto–enol tautomerism of the ketoacid (XXVI):

Numerous studies of the kinetics of hydrogen exchange in peptides and proteins (see, for example, Refs. 37–41) as well as polyamides, treated as models of protein[41–44], indicate, in the way already mentioned above for polynucleotides, a considerable influence of the polymer matrix (particularly a protein matrix) on the nature of the transition state and the exchange mechanism. The rate of exchange is determined by the steric accessibility of various sections of the protein molecule to the solvent and is a minimum for the most ordered structures. It has been shown for collagen[45] that, as a result of the rupture of intramolecular hydrogen bonds, the exchange with D_2O is accelerated.

The hydrogen atoms in aromatic compounds are also capable of isotope exchange in an alkaline medium (NaOT or KOT solutions in HTO or in HTO–DMF, MeONa in MeOT, and KNT_2 in liquid NT_3).[46] The exchange is promoted by the presence of methoxy-groups and particularly phenolic hydroxy-groups as substituents in the aromatic ring, which has been used to introduce tritium into the *ortho*- and *para*-positions relative to the hydroxy-group in phenolic aminoacids[47] and in phenolic alkaloids related to morphine[48–51]. Heteroaromatic compounds and their hydro-derivatives also exchange under analogous conditions; the exchange is most effective in liquid NT_3,[46,51] but experimental difficulties in studies using this solvent limit its practical application. The exchange involving nitrogen-containing heterocycles is greatly accelerated when powerful electron-accepting substituents (oxide oxygen or a nitroso-group) are present at the nitrogen atom[46,52,53]. The mechanism of the exchange involves two stages—the formation of a carbanion and its subsequent interaction with the labelled medium; both the first stage (in the exchange of methyl hydrogen atoms in ethyl-substituted heterocycles)[53] and the second stage (in the exchange of hydrogen at $C_{(3)}$ in 2-substituted indoles)[54,55] can be rate-limiting.

2. Acid Catalysis



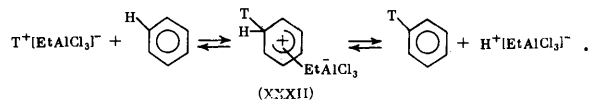
In the homogeneous acid catalysis of hydrogen isotope exchange the intermediate carbonium ion plays the same role as the carbanion in base catalysis (see above). The carbonium ion can be formed either as a result of the abstraction of a hydride ion from the molecule or (more often) as a result of the addition of T^+ or D^+ to an unsaturated carbon atom. The latter version obtains in numerous hydrogen exchange reactions in aromatic systems. The acid agents employed (see the review of Burrish et al.[56]) are strong protic acids (sulphuric, phosphoric, perchloric, and trifluoroacetic), weak acids (for example acetic), Lewis acids ($AlCl_3$, $AlBr_3$, and $EtAlCl_2$), and the complex $H_2TPO_4.BF_3$ (the so-called Yavorsky reagent[57]).

Virtually all these agents have been used successfully to introduce the tritium label into aromatic and heteroaromatic compounds, although in certain cases, involving $HTSO_4$ at elevated temperatures, undesirable side reactions do occur. Howver, tritium has been introduced into *l*-phenylalanine and its *p*-nitrophenyl ester with high yields on heating (90° to 100 °C, 48–72 h) with dilute $HTSO_4$ (or formed from SO_3 and HTO), approximately 95% of the incorporated tritium being contained in the benzene ring and approximately 5% in the β-position[58]. The exchange is accompanied by a slight (<4%) racemisation; the value of a for the preparations obtained amounts to several μc $mmol^{-1}$.

In order to obtain other labelled tritiated aromatic aminoacids with a of the same order of magnitude, 3–4 *N* solutions of TCl in HTO are most frequently used (heating at 40–90 °C). Under these conditions, 3-hydroxy-*l*-kynurenine exchanges only in the benzene ring[59] and *l*-5-hydroxytryptophan exchanges in the 2-, 4-, and 6-positions in the indole ring[60,61], while the side chains are unaffected and the exchange does not involve racemisation. On raising the temperature (100 °C, several hours), it is possible to achieve the exchange of all the hydrogen atoms in the benzene ring of L-5-hydroxytryptophan[60] and of the hydrogen atom in the 3- and 5-positions of tyrosine and in the 2-, 5-, and 6-positions of 3,4-dihydroxyphenylalanine[47], while it has been shown with the aid of deuterium that in tryptophan[62] the hydrogen atoms in the 2- and 6-positions exchange rapidly and those in the 4-, 5-, and 7-positions exchange slowly only in trifluoroacetic acid. Like tyrosine, 4-aminobenzoic acid also exchanges in the 3- and 5-positions on heating with 3 *N* TCl in HTO (90 °C, 36 h). This preparation with $a = 2.5$ μc mg^{-1} has been used[63] to synthesise the tritium-labelled 4-methylpiperazide of 4-[*N*-(7-trifluoromethylquinolinyl)amino]benzoic acid, which exerts an effect on the central nervous system.

It has also been shown with the aid of deuterium that an acid medium (DCl in D_2O or AcOD) is suitable for the introduction of the label not only into the benzene ring but also into non-benzenoid aromatic and heteroaromatic natural products—azulenes[64,65], indoles (in the 3-position)[66], chlorophylls[67], and porphyrins[68]. In the same medium [DCl (TCl) in AcOD (AcOT) at 120 °C] the α-hydrogen atoms of carboxylic and aminoacids exchange[69] and also certain aliphatic acids, for example stearic[70], exchange with HTO (130 °C, 48 h, a reaching 1 c g^{-1} after washing out the labile tritium) without any extra acid additives.

As regards tritium-containing aminoacids (XXXI), the latter are obtained most effectively by refluxing the Ac_2O in AcOT (the reagent is prepared by adding an excess of Ac_2O to HTO) and subsequent treatment with HTO.[71–74] In this case the hydrogen atom in the α-position exchanges exclusively (or almost exclusively) and the exchange is accompanied by racemisation and does in fact occur for the aminoacid (XXVIII) itself but involves the intermediate azlactone (XXIX), which is converted into the tautomeric form (XXX):



Despite the fact that DL-aminoacids are obtained by this method, in combination with enzymatic resolution of racemates it can be used also to obtain labelled L-aminoacids[73]. An analogous procedure (boiling with Ac_2O into AcOD followed by treatment with D_2O) has recently been proposed as a method for the introduction of deuterium into the α-position in aminoacids[75].

The use of the Yavorsky reagent (the complex $H_2TPO_4.BF_3$) as the tritiating agent for aromatic compounds and compounds containing tertiary hydrogen has a number of advantages (the exchange takes place even at room temperature and there are no side reactions, which leads to radiochemical purity of the products[57,76]); however, owing to the low values of a (at most tens of μc $mmol^{-1}$) attainable with its aid, it is hardly used for the preparation of labelled BAS. Insecticides (DDT, parathion, sevin, and their analogues)[77], tropine, and mescalin[78] are exceptions. Recently this list was extended by including insulin ($a \approx 6.5$ μc $mmol^{-1}$ [79] and also certain phenols ($a = 10–80$ μc $mmol^{-1}$), converted as a result of esterification into labelled hypolipidemic agents (including clofibrate)[80].

A modification of the Yavorsky reagent—the complex $AcOT.BF_3$ (prepared by the successive addition of a slight excess of Ac_2O and an equivalent amount of BF_3 to HTO)—was proposed from the very beginning[81] specifically for the introduction of the tritium label into BAS—aminoacids, peptides, proteins (α-lipoprotein, ribonucleoprotein, somatotropin, and insulin), and cholesterol. The exchange takes place under mild conditions (20–24 °C, approximately 20 h), but certain proteins (human albumin and ovalbumin) are

nevertheless denatured and the values of a attained do not exceed 150 μc g^{-1}.

Lewis acids ($AlCl_3$, $AlBr_3$, $MeAlCl_2$, $EtAlCl_2$, WCl_6, $SbCl_5$, and BBr_3) catalyse hydrogen isotope exchange mainly in aromatic compounds and their use for labelled BAS is therefore extremely limited. Best results have been achieved for polynuclear aromatic hydrocarbons—methylcholanthrene, 3,4-benzopyrene, and 9,10-dimethyl-1,2-benzanthracene, which are powerful carcinogens and are widely used in oncological research. After being kept with HTO and $AlCl_3$ in CS_2 for many days (14–50 days at 20 °C), these hydrocarbons are converted into the corresponding generally labelled compounds with $a \cong 20$–50 c mmol^{-1}.[82] The attempts to use $AlCl_3$ as the catalyst of the exchange between HTO and uracil, adenine, and glycine or its peptides (in CH_2Cl_2 at 80 °C) were less successful[83]. Among all the catalysts of this type, the most effective is apparently $EtAlCl_2$, in the presence of which full equilibrium between aromatic hydrocarbons is attained for benzene and its homologues and derivatives after only 30 min at 20 °C.[84] In this case the TCl formed as a rsult of the partial hydrolysis of the catalyst plays the role of a cocatalyst: the strong acid $T^+[EtAlCl_3]$, obtained from TCl and $EtAlCl_2$, adds to the aromatic ring to form the complex (XXXII). The equilibrium between the hydrocarbon, the acid, and the complex is responsible for the hydrogen exchange[85]:

(XXXII)

The catalysis by other Lewis acids proceeds via a similar mechanism. It has been suggested[86] that the HTO–$EtAlCl_2$ system be used for the introduction of tritium into alkanes and cycloalkanes (including steroids) containing at least one tertiary hydrogen atom. However, in order to attain satisfactory values of a, a fairly high temperature (96 °C) is necessary, which also promotes skeletal isomerisation reactions in the intermediate carbonium ion, which leads to the formation of labelled side products. For steroids or other BAS, this method has not found any serious applications.

In catalysis by Lewis acids of the reaction involving the exchange of H for D the experimental procedure is simplified, since deuterated aromatic hydrocarbons (usually C_6D_6) can be employed as the labelled medium[84,87].

The hydrogen isotope exchange in an acidic (sometimes weakly acidic) medium, initiated by various types of radiation (ultraviolet radiation[88–92], γ-radiation[93,94], and the intrinsic radiation of HTO with a high value of a [95,96]), constitutes a special variety of homogeneous acid catalysis. Such exchange involves both aromatic[88–92] and aliphatic[93–96] compounds (particularly carbohydrates[94,95]); the initiation is facilitated by the addition to the medium of substances readily forming radicals—potassium iodide[89,90] and mercaptans[94]. In all cases radicals are formed as an intermediate stage: for aromatic compounds as a result of the addition of T· and for aliphatic compounds as a result of the abstraction of H·. For example, in the exchange between benzene and HTO in an acid medium in the presence of KI irradiation induces primarily the decomposition of the I^- ion into I· and a solvated electron[89]. The interaction of the latter with the cation H_2TO^+ leads to H_2O and T·, the addition of which to the benzene molecule with subsequent elimination of H from the radical [PhHT]· is responsible for the incorporation of tritium into the aromatic ring. In a weakly acid medium the solvated electrons can be captured by benzene molecules with formation of the anion $[PhH]^-$, which is converted into the radical [PhHT]· as a result of the interaction with the tritium-containing medium[90].

On the basis of published data, isotope exchange initiated by irradiation appears to be relatively unsuitable for the preparative synthesis of labelled BAS, mainly because of side reactions. Even for simple compounds, an inversion of configuration is observed as a consequence of the homolysis of the C–H bond of an asymmetric carbon atom. Thus the isotope exchange between (+)-tartaric acid and HTO initiated by γ-radiation leads to a 1 : 1 mixture of labelled (+)- and *meso*-tartaric acids, while a mixture of labelled *meso*- and (±)-tartaric acids is obtained from *meso*-tartaric acid under these conditions[93]. The exchange between HTO and *chiro*-inositol, initiated by the intrinsic radiation, leads similarly to the formation of tritiated *chiro*-, *myo*-, and *allo*-inositols (but not *muco*-inositol)[95]. The greater ease of exchange of the equatorial hydrogen atoms compared with the axial atoms was noted in this instance.

3. Catalysis by Transition Metal Salts

From the point of view of the synthesis of labelled BAS, the preparative value of the last of the varieties of homogeneous catalysis considered here—isotope exchange with HTO in the presence of soluble chloroplatinates (Na_2PtCl_4 and K_2PtCl_4)—is low. This exchange also proceeds in an acid medium (acetic acid is added to homogenise the solution, while hydrochloric acid prevents the precipitation of metallic platinum) and requires an increased temperature (from 50° to 130 °C).[97–101] The mechanism of the exchange involves the formation of a complex of the type of a π-complex from the substrate and the transition metal[98]. The method described is therefore effective primarily for the hydrogen atoms of an aromatic ring, polynuclear compounds (napthalene, anthracene, and phenanthrene) exchanging specifically in the β-position. A comparative study[102] has shown that catalysis by K_2PtCl_4 is preferable (requires a lower temperature and a shorter time) than heterogeneous catalysis of the exchange with the solvent in the presence of platinum for the introduction of the deuterium label into hexoestrol, oestrone, testosterone, and cholesterol.

The homogeneous catalysis by mercury(II) chloride of the isotope exchange between a nucleoside [2-acetamido-6-chloro-9-(2′-deoxy-3′,5′-di-*O*-*p*-toluyl-D-ribofuranosyl)-9*H*-purine] and tritium-containing aromatic solvents—benzene and toluene (refluxing for 0.5 h)—has also been described[103]. Under these comparatively mild conditions, the efficiency of the exchange is low (a for the labelled nucleoside is smaller by a factor of approximately 10^4 than for the initial solvent) and the incorporated tritium is distributed between the purine and the carbohydrate moieties of the nucleoside molecule in proportions of 84 : 16.

IV. HETEROGENEOUS CATALYSIS OF HYDROGEN ISOTOPE EXCHANGE

The methods for the homogeneous catalysis of isotope exchange examined above make it possible to obtain tritium-containing compounds with a high value of a (of the order of several tens of c mmol^{-1} or at least several c mmol^{-1}) in only a few cases. In contrast to these procedures, in heterogeneous catalysis such high values of a can be obtained much more readily which constitutes the main advantage of this group of methods. In heterogeneous catalysis of isotope exchange in solution, both tritium-containing solvents (usually water) and gaseous T_2 can serve as sources of tritium.

1. Exchange with Tritium-Containing Solvents

In this case the experimental procedure usually consists in prolonged heating of a mixture of the test substance, the tritium-containing solvent, and the catalyst. The method has come to be widely employed since the 1950s and a compilation of early studies on this problem (up to 1964) can be found in the first edition of Evans's monograph[104]. The method is nowadays widely used and one of the largest centres of isotope production in the world—the Radiochemical Centre in Amersham—uses it for the industrial manufacture of a wide variety of tritium-labelled compounds, including a large number of BAS.

Table 1. Biologically active substances labelled by the method of heterogeneous catalytic exchange with the solvent (catalyst—Pt black)*.

Substance	a of solvent**	t, °C	Time, h	Yield, %	a of product, μc mmol^{-1}
	Solvent—HTO

*Reaction mixture—0.2–0.5 g of substance with 50–100 wt.% of catalyst in 2–4 ml of solvent.

**The values for the exchange with aminoacids and coumarin are quoted in c mmol^{-1}; in all other cases they are expressed in c ml^{-1}.

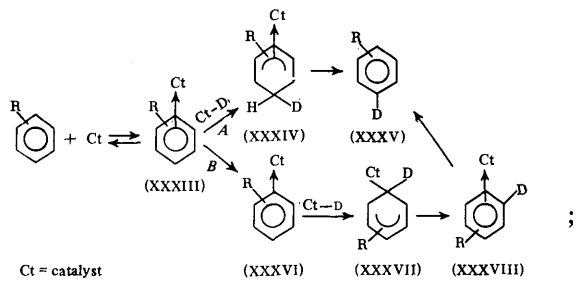
In the exchange with the solvent the catalysts can be virtually all Group VIII metals—platinum, palladium, cobalt, nickel, ruthenium, rhodium, and iridium—which are prepared by reducing their salts with $NaBH_4$ or by reducing their oxides with T_2 (or D_2) [105–108] and are used as such (platinum black, palladium black, etc.) or on various carriers (silica gel, activated charcoal, Al_2O_3, $BaCO_3$, $CaCO_3$). In Amersham preference is given to the platinum catalyst[105], but a high efficiency of the nickel (Raney nickel) and chrome-nickel catalysts has also been reported[109,110]. In choosing the catalyst, account must be taken of its influence on the intramolecular distribution of the added tritium (as a rule, platinum and palladium are less specific; for further details, see below) and also the fact that arsenic, sulphur, and certain nitrogen-containing compounds poison many (but not all) catalysts.

The most common medium in heterogeneous catalytic exchange in solution is HTO itself and also a 70 : 30 mixture of AcOT and HTO. In order to attain high values of a, a temperature of approximately 120–150 °C and a treatment time ranging from 2 to 20 h (in rare instances significantly longer—up to 65–90 h) are required. Under these conditions, tritium is introduced into the majority of low-molecular-weight BAS. The side reactions can be the migration of the Δ-bond (in unsaturated compounds), partial hydrolytic cleavage, and (when AcOT is used) acetylation, but the labelled side products have approximately the same value of a as the main compound. As a result, their separation does not as a rule present a specially difficult problem (which is an advantage over the Wilzbach method and its modifications). The activity a of the products naturally depends on the molar activity of the solvent and reaches up to 80% of the latter under most favourable conditions.

Table 1 presents specific results achieved by the Radiochemical Centre in the preparation by the method described (with platinum black as the catalyst) of certain low-molecular-weight BAS.[105] Evidently the ease of introduction of tritium into various compounds of even the same class (for example into aminoacids) is varied. In the majority of cases the exchange of the hydrogen in aromatic rings is easier than in aliphatic residues. One should also note that the values of a quoted in Table 1 for readily exchanging substances are by no means limiting values. Thus the synthesis of adenosine triphosphate with a = 23.3 c mmol^{-1} as a result of the platinum-catalysed exchange with HTO has been reported recently[21].

As regards the classes of BAS not mentioned in Table 1, the exchange with HTO in the presence of platinum (140 °C, 20–70 h) has been used to introduce tritium into terpenes (~2 μc mg^{-1});[111] the possibility of using the "self-activating" PtO_2 (HTO, 130 °C, 48 h) as a catalyst rather than platinum has been demonstrated for carbohydrates in relation to (−)-inositol (a = 3.39 μc mmol^{-1}).[112] However, Raney nickel, which catalyses the exchange between D_2O and α-methyl-D-mannopyranoside, β-methyl-D-galactopyranoside, 1,2-*O*-isopropylidene-α-glucofuranose, α,α-trehalose, melezitose, raffinose, and sucrose (100 °C, 10 h), is more promising for the introduction of a label into carbohydrates[109].

The principal disadvantages of the method under consideration are the use of very large amounts (up to 500 and more curies) of HTO and the relative severity of the exchange conditions. In order to overcome the first of these disadvantages, it has been suggested[113,114] that the labelled water required for the exchange be obtained by oxidising gaseous T_2 with a suspension of PtO_2 in AcOH, dioxan, or methanol in the apparatus where the exchange itself takes place; the exchange is catalysed by platinum formed on reduction of PtO_2, which makes it possible to obtain tritiated water with



the maximum specific activity, to remove the excess T_2, and in many cases to eliminate the problem of the dissolution of the starting material. With the aid of this modification of the method, folic acid and uridine with $a \cong 1$–3 c mmol^{-1} were obtained (AcOH, 120 °C, 24 h),[113] while under milder conditions (dioxan or MeOH, ~20 °C, 4–24 h) geraniol, linalool, gibberelic acid, hydroxytetracyclin, and phenylalanine were synthesised with a ranging from 50 to 500 μc mmol^{-1}.[114]

The last example demonstrates that, as stated above, the attainment of a high value of a requires an increased temperature. This disadvantage of the method significantly restricts the range of BAS to which it can be applied, since biopolymers (particularly polypeptides and proteins) decompose on heating in most instances, while optically active aminoacids racemise. Thus, although L-phenylalanine exchanges with HTO at 30 °C in the presence of platinum without racemisation (since the side chain is not involved and more than 90% of the incorporated tritium is localised in the benzene ring), the overall degree of incorporation of tritium is small, while at 130 °C generally labelled DL-phenylalanine is obtained[115]. A high degree of racemisation (20–50% of the D-form) under the conditions of the exchange with HTO at 120–150 °C has also been noted[105] for L-tyrosine, L-tryptophan, and L-methionine, while the degree of racemisation in the case of arginine, lysine, and leucine did not exceed 5% and the values of a were below 200 μc mmol^{-1}.

In addition it has been shown with the aid of deuterium that the hydrogen isotope exchange involving the aromatic ring and catalysed by platinum under mild conditions is observed for phenylalanine and its tripeptide, but hardly occurs for the phenylalanyl and tyrosyl residues in proteins such as lysozyme and ribonuclease (the possible causes are steric hindrance to the adsorption of these residues on the catalyst or irreversible poisoning of the catalyst by the protein)[116]. Nevertheless, it is most likely that conformational factors play a decisive role, because, after prolonged treatment (40 °C, 72 h) with 35 c HTO and platinum black, it was possible to obtain labelled ribonuclease with $a = 17.3$ c mmol^{-1}; the bulk of the tritium was present in the valine, lysine, arginine, and glutamic acid residues[117]. Under the same conditions, tritium was introduced into oxidised ribonuclease much less effectively ($a = 0.2$ c mmol^{-1})—mainly into histidine and sulphur-containing and aromatic aminoacid residues. Tritium-containing polypeptides—ochratoxins A, B, and C (yield 80%, a up to 3 c mmol^{-1})—have been obtained[118] with the aid of heterogeneous catalytic exchange with the solvent (a mixture of HTO and AcOT, platinum black, 80 °C), ochratoxin A being labelled mainly (to an extent greater than 80%) in the phenylalanyl residue[118].

One of the slight disadvantages of the method is the uncertainty in the predicted location of tritium in the labelled compound obtained. These compounds are referred to as generally labelled or indefinitely labelled (in contrast to specifically labelled and uniformly labelled). The intramolecular distribution of tritium depends on a number of factors (primarily on temperature and on the nature of the catalyst) and it has been stated[119] that the reproducibility of the results of studies of the intramolecular distribution are poorly reproducible. The influence of temperature on the localisation of tritium in phenylalanine was noted above but even in high-temperature exchange (135 °C, 18 h), accompanied by complete racemisation, tritium is not distributed uniformly between the side chain and the aromatic ring, but is concentrated mainly in the latter (in proportions of 27 : 73).[120] A definite selectivity also obtains in a number of other instances: in catalysis by platinum black uracil exchanges with HTO mainly the hydrogen atoms in the 5- and 6-positions[121]; the exchange between (−)-inositol and HTO in the presence of PtO_2 leads to preferential (to the extent of 92.5%) inclusion of tritium in the 1- and 6-positions[117]; the exchange of sugars with D_2O in the presence of nickel takes place at $C_{(5)}$ and $C_{(6)}$ much faster than at $C_{(2)}$ and $C_{(3)}$;[109] cobalt catalyses the exchange of hydrogen in heterocycles exclusively in the α-position[108]. Poisoning of the catalyst also influences the location of tritium: thus, when pyridine is added, the exchange between HTO or D_2O and alkylbenzenes catalysed by Pd/C is selectively inhibited in the *ortho*-position relative to the alkyl group[122].

As regards the mechanism of the heterogeneous catalysis of the exchange with the solvent, it has been found that the exchange on different catalysts takes place in different ways. In the most common exchange of aromatic compounds in the presence of platinum it has been suggested[123] (on the basis of the results of a study of deuterium exchange) that a π-complex (XXXIII) is formed in the first stage. The complex then either interacts with the deuterium (tritium) sorbed on the catalyst (as a result of the dissociative chemisorption of water), being converted via a transition state (XXXIV) into the labelled compound (XXXV) ("associative mechanism"; A) or ("dissociative mechanism"; B) is first converted into a σ-complex (XXXVI), which reacts slowly with the deuterium (tritium) sorbed on the catalyst to form the addition product (XXXVII). The labelled compound (XXXV) is obtained from the latter via the labelled π-complex (XXXVIII). The dissociative mechanism is believed to be more probable[123–125]:

2. Exchange with Gaseous Tritium

The use of gaseous T_2 as a source of tritium in the heterogeneous catalysis of hydrogen isotope exchange in solution has a number of advantages over the use of tritium-containing solvents (see reviews[105,126]). These include primarily the possibility of carrying out the exchange at the usual temperature and of obtaining over a period of only several hours labelled compounds with $a \cong 1$–10 c mmol^{-1} (and sometimes even higher). The method consists in stirring a solution of 10–50 mg of the test substance in several millilitres of a suitable solvent in an atmosphere of 10–25 c T_2 in the presence of a catalyst. The overall radioactivity in the experiment is thus approximately ten times lower than in the exchange with a solvent. The exchange is faster if the pressure of T_2 is equal to the atmospheric pressure, but this condition is not obligatory and sometimes high values of a are attained in several hours even at a pressure of 160 mmHg.[127] The reaction is carried out in a special vacuum system (for a detailed description of such vacuum apparatus tested in practice, see Mikhailov et al.[128]).

The influence of various factors (solvent, temperature, and catalyst) on the exchange with T_2 has been inadequately investigated, but it has been established that there are apparently no special limitations as regards the choice of the solvent. Both organic solvents (dioxan, methanol,

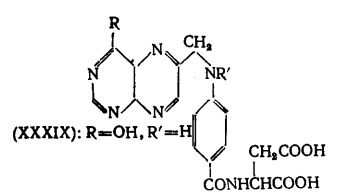
hexane, CCl_4, CS_2, acetic acid, etc.)[129,130] and water or aqueous buffered solutions at neutral or alkaline pH are used[131]. The isotope exchange between T_2 and organic solvents is slight under these conditions; it increases slowly in the series dioxan < tetrahydrofuran < ethyl acetate[132], but even ethyl acetate can be used successfully (for example, in the exchange between T_2 and cholesterol)[133]. Satisfactory results are obtained even at 20–25 °C, but there is evidence[130,134] that an increase of temperature to 60–65 °C makes it possible to increase a of the exchange products by a factor of 2–3.

Palladium and platinum or their oxides (in the latter case the exchange is preceded by the reduction of the oxides to the metals) are most frequently used as catalysts[131,134] either as such or deposited on various carriers ($CaCO_3$, $BaSO_4$, activated charcoal, and Al_2O_3; in addition nickel[135], Rh/Al_2O_3,[136] and certain other catalysts are also employed). The nature of the carrier is not important[137,138], although in certain cases the use of $CaCO_3$ suppressed side reactions[138]. The method of activation of the catalyst is more important: in the preliminary reduction of PdO or PtO_2 by H_2 (instead of T_2) the value of a of the products decreases by a factor of 30–60.[129,134]

Table 2. Compounds labelled with the aid of heterogenous catalytic exchange with T_2 in solution[131] (catalyst—$PdO/BaSO_4$)*.

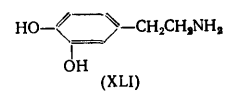
Compound	pH of solution	Time, h	Yield, μc	a, c mmol^{-1}
Adenosine	8.2	2	660	11.2
Adenosine monophosphate	10	16	295	—
Adenosine cyclic 3',5'-diphosphate**	10	16	290	28.3
Adenosine triphosphate	8	16	84	13.0
Deoxyadenosine triphosphate	10	16	250	9.6
Inosine monophosphate	8	0,33	195	4.9
Guanosine triphosphate	8.2	0,5	28	1.6
Puromycin	8	0,5	28	3.75

*10–30 mg of substance with a fourfold–fivefold excess (by weight) of catalyst in 1.5–2.5 ml of phosphate buffer (atmosphere of 10 c T_2).
**In an atmosphere of 25 c T_2.



Heterogeneous exchange with T_2 in solution has been used successfully to introduce the label into carbohydrates, nucleotides, steroids, and certain other BAS containing aromatic or heteroaromatic rings and in most cases the selectivity (or even specificity) of the exchange was noted. D-glucose-1-*t* is obtained very readily (~20 °C, 1 h) as a result of the exchange with T_2 in 0.1 M phosphate buffer in the presence of $PdO/BaSO_4$ (a = 5.4 c mmol^{-1}).[131] Other aldoses—L- and D-arabinoses, L- and D-fucoses, D-ribose, maltose, and lactose—exchange just as specifically. The presence of the aldehyde group is an obligatory condition for the exchange: under analogous conditions, it is not possible to introduce tritium into sorbitol, α- and β-methyl glucosides, or trehalose[131]. Tritium has been introduced by the above method also into more complex compounds containing carbohydrate residues: platinum catalyses the exchange of T_2 with the aminoglycoside antibiotic sagamicin[139] and 30% Pd/C catalyses the exchange with heparin [water–ethylcarbitol (monoethyl ether of diethylene glycol), ~20 °C, 48 h];[140] nucleosides and nucleotides as well as the antibiotic puromycin with a high value of a and a radiochemical purity of 90–98% have been obtained by exchange in the presence of $PdO/BaSO_4$ in phosphate buffer (Table 2).[131]

Hydrogen in the 8-position exchanges most readily in purine derivatives[131]; among pyrimidines, tritium is introduced selectively in the 6-position in 5-hydroxyuracil and 5-aminouracil (5% $Pd/BaSO_4$, water, 23 °C, 3 h) with a = 0.35 and 2.36 c mmol^{-1} respectively[127].

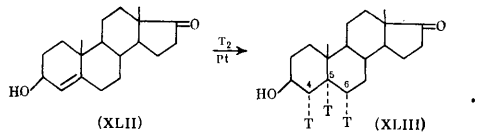


It is noteworthy that tritium introduced into galactosylceramide and glucosylceramide (10 c T_2, 10% Pd/C, on chloroform–methanol in the presence of pyridine, ~20 °C) is almost fully localised (to an extent greater than 98%) in the sphingolipid part of the molecule and of that more than 80% is in the aliphatic acid residue[141].

The exchange of T_2 with steroids—cholesterol (a up to 1 c mmol^{-1})[133,142] and oestrogens (oestrone, oestriol, and oestradiol; $a \cong 1.5$ c mmol^{-1})[134,143]—is catalysed by palladium or platinum, best results being obtained using benzoates in organic solvents (ethyl acetate or dioxan) with subsequent hydrolysis.

Among aminoacids, L-phenylalanine exchanges very readily with T_2 in solution in the presence of PtO_2 [134] or $PdO/BaSO_4$ [131]. In the latter case (phosphate buffer, pH 7, 20 °C, 1 h) a > 1 c mmol^{-1} was attained. The exchange is not accompanied by racemisation and involves almost exclusively (to an extent greater than 95%) the benzyl CH_2 group (the 3-position). Under analogous conditions, it was possible to obtain labelled L-alanine with a equal to only 10 μc mmol^{-1}.[131] This example illustrates strikingly the extreme ease of the exchange of the benzyl hydrogen atoms in the α-position, which has been confirmed also in other cases[129] and has been used to introduce tritium into a series of BAS containing benzyl or analogous groups. These compounds include, for example, folic acid (XXXIX), in which more than 60% of the incorporated tritium is localised in the 9-position after exchange with T_2 (10% Pd/CaO_3, 4 *N* KOH, ~20 °C, 1 h, a = 30–36 c mmol^{-1}), and 2-(3,4-dihydroxyphenyl)ethylamine (dopamine) (XLI), which belongs to the class of catecholamines, where more than 90% of the tritium label is introduced into the 2-position of the side chain after exchange with T_2 ($PdO/BaSO_4$, phosphate buffer, ~20 °C, 2 h, $a \cong 1$ c mmol^{-1}).[131] It is of interest to note that a compound related to folic acid—the medicinal preparation methotrexate (XL)—contains only 30% of the incorporated tritium in the 9-position (the conditions of the exchange were the same as for folic acid), evidently due to steric hindrance caused by the neighbouring methyl group[144]:

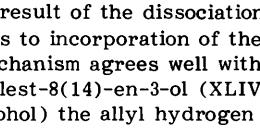
(XL): R=NH₂, R′=Me.



(XLI)

5-(3-Methylaminopropyl)- and 5-(3-dimethylaminopropyl)-10,11-dihydro-5*H*-dibenzo[*d*,*f*]azepins (the medicinal preparations desipramin and imipramin) as well as 5-(3-methylaminopropylidene)- and 5-(3-dimethylaminopropylidene-10,11-dihydro-5*H*-dibenzo[*a*,*d*]cyclopentenes (the medicinal preparations nortriptyline and amitriptyline), which exhibit a powerful antidepressant activity, exchange with T_2 (PdO, methanol, ~20 °C, 45 min, a = 45, 15, 2, and 1.7 c mmol^{-1} respectively) almost exclusively at the methylene group located between the two aromatic rings[145]. Among other labelled medicinal substances obtained by exchange with T_2 and

exhibiting a high value of a, mention should be made of DL-propranol (PtdO, dioxan, 4.5 h, yields 37%, $a = 27.3$ c $mmol^{-1}$)[146] and 1-(1-phenylcyclohexyl)piperidine (the medicinal preparation phencyclidine) (PdO, methanol, yield 25%, $a = 4$ c $mmol^{-1}$).[147]



The number of biologically active substances which can be selected for the introduction of the tritium label by exchange with T_2 in solution is limited by the side reduction of certain groups and by the saturation of multiple bonds. Thus the attempt to introduce tritium into uridine by the above method ($PdO/BaSO_4$, phosphate buffer, 1 h) led only to dihydrouridine-5,6-*t*.[131] However these limitations are not absolute: for example, the exchange of aldoses mentioned above is not accompanied by the reduction of the aldehyde group. As regards unsaturated compounds, the saturation and isotope exchange of the latter proceed competitively and depend markedly on the conditions (catalyst and temperature). Thus the activation energy for the exchange involving cyclohexene in the presence of $Rh(PPh_3)_3Cl$ (homogeneous catalyst) is higher than for saturation and the latter is the main process at 30 °C, but at 60 °C the exchange proceeds more readily[148].

In the isotope exchange between T_2 and tricyclic antidepressants (see above) in the presence of palladium (from PdO) the degree of retention of the double bond is much greater than in the presence of PtO_2 or $PdO/BaSO_4$. Even better results are achieved when the stages involving the reduction of PdO to palladium and the exchange with antidepressants are separated and are carried out consecutively[145]. In the platinum-catalysed reduction of 3β-hydroxyandrost-4-en-17-one (XLII) by tritium the saturation and isotope exchange also proceeds simultaneously: in the labelled 3β-hydroxyandrostan-17-one (XLIII) obtained the tritium is distributed between the 4α-, 5α-, and 6α-positions in the proportions 37 : 43 : 20:[149]

(XLII) (XLIII)

As in heterogeneous catalysis of the exchange with the solvent, the mechanism of the exchange with gaseous T_2 (or D_2) is different for different catalysts (see, for example, Rudakov et al.[150]). In particular, for substituted aromatic compounds, chemisorption on the surface of the platinum or palladium catalysts in the form of π-complexes has been postulated[151,152], while in the case of the nickel catalyst the formation of σ,π-complexes is more likely[135]. The mechanism of the exchange with T_2 in aqueous media cannot be regarded as finally established; it has only been demonstrated that the substrate exchanges directly with T_2 and not with water[131]. In the discussion of the ionic and radical versions of this mechanism preference was given to the latter[131], which presupposes the homolysis of the C–H bond in the substrate RH in the first stage with formation of an intermediate free radical, adsorbed on the catalyst surface. This radical then interacts with the T atoms obtained as a result of the dissociation of T_2 on the catalyst, which leads to incorporation of the tritium in the substrate. This mechanism agrees well with, for example, the finding that cholest-8(14)-en-3-ol (XLIV) exchanges with D_2 (Pd catalyst, alcohol) the allyl hydrogen atoms at $C_{(7)}$ and and $C_{(15)}$. Evidently these most mobile atoms are split off with formation of an intermediate π-allyl complex[152]:

(XLIV)

V. CATALYTIC DEHALOGENATION

The method used for catalytic dehalogenation (stirring of the solution of the test substance in an atmosphere of gaseous T_2 in the presence of the catalyst) is identical with the method for heterogeneous exchange with T_2 (and also with that for catalytic reduction by T_2); in essence, catalytic dehalogenation differs from exchange by the fact that the T atom replaces a halogen atom rather than a hydrogen atom in the substrate molecule. We thus have the chemical reaction $RX + T_2 \rightarrow RT + TX$ and catalytic dehalogenation is accordingly one of the synthetic methods for the preparation of tritium-containing compounds. However, as already stated above, the inclusion of this method in the present review is justified, firstly, by the fact that it is most general for the synthesis of labelled BAS of different classes, and, secondly, because of its evident theoretical and practical similarity to exchange methods.

The advantages of the catalytic dehalogenation method are fairly clear. In the first place it makes it possible to obtain compounds with a high value of a and in many cases close to the theoretical value (29 c $mmol^{-1}$) corresponding to the complete substitution of one halogen atom by tritium. It is very significant that catalytic dehalogenation proceeds under very mild conditions (even at temperatures approximately in the range 0–5 °C and at a T_2 pressure of approximately 150–200 mmHg) and goes almost to completion in several hours. This can be explained by the greater thermodynamic ease of substitution of a halogen by T compared with substitution of H by T and by the fact that, owing to the smaller carbon–halogen bond dissociation energies compared with the C–H dissociation energies, the activation energy for dehalogenation is lower than for the isotope exchange of H for T. An important advantage is also the specificity of the introduction of the tritium label, determined by the position of the halogen in the molecule of the initial halogen-containing compound. However one should note the side reactions—isotope exchange and saturation of multiple bonds—can infringe the specificity and in certain cases (which are admittedly very few) the infringement can be very considerable[153–155].

The formation, together with the labelled compound, of tritiated hydrogen halides TX, which are catalytic poisons, can be included among the disadvantages of the method. In order to bind these poisons, KOH, NaOH, NH_3, Et_3N or $BaCO_3$ are added to the solution, which also displaces the equilibrium, accelerates the dehalogenation, and suppresses side reactions. The necessary initial halogen-substituted compounds are in most cases fairly readily available.

As already mentioned, the experimental conditions for catalytic dehalogenation are almost the same as in the isotope exchange with T_2. The amounts of T_2 used vary from several curies at pressures ranging from 100 to 760 mmHg. The range of solvents employed is very wide—aqueous alkalis, ethanol, methanol, dioxan, DMF etc. (water and alkaline agents enumerated above are added to the organic solvents when necessary).

Palladium (in the form of a black or on various carriers—activated charcoal, $CaCO_3$, $BaSO_4$, and Al_2O_3) is most often used as the catalyst; more rarely employed are platinum, nickel (Raney catalyst), and rhodium and more rarely still—osmium, iridium, and ruthenium. It is recommended that catalysts on carriers be employed, since this increases the active surface area and decreases the risk of poisoning of the catalyst. Satisfactory results are obtained when Pd/C and $Rh/CaCO_3$ or Rh/Al_2O_3 are used simultaneously for the dehalogenation of peptides and proteins[155–161]. The ease of substitution of a halogen by tritium decreases in the sequence I > Br > Cl > F in conformity with the increase of the carbon–halogen bond strength. It is therefore preferred to ha-

with the corresponding iodides, particularly since even debromination sometimes proceeds unsatisfactorily[157], although, for example, 5-bromonicotinic acid is converted into labelled nicotinic acid in 94% yield (5% $Pd/CaCO_3$, tetrahydrofuran, in the presence of $BaCO_3$, 20 °C, 8 h).[162] However, in general the rate of reductive deiodination is several times greater than that of debromination (in the series of halogenobenzenes at approximately 20 °C, in the dark, and in the absence of a catalyst by a factor of 5.5) [163] and exceeds even more the rate of dechlorination and defluorination. Thus the homolytic dissociation of the carbon–halogen bond is the rate-limiting stage of the reaction and as a result of this it is in many instances possible to achieve the selective introduction of tritium into polyhalogeno-compounds[163–165].

Although catalytic dehalogenation has been used successfully for the introduction of the tritium label in virtually all classes of BAS, the method is most valuable in the preparation of labelled aminoacids, peptides, proteins, nucleotides, nucleosides, and nucleic bases. Catalytic dehalogenation is the main method for the synthesis of all aromatic aminoacids specifically labelled in the aromatic ring and having a high value of a (Table 3). In all cases dehalogenation is not accompanied by racemisation and leads to compounds with a high radiochemical purity. Hydrogenolysis in an atmosphere of pure T_2 yielded aminoacids with high values of a [for example, 14 c mmol^{-1} for L-tyrosine-3-t;[166,168] in other cases a mixture of T_2 and H_2 was used[167,170]].

Table 3. Labelled aminoacids obtained by catalytic dehalogenation.

Aminoacid	Initial halogen-containing compound	Catalyst	Medium	Chemical yield, %	Refs.
L-Phenylalanine-2,4-t_2	L-2,4-dibromophenylalanine	$Pd/CaCO_3$	aqueous ethanol	90–100	166
3,4-Dihydroxyphenylalanine-2,5,6-t_3	methyl ester of *O,O'*, *N*-triacetyl-2,5,6-tribromo-3,4-dihydroxyphenylalanine	Pd/C	dioxan (Et_3N)	54	167
3,4-Dihydroxyphenylalanine-2,5,6-t_3	2,5,6-tribromo-3,4-dihydroxyphenylalanine	$Pd/CaCO_3$	aqueous ethanol (KOH)	90–100	166
3,4-Dihydroxyphenylalanine-6-t	methyl ester of *O,O'*, *N*-triacetyl-6-bromo-3,4-dihydroxyphenylalanine	Pd/C	dioxan (Et_3N)	72	167
L-Tyrosine-3-t	3-iodo-L-tyrosine	10% Pd/C	aqueous methanol (KOH)	about 90	168
L-Tyrosine-3-t	3-iodo-L-tyrosine	$Pd/CaCO_3$	aqueous ethanol	90–100	166
L-Tyrosine-3,5-t	3,5-di-iodo-L-tyrosine	$Pd/CaCO_3$	aqueous ethanol	90–100	166
L-Tyrosine-3,5-t_2	3,5-di-iodo-L-tyrosine	Raney Ni	water (NaOH)	90–100	169
L-Tyrosine-3,5-t_2	3,5-di-iodo-L-tyrosine	Raney Ni	water (NaOH)	–	169
DL-Tryptophan-5-t	5-bromo-DL-tryptophan	10% Pd/C	water (KOH)	–	170
DL-Tryptophan-5-t	5-bromo-DL-tryptophan	$Pd/CaCO_3$	aqueous ethanol	90–100	166
DL-Tryptophan-4-t	4-chloro-DL-tryptophan	10% Pd/C	water (KOH)	–	170
L-Histidine-2,5-t_2	2,5-di-iodo-L-histidine	$Pd/CaCO_3$	aqueous ethanol (KOH)	–	166

The halogen can be substituted by tritium in the same way not only in the aromatic aminoacids themselves but also in their residues forming part of the composition of peptides and proteins. The interest of investigators was concentrated mainly on labelled peptide hormones (oxytocin, vasopressin, angiotensin (II), corticotropin, and α-melanotropin) and their analogues, for which values a of the order of several tens of c mmol^{-1} were attained. The results are presented in Table 4, which shows that the method is suitable for peptide molecules of different sizes (from 3 to 61 aminoacid residues). In all cases the dehalogenation was carried out at room temperature and almost all the labelled compounds of the peptide-protein type enumerated in Table 4 were obtained from iodine-containing precursors, i.e. peptides incorporating 3,5-di-iodotyrosine or 4-iodophenylalanine. The only exceptions are compounds Nos.3–6, which were synthesised from brominated precursors (containing 3,5-dibromotyrosine) or chlorinated precursors (containing 4-chlorophenylalanine). In one case (No.12) acetamido-D-alanyl(4-amino-3,5-di-iodo)-L-phenylalanine was dehalogenated and not the halogeno-analogue of the labelled peptide, the resulting tritium-containing dipeptide being converted into the labelled analogue of α-melanotropin by the usual methods of peptide synthesis.

The halogen is introduced into the initial halogenopeptides by various methods. Peptide synthesis makes it possible to obtain from a halogenoaminoacid halogenopeptides with a fixed position of the halogen, which is known exactly. The need for halogenopeptides of this kind stimulated the development of peptide syntheses from 3,5-di-iodo-L-tyrosine[178]. Another method consists in the treatment of the peptide (or of one of its synthetic precursors) with I_2 in a chloroform–methanol–water mixture (iodination of tyrosine residues in the 3- and 5-positions in the benzene ring)[176] or with iodine chloride, which iodinates the tyrosine ring or the histidine side chain depending on the conditions[159].

Catalytic dehalogenation is used very widely (particularly in recent times) for the synthesis of tritium-labelled nucleic bases, nucleosides, and their monophosphates. The label is introduced both into various positions of the nucleus of the base (usually with the aid of debromination) and into the methyl group (with the aid of dechlorination); for the compounds obtained, a varies in the range 5–25 c mmol^{-1} (Table 5).

Despite the fact that the conversion of the labelled bases into labelled nucleosides and their phosphates does not give rise to serious difficulties, it is frequently preferred to obtain the latter directly by the catalytic dehalogenation of the corresponding bromo-compounds. The same catalysts are used as a rule ($Pd/BaSO_4$, Pd/C) and the solvent usually consists of aqueous solutions of alkalis, the same values of a being attained (5–25 c mmol^{-1}). Adenosine-8-t,[179,188–190] guanosine-8-t,[189,190] inosine-8-t,[189] uridine-5-t,[179–181] 2-deoxyuridine-5-t,[179,180] cytidine-5-t,[181] adenosine monophosphate-8-t,[170,191,192] adenosine cyclic phosphate-8-t,[179,193] and uridine monophosphate-5-t [179] have been obtained in this way, but the yields did not exceed 50–60% owing to the reduced reactivity of the initial bromine-containing compounds. The latter is apparently determined by the existence in solution of a secondary structure stabilised by intramolecular forces[179]. The weakening of this stabilisation increases both the yield and the value of a of the labelled nucleosides and nucleoside phosphates obtained.

In order to convert the labelled monophosphates into labelled triphosphates, enzymatic phosphorylation is used. As in the case of peptides, the manufacture of tritium-containing nucleoside phosphates stimulated the development of methods for the synthesis of the monophosphates of the corresponding bromonucleosides[194].

Table 4. Labelled peptides and proteins obtained by catalytic dehalogenation.

No.	Substance	*n**	Labelled aminoacid residue	Catalyst	Medium	Yield, %	*a*, c mmol^{-1}	Refs.
1	Thyroliberin (releasing factor of thyrotropine)	3	histidine	Pd/Al_2O_3	phosphate buffer (pH 7.3)	–	60	171

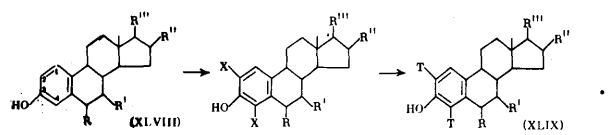
*Here *n* is the number of aminoacid residues.
**Tentatively.

Table 5. Labelled nucleic bases and their analogues obtained by catalytic dehalogenation.



Labelled compound	Initial compound	Catalyst	Medium	Yield, %	*a*, c mmol^{-1}	Refs.
Uracil-5-*t*	5-bromouracil	$Pd/BaSO_4$	aqueous KOH	95-100	20-24	179
Uracil-5-*t*	5-iodouracil	Pt black			25	180
Uracil-5-*t*	5-iodouracil	5% $Pd/BaSO_4$	aqueous KOH	–	20	181
Uracil-6-*t*	6-bromo-2,4-dimethoxypyrimidine	5% $Pd/BaSO_4$	acetic anhydride	–	5-25	182
Cytosine-5-*t*	5-iodocytosine	5% $Pd/BaSO_4$	aqueous KOH	–	–	181
Thymine-methyl-*t*	5-(chloromethyl)uracil	10% $Pd/BaSO_4$	dioxan	70	15	154
Thymine-methyl-*t*	5-(hydroxymethyl)uracil	5% $Pd/BaSO_4$	aqueous acetic acid	77	15	154
5-Ethyluracil-4-*t*	4-chloro-5-ethyluracil	Pd/C	aqueous methanolic NaOH	85	–	183
5-Methylcytosine-methyl-*t*	5-(chloromethyl)-cytosine	PdO	dimethylacetamide	–	8	184
2,3-Dihydro-1,3-oxazine-2,5-dione-5-*t**	5-bromo-2,3-dihydro-1,3-oxazine-2,6-dione	5% $Pd/BaSO_4$	ethanol	64	11	185
Adenine-8-*t*	8-bromoadenine	Pd black	DMF	85-90	15	186, 187

*Synonym—3-oxauracil-5-*t*.

For steroids, the method of catalytic dehalogenation is particularly valuable, since it makes it possible to introduce the tritium label not only into a specific position and with retention of the Δ-bond, but also stereospecifically. Since steroids of type (XLV) are brominated by *N*-bromosuccinimide (NBS) exclusively in the 7α-position, the dehydrobromination of the resulting bromosteroids (XLVI) using Pd/C or $PdCaCO_3$ leads to 7α-labelled steroids (XLVII). Cholesterol-7α-*t*, pregnenolone-7α-*t*, and dehydroepiandrosterone-7α-*t* [195-198] were obtained by this method in yields exceeding 90% and with $a \cong 10$ c mmol^{-1}:[198]

Steroids (XLVIII) with an aromatic A ring, particularly the derivatives of oestradiol, are readily brominated (NBS) or iodinated (I_2 in aqueous methanol) in the 2- and 4-positions, which makes it possible to obtain subsequently by catalytic dehalogenation the steroid compounds (XLIX) labelled with tritium in these positions; oestradiol-2,4-t_2 (Raney Ni, aqueous NaOH),[169] oestriol-2,4-t_2 (Pd/C catalyst),[199] 16-oxo-oestradiol-2,4-t_2,[200] and isomeric oestra-1,3,5(10)-trienols-2,4-t_2 (5% Pd/Al_2O_3, ethyl acetate, $a = 15$–28 c mmol^{-1} [201]). The introduction of tritium into the 16-position in the 3α, 17α-dihydroxypregnane molecule has also been achieved by debromination (Pd/C catalyst):[202]

Vitamin K, labelled in the 6-position of the naphthoquinone nucleus (obtained from 6-bromo-2-methylnaphthaquinone with subsequent synthetic stages; (Pd/C, aqueous alcoholic NaOH, 5 °C),[203] α-tocopherol-(5-methyl-T) (obtained from 5-chloromethyl-α-tocopherol; Pd/C catalyst),[204] the antibiotic tetracycline-(7-T) (obtained from 7-chlorotetracycline, Pd/C, dioxan in the presence of tributylamine, $a = 5$ c mmol^{-1}),[205] the alkaloids papaverine (obtained from 6'-bromopapaverine; 10% Pd/C, dioxan containing Et_3N, $a = 43$ c mmol^{-1}; dehalogenation accompanied by exchange in methoxy-groups)[153] and *O*-benzoylecgonine-(benzoyl-2-T) [obtained from

O-(2-iodobenzoyl) ecgonine; Pd/C catalyst, $a = 21$ μc mg^{-1}],[206] the carcinogenic polycyclic aromatic hydrocarbon 7,8-dibenzoyloxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene, indefinitely labelled in the pyrene nucleus (obtained from a mixture of the corresponding bromopyrenes; Pd black, dioxan containing Et_3N, $a = 1.25$ *c* mmol^{-1}),[207] *N*-(2-imidazolidinylidene)-2,6-dichloroaniline-4-*t*—the medicinal preparation clonidine exhibiting a hypotensive activity (obtained from the corresponding 4-bromo-derivative; Pd/C, tetrahydrofuran, $a = 1.6$ c mmol^{-1}),[165] and the cardiac preparations practol [practolol? (Ed.of Translation)] and isopractol [isopractolol? (Ed.of Translation)] (obtained from 3,5-dibromo-4-hydroxyacetanilide with subsequent synthetic stages; 10% Pd/C, methanol containing Et_3N, yield 86%, $a = 20$ c mmol^{-1})[208] should be mentioned as examples of the application of the method of catalytic dehalogenation for the synthesis of labelled BAS of other types.

In conclusion one should note that catalytic dehalogenation is not the only method for the replacement of a halogen by tritium. For this purpose, the following procedures have been recommended in recent years: reduction with sodium amalgam in HTO,[209] reduction with zinc and CH_3COOT in ether [in the conversion of 17α-bromopregnenolone into pregnenolone-17α-*t*],[210] reduction with Zn–Cu alloy in organic solvents in the presence of HTO (in the introduction of deuterium into the 3-*exo*-position of camphor starting from 3-bromocamphor),[211] electrochemical reduction in HTO [in the synthesis of uracil-5-*t* and deoxyuracil-5-*t* from the corresponding 5-bromo-derivatives][212,213], and finally simple heating of certain 5-iodopyrimidines (orotic acid, uracil, cytosine, and their derivatives) in dimethyl sulphoxide containing 5% HTO.[214] However, in all the instances enumerated the activity *a* of the resulting preparations was appreciably lower than in catalytic dehalogenation.

The Miscibility of Water and Non-polar Substances at High Temperatures

A.Yu.Namiot

Data on the phase equilibria in water-non-polar substance systems at high temperatures and on the relations between the volume, pressure, and composition of the phases involved in these equilibria are considered. The characteristics of the phase equilibria are analysed.
The bibliography includes 66 references.

I. INTRODUCTION

At normal temperatures the miscibility of water and non-polar substances is very low. With increase of temperature, the miscibility undergoes complex changes and under certain conditions can actually become infinite.

Fairly extensive experimental data have now accumulated on the phase equilibria in water–non-polar substance systems at high temperatures (see the relevant reviews[1-3]). Evidently the available data cannot exhaust the possible wide variety of such mixtures particularly when one takes into account mixtures of several non-polar components with water and mixtures with water containing dissolved salts. It is therefore necessary to formulate general ideas concerning the properties of mixtures of water and non-polar substances which determine the phase equilibria. Such properties are in the first place relations between the chemical potentials (fugacities) of the components and their concentrations, as well as the partial volumes and enthalpies of the components. It is also important to establish to what extent the experimental data obtained are consistent with the existing ideas concerning the molecular nature of the mixtures investigated.

After the description of the phase equilibria in water–non-polar substance systems, this review deals with the characteristics of the variation of the chemical potentials of the components in different phases with pressure, temperature, and composition. In conclusion the phase behaviour in water–non-polar substance systems is explained on the basis of the observed features.

II. GENERAL DESCRIPTION OF THE PHASE EQUILIBRIA IN WATER–NON-POLAR SUBSTANCE SYSTEMS

Two main types of phase behaviour are known for water–non-polar substance systems. The liquid–gas critical curve on the pressure–temperature diagram for the first type consists of two branches. The first branch begins at the critical point of water and either passes through a temperature minimum (Fig. 1*a*) or increases continuously with temperature (Fig. 1*b*) and is directed towards the region of high pressures. This branch probably terminates at very high pressures where the substance solidifies. The second branch begins at the critical point of the non-polar substance and terminates at the critical end point where the critical phase is in equilibrium with some other phase (a second liquid phase, ice, or a clathrate hydrate. For systems of the second type (Fig. 2), the liquid–gas critical curve joins together the critical points of the two components, without splitting into branches. At the same time there exists a liquid–liquid critical curve.

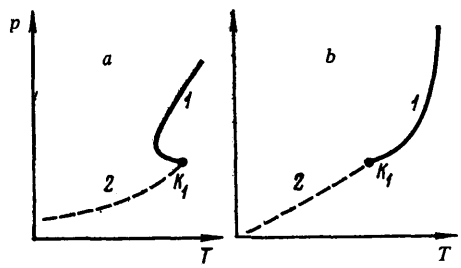

Figure 1. 1) The branch of the critical curve originating at the critical point of water for a water–non-polar substance system (system of type I) (K_1 is the critical point of water); 2) water vapour pressure curve.

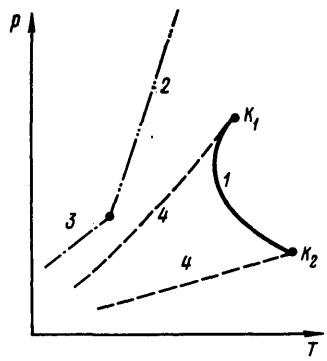

Figure 2. Critical curves for the water–naphthalene system (system of type II) (K_1 and K_2 are the critical points of water and naphthalene respectively): 1) and 2) liquid–gas and liquid–liquid critical curves; 3) liquid–liquid–gas three-phase curve; 4) vapour pressure of the pure substance.

The majority of the water–non-polar substance systems investigated belong to the first type. If the treatment is confined to systems for which the second branch of the critical curve is observed at temperatures where the formation of ice or clathrate hydrates is ruled out, then the pressure–composition diagrams shown in Figs.3–6 are characteristic of equilibria of this type. In Fig.3, which corresponds to a comparatively low temperature, *A* is the region of equilibrium between the solution in the non-polar liquid (henceforth the non-polar or specifically the hydrocarbon liquid) and gas and *B* is the region of equilibrium between the solution of the non-polar substance in water (henceforth the aqueous liquid) and gas. With increase of temperature, there is an increase in the vapour pressures of water and the non-polar substance, of the solubility of water in the non-polar liquid, and of the three-phase equilibrium pressure, and the properties of the non-polar liquid and the gaseous phase involved in the three-phase equilibrium become more similar. This increase in the similarity of the properties terminates with the establishment of the critical state.

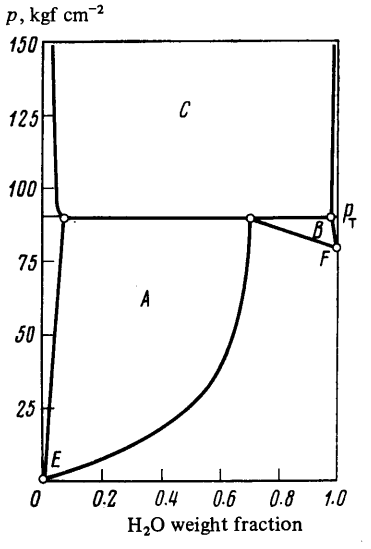

Figure 3. The pressure–composition diagram for a water–non-polar substance system at a temperature below that of the critical end point; *A*, *B*, and *C*—the regions corresponding to non-polar liquid–gas, aqueous liquid–gas, and liquid–liquid equilibria; *E*—vapour pressure of non-polar liquid; *F*—vapour pressure of water; P_T—liquid–liquid–gas three-phase equilibrium pressure.

Fig.4 presents the phase diagram for the same system as in Fig.3 but at a higher temperature, where the properties of the hydrocarbon liquid are the same as those of the gas phase and a critical point *K* appears in the region of the three-phase equilibrium. Since the substance at the critical point is in a region of three-phase equilibrium, it is involved in a phase equilibrium with the aqueous liquid. In this case the critical point is referred to as the critical end point. The equilibrium regions *A* and *B* are in contact at the critical end point.

Fig.5 presents the same system at a temperature exceeding that of the critical end point. At this temperature the three-phase equilibrium no longer exists and regions *A* and *B* are no longer in contact with one another and the critical point *K* is not in equilibrium with the aqueous liquid.

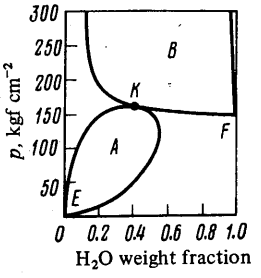

Figure 4. The pressure–composition diagram for a water–non-polar substance system at the temperature of the critical end point (*K* is the critical end point); for the significance of the remaining symbols, see Fig.3.

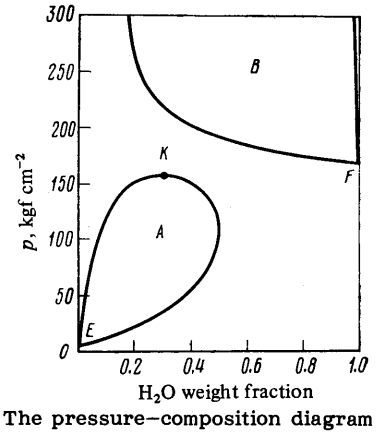

Figure 5. The pressure–composition diagram for a water–non-polar substance system at a temperature above that of the critical end point; for the significance of the symbols, see Figs.3 and 4.

Starting with the temperature of the critical end point and over a certain temperature range above it, region *B* extends up to high pressures without the establishment of the critical state. The establishment of the critical state in region *B* is observed only after the attainment of an extremely high temperature. This is evident from the location of the branch of the critical curve beginning at the critical point of water (Fig.1). For all the water–non-polar substance systems, this branch is bounded by temperatures which are comparatively close to the critical temperature of water. In terms of its nature, the critical curves are of two types in the given case (Figs.1*a* and 1*b*). The commonest type of the critical curve is illustrated in Fig.1*a*. In this case the critical curve is directed from the critical point of water towards low temperatures, reaches a minimum critical temperature, and then rises sharply towards high pressures as the temperature increases. The curve of the second type (Fig.1*b*) is directed from the critical point of water towards high temperatures with a sharp increase of pressure.

Below the minimum critical temperature on the curve illustrated in Fig. 1*a*, critical phenomena are not observed between the gas and the aqueous liquid. At higher temperatures (but not above the critical temperature of water) the constant temperature straight line intersects twice the critical curve and two critical points, characterised by different pressures and compositions, correspond to each temperature T_1 and T_2. The phase diagram in Fig. 6 illustrates precisely this case. The critical points at lower pressures belong to the region of the aqueous liquid–gas phase equilibrium, while those at high pressures belong to the special region of phase equilibria observed when mixtures split up into two layers[4,5] and referred to sometimes as the gas–gas equilibrium. The $p-T$ diagram for systems whose $p-N$ diagrams are illustrated in Figs. 3–6 is presented in Fig. 7. For the system whose critical curve is shown in Fig. 1*b*, the pressure–composition phase diagram has the form illustrated in Fig. 8.

A considerable number of binary systems showing the above type of phase behaviour have now been investigated at high temperatures. Table 1 presents certain characteristics of such systems. Almost all the systems investigated are binary. The phase equilibria in the nitrogen–hexadecane–water ternary systems have been studied[28,29]. The naphthalene–water[21], tetrahydronaphthalene–water[30], and decahydronaphthalene–water[30] systems exhibit the second type of phase behaviour of hydrocarbon–water systems.

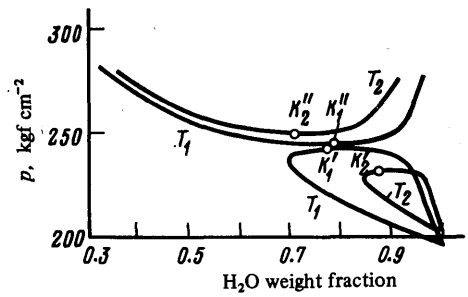

Figure 6. The pressure–composition diagram for a water–non-polar substance system in the vicinity of the critical point of water; K'_1 and K'_2—critical points for the liquid–gas equilibrium; K''_1 and K''_2—critical points for the gas–gas equilibrium.

III. GASEOUS MIXTURES OF WATER AND NON-POLAR SUBSTANCES

The fugacities, partial volumes, and partial enthalpies of the components of the gaseous mixture can be found from the relation between the volume, pressure, temperature, and mixture composition ($p-V-T-N$ data). Such data are available for a number of binary gaseous mixtures of water vapour and non-polar substances. Table 2 lists the mixtures investigated and gives the temperatures and pressure ranges where the relevant experimental determinations were made over a wide range of compositions.

Table 2. The temperature and pressure ranges in which the volumes of gaseous mixtures of water and non-polar substances were investigated.

The volumes of the gaseous mixtures of water vapour with hydrocarbons and nitrogen below the critical temperature of water and at pressures which do not exceed greatly the water vapour pressure are reproduced satisfactorily with the aid of the Redlich–Kwong equation of state modified by Prausnitz and coworkers[35] for mixtures of water and non-polar components. This equation is apparently suitable for the description of the volumes of gaseous mixtures of non-polar components with water vapour also above the critical temperature of water, provided that the pressure does not exceed 200–250 kgf cm^{-2}.

The Redlich–Kwong equation is

$$P = \frac{RT}{v-b} - \frac{a}{v(v+b)\,T^{0,5}} . \qquad (1)$$

The coefficient of Eqn.(1) for a mixture is usually expressed in terms of the coefficients of the mixture components and their mole fractions with the aid of the equations

$$b = \sum_i b_i N_i, \; a = \sum_i \sum_j a_{ij} N_i N_j, \qquad (2)$$

$$b_i = 0{,}0867 RT_{K_i}/P_{K_i}, \; a_{ii} = 0.4278\; R^2 T_{K_i}^{2,5}/P_{K_i}, \qquad (3)$$

$$a_{ij} = a_{ii}^{0,5} a_{jj}^{0,5},$$

where p is the pressure, v the molar volume, N the mole fraction, R the gas constant, and T the absolute temperature.

Eqns.(2) and (3) are relatively unsuitable for both water and for water–non-polar substance mixtures. Two modifications have been introduced[35] into Eqns.(3). Firstly, account was taken of the fact that the coefficient a for water is not constant but decreases appreciably with temperature. This is because the interaction between water molecules is to a large extent determined by hydrogen bonds and dipole–dipole interactions. The above interactions are extremely sensitive to the mutual orientation of water molecules and therefore diminish sharply with increased temperature. The coefficients a_{11} for water (henceforth water will be designated by subscript 1 and the non-polar substance by 2) at different temperatures have been determined from data for the dependence of the volume of water vapour on pressure; the corresponding values of a_{11} have been tabulated as a function of temperature[35].

The necessity for the second modification in Eqn.(3) arises from the fact that, when water molecules interact with non-polar molecules, neither hydrogen bonds nor dipole–dipole interactions, which play the main role in the interaction of water molecules with one another, occur. The coefficient a_{11} was divided into two parts:

$$a_{11}(T) = a_{11}' + a_{11}''(T). \qquad (4)$$

The quantity a_{11}' is independent of temperature and is determined by dispersion interaction forces, while a_{11}'' is determined by hydrogen bonds and dipole–dipole interactions. In the calculation of the mixed coefficient a_{1j} for water and the non-polar substance from the last Eqn.(3), account is not taken of the entire coefficient a_{11} but only of that part of it which contributes to the water–non-polar substance interaction (a_{11}')†:

$$a_{1j} = (a_{11}' a_{jj})^{0,5}. \qquad (5)$$

According to Prausnitz and coworkers[35], $a_{11}' = 35$ kg K$^{1/2}$ litre^2 mol^{-2}.

The unsuitability of the method of Prausnitz and coworkers[35] for the description of $p-V-T-N$ data for mixtures in which water vapour predominates at temperatures above the critical temperature of water and at pressures in excess of 200 kg cm^{-2} is due to the fact that the coefficient a_{11} of the Redlich–Kwong equation for pure water vapour begins to depend appreciably on pressure when the latter is above 200–300 kg cm^{-2}.

The Redlich–Kwong equation with the modifications described has been tested not only for the volumes of gaseous mixtures but also in relation to the phase equilibria. The equation

$$\ln f_i = \ln \frac{N_i RT}{v-b} + \frac{b_i}{V-b} - \frac{2\sum_j N_j a_{ij}}{RT^{3/2} b} \ln \frac{v+b}{v} + \frac{ab_i}{RT^{3/2} b^2}\left[\ln \frac{v+b}{v} - \frac{b}{v+b}\right] \qquad (6)$$

with the aid of which the chemical potential (fugacity) of the mixture component f_i is determined, corresponds to the equation of state (1). Eqn.(6) was tested with the aid of data for phase equilibria between water and gas. Since the solubility of non-polar substances in water is as a rule very low, the fugacity of water in the aqueous liquid can be set equal to the tabulated fugacity of pure water multiplied by the mole fraction of water in the liquid, which is close to unity, and by Poynting's correction, which takes into account the amount by which the pressure exceeds the water vapour pressure. Having substituted this value in Eqn.(6), we find from Eqns.(6) and (1) the concentration of water vapour in the gas saturated with water at the given pressure.

†An analogous approach has been proposed by M.I.Temkin[36].

Table 3[37] presents systems for which calculation of the water vapour content in the gas in equilibrium with water proved to be satisfactory over a specific range of temperatures and pressures.

Table 3. Errors in the calculation of the water vapour content of the gas in equilibrium with water (average for several pressures).

t, °C	P_{max}, kgf cm^{-2}	Error, %	t, °C	P_{max}, kgf cm^{-2}	Error, %
	Methane			n-Hexane	
150	400	2.7	200	37	1.8
200	400	3.6	220	53	2.2
250	400	3.4	235	150	3.1
300	400	2.8	250	150	3.7
			275	150	4.5
	n-Butane			n-Decane	
171.1	562	2.4	300	100	8.9
204.4	562	2.3	310	100	9.2
237.8	421	2.9			

Attention should be drawn to the fact that in many instances calculation of the water vapour content in a non-polar gas by Eqns.(1) and (6) leads to satisfactory results also at those temperatures and pressures at which Eqn.(1) is unsuitable for the calculation of the volume of pure water vapour. The cause of this discrepancy lies in the fact that the region of applicability of Eqn.(1) to non-polar gases is wider than the region of its applicability to water vapour. When the content of water vapour in the gaseous mixture is low, Eqn.(1) describes the volumes of the mixture at pressures where it is unsuitable for mixtures with a high content of water vapour.

The applicability (within certain regions of the parameters of state) of the equation of state to gaseous mixtures of water vapour and non-polar components makes it possible to calculate the chemical potentials of the components of the above systems and their dependence on pressure and composition, i.e. all the data required for calculations on phase equilibria. The majority of the calculations based on the equation of state are carried out on a computer; the calculations can yield information about the behaviour of specific systems. However, general analysis of the behaviour of systems as a function of the properties of a non-polar substance with the aid of a computer is difficult. The approximate method for estimating the volume behaviour of mixtures described below is therefore of interest. The volumes of mixtures are frequently described by means of a quantity called the excess volume:

$$v_{exc} = v - v_1^0 N_1 - v_2^0 N_2, \qquad (7)$$

where v_1^0 and v_2^0 are the molar volumes of the pure components and v is the molar volume of the mixture.

Figs.9 and 10 present the excess volumes in the water–methane[31,32] and water–octane[33] systems. At low and moderate pressures the excess volume is positive in all the systems investigated; in individual instances the volume exceeds by 20–30% the additive volume of the components. With increase of pressure, the excess volume behaves in a fairly complex manner in many instances. Thus in the water–octane system (Fig.10) mixtures in which water predominates are characterised, as before, by the increase of the volume above the additive value, while mixtures in which the hydrocarbon predominates have a volume smaller than the additive value, i.e. the excess volume curve has a maximum and a minimum. On further increase of pressure, the excess volume becomes negative over the entire range of compositions.

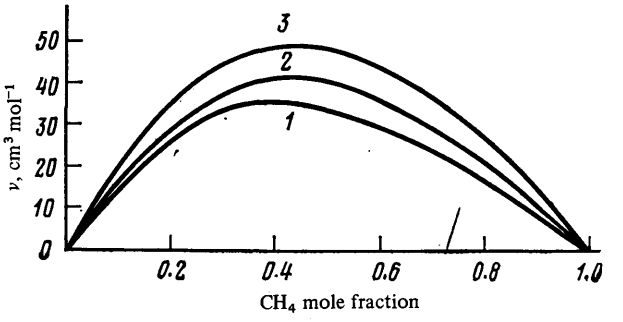

Figure 9. The excess molar volumes in the methane–water system at 350 °C and at different pressures (kgf cm^{-2}): 1) 60; 2) 100; 3) 140.

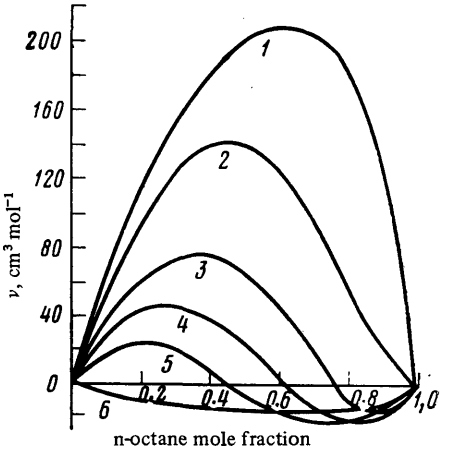

Figure 10. The excess molar volumes in the octane–water system at 350 °C and at different pressures (kgf cm^{-2}): 1) 40; 2) 60; 3) 80; 4) 100; 5) 120; 6) 140.

Calculations of the volumes by the Redlich–Kwong equation with Prausnitz's modifications reproduce the different forms of dependence on the excess volume and composition presented in Fig.10. On the assumption that this equation is applicable to the description of excess volumes in gaseous

solutions, it is possible to carry out a general analysis of the volume behaviour of the test systems as a function of the nature of the non-polar substance, which is determined by the coefficients a_{22} and b_2.

Since the equation of state (1) has been solved for pressure, analysis is greatly simplified when the excess pressure is used instead of the excess volume. The excess pressure is the difference between the true pressure of the mixture and the pressure calculated from Dalton's law, i.e. obtained by adding together the pressures of the pure components (p_1^0 and p_2^0) of the mixture occupying the same volume as the mixture:

$$p_{exc} = p - p_1^0 N_1 - p_2^0 N_2. \quad (8)$$

Since the behaviour of the excess pressure and excess volume is qualitatively similar, for an approximate estimate of the behaviour of the excess volume one can employ data for the behaviour of the excess pressure.

The form of the dependence of the excess pressure on composition is determined primarily by the sign of the derivatives $\partial p_{exc}/\partial N_1$ at the ends of the composition axis, i.e. at $N_1 = 0$ and $N_1 = 1$. For the excess pressure maximum, it is necessary that

$$(\partial p_{exc}/\partial N_1)_{v,T,N_1=0} > 0 \text{ and } (\partial p_{exc}/\partial N_1)_{v,T,N_1=1} < 0. \quad (9)$$

For the simultaneous presence of an excess pressure minimum in mixtures with a high content of the non-polar substance and an excess pressure maximum in mixtures with a high water vapour content, it is necessary that

$$(\partial p_{exc}/\partial N_1)_{v,T,N_1=0} < 0 \text{ and } (\partial p_{exc}/\partial N_1)_{v,T,N_1=1} < 0. \quad (10)$$

Finally, for an excess pressure minimum, it is necessary that

$$(\partial p_{exc}/\partial N_1)_{v,T,N_1=0} < 0 \text{ and } (\partial p_{exc}/\partial N_1)_{v,T,N_1} > 0. \quad (11)$$

The van der Waals equation

$$p = RT/(v-b) - a/v^2 \quad (12)$$

can be used for the approximate analysis of the above problem instead of the Redlich–Kwong equation (1). Eqn.(12) differs little from Eqn.(1) at constant temperature and at not unduly high pressures. It is noteworthy that, despite the identical designation of the coefficients of Eqns.(1) and (12), their numerical values are different. Using Eqns.(12), (2), and (5), it is possible to obtain the expressions

$$(\partial P_{exc}/\partial N_1)_{v,T,N_1=0} = \frac{RT(b_1-b_2)}{(v-b_2)^2} - \frac{RT}{v-b_1} + \frac{RT}{v-b_2} + \frac{a_{11}+a_{22}-2a_{12}}{v^2}, \quad (13)$$

$$(\partial P_{exc}/\partial N_1)_{v,T,N_1=1} = \frac{RT(b_1-b_2)}{(v-b_1)^2} - \frac{RT}{v-b_1} + \frac{RT}{v-b_2} + \frac{2a_{12}-a_{11}-a_{22}}{v^2}. \quad (14)$$

For higher values of v (i.e. at low pressures), the sum of the first three terms of Eqns.(13) and (14) can be neglected compared with the fourth term. Since $a_{12} < (a_{11}+a_{22})/2$ conditions (9) hold at low pressures. With increase of v, the first terms of Eqns.(13) and (14) begin to increase in absolute magnitude; their sign is negative for $b_2 > b_1$. The first term of Eqn.(13) then increases faster than the first term of Eqn.(14), so that, on passing to small volumes (i.e. high pressures), the derivative $(\partial p_{exc}/\partial N_1)_{v,T,N_1=0}$ can change sign before $(\partial p_{exc}/\partial N_1)_{v,T,N_1=1}$ and two extrema are observed [condition (10)]; finally, on further increase of pressure, the derivative $(\partial p_{exc}/\partial N_1)_{v,T,N_1=1}$ also changes sign and an excess pressure minimum is observed [condition (11)].

Thus, subject to the condition that the volume of the molecule of the non-polar substance exceeds that of the water molecule ($b_2 > b_1$), conditions (9), (10), and (11) should be established successively with increase of pressure. The greater the volume of the molecule of the non-polar substance, the higher the pressure at which the above changes in the excess volume (pressure) occur. One should recall that the behaviour described is observed only in the region of applicability of the equation of state adopted.

It is noteworthy that the principal specific feature of gaseous solutions of water and a non-polar substance is an extremely weak interaction between unlike molecules. This feature is manifested both at low and at high temperatures. The structural order characteristic of the liquid phase is not significant in gaseous solutions at low densities. The inapplicability of simple two-parameter equations of state to high-density water vapour should apparently be attributed to this factor.

IV. LIQUID SOLUTIONS OF NON-POLAR SUBSTANCES IN WATER

There are very few data for solutions of non-polar substances in water which could yield information about the thermodynamic quantities of the solutions over a wide range of temperatures and pressures. The solutions of methane in water have been most thoroughly investigated. Data for the solubility of methane in water and the volumes of the solutions at low and moderate temperatures have been available for a comparatively long time[38,39] and those for the range 200–350 °C were obtained more recently[7,40,41].

The Henry coefficient H_i can be found from solubility data. By definition[42], it is related to the difference between the chemical potential of component i at infinite dilution, extrapolated to the pure substance, and the chemical potential of the component in the ideal gas state at $p = 1$:

$$RT \ln H_i = \mu_i(p, T) - \mu_i(\text{id.gas}, T, p=1). \quad (15)$$

Here H_i is the Henry coefficient, μ_i is the chemical potential of component i, and the dot under the symbol means that the given quantity refers to the state of infinite dilution. Knowing the dependence of the Henry coefficient on temperature, it is possible to obtain by means of Eqn.(15), with the aid of a familiar thermodynamic relation, the enthalpy change for transfer of component i from the ideal gas state to an infinitely dilute solution:

$$\left(\frac{\partial \ln H_i}{\partial T}\right)_p = -\frac{(h_i - h_{i,\text{id.gas}})}{RT^2}, \quad (16)$$

where h_i is the partial molar enthalpy of component i.

The solutions of methane as well as the majority of other non-polar substances in water are characterised by two features at low temperatures: firstly, on formation of these solutions from an ideal gas and water, the enthalpy decreases (heat is evolved) and, secondly, the Henry coefficient of the non-polar substance dissolved in water is very high (and correspondingly the solubility is extremely low).

The characteristics of the solubility of non-polar substances in water at low temperatures are said to be related to the ideas concerning the structure of liquid water. It is known that at low temperatures liquid water to a large extent retains the structure of ice within the limits of short-range order. In the structure of ice water molecules are distributed relative to one another in such a way that each is involved in the maximum possible number of hydrogen bonds (four bonds). By virtue of the high energy of the hydrogen

bonds, ice is fairly stable despite the small coordination number; the small coordination number is responsible for the extremely loose packing characterised by the presence of comparatively large cavities. In liquid water at low temperatures some of the cavities are filled by water molecules[43], which are linked to the molecules surrounding the cavities by dispersion interaction forces.

Apparently at low temperatures the non-polar molecules incorporated in water disrupt the hydrogen bonds existing between water molecules to only a slight extent, but they transform the water structure around themselves in such a way that cavities arise in the latter in which the non-polar molecules can be accommodated. The evolution of heat (decrease of enthalpy) on formation of a liquid solution from a non-polar substance in the ideal gas state and water is then related to the absence of a significant energy expenditure on the dissociation of hydrogen bonds and to the gain of the dispersion interaction energy by the molecules of the non-polar substance. A certain amount of energy is also evolved because the water molecules displaced by the non-polar substance from the cavities form hydrogen bonds with one another[44-46].

The second feature of solutions of non-polar substances in water at low temperatures, namely their low solubility, has not yet received a generally accepted explanation[46,47]. Attempts to explain the low solubility of non-polar substances in water have been made in two investigations[48,49]. It has been suggested[49] that the formation of cavities in water, whose volume makes it possible to accommodate non-polar molecules larger than helium and neon atoms and hydrogen molecules#, is not accompanied by a change in enthalpy, but proceeds with a decrease of entropy. The decrease of entropy is associated with the increase of the Henry coefficient in accordance with the thermodynamic equation

$$RT \ln H_i = \Delta h_i - T\Delta S_i; \qquad (17)$$

where Δh_i and ΔS_i are the change in the enthalpy and entropy on transfer of the non-polar substance from the ideal gas state at $p = 1$ to the hypothetical state of the solute extrapolated to the pure substance.

At high temperatures (starting from ~100 °C) the solubility of methane in water increases with temperature at an increasing rate[41]. According to Eqn.(16), this corresponds to a negative heat of solution, i.e. to the absorption of heat. This finding is consistent with data showing that, under the conditions of intense thermal movement, ordered structures in water lose their importance. In the limit at a sufficiently high temperature both water and methane molecules in solutions are distributed completely at random and water–water interactions are replaced by water–methane interactions in the dissolution process. As already mentioned, this change should take place with loss of energy. The internal energy for the intermolecular interaction of the ideal gas is zero. Thus at high temperatures the change in the internal polar energy on dissolution will be greater than zero ($e_i - e_{i,\text{id.gas}} > 0$). The work associated with the decrease of the volume of the gas when the latter dissolves is also positive; consequently the entropy change is likewise positive ($h = e + pv$).

The difference in the nature of the solubility of non-polar substances in water at low and high temperatures is also indicated by the partial molar volume of the substance dissolved in water. For example, the partial molar volumes of methane dissolved in water at 0° and 50 °C [40] are much smaller than the corresponding quantities for the methane dissolved in other solvents[48].

Partial molar volumes of methane dissolved in water at 400 kgf cm^{-2} and different temperatures

t, °C	0	50	100	150	200	250	300	350
v, /cm^3	36	38	40	43	49	60	96	141

It is seen from the data presented that, starting from 250 °C and at higher temperatures (300° and 350 °C), the partial molar volume of methane dissolved in water increases sharply. This finding is consistent with the idea that at high temperatures the water–water interaction is replaced by the water–methane interaction on dissolution of methane, which should be accompanied by a considerable decrease of the forces of interaction between molecules.

A sharp difference between the mechanisms of the dissolution of methane in water is apparently observed at markedly different temperatures. For intermediate temperatures, there is probably a possibility of a mixed dissolution mechanism in which methane molecules are both incorporated in cavities and replace water molecules in the quasi-crystal lattice of the liquid (the "cavity" and "solvation" mechanisms according to Borina and Samoilov[52]).

Using data for the solubility of methane in water, the equations of state for the gas phase (the Lewis–Randall rule at low concentrations of water vapour and the Redlich–Kwong equation at high concentrations), and data for the change in the volume of water on dissolution of methane in the latter, it is possible to determine the changes in the fugacity of methane as a function of its concentration in solution. It has been established for the range 25–171 °C that a solution of methane in water at pressures up to 700 kgf cm^{-2} obeys Henry's law in terms of the thermodynamic formulation[53]:

$$f_2 = H_2(p, T)N_2, \qquad (18)$$

$$H_2(p,T) = H_2(p_1^0, T) \cdot 10^{\frac{v_2(p-p_1^0)}{2.303\,RT}}; \qquad (19)$$

here subscripts 2 and 1 correspond to methane and water respectively. When Eqn.(18) holds and v_2 is independent of pressure, there should be a linear relation between $\lg(f_2/N_2)$ and $p - p_1^0$.

Between 300° and 350 °C, the linear relation between $\lg(f_2/N_2)$ and $p - p_1^0$ does not hold, which can be attributed both to a decrease of the partial molar volume of methane with pressure at high temperatures and to the failure of the Henry law (or to both causes simultaneously). When Henry's law breaks down, an additional multiplier is introduced into Eqn.(18)—the activity coefficient γ, which determines the degree of deviation from Henry's law:

$$f_2 = H_2(p,T)N_2\gamma_2^\infty, \qquad (20)$$

where ∞ refers to infinite dilution. The activity coefficient γ_2^∞ is close to unity in the region of low methane concentrations, but apparently diminishes as the concentration increases. The hypothesis of the decrease of the activity coefficient with concentration is associated with the fact that, at temperatures exceeding the minimum critical temperature in the water–methane system (352 °C), the critical state can be reached; at the critical point of the mixture the fugacity of the component does not vary with concentration:

$$(\partial \ln f_i/\partial N_i)_{p,T} = 0. \qquad (21)$$

#Molecules whose size exceeds these dimensions cannot be accommodated within the cavities of the ice lattice[50,51].

Fig.11 illustrates the variation of the fugacity with the mole fraction when Henry's law holds (dashed line) and the variation of the fugacity in the vicinity of the critical point associated with condition (21), which is obligatory for the critical point of a binary system. It is seen from Fig.11 that, as the critical is approached, the fugacity deviates from the value which it should have when the Henry law holds. This means that the activity coefficient should become less than unity.

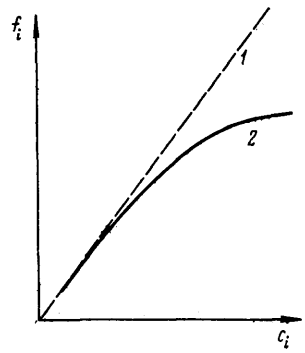

Figure 11. Variation of the fugacity of the component in solution with its concentration: 1) Henry's law; 2) real relation.

The problem of the variation of the properties of a solution of a non-polar substance in water under the influence of the addition of a salt to water is extremely interesting. Bearing in mind that the solubility of non-polar substances in water is extremely low, in most cases it is possible to assume that the chemical potential of water in the aqueous salt solution of a non-polar substance is the same as in the aqueous salt solution without the non-polar substance. The corresponding chemical potentials of water can be found from its vapour pressure over the salt solution. If necessary, a correction is introduced for the difference between the vapour pressure and fugacity and a correction for the Poynting effect when the external pressure exceeds the vapour pressure.

The influence of the salt dissolved in water on the chemical potential of the non-polar solute is much more complex. The solubility of non-polar substances in water in most cases decreases under the influence of salts. The change in solubility is usually described with the aid of Sechenov's equation

$$N_i^* = N_i \cdot 10^{-K_i n}, \qquad (22)$$

where the superscript * refers to the electrolyte solution.

Eqn.(22) holds fairly accurately only at low salt concentrations. At salt concentrations in excess of 0.5–1 M the Sechenov coefficient K_i usually decreases with increase of concentration.

An expression for the Henry coefficient of the non-polar component dissolved in a salt solution in water can be obtained from Eqn.(22) and the definition of the Henry coefficient:

$$H_i^* = H_i \cdot 10^{K_i n}.$$

It is usually assumed that the limits of the applicability of the Henry law [Eqns.(18) and (19)] to non-polar gases dissolved in aqueous salt solutions do not differ significantly from the limits of the applicability of this law to solutions of gases in water without salts.

The temperature dependence of the Sechenov coefficient has been investigated mainly in the range 0–70 °C. At high temperatures the influence of salts on the solubility of non-polar gases has been studied only for carbon dioxide[54,55] and methane[56] and it has been found that the Sechenov coefficient passes through a minimum as a function of temperature. To account for this phenomenon, one must relate the Sechenov coefficient to the thermodynamic functions of component i disssolved in water[57].

Consider the equilibrium between component i in the gas state and both pure water and a salt solution of water in the region where Henry's law holds:

$$\mu_i(\text{gas}) = \mu_i + RT \ln N_i = \mu_i^* + RT \ln N_i^*. \qquad (23)$$

It follows from Eqns.(22) and (23) that

$$\mu_i^* - \mu_i = 2.303\, RT\, n K_i. \qquad (24)$$

According to Eqn.(24), the Sechenov coefficient is related to the difference between the chemical potential of component i in pure water and in the salt solution. Differentiation of Eqn.(24) with respect to temperature yields

$$\frac{h_i - h_i^*}{RT^2} = 2.303\, n \frac{\partial K_i}{\partial T}, \qquad (25)$$

The minimum in the plot of the Sechenov coefficient against temperature is apparently associated with the different natures of solutions of non-polar substances in water at low and high temeratures. If the non-polar molecules in solution in water at low temperatures are located in cavities, then, according to Eqn.(25), the temperature variation of the Sechenov coefficient is determined by the difference between the internal energies of the non-polar substance in pure water and in the salt solution. The internal energy of the intermolecular interaction between the non-polar substance and the skeleton of the water lattice is relatively small and the change in this interaction under the influence of the salt is even smaller.

At a high temperature[57] the formation of the solution involves mainly the replacement of water molecules by those of the non-polar gas in the quasi-crystal lattice. The enthalpy of formation of the solution from the non-polar gas in the ideal gas state and from liquid water can then be regarded as consisting of two components: the main, positive part—the enthalpy of the separation of water molecules from one another on formation of a cavity for the incorporation of the non-polar molecules (e_1)—and a small negative part—the enthalpy of incorporation of non-polar molecules at a quasi-crystal lattice site of water (e_{inc}).

Neglecting the enthalpy of the incorporation of the non-polar substance compared with the enthalpy of formation of a cavity in the water lattice, we find that, for a small difference between the sizes of water molecules and the molecules of the non-polar substance,

$$\left(\frac{\partial K_i}{\partial T}\right)_p \approx \frac{h_1 - h_1^*}{2.3 n RT^2}; \qquad (26)$$

where n is the molality of the electrolyte in solution. It can be shown that

$$\frac{h_1 - h_1^*}{2.3 \cdot RT^2 n} = \left(\frac{\partial \lg (f_1^*/f_1^0)}{\partial T}\right), \qquad (27)$$

where f_1^0 and f_1^* are the fugacities of pure water and the water in the salt solution.

Calculations based on the experimental water vapour pressures over salt solutions[58] show that $h_1 - h_1^* > 0$ and increases with temperature. It follows from this finding that, in conformity with Eqn.(26), the Sechenov coefficient should increase with temperature at high temperatures. The available data for the variation of the Sechenov coefficients confirm Eqn.(26) approximately[54-56] (Fig.12).

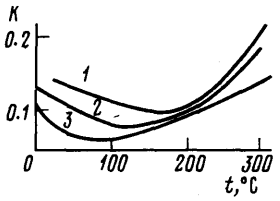

Figure 12. Temperature dependence of the Sechenov coefficients K of gases dissolved in aqueous salt solutions: 1) methane in NaCl solution; 2) carbon dioxide in $CaCl_2$ solution; 3) carbon dioxide in NaCl solution.

On the whole, one should note that the nature of solutions of non-polar substances in water at low temperatures is determined by the distribution of the molecules of the non-polar substance in the structural cavities. At high temperatures the specific features of the dissolution process involve the substitution of water molecules by solute molecules. The changes in the nature of the dissolution process with temperature lead to minima in the temperature variations of the Henry and Sechenov coefficients of non-polar substances dissolved in water.

V. LIQUID SOLUTIONS OF WATER IN NON-POLAR SUBSTANCES

It was noted above that water as a solvent for non-polar substances differs sharply from other solvents: the Henry coefficients of non-polar substances dissolved in it exceed by 2–3 orders of magnitude (and more) their values for the same substances in the majority of other solvents§. Water as a solute in non-polar solvents is not exceptional among other solutes. This is because the specific features of water are manifested in the interaction of its molecules with one another—mainly in the formation of hydrogen bonds. On the other hand, the separated molecules of the water dissolved in a non-polar solvent do not exhibit features characteristic of a collection of water molecules. If the properties of water in its dilute liquid solutions in non-electrolytes are extrapolated to the hypothetical pure substance, then the latter should have properties close to those of non-polar substances with small molecules—for example, methane or nitrogen, i.e. substances whose critical temperature is lower by hundreds of degrees than that of water.

Henry coefficients (kgf cm^2) of water and methane in different solvents (Refs.59-62)

Solvent	n-Butane	n-Decane	n-Hexadecane
t, °C	37.7	237.8	250
Water	140	150	190
Methane	190	250	200

§Certain aromatic hydrocarbons are an exception.

Evidently the Henry coefficients of water and methane in different non-polar solvents are of the same order of magnitude.

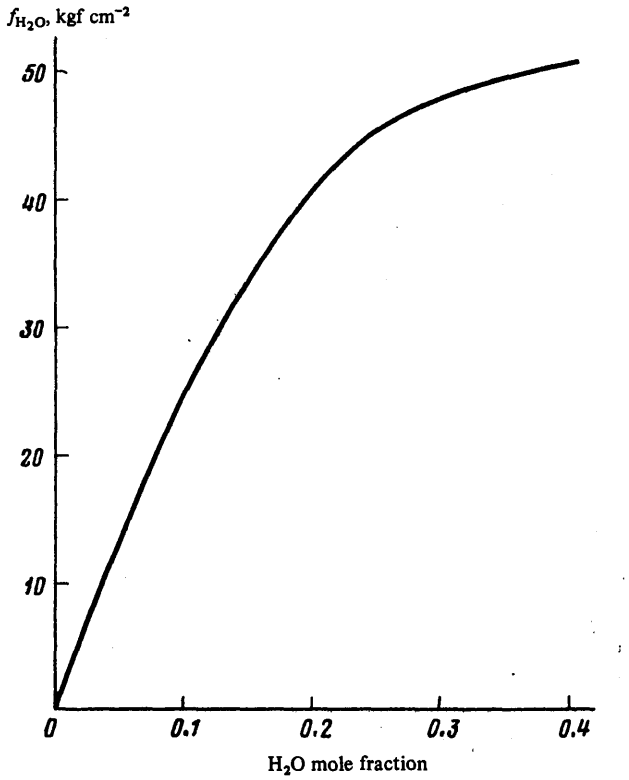

Figure 13. Dependence of the fugacity of water on its concentration in a decane–water mixture at 275 °C and a pressure of 73.2 kgf cm^{-2}.

There are at present numerous data for the phase equilibria between liquid non-polar substances and gaseous mixtures and between liquid non-polar substances and liquid aqueous solutions. Information concerning certain thermodynamic properties of solutions of water in non-polar substances can be obtained from these data. For example, in view of the possibility of calculating the fugacities of the components in gaseous solutions from the equation of state (see Section III), it is possible to find the fugacities of the components in liquid solutions in equilibrium with the gas phase along the saturation line. There are fewer data for the volumes of solutions of water in liquid non-polar substances.

Relatively detailed information is available about both phase equilibria and the volumes for solutions of water in decane at 275 °C.[34] The dependence of the fugacity of water on its mole fraction in its liquid solution at 275 °C and a pressure of 73.2 kgf cm^{-2} has been obtained from these results (Fig.13). Fig.13 shows that, at water concentrations not exceeding a mole fraction of 0.1, a linear relation holds between the fugacity and concentration (thermodynamic formulation of the Henry law) within the limits of experimental accuracy; for mole fractions in excess of 0.1, the increase of fugacity slows down. The activity coefficient γ_1^{∞} in Eqn.(20), corresponding to a mole fraction of 0.4, is appreciably smaller than unity (0.48). The decrease of the activity coefficient is apparently associated with the approach to the critical state [see Eqn.(27)].

The data of Lotter et al.[34] show that at 275 °C and 69.5 kgf cm^{-2} the molar volume of a liquid solution of water in decane varies linearly with concentration when the latter changes from a mole fraction of 0.1 to 0.35. From this it follows that the partial molar volume of water in the above concentration range is constant. Its value under these conditions is 119 cm^3 mol^{-1}, which is much greater than the molar volume of pure water under the same conditions (23.6 cm^3 mol^{-1}).

Measurements of the volumes of solutions of water in various non-polar substances at the same concentration for each hydrocarbon[63] made it possible to calculate the apparent molar volume of dissolved water as the ratio of the volume increment on dissolution of water in the non-polar substance to the number of moles of dissolved water:

$$v_1^{app} = [v - v_2^0(1 - N_1)]/N_1 . \qquad (28)$$

The results (Table 4) exceed severalfold the molar volumes of pure water, which varies from 21.4 to 28.1 cm^3 mol^{-1} under the given conditions.

Table 4. The apparent molar volumes of water v_{eff} dissolved in hydrocarbons.

Hydrocarbon	t, °C	p, kgf cm^{-2}	v_{eff}, cm^3 mol^{-1}	Mole fraction
n-Hexane	220	48	641	0.185
n-Decane	285	67	146	0.319
n-Hexadecane	275	56	86	0.338
	300	81	99	0.428
	330	125	110	0.531

The partial molar volumes of water dissolved in hydrocarbons apparently decrease markedly with increase of pressure. Using data for the phase equilibria in liquid water and decane at 275 °C and pressures up to 800 kgf cm^{-2},[34] neglecting the solubility of decane in water, and assuming (as mentioned above) that the Henry law holds for a water mole fraction in the hydrocarbon less than 0.1, the partial molar volume of water in decane can be found from the differential equation for the phase equilibrium

$$\left(\frac{\partial N_1^n}{\partial p}\right)_T = \frac{v_1^w - \bar{v}_1^n}{RT\,(\partial \ln N_1^n/\partial N_1^n)} \qquad (29)$$

where superscripts n and w refer to the non-polar liquid phase and to the aqueous phase respectively. It was found that, at a pressure of 700 kgf cm^{-2}, it is much smaller than the experimental partial volume of water at 70 kgf cm^{-2}.

VI. CHARACTERISTICS OF THE PHASE EQUILIBRIA IN THE SYSTEMS UNDER CONSIDERATION

The knowledge of the thermodynamic properties of the individual phases in a water–non-polar substance system makes it possible to explain the characteristic features of the phase equilibria in such systems. We shall consider individual types of phase equilibria.

Liquid Water–Non-polar Liquid Equilibria

For systems of the first type (see Section II), these equilibria exist in temperature and pressure ranges located on the $p-T$ diagram (Fig.7) above the three-phase curve. For systems of the second type, the equilibria are observed in the region above the critical liquid–liquid curve or above the three-phase curve in Fig.2.

As long as the temperature is not very high and the miscibility of the liquids considered is small, the solutions are dilute and the solubility of the non-polar component in the aqueous phase N_2^w as well as the solubility of water in the non-polar liquid N_1^w obey Henry's law:

$$N_2^w = \frac{1}{H_2^w(p,T)} f_2^n, \qquad N_1^n = \frac{1}{H_1^n(p,T)} f_1^w \qquad (30)$$

The Henry coefficients of non-polar substances in water at low temperatures are anomalously high, which is responsible for the low solubility of non-polar substances in water; the Henry coefficients of water and non-polar substances do not exhibit anomalies. However, apart from the Henry coefficients of the component dissolved in a given phase, the solubility is determined by the fugacity of the component in the phase in equilibrium with the given phase [Eqn.(30)]. At equilibrium between two dilute liquid solutions this fugacity is close to that of the component in the state of the pure liquid. Both pure water and non-polar liquids have in most cases low vapour pressures at low temperatures and hence low fugacities. According to Eqn.(30), this finding is one of the causes of the low miscibilities of the phases under consideration at low temperatures. With increased temperature, the vapour pressures of the pure liquids also increase, which leads to an increase in the miscibility of the liquids. Here one should bear in mind that, as a consequence of the high Henry coefficients of substances dissolved in water, their solubilities in water are in most cases small and the solubilities of water in non-polar substances, characterised by comparatively small Henry coefficients, become considerable. This factor is responsible for some asymmetry in the miscibility of water and non-polar substances.

An increase of pressure reduces the solubility of water in a non-polar liquid. In the region of the applicability of Henry's law this decrease is defined by Eqn.(29) and can be explained by the fact that the molar volume of pure water is much smaller than the partial molar volume of water dissolved in a non-polar substance. The effect diminishes with increase of pressure owing to the diminution of the partial molar volume of water as the pressure increases. As the critical state is approached, the decrease of the solubility of water in a non-polar liquid under the influence of pressure is intensified, since the denominator of Eqn.(29) should then be replaced by $RT\,\partial \ln f_1^n/\partial N_1^n$, which tends to zero at the critical point (and $\partial N_1^n/\partial p$ tends correspondingly to infinity).

The experimental data referring to both the first and second types of water–non-polar substance systems confirm these findings. Thus Fig.14 illustrates the pressure dependence of the water content in decane in equilibrium with liquid water[64]. The closer the state of the system to the critical end point (Fig.4), the sharper the decrease of the water content in the non-polar liquid with increase of pressure. Fig.15 presents the miscibility in the tetrahydronaphthalene–water system[30] (system of the second type); in this case too the influence of pressure on the solubility of water in tetrahydronaphthalene increases sharply as the critical point is approached.

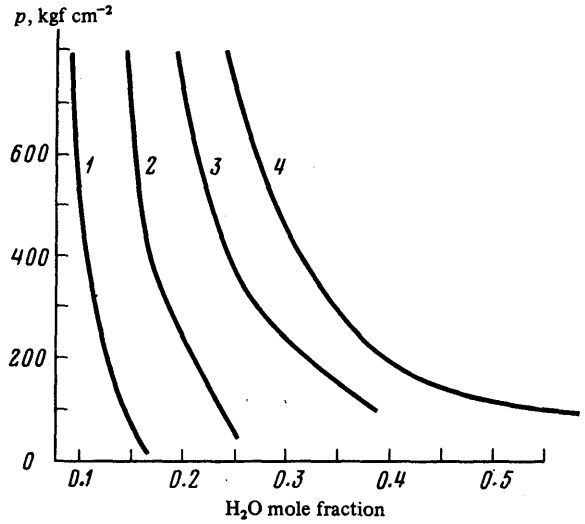

Figure 14. The influence of pressure on the water content in liquid decane in equilibrium with liquid water at different temperatures (°C): 1) 225; 2) 250; 3) 275; 4) 290.

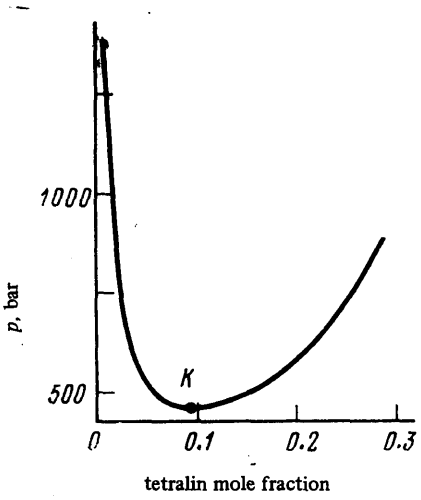

Figure 15. The influence of pressure on the compositions of the equilibrium liquid phases in the tetrahydronaphthalene–water system at 350 °C; *K*—critical point for the liquid–liquid equilibrium.

The solubility of non-polar liquids in water at low and moderate temperatures increases with pressure. This is because at low temperatures the vacancy mechanism of the dissolution[52] of non-polar substances in water plays a major role. In this dissolution mechanism the partial molar volume of the non-polar substances dissolved in water is anomalously small—smaller than the molar volume of the pure liquid non-polar substance. The dissolution of the liquid non-polar substance in water is then accompanied by a decrease of volume and, in conformity with the requirements of thermodynamics, an increase of pressure should promote an increase of solubility. As an example, one may quote data for the water–n-butane system[65]. At high temperatures the vacancy mechanism of dissolution loses its importance and the partial molar volumes of non-polar substances in water increase sharply (see Section IV) and an increase of pressure leads to a decrease of their solubility in water.

Thus at a high temperature the miscibilities of water and a non-polar substance decrease with pressure.

The Non-Polar Liquid–Aqueous Liquid–Gas Phase Three-Phase Equilibrium

If the miscibilities of the liquids are small, then the fugacity of each component in the gas phase in equilibrium with the two liquids is almost equal to the fugacity of this component in the state of the pure liquid. When Dalton's law holds, the pressure in the gas phase of the three-phase state is in this instance almost equal to the sum of the vapour pressures of both components and is therefore higher than the pressure of each component; the composition of the gas phase is intermediate between the compositions of the two liquid phases. The phase diagram then has the form illustrated in Fig.3.

With increase of temperature, the following possibilities for the evolution of the three-phase state exist.

(a) The properties of solutions of water in a non-polar liquid approach those of the gas phase and a critical end point is established (Fig.4). Since the three-phase equilibrium pressure is higher than the vapour pressure of the pure non-polar liquid, the pressure at the critical end point, which belongs to the three-phase equilibrium, is also higher than the vapour pressure of the non-polar liquid. The temperature at the critical end point must be lower than at the critical point of the non-polar substance. For this reason, the branch of the critical curve beginning at the critical point of the pure non-polar substance should be directed towards increasing pressures and decreasing temperatures on the $p-T$ diagram regardless of whether or not the critical temperature of the non-polar substance exceeds the critical temperature of water. Phase equilibria of this kind are characteristic of the first type of water–non-polar substance equilibrium.

(b) The critical end point is established as a result of the mutual approach of the properties of the solution of the non-polar substance in water and of the gas phase. Equilibria of this type are at present unknown.

(c) An azeotrope appears in the system and there is a change of the three-phase equilibrium from the type illustrated in Fig.3 to the type illustrated in Fig.16¶. A characteristic feature of this three-phase equilibrium is that the water content in the gaseous solution is greater than in the

¶If the non-polar substance passes from the solid to the liquid state at an extremely high temperature, there is a possibility of only the three-phase equilibrium of the type illustrated in Fig.16.

liquid aqueous solution. In this case there is a possiblity of the establishment of a critical end point as a result of the mutual approach of the properties of the two liquid phases. The establishment of the critical end point is possible at a temperature below the critical temperatures of both water and the non-polar substance. These features are characteristic of water–non-polar substance systems of the second type (Fig. 2).

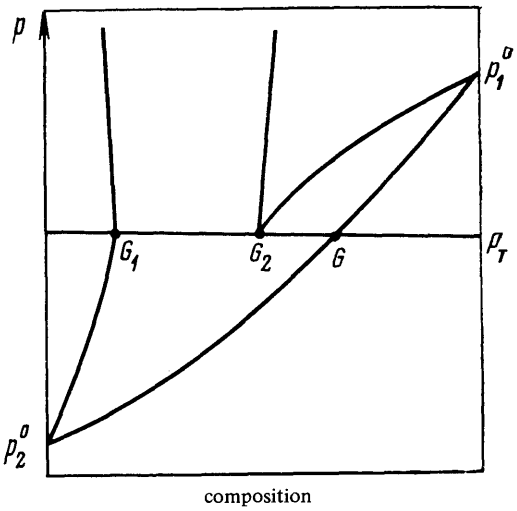

Figure 16. Three-phase equilibrium of the second type; L_1, L_2, and J—compositions of the coexisting liquid and gas phases.

For the above type of equilibria to occur, it is necessary that the content of the non-polar substance in the gas phase should be smaller than in the aqueous solution. For a rough estimate of the possibility of the realisation of this condition, we shall assume that the content of the non-polar substance in the gas phase N_2^g is determined by Dalton's law as the ratio of the partial pressure of the non-polar substance to the sum of the vapour pressures of water (p_1^0) and the non-polar substance (p_2^0):

$$N_2^g = p_2^0/(p_2^0 + p_1^0),$$

and the mole fraction of the non-polar component in the aqueous phase is determined by Henry's law: $N_2^W = p_2^0/H_2^W$. From the condition $N_2^g < N_2^W$, we obtain $H_2^W < p_1^0 + p_2^0$, which requires relatively low values of the Henry coefficient, i.e. a high solubility of the non-polar substance in water. Since a high solubility of the non-polar substance in water is possible at an extremely high temperature, the type of three-phase equilibria under discussion is apparently possible in systems incorporating a non-polar liquid with a high critical temperature and with an increased ability to dissolve in water.

The Aqueous Liquid–Gas Phase Equilibrium

The region of aqueous liquid–gas phase equilibria in systems of the first type is designated by the latter B in Fig. 3, which refers to temperatures below the temperature of the critical end point. Above the temperature of the critical end point (Fig. 4), the aqueous liquid–gas phase equilibrium frequently extends to extremely high pressures. Thus in the water–ethane, water–benzene, water–carbon dioxide, and water–xenon systems equilibria of the above type have been traced up to pressures of $(3–3.5) \times 10^3$ kgf cm^{-2}.

This behaviour of the equilibrium under consideration is observed in a range of temperatures between that of the critical end point and the minimum in the critical temperature. It resembles the behaviour of the aqueous liquid–non-polar liquid equilibrium discussed above, which is reasonable, because, at the terminal critical point of systems of the first type, the non-polar liquid and the gas phase become identical and the resulting phase "inherits" the properties of both phases. At high pressures and low temperatures the properties of the liquid phase are manifested to a greater extent, while at low pressures and high temperatures the properties of the gas phase predominate. As already stated, in the aqueous liquid–non-polar liquid equilibrium the pressure does not promote the mutual approach of the properties of the phases and in the equilibrium between the aqueous liquid and the gas phase at high pressures the compositions of the phases do not approach one another as the pressure is raised.

In systems of the first type, at temperatures exceeding the minimum critical temperature, a critical state arises under certain conditions between the gas and the aqueous liquid when the pressures are low. If the pressure is then increased under isothermal conditions, the system remains homogeneous over a certain range of pressures and then splits into two phases when the pressure attains a sufficiently high value; a further increase of pressure increases the degree of layer formation, as in the non-polar liquid–aqueous liquid equilibrium. Such behaviour is characteristic of the separation of gaseous mixtures of the second kind into layers (Fig. 1*a*). The majority of the water–non-polar substance systems investigated belong to this kind. In systems of the kind described by Fig. 1*b* there are no gas–aqueous liquid critical states at all and, starting from the critical point of water and at higher temperatures, there exist critical states referring to the so-called gas–gas equilibrium.

The gas–liquid critical phenomena beginning at the critical point of pure water in water–non-polar substance systems of the first type are in most cases possible over a short range of temperatures between the critical temperature of water and the minimum critical temperature. For paraffinic hydrocarbons, the minimum critical temperature does not fall below 350 °C, while for mixtures of water and aromatic hydrocarbonds it is lower (294 °C in the case of benzene).

--o0o---

Simple two-parameter equations of state (van der Waals and Redlich–Kwong) reproduce qualitatively the characteristics of the phase equilibria in the water–non-polar substance systems[66]. The quantitative agreement between the calculations and experiment is unsatisfactory, particularly for the van der Waals equation.

Reactions of Acetylene in Superbasic Media

B.A.Trofimov

The results of studies of fundamentally new reactions of acetylene and its substituted derivatives in media of very high basicity are surveyed. They lead to hitherto unknown or relatively inaccessible monomers, reagents, and intermediates: 2-vinyloxybuta-1,3-diene, pyrroles, and *N*-vinylpyrroles, divinyl sulphide, divinyl telluride, 4-methylene-1,3-oxathiolan, di(buta-1,3-dienyl) sulphide, dihydrothiophen, 1-vinyl-2-thiabicyclo[3,2,0]hept-3-ene, etc.
The most important properties of superbasic media consisting of an alkali metal hydroxide and a dipolar aprotic solvent as well as the probable mechanisms of their activating effect on anions and the triple bond are examined. An attempt is made to analyse these reactions in terms of coordination catalysis by alkali metal cations.
The bibliography includes 199 references.

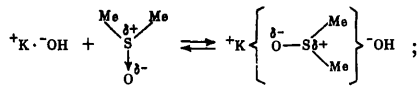
I. INTRODUCTION

As one of the key types of chemical raw material, acetylene, which was somewhat eclipsed in the 1960's by petrochemical ethylene and propene, is now again attracting the attention of investigators and technologists because of the progressive increase in the cost of petroleum and gas in the work markets[1].

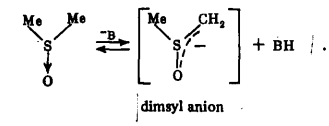
As a result of the development of plasma, laser, and ultrasonic techniques, cheap acetylene will soon be obtainable not only from the petroleum raw material but also from different kinds of coal and combustible shale[2]. Research programmes designed to create a plasma technology for the direct synthesis of acetylene from coal are being developed[3]. Successful studies are being made[4] on the utilisation of liquid acetylene for technological purposes.

The majority of chemical reactions of acetylene are known not to require a supply of energy and are in fact accompanied by its evolution. There are many reasons why acetylene should become in the future the sole raw material for industrial organic synthesis[5]. It has been calculated[6] that acetylene obtained from calcium carbide already constitutes a realistic alternative to the petroleum raw material. On the other hand, a fall in the consumption of ethylene has been noted; for example, in 1978 the ethylene factories in the USA failed to utilise almost half their capacity[7].

A further development of the foundations of the chemistry of acetylene, laid as early as the beginning of this century by Academician A.E.Favorskii, has therefore become an urgent necessity. A new field—the chemistry of acetylene in super basic media—is rapidly developing on the basis of Favorskii's research[8]. In the present review an attempt is made to summarise the main results obtained in this field.



II. THE GENERATION AND CERTAIN CHARACTERISTICS OF SUPERBASIC MEDIA

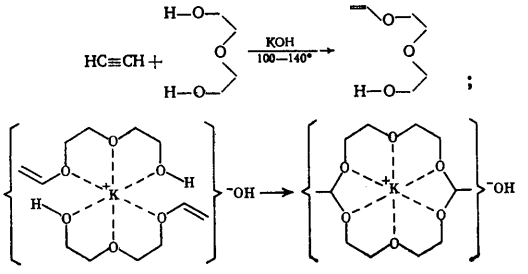


Superbasic media include those consisting of a strong base and a solvent or reagent capable of specific binding of the cation, "baring" the anion[8,9]. Superbasic systems can be obtained on the basis of linear and cyclic glycol ethers, macrocyclic polyethers (crown-ethers), dipolar aprotic solvents such as dimethyl sulphoxide (DMSO), sulpholane, hexamethylphosphoramide (HMP), and phosphine oxides, as well as amides, liquid ammonia, amines, etc. For example, the basicity of sodium methoxide in 95% DMSO is higher by 7 orders of magnitude than in pure methanol[10]:

0.025 M $NaOCH_3$	
Solvent	Acidity function H_
Methanol	12.2
95% DMSO + 5% methanol	19.4

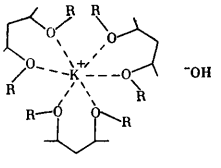
A particularly dramatic increase of basicity occurs at the maximum concentrations of a dipolar aprotic solvent. Thus tetramethylammonium hydroxide in 99.5% aqueous DMSO is more basic by 14 orders of magnitude than in pure water[11].

The superbasicity of the KOH–DMSO system is caused to a first approximation by the separation of the ion pair of the base[12] and by the formation of the highly basic and little solvated dimsyl anion[9] (B^- is a strong base):



However, this does not exhaust the role of DMSO. In the general case account must be taken of cooperative effects involving changes in factors such as the dielectric constant of the medium, hydrogen bonding, the activity of water, dispersion interactions, and changes in the structure of water and in the degree of ion hydration[11,13,14].

The situation arising under the conditions of interfacial catalysis[15,16], where one of the phases is highly concentrated alkali and hydroxide ions are transferred by bulky organophilic cations incapable of forming a contact ion pair, can also be regarded as superbasic.



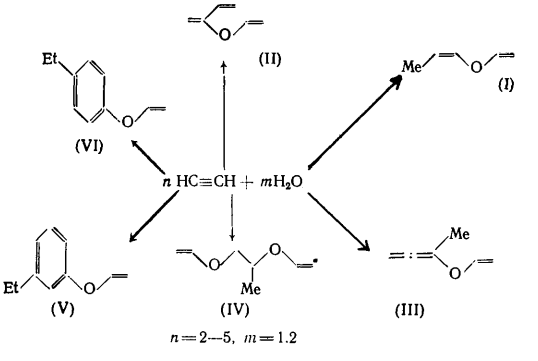
The significant acceleration of the nucleophilic addition to the triple bond in media specifically solvating the cation was first noted in a study of the vinylation of poly(ethylene glycol).[17] As a result of the chelation of the potassium cation

by poly(ethylene glycol) chains, side reactions involving the cleavage and disproportionation of the poly(ethylene oxide) fragments[18,19] and probably also "template" heterocyclisation, leading to macrocyclic crown-like acetals, which, together with linear oligomers, accelerate the process

autocatalytically, are characteristic of reactions of this kind.

The catalytic effects of the side products of the vinylation of monohydric alcohols[20,21]—low-molecular-weight thermopolymers of alkyl vinyl ethers $-[-CH_2-CH(OR)-]_n-$—also capable of chelating the cations, are apparently of the same type:

These studies led to the development and industrial application of a new technology for the vinylation of butanol at atmospheric pressure[20,21] and to the intensification of the processes involving the vinylation of diethylene glycol[22] and ethanolamines[23], which are nowadays carried out on an experimental industrial scale.

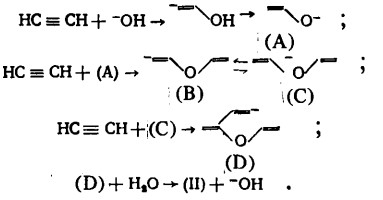


In aprotic dipolar solvents (DMSO, HMP, and methylpyrrolidinone) in the presence of catalytic amounts of alkali, primary alkanethiols add to acetylene even at atmospheric pressure and at a temperature of 10–20 °C, forming vinyl sulphides in 60–90% yield (reaction time 1 h),[24] which corresponds to an increase of the reaction rate by many orders of magnitude. Tertiary and aromatic thiols, which are more difficult to vinylate, react with acetylene much more readily in systems of this kind than under the usual conditions (30–50 °C, 10–15 atm).

Thus in superbasic media in the presence of "bared" anions of strong bases (alkalies, alkoxides, amides, and alkali metals) the nucleophilic addition to the triple bond is very greatly facilitated. However, a much more significant factor is that fundamentally new reactions become possible under these conditions. There exist fundamental thermodynamic grounds for this. Thermodynamic measurements have shown[25] that in aprotic dipolar solvents the free energy of the anions increases sharply and as a result they are converted into supernucleophiles. It is very significant that the activity of weak nucleophiles then increases to a much greater extent than that of strong nucleophiles. For example, on passing from ethanol to DMSO, the relative increment of the Gibbs free energy of the phenoxide anion (a fairly weak nucleophile) is greater by 10 kcal mol^{-1} than for the phenylsulphide anion, which is a stronger nucleophile[25].

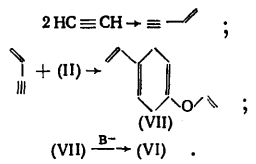
III. HYDRATION OLIGOMERISATION OF ACETYLENE

The characteristics of superbasic systems discussed above are responsible for the successful addition to acetylene even of a comparatively weak nucleophile such as the hydroxide ion, the low activity of protons characteristic of such systems inhibiting the prototropic transformation of the intermediate vinyloxide anion into acetaldehyde. However, it has not so far been possible to observe the formation of divinyl ether under these conditions. Instead of this natural pathway, a series of completely unusual reactions have been observed[8,26–31] in the DMSO–KOH system, which proceed under extremely mild conditions (80–120 °C) and which can be combined under the common name "hydration oligomerisation of acetylene" (Scheme 1).



Scheme 1

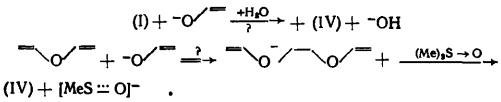
The simplest oligomer obtained under these conditions is a methylated hydratodimer—1-*cis*-propenyl vinyl ether[26] (DMSO acts as a methylating agent).



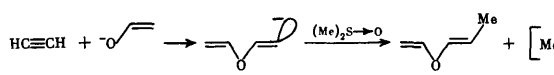
This is followed by the following substance in order of increasing complexity: a hydratotrimer—2-vinyloxybuta-1,3-diene (II) [8,27,29–31] and its allene isomer—3-vinyloxybuta-1,2-diene (III),[30] a methylated dihydratotrimer—1,2-di(vinyloxy)-propane (IV),[28,30] and finally hydratopentamers—*meta*- and *para*-ethyl(vinyloxy)benzenes (V) and (VI).[30] The yields are in general low; however, they depend significantly on the composition and nature of the superbasic catalytic system, particularly on the nature of the cation and the solvent and also on buffer additives such as alkali metal phosphates, which regulate the proton transfer processes. Conditions have been found[27,29,30] under which 2-vinyloxybuta-1,3-diene—one of the most interesting products of the hydration oligomerisation of acetylene—is obtained in a yield greater than 70%. The yields of other hydrato-oligomers can apparently also be increased to a preparatively acceptable level when necessary.

One of the possible ways of forming vinyloxybutadiene involves a multistage "threading" of three acetylene molecules onto the hydroxide ion:

A weak feature of this scheme is the assumption of a prototropic rearrangement of the vinyloxyvinyl β-carbanion (B) to the corresponding α-carbanion (C), which is in all probability less stable owing to the strong repulsion of the charge from the unshared electron pairs of the oxygen atom.



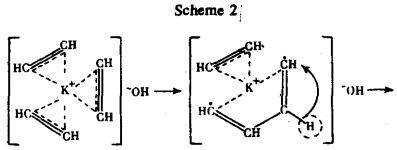
The ethyl(vinyloxy)benzenes (V) and (VI) could be regarded as products of the diene condensation of vinyloxybutadiene (II) and the intermediate vinylacetylene, which is completed by the prototropic rearrangement of the primary vinylcyclohexadiene adduct (VII):



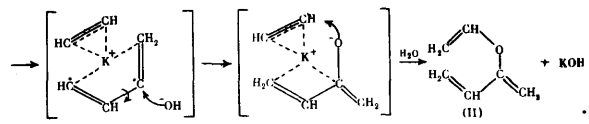
(VII) $\xrightarrow{B^-}$ (VI) .

However, ethyl(vinyloxy)benzene could not be obtained by the direct interaction of authentic vinylacetylene and vinyloxybutadiene (II).[29]

It is just as difficult to interpret the formation of 1,2-di(vinyloxy)propane (IV), because it is necessary to assume the highly unlikely nucleophilic addition of the vinyloxide anion to propenyl vinyl ether (I) or to divinyl ether:



Concluding the enumeration of facts which cannot be acceptably explained within the framework of generally accepted ideas, it is necessary to draw attention also to the configuration of 1-*cis*-propenyl vinyl ether (I). In nucleophilic addition to acetylenes, the intermediate anions usually have the *anti*-configuration, in which the repulsion of the charge and the unshared electron pairs of the heteroatom is a minimum[32]. The formation of the *trans*-isomer rather than the *cis*-isomer of the ether (I) was therefore to be expected:



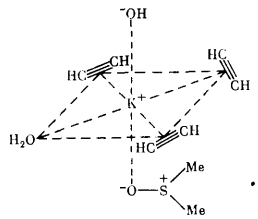
The complete *cis*-stereoselectivity in this case is evidence against simple nucleophilic attack by the vinyloxide anion on the triple bond. Evidently the reactions illustrated in Scheme 1 require other explanations. It was noted above that in superbasic media the anions become supernucleophiles as a result of desolvation and the separation of ion pairs under the influence of strong dipoles (solvent molecules). However, the same factors should also alter the electrophilic activity of the cation. In a system with a markedly reduced activity of water an alkali metal cation, lacking its usual hydration shell and separated by a solvent molecule from its anion, should attempt to compensate for its desolvation by coordinating to some extent to other nucleophiles present in the system, in the given instance acetylene molecules, formally in the same way as in the case of transition metal cations[33]. The coordination leads to the withdrawal of the π-electron density of the acetylene ligands to the cation and the consequent increase of the sensitivity of the triple bonds of the ligands to a nucleophilic attack.

One of the possible mechanisms of such coordination catalysis, involving a partly dehydrated potassium cation in the hydration trimerisation of acetylene, is illustrated in Scheme 2:

Scheme 2

This scheme explains the observed marked dependence of the result of the reaction on the nature of the coordinating cation and predicts the possibility of obtaining benzene (a nonhydrated acetylene trimer) on decrease of the concentration of water in the system. Benzene and toluene (in the DMSO–KOH system) have indeed been detected in the reaction mixtures—in some cases up to 20% and more[34]. The formation of toluene indicates yet again the ability of DMSO to methylate carbanions under these conditions.

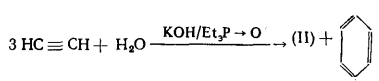
The cyclotrimerisation of acetylene is known to take place smoothly only in the presence of transition metal complexes[35]. Methods for the formation of stable adducts of acetylenes with dehydrated alkali metal hydroxides were patented[36,37] several decades ago. It has been stated in a patent[37] that the absorption of acetylene by potassium hydroxide in 1,1-dibutoxyethane increases sharply with increase of temperature, reaching 0.5 mole per mole of KOH at 75–90 °C, which is three times more than at temperatures between −10° and 0 °C. We are therefore dealing with the chemical interaction of acetylene with KOH and not with its simple dissolution. The important role of such complexes, as key intermediates in certain versions of the Favorskii ethynylation[38–41] and vinylation[42] reactions as well as selective hydrogenation[43–45] of acetylenic alcohols and glycols was demonstrated later. In many instances[38–40,45] these complexes were isolated and investigated. Compared with KOH, sodium hydroxide binds acetylene less strongly, while LiOH does not form complexes with acetylene at all according to Tedeschi et al.[45]



Unfortunately very few experimental data have been published hitherto concerning the nature and structure of the adducts of acetylene and alkali metal hydroxides. It has been reported only that the infrared spectra of complexes of KOH with acetylene[39] and acetylenic alcohols[38] or glycols[38] do not exhibit the usual C≡C and ≡C–H vibrational frequencies, while the O–H stretching vibration band (in the case of alcohols and glycols) is broadened and weakened. On this basis, it was concluded[38,39] that the potassium cation is involved in complex formation reactions with both the π-electrons of the acetylenic linkage and with the oxygen atoms of the hydroxy-groups. In the same study[38–41] evidence is presented showing that the adducts of acetylene with alkali metal hydroxides are chemically fundamentally different from acetylides. According to data obtained by ion-cyclotron resonance and high-pressure mass spectrometry[46], acetonitrile ($CH_3C{\equiv}N$), which is a full electronic analogue of methylacetylene, has a higher chemical affinity for the potassium cation than bases such as ammonia, amines, water, and ethers. Quantum-chemical calculations by the *ab initio* method have shown that this is wholly due to the unexpectedly large contribution of the polarisation of the CH_3CN molecule to the overall energy of its reaction with the cation[47]. Acetylenic compounds should exhibit an equally high affinity for the K^+ cation and an equally marked polarisability under its influence.

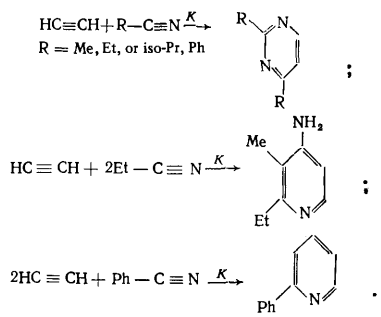
Another familiar group of acetylene complexes of alkali metals is derived from acetylides. For example, the oligomerisation of acetylenes under the influence of alkali metals begins with the formation of complexes of acetylides with the initial acetylenes[48–51]. Adducts of phenylacetylides with alkali metals, which are of a radical-ion type and actively initiate the polymerisation of vinyl monomers, have also been isolated recently[52].

According to calculations by the CNDO method[53], preference should be given to an octahedral hydration shell for alkali metal cations with a pronounced electron transfer from oxygen to the metal; the energy gain relative to other possible hydrates then ranges from 24 to 140 kcal mol^{-1}. The charge transfer in such aquo-complexes has been confirmed also by complete theoretical calculations[54]. According to experimental data[55], the sodium cation in the DMSO–dioxan mixture is surrounded by six donor molecules. It is well known that the most stable complexes with potassium cations are formed by crown-ethers containing six oxygen atoms[56].

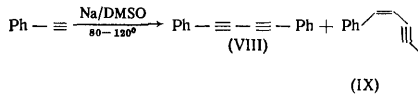


All this justifies the hypothesis that in superbasic catalytic systems a proportion of the usual ligands in the solvation shells of alkali metal cations can be substituted by acetylene molecules, which begin to interact both with one another and with the remaining ligands as a consequence of spatial proximity, polarisation, and partial covalent binding (charge transfer).

The formation of the acetylene hydratotrimers (II)–(IV) can be easily explained by the interaction of ligands, for example, in the following octahedral complex[28]:

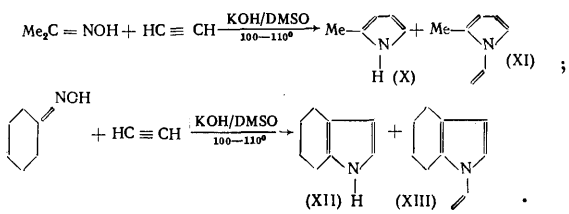


The hydratopentamers (V) and (VI) can be constructed on the same template, provided that two heteroatomic ligands (including DMSO) are replaced by acetylene molecules. Naturally, in real systems there must be a continuous variable spectrum of similar complexes, differing not only in the combinations of the ligands but also in solvation numbers.

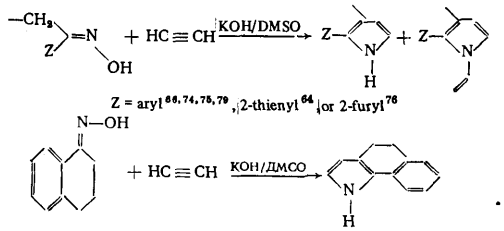


In conclusion of this section, it must be emphasised that DMSO does not constitute the only basis for catalytic systems propagating the reactions under consideration. The superbasic pair KOH–triethylphosphine oxide also catalyses the hydration trimerisation of acetylene. In this case the yield of 2-vinyloxybuta-1,3-diene (II) is 50% and the catalytic reaction mixture contains more than 20% of benzene[34]:

The heterocyclisation of acetylene with nitriles to form pyrimidines and pyridines (1–2% K, 175–200 °C, 13–17 atm, 6–8 h) is known[57]:

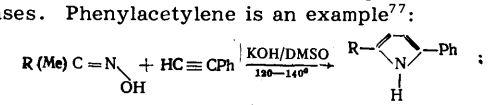


The catalytic system is prepared by the cautious dissolution of metallic potassium in the corresponding nitrile. The yields of 2,4-dialkylpyrimidines and the isomeric 4-aminopyridines are in the range 8–12% (relative to the nitrile which has reacted), but 2,4-diphenylpyrimidine was synthesised in 29–51% yield. The formation of a 2-substituted pyridine was observed only for R = Ph (yield 1.8%). These reactions have now been given a theoretical basis in the light of data[46,47], already quoted, concerning the strong specific interaction of the potassium cation with acetonitrile molecules[46], including their extensive polarisation[47]. The recently discovered[58] dimerisation of phenylacetylene under the influence of a small amount of sodium in DMSO or HMP can also be included in the group of new catalytic reactions under consideration:

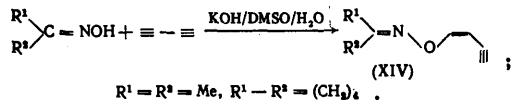


The yield of dimers (VIII) and (IX) reaches 43 and 14% respectively. Other conditions being equal, there is no dimerisation in benzene. Although the oxidative and "additive" dimerisation of acetylenes is well known[59], it has been believed hitherto that these processes can be catalysed only by copper salts.

IV. REACTIONS OF ACETYLENE WITH OXIMES AND AMIDES

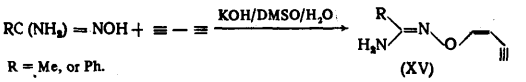


The reaction of acetylene with ketoximes, catalysed specifically by the KOH–DMSO superbasic pair and leading to pyrroles and *N*-vinylpyrroles, was discovered at the beginning of the 1970's.[60,82] For example, 2-methylpyrrole (X) and 2-methyl-1-vinylpyrrole (XI) are formed from acetone oxime[72] while cyclohexanone oxime gives rise to 4,5,6,7-tetrahydroindole (XII) and its 1-vinyl derivative (XIII):[60,67–68,73,78]:



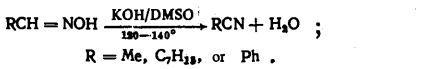
The process proceeds easily and smoothly even at 80–120 °C at atmospheric pressure, being accompanied by a small exothermic effect. The yields of pyrroles are on average 70–80%, reaching 90% and more in certain cases[72,81]. The reaction is of a general type: it involves virtually all ketoximes having at least one CH_2 group in the α-position relative to the oxime functional group, including aromatic[66,74,75,79], heteroaromatic[64,76], and annelated[70] oximes:

Positive results are to be expected when the reaction is extended to certain substituted acetylenes incapable of prototropic isomerisation and stable in the presence of strong bases. Phenylacetylene is an example[77]:



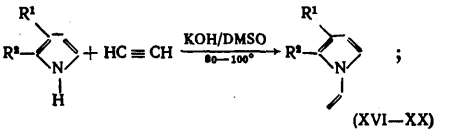
O-Ethynylvinyl derivatives of oximes (XIV) were isolated in 38–41% yield in the reaction with diacetylene instead of the expected 2-ethynylpyrroles[83]:

(XIV)



$R^1 = R^2 = Me$, $R^1 - R^2 = (CH_2)_4$.

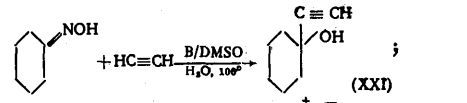
Under the same conditions, amidoximes react similarly with diacetylene, forming *O*-ethynylvinyl derivatives (XV) in 21–25% yield[84]:



R = Me, or Ph. (XV)

In contrast to ketoximes, aldoximes do not give rise to pyrroles on interaction with acetylene in the KOH–DMSO system, since they are dehydrated to the nitriles[85–87] (yield 65–92%):

$R = Me, C_7H_{15}$, or Ph .

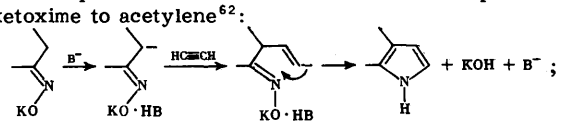


A secondary result of the study of the reactions of ketoximes with acetylene was the development of an effective method for the vinylation of pyrroles at atmospheric pressure[88,89], which is evidently suitable also for the vinylation of other NH-heterocycles. The formation of *N*-vinyl derivatives (XVI)–(XX) in the presence of the KOH–DMSO superbasic pair proceeds under mild conditions (80–100 °C) in 75–95% yield:

(XVI–XX)

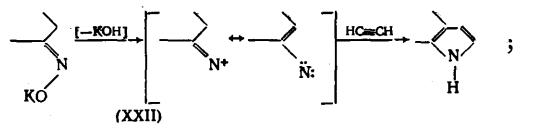
$R^1 = Me$, $R^2 = Et$ (XVI); $R^1 = Pr$, $R^2 = Bu$ (XVII);
$R^1 - R^2 = (CH_2)_4$ (XVIII); $R^1 = H$, $R^2 = Ph$ (XIX);
$R^1 = H$, $R^2 = MeOC_6H_4$ (XX) .

In aqueous DMSO the synthesis of pyrroles from ketoximes and acetylene is accompanied by the formation of α-acetylenic alcohols[90]. For the ratio H_2O : DMSO = 1 : 2 (by volume) and at 100 °C, the yield of 1-ethynyl-1-cyclohexanol (XXI) is 47%:[76]



(XXI)

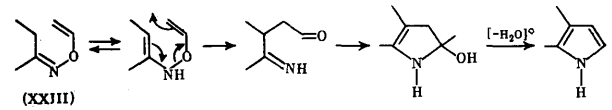
B = NaOH, KOH, RbOH, or $[(Bu)_4\overset{+}{N}]\overline{O}H$.



This reaction also proceeds in dioxan and dioxan–DMSO mixtures[90].

The mechanism of the formation of pyrroles from ketoximes and acetylene is not as yet entirely clear. The key stage of the reaction could be one of the following:

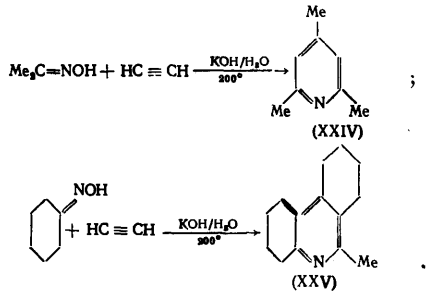
(a) nucleophilic addition of the carbanionic component of the ketoxime to acetylene[62]:



(b) 1,3-dehydration of the ketoxime and the addition of the 1,3-dipole (XXII) (or the corresponding vinylnitrene) to the triple bond[62,65,87]:

(XXII)

(c) sigmatropic rearrangement of the intermediate *O*-vinyloximes (XXIII):[90]

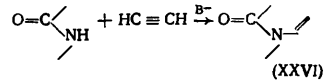


(XXIII)

So far there is no reason to reject only the last mechanism: the *O*-vinyloximes isolated in a low yield on thermolysis in the absence of acetylene do not give rise to pyrroles[92]. Furthermore, as mentioned above, the reaction involving phenylacetylene results in the formation of 5-phenylpyrroles, while the rearrangement of the intermediate (XXIII) should have resulted in the introduction of the phenyl group in the 4-position in the pyrrole ring (nucleophiles add to the terminal carbon atom of phenylacetylene)[32].

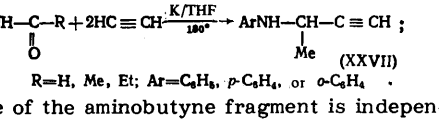
The systematic development of this new field, which has arisen at the boundary between the chemistries of acetylene and pyrrole, is being continued[93–106]. The data accumulated show convincingly that the reaction under consideration constitutes at present one of the simplest and most effective methods of synthesising pyrrole systems.

It is of interest that in an aqueous medium without DMSO the base-catalysed interaction of acetylene with ketoximes proceeds quite differently: instead of pyrroles, pyridines are formed[87,107]. For example, symmetrical collidine (XXIV) is obtained from acetoxime, and 9-methyloctahydrophenanthridine (XXV) is formed from cyclohexanone oxime:



(XXIV)

(XXV)

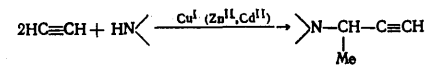


The yield of pyridines is 20–30%, but so far no attempt has been made to optimise this new and extremely promising reaction.

The vinylation of carboxylic acid amides with acetylene in the presence of bases leads to *N*-vinylamides (XXVI):[108–110]

(XXVI)

However, if the catalyst of this reaction is obtained by dissolving metallic potassium in a mixture of an anilide and tetrahydrofuran (THF) or dioxan, then 3-arylamino-1-butynes (XXVII) are formed from these reagents in yields up to 47% together with *N*-vinyl derivatives (XXVI).[111,112] Like the potassium derivatives of anilides obtained via alkoxides, the analogous sodium system does not catalyse the reaction:



(XXVII)

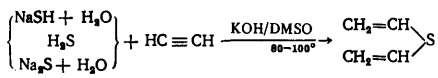
R=H, Me, Et; Ar=C_6H_5, *p*-C_6H_4, or *o*-C_6H_4 .

The structure of the aminobutyne fragment is independent of the substituent R, which means that the acid component of the anilide is split off, being replaced by the acetylene dimer.

The optimisation of the reaction[113] by mathematical design made it possible to suppress vinylation almost completely, maintaining the yield of acetylenic amines (XXVII) at the level of 35%. It was established that the formation of the

catalyst involves the reductive cleavage of the anilide, one of the products being potassium arylamide (ArNHK), which belongs to the class of superbases[114–118]. It was believed that the familiar reaction of acetylene with secondary amines, resembling to some extent the reaction considered here and leading to the same aminobutynes, proceeds only in the presence of transition metal salts[119]:

However, recently† an analogous reaction between acetylene and aniline was achieved also in the presence of potassium anilide:

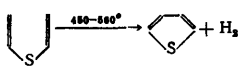


$$PhNH_2 + 2HC\equiv CH \xrightarrow{PhNHK} PhNHCH(Me)C\equiv CH$$

The yield of 3-phenylaminobut-1-yne was ~24%, while the degree of conversion of aniline was 21% (160 °C, 12 atm C_2H_2, 2 h, dioxan). The reaction proceeds with approximately the same yield (25%) albeit with a higher degree of conversion of aniline (41%) when it is catalysed by the specially prepared copper acetylide (20–60 °C, 14 atm C_2H_2 + 3 atm N_2, ethanol–acetic acid)[120].

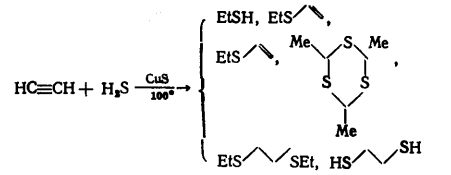
Thus a certain parallelism in the type of activation of acetylene by alkali metal cations under superbasic conditions and metal complexes is again revealed.

V. OLIGOMERISATION OF ACETYLENE WITH PARTICIPATION OF SULPHUR-CONTAINING NUCLEOPHILES



The reactions of acetylene with sulphur-containing nucleophiles are no less varied and unexpected in superbasic media. The simplest of these nucleophiles, the sulphide ion generated from hydrogen sulphide in the presence of an excess of alkali or from alkali metal sulphides in DMSO, adds under very mild conditions (at a temperature of only 80° to 100 °C) and almost quantitatively (under optimum conditions) to two acetylene molecules, forming divinyl sulphide[121–125]:

This at first sight simple and evident reaction has its history. At the beginning of the century the high-temperature catalytic addition of hydrogen sulphide to acetylene was investigated by Chichibadin[126,127], but he obtained thiophen instead of divinyl sulphide:

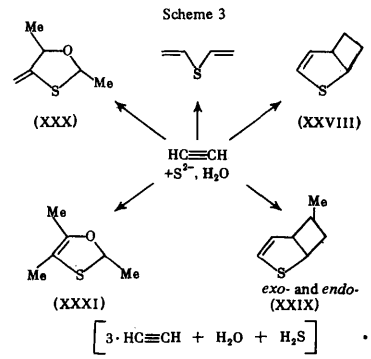


Subsequently investigators frequently returned to this synthesis using as catalysts metal sulphides[128–130], nickel and cobalt on alumina[131], and an aluminolanthanochromium catalyst[132], but the formation of divinyl sulphide was never mentioned. It has been shown recently that at high temperatures divinyl sulphide is thermodynamically unstable and is dehydrocyclised to thiophen[133]:

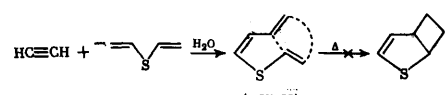
† See B.A.Trofimov, S.F.Malysheva, and E.P.Vyalykh, Zhur.Org.Khim., 15, 880 (1979).

Towards the end of the 1930's, Reppe again attempted to synthesise divinyl sulphide from acetylene and hydrogen sulphide. He obtained a complex mixture of organosulphur products[134,135], but divinyl sulphide was not present among them:

When a mixture of acetylene and hydrogen sulphide in the liquid phase (−78 °C) or in the gas phase (20 °C) is irradiated with ultraviolet light, ethylenethiol is formed in 33% yield[136]:

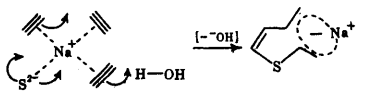


The homologues of acetylene react similarly, the yield of propenethiols (from methylacetylene) amounting to 87%.[136]

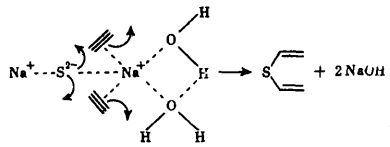


Thus neither high-temperature nor photochemical initiation nor heterogeneous catalysis permit the direct synthesis of divinyl sulphide from acetylene and hydrogen sulphide. This monomer has been obtained by multistage reactions via mustard gas[137–142], di(2-bromoethyl)sulphide[143–145], or thiodiglycol[146–148]. Until recently, it was therefore only of strictly theoretical interest. The reaction of acetylene with the sulphide ion in a superbasic medium made divinyl sulphide a very readily available and cheap product, which can now be manufactured industrially on any scale.

As in the case of the hydroxide ion, the addition of sulphide anions to acetylene in superbasic media is accompanied by unusual heterocyclo-oligomerisation reactions (Scheme 3). Thus the reaction in the NaOH–DMSO–H_2O system yields, together with divinyl sulphide, a new bridged heterocycle—2-thiabicyclo[3,2,0]hept-3-ene (XXVIII) and its *exo*- and *endo*-6-methyl derivatives (XXIX),[149–151] which are in essence thiylated trimers, as well as 2,5-dimethyl-4-methylene-1,3-oxathiolan (XXX) and its endocyclic isomer 2,4,5,-trimethyl-1,3-oxathiol (XXXI),[152–155] made up of three acetylene molecules, a hydrogen sulphide molecule, and a water molecule:



Scheme 3



Evidently template cyclisation again takes place under these conditions. The dark [2 + 2]-cyclisation of the probable intermediate 1-vinylthiobuta-1,3-diene (XXXII) is prohibited by orbital symmetry rules:

However, in the electric field of the coordinated cation, where the π-symmetry of the ligands is violated, the prohibition of cyclisation is removed:

One cannot rule out the possibility that the divinyl sulphide molecule (which in this context can be regarded as a sulphur-containing acetylene dimer) is also produced by a single-stage process in the initial matrix:

One of the roles of DMSO under these conditions may involve the partial dehydration of the Na^+ cation as a result of the formation of stable complexes of the type $Me_2SO.2H_2O$ [156,157] as well as hydrogen bonds between H_2O and DMSO molecules, which are stronger than in the self-associated water species[158].

The second order of the reaction with respect to phenylacetylene in the synthesis of di(2-phenylvinyl)sulphide (XXXIII) from phenylacetylene and hydrated sodium sulphide in DMSO, HMP, and triethylphosphine oxide may be regarded as the kinetic confirmation of the reality of the "template effect":[159]

$$PhC\equiv CH + Na_2S\cdot 9H_2O \xrightarrow{80\text{–}100^\circ} Ph\!\!\diagup\!\!\diagdown S\!\!\diagup\!\!\diagdown Ph \quad (XXXIII)$$

Such formal kinetics are characteristic of many metal complex reactions of acetylene via a coordination mechanism[160]. The activation parameters—the unusually low energy barrier ($\Delta H^{\neq} \cong 7$ kcal mol^{-1}) accompanied by an enormous decrease of entropy ($\Delta S^{\neq} \cong -50$ e.u.)—are consistent with this mechanism; thus the transition state of the reaction does indeed have a highly ordered structure and the dissociation and formation of bonds are to a large extent synchronised. When the reaction was followed by ^1H NMR over a wide range of conversions (up to 70%), the splitting of the signals due to the olefin protons, which might have been caused by the formation of an intermediate 2-phenylvinyl sulphide anion in the case of a multistage addition of the sulphide ion to two phenylacetylene molecules, was not observed[159].

Yet another property is characteristic of superbasic catalytic systems, which distinguishes them from typical metal complex catalysts, namely the outcome of the reaction frequently depends fundamentally on the nature of the components of these systems. Thus, when DMSO is replaced by HMP, it is possible to select conditions for the reaction of acetylene with hydrogen sulphide[161] such that its only product is ethanethiol:

$$HC\equiv CH + H_2S \xrightarrow[90^\circ]{KOH/HMP} \begin{cases} \diagup\!\!\diagdown S\!\!\diagup\!\!\diagdown \\ EtSH \end{cases}$$

This synthesis is of fundamental importance, because it illustrates strikingly the ability of certain superbasic systems to stimulate oxidation-reduction processes of the type

$$\diagup\!\!\diagdown S^- + H_2S \xrightarrow{KOH/HMP} EtS^- + S$$

In a superbasic system involving DMSO or HMP the cyclic octamer of elemental sulphur is readily cleaved already at 80 °C, forming as a result of reaction with acetylene the same product as the sulphide ion; the main product is divinyl sulphide[29,162,163], which can be obtained in 75–80% yield by this reaction:

$$HC\equiv CH + S_8 \xrightarrow{KOH/DMSO/H_2O} \diagup\!\!\diagdown S\!\!\diagup\!\!\diagdown$$

The elemental sulphur–alkali metal hydroxide–DMSO system was later proposed[163] as a new reagent for the synthesis of organosulphur compounds from organic halides. Analogous direct oxidation-reduction vinylation reactions proved to be possible also for elemental selenium[27,29,31] and tellurium[29,164–166]. The latter reacts more effectively in HMP. The yield of divinyl derivatives (XXXIV) and (XXXV) is greater than 50%:

$$HC\equiv CH + Se_\alpha \xrightarrow[95\text{–}120^\circ]{KOH/DMSO/H_2O} \diagup\!\!\diagdown Se\!\!\diagup\!\!\diagdown \quad (XXXIV)$$

$$HC\equiv CH + Te \xrightarrow[110\text{–}120^\circ]{KOH/HMP/H_2O} \diagup\!\!\diagdown Te\!\!\diagup\!\!\diagdown \quad (XXXV)$$

The direct synthesis of divinyl selenide (XXXIV) and divinyl telluride (XXXV) from the elements and acetylene leads to interesting prospects for the development of the chemistry of unsaturated organoselenium and organotellurium compounds.

The reactions with alkali metal polysulphides, which also proceed with the cleavage of the polysulphide chain and the formation of divinyl sulphide in 70–92% yield[167], are closely related to the above group of oxidation-reduction processes:

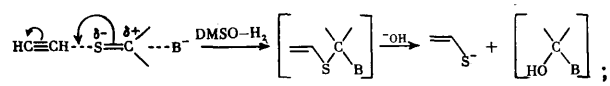
$$HC\equiv CH + Na_2S_n \xrightarrow[100^\circ]{KOH/DMSO/H_2O} \diagup\!\!\diagdown S\!\!\diagup\!\!\diagdown \quad n = 2-4$$

In the reaction with organic disulphides acetylene is readily inserted in the S–S bond, forming *cis*-1,2-di(organylthio)-ethylenes (XXXVI) in 60–80% yield:[168–170]

$$HC\equiv CH + \begin{matrix} R & S \\ S & R \end{matrix} \xrightarrow[120^\circ]{t\text{-}BuOK/DMSO} \begin{matrix} R & & R \\ S & & S \end{matrix} \quad (XXXVI)$$

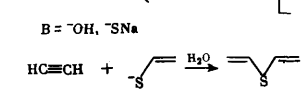
R=Alk or Ph.

If favourable conditions are created at the same time for the transfer of a proton (for example, by adding H_2O to the system), alkyl vinyl sulphides are also formed[171–174] in a yield which can be raised to 80%:[172]



$$HC\equiv CH + \begin{matrix} Alk & S \\ S & Alk \end{matrix} \xrightarrow{KOH/H_2O} \diagup\!\!\diagdown S\!\!\diagup\!\!\diagdown Alk$$

The ease of cleavage of the S–S bond under these conditions hinders the synthesis of divinyl polysulphides. However, they are probably nevertheless formed as intermediates, as shown by the formation of 1,2-di(vinylthio)ethylene (XXXVII) from acetylene and sodium disulphide[155,167,175]:

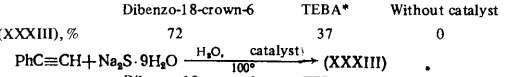


$$HC\equiv CH + Na_2S_2 \xrightarrow[80^\circ]{KOH/DMSO/H_2O} \diagup\!\!\diagdown S\!\!\diagup\!\!\diagdown S\!\!\diagup\!\!\diagdown$$

$$\left[\diagup\!\!\diagdown S\!\!\diagup\!\!\diagdown S\!\!\diagup\!\!\diagdown\right] + HC\equiv CH \quad (XXXVII)$$

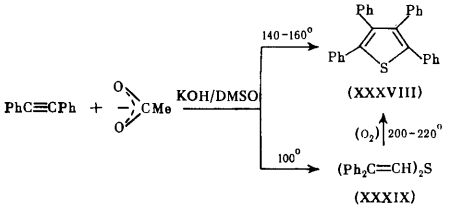
Unusual reactions of acetylene with thione systems—carbon disulphide[177,178], thiourea[176,179,180], dithiocarbamate[176,181–184] and phosphorothioate[185] esters and salts, and even sodium thiosulphate[176]—take place readily in a superbasic medium[176]. As a result of its high polarisability, the thione fragment behaves under these conditions as a powerful uncharged nucleophile. Ultimately the series of successive (or synchronous) addition and substitution steps usually leads to divinyl sulphide (yield 70–80%):

B = ^-OH, ^-SNa



Under superbasic conditions, extremely weak nucleophiles such as the thioacetate anion, add readily to the triple bond[182,184,186], although previously they were believed to be incapable of this:

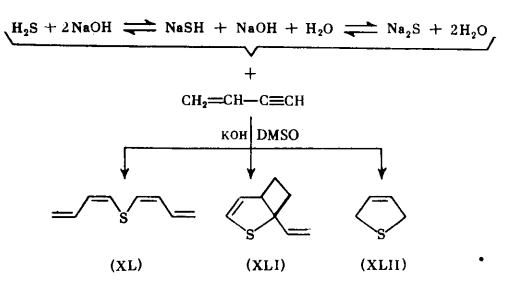
The yield of divinyl sulphide by this reaction is 60%.[186] The same reaction with phenylacetylene served as one of the examples used to demonstrate for the first time that interfacial catalysis by crown-ethers and tetraorganylammonium salts can be used successfully to accelerate nucleophilic addition to the triple bond[187]:



Catalyst	Dibenzo-18-crown-6	TEBA*	Without catalyst
yield of (XXXIII), %	72	37	0

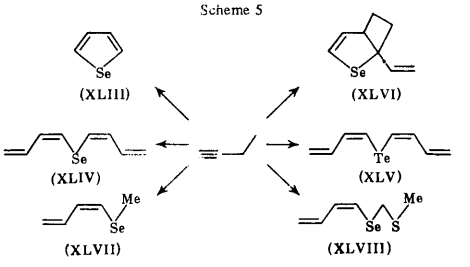
Catalyst	Dibenzo-18-crown-6	TEBA	Without catalyst
Yield of (XXXIII), %	40	22	9

*Triethylbenzylammonium chloride.



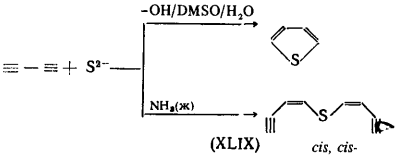
Depending on the conditions, either tetraphenylthiophen (XXXVIII) or di(2,2-diphenylvinyl) sulphide (XXXIX) can be obtained by the reaction of the thioacetate anion and diphenylacetylene[190]:

The "geminal" structure of the sulphide (XXXIX) is a result of an unexpected rearrangement with transfer of the phenyl group. The thermo-oxidative cyclisation of this sulphide to tetraphenylthiophen involves the reverse 1,2-migration of the phenyl groups[190]. A similar 1,2-migration is observed on heating the sulphide (XXXIX) with alkali in DMSO, which results in the reformation of diphenylacetylene[180,190].



In conclusion of this section, it must be specially emphasised that almost all the reactions considered here are fairly general and are characteristic not only of acetylene itself but also of substituted acetylenes. For example, vinylacetylene reacts with sulphide anions in a superbasic medium to form di(buta-1,3-dienyl) sulphide (XL) [191] in a yield exceeding 90% (Scheme 4). By altering the conditions, it is possible to induce heterocyclisation reactions leading either to 1-vinyl-2-thiabicyclo[3,2,0]hept-3-ene (XLI) [192] or to dihydrothiophen (XLII),[193,194], which has been hitherto difficult to synthesise. The latter can be obtained in a virtually quantitative yield.

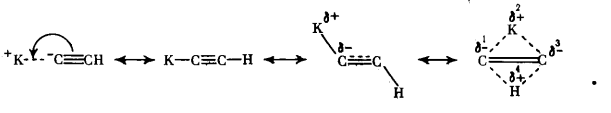
Scheme 4



Direct single-stage syntheses (Scheme 5) of selenophen (XLIII), di(buta-1,3-dienyl) selenide (XLIV),[195] di(buta-1,3-dienyl) telluride (XLV),[195] 1-vinyl-2-selenabicyclo[3,2,0]-hept-3-ene (XLVI), as well as buta-1,3-dienyl methyl selenide (XLVII) [196] and buta-1,3-dienyl methylthiomethyl selenide (XLVIII), formed with participation of DMSO, have been achieved on the basis of vinylacetylene and the corresponding elements in superbasic media. The syntheses based on vinylacetylene and elemental selenium or tellurium in the KOH–HMP–H_2O and KOH–DMSO–H_2O systems at 100–120 °C are illustrated in Scheme 5 below:

Scheme 5

Sulphide anions react with diacetylene in superbasic media to give a quantitative yield of thiophen[197] or *cis,cis*-di(but-1-en-3-ynyl) sulphide (XLIX) in 89% yield[198]:



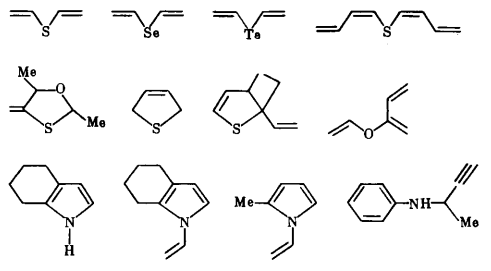
The last reaction has been achieved in liquid ammonia, which is also an effective superbasic medium, since it exhibits a high dielectric constant and an unsurpassed ability to solvate alkali metals, while its autoprotolysis constant is negligible.

VI. CONCLUSION

In conclusion one must say that, in order to avoid making the schemes and discussions unduly cumbersome, we excluded the ionisation of acetylene and the dissociation of acetylides:

$$HC\equiv CH + KOH \rightleftarrows {}^{+}K^{-}C\equiv CH + H_2O;$$
$${}^{+}K^{-}C\equiv CH \rightleftarrows K^{+} + {}^{-}C\equiv CH .$$

It would be a mistake to underestimate the influence of these reactions, particularly when one is dealing with superbasic media. Ideed, in the acetylide ion pair the triple bond, subjected to the influence of the charge and the electron cloud of the cationised alkali metal atom, should be very highly polarised and loosened:



The extensive rehybridisation and stretching of the C≡C bond under the influence of the alkali metal attached to it directly is indicated particularly by the considerable decrease of the stretching vibration frequencies ν(C≡C) and ν(≡C–H) in the spectra of acetylides compared with alkylacetylenes[199]:

Acetylenic compound	$\nu_{C\equiv C}$, cm^{-1}	$\nu_{\equiv C-H}$, cm^{-1}
$CH_3C\equiv CH$	2121	3320
$LiC\equiv CH$	1990	3245
$NaC\equiv CH$		3216
$KC\equiv CH$		3224

One cannot rule out the possibility that the formation of acetylides makes a decisive contribution to the activation of acetylene by superbasic media. It may be that acetylene undergoes complex formation and is involved in key inner-sphere transformations precisely in the form of a polarised anion.

The review can be aptly concluded by listing the structures of the most readily available monomers, intermediates, and synthons (Scheme 6), which can now be readily obtained from acetylene in superbasic media and to which it is desirable to draw the attention of synthetic chemists, specialists in polymer chemistry, pharmacologists, biologists, and technologists.

Scheme 6

Thus a new stratum of fundamental and applied developments has arisen in acetylene chemistry. The possibilities of superbasic catalytic systems are by no means exhausted. The next development should be the creation of a rigorous quantitative theory, which would permit the specific employment of the above systems in practice as well as in further research.

The Mechanism of the Electrophilic Addition of Halogens to a Multiple Bond

K.A.V'yunov and A.I.Ginak

A systematic account is given of the literature data on the mechanism of the electrophilic halogenation of olefins. Particular attention is devoted to the experimental methods for the investigation of the structures and reactivities of the intermediate unstable adducts produced by the electrophilic addition of the halogen to the multiple bond. The relation between the mechanisms of electrophilic halogenation and other *Ad* reactions is discussed. Certain aspects of the stereochemistry of the addition of halogens and hypohalites to olefins are examined.
The bibliography includes 192 references.

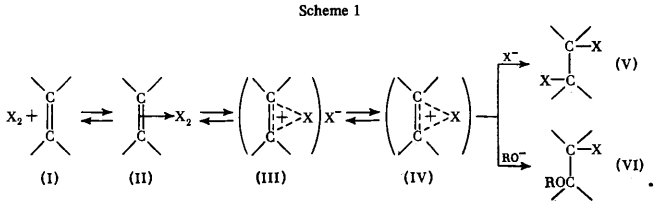
I. INTRODUCTION



The electrophilic addition of halogens and hypohalites to olefins is a fairly well known reaction[1], but the study of its mechanism is still being continued[2-4]. The present review attempts to give a systematic and critical account of the available data (using studies published up to 1978), mainly from the standpoint of the reaction mechanism, the structure of the intermediates, and the influence of the structure of the reactants on the rate of their interaction. The synthetic aspects of the problem as well as the role of the donor–acceptor complexes are considered briefly, mainly in relation to new data which have not been included in recently published reviews[3-5].

II. THE REACTION MECHANISM. GENERAL KINETIC FEATURES

1. General Consideration of the Mechanism

The mechanisms of the halogenation and coupled halogenation of olefins (I) are closely related, as can be readily seen from Scheme 1 below:

Scheme 1

The first stage involves the formation of a π-complex (II) from the initial reactants, which is then converted into a "close" ion pair (III) (analogous to a σ-complex in aromatic substitution reactions); the latter then dissociates in media with a high solvating capacity into two solvated ions—the anion X^- and the cation (IV).[6-11]. In non-polar weakly solvating media the intermediate is a solvate-separated pair (IV) $\| X^-$.[6,12-14].

The rate-limiting stage of the entire process is ionisation of the π-complex (II) with formation of ion pairs[5,15,16]. Products (V) and (VI) are formed simultaneously, since the ratio of their yields is independent of the extent of reaction and remains constant[17,18]. Depending on specific conditions (the polarity of the medium, the structure of the components, and the reaction temperature), the proposed mechanism can be modified. The rate of formation of the final products depends not only on the rate of conversion of intermediates (III) or (IV) but also on their absolute concentrations. The rates of formation and decomposition of the unstable intermediates have not been determined directly but with the aid of low-temperature infrared, untraviolet, and ^1H NMR spectroscopy it has sometimes been possible to identify the intermediate[19,20] whose structure determines the mode of addition of the reactants and the stereochemistry of the final adducts[21].

On the other hand, during the last 15 years new facts have been observed, which can be regarded as evidence in support of the mechanism described in Scheme 1.

1. An anomaly in the temperature variation consists in the fact that k_{eff} for electrophilic addition either increases slightly[22-24] or actually decreases as the temperature rises[25-27], i.e. the effective activation energy is less than zero. This agrees well with the concept of the reversible formation of the intermediates (III) and (IV) with a considerable energy release. A negative temperature coefficient ($E_{act}^{eff} \leq 0$) was found initially only for chlorination[22] and bromination[27] reactions and was later noted for the addition of mixed halogens[28] and for coupled bromination or chlorination[26,29]. Since it is clear from Scheme 1 that $E_{act}^{eff} = \sum \Delta H + E$, where E is the activation energy for the conversion of (IV) or (III) into (V) and (VI) and $\sum \Delta H$ is the sum of the exothermic heats of the equilibrium stages, it follows that, when $\Delta H \ll 0$, the effective (or apparent) activation energy can become zero or even less than zero. Only one of the components is determined experimentally, namely the enthalpy of formation of the donor–acceptor complex (II), the absolute

value of which varies in the range 2–10 kcal mol^{-1} depending on the nature of the olefin and the halogen[5,30,31].

2. The halogenation of pure *cis*- or *trans*-isomers of olefins takes place stereospecifically. Thus it has been noted for *cis*- or *trans*-but-2-ene[32], d_3-styrene[33], and di-isopropylethylene[34] that the *anti*-addition of the halogen to the olefin takes place to the extent of 99.5%; this forced the investigators[32–34] to postulate that a cyclic halonium ion, with restricted rotation about the carbon bond, is involved exclusively in the reaction. Because of this, pure stereoisomers were isolated as a result of the reaction.

3. In the study of the behaviour of vicinal dihalogenoderivatives in strongly acid media, the ^1H NMR spectra demonstrated unambiguously the existence of intermediates whose interaction with methanol yields mixed adducts of type (VI), equivalent to products obtained in the coupled halogenation of an unsaturated compound in the presence of methanol[35].

It is seen from the evidence presented above that the structure of the intermediate determines the mode and rate of electrophilic addition to the double bond.

The existence of an equilibrium stage preceding the formation of adducts (V) and (VI) has been demonstrated most readily and convincingly with the aid of ultraviolet spectroscopy[30,31]. When equimolar amounts of bromine and cyclohexene are mixed, a 1:1 charge-transfer complex is formed and can be detected by the stopped flow method ($\lambda_{max} = 290$ nm; $\varepsilon \cong 15400$).[31] Similarly charge-transfer complexes have been identified in the chlorination of cyclohexene and hexene ($\lambda_{max} = 248$ and 263 nm; $\varepsilon \cong 1400$ in both cases).[30] The main difficulty arising in the study of the intermediate compound in olefin–halogen systems by ultraviolet spectroscopy arises from the fact that the σ- and π-complexes absorb in approximately the same spectral region; the initial molecules and electrophilic adducts as a rule also absorb in this region of the spectrum. It is therefore impossible to detect and identify the ultraviolet spectra of the separated and non-separated ion pairs whose concentration determines the mode and rate of electrophilic addition of the halogen.

The thermodynamic parameters of the reversible formation of charge-transfer complexes were found from the temperature variation of the equilibrium constants. The enthalpy of formation of the bromine–cyclohexene complex ($\Delta H \cong -4$ kcal mol^{-1}) [31] proved to be greater in absolute magnitude than for the chlorine complexes of hexene and cyclohexene ($\Delta H = -1.7$ and -2.7 kcal mol^{-1} respectively),[30] which indicates a lower stability of the olefin—chlorine complexes and is associated with a weaker polarisability of chlorine compared with bromine. The influence of the structure of the olefin on the thermodynamic parameters of the complex is related to the ionisation potential of the unsaturated compound (I) and the σ constants of the substituents[12,36]; the observed linear relations are described by the equations $h\nu_{eV} = 0.56I + 2.39$ and $\lg(k/k_0) = -3.16\sigma$.

The enthalpies of formation of the complexes obtained do not exceed 7.5 kcal mol^{-1} (for bromine iodide) and cannot explain the anomalous temperature variation of the rate constants for the electrophilic halogenation and coupled reactions, for which a negative temperature coefficient has been frequently observed[22,26,27,29,37]. It is logical to postulate the existence of at least yet another exothermic process[33,39] whose contribution would account for the decrease of the apparent activation energy to negative values. At the present time there is no unanimous view concerning the equilibrium which gives rise to the additional energy. A number of workers believe that the initially formed π-complexes rearrange to more closely linked "internal" complexes characterised by a higher degree of charge transfer[37]; the concept of the "internal" complex is apparently equivalent to the σ-complex and that of the "external" complex is equivalent to the π-complex.

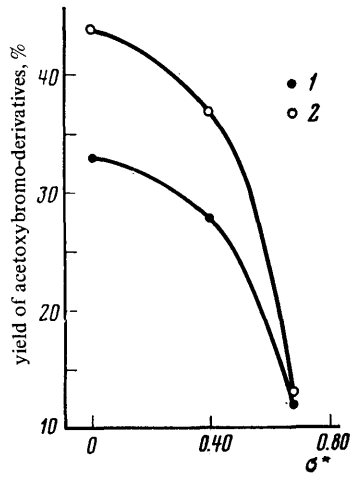
Different exothermic processes are important for the mechanism of the electrophilic reaction: the formation of 2:1 halogen–olefin complexes[27,38] and the formation of complexes between the reactants and the solvents, including weakly polar solvents[39]. In polar solvents, particularly those which contain a heteroatom and are effective *n*-donors, the halogen forms a complex with the solvent. The enthalpy of formation of halogen–*n*-donor complexes is frequently higher[40] than that for olefin–halogen complexes. For example, $\Delta H = -8$ kcal mol^{-1} for the complex of epoxycyclohexane and bromine[41], which is twice as high as the enthalpy of formation of a complex between cyclohexene and bromine[31]. *n*-Donors are in fact most frequently involved in a coupled electrophilic reaction leading to the formation of mixed adducts, which have been established for α- and β-oxides[37,42–47], alcohols[48], and aliphatic[49–51] and acyclic[52,53] esters and anhydrides[54].

The reversible reaction between halogens and oxygen-containing *n*-donors can proceed via a two-well kinetic model[41,55] (like the interaction of a halogen with olefins) with conversion of the "external" complex formed initially into an "internal" complex[41]. The high exothermic heat of formation of complexes between *n*-donors and halogens is responsible for the occurrence of side reactions involving the isomerisation and polymerisation of the oxygen-containing donors; thus, depending on temperature and other conditions, in the case of an epoxide different amounts of dioxans and epoxide polymers were detected in the reaction mixture as well as the product of addition to the double bond[56].

Electrophilic halogenation begins with a series of reversible stages, including the formation of π- and σ-complexes. The problem therefore arises whether these two intermediate species, separated by a transition state with a low energy level, are in a state of equilibrium or whether their transformation is irreversible. The salt effect can serve as an indirect characteristic of the position of the equilibrium between intermediates (II) and (III). The addition of an electrolyte containing an anion common to the reactants increases the rate of conversion of the π- or σ-complex as a result of an increased concentration of the nucleophile attacking the intermediate; this phenomenon will be considered in detail below. The introduction of neutral electrolytes, without anions common to the reactants, into the electrophilic addition reaction will have an effect only in those cases where a solvate-separated ion pair (σ-complex) arises as an intermediate or individual ions are formed[57,58]. The positive salt effect is explained in this case by the fact that the electrolyte increases the degree of charge separation in the intermediate (III) and stabilises the latter as a result of association; the changes enumerated above lower the apparent activation energy for the entire electrophilic halogenation process. In the chlorination of *trans*-cinnamic acid the reaction rate constant increases by a factor of three in the presence of 0.1 M $LiClO_4$.[10]

The introduction of a neutral salt prevents the association of the separated ion pair into a non-separated pair (Scheme 1) and therefore displaces the equilibrium towards the more reactive σ-complex, so that the reaction rate constant increases. Added electrolyte increases the rate constant for the bromination of styrene by a factor of seven[57]. The increase in the degree of charge separation in the intermediate should increase the sensitivity of the halonium ion to the influence of substituents and the reaction rate constant should therefore increase in absolute magnitude. With

increase of the $LiClO_4$ concentration from 0 to 10^{-1} M in the acetoxy-bromination of R-styrene (Fig.1), the reaction rate constant increases owing to the increased dipole moment of the intermediate; the intersection of the two relations at the point corresponding to *m*-nitrostyrene can be explained only by the fact that the bromination involves the existence of only a solvate-separated ion pair whose state does not change with increase of the electrolyte concentration[57].



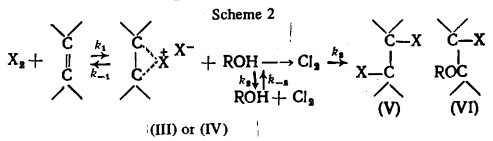


Figure 1. Dependence of the yield of the acetoxybromo-derivative in the bromination of R-styrene in acetic acid on the σ^+ constants of the substituents: *1*) acetic acid; *2*) acetic acid + 0.10 M $LiClO_4$.

2. The Ratio of the Rates of Individual Stages

Since the interaction of a halogen with an olefin proceeds at a high rate, it is frequently assumed that the electrophilic addition is irreversible. On the other hand, a number of facts are presented above confirming the formation of intermediates which are subsequently converted into the reaction products (V) or (VI). The entire reaction involving the electrophilic addition of a halogen to an olefin proceeds under pseudostationary conditions, so that the intermediates do not accumulate in large amounts. It is not possible to detect the intermediate species, because the rate of their formation is comparable to the rate of their conversion into the reaction products. The rate constant for the rate-limiting stage of a complex process involving the formation of products from an intermediate (III) or (IV) is close to the apparent rate constant for the entire process determined experimentally. The absolute value of k_{eff} varies within broad limits, depending on the structure of the olefin; thus k_{eff} varies in the range from 5×10^{-2} to 5×10^5 litre mol^{-1} s^{-1} in the bromination of *cis*- and *trans*-substituted olefins at 25 °C.[34,59]

In the coupled reaction the formation of a second donor–acceptor complex is no less important than the formation of the halogen–olefin σ-complex (Scheme 2):

Scheme 2

The exothermic heat of the two reversible processes lowers the effective activation energy for the electrophilic reaction. The addition of π- and *n*-donors not involved directly in the electrophilic addition reaction should have a catalytic effect owing to the formation of donor–acceptor complexes with the halogen. Thus, in the study of the electrophilic addition of chlorine to hexene in CCl_4, an increase of the rate constant and a change of the kinetic equation were observed in the presence of benzene or dioxan; on passing from CCl_4 to an electron-donating solvent, the rate constant changes from 1.7 litre mol^{-1} min^{-1} to 4800 $litre^2$ mol^{-2} min^{-1}.[60] Analogous results have been obtained also for other electron-donating solvents (diethyl and dibutyl ethers) which do not enter directly into the reaction under the experimental conditions[61].

However, a whole series of donors react with the halogen–olefin π-complex, forming mixed adducts[23,24,26,29,62]. The formation of donor–acceptor complexes of *n*-donors with chlorine has been indicated in kinetic studies by an increase in the reaction order with respect to the halogen in coupled reactions[23,24,63] and by the necessity for an excess of the oxygen-containing donor for the reaction to occur at a high rate. A decrease of the concentration of both chlorine and the *n*-donor inhibits the coupled reaction; in this case the kinetic curve acquires the S-shape characteristic of auto-catalytic reactions. The induction period of the auto-catalytic reaction is associated with the need to accumulate a considerable amount of the intermediate[64]. The presence of an induction period has been noted, for example, in the coupled bromination of cyclohexene in the presence of epoxycyclohexane[37].

With increase of temperature, the specific rate constants corresponding to the elementary stages of the process shown in Scheme 2 increase unequally; the dependence of the effective rate constant for the coupled halogenation on temperature is therefore anomalous—the absolute value of the effective rate constant decreases with increase of temperature[29,37]. Analysis of the process in Scheme 2 readily shows that an *n*-donor concentration higher than the stoichiometric value is necessary for the practical realisation of the coupled reaction. Reactions involving the coupled chlorination of allyl chloride together with α-oxides[29] and β-oxides[63] as well as 2-chloroethanol[24] take place in precisely this manner in the presence of an excess of the oxygen-containing compound.

If an appreciable charge separation takes place in the intermediate of the electrophilic reaction and the intermediate acquires the character of a solvate-separated ion pair, an increase in the concentration of the common halide ion should increase the rate of the electrophilic addition of the halogen to the multiple bond, i.e. a positive salt effect should be observed. Stimulation of the electrophilic bromination of olefins in methanol under the influence of NaBr has been most widely studied[65–67]. An increase of the concentration of the nucleophile increases (as a result of the dissociation of the electrolyte) not only the rate of the electrophilic reaction but also the fraction of *trans*-addition to the double bond. Nucleophilic attack on the carbon atom does not require in this case either a reorientation of the nucleophilic bromine or rotation about the carbon–carbon bond in the intermediate. With increase of the LiBr concentration in the bromination of styrene from 0 to 0.1 M, the fraction of *trans*-addition increases from 72 to 95%.[68]

The positive salt effect of the halide anion is described by a third-order kinetic equation incorporating the concentrations of both the halogen and the halide anion[69]. Electrophilic addition to an olefin in the presence of metal halides is a process which proceeds via two bimolecular collisions; the effective activation energy for this reaction is reduced,

since the energy expended on the dissociation of the halogen–halogen bond is compensated by the energy of formation of the halogen–carbon bond[70,71].

In those cases where the intermediate in the electrophilic addition of a halogen to a multiple bond acquires the character of a close ion pair (a π-complex) the addition of metal halides does not alter either the rate of reaction or the proportions of the *cis*- and *trans*-additions. In the chlorination of phenanthrene the addition of LiCl does not effect the stereochemistry of the halogen addition products[72]. An increase of the chloride ion concentration does not change the rate constants for the chlorination of *trans*-cinnamaldehyde[10] and *trans*-cinnamic acid[11]. In the study of salt effects it is important to take into account the formation of mixed adducts with protic solvents, since in this case hydrogen chloride is generated, increasing the rate of the electrophilic reaction by a factor of 10–12, which makes the addition of the halogen to the multiple bond autocatalytic[10,73].

The kinetic equation for the electrophilic addition of bromine to olefins is more complex: the reaction proceeds via two parallel competing pathways[58,59,74,75], involving the interaction of the olefin with molecular bromine (k_1) and with the tribromide anion (k_3); the latter interaction is described by the equation

$$Br_2 + Br^- \rightleftarrows Br_3^-$$

$$-\frac{d[Br_2]}{dt} = k_1\,[\text{olefin}]\,[Br_2] + k_3\,[\text{olefin}]\,[Br_3^-] \ .$$

The equilibrium constant for the formation of the tribromide anion has a high absolute value, so that minimal amounts of the common ion produced in the dissociation of the electrolyte shift the equilibrium towards the tribromide anion and reduce the contribution of the "molecular" reaction pathway. The equilibrium constant K_{25} depends on temperature, the source of the counterion, and the solvent. Thus, on passing from acetic acid to methanol, the equilibrium constant changes from 92 litre mol^{-1} (Rolston and Yates[57]) to 177 litre mol^{-1} (Dubois et al.[8]). The equilibrium constant changes even more when the nature of the electrolyte is altered; thus in the presence of HBr the equilibrium constant is 125 litre mol^{-1}, which is 2.5 times more than in the presence of added NaBr (53 litre mol^{-1}).[57,75] The equilibrium constant in the formation of the tribromide anion increases also with increase of the $LiClO_4$ concentration[57].

The relative contributions of the two parallel pathways are usually described by the ratio $Q = k_{Br_2}/k_{Br_3^-}$, which varies from 0.01 (Yates and Wright[58]) to 85 (Dubois et al.[8]). The change in the relative contributions of the competing pathways can be accounted for by the change in the bromide anion–tribromide anion equilibrium constant under the influence of the factors enumerated above. However, in all cases, ranging from dominant bromination by the tribromide anion ($Q < 1$) [58,74] to virtually complete absence of the reaction with the tribromide anion ($Q \gg 1$),[8,76–78] the rate of reaction of Br_3^- is higher than that of Br_2. The anomalously high values of Q observed by Dubois et al.[8] can be explained by the steric hindrance in the diphenylethylene being brominated and also by the autocatalytic effect of HBr, which is evolved on formation of mixed adducts with the solvent.

The interaction with the trichloride anion is less characteristic of chlorination owing to the low value of the equilibrium constant for the formation of the Cl_3^- anion[5,79,80]. On the whole, as in the cases enumerated above, the exothermic reversible formation of the trihalide ion exhibits a catalytic effect on the conversion of the intermediate into the reaction product; a change of temperature can alter the rate-limiting stage of the process, the rate constant for the reversible stage involving the formation of a π- or σ-complex being smallest.

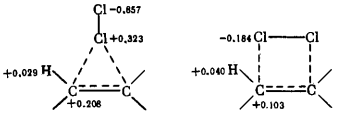
III. PHYSICOCHEMICAL METHODS FOR DETECTING THE INTERMEDIATE SPECIES INVOLVED IN ELECTROPHILIC ADDITION REACTIONS

The electrophilic addition of a halogen usually takes place under pseudostationary conditions, so that the intermediate does not accumulate in considerable amounts, which hinders its detection by physicochemical methods. By carrying out the reaction at reduced temperatures, it is possible to separate the reversible and irreversible stages of the process (Scheme 1) and to investigate the structure of the unstable intermediates.

It has been shown[20,81–86] by low temperature infrared spectroscopy that, when an olefin and a halogen are sputtered onto a cooled (~–200 °C) cryostat support under molecular beam conditions, the spectrum shows initially only bands characteristic of the parent compounds. Heating of the cryostat support to between −180 °C and −165 °C leads to the mutual diffusion of the components and to the appearance in the infrared spectrum of a group of new bands which are not characteristic of either the initial compound or the reaction product[82,83,85].

The changes occurring in the infrared spectra can be explained solely by the formation of intermediates of the olefin–halogen type, which are converted on heating into dihalogeno-derivatives[81]. The decrease of the vibration frequency of the multiple bond suggests a decrease of its electron density compared with the initial olefin[83,84]. Analysis of the frequencies and modes of the normal vibrations shows that the olefin–halogen complexes have C_{2v} symmetry, which is characteristic of three-membered heterocycles[81]. Simultaneously with the structure, the equimolecular composition of the unstable intermediate was demonstrated[81–84]. In the presence of an excess of bromine an intermediate containing two bromine molecules per olefin molecule was detected[87]. In a mixture of bromine and propene the disproportionation of a 1 : 1 complex to give a 2 : 1 complex and free propene, identified in a mixture of complexes, was noted[84].

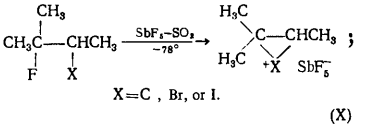
The conclusions reached in the study of the low-temperature spectra of halogen–olefin complexes were confirmed by quantum-mechanical calculations. The formation of the open-chain carbonium ion (VII)



(VII)

incorporating an sp^3-hybridised carbon atom and a covalent carbon–carbon bond of normal length (1.53 Å), is unlikely; the existence of the carbonium ion is possible only when it is stabilised by the attacking nucleophiles[88,89]. Theoretically, the structure of the centrosymmetric halonium ion (IV) with a partially rehybridised carbon atom and altered valence angles is energetically most favourable[90,91]. The changes occurring on formation of intermediates can be followed in the infrared spectra of solid solutions of chlorine in olefins; the observed effects can be accounted for by a decrease of the electron density in the multiple bond and by the formation of partial C—Cl bonds.

For 1 : 1 donor–acceptor complexes of C_{2v} symmetry, two structures can be postulated[91,92]. The first is the axial structure (VIII) in which the halogen molecule is located on the symmetry axis of ethylene perpendicular to the carbon–carbon bond. In the alternative structure (IX) the halogen–halogen bond is parallel to the plane of the carbon–carbon bond. The complex (IX) presupposes the formation of a four-centre transition state and the *cis*-addition of a halogen

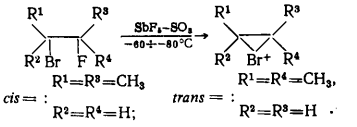


molecule to the multiple bond. Comparison of the distributions of electron density in the intermediates (VIII) and (IX) in the reaction involving chlorine shows that the former is energetically favoured, since it involves a greater charge separation[90].

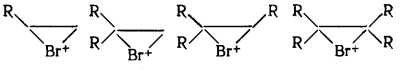
(VIII) (IX)

According to quantum-mechanical calculations[90], the stability of the intermediate complexes decreases in the sequence Br > Cl > F, which agrees well with experiment[93]. The cyclic structure of the intermediate ion makes it possible to explain the *trans*-specificity of the electrophilic halogenation in non-polar media, associated with the inhibition of the free rotation about the carbon–carbon bond in the cyclic ion (VIII), compared with the open-chain carbonium ion (VII).[94,95] In polar media where there is a possibility of the formation of solvate-separated ion pairs, the open-chain ion may be stabilised† and the stereospecificity of the reaction may be infringed[96]; *cis*-addition to the multiple bond is possible only when there is rotation about the carbon–carbon bond in the intermediate. α-Substitution in the olefin molecule distorts the symmetrical distribution of electron density on the carbon atoms and in the limiting case such an intermediate may become open-chain[98–100]. Quantum-mechanical calculations have now been made only for the simplest olefins (ethylene and propene); the stabilising influence of the solvent on the charge distribution in halonium ions has been taken into account only indirectly[99]. The latter factor precludes an unambiguous utilisation of the quantum-chemical results for the consideration of the mechanism of electrophilic halogenation.

NMR has been widely used in recent years in the study of labile intermediates. A major achievement of NMR has been direct detection of non-classical cyclic halonium ions. Olah and coworkers frequently detected the formation of a cyclic intermediate from the corresponding vicinal dihalides when the latter were dissolved in superacids at low temperatures[35,93,101–108]. The dissolution of 3-chloro-, 3-bromo-, or 3-iodo-2-fluoro-2-methylbutane in an SbF_5–SO_2 mixture at −78 °C leads to the formation of the stable trimethylethylene–halonium ion (X):[104]



X=C , Br, or I.

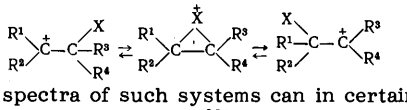


(X)

In the case of symmetrical ethylenehalonium ions[103,109] the conclusion that the ion had a bridged structure is based mainly on three pieces of evidence: the detection of a singlet signal due to the methylene protons in the ^1H NMR spectra, the upfield shift of the signal of the α-carbon atoms (to 40 ppm.) [105] relative to the spectra of typical open-chain ions[93], and the stereoselective methanolysis of the halonium ion generated from the optically active vicinal dihalides[93]. The presence of even insignificant amounts of a classical carbonium ion containing an sp^3-hybridised carbon atom should lead to the non-equivalence of the signals of the methylene protons and to the formation of racemates on solvolysis[102,103,162].

When *erythro*- and *threo*-3-fluoro-2-iodobutanes were ionised in superacids, the *trans*- and *cis*-iodonium ions were obtained, their reactions with CH_3OH proceeding stereospecifically with formation of *erythro*- and *threo*-*dl*-2-iodo-3-methoxybutanes respectively[35]. Indeed, if the non-classical halonium ions are three-membered cyclic species, they should have both *cis*- and *trans*-isomers. In a study of the low-temperature ^{13}C NMR spectrum of *erythro*-*dl*- and *threo*-*dl*-2-bromo-3-fluorobutanes in superacids both the *trans*-isomer ($\delta_{C_1} = \delta_{C_2} = 85.0$ ppm., $\delta_{CH_3} = 175.4$ ppm.) and the *cis*-isomer ($\delta_{C_1} = \delta_{C_2} = 82.9$ ppm., $\delta_{CH_3} = 174.4$ ppm.) of the dimethylethylenebromonium ion were identified[107]:

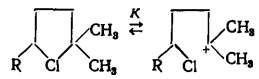
The introduction of alkyl substituents at the α-carbon atom stabilises the bridged ion; this has been demonstrated not only by NMR [103,107] but also by special thermochemical studies in superacids at −60 °C. The heat of formation of methyl-substituted bromonium ions varies in the following sequence[110]:



ΔH, kcal mol^{-1} −3.29 −8.39 −13.5 −22.5 .

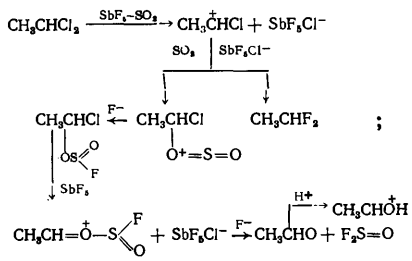
The tetramethylbromonium ion proved to be the most stable, in agreement with conclusions which follow from spectroscopic studies[108]. The halonium ions of olefins substituted in the α-position by bulky alicyclic groups, for example, the adamantane ring, are particularly stable and can be isolated at the usual temperatures[111,112]. The structure of the adamantylbromonium ion has been confirmed mass-spectrometrically[111].

The substitution of the protons at the α-carbon atom of the olefin by arene rings leads to the destabilisation of the cyclic halonium ion and to the appearance of considerable amounts of an open-chain halonium ion; the presence of the latter has been demonstrated not only by NMR but also by the formation of a mixture of isomers in the solvolysis reaction[105,106].



The stability of the cyclic ions increases in the following sequence of halogens: F < Cl < Br ≪ I,[107] which corresponds to the increase of the ionic radius and the polarisability of the atoms. The formation of a non-classical ion from fluorine is doubtful[113]. Bridged (butene[103] and ethylene[109]) and open-chain (propene[102]) ions are apparently characteristic of chlorine. It is logical to suppose that both forms under consideration are in a state of dynamic equilibrium:

The ^1H NMR spectra of such systems can in certain cases show a broadened singlet signal[114], which hinders its assignment to a specific type of ion. The problem can be solved using the temperature variation of the ^1H NMR spectra, which provides an unambiguous answer to the question whether or not a reversible reaction of the ions takes place in the given case. Such a temperature dependence has now

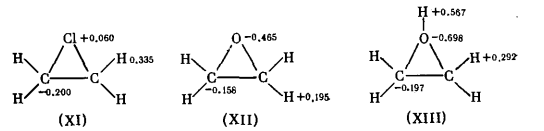


†According to quantum-mechanical calculations, the open-chain form $CH_3CH_2^+$ of the cation $C_2H_5^+$ is more stable than the cyclic form by 6.7 kcal mol^{-1}.[97]

been investigated only for the substituted tetramethylene-chloronium ion, whose stability is higher than that of the ethylenehalonium ion[115]. The predominance of the open-chain form of the ion over the cyclic form has been noted; the equilibrium constants K are 0.31 litre mol^{-1} in SO_2ClF and 0.21 litre mol^{-1} in SO_2.[115] An increase of temperature from −100° to −33 °C increases the content of the cyclic form from 10.5 to 25%:[115]

An increase of the size of the ring for the same number of methyl substituents in the α-position relative to the halogen atom greatly increases the stability of penta- and hexamethylenechloronium ions[116] compared with ethylenehalonium ions[110,117]. The available information about the trimethylenehalonium ion is contradictory[113,116]; the attempts to detect this ion proved unsuccessful owing to its rapid isomerisation to an ethylenehalonium ion[113]. In terms of their reactivities, the five- and six-membered halonium ions are analogous to ethylenehalonium ions[76,115,118–120].

The data concerning the formation of non-classical bridged ions, obtained with the aid of low-temperature NMR, cannot be transfered mechanically to the consideration of different aspects of electrophilic reactions, since highly ionising media (SbF_5–SO_2 and SO_2ClF–SO_2) and a low temperature have a stabilising influence on the unstable intermediates. The conversion of the latter on heating does not always proceed solely with the electrophilic addition of the halogen to the multiple bond, with formation of an adduct, but can be complicated by a whole series of side reactions. An example of degradative decomposition is provided by the conversion of the cation obtained from 1,1-dichloroethane in the SbF_5–SO_2 medium[35]; in this case only the products of the conversion of the initially formed ion were identified in the reaction mixture[35]:



The formation of the ethylenechloronium ion in SO_2ClF is complicated by the 1,2-hydride shift[109].

Overall, the study of the NMR spectra of dihalides at low temperatures confirms the validity of the concept of cyclic halonium ions, because *cis–trans*-isomerism has been observed, the solvolysis proceeds stereoselectively, and the absolute values of the chemical shifts are not characteristic of classical carbonium ions.

IV. THE *Ad* MECHANISM OF THE ADDITION OF A HALOGEN TO A MULTIPLE BOND

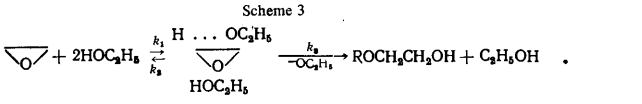
If it is assumed that a bridged non-classical ion is involved in the electrophilic addition of a halogen to a multiple bond in non-polar media, then the conversion of the ion into products is a typical *Ad* reaction[18,121], the kinetics of which are common to other analogous reactions, for example, those involving the opening of the ring in epoxides under the influence of nucleophiles[122]. The principal objection to the proposed analogy is the nature of the distribution of electron density in the "bridged" ion (XI)—the intermediate in the electrophilic reaction[97]—and in the epoxide (XII):[123]

(XI) (XII) (XIII)

Systematic study of the quantitative characteristics of the opening of the epoxide ring under the influence of nucleophiles showed that the species which usually reacts is the protonated epoxide (XIII),[123,124] where the distribution of electron density differs significantly from that known for the epoxide (XII). The reactions of epoxides with nucleophiles under the conditions of both acid[125–129] and base[130,131] catalysis proceed via a trimolecular transition state incorporating both the nucleophile and the proton donor molecule. Protonation of epoxides increases the polarisation of the C–O bond, which facilitates its dissociation; the nature of the distribution of electron density in the intermediates (XI) and (XIII), formed respectively in the electrophilic addition of the halogen and in the opening of an epoxide, is the same, as has been frequently confirmed by quantum-mechanical calculations[98,123].

The chemical shifts (δ, ppm.) of the protons of protonated epoxides and certain halonium ions[132].

Ion	δ_{CH}	δ_{CH_2}	δ_{CH_3}
$CH_2(I^+)-CH_2$	—	5.77	—
$CH_2(Br^+)-CH_2$	—	5.53	—
$CH_2(OH^+)-CH_2$	—	5.00	—
$CH_2(SH^+)-CH_2$	—	3.63	—
$CH_3CH(I^+)-CH_2$	7.73	5.77	3.32
$CH_3CH(Br^+)-CH_2$	7.48	5.86	2.98
$CH_3CH(OH^+)-CH_2$	5.80	5.20	1.53
$CH_3CH(SH^+)-CH_2$	4.40	3.66	1.63
$(CH_3)_2C(I^+)-CH_2$	—	5.72	3.43
$(CH_3)_2C(Br^+)-CH_2$	—	5.55	3.32
$(CH_3)_2C(OH^+)-CH_2$	—	5.20	1.63



The genetic relation between the intermediates in reactions proceeding via the *Ad* mechanism has been demonstrated experimentally; Olan and Szilagy[132] established that the chemical shifts of the protons of the methylene groups in protonated epoxides and thiirans are similar to those of the cyclic halonium ions (see Table). It is easy to see that the change in the electronegativity of the heteroatom required

an increase of the chemical shifts of the methylene protons giving the following sequence: O > Br > S ≅ C > I.[133] The breakdown of this sequence can be accounted by the different directions of the shifts of electron density in the three-membered heterocycle: if the electronegativity of the heteroatom (Br, Cl, O) is greater than that of carbon, the electron shifts to a centre of the antibonding type (the carbon atom); if the heteroatom is less electronegative than carbon, the electron density of the carbon–heteroatom bond shifts in the opposite direction[99]. A second factor which distorts the sequence of the changes in the chemical shifts arising from the electronegativity series of heteroatoms, is protonation of the heteroatom.

The isotypical distribution of electron density in three-membered protonated heterocycles and in cyclic halonium ions, presupposes a close relationship between the mechanisms of the electrophilic halogenation and the opening of the epoxide rings under the influence of nucleophiles, which is shown particularly clearly in relation to coupled electrophilic reactions.

The π- or σ-complex formed in the first stage of the electrophilic addition is converted into an ether under the influence of the alcohol anion (Scheme 1);[23,24] the protonation of the epoxide under the influence of an alkoxide[124,130] or a phenoxide[126] (Scheme 3) proceeds in exactly the same way:

Scheme 3

The involvement in the transition state of the opening of the epoxide rings of at least two molecules—one proton donor molecule and one nucleophile molecule—has been confirmed by the high kinetic orders of the reactions of epoxides with phenols[126,134] and alcohols[125,135]. The high kinetic orders observed for the electrophilic addition of a halogen to an olefin ($n = 3$) [14,136] and for the coupled reaction[23,24,26] ($n \geq 3$) presuppose the formation of a trimolecular transition state via two bimolecular processes.

The identical characteristics of the charge distribution in the unstable intermediate adducts suggest the identical influence of the ionic strength of the solution on the rates of the two reactions. A positive salt effect has been noted for the opening of the epoxyethane ring under the conditions of acid catalysis[128] for the electrophilic addition of chlorine[71] or bromine[51] to a multiple bond.

The energy profiles of the reactions compared (Fig. 2) are identical[5,7,13], which permits the conclusion that the formation of the unstable oxiran–catalyst (or alcohol) adduct[124,131] is equivalent, from the standpoint of thermodynamics, to the formation of a σ- or π-complex in electrophilic halogenation. The exothermicity of the pre-reaction donor–acceptor interaction lowers the experimental apparent activation energy.

A decrease of the concentration of one of the initial reactants (Schemes 1, 2, and 3) or an increase of temperature leads to a shift of the pre-reaction equilibrium towards the initial reactants in accordance with the Le Chatelier principle, which lowers the concentration of the intermediate and the rate of the process as a whole. The inhibition of the reaction leads to the S-shape of the kinetic relation characteristic of an autocatalytic reaction[137]. Such relations, with an induction period, have been found for the reactions of epoxides with alcohols[130] and for coupled reactions[37].

The formation of cyclic halonium ions in electrophilic halogenation reactions in non-polar media inhibits the rotation about the carbon–carbon bond and increases the percentage of the *trans*-addition to the multiple bond[32,68]. In substituted epoxides, where rotation about the C–C bond is impossible, the probability of the *trans*-opening of the epoxide ring reaches 100%.[129]

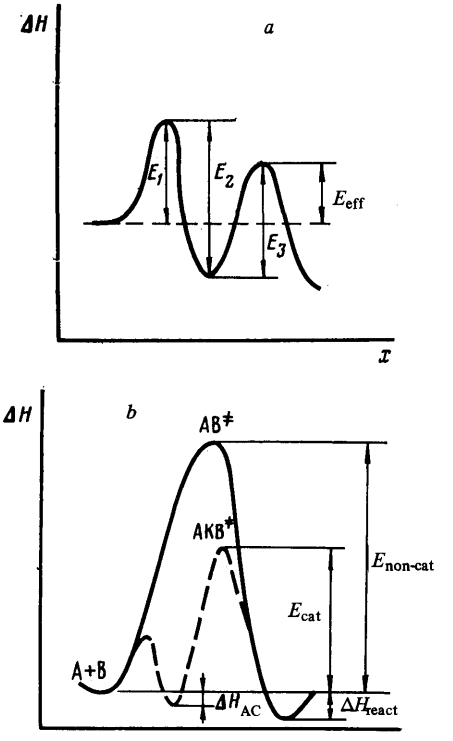


Figure 2. Variation of the potential energy along the reaction coordinate x: *a*) for the coupled halogenation of olefins:

olefin + halogen ⇄ olefin.halogen → mixed adducts / dihalogeno-derivatives;

b) for non-catalytic and homogeneous-catalytic reactions of an epoxide with alcohols:

epoxide + alcohol $\xrightarrow{\text{catalyst}}$ epoxide.alcohol.catalyst → products.

V. STEREOCHEMICAL ASPECTS OF ELECTROPHILIC HALOGENATION

1. The Influence of the Structure of the Halonium Ion on the Stereochemistry of Electrophilic Halogenation

The study of the stereochemistry of the addition of halogens and hypohalites yields important information about the structure of the intermediate, the degree of ionisation, and the symmetry of the distribution of electron density between carbon atoms. In those cases where the intermediate is a typical halonium ion, the electrophilic reaction proceeds stereoselectively with the formation only of the products of *trans*-addition to the multiple bond[138]. The chlorination of butenes[21,95] and the bromination of ethylenes[21,34] can serve as examples of the stereoselective *trans*-addition.

The addition of mixed reagents, for example bromo- and chloro-acetoxylation, proceeds stereoselectively[34,139]. The stability of a cyclic halonium ion increases with increased atomic radius of the halogen; the stereoselectivity of the addition of a halogen to allyl ethers increases in precisely this sequence[21].

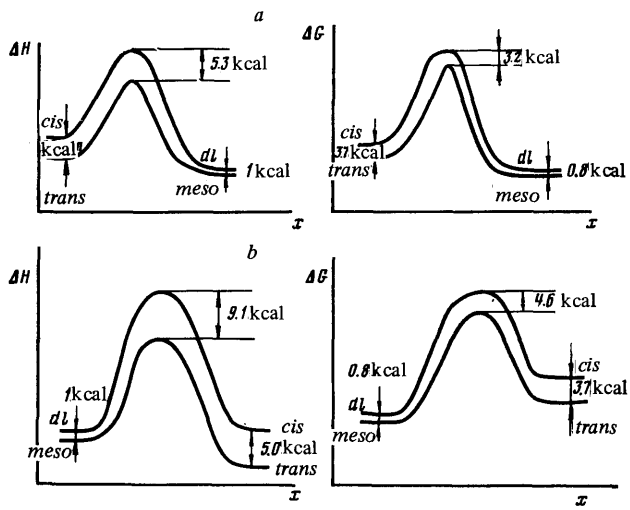
The increase of the degree of charge separation in the intermediate, due to external factors such as the polarity of the solvent[69,140] and the addition of salts[10], increases the probability of the formation of an "open-chain" ion and the stereoselectivity of the electrophilic addition of the halogen is then limited. An increase of solvent polarity in the bromination of *cis*-β-methylstyrene in the series from carbon tetrachloride to nitrobenzene reduces the percentage *trans*-addition from 70 to 45%; for *trans*-β-methylstyrenes, the effect of the change in solvent polarity is less pronounced (71% *trans*-addition for dioxan and 82% for nitrobenzene).[68]

The positive salt effect observed in the electrophilic addition of a halogen was discussed above[57]; the addition of an electrolyte alters not only the reaction rate constant but also the stereoselectivity of the process. The ability of the salt to stabilise the solvate-separated ion pair as a result of electrostatic interaction increases the probability of rotation about the carbon–carbon bond and infringes the stereospecificity of the electrophilic addition of a halogen to a multiple bond. In the chlorination of acrylic acid derivatives the yield of the *trans*-addition product is reduced by 30–35% in the presence of added $LiClO_4$.[9-11] In those cases where the electrophilic addition of a halogen in non-polar media proceeds with participation of a close ion pair, the influence of added electrolytes on the stereochemistry of the addition reaction should be minimal[32,68].

The comparatively simple postulates explaining the proportions of the *cis*- and *trans*-addition of a halogen to a multiple bond are distorted when the molecular reaction pathway is accompanied by a significant contribution by the radical non-stereospecific pathway[141], which is especially characteristic of reactions involving chlorine[142,143]. In the chlorination of *trans*-but-2-enes the contribution of the radical reaction increases as the olefin concentration is reduced and the number of alkyl substituents in the olefin is decreased[94]. The probability of the radical reaction changes in the sequence which is the opposite of that based on the stabilities of cyclic halonium ions (Cl > Br > I); for the addition of bromine to a multiple bond, the contribution of the free-radical reaction pathway is small[144].

In connection with the difficulty of determining the angle of rotation in the intermediate, which is rapidly converted into the reaction products, the stereochemistry of the electrophilic addition of a halogen to the multiple bonds of acyclic compounds, where rotation in the intermediate labile complex is impossible, acquires particular importance[72,145]. The interaction of chlorine with unsubstituted cyclohexene proceeds stereoselectively[72], while the addition of chlorine to acenaphthylene and phenanthrene results in a mixture of stereoisomers[72]. The absence of a definite stereospecificity for the electrophilic addition of chlorine to a multiple bond can be explained by the contribution of a free-radical process, which has been confirmed by the detection in the reaction mass of different amounts of radical-substitution products[145,146]. The principle, according to which an increase of the reactivity of the reagent reduces the selectivity of the reaction, holds for the electrophilic addition of a halogen to unsaturated acyclic compounds[147].

The high absolute rates preclude at the present time the estimation of the relative rates of rotation in the open-chain ion and of the addition of a halogen to the intermediate cation, but it is possible to estimate the thermodynamic parameters of these two processes. The thermodynamic parameters of the electrophilic reaction involving the geometrical isomers of olefins have been compared[57,68,148,149] with the enthalpies of their *cis*–*trans* isomerisation, estimated as differences between the heats of combustion of the *cis*- and *trans*-isomers. It is postulated[148] that, when the activated complex resembles an "open-chain" ion, the interaction of bulky alkyl substituents at the sp^3- and sp^2-hybridised atoms of the intermediate will be weakened as a result of the rotation; the difference between the enthalpies of the electrophilic halogenation of *cis*- and *trans*-isomers will then decrease relative to the enthalpies of isomerisation of the same geometrical isomers. In those cases where the activated complex has the structure of a halonium ion the steric influence of the bulky substituents is more pronounced; the difference between the enthalpies of the electrophilic addition reactions involving geometrical isomers therefore increases compared with the enthalpy of their isomerisation. The energy profiles of the bromination reactions of *cis*- and *trans*-stilbenes (Fig.3) show that the enthalpy difference in the transition state is greater than in the initial state, which corresponds to a cyclic bromonium ion and not an open-chain ion[148].



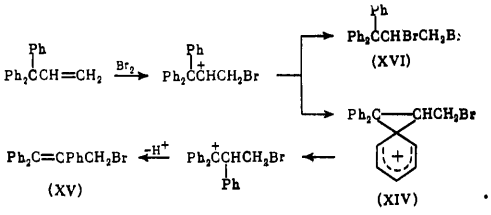


Figure 3. Variation of the enthalpy and free energy along the reaction coordinate for the bromination of *cis*- and *trans*-stilbenes in acetic acid[148] (*a*) and for the debromination of *dl*- and *meso*-stilbene dibromides in dimethylformamide catalysed by lithium bromide[151] (*b*).

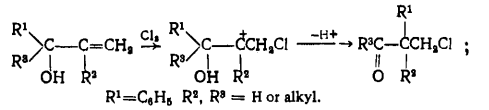
Examination of the nature of the variation of the enthalpy along the reaction coordinate explains the higher rate constant for the electrophilic reaction involving the *trans*-olefins than for the *cis*-olefins, usually observed, since the potential barrier to the latter reaction is greater (Fig.3*a*) than the barrier to the former[69,138,150]. The difference between the energetic parameters of the electrophilic addition reaction agrees satisfactorily with the difference between the enthalpies of the debromination of the *dl*- and *meso*-dibromo-derivatives in dimethylformamide (Fig.3*b*) which apparently also proceeds via a stage involving the formation of a bromonium ion[151–153].

The joint study of the thermochemistry, kinetics, and stereochemistry of the addition of a halogen to the *cis*- and *trans*-isomers of an olefin yields the most complete information about the structure of the intermediate species.

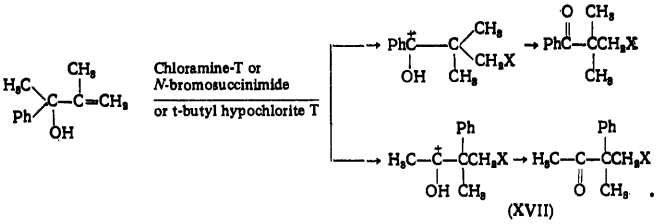


2. The Effect of the Involvement of Neighbouring Groups

The introduction of several substituents at one carbon atom alters the charge distribution in the intermediate[154], infringes the additivity of the influence of the substituents[155-158], and causes additional stabilisation of the charge on the cationic centre[159,160] due to interaction with the electron-donating groups located at the α-atoms of the carbon chain, which permits the migration of one of the substituents to an unsubstituted carbon atom of the olefin[161,162]. A characteristic example of the rearrangement of the carbon skeleton is the migration of the arene ring on bromination of 3,3,3-triphenylpropene[161]:

The presence of unduly bulky substituents at the carbon atom in 3,3,3-triphenylpropene, together with the stabilisation of the charge on the intermediate cation in the reaction with bromine, permits a direct interaction of the carbonium centre with one of the benzene rings. The intermediate phenonium ion has much in common with halonium ions; thus, when the reaction is carried out in methanol, a mixed adduct, incorporating the solvent, is obtained, apart from the rearrangement of product (XV) and the dibromide (XVI), as in other electrophilic reactions[161]. The bromination of 4-allylanisole leads to the formation of a mixture of a dibromide and a rearranged product, which are formed via two parallel pathways with participation of the bromonium and phenonium ions respectively[163]. The substitution of the benzene rings in 3,3,3-triphenylpropene with methyl groups increases the steric hindrance and makes the addition of a second bromine atom to the double bond more difficult; only the rearranged product is isolated from the reaction mixture in this case[161].

The reaction of olefins containing alkyl substituents proceeds in a more complex and more ambiguous manner[162, 164,165]. The reactions of alkenylalkylphenylmethanols with halogens and hypohalites have been studied in greatest detail[166-168]:



$R^1 = C_6H_5$; R^2, R^3 = H or alkyl.

In the case of acyclic compounds the rearrangement of the carbon skeleton proceeds with ring expansion[169,170]. Thus, for triphenylethylenes[161] in methanol, not only rearranged products and dihalides but also mixed products incorporating the solvent are formed[164,171,172].

The probability of the rearrangement of the halonium ions increases in the sequence Cl << Br < I;[173] the degree of stabilisation of the intermediates in the electrophilic addition reaction increases in precisely the opposite sequence[107].

The degree of delocalisation of the positive charge of the carbonium centre can increase under the influence of electron-donating substituents introduced into the migrating ring, which increases the rate of rearrangement[174]. In order to compare the stabilities of the phenonium, chloronium, and bromonium ions, Kartashov and Bodrikov[173] investigated the rearrangement of isopropenylmethylphenylmethanol under the influence of different agents:

(XVII)

A change in the nature of the halogenating agent does not alter the ratio of the reaction products: in all cases the ketone (XVII)—the product of the migration of the phenyl group—predominates, i.e. the interaction of the positively charged carbonium ion with the aromatic ring is more effective than the interaction with the unshared electron pair of the halogen atom; thus the phenonium ion is more stable than the chloronium or bromonium ion[173].

With decrease of solvent polarity as a result of the destabilisation of the positive charge in the intermediate, the rate of rearrangement increases[175]. Special experiments have shown that the competing reactions—rearrangement, substitution, or addition—are parallel pathways leading to the conversion of the intermediate halonium and phenonium ions[163,176] and that the thermodynamic parameters (enthalpy and entropy) of the rearrangement of the carbon skeleton[177] are similar to those usually observed for the electrophilic halogenation of olefins[178].

VI. THE ELECTROPHILIC PROPERTIES OF THE REACTION CENTRES OF THE INTERMEDIATE

The mode of addition of anions to the halonium ion arising in the intermediate stage of an electrophilic kinetically controlled reaction is determined by the relative electrophilicity of each atom of the intermediate. The reactivity of the latter depends on the basicity and polarisability of each carbon atom of the unstable intermediate and on the electronic nature of the substituents in the α-position relative to the multiple bond[4]. It is impossible to determine independently the basicities and polarisabilities of each reaction centre, because the two atoms are linked into a mesomeric system. The lack of quantitative characteristics necessitates the use of qualitative estimates for each electrophilic atom of the intermediate; Pearson's principle of hard and soft acids and bases (HSAB) [179-183] is most convenient for this purpose. Pearson's empirical principle has been explained on the basis of the quantum theory, where its fundamental concepts (softness and hardness) are related to the different energies of the highest occupied and lowest vacant orbitals[184].

The application of the HSAB principle is particularly effective when the relative amounts of the isomeric products of electrophilic addition to a multiple bond are considered. With increase of the number of methyl substituents at the carbon atom in the series ethylene, propene, isobutene[144,185], the hardness of the cationoid centre increases with a simultaneous increase of the amount of the mixed adduct involving methanol, because the latter is a harder reagent

than the bromide anion. The relative amount of the bromomethoxyalkane varies as a function of the degree of substitution, increasing from 38% for ethylene to 84.7% for isobutene[185]. The degree of formation of mixed adducts increases similarly in the chlorination of olefins in acetic acid[181] and methanol[187].

The addition of the elements of a hypohalite to allyl chloride can also be explained on the basis of the HSAB principle: the hardest reagent (the alkoxide anion) is coordinated to the hardest central atom of the allyl chloride molecule[188-191]. The study of the products of the addition of chlorine and acetate to allyl chloride and hexane showed that the amount of adducts formed in accordance with the Markovnikov rule decreases from 77.5 to 67%, which reflects the increase in the hardness of the carbon atom in the allyl chloride molecule[18].

Pearson's principle can be applied no less successfully when the influence of the solvent is considered; when solvent polarity varies in the sequence carbon tetrachloride < methylene chloride < methanol, the degree of charge separation in the intermediate increases and hence there is an increase in the tendency towards reactions with the harder reagent—an alcohol[190], an acid[17,95], an epoxide[188,189], or a β-oxide[63] rather than a halide anion.

The joint influence of several factors varying simultaneously is more difficult to interpret on the basis of the HSAB principle; thus, when the methyl group of propene is substituted by the benzene ring, the polarisability and hence softness of the carbon atom increase. Nevertheless, in polar media such as acetic acid[95,139,192] and alcohols[122,185] the preferential coordination of the α-phenyl-substituted atom of 1-phenylprop-1-ene to the hard base is observed and mixed adducts are formed; this can be explained by the considerable charge separation in the intermediate under the influence of the polar solvent, which increases the hardness of the system as a whole.

In all cases examined above the factors increasing the hardness and reducing the polarisability of the intermediate lead to the formation of mixed adducts in the electrophilic reaction rather than dihalides.

On the whole, one can conclude that the pre-reaction equilibrium stage in the addition of a halogen to a multiple bond is characteristic of all electrophilic halogenation processes without exception. The structure of the intermediates in the electrophilic halogenation reaction requires further refinement. The low-temperature infrared and NMR spectroscopic methods are the most promising for the solution of this problem. Another important task in the study of the mechanism of the electrophilic reaction is estimation of the partial constants for the multistage process. A detailed investigation of the mechanisms of the electrophilic addition of a halogen to a multiple bond is undoubtedly important for the development of ideas concerning electrophilic reactions.

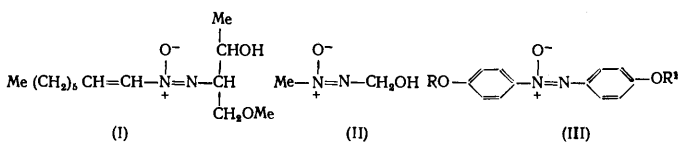
The Formation of the Azoxy-group in the Oxidation of Compounds with Nitrogen-Nitrogen Bonds

V.N.Yandovskii, B.V.Gidaspov, and I.V.Tselinskii



Methods for the formation of the azoxy-group by the oxidation of compounds with nitrogen-nitrogen bonds, namely azo- and hydrazo-compounds, indazoles, and hydrazones, are considered.
The bibliography includes 352 references.

I. INTRODUCTION

The first example of azoxy-compounds, namely azoxybenzene, was obtained by Zinin in 1845.[1] During the succeeding century only episodic interest was shown in these compounds. The vigorous development of studies on such compounds was stimulated by the presence of the azoxy-group in certain natural products [macrozamin[2-4], elaiomycin (I),[5,6] cycasin[7-17], and LL-BH872α [18-20]] exhibiting a powerful pharmacological activity. It was found that the incorporation in food of the fruit of certain species of the coconut palm can give rise to cancer[7-17], the active principle being methylazoxymethanol (II) substituted in the hydroxy-group by a glycosidic residue[7-17]:

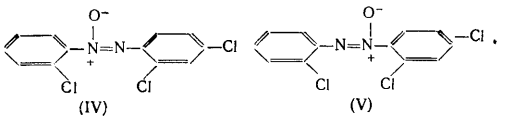
(I) (II) (III)

Methylazoxymethanol proved to be a powerful carcinogen, teratogen, and mutagen[7-17,21-24], the mechanism of the action of which is attributed to the alkylation of the amino-groups in DNA.[12-17,21-24] Many azoxy-compounds are now known to possess a powerful pharmacological activity[2-48] and the ability of the azoxy-group to induce mutations at a cellular level is used in preparations with tuberculostatic [compound (I)] and fungicidal activities[5,6,18-20]. It is remarkable that chemists were for a long time unable to establish the position of the *N*-oxide oxygen atom in compound (II); it was isolated for the first time as late as 1965 by the enzymatic hydrolysis of cycasin[21].

Another important stimulus of the development of the chemistry of azoxy-compounds was the discovery among azoxyarenes (II) of substances with liquid-crystal properties, exhibiting a positive dielectric anisotropy. In terms of thermal stability and a wide range of the existence of the mesophase, they are superior to many other substances of this type[49,50] and are therefore used in optical instruments, as phases in gas–liquid chromatography (GLC), and also in structural assignments with the aid of NMR and EPR.[49-59]

Finally, the chemistry of azoxy-compounds is of interest in view of the practical applications of pesticides, medicinal preparations, and dyes, whose structures include nitrogen-containing functional groups. The study of ways of converting these groups and the elucidation of the role of azoxy-compounds in the nitrogen turnover constitute an important fundamental task. As a result of the high thermal and chemical stabilities of the azoxy-group, azoxy-compounds serve, together with molecular nitrogen, as "trapping agents" in various changes of the valence state of nitrogen. Azoxy-compounds can be readily obtained from virtually any nitrogen-containing group by oxidation or reduction (including biochemical processes), but the reverse transformations are few and the synthetic value of the azoxy-group is not great.

Familiar monographs[60-67] contain chapters devoted to the azoxy-group. The early studies of the Italian and German schools on azoxyarenes were summarised by Angeli[68] and Bigelow[69]. The individual properties of the azoxy-group—photochemical reactions[70,71] and the Wallach rearrangement[71-73]—have also been considered. The properties of this group are described most fully in Patai's monograph[74] (see also the relevant reviews[75,76]).



In the present review we shall consider methods for the synthesis of the azoxy-group by the oxidation of compounds with a nitrogen–nitrogen bond. Studies published up to the end of 1979 are discussed.

II. THE NOMENCLATURE OF AZOXY-COMPOUNDS

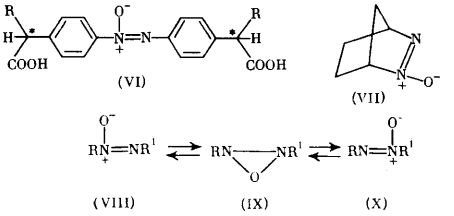
Publications on the nomenclature of azoxy-compounds[63,67,69] show that there is no unanimous point of view on this problem. The general name "azoxy-" for the group $-N=N^{+}-$ (with O^{-}) is used most frequently. If the group is linked to two identical substituents, the old nomenclature, in which the prefix "azoxy-" is placed before the name of the corresponding hydrocarbon [for example, azoxybenzene for $C_6H_5N=N(O)C_6H_5$] is entirely suitable. In the case of an asymmetric substitution at the $-N=N(O)-$ group the IUPAC nomenclature recommends the prefixes *–ONN–* or *–NNO–* to define the position of the oxygen atom[63,67,77]. When the atoms are arranged in the sequence *–ONN–*, the position of the substituent at the group linked directly to the

$\overset{+}{N}-O^-$ fragment is designated by a prime or, in the case of the reverse formulation of the azoxy-group (*–NNO–*), the prime denotes the position of the substituent at the group not linked to the NO fragment.

For example, in this nomenclature compound (IV) is called 2,2′,4-trichloro-*ONN*-azoxybenzene and compound (V) is 2,2′,4-trichloro-*NNO*-azoxybenzene:

(IV) (V)

Owing to their inconvenience and ambiguity, the IUPAC rules have not found extensive applications in complex cases.



After the publication of the review of Spence et al.[70], the terminology employed by them began to be actively employed. Thus substituents in an aromatic ring linked to the $\overset{+}{N}-O^-$ fragment are given primed numbers and substance (IV), for example, is called 2,2′,4-trichloroazoxybenzene. At the same time a system of alphabetical designations is introduced. α-Compounds is the name given to isomers in which the $\overset{+}{N}-O^-$ fragment is linked to the smaller (phenyl relative to naphthyl) or less substituted aryl. These rules constitute a slight modification of the system of alphabetical designations introduced by Angeli (for examples, see Refs. 61, 62, and 69). At the same time, a nomenclature in which azoxy-compounds are designated as substituted diazene *N*-oxides[78] or di-imide *N*-oxides[79], has been used. The Chemical Abstracts Nomenclature (introduced from Volume 76) is the most promising, unambiguous, and consistent with the nomenclature of other functional groups (–N = N–, –N(O) = N(O)–, $>\overset{+}{N} = N^-$, etc.]. It is based on the name diazene oxide in which numerals 1 and 2 denote the positions of the substituents and the oxygen atom. However, this system is very cumbersome.

The terminology introduced by Moss and Love[80], in which the group linked to the $\overset{+}{N}-O^-$ fragment is designated as proximal and the group remote from the fragment is designated as distal, is suitable for asymmetrically substituted azoxy-compounds. Similarly, the position of oxygen at the nitrogen atom, adjoining the group Z in XN = N(O)–Z, is designated as proximal in relation to Z and the opposite position is designated as distal.

III. ISOMERISM OF THE AZOXY-GROUP AND STRUCTURAL ASSIGNMENTS

Several types of isomerism are possible for azoxy-compounds: the azoxy-compounds–oxadiaziridine valence isomerism, the *cis-trans* isomerism, and the isomerism based on the position of the oxygen atom at the nitrogen atom.

The azoxy-compound–oxadiaziridine isomerism is a special case of the ring–chain valence isomerism in a triad system; the total number of combinations of the CNO atoms has been examined by Greene and Hecht[81]. The asymmetry of the azoxy-group was first demonstrated by Angeli by chemical methods and was later confirmed by physicochemical studies[61–67,72]. Final evidence was provided by the resolution into optical isomers of the *trans*-azoxy-compound (VI, R = Et),[82] formed when the *meso*-azo-compound is oxidised, by the formation of the racemate and the optically active compound (VI, R = Me),[83] and by the asymmetric synthesis of the *cis*-azoxy-compound (VII)[84]:

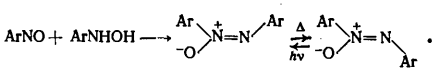
(VI) (VII)

(VIII) (IX) (X)

After the asymmetry of the azoxy-group as well as the erroneous nature of certain reports of the isolation of oxadiaziridines had been firmly demonstrated, much effort was devoted to the synthesis of this cyclic form.

Numerous attempts to detect 2,3-diaryloxadiaziridines (IX, R,R^1 = aryl) proved fruitless. Neither treatment of azoxy-compounds with strong acids[71,72,85], nor their irradiation[71,86–94,97,98], nor the oxidation of *trans*- or *cis*-azoarenes[95–97], nor other reactions[87] yielded the three-membered ring. However, these negative results did not resolve finally the problem of whether or not the migration of oxygen from $N_{(1)}$ to $N_{(2)}$, i.e. the transformation (VIII) → (IX) → (X), is possible. Together with the categorical view that azoxy-arenes are incapable of such transformation[85–87], reports claiming to demonstrate the possibility of the migration of oxygen in individual instances are being constantly published[92–94,99,100]; for a discussion of this question, see Refs.71, 72, 87, and 99.

The attempt to isolate aliphatic-aromatic oxadiaziridines (IX, R = Ph, R^1 = Me, or Et) in the photoisomerisation of the azoxy-compounds (VIII) and (X) was also unsuccessful. However, the fact that the photolysis of compound (VIII) yields compound (X) and that the addition of O_2 does not affect the results of photolysis apparently indicates the intermediate formation of compound (IX).[101] The difficulty of isolating oxadiaziridines with aryl substituents can be understood if account is taken of the lability of the analogous *N*-aryloxaziridines in relation to the *N*-alkyl derivatives[102,103]. However, it is remarkable that the azoxy-compounds (X, R = Ph, R^1 = Me or Et) are not converted into compounds (VIII),[101] while the latter are the main products of the oxidation of the corresponding diazenes[104].



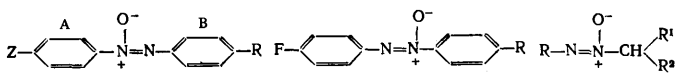
The attempts to synthesise oxadiaziridines with alkyl substituents were more successful. Compounds (IX, R = R^1 = t-Bu,[81,105] n-Bu,[81] or iso-Pr[106]) were obtained by the photolysis of the corresponding azoxy-compounds, into which they are reconverted at the usual temperatures with a half-life of several hours. The oxadiaziridine (IX, R = Me, R^1 = t-Bu) proved to be unstable[81] and *cis*-oxadiaziridine is not formed on photolysis of compound (VII).[81] In a recent study[107] the methods of synthesis and the properties of oxadiaziridines were carefully investigated.

The possibility of the migration of oxygen in the azoxy-sulphones (VIII, R = Ar, R^1 = SO_2Ar^1) via the intermediate formation of an oxadiaziridine has been examined[108,109] (cf.Neiman et al.[86]).

The second type of isomerism of azoxy-compounds, namely *cis*(*E*)–*trans*(*Z*) isomerism, is a consequence of the double bond between the nitrogen atoms. In the acyclic series *cis*-azoxy-compounds are obtained by the photochemical isomerisation of the corresponding *trans*-isomers[70,87–91,93,97–99,106,107,110] or by the oxidation of the *cis*-azo-compounds at reduced temperatures[95,97,106,111,112].

Having analysed the initially seemingly puzzling results of Reisserts's study[113], Muller and coworkers[114,115] showed that the condensation of hydroxylamines with nitroso-compounds in an alkaline medium yields a mixture of *cis*- and *trans*-azoxyarenes, while under neutral conditions only the

trans-isomer is formed:



The validity of the structural assignments for pairs of isomers has been confirmed[116-118], but the influence of the pH of the medium has not so far been satisfactorily explained[119].

Aliphatic *cis*-azoxy-compounds can be obtained in a mixture with the *trans*-isomers by the thermolysis of acid-catalysed opening of the oxadiaziridine ring[106,107]. The observation that the azoxidation of *trans*(*Z*)-azoisopropane yields a certain amount of the *cis*(*E*)-azoxy-derivative together with the *trans*-isomer is also remarkable[107].

Acyclic *cis*-azoxy-compounds are unstable substances which are converted into the *trans*-isomers at the usual or slightly elevated temperatures. The mechanism of this transformation is obscure, but is apparently analogous to the *cis*–*trans* isomerisation of azo-compounds[87,98]. The instability of the *cis*-azoxy-compounds is associated solely with their easy conversion into the *trans*-isomers and not with the loss of functionality. Skeletal azoxy-compounds, in which the *cis*–*trans* transition is impossible, are highly stable[120] and can be obtained by various methods—by oxidising the N = N compound, by the interaction of vicinal nitrogen-containing groups, etc. A reliable method now exists for the identification of *cis*-azoxy-compounds, which made it possible to correct individual erroneous assignments to the *cis*-series[20,101,121]; nevertheless, acyclic *cis*-azoxy-compounds are still being inadequately investigated.

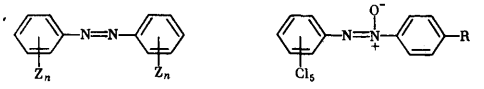
The third type of isomerism—the isomerism based on the position of the nitrogen atom at $N_{(1)}$ or $N_{(2)}$—is a consequence of the asymmetry of azoxy-group. Thus ring A in azoxybenzene (XI, Z = R = H) is deactivated in relation to electrophilic reactions; on the other hand, ring B is readily brominated, nitrated, etc.[61-64,68,69] and the azoxy-group in the distal position acts as an *ortho-para*-directing substituent, while in the proximal position it is *meta*-directing. The transmission of electronic effects via the conjugation chain in compounds (XI, Z = F) and (XII), determined from the chemical shifts of the ^{19}F signal in NMR spectra, takes place with different transmission factors and confirms the anisotropy of the polarisability of the π-system of the azoxy-group[112,122]. In aliphatic compounds (XIII) the group R in the distal position exhibits a tendency towards homolytic elimination[123], while the group RR^1CH in the proximal position can be converted into a functional group, for example, via the corresponding carbanion, and then subjected to classical addition, dehydration, etc. reactions[80]:

(XI) (XII) (XIII)

The need to synthesise substances with specific properties is dictated by the necessity to solve the problem of the location of the oxygen atom in azoxy-compounds. Infrared and ultraviolet spectroscopic methods are hardly useful for this purpose. In the aliphatic series the structural assignments of the *trans*-isomers are based on Freeman's classical study[104] using ^1H NMR; the systematic data of Snyder et al.[124] and also those of Taylor and coworkers[107,119] may prove useful for the *cis*-isomers. In the case of azoxyarenes the chemical shifts of the protons in the *o*- and *p*-positions as well as the signals of the methyl groups in the *p*-positions (for example, in azoxytoluene) are different as a result of the distal and proximal orientations of the aryl substituents[53,95,125]. ^1H NMR using shift reagents is more fruitful[53,54,126-128]. Few mass-spectrometric data are available as yet[125,129-134].

It is now possible to distinguish certain approaches to the solution of the problem: firstly, the search for new specific methods of synthesis which do not require structural proof for each individual compound; secondly, the determination of the general characteristics of the synthetic reactions in order to unify the methods for the separation and identification of the isomers. By combining all these tasks, investigators are developing methods for the simplest and fastest determination of the structure, which is demonstrated by the spectroscopic studies quoted above.

IV. OXIDATION OF AZO- AND HYDRAZO-COMPOUNDS



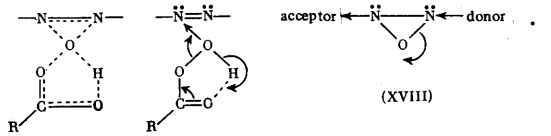
The oxidation of azo-compounds by peracids is preparatively the most convenient method for the introduction of the azoxy-group. Starting with the studies of Angeli[135-139], this procedure has been frequently used by a number of workers (see the relevant reviews of the early studies[68,69,140]). The reaction is equally applicable to aromatic and aliphatic compounds and the oxidation of *cis*- and *trans*-azo-compounds proceeds with retention of the geometry of the N = N bond[63,95,106]. The oxidation of azoarenes has been most fully studied; the investigations by Badger and coworkers[111,141,142] played a major role in explaining the mechanism of this process. It was shown that the oxidation of azobenzenes[111,141] and other azoarenes[142] by perbenzoic acid is a bimolecular reaction, the rate of which increases with electron density at the nitrogen atoms. The introduction of electron-donating substituents increases and that of electron-accepting substituents decreases the rate of oxidation, the rate constant being satisfactorily correlated with the Hammett σ constants[141] (apart from some deviation of the points for *p*-NO_2 and *p*-MeO, the best correlation was achieved with the σ* constants[143]). The oxidation of *cis*-azobenzene is 50–60 times faster than that of the *trans*-isomer and the ratio $\lg(k_{cis}/k_{trans})$ is fairly constant in the range 20–30 °C. Badger and coworkers explained this by the fact that the *trans*-azobenzene molecule is planar and there is a possibility of the delocalisation of electrons over the entire conjugation chain. Owing to the steric interaction of the phenyl groups, in the *cis*-isomer they are displaced from the plane of the azo-group by 56° and the coplanarity of the system is infringed[111] (see also, Webb and Jaffe[95] and Mitchell and Phillips[112]). This decreases the degree of conjugation and the localisation of electron density at the neighbouring nitrogen atoms, which leads as a consequence to an increase of the rate of interaction with the electrophile (the peracid)†. [111]

The influence of two substituents in the *m*- and *p*-positions in azobenzene on the rate of oxidation corresponds to the expectation based on the sum of their σ constants. The oxidation of 2-(2-naphthyl)-1-phenyldiazene yields a mixture of

† The difference between the heats of formation of the *cis*- and *trans*-isomers of azobenzene is approximately 10 kcal,[144] makes an additional contribution to the free energy of activation, and explains the increase of the rate of oxidation of the *cis*-isomer. The corresponding quantity for stilbene is small (3.0 kcal),[145] which is reflected in an insignificant difference between the rates of epoxidation of its *cis*- and *trans*-isomers[146,147].

isomeric azoxyarenes in proportions corresponding to the ratio of the rate constants for the oxidation of the individual azobenzene and 2,2′-azonaphthalene[142].

The conclusion that the oxidation of the N=N bond by peracids has an electrophilic mechanism was supported by experimental findings in a number of subsequent studies. Thus azobenzenes# (XIV) were not oxidised by the peracids usually employed (performic, peracetic, and perbenzoic) and only trifluoroperacetic acid converted them into azoxybenzenes. Similarly, compound (XV) [125] is obtained on treatment with this oxidant, while other oxidants give rise to its formation at a low rate and only at elevated temperatures.



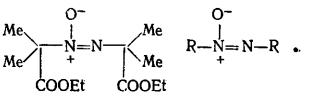
(XIV) (XV)

$Z_n = F_5$[148] (cf.[149]); $Z_n = F_4$[148,149]; $Z_n = Cl_5$[125] (cf.[150]).

Since the oxidising capacity of the peracid varies in parallel with the pK_a of the corresponding acid (the acyloxy-anion of a strong acid is more stable and is therefore satisfactorily eliminated), it follows that, among all the peracids, CF_3COOOH is the strongest oxidant[151]. The need for its employment arises as a consequence of the depletion of the N=N bond in electrons.

All these findings lead logically to the question whether or not the oxidation of azo-compounds involves a spirocyclic transition state (XVI) analogous to that proposed by Bartlett for the oxidation of the C=C bond[151-154] or whether the reaction proceeds via direct transfer of electrophilic oxygen to the nitrogen atom in (XVII) [96,154,155]:

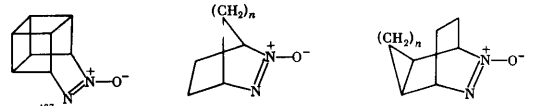
(XVI) (XVII) (XVIII)



The conclusion that the addition to the N=N bond is asymmetric apparently also follows from a study[142] in which it was shown that the oxidation of azo-compounds with different substituents leads to a mixture of two isomers in proportions corresponding to their electron-donating influences. If the transition state has the symmetrical structure (XVI), then its conversion into the final product via (XVIII) leads to a ratio of isomers inversely proportional to their electron-donating influences. This idea was developed in another investigation[96].

The hypothesis of a symmetrical structure of the transition state (XVI) and the consequent possibility of the formation of oxadiaziridines was also disproved by an investigation of the oxidation of *cis*-azoarenes[95]. Among aliphatic compounds, where the stability of oxadiaziridines is sufficiently high for their identification[81,101,107], the low-temperature oxidation of azo-t-butane, for example, yields the azoxy-compound immediately, which was demonstrated by infrared spectroscopy[81] (see also Taylor et al.[107]).

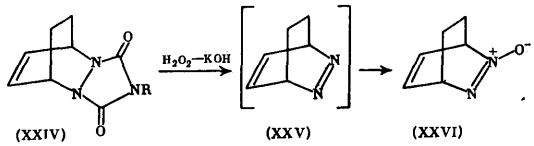
At the present moment the question of the structure of the transition state in the oxidation of the N=N bond by peracids must be regarded as resolved in favour of the asymmetric structure. Comparison of the rate constants for the oxidation of stilbenes[146,147,151] and azobenzenes[111,141] showed that the latter are oxidised at a rate higher by an order of magnitude. This may also constitute a piece of evidence showing that the interaction of the electrophilic oxygen with a free electron pair is preferred to the interaction with the π-electron system. The electrophilic oxidation of different heteroatoms (N, P, and S) has been considered in a number of studies[154,155] and analysis of the available data shows that it is usually faster than epoxidation. In full conformity with this observation, it was found[156,157] that the oxidation of compounds with the C=C–N=N or C=C–C–N=N structural unit leads to azoxidation and not to the formation of epoxides.



The oxidation of the N=N bond by peracids is widely used in practice, particularly for the synthesis of azoxyarenes (see the relevant reviews[61-64,68,69,74-76,140], the examples already quoted, as well as a number of other communications[158-178]).

Azoxidation has been used much less among aliphatic compounds. Thus Aston and Parker[179] were the first to obtain a ditertiary azoxy-compound (XIX) by treating an azo-compound with the H_2O_2 + MeCOOH mixture:

(XIX) (XX)

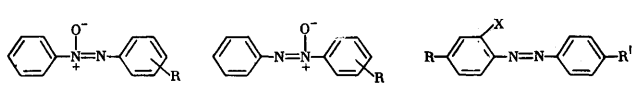


Subsequently, it was shown that this oxidising mixture is sometimes unsuitable for the preparation of diprimary and disecondary azoxy-compounds, since the transformation of the initial azoalkanes into hydrazones, catalysed by acetic acid, is faster than azoxidation. The difficulty was overcome by employing aromatic peracids, for example, perbenzoic acid; a satisfactory yield of the corresponding azoxy-compounds (XX, R=Me, n-Pr, iso-Pr, or $PhCH_2$) was then obtained[3,4]. The fact that the MeCOOH + H_2O_2 mixture is not equivalent to MeCOOOH has been frequently mentioned[151]. The employment of the former creates an excess acidity of the medium owing to the high concentration of MeCOOH at the beginning of the reaction and the slow stage involving equilibration with the peracid. It is therefore not surprising that azoisobutane (XX, R=iso-Bu) (disecondary azoalkane) was oxidised smoothly under the influence of MeCOOOH.[104] Evidently, both peracetic and perbenzoice acids are very suitable for the oxidation of ditertiary and disecondary azoalkanes. The oxidation of diprimary azoalkanes, for example, azobutane and particularly compounds of the type of ω-azotoluene, where the possibility of a prototropic transformation into hydrazones is facilitated, requires the use of aromatic peracids[104,180]. The use of trifluoroperacetic acid may be complicated by secondary reactions of the latter with azoxyalkanes[81,181,182]. Compounds are known in which the structural unit N=N(O) is a partly aromatic system (see, for example, a number of reviews[183-185]). In 1962 Freeman also obtained several Δ^2-pyrazoline *N*-oxides[186], which are isomeric with azoxy-compounds. Nevertheless, the ease with which cyclic azo-compounds are oxidised to skeletal azoxyalkanes (XXI–XXIII) and the high thermal stability of the latter were found to be somewhat surprising.

(XXI)[187] (XXII), $n = 1$[84]; $n = 1$-4[124,188,189] (XXIII), $n = 1, 2$[124,188,189]

Here and throughout the review the *trans*-configuration of the azo- and azoxy-compound is understood unless stipulated otherwise.

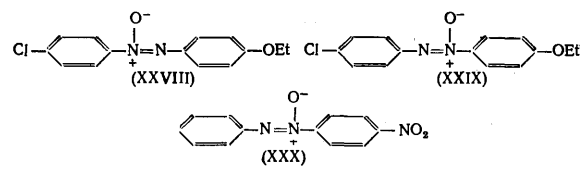
In order to obtain the azoxyalkanes (XXI)–(XXIII) as well as certain others, for example (XXVI), bicyclic and polycyclic triazolinediones were oxidised with hydrogen peroxide in an alkaline medium[120,188–190]:



A similar synthetic procedure, involving the removal of the protective group with simultaneous oxidation, had been used earlier to synthesise 3-alkyldiazirines[191,192], since the latter are not oxidised further to the corresponding azoxy-compounds[193] (see also, Snyder et al.[120]). However, the azo-compound (XXV), which could have been a precursor of compound (XXVI), is extremely unstable (the decomposition period at −78 °C is ≤30 s), while the transformation (XXIV) → (XXVI) proceeds at much higher temperatures (80–100 °C). Evidently, azoxidation in an alkaline medium involves a sequence other than (XXIV) → (XXV) → (XXVI).[120,124]

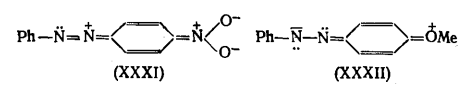
Apart from triazolinediones, other precursors of azo-compounds, for example dialkyl- or diaryl-hydrazines, can be oxidised. *sym*-Disubstituted hydrazines are oxidised even on storage in air; various oxidants, including H_2O_2, are used to convert them into azo-compounds[194–196]. It is therefore natural that azoxyarenes are obtained by the single-stage oxidation of hydrazobenzenes with an excess of a peracid[197,198]. It is of interest that, for a 1:1 reactant ratio, an azoxy-derivative may be formed together with the azo-compound[198], apparently because the rates of oxidation of the NH–NH and N=N groups are comparable.

A serious obstacle to a more vigorous synthetic employment of the oxidation of azo-compounds or their precursors is the formation of isomers with different positions of the *N*-oxide oxygen. As early as 1911, Angeli concluded that the oxidation of 3- and 4-nitro-azobenzenes does not yield individual substances[136,137]; this conclusion was later confirmed[99,171–173,197].



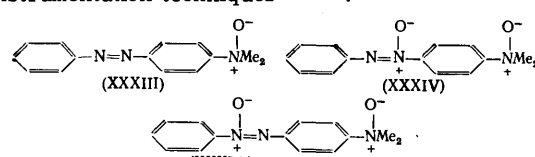
Two reviews[68,69], giving a systematic account of early data, and numerous reports by Italian chemists[136–139,158–173] quote tens of examples of the formation of a mixture of azoxyarenes in the oxidation of azobenzenes by peracids, but the lack of a quantitative estimation of the isomeric composition greatly reduces the value of these studies. Kinetic measurements of the rates of oxidation of azo-compounds seemingly suggested the possibility of estimating the ratios of the isomers from the σ constants of the substituents in azobenzenes[141,142] (see also, Mitsuhashi[96]). However, Risaliti[172,173] found that, although electron-accepting groups do direct the oxidation preferentially to the distal position, there is no linear relation between the ratios of the isomers and the σ constants:

R = *m*- and *p*-NO_2, SO_2Ar, NHAc, F, Cl, or Br.



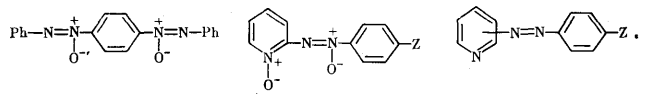
The picture is more complex for disubstituted azobenzenes. Thus it has been shown[54,199,200] that, when compounds (XXVII, X = H) with substituents R and R^1 = H, Me, MeO, COOR, or Cl in different combinations, are oxidised, the standard ratio of the isomeric azoxy-benzenes (1:1) is hardly altered. The explanation of these data requires the use of more detailed features of the azo-group and leads to a fairly complex picture. Firstly, the authors of the above reports[54,199,200] worked with the H_2O_2–MeCOOH–(H_2SO_4) § mixture, while the kinetic experiments were performed with perbenzoic acid[96,141,142] and Badger[111] emphasised specially that perbenzoic acid did not contain even an admixture of benzoic acid. Evidently, in the presence of acids stronger than acyl hydroperoxides, the nitrogen atom of the asymmetrically substituted azoarenes, which should have been preferentially azoxidised, is protonated (and hence blocked). The sum of these effects leads to an average ratio of the isomers. This hypothesis is supported by the finding that, in the presence of the chelate dipivaloylmethanemolybdenum(VI), t-butyl hydroperoxide oxidises 4-methoxyazobenzene exclusively to a single isomer[133]; the mechanism of the action of this oxidant is analogous to the mechanism of electrophilic oxidation by peracids, but the reaction is not complicated by protonation. At the same time peracetic and perbenzoic acids lead to a mixture of azoxy-compounds.

Other observations which can be interpreted from these standpoints have also been made. Thus the oxidation of 4-chloro-4′-methoxyazobenzene with hydrogen peroxide in 100% acetic acid yields compound (XXVIII), while the isomer (XXIX) is formed in 80% acetic acid[201]:



The oxidation of 4-nitroazobenzene with 30% H_2O_2 in acetic acid similarly gives a mixture in which the α-isomer (in Angeli's terminology) of compound (XXX) predominates, while anhydrous hydrogen peroxide in acetic acid gives preferentially the β-isomer[99].

Secondly, the presence of groups similar to NO_2 and MeO in the *p*-position leads to an appreciable contribution of the boundary structures (XXXI) and (XXXII) to the ground state of substituted azobenzene. Evidently, the nitro-group deactivates both nitrogen atoms, but the distal atom is deactivated much less; the methoxy-group activates both positions, but the distal position is activated to a much greater extent. Accordingly, in the azoxidation of *p*-nitro- and *p*-methoxy-derivatives (XXXI) and (XXXII) the distal isomer predominates in both cases[133]:

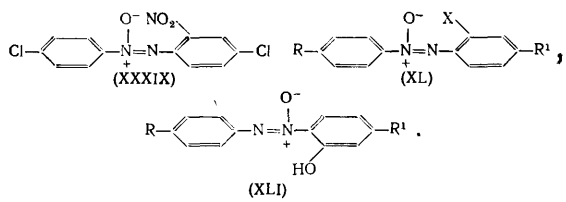


The difficulty of taking into account all these factors is effectively illustrated by the oxidation of *p*-dimethylamino-azobenzene. Starting with the work of Angeli in 1915, who attributed structures (XXXIII) and (XXXIV) to the monoxidation and dioxidation products[68,202], there have been periodic attempts to explain the course of these reactions in terms of the new advances in the electronic theory of structure and instrumentation techniques[203–207]:

§ The mixture H_2O_2–MeCOOH to which small amounts of sulphuric acid have been added is sometimes used in the synthesis of azoxyarenes without isolating peracetic acid by distillation.

Whereas the structure of the primary oxidation products (XXXIII) gives rise to no doubts so far, the views of investigators diverged as regards the dioxidation product, which can have structure (XXXIV) [68,202,205,207] or (XXXV) [204,206].

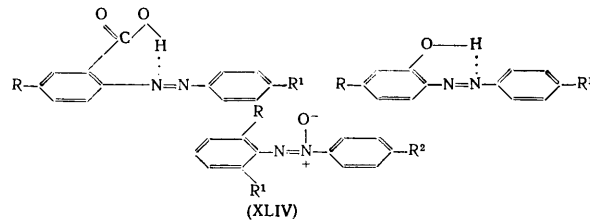
The divergence of views concerning the directing effect of the dimethylamine oxide group extends also to other instances. The azoxy-group is an electronic analogue of the $Me_2\overset{+}{N}\overline{O}$ group and, since Angeli attributed structure (XXXIV) to the product of the dioxidation of dimethylaminoazobenzene, he defended formula (XXXVI) also for the product of the dioxidation of bisazobenzene[208,209]:



(XXXVI) (XXXVII) (XXXVIII)

According to other investigators, the dimethylamine oxide group directs oxidation to the distal position. Therefore its analogues, for example, the pyridine oxide group, act similarly and azoarenes (XXXVIII, Z = H [210-214] or NO_2 [215]), in which the nitrogen atom in the pyridine ring is oxidised first, give rise to the azoxy-derivatives (XXXVII).

The competitive involvement of nitrogen atoms in the oxidation of the compound (XXXVIII, Z = NMe_2) by peracids is of interest. The nitrogen of the NMe_2 is oxidised first, being followed by the nitrogen of the pyridine ring, while the N = N bond is unaffected[216]. Certain examples of competitive oxidation processes have been examined in a review[69].

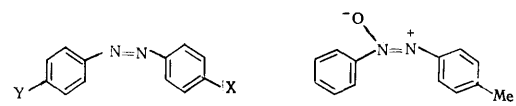


An important feature of the oxidation reactions of azoarenes is the marked influence of *ortho*-substitution on the position of the *N*-oxide oxygen atom. The influence of *ortho*-substitution (OH, COOMe, OCOPh) on the course of the oxidation of azoarenes was first investigated by Bigiavi and coworkers[159-163], but they did not obtain an unambiguous result. Other investigations were more decisive in this respect[54,197,217,218]. It was shown, for example, that the azoxybenzenes (XXXIX), (XL), and (XLI) are formed as the sole products in the oxidation of the corresponding azobenzenes:

(XXXIX) (XL)

(XLI)

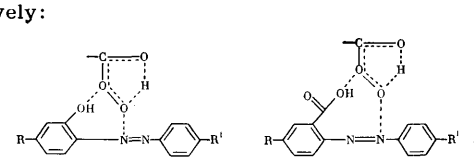
These seemingly relatively incompatible results were explained and developed by Berwick and Rondeau[54]. They found that, in the presence of the *ortho*-substituents X = Me, MeO, Cl, COOMe, or COOH in one of the aryl groups, azobenzenes give rise preferentially to isomer (XL) with the distal location of the oxygen atom relative to this group regardless of the nature of R and R^1. The selectivity (the quantity defined as the ratio of the isomers formed with the distal and proximal location of the oxygen atom) varies for different X and, although the effective volume of the COOMe group is greater than that of COOH, the process selectivity is greater in the presence of COOH than in the case of COOMe. The influence of the *o*-hydroxy-group, which caused a complete rearrangement of the position of the oxygen atom in favour of the proximal isomer (XLI) is still more surprising. All these findings were explained by Berwick and Rondeau[54] (see also Dziomko and Dunaevskaya[217]) by the fact that the influence of the *ortho*-substituent is in general related to the shielding of the neighbouring nitrogen atom. On the other hand, the introduction of specific substituents (COOH, HO), capable of forming a hydrogen bond with the N = N group, increases the selectivity of the β-oxidation (for COOH) or, on the contrary, leads to a complete rearrangement (for the OH group) ¶:



(XLIV)

Protonation of the distal nitrogen atom (and hence its deactivation in relation to oxidation) creates an unprecedented situation where the group in the *ortho*-position directs oxidation to the proximal position[54,217]. It is therefore natural that the oxidation of 2-alkyl-2'-hydroxyazoarenes yields exclusively a single isomer[217].

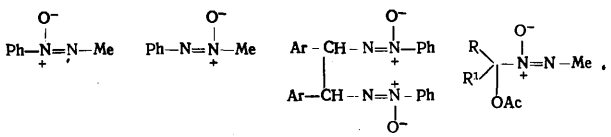
In the presence of two substituents in the 2- and 6-positions in the phenyl group, their directing effect is greatly enhanced and the oxidation of such azo-compounds by peracids[167,222] or the CrO_3–HNO_3 mixture[223,224] leads to only the distal isomer (XLIV).



In the oxidation of the *cis*-azoarene (XLV, Y = H, X = Me) it was possible to isolate only one isomer (XLVI). However, it was shown that both isomers are formed in reality, but the azoxy-compound with the proximal location of oxygen in relation to the tolyl groups is converted much more readily into the corresponding *trans*-isomer and compound (XLVI) and it was therefore not possible to identify it[95]:

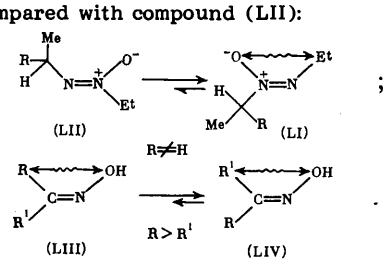
(XLV) (XLVI)

In the oxidation of compounds (XLV, Y = F, X = Me, MeO, or CF_3) one isomer was also obtained; it was postulated that the oxygen atom is located in the proximal position relative to the fluorine-containing aryl group[112]. In the case of *cis*-azoarenes (XLV, Y = H, X = Cl or Br) only one *cis*-azoxy-compound was also isolated, but its structure was not determined[95].



¶ Another explanation of the directing effect of hydroxyl-containing substituents can be the acceleration of the azoxidation of the N = N bond in the proximal (for the OH group) or distal (for COOH) position as a result of the additional stabilisation of the transition complex (XLII) or (XLIII) respectively:

(XLII) (XLIII)

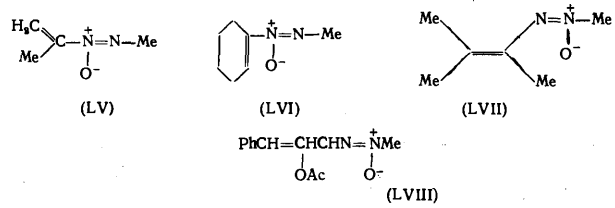


The formation of a hydrogen bond facilitates the elimination of the anion. Examples of the acceleration of the reactions by neighbouring groups as well as the consequence of hydrogen bonding in the epoxidation of allyl alcohol, *o*-allyl-phenols, etc. are well known[219-221].

The problem of the location of oxygen in the oxidation of aliphatic-aromatic azo-compounds and asymmetric azoalkanes by peracids has not been studied systematically and only a few observations have been made. The oxidation of methylphenyldiazene yields predominantly the azoxy-compound (XLVII) with a small admixture of the isomer (XLVIII)†.[104] Similarly the azoxy-compound (XLIX) was obtained in the oxidation of the bisazo-compound[121] and the location of oxygen agrees with Freeman's data[104], already quoted, concerning the preferential formation of compound (XLVII) compared with compound (XLVIII):

(XLVII) (XLVIII) (XLIX) (L)

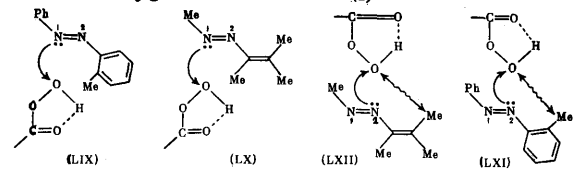
The oxidation of α-acetoxyazoalkanes gives rise to azoxy-compounds [L, $R = R^1 = Me$, $R, R^1 = (CH_2)_5$],[226] although the oxygen atom in the natural products macrozamin[2-5] and cycasin[9,12,13,21], containing methylazoxymethanol as the aglycone, is located in the proximal position relative to the methyl group and not in the distal position as in compounds (XLVII) and (L). In this connection one should recall that irradiation at 254 nm of the azoxyalkanes (LI) or (LII) in hexane leads to a steady-state mixture of two isomers in the proportions (LI) : (LII) = 1.28,[227] which reflects the weak steric interactions of the alkyl group with the oxygen atom in compound (LI) compared with compound (LII):



(LII) (LI) (LIII) (LIV)

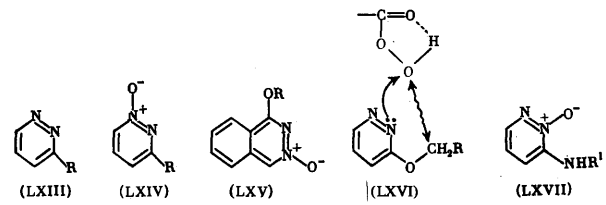
Similarly the Z-configuration (LIV) is preferred in the case of the ketoximes (LIII) and (LIV).[228]

The question of the stability of the isomeric azoxyalkanes for asymmetric substitution at the $N_{(1)}$ and $N_{(2)}$ atoms, arising in the photochemical reactions and on opening of the oxadiaziridine ring, has been discussed[107].



The natural antibiotics and carcinogens elaiomycin[5,6] and LL-BH872α [18-20] are α,β-unsaturated azoxy-compounds and this is why several studies have been devoted to the oxidation of model compounds with the structural elements N=N–C=C and N=N–C–C=C. The corresponding azoxy-compounds (LV)–(LVII) [156] and (LVIII) [157] were obtained, but the regioselectivity of the oxidation process was not discussed by the authors:

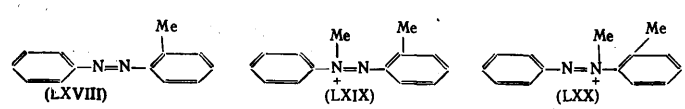
(LV) (LVI) (LVII)



(LVIII)

All these data on the oxidation of aliphatic and aliphatic-aromatic azo-compounds do not throw light on the question which factors determine the attack by oxygen of a particular nitrogen atom in the N=N bond, namely the inductive, resonance, or steric effects of the substituents. Nevertheless, many experimental data concerning the isomeric composition of azoxy-compounds can apparently be explained on the hypothesis that the location of oxygen in azoxidation is determined by the kinetic parameters of the irreversible reaction and is strongly subject to the steric effect of the groups located at the N=N bond. Distal groups have a weak influence in the approach of electrophilic oxygen [see compounds (LIX) and (LX)], while the influence of the proximal group is more significant [see compounds (LXI) and (LXII)] and in the oxidation reactions of the azo-compounds listed below oxygen is located at $N_{(1)}$:

(LIX) (LX) (LXII) (LXI)



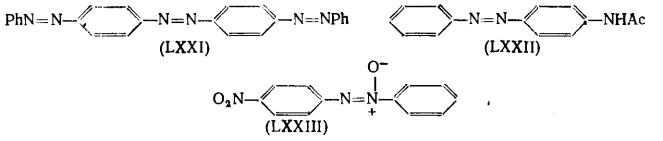
Data for the oxidation of 3-substituted pyridazines (LXIII) [185,229] confirm the marked influence of the substituent on the course of oxidation. For example, when R = Me, a mixture of *N*-1- and *N*-2-oxides is obtained[185,229,230], while for R = MeO, EtO, PrO, or $C_6H_5CH_2O$,[185,229-233], the products are only the *N*-1-oxide (LXIV). The oxidation of 1-alkoxyphthalazines yields the *N*-3-oxides (LXV) [229,234,235].

(LXIII) (LXIV) (LXV) (LXVI) (LXVII)

The structure (LXVI) is not formed [cf. (LXI) and (LXII) [54,197,217]]. The 2-oxide (LXVII) is formed exclusively from the compounds (LXIII, R = NH_2 [185,229,236-239] or NHR [1,185,229,240]), and the analogy with the proximal directing effect of the *o*-hydroxy-group in the oxidation of azoarenes[54,217] is evident.

It is of interest to compare the azoxidation reaction with other processes involving electrophilic addition to the N=N bond. Thus Fergusson[241] investigated the quaternisation of azoarenes by methyl fluorosulphonate and found that the azoarene (LXVIII) gives rise to a mixture of isomers (LXIX) and (LXX). The distal isomer is known to predominate appreciably in azoxidation[54].

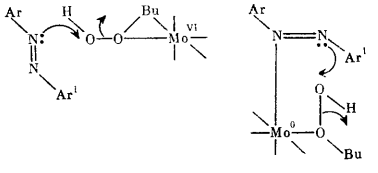
(LXVIII) (LXIX) (LXX)



This can be explained by the fact that the quaternisation is a reversible reaction and leads to a product ratio determined by process thermodynamics, while azoxidation is irreversible and the final isomer ratio reflects the results of a kinetically controlled reaction. A comparative study of the steric factors in the oxidation and quaternisation of pyridines has been described by Foucart et al.[242].

The irreversible nature of the azoxidation reaction has been confirmed experimentally. For example, the oxidation of methylphenyldiazene yields the isomer (XLVII),[104] which is converted by photolysis into the isomer (XLVIII).[101] Since

† We may note incidentially that the oxidation of phenylazoformamide yields $PhN(O)=NCONH_2$,[48,225], i.e. oxygen is also located at the nitrogen atom of the aryl group.

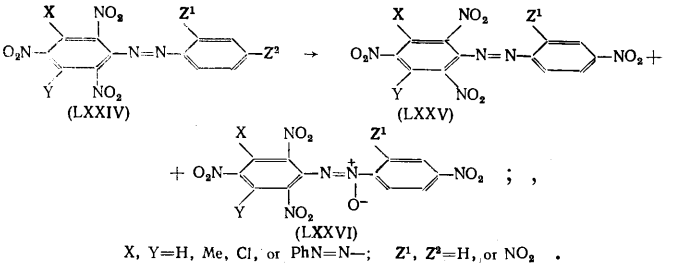


equilibrium conditions are apparently obtained on irradiation of azoxy-compounds and substance (XLVIII) cannot be converted into (XLVII),[101] the isomer (XLVIII) is evidently thermodynamically more stable than the isomer (XLVII).

Apart from the difficulty of identifying the structural isomers, the peracid method suffers from yet another disadvantage, associated with the effect of the peracid on other functional groups. Thus the oxidation of 4-aminoazobenzene involves primarily the amino-group and the product is trisazobenzene (LXXI).[243] The latter can be oxidised further, giving rise to monoazoxybisazobenzene and trisazoxybenzene[243,244]:

Protection of the amino-group by the acyl group in compound (LXXII) favours the "normal" oxidation of the N = N bond with formation of the proximal and distal isomers[243], but in this case nitroazoxyarene (LXXIII) is formed as a side product owing to the hydrolysis of the amide linkage[169,170,245]. Several examples of secondary reactions in azoxidation were examined above and are dealt with more fully in Bigelow's review[69].

Apart from peracids, other reagents have also been used occasionally for the azoxidation of the N = N bond. A remarkable variant of the peracid method is oxidation of azo-compounds by alkyl hydroperoxides in the presence of transition metal complexes[133]. Coordination to transition metal complexes causes the polarisation of the O—O bond and the peroxides, which are usually homolysed at this bond, become sources of electrophilic oxygen[153,246-249]. The complexes $Mo^{VI}[MoO_2(dipivaloylmethane)_2]$ or $Mo^0[Mo(CO)_6]$ with t-butyl hydroperoxide oxidise substituted azobenzene to azoxy-compounds, while vanadium(IV), manganese(III), and cobalt(II) complexes, which promote the homolytic decomposition of t-BuOOH, proved to be inert[133] (for the principles of the selection of the transition metal, see Gould et al.[249]). Two different types of transition states, taking into account the selectivity in the location of oxygen at the N = N bond for the molybdenum(VI) complex and the statistical distribution of the isomers for zero-valent molybdenum, have been proposed:

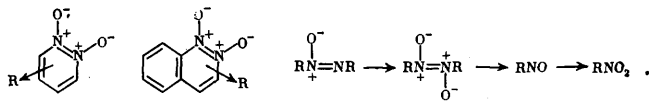


The involvement of transition metals and mild reaction conditions constitute a similarity between these processes and those in living organisms, and, together with the oxidation of diacylhydrazines to azoxyalkanes, by-passing the azo-compound stage[120,124], and the fixation of oxygen by hydrazyl radicals[250], demonstrates the multiplicity of pathways leading to the formation of the N = N(O) group under conditions close to those in biological systems. A number of azoxy-compounds[2-21] and those formed in the microbiological or photochemical oxidation of amines[251-253] can be obtained not only by the classical reaction between RNO and RNHOH, but also by the direct microsomatic oxidation of azo- and hydrazo-groups by *N*-oxidase. The detection of the familiar carcinogens and mutagens azoxymethane and methylazoxymethanol in the product of the metabolism of 1,2-dimethylhydrazine evidently demonstrates the validity of this point of view[254,255]. The general problems of the biogenetic relations in the series of nitrogen-containing functional groups have been examined in a number of studies[17,22].

The azoxidation of the N = N bond in the nitration of azobenzenes was first reported by Petriew[256] and this observation was confirmed by subsequent studies[223,224,257-261]. The nitration process is normally accompanied by the formation of the *p*-isomer, but if both *p*-positions are blocked, as in 4,4'-dichloro-[257,260] or 4,4'-dinitro-azobenzene[259], then, together with nitration products, the *o*-azoxy-derivative is formed.

The formation of 2,4,3'-trinitroazoxybenzene in the nitration of azobenzene[258] has also been reported (cf. Sharnin and Buzykin[223]; for the review of early studies on the nitration of azo- and azoxy-arenes, see, Werner and Stiasny[259]). Among aliphatic compounds, oxidation by nitric acid has been used to synthesise azoxycyclohexane from azocyclohexane[3], but a negative result was obtained for 1-azoheptane and 2-azopropane[4]. When the menthylhydrazone of menthone was treated with nitric acid, the product was azoxymethane[262].

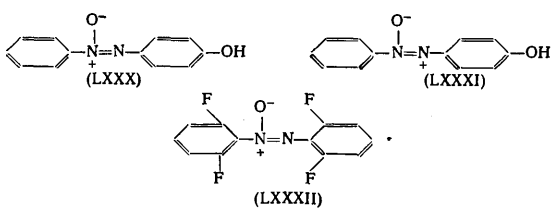
A detailed study showed[223,224] that the nitration of azoarenes (LXXIV) by various reagents (98% HNO_3, HNO_3–H_2SO_4, and HNO_3–CrO_3) leads to mono- and dinitration products (LXXV) and also to azoxy-derivatives (LXXVI):



X, Y=H, Me, Cl, or PhN=N–; Z^1, Z^2=H, or NO_2 .

Sharnin and Buzykin[223,224] observed several interesting features: (1) the azoxy-compounds (LXXVI), with a distal location of oxygen relative to the picryl group, are formed in oxidation processes; (2) the azo-compounds (LXXIV, $Z^1 = NO_2$, Z^2 = H or NO_2) do not give rise to azoxy-compounds at all or produce them with much difficulty under the influence of the most powerful oxidant ($CrO_3 + HNO_3$); (3) the accumulation of electronegative substituents in the picryl ring of compounds (LXXIV, X, Y = Cl) hinders the formation of azoxy-compounds.

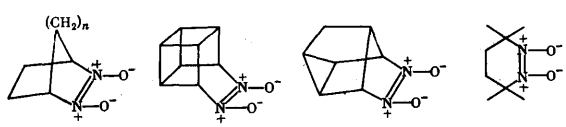
Evidently, these features are the same as those in the electrophilic oxidation of azoarenes by peracids, in particular the pronounced directing effect of the *ortho*-substituent, the retardation of oxidation in the presence of 2,2'-substituents, the distal directing effect of electron-accepting groups at the N = N bond, and the need for a more "electrophilic" oxidant on accumulation of electronegative substituents at the N = N bond. All this apparently constitutes evidence supporting an electrophilic mechanism of oxygen transfer to the azo-group.



The formation of azoxy-compounds is observed in the oxidation of azo- and hydrazo-arenes by chromium trioxide in MeCOOH,[256] dimethyl sulphoxide at 110 °C,[198] ozone,[263] hydrogen peroxide[188-190,264,265] (cf. Singh[182]), and a mixture of hydrogen peroxide and sodium tungstate[266]. Studies have been published on the use of polymers containing peracid groups for the oxidation of azobenzene[267,268]. Such polymers are obtained, for example, by modifying cross-linked structures with polyacrylic acid.

The oxidation of azo-compounds results in the incorporation of one oxygen atom. It is of interest to attempt to introduce also a second atom and thus form azo-dioxy-derivatives. Among heteroaromatic compounds, such cases have been described. For example, when pyridazines[269], cinnolines[270-274], and benzocinnolines[274] are acted upon by peracids under conditions more severe than those in the usual azoxidation, the dioxides (LXXVII) and (LXXVIII) are obtained together with azoxy-derivatives. The stepwise course of the process was demonstrated by the conversion of the monoxides into the dioxides under the reaction conditions[269-274]:

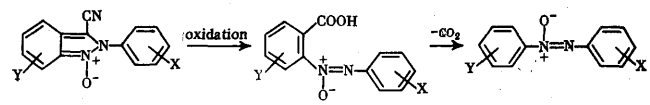
(LXXVII) (LXXVIII) (LXXIX)



In the case of linear azoxy-compounds it is difficult to detect the individual stages, since on monomerisation and subsequent oxidation of the diazene dioxides (LXXIX) formed, nitro-compounds are produced[202]. Thus compound (LXXX) is oxidised by hydrogen peroxide to nitrophenol[158], which does not, however, demonstrate the validity of the mechanism described and can be explained by the primary effect of the oxidant on the hydroxy-group and subsequent decomposition of the quinonoid intermediate at the nitrogen–nitrogen bond:

(LXXX) (LXXXI) (LXXXII)

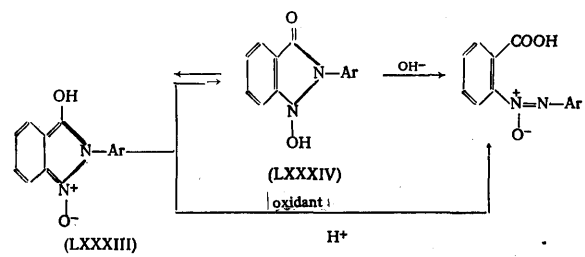
In conformity with this hypothesis, it has been found that, in contrast to compound (LXXX), azoxyphenol (LXXXI) is not oxidised by H_2O_2, $KMnO_4$, or HNO_2, since the azoxy-group deactivates the neighbouring aryl group[158,275,276]. On the other hand, indirect data show that the sequence azoxy-compound → azodioxy-compound → nitroso-compound → nitro-compound is possible. Thus the azoxyarenes (LXXXII) [277] and (LXXVI) (see above) are exceptionally resistant to the action of the most vigorous oxidants (CF_3COOOH, HNO_3–CrO_3), since the non-quaternised nitrogen atom is blocked by the *ortho*-substituents and its basicity is reduced due to the electron-accepting effect.



It has been shown in a recent series of studies that diazene dioxides can be obtained by the direct oxidation of the corresponding azoxy- or azo-compounds by hydrogen peroxide, *m*-chloroperbenzoic acid[189,266], and trifluoroperacetic acid[182].

An attempt has been made to explain why the usual monomerisation of nitroso-dimers does not occur in the case of highly strained rings[189,266].

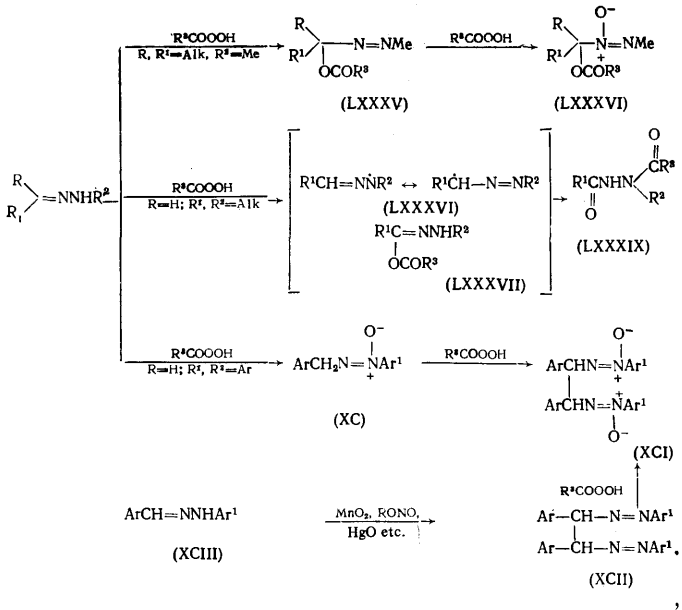
V. OXIDATION OF INDAZOLES



An elegant method of synthesis of azoxyarenes was developed by Behr[278,279]:

Y = H, X = 4-Br, 4-EtO, or 3-NO_2; X = H, Y = 4-Br, 4-EtO, or 3-NO_2.

The comparatively readily available 2-aryl-3-cyanoindazole 1-*N*-oxides, obtained from the corresponding *ortho*-substituted nitrobenzaldehydes (or nitriles of *o*-nitro-mandeleic acids) and arylamines (see the reviews of methods of their synthesis[280,281]) are subjected to oxidative cleavage. Starting with well known compounds, in which the positions of substituents have been determined and none of the subsequent stages of the synthesis entail the loss of asymmetry by the N=N(O) fragment, it is possible to obtain specific isomers of substituted azoxybenzenes. Behr's method played an important role in its time in the solution of this confused problem. We may note that the structural assignments of pairs of isomers of *p*-bromo- and *p*-ethoxy-substituted azoxybenzenes made by this method agree with those of Angeli.

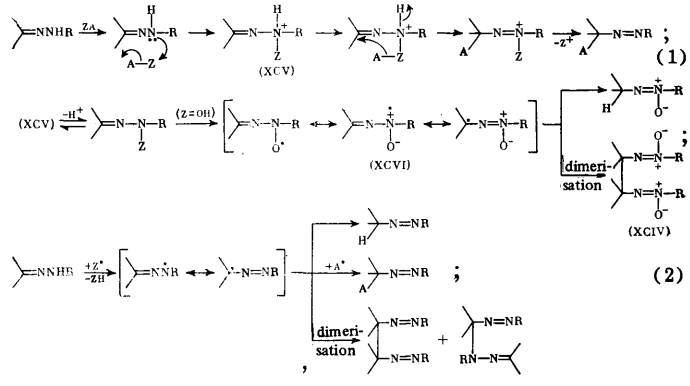


In analysing Behr's procedure for the synthesis of azoxybenzenes, one may conclude that the protection of the 3-position in indazole by the cyano-group is unnecessary since this group undergoes oxidative decarboxylation with formation of 1-hydroxyindazol-3-one (LXXXIV), which is tautomeric with 3-hydroxyindazole 1-*N*-oxide (LXXXIII). Subsequent cleavage of the tautomeric pair in an acid medium [via compound (LXXXIII)] involves the decomposition of the hemiaminal linkage and the nitrone–azoxy-migration of the double bond[186]. The oxidative hydrolysis of the N–CO bond in the intermediate (LXXXIV) proceeds also in an alkaline medium, like the oxidation of compound (XXIV):

(LXXXIII) (LXXXIV) H+

VI. OXIDATION OF HYDRAZONES

Hydrazones are isomeric with azo-compounds, but their oxidation with peracids proceeds quite differently. Typical instances are presented schematically below:



The simplest case is that of the oxidation of alkylhydrazones of ketones (acetone, cyclohexanone).[157,226]. For the ratio peracid : hydrazone = 1 : 1, a mixture of the azo-compound (LXXXV) and azoxy-compound (LXXXVI) is formed; for the reactant ratio 2 : 1, the only product is the azoxy-compound, but in a low yield (17%). The oxidation of alkylhydrazones of α,β-unsaturated ketones (cyclohexenone, cyclopentenone) with one equivalent of a peracid confirms that the primary products are acyloxyazoalkanes[157].

The oxidation of alkylhydrazones of aliphatic aldehydes does not lead to azoxy-compounds, the products being diacylhydrazines (LXXXIX).[226] Different mechanisms, involving intermediate acyloxyhydrazones (LXXXVII) or radicals (LXXXVIII), can be put forward. The oxidation of the methylhydrazone of cinnamaldehyde yields the azoxy-compound (LVIII).[157]

The oxidation of alkyl(aryl)hydrazones of aromatic aldehydes by peracids has been frequently studied[282-289]. Different structures have been attributed to the high-melting products formed as a result of the reaction and, whereas the general view inclined towards the *cis*-azoxy-compounds (XC),[154,288,289] Woodward and Wintner[121] showed that they are in reality bisazoxy-compounds (XCI). In the oxidation of the *p*-bromophenylhydrazone of *p*-chlorobenzaldehyde, they succeeded in isolating the intermediate (XC), which gave rise to a dimeric azoxy-compound (XCI) on further oxidation; thus the primary oxidation product is an azoxy- and not an azo-compound, in contrast to the aliphatic analogue[121]. Compound (XC) had been isolated earlier, but its reactions were incorrectly interpreted (see, for example, Brough et al.[288]). It is also known that the oxidation of the phenylhydrazones of aromatic aldehydes by HgO, MnO_2, $C_5H_{11}ONO$, etc. yields the bisazo-compound (XCII) (together with other products) as a result of the dimerisation of a centred radical[290-293]. The oxidation of this dimer by perbenzoic acid leads to the formation of the bisazoxy-compound (XCI), identical with the product of the oxidation of a hydrazone or the monoazoxy-compound (XC).[121]

The interaction of peracids with an NH group can be interpreted in two ways—from the standpoint of the electrophilic addition of oxygen to the nitrogen or the radical abstraction of hydrogen from the NH group. In the oxidation of the aryl hydrazones of aromatic aldehydes (XCIII) Lynch and Pausacker[286] found a direct relation between the electron-donating properties of the substituent in the aromatic ring Ar^1, linked to the extreme nitrogen atom, and a second-order reaction rate constant, which is consistent with an electrophilic oxidation mechanism (see also Pausacker[283]). However Gillis and LaMontagne[157] defended the radical mechanism involving the primary capture of the NH proton (see also Woodward and Wintner[121,292]).

Accordingly, it is possible to put forward two mechanisms# involving as the primary step the electrophilic addition of a peracid (1) or the radical capture of a hydrogen atom (2) (Z = OH, A = OCOR):

Z = OH, $Pb(OAc)_3$, OH, Hal, RC(=O)O, or NO_2;
A = OCR, OAc, OH, Hal, RCOO, or NO_2.

Mechanism (1), involving the primary (electrophilic) addition of the oxidant to the nitrogen atom, was put forward by Busch and Dietz[294] and still remains attractive. In the specific instance of oxidation by peracids this possibility is supported by the following findings: (1) in the oxidation of a secondary nitrogen atom, for example, in diarylamines, the product is a nitroxy-radical[295-298]; (2) the direct dependence of the rate of reaction of peracids on the electron density at the NH group in compound (XCIII), discovered by Lynch and Pausacker[286], is consistent with the slow stage of the bimolecular reaction (1); (3) the dimerisation of the C-centred radical, containing the complete N = N(O) functional group, leads to the bisazoxy-compound (XCIV), since the isolation of an azoxyazo-product of the monoxidation of the N = N bond in the bisazo-compound (XCII) has not been reported[121,282-289]; (4) the oxidation of the *p*-bromophenylhydrazone of *p*-chlorobenzaldehyde leads to 4,4′-dibromoazoxybenzene as a side product[121], which is apparently a dimer of the fragment obtained in the homolysis of the N = N bond in the intermediate (XCV) or (XCVI).

We may note that the oxidation of the phenyl hydrazones of 2- and 4-formylpyridines with perbenzoic acid involves the pyridine nitrogen atom[299]. The fundamental mechanisms of

Mechanisms (1) and (2) represent in a general form the mechanisms of the oxidation of hydrazones by peracids, lead tetra-acetate, hydrogen peroxide, halogens, diacyl peroxides, and nitrogen tetroxide.

the oxidation of hydrazones by various reagents have been examined in detail in a monograph[300].

---oOo---

Thus the methods of synthesis of azoxy-compounds are simple and varied, which is one of the reasons for the great interest in these substances. Nevertheless, both in the series of methods considered here and among other possibilities, the oxidation of azo-compounds is used most frequently as the method of synthesis of azoxy-derivatives. The availability of the initial azo-compounds and the simplicity of the isolation of the final product make the method of practical importance. This is indicated, for example, by numerous patent data on the synthesis of azoxyarenes used as liquid crystals or forming part of such compositions.

Since this review was written, fairly numerous studies on alkoxy-compounds, mainly devoted to the practical applications of liquid crystals and to the study of their physicochemical properties, have been published. The carcinogenic properties of azoxymethane [301-308] and the influence of various substances on the inhibition of carcinogenesis[309-314] are being vigorously investigated. There is much similarity in the action of 1,2-dimethylhydrazine and azoxymethane, but the mechanism of the oxidative transformation of this pair of compounds *in vivo* is obscure; methylazoxymethanol has been detected in the products of their metabolism.

The physicochemical properties of azoxy-compounds are being vigorously investigated. The ^1H and ^{19}F NMR spectra of polyfluoroazoxybenzenes[315], the ^1H NMR spectra of partly deuterated azoxyanisoles[316], the ^{14}N and ^{15}N spectra of various compounds containing the N(O)=N fragment[317,318], and the ^{14}N NQR spectra of *p*-azoxyanisole and related compounds[319] have been studied. Calculations by the CNDO method of the spin–spin coupling constants for compounds containing single and double nitrogen–nitrogen bonds agree satisfactorily with experiment[320]. The ultraviolet spectra of azoxybenzenes[317,321] as well as the mass spectra of azoxybenzenes[321], azoxycyanides ArN(O)=NCN,[322] tetranitroazoxytoluenes[323], and compounds of the type PhN(O)=NOR, where R = alkyl or $CH_2C(OH)R^1R^2$, [324-326] have been examined.

The crystal and molecular structures of deuterated azoxyphenetole[327], *cis*-2-cyclohexyl-1-methyl- and *cis*-1-cyclohexyl-2-methyl-diazene 1-oxides[328], as well as the structure of complexes of azoxybenzenes with chloranil, 2,3-dichloro-5,6-dicyano-*p*-benzoquinone, etc.[329-331] have been studied. Calculations have been made by the CNDO method of the electron densities, dipole moments, and overall energies of various conformations of *p*-azoxyanisole[332]. The thermo- and photochemical transformations of azoxyalkanes and related oxadiaziridines have been examined[333-335]. New data have been obtained on the photochemical transformation of azoxybenzenes into 2-hydroxyazobenzenes, demonstrating the involvement of the diazonium ion in this reaction[321,336,337]. The radical decomposition of *p*-alkoxyazoxybenzenes in the solid phase under the influence of X-rays has been studied[338].

Oxidation with H_2O_2 + AcOH mixtures has been used for the synthesis of azoxyarenes having the general formula $4\text{-}RC_6H_4N(O)=NC_6H_4R^1\text{-}4$ (R and R^1 are alkyl or alkoxy-groups containing between 1 and 10 carbon atoms), which are widely used as liquid crystals, phases in GLC, dye sensitisers, etc.[321,339-344]. The addition of acid anhydrides, particularly boron trioxide, improves the process[345]. The direct oxidation of mixtures of ArNO and $ArNH_2$ to azoxyarenes, by-passing the stage involving the isolation of the corresponding azo-compounds, has been described in a patent[346]. In all these cases a mixture of isomers was usually obtained. Permaleic acid or the $H_2O_2 + CF_3COOH$ mixture is used for the synthesis of asymmetric azoxy-compounds of the type $4\text{-}RC_6H_4N(O)=NR^1$ (XCVIII), where R^1 = COOMe, CN, or C(O)Ph, which contain electron-accepting groups[347-349]. The azoxy-cyanides (XCVIII, R^1 = CN, R = alkyl, halogen, or NO_2) are of interest because of their microbiological activity[347-350].

It has been shown[351] that the one-electron reduction of $PhN(O)=NC_6H_4NO_2\text{-}4$ by potassium cyclo-octatetraenide in tetrahydrofuran does not involve the migration of the oxygen atom to the neighbouring nitrogen atom. It has also been shown that there is no exchange of ^{18}O between labelled dimethyl sulphoxide and azoxybenzene when their mixture is heated for a long time in toluene[352].

Fluorine-containing β-Diketones

K.I.Pashkevich, V.I.Saloutin, and I.Ya.Postovskii (deceased)

The methods of synthesis, the keto-enol tautomerism, the chemical reactions (including the formation of heterocycles), and the applications of fluorine-containing β-diketones are examined. The influence of the introduction of fluorine-containing substituents on the properties of β-diketones is discussed.
The bibliography includes 292 references.

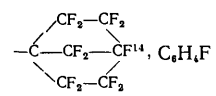
I. INTRODUCTION

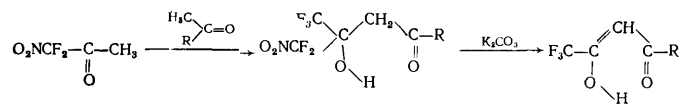
β-Diketones and their metal chelates are widely used in industry and in laboratory practice as extractants and analytical reagents for the lanthanides, as shift reagents, as biologically active substances, and as catalysts of various reactions. By virtue of the presence of two carbonyl groups and their tendency towards enolisation, they lead to the possibility of investigating the keto–enol tautomerism, dual reactivity, the nature of the intramolecular hydrogen bond, and the synthesis of various heterocyclic compounds. Fluorine-containing β-diketones are in many instances superior as regards their useful properties to their non-fluorinated analogues [extraction, gas-liquid chromatography (GLC) of chelates, and biological activity] and have a number of characteristic features due to the presence of fluorine atoms in the molecule.

Extremely extensive data concerning the synthesis, chemistry, and possible applications of polyfluorinated β-diketones and heterocycles based on them have now accumulated in the literature, but the problem has not been surveyed, with the exception of a review[1] covering the literature up to 1968 and devoted to a large extent to the metal chelates of fluorine-containing β-diketones. Data on the metal chelates of fluorinated β-diketones are also contained in another review[2] and those on the applications of non-fluorinated metal β-diketonates are given in two other publications[3,4]. This review provides a survey of the literature data on the synthesis, keto–enol tautomerism, and the most characteristic synthetic reactions and practically useful properties (including biological activity) of polyfluorinated β-diketones. The literature up to 1979 inclusive is covered.



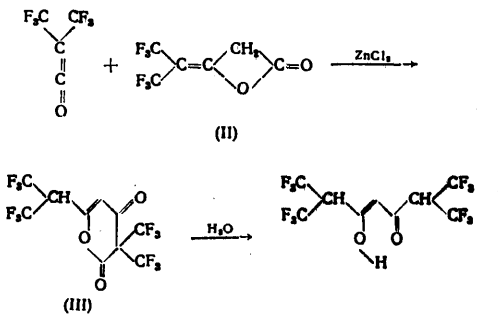
II. METHODS OF SYNTHESIS

The most common and universal method of synthesising polyfluorinated β-diketones is the Claisen condensation[5,6] using the esters of carboxylic polyfluoroacids and methyl ketones as the starting materials and sodium alkoxides[7,8], sodium amide[9,10], sodium hydride[11], and boron trifluoride[12] as the condensing agents. The condensation is usually carried out in anhydrous diethyl ether[5,6], but benzene[13], dimethoxyethane[14], dimethyl sulphoxide (DMSO),[11] and acetic acid[12] are used sometimes. Depending on the solvent, the condensing agent, and the nature of the carbonyl and methylene components, the yields vary from 20 to 80%:

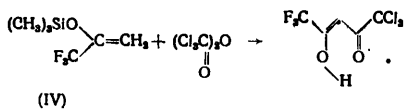


(I)

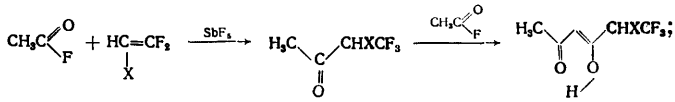
β-Diketones with a single fluorinated substituent have been obtained by this method: $R^F = CH_2F$,[12,15] CCl_2F,[16] CHF_2,[17] $CClF_2$,[18] CF_2OCF_3,[19,20] $CF_2\overline{CFCF_2CF_2CF_2}O$,[19,20] CF_3,[7,8] C_2F_4H,[21] C_2F_5,[18] C_3F_7,[22] C_4F_8H,[17] C_4F_9,[23] C_5F_{11},[24] C_7F_{15},[24,26] C_8F_{17},[27] C_6H_3XF (X = CH_3, Cl, OH, or CF_3),[9,10,28] $C_6H_4CF_3$,[29] or C_6F_5[11] (the second substituent is R = alkyl, aryl, or heteroaryl). Diketones with two fluorinated substituents have also been synthesised: $R^F = R = CF_3$,[7,15,30] HCF_2,[31] HC_2F_4,[31] C_7F_{15},[24,25] or C_6F_5;[11] $R^F = CH_3$, R = HCF_2,[31] C_2F_5,[32] C_3F_7,[32] C_7F_{15},[25] or



A number of other methods of synthesising polyfluorinated β-diketones are known. Knunyants and coworkers[34] described a synthesis of β-diketones containing the trifluoromethyl group; it is carried out by eliminating difluoronitromethane from β-hydroxyketones obtained by the condensation of pentafluoronitroacetone with methyl ketones:

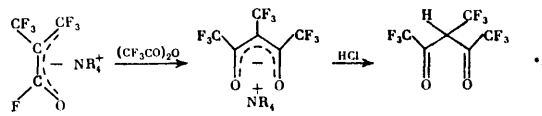


A novel method of synthesising 1,1,1,7,7,7-hexafluoro-2,6-bis(trifluoromethyl)heptane-3,5-dione in 70% yield has been patented; it consists in condensing bis(trifluoromethyl)keten with the β-lactone of 3-hydroxy-4,4-bis(trifluoromethyl)but-3-enoic acid (II) [acetyl chloride can be used instead of compound (II)] in the presence of zinc chloride and subsequent hydrolysis of the resulting δ-lactone of 5-hydroxy-2,2,6,6-tetrakis(trifluoromethyl)-3-oxohex-4-enoic acid

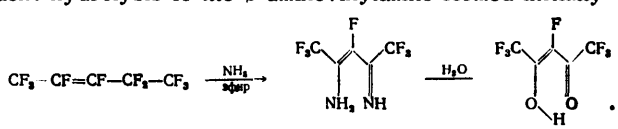


(III):[35]

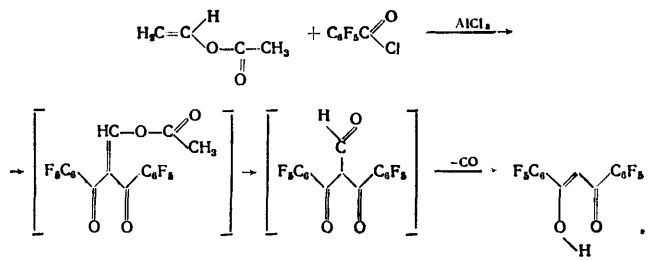
Fokin and Uzun[36] showed that, when β-nitrotetrafluoroethyl nitrite reacts with acetone or acetophenone, up to 40% of the corresponding β-diketones (*I*, $R^F = CF_2NO_2$; $R = CH_3$ or C_6H_5) is formed. It has been established[37] that *O*-silyl-substituted enols (IV) are acetylated by the anhydrides of carboxylic halogenoacids at the terminal sp^2-hybridised carbon atom with formation of up to 43% of the corresponding β-diketone:



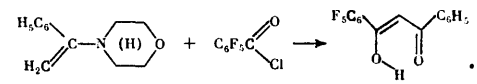
An interesting and promising method has been proposed[38] for the synthesis of β-diketones which are difficult to obtain, consisting in the interaction of fluoro-olefins with acid fluorides under pressure in the presence of antimony pentafluoride. The authors[38] suggest that a ketone is formed initially in the reaction and then reacts with the acid fluoride via a mechanism involving an acid-catalysed Claisen condensation:



X = F or H.

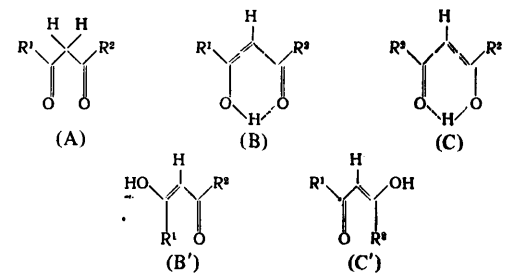


Knunyants and coworkers[39] succeeding in synthesising β-diketones with a fluorinated substituent in the α-position by treating mesomeric fluorocarbanions with the anhydrides of carboxylic perfluoroacids:



Heptafluoroacetylacetone has been synthesised recently by treating *trans*-perfluoropent-2-ene with ammonia and subsequent hydrolysis of the β-aminovinylimine formed initially[40]:

The use of the Claisen condensation[11,33] for the synthesis of β-diketones with pentafluorophenyl substituents frequently leads to the formation of chromones and flavones[41,42] owing to to ease of displacement of the *ortho*-fluorine atom from the pentafluorobenzoyl group by nucleophiles. A number of specific methods are therefore used for the synthesis of such diketones[11,42]. Thus Osadchii and Barkhash[42] synthesised decafluorodibenzoylmethane (DFBM), pentafluorodibenzoylmethane (PFDM), and 1,4-bis(pentafluorophenyl)butane-1,3-dione by acylating pentafluorobenzoylacetic ester with the chlorides of pentafluorobenzoic, benzoic, and pentafluorophenylacetic acids respectively and subsequent hydrolysis and decarboxylation under the influence of concentrated sulphuric acid. They were also the first to obtain perfluorodibenzoylmethane by fluorinating the sodium salt of DFBM with perchloryl fluoride[43]. Although DFBM is formed also when the dichloride of malonic acid is acted upon by pentafluorophenylcopper in absolute ether (yield 20%),[11] the difficulty of obtaining pentafluorophenylcopper and the low yield of DFBM limit the employment of this method. The same compound was synthesised by condensing pentafluorobenzoyl chloride with vinyl acetate in the presence of aluminium chloride (yield 34%):[11]



PFBM is obtained in 25% yield by the reaction of α-morpholinostyrene with pentafluorobenzoyl chloride in anhydrous dioxan[11]. The attempt to extend the method to the synthesis of DFBM proved unsuccessful.

In order to isolate and purify them, β-diketones are distilled[8,19,20] or converted into copper chelates, which are then recrystallised from organic solvents and decomposed with sulphuric acid[22] or hydrogen sulphide[7]. Vacuum sublimation is used to prepare high-purity chelates[25].

III. STRUCTURE AND ENOLISATION

β-Diketones constitute a prototropic system, which can exist in three tautomeric forms (A)–(C), for two of which [(B) and (C)] there is a possibility of geometrical *cis–trans* isomerism [(B') and (C')]. However, a number of studies have shown[44] that non-cyclic β-diketones exist only in the tautomeric forms (A)–(C).

The introduction of electron-accepting fluorine-containing groups greatly alters the distribution of electron density in the β-diketone molecule, which influences the keto–enol equilibrium. Indeed, a higher degree of enolisation of polyfluoro-β-diketones compared with the non-fluorinated compounds

was established as early as 1953 (with the aid of bromination) and infrared spectra have led to the hypothesis that they exist in the *cis*-forms (B)–(C) with an intramolecular hydrogen bond (IAHB).[23] Subsequently this hypothesis was confirmed by infrared spectroscopic[33,45–49], ultraviolet spectroscopic[33,45,50,51], and ^{1}H NMR [44,52,53] data.

The study of the ^{1}H NMR spectra of liquid β-diketones showed that the increase of the fluorine content shifts the keto–enol equilibrium towards the enol (Table 1) and that in the presence of four or more fluorine atoms in the molecule the enolisation is complete[12,17,20,54]. This agrees well with data for the enolisation of esters of fluorine-containing β-ketoacids[55] and is associated with the pronounced electron-accepting properties of the fluoroalkyl groups[46,56]. It is of interest that 1,1,1,5,5,5-hexafluoro-3-trifluoromethylpentane-2,4-dione, containing three CF_3 groups, is not enolised and exists fully in the diketo-form[39], although its non-fluorinated analogue is 30% enolised[57]. The influence of the solvent on the keto–enol equilibrium and on the chemical shifts of the protons of trifluoroacetylacetone (TFAA) and hexafluoroacetylacetone (HFAA) has been investigated[58].

The pronounced electron-accepting properties of fluoroalkyl substituents are also manifested by the weakening of the IAHB in fluorine-containing β-diketones compared with the non-fluorinated compounds. Thus it has been established[59] that the signal of the O–H proton is displaced upfield on passing from acetylacetone (AA) to TFAA and HFAA and also from benzoylacetone (BA) to trifluorobenzoylacetone (TFBA); according to the authors[59], this demonstrates a weakening of the IAHB. An analogous relation has been found[60] for β-diketones of the selenophen series. On the basis of HFAA as an example, Gunnarsson et al.[61] suggest that the strength of the IAHB be estimated from the correlation between the proton chemical shifts and the isotope effect on replacement of the OH proton by deuterium for the same hydrogen-bonded systems; however, studies of this kind have not been carried on fluorine-containing β-diketones.

Asymmetric polyfluoro-β-diketones with a fluoroalkyl substituent at only one carbonyl group are convenient objects for the investigation of the position of the proton in the *cis*-enol form with an IAHB (a study of the enol–enol equilibrium), but here too the studies which have been carried out are restricted mainly to the non-fluorinated dicarbonyl compounds. Thus, analysis of the chemical shifts of the enol protons in the ^{1}H NMR spectra of *para*-substituted BA led to the conclusion[62] that the fraction of the enolic form with the proton at the oxygen atom linked to the benzene ring increases as the electron-accepting properties of the *para*-substituent in the ring are enhanced. This is also confirmed by data[63] where an analogous conclusion concerning the preferred mode of enolisation of β-diketones involving the oxygen atom linked to the more electron-accepting substituents was reached on the basis of a study of ^{17}O NMR. This mode of enolisation was confirmed elegantly for asymmetrical polyfluoro-β-diketones by the results of a study[64] in which the influence of the solvent on the chemical shifts of the carbon nuclei of both carbonyl groups in AA, dibenzoylmethane (DBM), TFAA, and salicylaldehyde was investigated by ^{13}C NMR; it was established that in TFAA the carbonyl group linked to the trifluoromethyl group is enolised.

On the basis of the study of the ^{13}C NMR spectra of the enolic forms of fluorine-containing and hydrocarbon β-diketones, it was concluded that they do not undergo the enol–enol tautomerism and the observed changes in the chemical shifts of the carbon nuclei were explained by a redistribution of the electron density in the chelate ring with an IAHB.[65] Nevertheless the same investigators[66] proposed a method for determining the position of the proton in the chelate with an IAHB from the ^{13}C NMR spectra of metal chelates; the presence of two equivalent potential wells for the bridging hydrogen atom in HFAA was pointed out in an earlier study[67].

The recently observed simultaneous presence of the enolic and enthiol forms in solutions of fluorine-containing monothio-β-diketones cooled to −70 °C constitutes a convincing confirmation of the occurrence of intrachelate tautomerism in β-diketones[68].

The bond lengths (in Å) and angles (in degrees) in BA [71] and TFAA [69] molecules.

Molecular Structure

The determination of the molecular geometries of the enolic forms of TFAA [69] and HFAA [70] by electron diffraction in the gas phase and X-ray diffraction study of the crystal and

molecular structures of BA,[71] *p*-nitrobenzoylacetone[72], and DBM [73] also failed to provide an unambiguous answer to the question of the position of the proton in the enolic tautomers (see Figure). According to Andreassen and coworkers[69,70], the experimental distances between the two oxygen atoms are in best agreement with the symmetrical form (an analogous conclusion was reached by Jones[72]); on the other hand, an asymmetric structure of BA and DBM molecules was indicated in other investigations[71,73].

Two O(1) ionisation bands, differing by 1.5 eV, were recently found by photoelectron X-ray spectroscopy and it was established that AA and HFAA exist in two tautomeric forms (B) and (C), the barrier to their interconversion via the enolic form with a symmetrical location of the proton being low.[74] For HFAA, this conclusion was confirmed[61] by a study of the ^1H NMR and ^2H NMR spectra.

Distribution of Electron Density

The distribution of electron density in the enolic forms of polyfluoro-β-diketones has been calculated by the CNDO method[75-77]. An increased electron density at the carbon atom linked to the fluorinated substituents has been observed for TFAA.[75,76] The study of the influence of the structure of the fluoroalkyl substituent on the distribution of electron density showed[77] that the distribution depends little on the position of the proton in the enolic forms of β-diketones.

IV. ACID–BASE PROPERTIES

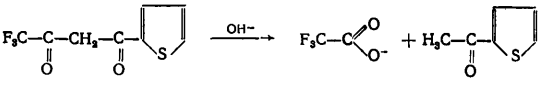
Depending on the acidity of the medium, β-diketones exhibit the properties of acids or bases, splitting off or combining with a proton. In aqueous media polyfluoroalkyl-β-diketones are stronger acids by 2–3 orders of magnitude than the corresponding non-fluorinated analogues. This was demonstrated by the determination of their ionisation constants in a series of aqueous organic systems (50% dioxan–water[78], 75% dioxan–water,[79,80] 46% acetone–water,[81] 80% methanol–water,[20] 5% ethanol–water,[31] and dimethylformamide [82]) and in water[83-85] and are clearly illustrated by measurements[85] of the pK_a of *m*- and *p*-substituted benzoyltrifluoroacetones.

The influence of the structure of the fluorinated substituent on the acid dissociation constants of polyfluoro-β-diketones in solutions are illustrated in Table 2. However, even the lowest of the available literature values of pK_a for HFAA, which is 4.6,[84] is in poor agreement with the pK_a of other β-diketones and in all probability characterises the acidity of the dihydrate of hexafluoroacetyl-1,1,1,5,5,5-hexafluoropentane-2,2,4,4-tetraol which is formed extremely readily when HFAA comes into contact with water (see Section V).[31] A linear relation has been found between pK_a and the Taft σ* constants of the substituents R for constant R^F, which is not observed when R^F is varied and R is kept constant; it was established that the acidity of polyfluoro-β-diketones increases with the chain length of R^F from CF_3 to $(CF_2)_4H$.

In weakly acid solutions non-fluorinated β-diketones form both monocations (96% H_2SO_4) and dications ($HFSbF_5$ in SO_2);[86,87] polyfluoroalkyl-β-diketones undergo monoprotonation under the same conditions[87,88]:

The basicity constant pK_b of thenoyltrifluoroacetone (TTFA) in sulphuric acid proved to be −5.2 in a spectrophotometric determination and −5.3 in a potentiometric determination[89].

V. CHEMICAL REACTIONS

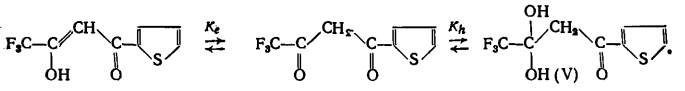


1. Reactions of Carbonyl Groups

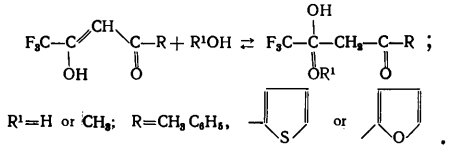
Most of the synthetic studies on polyfluoro-β-diketones are associated with the investigation of the reactions of carbonyl groups with nucleophiles, since these reactions in fact open the way to different β-diketone derivatives and make it possible to obtain a wide range of compounds, including aza-heterocycles, with fluorine-containing substituents in the heteroring, many of which exhibit a high biological activity.

(a) Interaction with hydroxy-compounds.

The interaction of polyfluoro-β-diketones with hydroxyl-containing nucleophiles (water and alcohols) has been little studied, although it is of interest, because β-diketones are used fairly widely as extractants of metal cations from aqueous media[90].

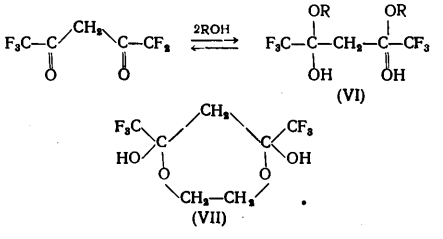


In an alkaline medium polyfluoro-β-diketones are cleaved like their hydrocarbon analogues[91] and diketones with a single polyfluoroalkyl substituent form a salt of a carboxylic polyfluoroacid and a methyl ketone[92]:



This shows that the nucleophilic attack is directed to the carbonyl linked to the fluorinated substituent. The replacement of one of the fluorine atoms of the trifluoromethyl group by the nitro-group facilitates hydrolytic cleavage still further and 1,1-difluoro-1-nitropentanedione is cleaved on being simply boiled with water[36].

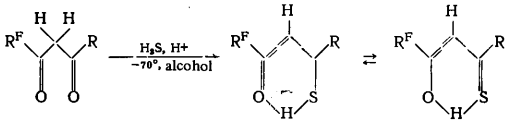
Nevertheless asymmetric polyfluoro-β-diketones without NO_2 groups in the molecule are not hydrolysed under the usual condition in an acid or neutral medium and, like other halogen-containing carbonyl compounds[94], form geminal



adducts. Thus, when TTFA was dissolved in the benzene–water two-phase system, it was observed[95] that the diketone in benzene solution is hydrated to a large extent (12%). These data are confirmed by the anomalously low (2%) content of the enolic form of TTFA in aqueous solution, which has been attributed[96] to the formation of the hydrate (V), which shifts the diketone–enol equilibrium towards the diketo-form and further towards the hydrate:

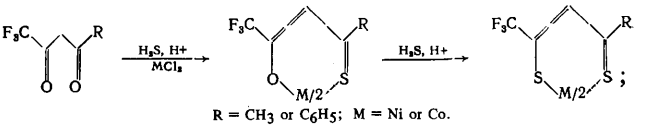
In a series of studies[97–99] investigation of the NMR ^{19} and ^{1}H NMR spectra of a series of trifluoromethyl-β-diketones showed that water or an alcohol adds reversibly to one of the carbonyl groups. The equilibrium constants and the heats of formation of the adducts have been determined. From the study of the equilibrium between the initial forms of the trifluoroacetoacetic ester (the keto- and enolic forms), on the one hand, and the corresponding hydrates and hemiketals, on the other, it was concluded that water interacts exclusively with the keto-form[100]. The rate of this interaction exceeds the rate of the keto–enol transformation. It has been shown[101] that the tendency of fluorine-containing β-diketones to form geminal adducts diminishes when one CF_3 group in HFAA is replaced by the α-thienyl (TTFA), phenyl (BTFA), or methyl (TFAA) groups:

In the case of HFAA, which contains two trifluoromethyl groups, water or alcohol adds to both carbonyl groups and the resulting geminal adducts (IV) (tetraols and bishemiketals) are so stable that they can be isolated in a free form[30,102,103]. The reaction of HFAA with ethylene glycol leads to 5,7-dihydroxy-5,7-bis(trifluoromethyl)dioxepan (VII):[104]



The equilibrium in the reaction of HFAA with water is strongly displaced towards the adduct, while in ethereal solution only an insignificant amount of the enolic form is present[30] and the abstraction of both water molecules requires prolonged refluxing over P_2O_5.

It is of interest that an increase in the length of even one of the two fluoroalkyl substituents in β-diketones (analogues of HFAA) reduces sharply the stability of the dihydrates. For example, the crystalline adducts of water with a diketone incorporating CF_3 and C_3F_7 groups, namely 1,1,1,5,5,6,6,7,7-decafluoroheptane-2,4-dione is stable only at −25 °C, decomposing on heating to room temperature with elimination of water[32], although the similar adduct of a β-diketone containing the CF_3 and C_2F_5 groups is entirely stable. On the other hand, a stable dihydrate is formed when one trifluoromethyl group is retained in the molecule, while the other is replaced by the difluoromethyl-containing group $-HCF_2-C(OH)_2-CH_2-C(OH)_2-CF_3$.[31]

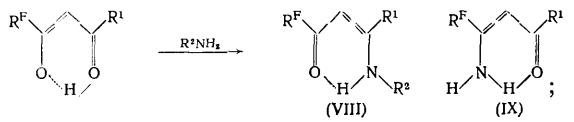


(b) Interaction with hydrogen sulphide.

The interaction of β-diketones with hydrogen sulphide in the presence of basic[105,106] or acid[107,108] catalysts leads to the replacement of one or both oxygen atoms in the carbonyl groups by sulphur. The study of this reaction in relation to polyfluoro-β-diketones demonstrated the necessity to increase the concentration of the catalyst (anhydrous hydrogen chloride) as the electron-accepting properties of the substituents at the carbonyl groups are enhanced, which can be accounted for[108] by the necessity to displace the keto–enol equilibrium towards the reactive diketo-form. A series of monothio-β-diketones with different fluoroalkyl (CF_3,[108–113] HCF_2CF_2,[114] C_2F_5,[110,113] and C_3F_7 [113,115]) and hydrocarbon groups have now been obtained by this method:

It has been shown by mass spectrometry that the condensation involves the carbonyl group linked to the least electron-accepting substituent[108,116]. On this basis, it is suggested[117] that the attacking species in the reaction of β-diketones with hydrogen sulphide is H_3S^+ and the reaction is electrophilic. The mechanism involving the protonation of the carbonyl group and nucleophilic attack by hydrogen sulphide is more probable[118].

The replacement of the oxygen of the second carbonyl group by sulphur with formation of dithio-β-diketones is possible, but these compounds are relatively unstable and readily dimerise[119,120]. The attempts to synthesise dithiohexafluoroacetylacetone and its chelates proved unsuccessful[121,122]. Only the synthesis and spectroscopic study of the nickel and cobalt chelates of dithiotrifluoroacetylacetone and dithiodifluorobenzoylacetone when hydrogen sulphide is passed into concentrated solutions of β-diketones and salts of the corresponding metals in absolute alcohol saturated with hydrogen chloride has been reported; the yields amount to 15–30%. The reaction mechanism proposed by Barraclough et al.[122] involves the formation of a monothio-β-diketone, which is then coordinated to the metal, so that the subsequent introduction of sulphur takes place, as it were, on a matrix. In all probability this reaction is possible by virtue of the presence of hydrogen chloride, which prevents the formation of the metal sulphide and the reversible decomposition of the metal chelate by hydrogen sulphide:



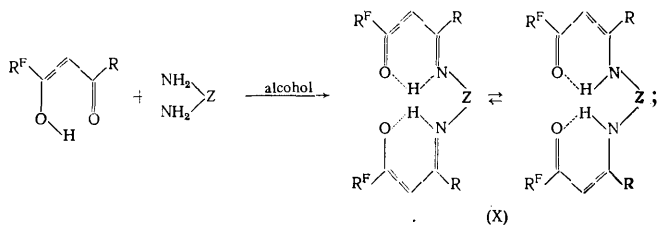
(c) Reactions with amino-compounds

The interaction of polyfluoro-β-diketones with an amine can involve one or both carbonyl groups of the β-diketone molecule (and sometimes also the α-carbon atom), depending on the nature of the amine, the reaction conditions, and the

structure of the substituents at the carbonyl groups, with formation of β-aminovinyl ketones (β-AVK), as well as various saturated or aromatic heterocycles.

Reactions with ammonia and primary amines. When solutions of polyfluoro-β-diketones are refluxed with ammonia or primary amines under the conditions of acid catalysis or in the absence of a catalyst, β-AVK (VIII) are formed[29,123–127] and, in the case of asymmetric β-diketones with a single fluoroalkyl substituent, the carbonyl group linked to the non-fluorinated substituent is involved in condensation. This has been established by the synthesis of isomeric β-AVK (IX) with the amino-group at the fluoroalkyl substituent[128] and has been confirmed mass-spectrometrically[127]:

(VIII) (IX)



R^F=CF_3[123], HCF_2[127], H $(CF_2)_2$[126,127], H $(CF_2)_4$[127],

$CF_3C_6H_4$[29]; R^1 — alkyl, fluoroalkyl, or aryl; R^2—H, alkyl, aryl, or $N{=}C(CF_3)_2$

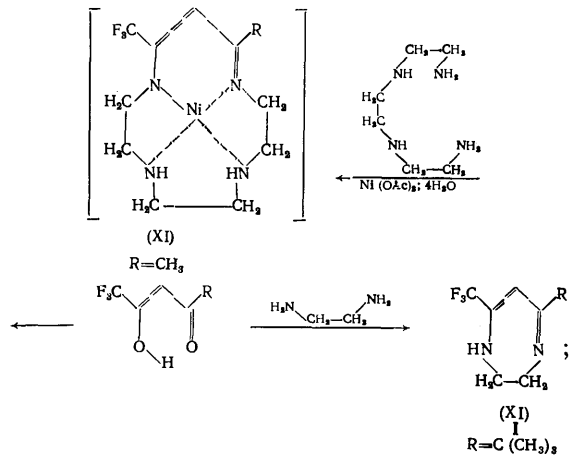
The analogous reactions of the esters of fluorine-containing β-ketoacids involve the ketone carbonyl group linked to the fluorinated substituent[129,130].

The condensation of both carbonyl groups in polyfluoro-β-diketones with free monoamines, leading to the formation of fluorine-containing β-di-imines, is unknown, but treatment of an alkaline solution of TFAA with platinum hexammine gave a β-di-imineplatinum complex in 40% yield[131,132]. According to the authors[131,132], the reaction constitutes a promising method for the synthesis of β-aminovinylketimines, but they did not describe the isolation of the ligand in a free form. In our view the interaction of perfluoro-olefins with ammonia may serve as a simpler and more reliable method of synthesising fluorine-containing β-aminovinylketimines[40].

In the interaction of polyfluoro-β-diketones with polyalkylenepolyamines one carbonyl group from each two diketone molecules and both terminal amino-groups of the polyalkylenepolyamine are as a rule involved in condensation; this leads to high yields of the corresponding bis(β-dioxo)-alkylenedi-imines (X):[133–140]

(X)

Z=CH_2CH_2[133,134,136,138], $CH_2CH(CH_3)$[134],



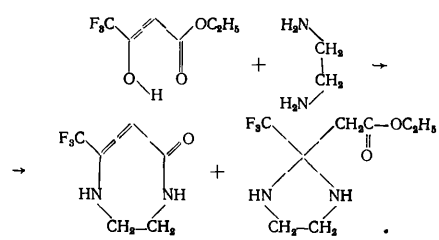
$CH_2CH_2CH_2$[135,136,138], $CH_3CHCHCH_3$[137],

$(CH_2)_2NH(CH_2)_2NH(CH_2)_2$[139], or $(CH_2)_2NH(CH_2)$—$_2$[140].

Recently there has been a growth of interest in these compounds in view of the discovery of their properties satisfying many of the requirements of the metal chelate gas chromatography[136–138]. The monomeric structure of bis(β-dioxo)alkylenedi-imines has been confirmed by the determination of their molecular weights[139] and by the formation of individual metal chelates[134,137,138]. The direction of nucleophilic attack in the case of asymmetric β-diketones on the carbonyl linked to the non-fluorinated substituent has been established by determining the dipole moments[134,135] and by the mass-spectrometry[93,141] of the compounds themselves, as well as the X-ray diffraction analysis of their nickel(II) chelates[142]. On the basis of this direction of attack, it is suggested that the electron-accepting CF_3 group induces a larger δ+ charge on the remote carbonyl than on the carbonyl linked to this group[142].

The question of the tautomeric structure of the compounds remains controversial: some workers[134,135] are inclined towards the iminoenol structure, while in other investigations[93,139] preference is given to the enaminoketone form on the basis of the ^1H NMR spectra and dipole moments, which appears to be more correct.

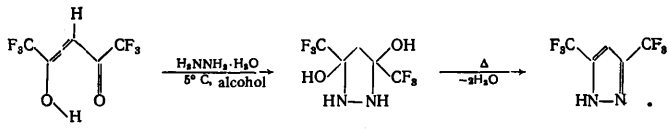
Only isolated instances of the formation of cyclic compounds in this reaction have been described. Thus the reaction of TFAA with triethylenetetramine in the presence of nickel ions yielded compound (XI),[143] and the synthesis of dihydrodiazepine (XII) has been reported[144]:



(XI)

R=CH_3

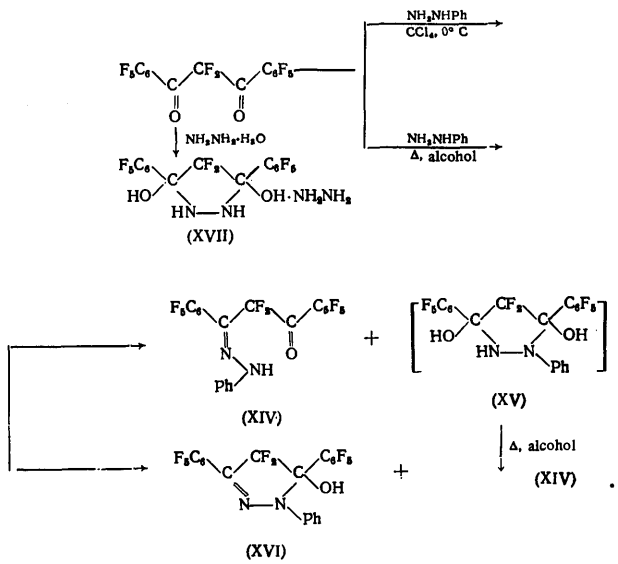
(XI)



R=$C(CH_3)_3$.

Depending on the conditions, the condensation of the esters of fluorine-containing β-ketoacids with ethylenediamine leads either to a mixture of a substituted 2,3-dihydro-1,4-diazepin-5-one and imidazolidine in various proportions or to the imidazolidine alone[129,145]:

Reactions with hydrazines and hydroxylamine. Like their hydrocarbon analogues[146], polyfluoro-β-diketones react with hydrazines at room temperature[147] or on heating to form pyrazoles[93,148–153], among which compounds with anti-inflammatory and analgesic activities[147,148], highly active herbicides[150], preparations for the treatment of hyperglycemia[152], heat resistant heat exchanger, and surfactants[153] have been patented. Interaction of bis-β-diketones with hydrazines proceeds similarly and leads to bispyrazoles[93].

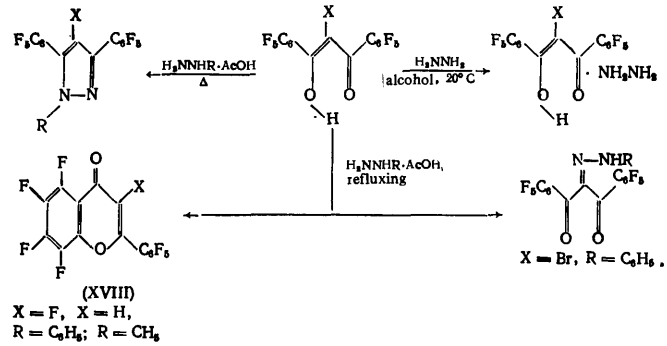


In contrast to this, the interaction of HFAA with hydrazine hydrate in alcohol (5 °C) gives rise to 3,5-dihydroxy-3,5-bis(trifluoromethyl)pyrazolidine (XIII),[154] which splits off two water molecules only on heating and is converted into pyrazole:

(XIII)

For symmetrical polyfluoro-β-diketones with large aliphatic fluorosubstituents [153] and with fluorinated substituents containing an ω-hydrogen atom[93], the formation of pyrazolidines was not observed at all in this reaction; this is consistent with the reactivity of symmetrical polyfluoro-β-diketones in relation to hydroxylated nucleophiles.

The behaviour of β-diketones with perfluorophenyl substituents in reactions with hydrazines is unusual; perfluorodibenzoylmethane, which has no α-hydrogen atom, reacts with phenylhydrazine at 0 °C to give a mixture of the β-ketohydrazone (XIV) and the unstable pyrazolidine (XV), the refluxing of which in alcohol results in the elimination of one water molecule and the formation of the pyrazoline (XVI), together with the partial opening of the ring and conversion into compound (XIV).[155] The reaction with hydrazine hydrate yields the pyrazolidine (XVII) as an adduct with a hydrazine molecule:

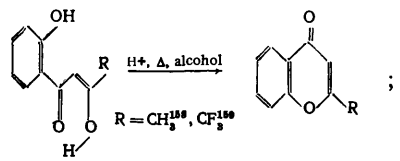


(XVII)

(XIV)

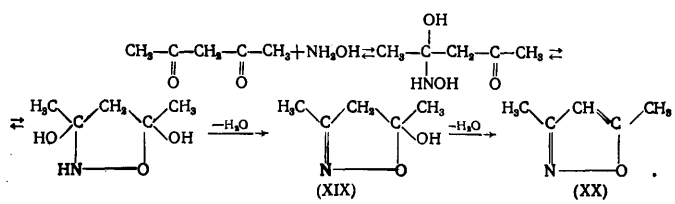
(XV)

(XVI)



The enolising aromatic polyfluoro-β-diketones react with hydrazine at room temperature to form salts, pyrazoles being produced only on boiling. However, depending on the nature of the α-substituent in the β-diketone and the structure of the hydrazine, on heating with hydrazine acetates they form either pyrazoles or the flavones (XVIII) via the intramolecular elimination of an *ortho*-fluorine atom from the pentafluorophenyl ring[156]:

(XVIII)

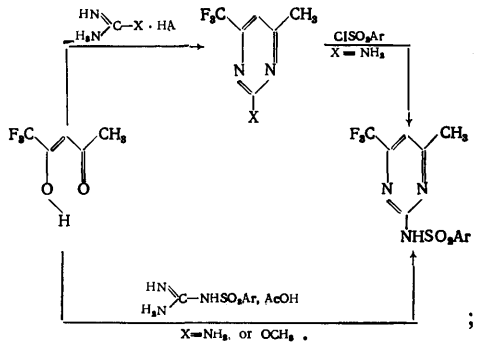


X = F, X = H,
R = C_6H_5; R = CH_3

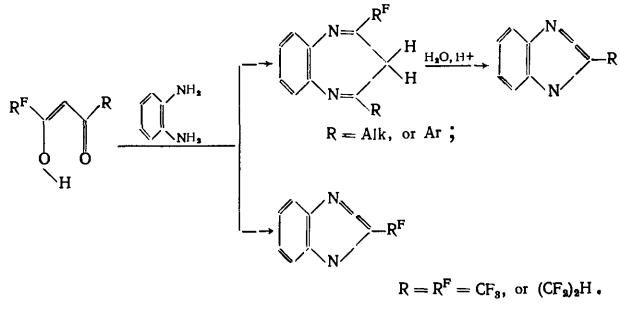
A similar reaction, leading to the formation of flavones by the intramolecular cyclisation of β-diketones with a non-fluorinated phenyl substituent, occurs only on heating in the presence of an inorganic acid and requires the obligatory presence of a hydroxy-group in the *ortho*-position in the benzene ring[157,158]:

Recent studies of the reaction mechanism by NMR in relation to AA have shown that the interaction of β-diketones with hydroxylamine involves several stages and ultimately leads to isoxazoles (XX).[159,160]

In the case of polyfluoro-β-diketones the intermediate 5-hydroxy-Δ^2-isoazoline of type (XIX) is so stable that it can be isolated in a free form and its conversion into isoxazole requires heating with polyphosphoric acid[161,162]. This demonstrates yet again the stabilisation of the intermediates of the nucleophilic addition reaction by fluoroalkyl residues:

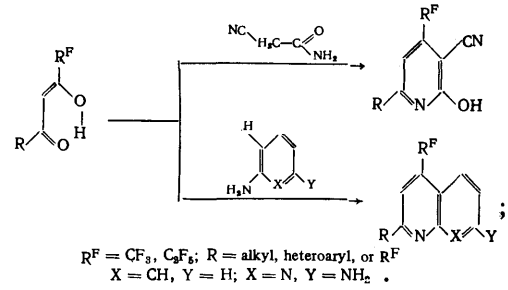


(XIX) (XX)



Fluoroalkylisoxazoles have been patented as high-temperature heat exchangers and surfactants[161] and also as substances reducing the sugar content in blood[163].

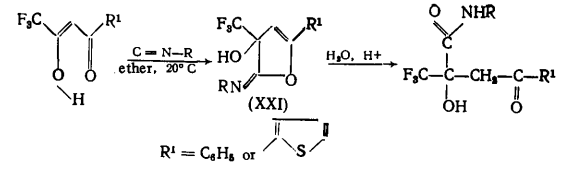
Reactions with urea derivatives and o-phenylenediamine. When TFAA is fused together with guanidine carbonate[149] and on heating alcoholic solutions of TFAA with guanidine carbonate[164] or *O*-methylisourea hydrochloride[175], 2-amino- or 2-hydroxy-pyrimidines with the trifluoromethyl group in the heteroring are formed, among which trifluoromethylsulphonamides—the analogues of the familiar non-fluorinated preparation sulphamethazine and sulphisoamidine—have been obtained[164]. The synthesis of these compounds in a single



stage by refluxing TFAA with arenesulphonylguanidines has been patented[166]. The same patent reports their higher biological activity compared with the hydrocarbon analogues. It has been shown[167] that in an acid medium the reaction mechanism involves the acid-catalysed attack by urea on the keto–enol with subsequent cyclisation:

Although the formation of substituted 1,5-benzodiazepines from o-phenylenediamine (OPD) and β-diketones without fluorine was described as early as 1907,[168] the study of the interaction of fluorine-containing β-diketones with OPD was begun only in recent years. It has been established[169] that the condensation of fluoroalkyl-β-diketones with OPD results in the formation of between 3 and 25% of the open-chain β-aminovinyl ketone, depending on the substituents in the β-diketone, together with 1,5-benzodiazepines. It is recommended that the 1,5-benzodiazepines with a fluoroalkyl substituent in the heteroring obtained in this reaction be used as surfactants and heat exchangers[170]. It has been observed[93] that benzodiazepines can be obtained successfully only from β-diketones containing a single fluoroalkyl substituent, while β-diketones with two fluoroalkyl substituents give rise to salts under the usual conditions of condensation with OPD,[168] refluxing in alcohol in the presence of acetic acid producing 2-fluoroalkylbenzimidazoles[93]. This course of the reaction is associated in all probability with the enhanced reactivity of the C=N bond adjoining the fluoroalkyl substituent, which leads to attack by the free amino-group on this bond and not on the carbonyl group:

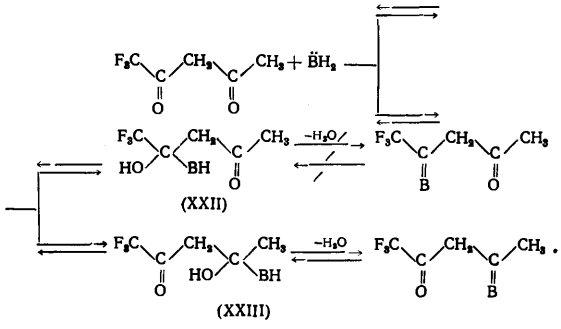
Reactions with amino-compounds containing mobile α-hydrogen atoms. Under the influence of basic reagents[171,172], sulphur[173], polyphosphoric acid[174,175] phosphoric acid[176–178], and also on heating[179], polyfluoro-β-diketones readily condense with amino-compounds containing a mobile hydrogen atom in the β-position with formation of a pyridine ring:



The reaction is of interest from the standpoint of the introduction of fluorine-containing substituents into the pyridine ring and the synthesis of potential biologically active compounds. Thus the substituted 4-trifluoromethylpyridone, synthesised from cyanoacetamide and TFAA, has been used to prepare trifluoromethyl analogues of vitamin B_6,[171] pyrazolopyridines with a 4-fluorophenyl substituent have been patented as anti-inflammatory preparations[174], and the naphthyridines obtained from fluorine-containing β-diketones and 2,6-diaminopyridine have been patented as compounds with hypotensive and bronchodilating activities[175,177,178]. The analogous cyclisation with esters of fluorine-containing β-ketoacids leads to γ-pyridones[180], from which trifluoromethyl analogues of quinine and quinidine have been obtained. The formation of trifluoromethylpyrazolo[1,5-d]pyrimidines by the condensation of TFAA with 2-aminopyrimidine has been described[181]. The compounds obtained are depressants of the central nervous system.

(d) Reactions with other nucleophiles

Selenothenoyltrifluoroacetone has been obtained by the reaction of an alcoholic solution of TTFA with hydrogen selenide in a stream of nitrogen in the presence of anhydrous hydrogen chloride[182]. The site of nucleophilic attack has not been established, but, by analogy with hydrogen sulphide[108], it has been suggested[182] that the oxygen of the carbonyl group linked to the non-fluorinated substituent is substituted (see also Section V).



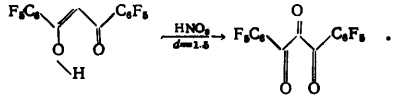
In contrast to their non-fluorinated analogues[183], fluoroalkyl-β-diketones readily give rise to cyclicadducts with isonitriles in the absence of catalysts[184], which is attributed to their virtually complete enolisation. The structure of the reaction product (XXI) and hence the direction of nucleophilic attack† on the carbonyl linked to the fluoroalkyl substituent have been established by ^{19}F NMR and the acid hydrolysis of the cyclicadduct:

† The authors[184] do not rule out the possibility of 1,4-cycloaddition.

The interaction of fluorine-containing β-diketones with the hydride ion leads to the reduction of both the carbonyl group and of the C=C double bond of the enol with formation of diols[185].

Thus polyfluoro-β-diketones readily react with nucleophiles, forming geminal adducts or condensation products. The unusual direction of nucleophilic attack on the carbonyl carbon atom linked to the less electron-accepting substituent can be accounted for either by the initial protonation of the carbonyl group linked to the non-fluorinated substituent or by treating the reaction as a series of reversible stages involving intermediate and final products[127]:

(XXII)

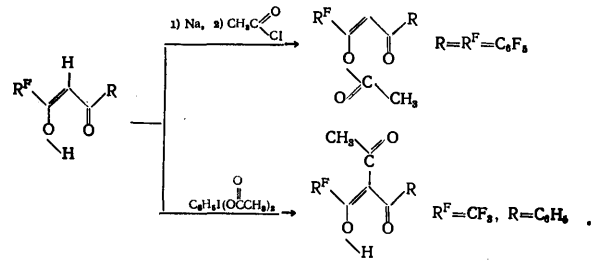


(XXIII)

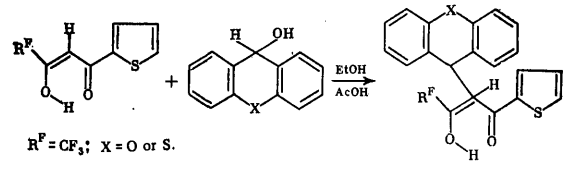
The formation of the adduct (XXII) is more likely than that of the adduct (XXIII), but the former does not tend to eliminate a group and the reaction virtually stops at the stage involving its formation. The adduct (XXIII) readily eliminates either the added nucleophile molecule, being reconverted into the initial β-diketone, or a water molecule, forming a condensation product; in the presence of a large excess of the reagent, the equilibrium is displaced towards the condensation product. In an alkaline medium, the β-diketone molecule is cleaved irreversibly at the C–C bond.

2. Other Reactions

(a) Electrophilic reactions

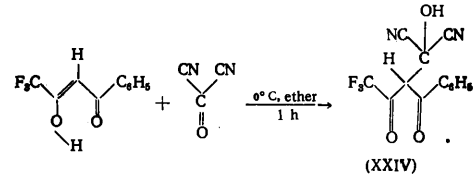


The interaction of fluorine-containing β-diketones with electrophiles has been studied less thoroughly than the interaction with nucleophiles, probably owing to the smaller practical and synthetic importance of the compounds formed. However, the available data emphasise certain features due to the presence of fluorine-containing substituents. For example, under conditions characteristic of the introduction of the nitro-group in the α-position of DBM, the fluorinated analogue of the latter is not nitrated and treatment with more concentrated HNO_3 results in the formation of a triketone, which is entirely stable in air[42]:



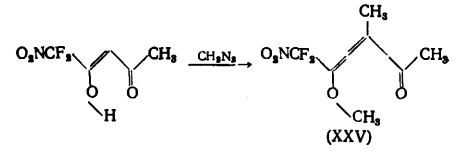
An analogous reaction has been observed for pentafluorobenzoylacetic ester on treatment with selenium dioxide[186].

Fluorine-containing substituents also hinder the bromination and nitration of chromium and copper β-diketonates. This is associated both with the reduction of the nucleophilicity of the α-position and with the decrease of the stability of the metal chelates themselves[187,188].



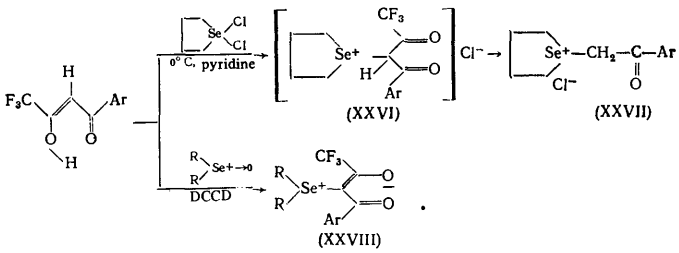
The dual reactivity of fluorine-containing β-diketones and their enolate ions has been very little investigated. It has been established that treatment of the sodium salt of DFBM with acetyl chloride results in the exclusive formation of the *O*-acetyl derivative[43]. The interaction of BTFA with diacetoxyiodobenzene leads to C-acylation[189]:

Alkylation of TTFA with xanthydrol and thioxanthydrol in acetic acid takes place at the α-carbon atom[190] and does not differ from the similar reaction of the non-fluorinated analogues:



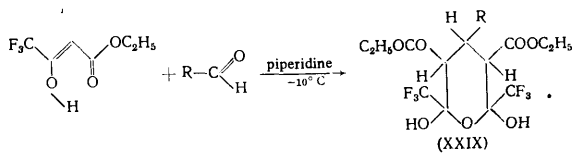
O-Alkylation also does not occur on interaction of TFBA with carbonyl cyanide, the relatively unstable C-alkylation product (XXIV) being formed in quantitative yields[191]:

(XXIV)



On the other hand, 1,1-difluoro-1-nitropentane-2,4-dione is methylated by diazomethane at the oxygen and α-carbon atoms, being converted into 5,5-difluoro-4-methoxy-3-methyl-5-nitropent-3-en-2-one (XXV);[36] this is yet another example of the dual reactivity of fluorine-containing β-diketones:

(XXV)

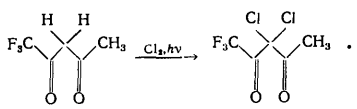


The attempt to extend to fluorine-containing β-diketones the reaction leading to the formation of selenonium ylids by treatment with selenolane dichlorides, which is usual for the non-fluorinated analogues, led to the selenonium salts (XXVII).[192] According to the authors, this is associated with the cleavage of the selenonium derivative of the diketone (XXVI) formed initially. The instability of the latter is

caused by the high positive charge on the carbonyl carbon atom linked to the trifluoromethyl group due to the inductive effect of the CF_3 and $>Se^+$ groups. The selenonium ylids (XXVIII) have been obtained only from selenoxides and the benzoyl- and thenoyl-trifluoroacetone in the presence of dicyclohexylcarbodi-imide (DCCD):[192]

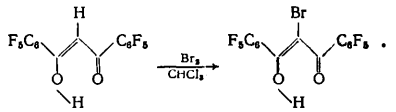
(XXVI) (XXVII) (XXVIII)

The condensation of the α-methylene group of fluorinated β-diketones with polymethine compounds containing a terminal aldehyde group has been described; the products have been patented as filtering dyes for photographic and textile materials[193]. The condensation of the trifluoroacetoacetic ester with aqueous solutions of aldehydes leads to the tetrahydropyrans (XXIX) containing fluoroalkyl substituents in the heteroring[194]:



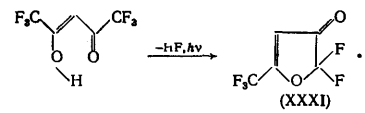
(XXIX)

Heating of TFAA with thionyl chloride leads to the substitution of the hydroxy-group by chlorine with formation of 2-chloro-1,1,1,5,5,5-hexafluoropentan-1-one.[195,196]



(b) Radical reactions

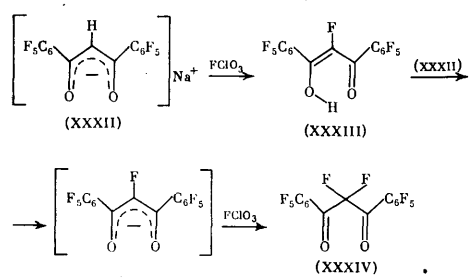
There have been several examples of radical reactions of fluorine-containing β-diketones. Chlorination of TFAA in the light leads to 3,3-dichloro-1,1,1-trifluoropentane-2,4-dione (XXX):[23]



(XXX)

The bromination of DFBM with bromine results in the formation of only the monobromo-derivative, although under the same conditions the non-fluorinated analogue can give rise to both mono- and di-bromo-derivatives[42]:

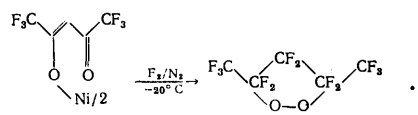
It has been shown by EPR that trifluoronitrosomethane adds to TFAA and HFAA in the α-position with formation of nitroxy- and iminoxy-radicals[197]. Irradiation of HFAA with ultraviolet light leads to the elimination of HF and to cyclisation to 2,2-difluoro-5-trifluoromethyl-2,3-dihydro-3-furanone (XXXI):[198]



(XXXI)

в) Фторирование

(c) Fluorination



It has been shown[43] that the sodium salt of DFBM (XXXII) is fluorinated by perchloryl fluoride at the α-carbon atom with formation of perfluorodibenzoylmethane (XXXIV), which is consistent with data[199–201] for the interaction of non-fluorinated β-diketones with perchloryl fluoride and can be accounted for[43,199] by the higher acidity of the diketone (XXXIII) compared with DFBM, leading to its metallation by the sodium salt (XXXII) and further exhaustive fluorination:

(XXXII) (XXXIII) (XXXIV)

The introduction of only one fluorine atom at the α-carbon atom has been achieved[43] by fluorinating α-bromodecafluorodibenzoylmethane with subsequent debromination and also by fluorinating the sodium salt of bis(pentafluorobenzyl)acetic ester, and the acid cleavage of the resulting product with 100% sulphuric acid. The possible mechanism of the fluorination of CH-active compounds by perchloryl fluoride has been discussed in a book[202].

Fluorination with elemental fluorine has been described only for the copper and nickel chelates of hexafluoroacetylacetone; the authors were able to isolate perfluoro-3,5-dimethyl-1,2-dioxolan in 5% yield:[203]

VI. APPLICATIONS

1. Extraction and Extraction-Photometric Determination of Metals

The presence of fluorine-containing groups is reflected also in the applications of β-diketones, giving rise to new fields of application of these compounds or improving the properties for employment in familiar fields.

Thus the acidity of polyfluoro-β-diketones exceeds by 2–3 orders of magnitude the acidity of their non-fluorinated analogues[204,205], which permits the extraction of readily hydrolysable metal β-diketonates from much more acid solutions[90]. The studies on the extraction properties of TTFA and furoyltrifluoroacetone, which have been investigated in greatest detail in this sense, have been reviewed in a monograph[90] and the synergism of TTFA in combination with various compounds has been discussed in a review[206].

In publications of recent years much attention is devoted to the study of the extraction of metals with TTFA in the presence of tertiary amines[207-214] and phosphorus compounds[215-217] and also to the application of TTFA in the extraction-photometric determination of the elements[218-222]. Other polyfluoro-β-diketones are more rarely used in the extraction and spectrophotometric determination of metal ions[223-225], although perfluoroalkylvinylphenylpropanediones have been patented as monomers for the synthesis of polymers capable of extracting metals ions from highly acid media[226], while β-diketones containing the pentafluorophenyl substituent together with a perfluoroalkyl substituent have been patented as extractants of vanadium from highly acid media[26,227].

2. The GLC Separation and Determination of Metal Cations

Fluorine-containing substituents increase the volatility of metal β-diketonates, which permits their gas-chromatographic separation and determination at much lower temperatures[228] and with the aid of electron-capture detectors; the sensitivity and selectivity of the analysis are thus improved[229]. The problems of the application of polyfluoro-β-diketones in the GLC of metal cations have been considered in a monograph[228] and the advances in recent years are described in reviews[229-234].

3. The Biological Activity of Fluorine-containing β-Diketones

Several forms of the biological activity of non-fluorinated β-diketones are known. The antiviral activity of α-substituted β-diketones and its relation to their structure[235-239], the antiallergic activity of α-cyano-derivatives[240], and the inhibition of the central nervous system by and the weakening effect of α-amino-β-dicarbonyl compounds on muscles[241] have been reported. A weak antitumour activity of β-diketones has been observed[242]. Derivatives of β-diketones have been patented as insecticides[243] and herbicides[244]. Few data are available on the biological activity of polyfluoro-β-diketones. The insecticidal activity of BTFA derivatives[245] as well as the fungicidal activity of TTFA and benzofuroyltrifluoroacetone[246] have been reported.

TFFA is also known to have an effect on enzymes. It has been shown that TTFA inhibits the oxidation of succinates[247, 248] and lowers the activity of cytochrome reductase[249-262] and malate dehydrogenase[263]. The mechanism of the action of TTFA on enzymes has not been elucidated, but it has been suggested that TTFA interacts with the components of the respiratory chain and not with the enzymes themselves, the inhibiting effect being attributed to the ability of TTFA to form complexes with iron[251]. The differences in the effects of TTFA on various enzymes are most probably associated with the differences in the structures of the membranes and not with the differences in the structures of the enzymes[262], the inhibition in plant mitochondria being weaker than in animal mitochondria[264]. As regards other β-diketones, it is only known that AA and BA prevent the thermal inactivation of enzymes[265] and that furoyltrifluoroacetone inhibits the electron transfer in the oxidation of hexacyanoferrate in mitochondria[266].

4. Other Applications

Apart from their wide-scale employment for the separation and determination of metal cations, polyfluoro-β-diketones have also other less familiar applications. It has been established, for example, that TTFA retards the corrosion of engine cylinders[267]; HFAA has been recommended as an additive preventing gel formation in polymer solutions for spinning[268].

A number of fluorine-containing β-diketones have been patented as compounds imparting water repellant properties to paper[35]. 4,4,4-Trifluoro-1-(2-naphthyl)butane-1,3-dione has been patented as an additive increasing the light sensitivity of mixtures polymerisable by light[269], and TTFA is used in the membranes of ion-specific electrodes, particularly for Ca^{2+} ions[270,271], and for impregnating electrode membranes designed for the determination of 'onium ions[272].

---o0o---

Analysis of the present state of research into the chemistry, properties, and applications of fluorine-containing β-diketones permits the conclusion that, while the methods of their synthesis have been thoroughly developed and a number of their properties of applied and theoretical importance are known, many questions have still been little investigated. The study of the interaction of fluorine-containing β-diketones with eletrophiles (alkylation, acylation, reactions with fluoro-olefins, oxirans, and thi-irans), the expansion of studies on nucleophilic reactions, determination of quantitative data concerning the influence of the introduction of fluorine atoms on the properties and reactivity of β-diketones, as well as the study of reaction mechanisms are of interest. Studies and comparative estimates of the biological activity of fluorine-containing β-diketones and heterocycles based on them are promising.

During the preparation of the manuscript for the press, the synthesis of pentafluorobenzoylacetone (I, $R_F = C_6H_5$, $R = CH_3$) by the condensation of pentafluoroacetophenone with its enolate anion was reported. In view of the splitting of the signal due to the vinyl proton by the *ortho*-fluorine atoms, the authors postulate the enolisation of the resulting compound at the carbonyl group linked to the non-fluorinated substituent[273]. The existence of the enols of symmetrical β-diketones in the *cis*-form with an asymmetric hydrogen bond has been confirmed by photoelectron spectroscopy and it has been established that the upper limit to the barrier in the interconversion of the C_S-forms via the C_{2v}-form is 6 kcal mol^{-1}.[274] The ionisation potentials and the electronic spectra of TFAA and HFAA have been calculated[275]. It has been established by ^1H, ^{19}F, and ^{13}C NMR that the interaction of asymmetric fluorine-containing β-diketones with alcohols results in the preferential formation of adducts via the carbonyl group linked to the fluorinated substituent[276]; this confirms the mechanism of the interaction of β-diketones with nucleophiles described above. Pyrazolo-β-diketones have been obtained for the first time from fluorine-containing bis-β-diketones[277] and their high catalytic activity in the formation of polyurethanes has been established. A number of studies published during this period have been devoted to the interaction of polyfluoro-β-dicarbonyl compounds with urea[278] and its derivatives[279-281] and also to their condensation with amino-compounds containing a mobile hydrogen atom in the α-position: aminopyrazolone[282], aminocyclohexane[283], aminopyrazole[284], and substituted aminodihydroindole[285]. 1,2,3,3,8-Pentamethyl-7-oxo-5-trifluoromethyl-2,3,7,8-tetrahydro-1*H*-pyrrolo[3,2-*d*]quinoline has been patented as a source of blue-green laser radiation[285]. The formation of a γ-trifluoromethylpyridone in the condensation of TFAA with malonodinitrile has been demonstrated[286]. The polarographic reduction of polyfluoro-β-diketones has been investigated[287]. Numerous studies have been devoted to the

applications of polyfluoro-β-diketones in the extraction of metal cations[288–292].

Modern Theories of the Adsorption of Polymers on Solid Surfaces

Yu.S.Lipatov

Studies concerned with the theoretical description and experimental assessment of the state of adsorbed macromolecules as well as the experimental estimation of the thickness of the adsorption layer are examined. The methodological approaches based on modern physical and physicochemical procedures for the investigation of the structure of the adsorption layers are discussed and the accumulated experimental data are analysed in detail. The role of the configurational state of macromolecules in the adsorption layer and of its structure in the establishment of the properties of polymeric compound materials is emphasised.
The bibliography includes 71 references.

CONTENTS

I. Introduction 196
II. Theoretical description of the configurational state of adsorbed chain molecules 196
III. Experimental estimation of the structure of the adsorption layer 203
IV. Conclusion. 206

I. INTRODUCTION

Despite the large number of studies carried out on the adsorption of polymers from solutions on solid surfaces, questions associated with the theoretical description of the process and the experimental determination of its fundamental features still remain at the centre of attention. This is because it has not been so far possible to bridge the gap between theoretical predictions and experimental results. This review deals with the present state of the problem of adsorption on the basis of the results of studies carried out predominantly during the last five years. Hitherto the only surveys of this field have been a monograph[1] and reviews specially devoted to adsorption from concentrated solutions[2,3].

II. THEORETICAL DESCRIPTION OF THE CONFIGURATIONAL STATE OF ADSORBED CHAIN MOLECULES

One of the central problems of the theory of adsorption is that of the conformations of the adsorbed chains. In a number of studies, examined in detail previously[1], ideas were developed according to which adsorption takes place in the form of sequences of segments ["trains"], linked to the surface, and loops extending into the solution. The lengths of the trains and loops have been calculated by methods of statistical thermodynamics on the basis of the existing theories of polymer solutions as a function of the principal parameters of the polymer chain. In most cases simplified models, which do not take into account the real behaviour of macromolecules in solutions, were used for the calculations. Therefore, despite the fairly complex mathematical procedures, the theoretical density distributions of the segments of the polymer chain obtained near the surface permitted only a qualitative description of this distribution.

1. The Lal-Stepto Theory

A significant improvement of the model of adsorbed sequences of segments and loops was achieved by the studies of Lal and Stepto[4-6]. In contrast to the previous theories, in order to attain a better agreement between the results of the calculation and the real behaviour of the adsorbed chain, they took into account the excluded volume for the chain interacting with the surface and also considered the influence of the nature of the solvent, manifested by its interaction with the segments of the polymer chain and sites on the adsorbent surface.

However, the study was confined to the case of an isolated chain. It was based on the model of a chain on a tetrahedral lattice, the lattice sites being occupied either by chain segments or solvent molecules. The chain conformations in the lattice were calculated by the Monte Carlo method, with successive generation of different conformations. Homogeneous Markov sequences were generated with probabilities of a single-step transition P_{ij} specified in a way such that the resulting set of conformations was characterised by a Boltzmann distribution within the limits of a fairly long sequence. The conformations generated differed in their energies and, when the condition $U \leq 0$ was valid for the energy change in the generation of a new conformation, this conformation was adopted with a probability of unity, while in the case $U > 0$ the new conformation was adopted with a probability $\exp(-U/kT)$ and was rejected with a probability $1-\exp(U/kT)$. If the new conformation was rejected, the previous ("current") conformation was recalculated. In this case one can write

$$P_{ij}=1 \text{ for } U_j \leqslant U_i;$$

$$P_{ij}=\exp(-U_j/kT)/\exp(-U_i/kT) \text{ for } U_j > U_i;$$

$$P_{ii}=1-P_{ij}.$$

The initial conformation was selected arbitrarily as any allowed conformation. As stated above, the conformation whose energy U' was smaller or equal to the energy of the preceding conformation U was included in the sequence of chain conformations on the lattice, i.e. a random number x between 0 and 1 was selected and compared with the quantity

$$r=\exp(-U'/kT)/\exp(-U/kT).$$

If $r \geq x$, then each new conformation was added to the sequence of conformations and a sequence of any length could thus be constructed.

In previous studies no account had been taken of internal rotation. In the model developed here it was assumed that the transition from one conformation to another takes place as a result of changes in the rotational positions, following one after another, of only a small number of consecutive linkages (in the given case four), subject to the condition that the remainder of the chain does not undergo any changes. The position of this transitional region in the molecule is assumed to be stochastic in nature. Four is the minimum number of linkages which can be used to generate all possible chain configurations on a tetrahedral lattice.

In a calculation made by the Monte Carlo method account was taken of only those conformations in which the macromolecule interacted with the surface. The chain is then described by three energy parameters characterising the transition from the *trans*- to the *gauche*-conformations with an energy difference $\Delta\varepsilon_g$ (the *gauche*-conformation is known to have a higher energy). In the lattice account is taken of the energies corresponding to the following angles between groups of three or four bonds: 0°, +120°, and −120°.

We believe that the main disadvantage of the model[4] is the initial postulate in the calculations of the conformations of the adsorbed chain consisting in the assumption that one end of the chain is permanently fixed in the plane of the absorbent ("anchor" units). This postulate appears relatively unjustified and is not introduced by the same workers in other instances[6]. The normal excluded volume conditions for the lattice chain, namely the exclusion of multiple occupations of a single site in the lattice, were automatically included in the program for calculations of the conformations[6]. In addition account was taken of the interaction between segments at the nearest neighbouring sites with the aid of the parameter of the Flory theory:

$$\Delta\varepsilon_{12} = \varepsilon_{12} - \frac{1}{2}(\varepsilon_{11} + \varepsilon_{22}).$$

In the model proposed the solvent molecule and the segment occupying adjacent sites have an energy ε_{12}, the solvent molecules in the lattice have an energy ε_{11}, and the adjacent segments have an energy ε_{22}. Thus, when the configuration changes, the segment passes to a site adjoining another segment, two segment–solvent contacts are broken, and solvent–solvent and segment–segment contacts are formed, the overall energy change being $-2\Delta\varepsilon_{12}$. For a chain on a tetrahedral lattice, the number of possible non-bonded nearest neighbours in relation to a given chain segment is two. Hence, for an infinite chain and a random distribution on the lattice of both segments and solvent molecules, the quantity $2\Delta\varepsilon_{12}/kT$ can be set equal to χ (the usual Flory–Huggins interaction parameter). It is assumed that adsorption also takes place for negative adsorption energies:

$$\Delta\varepsilon_s = \varepsilon_{2s} - \varepsilon_{1s}.$$

The calculations were performed for $\Delta\varepsilon_g = 0$, and $\Delta\varepsilon_{12} = 0$, i.e. for a chain with free rotation and adsorption from an athermal solution. For numerical calculations, use was made of segment–surface energies of $-0.5kT$ and $-0.9kT$ and of numbers of chain segments $n+1 = 31$, 51, 76, and 101 (which correspond to 30, 50, 75, and 100 bonds). The calculations made it possible to determine the average fraction of the adsorbed segments $\langle\nu\rangle$ as a function of the adsorption energy $\Delta\varepsilon_s/kT$ for a chain of 100 segments[4] and also the average maximum thickness of the layer $\langle\tau_m\rangle$. The quantity $\langle\tau_m\rangle$ is expressed in units of the distance between two planes in the lattice, which is $\sqrt{2}l/\sqrt{3}$, where l is the "skeletal" bond length.

A general tendency in the variation of conformations in the adsorption layer is that the fraction of bound segments increases and the thickness of the layer diminishes with increase in the energy of the bond between the segment and the surface[6]. The changes in $\langle\nu\rangle$ and $\langle\tau_m\rangle$ following a change in chain length are more pronounced for weak adsorption; $\langle\nu\rangle$ and $\langle\tau_m\rangle$ are less sensitive to chain length than the adsorption energy. It follows from calculations that, when $\Delta\varepsilon_s/kT = -0.9$, the adsorbed molecule is tightly fitted on the surface and the slight increase of $\langle\nu\rangle$ and decrease of $\langle\tau_m\rangle$ with chain length indicate an increased compatibility between the chain and the surface with increase in chain length.

The use of the familiar scheme of adsorbed trains and loops, differing in the allowance for the presence of unbound tails, in order to describe the conformations of adsorbed macromolecules, makes it possible to estimate the changes (in units of the number of segments) in the average lengths of the trains $\langle L_{tr}\rangle$, loops $\langle L_l\rangle$, and tails $\langle L_e\rangle$ as functions of the energy of adsorption and to show that $\langle L_{tr}\rangle$ and $\langle L_l\rangle$ do not vary significantly with adsorption energy (the length of the trains increases, while the size of the loops diminishes as the adsorption energy increases).

The changes in $\langle L_e\rangle$ are more significant consequently, at least in the case of weak adsorption, the thickness of the adsorbed layer is determined by the length of the tails. For $\Delta\varepsilon_s/kT = -0.8$, $\langle L_e\rangle$ is twice as large as $\langle L_l\rangle$ for all chain lengths. For weak adsorption, the chain length is proportional to the length of the tail. Analysis of the size distribution of the trains and loops shows that it is very narrow, while that for tails it is very broad. The quantities $\langle L_{tr}\rangle$, $\langle L_l\rangle$, and $\langle L_e\rangle$ can be used to characterise the so-called average adsorbed chain. If these quantities are known, the number of trains and loops can be determined[6].

Suppose that m is the number of trains which can be found from the equation

$$m\langle L_{tr}\rangle + (m-1)\langle L_l\rangle + 2\langle L_e\rangle = n+1,$$

and the fraction of bound segments is

$$\nu' = m\langle L_{tr}\rangle/(n+1).$$

Thus the quantities m and ν determine, together with $\langle L_{tr}\rangle$, $\langle L_l\rangle$, and $\langle L_e\rangle$, the configurational characteristics of the average adsorbed chain. Such quantities have been calculated for different n and $\Delta\varepsilon_s/kT$.

The size and shape of the adsorbed chain can be treated also in terms of mean square dimensions of the molecule $\langle r^2\rangle$ and the radius of rotation $\langle s^2\rangle$. The ratio $\langle r^2\rangle/\langle s^2\rangle$ for the adsorbed chain and the chain with free rotation in solution depends on n. The quantities $\alpha_r^2 = \langle r^2\rangle/\langle r_0^2\rangle$, where $\langle r_0^2\rangle$ are the unperturbed dimensions in solution, have also been calculated. They indicate an appreciable extension of the chains on the surface.

The results of the calculations make it possible to describe also the density distribution of the segments with respect to the thickness of the layer for different adsorption energies. For $\Delta\varepsilon_s = 0.5kT$, the density of the segments changes little in the first layers near the surface and then slowly decreases. For strong interactions, the initial sharp fall of the density is followed by a very much slower decrease. For adsorption from a non-athermal solvent, the model of an anchored chain has been adopted and $\Delta\varepsilon_g = 1.0kT$ and $\Delta\varepsilon_s = -0.5kT$.[4] The calculations were performed for a chain consisting of 100 segments.

The quantities $\langle r^2 \rangle$, $\langle s^2 \rangle$, $\langle \nu \rangle$, and $\langle \tau \rangle$ were calculated (see Table). The calculation showed that, for good solvents ($\Delta\varepsilon_{12}/kT = 0.50$ and 0.00), the molecules exist on the surface in the extended state. In a bad solvent the chain conformation is close to that of a coil[5]. Calculation[4] showed that the average fraction of adsorbed segments increases as the solvent becomes less effective and the thickness of the layer diminishes.

Calculated values of $\langle r^2 \rangle$, $\langle s^2 \rangle$, $\langle \nu \rangle$, and $\langle \tau \rangle$.

On the assumption of the "anchored" model, the conformations of the adsorbed chains are illustrated schematically in Fig. 1,[4] and the density distribution of the segments is shown in Fig. 2.[4] The conformation is shown as the height of each segment above the surface in a non-dimensional representation. Fig. 1 shows that, in a good solvent ($\Delta\varepsilon_{12} = 0.5kT$), there is a distinct tendency towards the formation of long trains in the initial part of the chain and there is an appreciable fraction of non-adsorbed segments in the tails.

The formation of loops is less favoured and only a few configurations contain more than two loops. The configuration consists very often of a bound train and a tail.

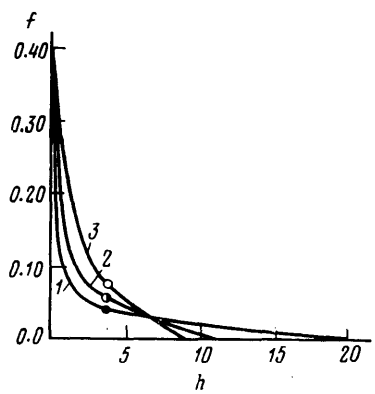

Figure 1. The calculated average fractions of bound segments in each successive layer over the plane of the adsorbent for different values of $\Delta\varepsilon_1$ (Clark et al.[4]); *1*) $0.5kT$; *2*) $0.0kT$; *3*) $-0.5kT$.

In a good solvent the repulsion of the segments leads to an extended rigid state of the chain together with a positive value of the parameter $\Delta\varepsilon_g$. This state induces a cooperative effect among the segments, leading to the formation of trains adjoining the anchored sections. This effect also leads to the appearance of groups of non-adsorbed segments behind the adsorbed train. Long trains and tails in a system with $\Delta\varepsilon_{12}/kT = 0.5$ can be regarded as the manifestation of the cooperative effect. The absence of loops can be attributed to the high energy required to bend the molecules.

In a bad solvent the probability of a strong interaction of the segments with one another and with the surface is a maximum. Therefore in the given case the molecules are in a tightly coiled state with a large number of segments bound to the surface. The presence of a relatively large number of loops is inevitable under these conditions.

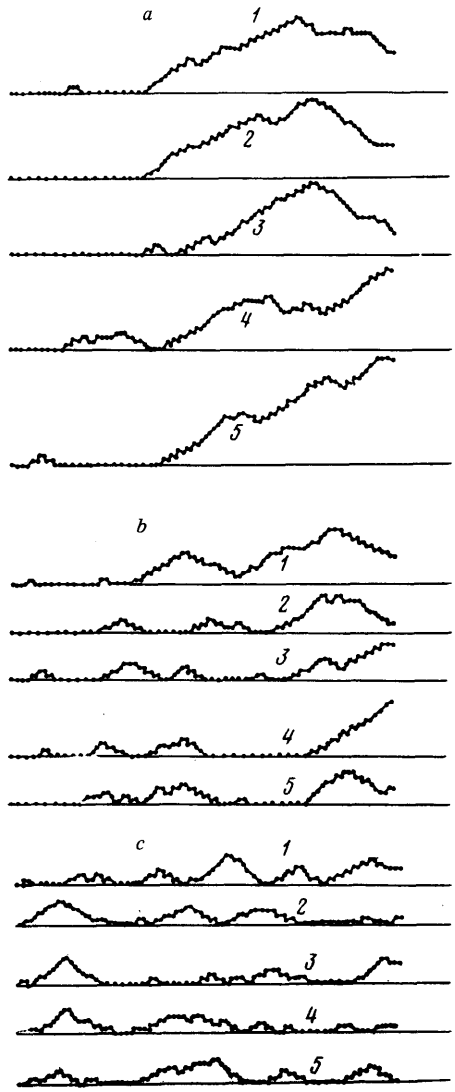

Figure 2. Certain typical configurations appearing with high frequencies in calculations by the Monte Carlo method[4]; $\Delta\varepsilon_1$: *a*) $0.5kT$; *b*) 0.0; *c*) $-0.5kT$; for the parameters of the curves, see Table.

The ideas of Lal and Stepto were described here in fair detail, since they must be regarded as a significant step forward in the theoretical description of adsorption, despite the fact that the model was developed for an isolated chain. On the basis of calculations of the conformations on a computer, the authors produced a cine-film demonstrating the behaviour of macromolecules near the interface and on the surface. This film was shown by Stepto at the IUPAC Microsymposium on Interfacial Phenomena in Prague in 1976. The film characterises the conformations of molecules in dynamic adsorption and desorption equilibrium and shows that in weak adsorption the molecules frequently leave the surface and assume the conformation typical for the molecules in solution. For strong adsorption, the molecule is retained closer to the surface and assumes an extended conformation. The author of this review was present at the showing of this film and can testify that the clarity of the representation makes it possible to illustrate the real picture of adsorption. A cartoon film characterising the behaviour of macromolecules in adsorption has also been made by Lumb[7].

2. The Hoeve Theory

Another fundamental approach to the theoretical estimation of the density distribution of segments in the adsorption layer as a function of the distance from the adsorbent surface is that developed by Hoeve[8-11]. The calculations were made for a single adsorbed chain consisting of n segments on the assumption that the loops are fairly large, but Hoeve did not take into account the effect of the excluded volume.

The number of segments at a distance from the surface in the range between z and $z+dz$ is defined as $n\rho(z)dz$, where $\rho(z)dz$ is the normalised function of the density distribution of the segments. The calculation performed for a one-dimensional lattice model yields[8]

$$\rho(z) = 4\pi^{1/4}\beta_1 C \exp[-4\beta_1 z(-\lambda)^{1/4}](1 + S_{-1/4} + S_{-3/4})^{-1}, \qquad (1)$$

where β_1 is determined by the condition

$$\beta_1^2 = 2\langle r_n^2\rangle_0/3n,$$

where $\langle r_n^2\rangle$ is the mean square distance between the ends of the free chain in the absence of volume effects, C a constant characterising the rigidity of the chain, λ the Lagrange multiplier, and $S_{1/2}$ and $S_{3/2}$ are functions of λ and of the size of the loops i.

Eqn.(1) is valid for $r > \delta$, where δ is the effective thickness of the segments adsorbed on the surface. It is seen that $\rho(z)$ is an exponential function of z for large loops and weak adsorption. For strong adsorption, the average size of the loops is small and the latter are not Gaussian chains. In this case the distribution depends on specific interactions, which are different for different chains. It is significant that in the chosen model there is a sharp decrease in the density distribution at distances from the surface exceeding the effective thickness of the segment $z = \delta$. In the adsorption layer near the surface ($0 < z < \delta$) Eqn.(1) is inapplicable; the fraction of bound segments is given by another relation and the density $\rho_a = P\delta^{-1}$, where

$$P = (1 + S_{-3/4})(1 + S_{-1/4} + S_{-3/4})^{-1}.$$

The density of the segments in solution at a distance $z = \delta$ is given by the equation

$$\rho(\delta) = K(1 + S_{-1/4} + S_{-3/4})^{-1},$$

where K is a numerical coefficient. Comparison of this equation with Eqn.(1) shows that the density falls for $z = \delta$.

For a real chain, more rigid than that assumed in the calculations, the decrease of density will be greater the more rigid the chain. This decrease is consistent with expectation, since there must be a compromise between the random distribution of the segments in all the layers and the greatest possible saturation of the first layer, where attraction takes place.

Hoeve[8] also calculated conformations taking into account the rigidity of the polymer chain. The rigidity parameter was introduced into the calculation of the number of random movements of the chain in a three-dimensional lattice in the form of a factor w when the step taken in the lattice was in the same direction as the previous one; if the step was taken in any of the four directions perpendicular to the previous one, the factor was unity.

The factor $w = \exp(-\varepsilon/kT)$, where ε is the difference between the energies of conformations in one of which two consecutive bonds lie in the same direction while in the other they are perpendicular to one another. If ε/kT diminishes, then w and hence the rigidity of the chain increase. In the limit, where ε/kT tends to an infinitely large negative value, the chain becomes rigid and rodlike. In the case where the first step in the lattice begins at the interface the partition function for a single chain is defined. The grand partition function for a chain fixed at one end at the interface is

$$\theta(s) = |E|^{-1}\{\{(\lambda - sw)^{-1} + s(1 - sw\lambda)^{-1}\}4s^2t +$$
$$+ \{s + s^2(\lambda - sw)^{-1} + s(1 - sw\lambda)^{-1}\}\{1 + (2 - w)st\}(1 - \lambda)^{-1}\};$$

where $s = \exp\mu/kT$, $|E|$ is a function of w, s, t and λ, and μ is the chemical potential of a monomer unit under the conditions of the equilibrium distribution of the N-mers bound to the surface by one end only; $t = \exp(-\varepsilon_a/kT)$, where ε_a is the adsorption energy (the necessary condition for adsorption is $\varepsilon_a < 0$ and $t > 1$) and λ is the Lagrange multiplier. The average number of bonds in the chain can be found from the equation:

$$\langle N\rangle = \partial \ln\theta/\partial \ln s$$

while the average number of bonds adsorbed at the interface is $\langle N_0\rangle = \partial \ln\theta/\partial \ln t$. Then at a distance from the surface the average number of segments in the layer is $\langle N_0^k\rangle = [\partial \ln\theta/\partial \ln u]$, where u is the exponent of the polynomial in the function describing θ. Calculations showed that, for low values of λ, the density of the segments decreases sharply on moving away from the surface and that the majority of the segments are adsorbed in the first layer. Only when λ approaches 1 does the density of the segments near the surface become appreciable. In the limit at $\lambda = 1$ the density of the segments near the interface is a maximum and constant for all the layers. The critical values of t for adsorption are in this case defined by the relation

$$t = (w+4)^2(w^2+6w+12)^{-1}.$$

Thus, whereas previously Hoeve[8] introduced the flexibility parameter C for the Gaussian chain, which is difficult to determine quantitatively, in the present model the flexibility of the chain is taken into account by the parameter w, which constitutes an advantage of the approach under consideration. For an adsorbed chain consisting of a sequence of adsorbed segments and loops, the following relation holds:

$$\theta = \theta_{tr} + \theta_{loop} = 1,$$

where θ is the grand partition function, which is a function of the ratio of the activities of the adsorbed and free chains and θ_{tr} and θ_{loop} are the grand partition functions for trains and loops. It can be shown that

$$\theta_{tr} = (w+2)st[1-(w+2)st]^{-1},$$
$$\theta_{loop} = 4s(\lambda - sw)\ (1-sw\lambda)^{-1}(w+2)^{-1}.$$

At the same time Hoeve[9] emphasises the unrealistic nature of the model which he chose, as well as all other models examined previously. However, he reaches the important conclusion that the sharp subdivision into surface and diffuse layers is artificial. In practice density as a function of distance depends on specific chain conformations. Unfortunately, the thickness of the layer cannot be determined exactly experimentally regardless of theoretical postulates. A specific density profile is usually postulated beforehand after which the average thickness of the layer is calculated.

Hoeve notes that in such calculations one cannot ignore the effect of the excluded volume, which is bound to occur in real systems as a result of the interchain interaction. However, one can assume that, in the diffuse layer beyond the interface[10,11], the effects of the excluded volume are insignificant if the volume fraction of the segments is much lower than at the interface.

3. Other Theories

The distribution functions examined above contain parameters which are virtually impossible to estimate for real systems. Despite this, the segment distribution functions have been modelled in a number of studies. Hoffman and Forsman[12] attempted to estimate the parameters of the distribution function on the basis of the Flory–Huggins theory of polymer solutions, but they began with the inadequately justified hypothesis that the adsorbed segments have the normal density. They analysed the Gaussian distribution and the distribution proposed by Hoeve[8] and proposed a double Gaussian model of the type

$$\rho = \rho_0[\exp\{-B^2(x^2+y^2)/\alpha_{xy}\}] \times [A\exp\{-z^2/B\} + (1-A)\exp\{-z^2/C^2\}],$$

where ρ is the density of the segments, α_{xy} the broadening factor for chains in the x and y directions, z the distance from the surface, x and y the distances along the surface, and A, B, and C are independent model parameters. In the z direction, perpendicular to the surface, the model can be reduced to the Gaussian distribution for $A = 0$ and is close to the Hoeve distribution for $B > C$.

A probability density distribution function has also been proposed[12] for the radius of inertia and has been used to represent the configurational entropy as a component of the free energy of the adsorbed molecules. A numerical algorithm has been proposed for the determination of the parameters of the distribution function by minimising the free energy at the interface. However, the calculations are very difficult and require a very large amount of computation.

A statistical method for finding the density distribution of the segments for an anchored chain has been proposed[13]. For a layer of constant density, the parameters of the distribution function have been determined from the equilibrium degrees of adsorption and the area of the monomer unit[14]. A distribution function taking into account the formation of surface layers of different thickness and the deformation of macromolecules in adsorption has been proposed[14] and used to estimate the average thicknesses of the layer. The results indicate a satisfactory description of the conformations of the macromolecules in the surface layer by the proposed distribution function and the possibility of its employment for the determination of the thickness of the adsorption layer.

Lax[15] examined the configurational behaviour of an isolated polymer molecule and the influence on the latter of the interaction with the solvent. The necessity for taking this into account was pointed out in an earlier study by Silberberg[16], who demonstrated theoretically that the influence of the solvent and concentration can induce appreciable conformational changes. Lax calculated the conformations by generating random self-avoiding movements in the lattice in the presence of an interacting rigid barrier. Relations were obtained for the mean square distance between the ends of the chain $\langle R_N^2 \rangle$ corresponding to different numbers of segments N and different adsorption energies and for the average and mean square distances from the end of the chain to the surface $\langle z_N \rangle$. Calculations showed that the latter quantities, determined taking into account the influence of the interaction with the solvent, are large. The average maximum quantity $\langle z_N^{max} \rangle$ increases with decrease in adsorption energy. The average numbers of segments on the surface have also been calculated as functions of the adsorption energy and the attainment of saturation for high energies ($\varepsilon > 2.2\ kT$) has been demonstrated.

The influence of the excluded volume of the conformations of the adsorbed polymers has also been examined in a study[17] where it was assumed that the density of the adsorbed molecules is high and homogeneous and that partial overlap of the molecules and their interaction take place on the surface. An expression was found for the critical value of the free energy of the adsorbed segments:

$$\varphi_c = \varphi_c^0(1 + 6n\nu z_0/l^2 + \ldots),$$

where ϕ_c^0 is the critical free energy of the adsorption of the segment at the θ-point, n the total number of adsorbed segments, l the bond length, z_0 the range of action of the adsorption potential, and ν the excluded volume defined by

$$v = (1/2 - \chi/V_2^2)V_1$$

(χ is the interaction parameter and V_2 and V_1 are the volumes of the segment and the solvent molecule).

The average thickness of the adsorption layer is

$$t(\gg z_0) = t_0(1 + 6n\nu t_0)/l^2,$$

where t_0 is the average thickness of the layer at the θ-point.

In recent years Hesselink developed a model of the structure of the adsorption layer[18,19], according to which the adsorption layer consists of a dense first layer, at whose boundary there is an abrupt change in the density of the segments, and of a loose layer of tails and loops directed towards the bulk of the solution. Hesselink[19] determined for a cubic lattice the distribution of the units in a macromolecule adsorbed by its end in a tail of i segments and in a loop (adsorption via two terminal groups) using a method similar to that developed by Hoeve[14].

The following function has been obtained for the distribution of segments in a molecule attached via the tail[19]:

$$\rho_1(x) = 6\,(il_c^2)^{-1} \int_x^{2x} \exp\{-3t^2/2il_c^2\}\,\mathrm{d}t,$$

where x is the distance from the surface, i the number of segments in the macromolecule, and l_c the length of the segment. The distribution of the segments in the loop is

$$\rho_2(x) = 12\,(il_c^2)^{-1} \exp\{6x^2/il_c^2\}\,.$$

From these equations, it is possible to find the mean square distance between the segments and the surface. For a chain attached at one end, $\langle x^2\rangle = \frac{7}{18} il_c^2$, and for a chain attached at two ends, $\langle x^2\rangle = \frac{1}{6} il_c^2$. This calculation shows that the loop is more tightly compressed on the surface than the tail comprising the same number of segments only by a factor of $\sqrt{7/3}$. This distribution can be applied also to a chain adsorbed by several loops, provided that the number of segments in each loop is the same. This problem was examined in detail by Hesselink[19], who analysed statistically the changes in the configurational properties of adsorbed macromolecules as an impermeable surface is approached.

The distribution functions have also been calculated for the adsorption of the molecules of copolymers in which the size distribution of the loops is determined by the distribution of the lengths of sequences of different units. The distribution curve for the case of a large number of loops is less steep than for the distribution in the case of only one loop. It is significant that in the adsorption of a copolymer via one loop the density in the immediate vicinity of the surface is lower than at some distance from the latter. This is because in a homopolymer any segment can be sorbed, while in a copolymer only a segment capable of interaction can be sorbed[19].

Next Hesselink examined the configurational free energy of the tails, loops, and bridges formed by macromolecules between particles (in connection with the consideration of the problem of the stabilisation of colloid particles and the behaviour of macromolecules between two adsorbing planes). The case of the mutual approach of particles coated by adsorbed molecules, where the adsorption layers should be capable of interpenetration, was examined; the density distribution of the segments in the tails and loops then changes as the two surfaces approach one another[20].

It has been suggested[21,22] that the density of the segments decreases with the distance from the surface and that the effective density of the adsorption layer is related to the average size of the loops in the same way as the change in the density of the segments $\rho(\tau)$ of a free coil with the distance from its centre of gravity is related to the number of segments in the macromolecule, i.e. it is assumed that $\rho(\tau) = \rho_{\text{eff}}$ for $\tau = \Delta$ (Δ is the thickness of the layer). This is a fairly rough approximation, since the density distribution of the segments in solution is Gaussian and that in the adsorption layer is in most cases exponential.

Theoretical calculations of the density distribution of the segments and of the thickness of the layers are important for the description of processes involving the stabilisation of dispersed particles by polymers or their flocculation. These problems, associated with the structure of the adsorption layer, have been discussed in detail in a number of studies[20,23,25]. They are based on the postulate of the adsorption interaction of the macromolecules with two flat plates.

Using a simple model of the macromolecules adsorbed on two parallel plates with a specific surface area A and separated by a distance L, it is possible to calculate the resultant pressure on the plates under conditions of repulsion associated with configurational entropy[24]. Neglecting the adsorption of the polymer on the surface, the conformations of a chain with a specified length N, beginning at a point r on the surface and terminating at a point r' in the gap between the plates, are then calculated by statistical methods. The free energies can then be found from the expression for the partition function for such a chain and can be used to obtain the effective pressures. For plates remote from one another ("short" polymer chains) and for plates close to one another (long chains), the following equations have been found (l is the chain length):

$$p = -\frac{1}{A}\frac{\partial F}{\partial L} = \frac{kT}{AL}\left[1 + \frac{2}{\pi^{1/4}}\left(2\,\frac{Nl}{3L^2}\right)^{1/4}\right],$$

for the case where $2Nl/3L^2 \ll 1$ and

$$p = \frac{kT}{AL}\left[\frac{4\pi\rho^2 N}{3L^3} + 1 \ldots\right].$$

for $2Nl/3L^2 \gg 1$.

These theoretical results show that the polymer adsorbed on the surface can stabilise colloid particles by virtue of the repulsion due to the entropy factor. On the other hand, flocculation can occur in the case of strong adsorption of polymer segments on the surface of the colloid particles.

4. The Adsorption Isotherm of Compact Macromolecules

In the studies discussed above the problem of adsorption isotherms, which had been the subject of thorough investigations in previous years[1], was not considered. A new feature in this field is Silberberg's attempt[26] to derive an equation for the adsorption of compact macromolecules, which include those of biopolymers present in solution in the form of dense self-aggregated globules. It is assumed that the electrostatic effects specific to given systems are of secondary importance compared with the large size of the macromolecules (for a high ionic strength of the solution and a sufficient charge separation in the molecules) and one considers a compact ("cubic") macromolecule whose volume is greater by a factor P than that of the solvent molecule. In a three-dimensional lattice such a macromolecule occupies P sites. If each site in the lattice has c_B neighbours in the

bulk phase and c_S neighbours on the surface, then the macromolecule itself in its natural coiled conformation is characterised by the following number of interactions:

$$\frac{1}{2}Pc_B-(P-1)-\frac{1}{4}P_S(c_B-c_S),$$

where P_S is the number of segments on the surface of the compact molecule. In adsorption z out of the P_S outer segments are bound to the surface. Then, for a cubic molecule, the adsorption would extend from the surface into the bulk phase over $1/p=P/z$ layers, forming the surface phase, among which only the first layer is in direct contact with the surface, but all the $1/p$ layers have the *same* concentration of polymer segments (in contrast to the adsorption of the usual flexible chains)[26] (here p is the fraction of segments bound to the surface).

If there are M^S sites and N_p^S polymer molecules on the surface and N_0^S solvent molecules form the surface phase, then

$$(1/p)M^S=N_0^S+PN_p^S.$$

If the system contains N_p^T polymer molecules and N_0^T solvent molecules, then the bulk phase contains $N_p=N_p^T-N_p^S$ polymer molecules and

$$N_0=N_0^T-N_0^S=N_0^T-(1/p)M^S+PN_p^S$$

solvent molecules.

We shall define $\theta=xN_p^S/M^S$ and $\Phi^*=PN_p/(N_0+PN_p)$ as the degree of surface coverage and volume saturation. For specified M^S, N_p^T, and N_0^T, these quantities are a function of N_p^S alone. If the unmixed pure polymer phase comprising N_p^T molecules and the solvent phase comprising N_0^T molecules in contact with M^S sites are regarded as the initial state, it is possible to determine the number of different configurations on mixing in contact with the surface subject to the condition that all the configurations have the same energy. When there is a difference between the energies of the configurations, i.e. when the energies of the polymer–polymer, solvent–solvent, and polymer–solvent junctions are different, it is possible to determine the energy of mixing of the macromolecules with the solvent in the presence of a surface:

$$\Delta U/kT=\chi(c_pz/c_BP)(PN_p)N_0/(N_0+PN_p)+$$
$$+\chi\{(c_p-1)z/c_BP\}(PN_p)N_0^S/(N_0^S+PN_p^S)-\chi_S(z/c_{SB}P)(PN_p^S),$$

where χ is the usual Flory–Huggins parameter, χ_S a parameter characterising the sorption of a flexible molecule, and c_p the coordination number.

Starting with these postulates, one can find the partition function determined by the maximum in the derivative of $\Omega\exp(-\Delta U/kT)$ with respect to the single independent variable N_p^S:

$$\partial\ln[\Omega\exp(-\Delta U/kT)]/\partial\ln N_p^S=0.$$

Hence we obtain finally an expression for the adsorption isotherm:

$$\ln(\theta/\Phi^*)=P\{\ln(1-\theta)/(1-\Phi^*)+p\ln p+(1-p)\ln(1-p)+$$
$$+(p\chi/c_B)[c_p(1-2\Phi^*)-(c_p-1)(1-2\theta)]+p\chi_S/c_{SB}\}.$$

Comparison of the theoretical isotherms obtained by plotting the number of equivalent monolayers $\theta/p=P^{1/3}\theta$ against the volume fraction of the polymer in the solvent with the degree of adsorption of flexible chains shows that the degree of adsorption of compact chains is greater and the fraction of the polymer on the surface $p=P^{-1/3}$ and the degree of surface coverage θ are smaller than for flexible chains. Consequently the surface layer is less compact. Calculation also shows[26] that in this case the possibility of a change in conformation in the surface layer (the uncoiling of the chain) plays an insignificant role.

However, in real systems, in the case of the adsorption of charged and compact macromolecules, there is a possibility of other relations. It has been shown[27] that there is virtually no adsorption of poly(methacrylic acid) (PMAA) in the globular unionised form from aqueous solutions. However, the nature of the adsorption of ionised PMAA [28] is determined by the charge on the adsorbent surface (the ζ-potential of its particles). The surfaces of alumina and quartz are negatively charged and the degree of adsorption of negatively charged macromolecules diminishes. Thus electrostatic effects, which cannot be described by statistical theories of adsorption, can play a decisive role in the given case.

The complexity of the theoretical description of the adsorption interaction of polymers with the surface of a solid absorbent consists in the fact that in such systems a number of inter-related phenomena occur during the adsorption process. It has now been established that the degree and nature of adsorption depend significantly on the formation of aggregates of macromolecules and the development of coagulation in the disperse phase[2,3,20]. On the other hand, the adsorption of the polymer is responsible for the establishment of a new aggregate–macromolecule equilibrium and also alters the rate of coagulation of dispersions. As a consequence of such correlation, an unambiguous interpretation of the experimental data obtained is in many instances impossible.

For a theoretical determination of the mechanism of the adsorption interaction at the interface, it is necessary to consider also the kinetics of all the processes occurring in the adsorption of macromolecules in the dispersions, namely the adsorption and aggregation of macromolecules and the coagulation of the disperse phase. Such a treatment, carried out by Lipatov et al.[29], has been based on Smoluchowski's kinetic equations for the coagulation of dispersions[30]. If macromolecules and their aggregates are considered as separate kinetic units, analogous to colloidal particles, then the kinetics of the aggregation of macromolecules and the kinetics of adsorption can be described by analogous equations.

The system of differential equations thus obtained cannot be solved analytically but, with the aid of numerical methods, it is possible to obtain on a computer the overall time pattern of the changes in the number of macromolecules, the particles of the solid phase, and their aggregates, as well as adsorbed macromolecules as functions of the size distribution of the micro-objects. The size distribution functions of macromolecules, the particles of the disperse phase, and the adsorbed macromolecules, characterising

the establishment of an equilibrium between the macromolecules, the particles of the solid phase, and their aggregates as a function of time and making it possible to follow the transition from the initial to the final equilibrium, were thus obtained.

5. The Application of Computer Modelling Methods in the Calculation of the Conformations of Adsorbed Chains

Computer modelling methods have been widely used recently to estimate the conformations of adsorbed polymer chains[31-35]. The configurational properties of oligomers have been calculated by the total sorting method, based on the generation of all possible N-unit chains, with subsequent extrapolation to high polymers[33]. Computer modelling has been carried out for chains with $N \leq 14$ on a cubic lattice with four selections, the energy of the junction between a section of the chain and the surface being varied from 0 to $1.5kT$. The number of segments on the surface, the number of returns to the surface (the number of loops), the length of the normal from the end of the molecule to the surface and its square, the distance from the surface to the most remote segment, and the distance between the ends of the chain were determined. These computer simulations showed that, with increase of adsorption energy, the mean square distance between the ends initially diminishes to a minimum at $-\varepsilon/kT = 0.375$ and then increases. The curves relating the number of loops to $-\varepsilon/kT$ pass through a maximum at $-\varepsilon/kT = 0.75$.

Thus the extremum values of different properties of the polymer chain are observed for different energies of their interaction with the surface. The calculations demonstrated the validity of the empirical relations $\langle R_N^2 \rangle = \alpha N^{\gamma}$, where α and γ are constants. For $-\varepsilon/kT \cong 0.5$, the quantity γ is close to 1.30, while for high interaction energies γ increases until it reaches, at $-\varepsilon/kT = 0.875$, the value 1.47 characteristic of two-dimensional lattices (1.50). This finding demonstrates the virtually complete adsorption of the polymer on the surface for $-\varepsilon/kT \geq 0.875$. It has been shown that, for energies $-\varepsilon/kT \geq 0.75$, the average distance between the most remote atom of the chain and the surface is less than two lengths of the chain.

The mean squares of the distance between the ends of the chains $\langle R_N^2 \rangle$ and of the radius of inertia $\langle s_N^2 \rangle$ as well as the average number of closed chains (not only beginning but also terminating on the surface) have also been estimated[32]. The conformational characteristics have been calculated for $N \leq 14$ and for different values of $-\varepsilon/kT$. It has been shown that, for open chains at $-\varepsilon/kT \to 0$, surface effects do not play any role, the ratio $\langle s_N^2 \rangle / \langle R_N^2 \rangle = 0.1314$, and the power exponent $\gamma = 1.20$. With increase of $-\varepsilon/kT$, these quantities change somewhat and the ratio $\langle s_N^2 \rangle / \langle R_N^2 \rangle$ diminishes sharply only for $-\varepsilon/kT \geq 1.6$ (critical value). The oligomer chain is then virtually completely sorbed on the surface. The behaviour of closed chains obeys another statistic. For such chains, $\langle s_N^2 \rangle / \langle R_N^2 \rangle \to 0.200$ and $N \to \infty$. It has been noted that the models considered in computer simulations are also useful for the derivation of information about the entropy effect associated with the folding of the chains in crystals, about the role of configurational effects in the stabilisation of colloidal solutions, etc.

The dependence on the molecular weight of the first and second moments of the extent of the chains attached to the surface at one end (by extent, we understand the maximum distance between the planes bounding the chain segments[34]) has also been calculated by the method of the total sorting of configurations. The calculations were performed for a tetrahedral lattice with prohibition of self-intersections of the chain and $N = 5-14$. It was shown that, if the average extent is represented by the expansion $\langle x_N \rangle = AN^{\gamma} + BN^{\gamma-1} + \ldots -1$, then the asymptotic value of γ for the adsorbed chains at $1/N \to 0$ is 0.53, which is somewhat smaller than the corresponding value for chains which do not interact with the surface (0.61). The mean square of the radius of inertia $\langle s_N^2 \rangle$ is proportional to a $N^{1.27}$ according to calculated data, i.e. the power exponent for adsorbed chains differs from the exponent characteristic of all non-intersecting three-dimensional chains (6/5). Apart from the average characteristics, different distribution functions have also been obtained[34]. It has been shown that they change sharply if, instead of the prohibition of self-intersections, one introduces the parameter of the interaction between chain segments. If this parameter is sufficiently large, certain distribution functions become bimodal or multimodal.

One should note that the average changes in the internal and free energies, the entropy, the heat capacity, and the effective coordination number have been calculated as a function of $-\varepsilon/kT$ by the total sorting method for non-intersecting chains at the boundary with the surface[35]. For certain values of $-\varepsilon/kT$ (1.8), the plots of C_V/k against $-\varepsilon/kT$ (C_V is the heat capacity at constant volume) pass through a maximum, which indicates a second-order phase transition. At the transition point the mean squares of the distance between the chain ends and of the radius of inertia reach a minimum. When the specific energy of the interaction of the chains with the surface is attained, the system becomes two-dimensional, which corresponds to the adsorption of the polymer on the surface.

The machine experimental methods in relation to problems of the adsorption of polymers were developed further by Birshtein and coworkers[36-39]. It was shown that increased rigidity of the chain facilitates the adsorption process and increases the fraction of adsorbed units. It follows from the results of [38,39] that, in the region of strong interactions with the sorbent, the chain "spreads out" on the surface via its extended sections. Calculation of the free energy of adsorption showed that, for the critical energy of adsorption, the polymer chain undergoes a second-order phase transition, which is consistent with Lax's results[35]. The computer simulation also made it possible to estimate the fraction of chain segments linked directly to the surface as a function of chain length and the adsorption energy[38]. The calculation of the structure of the chains in the surface layer[39] is also of interest.

III. EXPERIMENTAL ESTIMATION OF THE STRUCTURE OF THE ADSORPTION LAYER

Despite the different attempts to calculate the conformation of adsorbed chains near the interface, a direct comparison of the results of such calculations with experiment still does not yield satisfactory agreement. This is because in the majority of calculations simplifying assumptions, which do not hold in real systems, are made. For example, one always calculates the conformation of isolated chains, whereas all the experimental results reflect the existence of a large number of chains competing for surface sites. As a result, the conformations of real chains are very different from those calculated theoretically for isolated chains. From this standpoint, the experimental estimation of the conformations of adsorbed chains and of the thickness of the adsorption layer is still of significant interest.

1. The Hydrodynamic Thickness of the Adsorption Layer

Theoretical ideas concerning the hydrodynamic thickness of the adsorption layer, based on fundamental hydrodynamic equations, have been developed[40]. The calculations are based on the following experimental fact: the rate of flow of the polymer solution through a capillary diminishes as a result of the adsorption of the polymer on the walls. The measurement of this change makes it possible to calculate the hydrodynamic thickness of the adsorption layer, which is defined as follows:

$$L_H = R[1-(I_v/I_v^0)^{1/4}],$$

where I_v and I_v^0 are the volumes of the liquid which pass through the capillary in the presence and in the absence of the polymer for the same shear stresses and R is the radius of the capillary.

The ratio I_v/I_v^0 is a complex function of R, b (where b is the average distance between the given monomer unit and the wall of the capillary), and the shielding factor b/d, where $d=(\eta/fn_0)^{1/2}$, η is the viscosity of the liquid, n_0 the density of the segments in the first layer at the surface, and d the frictional force between the polymer molecules and the liquid. An exponential distribution of the density of the segments near the interface and the parameters introduced in Hoeve's theory were used for the theoretical calculations. Theoretical relations between L_H and R/b were plotted for a number of values of b/l, for different volume fractions of the polymer in the first layer, and for three different chain lengths.

Comparison of the theoretical calculations with experiment showed that L_H varies linearly with the intrinsic viscosity $[\eta]$ and that the experimental thickness of the layer is of the order of magnitude of the size of the coil in the polymeric solvent. This yields the conclusion that the dimensions of the polymer coils are not distorted in the adsorption process[40].

The behaviour of the adsorbed molecule in the layer in contact with the flowing solvent is significant for the determination of the hydrodynamic thickness relative to the thickness of the adsorption layer of the polymer. This problem has been considered theoretically[41] on the basis of the Rouse-Zimm model for a polymer chain attached to the surface by one end. The main result of the calculations of the dynamic behaviour of the chain was to show that, in the Brownian movement of the anchored chain, the energy scattering exceeds by a factor of two the corresponding value for a free molecule in solution. These effects are attributed to the influence of the surface on the number of accessible conformations of the macromolecule.

Methods are available for the determination of the thickness of the layer from the apparent increase in the effective volume of the dispersed particles carrying the adsorption layer, which is determined viscometrically using an equation of the Einstein type and from sedimentation data[42,43].

The thickness of the layer is calculated with the aid of the sedimentation coefficient, which can be expressed in terms of the thickness of the layer δ and its density ρ_z for a particle with a radius a and a density ρ_1 in a liquid having a density ρ_0 by the following equation:

$$s^0=[2a^2(\rho_1-\rho_0)+2(3\delta a^2+3a\delta^2+\delta^3)\times(\rho_2-\rho_0)]/9\eta_0(a+\delta),$$

where s^0 has been adjusted to the zero concentration of particles. It is then assumed that the adsorption layer is a rigid impermeable cell. The density of the layer is determined as follows:

$$\rho_z=0.997+2.39\cdot10^{-7}\cdot4\pi a^2\Gamma/[{}^4/_3\pi(a+\delta)^3-{}^4/_3\pi a^3],$$

where Γ is the degree of adsorption on the plateau of the isotherm. When account is taken of this, one obtains

$$s^0=[2a^2(\rho_1-\rho_2)+1.434a^2\Gamma\cdot10^{-6}]/9\eta_0(a+\delta),$$

which is in fact used for the calculations[42,43].

As a result of the sedimentation and flocculation of particles coated by the adsorption layer, the rate of sedimentation decreases and the sedimentation half-period and the sedimentation volume increase, which can, in principle, yield information about the thickness of the adsorption layer. Thus the adsorption of poly(vinyl alcohol) has been studied[43] in the form of fractions with different molecular weights on polystyrene. It was found that the degree of adsorption and the thickness of the adsorption layer δ, calculated from the sedimentation data, increase with increase of $\bar{M}_w^{1/2}$. The volume occupied by the macromolecule in the adsorbed state is approximately equal to the volume of the effective hydrodynamic sphere of the poly(vinyl alcohol) molecules in the solution. However, δ is smaller than the effective hydrodynamic diameter of the polymer coils in solution. The results were interpreted in terms of the possible deformation of the coils without the mutual interpenetration or compression of neighbouring adsorbed macromolecules.

2. Calorimetric Methods

The use of direct calorimetric measurements of the heats of adsorption of polymers and the establishment of relations between them and adsorption isotherms, which makes it possible to estimate the enthalpy of adsorption and the number of bound segments, constituted definite progress in the study of adsorption[42,44-46].

The integral heat of adsorption is determined by the relation

$$-\Delta H(\theta)=-n\Delta H_{P,A}+n\Delta H_{L,A}+n\Delta H_{P,L}+\Delta H_{P,P},$$

where n is the number of points on the surface coated by the polymer segments, $\Delta H_{P,A}$ the enthalpy of binding per mole of monomer units, $\Delta H_{L,A}$ the heat of wetting per mole of active points on the surface, $\Delta H_{P,L}$ the enthalpy of desolvation per mole of adsorbed monomer, and $\Delta H_{P,P}$ the energy of the interaction of the adsorbed polymer molecules. If the last term is neglected, then

$$-\Delta H(\theta)=-n(\Delta H_{P,A}-\Delta H_{L,P}-\Delta H_{L,A}),$$

i.e. the enthalpy of adsorption is proportional to the number of centres on the surface and to a constant enthalpy contribution (the expression in brackets).

The differential enthalpy of adsorption is

$$D_A=\frac{d\Delta H(\theta)}{dN}=\frac{dn}{dN}(\Delta H_{P,A}-\Delta H_{L,P}-\Delta H_{L,A}),$$

where $N = A/M_M$ is the number of adsorbed polymer molecules in monomer units, A is the amount of the adsorbed polymer in grammes, and M_M the molecular weight of the monomer unit; thus D_A is a measure of the fraction of segments bound to the surface[46]. The enthalpies of adsorption of poly(ethylene glycols) of different molecular weights on aerosil have been determined experimentally. A linear dependence of the enthalpy of adsorption on the extinction coefficient of the band associated with the hydrogen bonds between poly(ethylene glycol) and aerosil (3300 cm^{-1}) was also established. The energy of the binding of poly(ethylene glycol), amounting to 41.4 kJ per mole of SiOH, which corresponds to the energy of the hydrogen bonds, was found from the enthalpy taking into account the density of the SiOH groups on the surface (which is 2.74/100 A^2).

The heat of adsorption data show that, along the initial sections of the isotherms, approximately 50% of the segments are bound, in satisfactory agreement with the estimates of the fraction of bound segments by infrared spectroscopy, and $p = 0.2-0.5$ at saturation. Thus calorimetric measurements yield, in principle, the same conclusions concerning the conformations of the macromolecules in the boundary layers as the other methods used previously[1]. However, calorimetric measurements yield more information about the mechanism of the adsorption and the interaction. The enthalpy of the adsorption per segment estimated from calorimetric data depends on the competing effects of the polymer–adsorbent, polymer–solvent, and solvent–polymer interactions[42].

A strong interaction between the solvent and the surface leads to a lower enthalpy of adsorption per segment than in the case of a non-polar solvent. In order to obtain a definite enthalpy of adsorption in a polar solvent, it is necessary that the degree of binding of the macromolecule be greater than in a non-polar solvent, which leads to a more planar conformation of the adsorbed macromolecule and to a smaller thickness of the adsorption layer.

In principle, when one considers the adsorption of polydisperse polymers, one must also consider the influence on adsorption of the particular level of thermodynamic incompatibility of fractions having different molecular weights, which follows from the dependence of the Flory–Huggins interaction parameter for the fraction χ_{23} or the parameter X_{23} of the new Flory theory on the composition of the mixture of polymer homologues[47]. A partial incompatibility of fractions of different molecular weight leads to the formation of molecular aggregates, which can be adsorbed on the surface independently. This follows from direct adsorption measurements[48], demonstrating the adsorption of aggregates of different structure, for a fairly broad molecular weight distribution, from solutions in a thermodynamically poor solvent.

In this connection one should note that at one time a number of workers[1] estimated the so-called isosteric heats of adsorption. The present state of the problem shows that these estimates cannot be regarded as correct. A change of temperature entails a change in the conformation of the polymer chain and in the interaction of the macromolecules with one another and with the solvent. As a consequence of this, when the temperature is altered, the conditions governing the junction between the macromolecule and the surface are different and the number of bound segments and hence also the overall enthalpy of adsorption per macromolecule (or the number of bound units) are not the same. One should also take into account the different adsorbabilities of high- and low-molecular-weight fractions and in principle the different temperature variations of their solubilities. All this suggests that the required results can be obtained only by the direct experimental determination of the heats of adsorption, as was done for the first time by Killmann et al.[42]

3. Spectroscopic Methods

The structure of adsorption layers has been studied by infrared spectroscopy[49] for linear saturated aliphatic polyesters and polystyrene. When the adsorbent is aerosil, the polyester is bound by hydrogen bonds on adsorption, as expected, which makes it possible to estimate the fraction of bound segments readily by infrared spectroscopy. For polyesters, this fraction is $p = 0.80$, which indicates the formation of layers with a relatively small number of loops. On the other hand, polystyrene does not interact with more than 50% of the surface hydroxyls via its benzene rings. The experimental adsorption isotherms can be described by the equation of the Langmuir isotherm.

Continuation of studies of the adsorption layers of various polymers by ellipsometric methods by Killmann and coworkers[50,51] permitted the subsequent development of a method based on the construction of isotherms for the thickness of the layer, the polymer concentration in the surface layer, and the degree of adsorption as a function of the solution concentration as well as the same quantities at saturation as a function of the molecular weight of the polymer. The influence of the molecular weight and the polarity of the polymer or adsorbent on these characteristics was established and a conclusion was reached concerning the possible conformations of the macromolecules in the adsorbed layer, which corresponds to the features already described and in our view leads to only isolated refinements in relation to specific polymers.

Thus it has been established that the thickness of the adsorption layer is described by the Mark–Houwink relation $d = KM^{\alpha}$, where M is the molecular weight and K a constant. For adsorption in the form of isolated coils, $\alpha = 0.5$ and for molecules extended on the surface, $\alpha \to 0$. An increase of α from 0.15 for low coverages to 0.5 for high coverages confirms the hypothesis that the conformation of the adsorbed chain depends on the solution concentration (degree of surface coverage). The dependence of the mean square thickness of the layer at the maximum solution concentration investigated (5 mg ml^{-1}) on the square root of the molecular weight (straight line) confirms that in the region of high concentrations the molecules are adsorbed in the form of a θ-coil[50,51].

Methods for the estimation of the conformations of adsorbed chains, based on the use of electron paramagnetic resonance (EPR)[52,53] have been developed in recent years together with the infrared spectroscopic method for the determination of the fraction of segments adsorbed on the surface. For this purpose, one uses polymers with a spin label, which gives rise to three lines in the EPR spectrum; their form and width being determined by the rotational correlation time. For a polymer adsorbed at the solid–solution interface, providing the spin label is distributed at random along the chain and does not influence the adsorption process, the differences in the mobilities of the side groups of the chains are clearly manifested in the width of the spectral lines and in their positions. The segments adsorbed in the form of trains on the surface have shorter correlation times than the segments in loops.

The adsorption of the *N*-vinylpyrrolidinone–allylamine copolymer on aerosil has been studied by this method[53]. The label was introduced by the interaction of the polymer via its NH_2 groups with 4-isothiocyanato-2,2,6,6-tetramethylpiperidine oxide (one label for five polymer molecules).

The ratio of the number of segments in the loops to the ratio of the number of segments in the adsorbed trains can be estimated from the EPR data for the linear polymer subject to the assumption made above. However, one cannot then take into account segments with intermediate mobility, i.e. the segments in the loops but close to the surface. Since the complex spectrum can be resolved into two simple spectra, it is suggested that the number of such segments is small compared with the total number of segments. It has been established by this method[52,54] that the conformation of the polymer chain varies from relatively planar to a conformation characterised by the presence of loops with increase of surface coverage of the adsorbent. This follows from the dependence of the fraction of adsorbed segments p on the degree of surface coverage.

Thus the overall pattern revealed by the EPR method is consistent with that already described on the basis of the results of measurements by other methods. However, the following result is of interest. It has been shown that, when an additional portion of pure sorbent is added to the sorbent saturated by the adsorbed polymer, a significant increase of the degree of binding of the segments p, determined by NMR, is observed[53]. This demonstrates the formation of bridges between different sorbent particles bound to the macromolecule, which is important for understanding the mechanism of the interaction of the dispersed particles following the introduction of polymer molecules into the disperse system. The authors suggest[53] that this effect is associated with the fact that some of the segments present initially in the loop are converted into an adsorbed train of segments as a result of the adsorption of added particles on the unoccupied surface. The formation of a bridge implies that some of the molecules pass from an adsorption-saturated particle to an unsaturated particle, which can entail an increase of p.

The application of the EPR method in the study of the influence of the solvent on the conformation of the adsorbed molecule showed that an impairment of the "thermodynamic quality" of the solvent leads to an increase of the fraction of segments in the trains of segments bound to the surface, which conflicts with Hoeve's data[10] showing that the size of the loops increases with "impairment" of the solvent.

The conformations of adsorbed chains have been studied experimentally[54] by high-resolution NMR in adsorption of poly(methyl methacrylate) on silica gel. The method is based on the decrease in the molecular mobility of the adsorbed chains (segmental mobility). Its advantage over infrared spectroscopy is its applicability to the study of stereoregular polymers. Isotactic and syndiotactic polymethacrylates served as the objects of study. The complete disappearance of the signal associated with the segmental mobility, observed by the authors, shows that the polymer forms a large number of contacts with the surface and that the loops formed are relatively short and immobile. Isotactic poly(methyl methacrylate) is adsorbed preferentially relative to the syndiotactic polymer, as shown by data for the adsorption of their mixture.

The NMR method has also been used to determine the molecular mobility in adsorption layers of polystyrene and polycarbonate on aerosil; it is significant that the measurements were performed in the adsorption system itself without separating the adsorbent[55]. The experimental data obtained demonstrated the dependence of the mobility at a given solution concentration on the adsorbent content, which made it possible to regard the structure of the adsorption layers as one formed by adsorbed isolated loops and chain aggregates, in agreement with the concepts developed by the present author[2,3].

4. Colloidal-Chemical Methods

Interesting possibilities for the estimation of the thickness of adsorption layers of polymers arise from the measurement of the ζ-potential of colloidal particles coated by the adsorbed layer of polymer. However, this method can be applied only to adsorbent particles of colloidal dimensions. When it is used, one measures simultaneously the degree of adsorption of the high-molecular-weight substance and its influence on the electrokinetic potential of the particles[56-58]. It is assumed that the decrease of the ζ-potential with increasing degree of adsorption of the polymer is due to the displacement of the slip plane to the bulk of the solution as a result of the formation of the polymer layer on the surface and that the adsorption of the polymer does not entail a change in the distribution of charges in the diffuse ionic layer. In this case[59]

$$\tanh\left(\frac{ze\zeta}{4kT}\right) = \tanh\left(\frac{ze\psi_\delta}{4kT}\right)\exp\left[-\varkappa(\Delta-\delta)\right].$$

On the basis of this equation, it is possible to calculate for each measured electrokinetic potential the distance of the slip plane from the surface, which is assumed to be the thickness of the adsorption layer. In this equation e is the elementary charge, δ the thickness of the Stern layer, ψ_δ the potential at the boundary of the Stern layer for which one adopts[58] the ζ-potential at the initial (unprotected polymer) sol, and $\varkappa$ the Debye radius.

This method has been developed in detail for polymer-stabilised sols by Kocherga and Baran[60], who determined also the dependence of the thickness of the layers on the degree of adsorption of polymers. According to their data, the thickness of the adsorption layers increases monotonically with increasing degree of adsorption, reaching 100–200 Å, which is in good agreement with other data. The fact that the thickness of the layer depends in the first place on the degree of adsorption and not on the molecular weight of the polymer led to the conclusion that the average length of the adsorption loops also depends little on the molecular weight[60,61]. However, it must be emphasised that the determination of the thickness of the polymer layers on the surface of colloidal particles from electrophoretic measurements constitutes a fairly rough approximation.

At the same time comparison of the thickness of the layers[61] of poly(ethylene oxide) with the dimensions of the macromolecules in solution permits the conclusion that the polymer chains are appreciably deformed on adsorption. The experimental data obtained by this method suggest that the degree of deformation of the coils in the adsorption layer decreases with increasing rigidity of the macromolecular chains[25,60].

IV. CONCLUSION

The problem of the conformations of the macromolecules and of the structure of the adsorption layers is closely related to the elucidation of the mechanism of the adhesion of polymers to solids. However, in this case we are dealing with an adsorption interaction uncomplicated by the presence of a solvent in the system.

The problem of macromolecular conformations in adsorption layers in polymer compositions, i.e. in the absence of a solvent, is very important from the theoretical and practical points of view. Few experimental data have as yet been obtained on the thicknesses of the adsorption layers in the

absence of a solvent and on the conformations of macromolecules in such layers[62-66]. The single theoretical study by Silberberg[67] concerning adsorption in the absence of a solvent is of significant interest. The initial postulate was that adsorption leads to two main consequences—to an increase in the extent of the interfacial zone, where there is a transition from one homogeneous phase to another, and to an appreciable alteration of the conformation of the macromolecules in this region.

The theoretical models of the adsorption considered previously, the most general form of which is that developed by Silberberg, do not predict interfacial zones of considerable thickness. In the usual models of loops of different dimensions the distribution of segments is described by an exponentially decreasing function of the distance from the surface with a characteristic width proportional to the average length of loops. For chains with a large molecular weight, this model predicts that their size is independent of the molecular weight and the observed dependence of the thickness of the surface phase on the molecular weight cannot therefore be explained. For this reason, the model which is more realistic takes into account the influence of "tails" and postulating that the thickness of the layers is determined mainly by the "tails" [19,67] and not by the loops and that the number of segments in the loops is smaller than in the "tails" (this is consistent with the results of the studies by Lal and Stepto described above). The distribution of the segments in the tails should depend on the molecular weight.

Silberberg[67] considered theoretically the distribution of the segments in a pure polymer phase (in the absence of a solvent) in contact with the surface. The treatment is restricted to completely flexible chains whose arrangements correspond to identical energies and are equally probable. It is assumed that, at a distance h from the surface, the macromolecules are not subject to its influence, i.e. their conformations are unperturbed. The molecules in the layer with a thickness h adjoining the surface are then perturbed. By introducing the distribution functions for the density of the segments at different distances from the surface and the distribution functions of the centres of gravity of the macromolecules, the author obtained simple expressions for the number of macromolecules adsorbed by a unit surface ("perturbed") in the form

$$h/PV_0,$$

where P is the number of segments and V_0 the volume of the segment. Among this number, on average PV_0/A_0h segments of each chain are adsorbed on the surface, A_0 being the area per segment on the surface. The fraction of adsorbed segments is then

$$p = V_0^{1/3}/h.$$

Since h is comparable to the mean square radius of rotation at least as regards the order of magnitude, $h \cong V_0^{1/3}P^{1/2}$, it follows that

$$p \simeq 1/P^{1/2}.$$

On the basis of this estimate, Silberberg concluded that the width of the interfacial zone is proportional to the average radius of rotation and that in this region only a small section of the segments are in actual contact with the surface and that the "tails" exert the dominant influence on the thickness of this zone. According to Silberberg, the extent of the interfacial region is a consequence of the fact that the unperturbed macromolecules cannot approach the surface to a distance shorter than the radius of rotation and the remaining space is therefore filled with macromolecules with perturbed conformations. Because of this, the adsorbing surface exerts a significant influence on the form of the distribution functions of the segments and the centres of gravity of the macromolecules. This concept is closely related to the concept of the long-range influence of the surface on the structure of the adsorption layer, developed previously by the present author[1], and therefore confirms theoretically the numerous experimental facts that accumulated in earlier studies[1,68].

The above analysis of experimental data shows that, despite the definite progress achieved in recent years in the study of the structure of adsorption layers, and the development of fairly reliable methods for the estimation of their thickness, the problem of the conformations of the macromolecules at the interface remains open. The present author believes that this situation to some extent reflects that which has arisen in the study of molecular conformations in the amorphous state, where conflicting views exist[69-71]. At the same time it is evident that further investigation of this problem is of primary importance for the physical chemistry of polymeric compound materials.

Study by ESR and Optical Spectroscopy of Transition-metal Ions in Zeolites and of Their Complexes with Adsorbed Molecules

V.D.Atanasova, V.A.Shvets, and V.B.Kazanskii

Studies by ESR and optical spectroscopy of zeolites containing transition-metal ions are reviewed. The locations of transition-element ions introduced into zeolites of various types by cation exchange and identified by these techniques are generalised. It is shown that these methods give useful information on the accessibility of the ions by adsorbed molecules and on the electronic structure of the complexes formed by the interaction betweeen adsorbed molecules and transition-metal ions. The properties of these complexes are discussed. 122 references.

I. INTRODUCTION

Cation-exchange forms of zeolites are being used increasingly as catalysts, adsorbents, etc., and many papers on these materials have been published recently. ESR and optical (u.v.) spectroscopy methods have been used to identify the state of the cations in the zeolites, especially in the case of zeolites containing transition-metal ions. Very detailed information has been obtained by these methods: not only the valency and co-ordination states, and the localisation sites of the ions, but also the complexes formed by the interaction of the ions with various adsorbed molecules have been identified.

Mikheikin and coworkers[1] have reviewed the application of spectral methods of investigation to zeolites containing transition-metal ions, and the results obtained, but many new papers have appeared since that review was published. The more recent results have resolved the inconsistencies in some of the earlier work. A new review of the subject therefore seemed desirable.

The present review includes the whole of the work which has come to our notice since the publication of Mikheikin's review[1]. Most of the papers which we shall quote describe studies of ions from the first transition period (Ti–Cu), but we shall also discuss the more recent (and not very extensive) work on ions of metals from the second and third transition periods. With a few exceptions, dictated by the need for clarity in the discussion, we have avoided reference to work mentioned in Ref.1. The discussion is arranged in order of increasing atomic number of the transition elements incorporated in the zeolite, and the nomenclature used by Breck to denote the different localisation sites has been adopted[2].

II. IONS OF THE METALS FROM THE FIRST TRANSITION PERIOD

1. Titanium

The electronic configuration of the ground state of the atom is $(A)(3d)^2(4s)^2$, where (A) is the complete electronic structure of the argon atom. Titanium-containing type Y zeolites have been prepared and studied by ESR.[3] Ion exchange was carried out in an aqueous solution of $TiCl_3$, and it was assumed that after exchange the Ti^{3+} ions are located in the large zeolite holes[3].

Adsorption of oxygen and sulphur dioxide on these samples (after dehydration at 500 °C) produces ESR signals with the parameters $g_1 = 2.0196$, $g_2 = 2.0089$, $g_3 = 2.0031$, and $g_1 = 2.001$, $g_2 = 2.003$, $g_3 = 2.004$, assigned to the O_2^- and SO_2^- anion-radicals respectively. Adsorption of N_2O, followed by heating at 200 °C, gives an ESR signal with the parameters $g_1 = 2.017$ and $g_2 = 2.001$, tentatively assigned to the O^- anion-radicals. Since the adsorption centres are accessible to O_2, SO_2, and N_2O molecules they probably consist of Ti^{3+} ions localised in S_{II}, $S_{II'}$, or possibly S_{III} sites.

2. Vanadium

The electronic structure of the ground state of the atom is $(A)(3d)^3(4s)^2$. Vanadium has been introduced into zeolites only in the form of the vanadyl ion VO^{2+}. The localisation and mobility of vanadyl ions in type X and Y zeolites as a function of the degree of dehydration of the zeolite has been studied in detail by ESR at 77–300 K.[4]

Fully hydrated type Y zeolites at 20 °C give ESR spectra with the parameters $g_\parallel = 1.944$, $g_\perp = 1.978$, and $A_\parallel = 175 \times 10^{-4}$ cm^{-1}, $A_\perp = 70 \times 10^{-4}$ cm^{-1} (I), whereas at 77 K the spectral parameters are $g_\parallel = 1.938$, $g_\perp = 1.986$, $A_\parallel = 178 \times 10^{-4}$ cm^{-1}, $A_\perp = 70 \times 10^{-4}$ cm^{-1} (II). Reversibility of these spectral changes was demonstrated by dehydration at 350 °C followed by rehydration. In this case the dehydrated samples give an ESR signal with the parameters $g_\parallel = 1.917$, $g_\perp = 1.989$, $A_\parallel = 190 \times 10^{-4}$ cm^{-1}, $A_\perp = 79 \times 10^{-4}$ cm^{-1} (III), whose intensity increases with the dehydration temperature. Dehydration at temperatures above 350 °C gave irreversible changes in the intensity of the ESR signals, suggesting changes in the zeolite structure.

Both at −196 and at 20 °C the ESR spectra of fully hydrated type X zeolites gave a signal with the parameters $g_\parallel = 1.943$, $g_\perp = 1.983$, $A_\parallel = 170 \times 10^{-4}$ cm^{-1}, $A_\perp = 60 \times 10^{-4}$ cm^{-1} (IV), whereas after dehydration of the sample at 350 °C the parameters of the signal became $g_\perp = 1.989$, $g_\parallel = 1.918$, $A_\parallel = 178 \times 10^{-4}$ cm^{-1}, $A_\perp = 66 \times 10^{-4}$ cm^{-1} (V).

Spectra (I) and (IV) are similar to those of vanadyl ions in aqueous solution, and have been assigned[4] to VO^{2+} ions in large zeolite holes. Spectra (III) and (V) are believed to arise from VO^{2+} ions also localised in large holes but co-ordinated to OH^- or oxygen ions from the zeolite lattice. All these complexes have distorted octahedral surroundings with C_{4h} symmetry.

A study[5] of type Y zeolites containing vanadyl ions has shown that the VO^{2+} ions are stabilised mainly in S_{III} (and some S_{II}) sites by dehydration at temperatures up to 350 °C. Interactions between neighbouring vanadyl ions can be detected at exchange levels higher than 20%.

3. Chromium

The electronic configuration of the ground state of the atom is $(A)(3d)^5(4s)^1$. The commonest oxidation states of the chromium ions in solution under ordinary conditions are Cr^{3+} and Cr^{6+}. Because of the difficulty of introducing complexes with a charge greater than three into the zeolites all the work so far reported (with a few exceptions[6–8]) has been on zeolites prepared by exchange with trivalent chromium compounds.

Leaving aside the work on the localisation sites and on the properties of Cr^{3+} in zeolites, which has already been reviewed[1], we shall examine only the most recent work. The following zeolites have been studied[9,10] by ESR: CrNaA (8% exchange), CrNax (9.3% exchange), and CrNaY (13.6% exchange). The complex ions $Cr(H_2O)_6^{3+}$ and $Cr(NH_3)_6^{3+}$ were shown to be present, after exchange, in the S_{IA} and S_{II} sites of the type A and X zeolites and in the large holes of the type Y zeolites. We should note that in type A zeolites the symbol S_{IA} denotes the cation stabilisation sites in the hexagonal windows of oxygen ions giving access to the cubo-octahedra[2] whereas in type X and Y zeolites the same sites are denoted S_{II} or $S_{II'}$ (depending on the side of the window plane in which the cation is stabilised). Treatment of the zeolite in a stream of dry air at 350 °C causes oxidation of the Cr^{3+} ions to the Cr^{6+} and Cr^{5+} states, though the proportion of quinquevalent cations is always small. Between 80% (type A) and 30% (type X) of the originally present Cr^{3+} ions is oxidised. The parameters of the ESR spectra of the Cr^{5+} ion in oxidised chromium-containing A, X, and Y zeolites are consistent with the formation of chromyl ions (CrO^{3+}) in an octahedral configuration. The perpendicular component of the ESR spectra showed a hyperfine structure assigned[9,10] to the aluminium atoms of the zeolite skeleton. However, the proposed model includes four oxygen ions from the lattice as equatorial ligands, which it is difficult to reconcile with the suggestion that the cations are localised preferentially in S_{II} (or S_{IA}) sites to give a C_{3v} (or D_{3h}) symmetry. We should also note that the oxidation of chromium ions to Cr^{5+} and Cr^{6+} must involve some breakdown of the zeolite crystal lattice[1].

Vogt and coworkers[11,12] studied CrNaY zeolites with different chromium content by optical spectroscopy, and showed that on dehydration the chromium ions are localised initially in S_{II} sites (at 200 °C), then in $S_{I'}$ or $S_{II'}$ sites (400 °C) and lastly (at least partly) in S_I sites (500–600 °C). The occupation of S_I sites is inferred from the appearance of absorption bands at 14 300 and 18 800 cm^{-1}. This red shift from the spectrum of the hexa-aquo complexes (16 400 and 23 600 cm^{-1}) is explained by postulating that the lattice oxygen is a weaker ligand than the oxygen in a water molecule. Similar conclusions were obtained from X-ray diffraction studies.

Vacuum heat treatment at 450 °C suppressed the ESR signal from the Cr^{3+} hexa-aquo complex ions[11,12], indicating a transition from octahedral co-ordination of the chromium ions to a tetrahedral co-ordination distorted along a trigonal axis[1]. This conclusion was confirmed by measurements of magnetic susceptibility as a function of temperature. It was pointed out that heat treatment in a stream of dry air at 450 °C causes breakdown of the zeolites as a result of the oxidation of the Cr^{3+} ions to Cr^{5+} and Cr^{6+}. Breakdown is produced also by dehydration of the chromium-containing zeolites when the degree of exchange is more than 40%. Breakdown of the crystal structure of chromium-containing zeolites under oxidising conditions was first suggested in Ref. 13.

Thus the work published since the last review[1] is mainly a confirmation of previous results. The only novel feature is the discovery of Cr^{3+} ions in S_I positions in samples dehydrated at 500–600 °C.[9,10]

We shall now review the work on the adsorption of some molecules on chromium-containing zeolites. Formation of cation radicals has been observed during adsorption of naphthalene, anthracene, and perylene on CrNaY samples heat treated in a stream of air at 150–400 °C,[14] and ascribed to interactions of the Cr^{6+} ions with adsorbed molecules in the large zeolite holes. However, as we have already pointed out, the chromium-containing zeolites tend to break down under these conditions, and it is no longer legitimate to assume the presence of large holes.

The adsorption of nitric oxide and nitrogen dioxide on chromium containing type Y zeolite and mordenite is discussed in Ref.15. If the zeolites are oxidised at 500 °C the adsorption of NO and NO_2 produces ESR signals only from molecules loosely bound to the surface, whose characteristic ESR spectra are well known. However, if the same molecules are adsorbed on zeolites which have been reduced in hydrogen after the oxidising treatment a new ESR signal appears ($g_\perp = 2.000$, $g_\parallel = 1.917$ for both molecules and both types of zeolite): this is ascribed to the formation of complexes with the d^5 electronic structure (Cr^+NO^+ and $Cr^+NO_2^+$ for the NO and NO_2 molecules respectively). These complexes are formed by the interaction between the adsorbed molecules and the Cr^{2+} ions produced by the reducing treatment. We should once again point out that although the zeolites used in this work[15] had been reduced in hydrogen they had been previously subjected to an oxidising treatment, which must have destroyed the crystal structure and produced an amorphous alumina–silica. This probably explains why identical complexes were obtained with faujasite and mordenite.

Studies of zeolites containing Cr^{2+} ions introduced directly from solutions have also been reported[6–8]. Kellerman and coworkers[6] studied the adsorption of oxygen on Cr(II)NaA zeolite dehydrated at 300 °C, and concluded that the Cr^{2+} ions (stabilised mainly in S_{IA} sites) produce weak oxygen complexes at room temperature, with optical spectra characterised by absorption bands at 4000, 10 000, 14 200, 18 000, 20 600, and 26 200 cm^{-1}. Further work[7] showed that trigonally co-ordinated Cr^{2+} ions can form weak complexes with N_2O, CO_2, and C_2H_4 molecules also at room temperature. In this case the Cr^{2+} ions adopt a distorted tetrahedral co-ordination. At 150 °C the adsorption of O_2 and N_2O is dissociative, with formation of Cr^{4+} ions by oxidation of Cr^{2+}. The Cr^{4+} ions have an approximately tetrahedral co-ordination consisting of three oxygen atoms from the zeolite skeleton and one from the adsorbate. This latter oxygen atom can react with CO at 300 °C, thus re-establishing the initial valency and co-ordination state of the chromium ions.

A detailed study of type Y zeolites containing Cr^{2+} ions (prepared by exchange with a solution of $CrCl_2.4H_2O$) has been reported from our laboratory[8]. Dehydration of these zeolites at temperatures up to 500 °C was not accompanied by breakdown of the crystal structure for degrees of exchange up to 70%. The following results were obtained with samples in which the degree of exchange was 14%. The optical spectrum of the zeolite dried in a vacuum at room temperature had an absorption band at 13 500 cm^{-1}, characteristic of octahedrally co-ordinated Cr^{2+} complexes. Dehydration at 500 °C causes this band to split into two (12 200 and 16 200 cm^{-1}) as a result of a change in symmetry of the co-ordination sphere and of the formation of co-ordinationally unsaturated Cr^{2+} ions. Dehydration also causes replacement of the water ligands by oxygen from the zeolite skeleton, as shown by the shift of the charge-transfer absorption peak from 38 000 to 30 000 cm^{-1}. Adsorption of water or ammonia re-establishes the octahedral co-ordination of the Cr^{2+} ion. The formation of weak ethylene complexes at room temperature was also reported. The accessibility of the Cr^{2+} ions in dehydrated zeolites to various adsorbed molecules suggests that these ions are stabilised in S_{II} or $S_{II'}$ sites.

We also showed[8] that the redox properties of the Cr^{2+} ions in dehydrated zeolites are different from those of the same ions in solutions or on the surface of SiO_2. The co-ordinationally unsaturated Cr^{2+} ions in dehydrated zeolites are more stable in an oxygen atmosphere, and their valency is not changed by adsorption of oxygen at room temperature. The only effect of oxygen adsorption is the formation of weak complexes between O_2 molecules and Cr^{2+} ions, characterised by maxima in the optical spectrum at 12 000, 16 600, 18 300, 21 200, 28 000, and 31 000 cm^{-1}.

4. Manganese

The electronic structure of the ground state of the atom is $(A)(3d)^5(4s)^2$. Only bivalent manganese ions have been introduced into zeolites by ion exchange. Since the intensity of the d–d absorption bands of the Mn^{2+} ions is low, optical methods of investigation have not been widely used. On the other hand, manganese-containing zeolites have been studied in depth by ESR because the ESR signals from Mn^{2+} ions can be observed over a wide range of temperature and concentration.

The ESR work published up to 1972 is described in detail in Ref.1. That work established the existence of Mn^{2+} ions in zeolites in different co-ordination states, but it left unresolved a number of inconsistencies in the treatment of the experimental results.

More recent work on manganese-containing zeolites was reported by Tikhomirova and coworkers[16–20] and by Taranukha and coworkers[21–24]. The samples examined contained, in addition to manganese ions, the cations Li, K, Cs, Mg, Ca, Co, Sr, Ba, La, or Y. The Mn^{2+} ions, introduced to an extent of 0.05–2 ions per elementary cell, were used as paramagnetic probes.

Tikhomirova and coworkers[16–20] studied manganese-containing zeolites of types Y and A. The ESR spectra were measured at Q band (35 GHz). The localisation sites of the Mn^{2+} ions were identified from the change in g-factor and from the splitting between the central components of the hyperfine structure, and also from the width of the first and the sixth component, which allowed the different spectra to be clearly distinguished. Measurements on manganese-containing sodalite and erionite (in which hexagonal prisms are absent) gave, for the first time, pure ESR spectra which could be assigned with full confidence.

By analysing the spectra of samples before and after dehydration these workers concluded that in type Y zeolite ion migration occurs in the direction large hole → $S_{II}(S_{II'})(O_h)$ → $S_{II}(S_{II'})(T_d)$ → $S_{I'}$ → S_I, and in the opposite direction during hydration[20]. The adsorption of ammonia, pyridine, and some other molecules also causes Mn^{2+} ions to migrate along the zeolite skeleton.

It was also noted that the changes in the ESR spectra accompanying dehydration and the adsorption of various molecules are very sensitive to the nature of the second cation present in the zeolite. Thus, in the dehydration of CaY and CdY zeolites these cations effectively block the S_I sites and impede the penetration of manganese ions. In the MgY zeolite a significant fraction of the Mn^{2+} ions can find its way into S_I sites, and in ZnY all the S_I sites are occupied

by manganese ions. These results are explained[20] by postulating a heat of dehydration of the Mn^{2+} ions greater than that of Ca^{2+} and Cd^{2+} ions but smaller than that of Mg^{2+} and Zn^{2+} ions. Since the S_I sites are accessible only to ions which have lost the whole of their co-ordinated water they should be occupied, in the first instance, by the ions with the lowest heat of hydration, as is found in practice.

The existence in type Y zeolites of Mn^{2+} ions in octahedral, distorted octahedral, tetrahedral, and lower symmetry configurations has been confirmed by ESR and by optical and luminescence spectroscopy[21-24].

5. Iron

The electronic structure of the ground state of the atom is $(A)(3d)^6(4s)^2$. Relatively few studies of iron-containing zeolites by ESR have been reported, and none by optical spectroscopy. The first publication[25] on this topic described a study by ESR and magnetic susceptibility measurements, showing that dehydration of the ammonium form of a type Y zeolite (10^{-2} at.% Fe) produces ferromagnetic structures with $g_{eff} = 2.4 \pm 0.1$ and $\Delta H = 1600$ Oe. It was assumed[25] that the diameter of the ferromagnetic particles is less than 20 Å, and their composition is $Al_{3-x}Fe_xO_4$ (where $x \leq 3$).

Other work[26,27] on iron in zeolites has relied on ESR and luminescence methods. The Na and NH_4 forms of zeolite Y and mordenite (0.1 wt.% Fe) were studied in this way. The initial zeolites contained isolated Fe^{3+} ions in tetrahedral co-ordination, as shown by the ESR spectra ($g_{eff} = 4.3$) and the luminescence spectra. As the zeolites are dehydrated at temperatures up to 600 °C the ESR signal is gradually suppressed, and the ESR spectra of the dehydrated ammonium forms of both zeolite types develop a broad signal with $g_{eff} \cong 2.3$ which is ascribed to the formation of ferromagnetic particles. In the Na forms a weak signal from ferromagnetic particles is observed only from the type Y zeolite dehydrated at temperatures above 500 °C. This behaviour is explained[26,27] in terms of the deficit of Na^+ ions in the type Y zeolite ($Na^+ : Al^{3+} = 0.97$).

The ESR method has been used also to study FeNaY zeolites containing Fe^{3+} ions introduced from a solution of $FeCl_2$ (27% exchange)[28]. The ESR spectrum immediately after exchange was almost indistinguishable from that of the initial NaY zeolite, and consisted of a single broad line. Dehydration led to the appearance of a signal with $g \cong 4.31$, whose intensity increased with the dehydration temperature. This signal was assigned[28] to Fe^{3+} ions in a co-ordination "substantially" different from octahedral". By using the molecular probe method it was concluded that the Fe^{3+} ions are localised in $S_{I'}$ ($S_{II'}$) sites.

Ref. 29 describes a study of iron-containing type Y zeolites prepared by exchange with an iron thiocyanate solution. The ESR spectra obtained after exchange include a signal from Fe^{3+} ions in a distorted octahedral configuration with $g \cong 3.75$. Heat treatment of the samples in a stream of He at 550 °C lowered the width of the signal by a factor of 2 without affecting the g-factor, which the authors ascribe to changes in both the relative position and the immediate surroundings of the Fe^{3+} ions. Heating the samples in a hydrogen–nitrogen mixture at 350 °C (the temperature of incipient reduction of the iron) produces a signal with $g = 2.04$ ($T_{meas} = -196$ °C) which is assigned to Fe^{2+} ions. Reduction in the same atmosphere at 550 °C causes the formation of metallic iron and the appearance of ferromagnetism. By comparing the ESR results with those of nuclear gamma-resonance (NGR) (i.e. Mössbauer) spectroscopy the authors conclude that in this gas mixture the transition from Fe^{3+} to Fe^0 takes place through the Fe^{2+} state in the range 350–550 °C. They also showed that the crystal structure of the iron-containing zeolites is distorted in the reduced samples.

The interactions of adsorbed NO and NO_2 molecules with bivalent iron ions in NaY zeolites and in mordenite have been studied[30] by ESR and i.r. spectroscopy. Two types of nitrosyl $Fe(I)NO^+$ complexes, differing in the effective spin number ($S = 3/2$ and $S = 1/2$), were detected. The high-spin complexes are formed by the adsorption of nitric oxide at pressures of several Torr, and are characterised by the parameters $g_\perp = 4.07$ and $g_\parallel = 2.003$. When samples containing high-spin complexes are treated in a vacuum at 25–100 °C this ESR signal is gradually replaced by a new signal with $g_1 = 2.015$, $g_2 = 2.055$, $g_3 = 2.089$, produced by the low-spin complexes. The complexes are formed by the interaction of the NO molecules with Fe^{3+} ions, involving the transfer of the unpaired electron from the molecule to the cation. The adsorption of NO_2 molecules on these zeolites leads to oxidation of the Fe^{2+} ions to Fe^{3+} ions (in a distorted tetrahedral co-ordination). The ESR spectra contain, in addition to the signal from these ions, a characteristic triplet with $g = 2.005$ and $A = 56$ Oe, assigned to NO_2 molecules vibrating in the zeolite holes. Since the samples used in that work[30] had been reduced in hydrogen the possibility of a breakdown in their crystal structure[29] must be borne in mind.

An extensive investigation by Krzyzanowski[31-36] of Fe-containing type Y zeolites revealed that the Fe^{2+} ions are easily oxidised to Fe^{3+} in oxygen. Though the main theme of that work was the formation of radicals during the adsorption of unsaturated hydrocarbons and benzene on cerium-containing zeolites, FeY zeolites were shown to have very similar properties in respect to radical formation. Kinetic measurements by the ESR method led to a mechanism of radical formation involving the transfer of an electron from the oxygenated adsorbed species to the organic molecule. In the case of FeY zeolites these species are diamagnetic, and their structure is thought to be O_x^{2-}, where $x = 2$ and (or) 1.

Paramagnetic forms of adsorbed oxygen have been observed on reduced iron-containing FeNaHY zeolites: O_2^- anion radicals and oxygen-containing particles stable up to 500 °C whose structure has not been established[37]. Even small amounts of iron (≤0.07 wt.%) added to NaHY and LiY zeolites have been shown to induce the formation of these oxygen radicals following oxygen adsorption, the Fe^{2+} ions acting as electron donors.

6. Cobalt

The electronic structure of the ground state of the atom is $(A)(3d)^7(4s)^2$. Whereas very few papers on cobalt-containing zeolites had been published when the previous review[1] was written, in recent years these systems have attracted much attention. Klier[38,39] has extended his early work[1] on CoNaA zeolites, and has shown that in the hydrated zeolites the Co^{2+} ions are located in large holes as the $[Co(H_2O)_6]^{2+}$ hexa-aquo complexes, giving an absorption band at 19000 cm^{-1} in the optical spectrum. Dehydration of the zeolites causes localisation of the Co^{2+} ions at the centres of triangles of oxygen ions forming the windows of cubo-octahedra (S_{IA} sites). The adsorption of cyclopropane, olefin, and acetylene molecules causes complex formation between these molecules and the Co^{2+} ions: the complexes have a distorted

tetrahedral co-ordination consisting of three oxygen ions from the zeolite skeleton and one adsorbed molecule. The adsorption of ammonia and water molecules is accompanied by complex formation followed by a change in co-ordination in the sequence triangle → tetrahedron → octahedron, depending on the amount of adsorbate present.

An ESR study of CoNaA zeolites is reported in Refs. 40 and 41. The dehydrated zeolites at 4.2 K give a signal with $g_{\parallel} = 2.003$ and $g_{\perp} = 5.7$, consistent with localisation of the Co^{2+} ions in a trigonal co-ordination (S_{IA} sites). The hydrated zeolites give a signal with $g_{\parallel} \cong 2.2$ and $g_{\perp} \cong 5.1$, assigned to hexa-aquo cobalt complexes in large zeolite holes. We should note that data on the localisation of Co^{2+} ions in dehydrated type A zeolites obtained by ESR and optical spectroscopy methods agree with X-ray structural studies[42] of these zeolites, according to which the Co^{2+} ions are localised near the centres of the entry windows of the cubo-octahedra, with a slight shift (0.16 Å) from the plane of the window towards the centre of the hole.

There is general agreement[43–48] that the cobalt ions in hydrated X and Y zeolites are present as $Co(H_2O)_6^{2+}$ complexes in the large holes. Upon dehydration of the CoX zeolites the Co^{2+} ions acquire a tetrahedral co-ordination, and become stabilised in S_{II}, SII', or SI' sites[43–46], whereas in CoY zeolites the ions are either tetrahedrally co-ordinated[45–47] or octahedrally co-ordinated (in S_I sites)[48] and inaccessible to adsorbed H_2O and NH_3 molecules at room temperature[45,46].

A detailed comparative study of the properties of A, X, and Y zeolites containing Co^{2+} ions, carried out by reflectance u.v. spectroscopy and ESR, is described in Ref. 49. Under specified conditions the ESR spectra of Co^{2+} ions in the zeolites could be observed at 77 K and above. It was shown that A, X, and Y zeolites differ in their ability to stabilise the Co^{2+} ions, depending on the dehydration conditions, and this was ascribed to the difference in polarisability of the zeolite lattice for different Si/Al ratios. Thus, differences can be detected even in the hydrated zeolites: in type A zeolites the $Co(H_2O)_6^{2+}$ complexes interact with the zeolite lattice, whereas in X and Y zeolites they are relatively free. Tetrahedrally co-ordinated Co^{2+} ions are formed in type Y zeolites under dehydration conditions more rigorous than in types A and X.

Dehydration of zeolite A under mild conditions (110 °C, 12 h, helium stream) leads to stabilisation of the Co^{2+} ions in six-sided windows (S_{II} sites) to give tetrahedral $Co(Ox)_3 . H_2O$ complexes. As the dehydration temperature is raised to 600 °C the ions migrate to SI' or SII' sites, forming $Co(Ox)_3OH^-$ or $Co(OX)_3O^{2-}$ complexes, where Ox is an oxygen atom from the zeolite skeleton and OH^- and O^{2-} are residual fragments of H_2O molecules. On the other hand dehydration of X and Y zeolites at 600 °C leads to the formation of both tetrahedral $Co(Ox)_3O^{2-}$ complexes (in SI' or SII' sites) and of octahedral $Co(Ox)_6$ complexes (in S_I sites). We note that the reported[49] stabilisation of Co^{2+} ions with a tetrahedral co-ordination in strongly dehydrated type A zeolites is inconsistent with reports[38–42] that Co^{2+} is stabilised in a trigonal co-ordination after drastic dehydration. This discrepancy may be due in some measure to differences in the sample activation conditions: Heilbron and Vickerman[49] dehydrated their materials in a stream of helium, whereas most other workers have used vacuum dehydration. Differences in the heating rate of the samples may also have had some effect.

Measurements of the optical spectra of Co-containing A, X, and Y zeolites are reported also in Ref. 50. It is concluded that the Co^{2+} ions in dehydrated CoNaA zeolite have a trigonal co-ordination, whereas in CoNaX and CoNaY samples these ions adopt both tetrahedral and octahedral co-ordinations.

The adsorption of various molecules on dehydrated A, X, and Y zeolites containing Co has attracted much attention. We have already mentioned a study[39] of the adsorption of olefins and acetylene on CoNaA zeolite. The adsorption of alkane and alkene hydrocarbons (ethylene, propene, but-1-ene, and pent-1-ene) has been studied, by optical spectroscopy, also in CoNaX zeolites, which are catalytically active towards olefin oxidation[44]. The optical spectra were found to be unaffected by alkane hydrocarbons, whereas the adsorption of alkenes distorts the co-ordination sphere of the tetrahedral Co^{2+} complexes.

The adsorption of various nitrogen-containing molecules has been studied by two groups of workers[45,51–55]. Adsorption of ammonia leads to the formation of octahedral complexes. Adsorption of methyl isocyanide on CoCaY zeolite at room temperature[51,52] produces the five-co-ordinated $Co(CH_3NC)_5^{2+}$ complexes, which are converted (in the presence of an excess of methyl isocyanide) into the six-co-ordinated $Co(CH_3NC)_6^{2+}$ complexes, with ESR spectral parameters $g_{\parallel} = 2.003$, $g_{\perp} = 2.172$ and $g_{\parallel} = 2.008$, $g_{\perp} = 2.087$ respectively. Adsorption causes the Co^{2+} ions to migrate into large zeolite holes, where the complexes are formed.

Lunsford and coworkers[53–55] found that the Co^{2+} complexes formed in the large holes of CoNaY zeolites by the adsorption of amines interact with oxygen to give O_2^- anion radicals in the co-ordination sphere of the cobalt ion: $[Co(III)L_xO_2^-]^{2+}$, where $L_x = NH_3$, CH_3NH_2, and $C_3H_7NH_2$. In the case of NH_3 and CH_3NH_2 storage of the zeolites at 20 °C for 10–15 h produces also the binuclear complexes $[L_xCoO_2^-CoL_x]^{5+}$. The ESR spectral parameters of both types of oxygen adduct are similar to those of the analogous complexes in solution.

Some of the most recent publications describe studies by u.v. and ESR spectroscopy of the localisation sites of Co^{2+} ions in natural zeolites (montmorrillonite[56] and clinoptilolite[57]). The conclusion was that, as in type X and Y zeolites, dehydration leads to the formation of tetrahedrally co-ordinated Co^{2+} ions. In clinoptilolite trigonal co-ordination of the ions is also possible.

7. Nickel

The electronic structure of the ground state of the atom is $(A)(3d)^8(4s)^2$. All the studies of zeolites containing nickel(II) so far reported have been by optical spectroscopy. The earliest work[58–60] was on the state of the Ni^{2+} ions in type A zeolites (see Ref. 1). Further developments of that investigation are reported in Refs. 61–63. The observed[61,62] migration of Ni^{2+} ions from large holes into S_{IA} sites upon dehydration of the type A zeolites is consistent with the conclusions from earlier work[58–60].

Studies of X and Y zeolites[61–63] have shown that Ni^{2+} ions present in the large holes as hexa-aquo complexes after exchange will gradually migrate, during dehydration, into S_{II} sites (up to 200 °C), then into SII' and SI' sites, and lastly into S_I sites (at 500 °C), where they are stabilised in a distorted octahedral co-ordination (with adsorption bands at ~10000, 16000, and ~22000 cm^{-1}). These conclusions on the stabilisation of Ni^{2+} ions in S_{IA} sites (A zeolites) and in S_I sites (X and Y zeolites) are consistent with results obtained by X-ray diffraction analysis[64,65].

The diffuse reflectance spectra of type Y zeolites have revealed[66,67] in addition to isolated ions, aggregates of Ni^{2+} ions. The degree of aggregation of the ions was shown to

be very sensitive to the exchange conditions. In the absence of hydrolysis of the salt used for ion exchange different types of isolated Ni^{2+} ions are detected, localised in different sites, depending on the concentration of the ions and on the heat treatment conditions of the zeolite. If the ion-exchange salt is partially hydrolysed the nickel ions are incorporated in the zeolite as polynuclear hydroxo complexes, yielding aggregates of nickel ions when the samples are heated. The bridging oxygen of these aggregates (Ni–O–Ni) does not belong to the zeolite skeleton. The aggregates of nickel ions give a charge-transfer absorption band at a lower frequency than the isolated ions.

In addition to the work on nickel-containing A, X, and Y zeolites, one paper has been published on NiL zeolite[68]. In this work the nickel ions were found to take up two co-ordination states as the dehydration temperature was raised. In the first of these states the nickel is bound to the zeolite skeleton through the residual water molecules, whereas in the second state (observed for dehydration temperatures above 300 °C) the Ni^{2+} ions are co-ordinated directly to the skeleton. As the temperature is raised above 100 °C the Ni^{2+} ions become gradually more accessible to water and ammonia molecules adsorbed from the gas phase.

The adsorption on NiA, NiX, and NiY zeolites dehydrated at temperatures up to 500 °C of strongly polar molecules such as water (at room temperature) and pyridine (at 200 °C) causes inverse migration of the Ni^{2+} ions from S_I (or S_{IA}) sites into large holes[61,62]. In the case of pyridine the planar complexes $[Ni(Py)_4]^{2+}$ are formed, with absorption bands at ~10 000, 16 000, ~20 000, and ~25 000 cm^{-1}. Adsorption of NH_3 on zeolites dehydrated at temperatures up to 200 °C leads to the formation of ammine complexes of the Ni^{2+} ions. On the other hand no complex formation is observed on zeolites dehydrated at higher temperatures[63]. This is explained by pointing out that the Ni^{2+} ions in S_I and S_{IA} sites (unlike those in $S_{I'}$ and $S_{II'}$ sites) are not accessible to ammonia molecules.

The adsorption of acetylene on type Y zeolite containing dehydrated or partially dehydrated Ni^{2+} ions causes reduction to the Ni^0 or Ni^+ state[69], and the Ni^+ ions react with acetylene to give $[Ni(C_2H_2)_n]^+$ complexes, where $n = 2, 3$. Complex formation between Ni^+ ions and acetylene or ethylene molecules was observed also on partially reduced X and Y zeolites[61]. By combining X-ray diffraction results with measurements of magnetic susceptibility the authors[61] were able to assign the Ni^+ ions which interact with alkene molecules to S_{II} (or $S_{II'}$) stabilisation sites.

The formation of Ni^+ ions has been observed also after reduction in H_2 or Co at 200–400 °C of nickel-containing NaA, NaX, NaY, NH_4A, NH_4X, NH_4Y, and CaNaY zeolites[70–73]. The concentration of Ni^+ ions was found to depend on the crystal structure type of the zeolite. In NiCaNaY zeolites[71,72] two types of Ni^+ ions were detected, with different stabilisation sites and characterised by ESR spectra with $g_\perp = 2.09$, $g_\parallel^1 = 2.48$, and $g_\parallel^2 = 2.80$. Adsorption of O_2 produced an ESR spectrum from the O_2^- anion radical ($g_1 = 2.045$, $g_2 = 2.008$, $g_3 = 2.0015$), whereas in an NO atmosphere the Ni^+ ions were oxidised to the bivalent state. The interaction of Ni^+ ions with CO produces the $Ni(CO)_2^+$ and $Ni(CO)_3^+$ complexes[72,73].

The adsorption of NO on nickel-containing zeolites is discussed in Refs.74–76. The interaction between NO molecules and Ni^{2+} is shown to lead to the formation of a charge-transfer complex in which the nickel ions initially occupy S_I positions but are subsequently transferred to $S_{I'}$ positions. The adsorption of NO and NO_2 is discussed also in Ref.15: as in the chromium-containing samples, mentioned above, the $[Ni^+NO^+]$ and $[Ni^+NO_2^+]$ complexes, which have identical ESR spectra, were detected ($g_\perp = 2.169$ and $g_\parallel = 2.33$).

8. Copper

The electronic structure of the ground state of the atom is $(A)(3d)^9(4s)^2$. Copper is particularly convenient for ESR and optical spectroscopy studies, and therefore many publications on copper-containing zeolites have appeared since the last review[1]. The more recent work has largely resolved the inconsistencies noted in the earlier review[1].

Refs.77 and 78 discuss copper-containing type A zeolites. Hydration of CuNaA and CuLiA zeolites was found to produce tetrahedral complexes of Cu^{2+} ions with one water molecule and three oxygen anions from the zeolite lattice as ligands, located near the hexagonal windows (S_{IA} sites). It was also found that hydration of Ca^{2+}- and Mg^{2+}- substituted type A zeolites causes migration of the Cu^{2+} ions into the large holes, where hexa-aquo complexes can be accommodated. A study[79] of the effect of copper content on the ESR spectra of type A zeolites has shown that electronic exchange interaction between the copper ions sets in when the copper content reaches one ion for every seven elementary cells, and this leads to the appearance of a new signal (in addition to the signal from isolated ions): a somewhat distorted singlet ~120 Oe wide.

The localisation sites of Cu^{2+} ions in type X zeolites are discussed in Refs.80–84. Kenzi and coworkers[80] examined, by ESR, samples of CuNaX containing 1.9 Cu^{2+} ions per elementary cell, and found that the copper ions migrate during dehydration and become stabilised in S_{III}, S_{II} (or $S_{II'}$), and $S_{I'}$ sites at 70–200 °C, whereas at 400 °C they penetrate into S_I sites. Localisation of Cu^{2+} ions in S_I sites during dehydration is reported also in Ref.81, but these results should be accepted with caution because the samples were exposed to an atmosphere of butene at 200 °C, followed by oxygen at the same temperature, before the measurements. In an extension of this work[82] the authors point out that Cu^{2+} ions become strongly bound to the zeolite skeleton even for dehydration temperatures as low as 80–100 °C. ESR measurements at 77 K revealed three distinct signals, corresponding to stabilisation of the copper ions at different locations in the skeleton (S_{III}, S_{II}. and $S_{II'}$). After dehydration at 120–200 °C a substantial fraction of the copper ions is localised in $S_{II'}$ sites, and raising the dehydration temperature to 400 °C causes migration of the ions to S_I sites. However, as the authors themselves point out[82], additional evidence is needed to confirm these conclusions.

Vansant[83] does not discuss the stabilisation sites of Cu^{2+} ions specifically, but he points out that in dehydrated zeolites these ions are co-ordinated by three lattice oxygens, suggesting localisation in $S_{II}(S_{II'})$ or $S_{I'}$ sites. Lastly, Peigneur and coworkers[84] also mention S_{II} and $S_{II'}$ sites as possible localisation positions in the zeolite X skeleton.

Most of the work on copper ions has been done with type Y zeolites. Changes in ESR spectra similar to those described in Ref.1 have been observed[85] after dehydration of CuNaY zeolites, though in this case there was no decrease in the intensity of the ESR signal after dehydration at 400 °C. This difference is apparently due to the oxidising treatment (O_2, 400 °C) to which the sample were subjected after dehydration. Turkevich and coworkers[86] reported, in addition to the signals described in the previous review[1], a symmetrical signal with $g \cong 2.17$ whose intensity increased with the degree of exchange. They ascribed this signal to cluster

formation without defining the cluster structure. Cluster formation is reported also by Mörke and coworkers[87], who studied the state of copper ions in CuNaY zeolites (9–64% exchanged) dehydrated at 200–600 °C. A substantial fraction of the copper ions was found to be localised in S_I, $S_{I'}$, and $S_{II'}$ sites, and it was noted that cluster formation is favoured not only by an increase in the degree of exchange but also by an increase in the dehydration temperature. Reports of the localisation of copper ions in S_{III} and S_{II} sites of hydrated zeolites were confirmed by Soria and coworkers[88], and the localisation in $S_{I'}$ and $S_{II'}$ sites after dehydration of the zeolites at 400–600 °C was confirmed by X-ray structural analysis[89]. The stabilisation of copper ions in S_I sites was further confirmed by Jacobs and coworkers[90], who pointed out that the ease with which the copper ions are reduced depends on the localisation sites of the ions.

Cu^{2+} ions stabilised in S_I, $S_{I'}$, and $S_{II'}$ sites can form ion pairs of various types at high degrees of exchange[91–94]. The stabilisation of copper ions in S_I and $S_{I'}$ sites has been shown[94] to be influenced by the heating rate of the zeolite during dehydration. Thus, for a heating rate of 1.7 K min^{-1} the Cu^{2+} ions can be localised in hexagonal prisms, but an increase in the heating rate to 25 K min^{-1} prevents the ions from entering those sites. This effect can explain the slight discrepancies which still exist between the conclusions of different workers on the ability of copper ions to be stabilised in S_I sites of type Y zeolites.

Investigations by optical spectroscopy[95,96] also suggested the possibility of forming copper ion pairs at high degrees of exchange. Again, S_{III} sites were found to be the preferred stabilisation point of Cu^{2+} ions in the hydrated zeolites. Dehydration at gradually increasing temperatures initially causes migration to S_{II} and $S_{II'}$ sites (100–300 °C), followed by migration to S_I and $S_{I'}$ sites (300–600 °C).

Extensive studies[66,67,97–103] of the effect of exchange, dehydration, and redox conditions on the state of copper ions in type Y zeolites have been carried out by ESR, i.r., and optical spectroscopy methods. The stabilisation sites of isolated copper ions identified by this work agree, on the whole, with conclusions from earlier work. The suggested formation of "strong" or "weak" associations of copper ions, differing in the intensity of the spin–exchange interaction, is interesting. The "weak" associations are assumed to have characteristics similar to those of isolated copper ions localised in S_{III} and S_{II} sites, whereas the "strong" associations differ very substantially from isolated ions: they are formed by heat treatment under oxidising conditions of the clusters arising from the hydrolysis of the copper ions in the zeolite holes during exchange at pH 8–9. The "strong" associations are thought to be bridging structures of the M–O–M type, including non-lattice oxygen.

Many recent publications discuss the adsorption of ammonia, pyridine, and other nitrogen-containing molecules on copper-substituted zeolites. The interest in this type of investigation appears to stem from the specificity of the resulting complexes, which makes it very easy to identify them by ESR and optical spectroscopy.

The ESR method has been used[104] to study the adsorption of ammonia and pyridine on CuNaY zeolite, and the formation of the square coplanar complexes $[Cu(NH_3)_4]^{2+}$ and $[Cu(Py)_4]^{2+}$ has been demonstrated (ESR spectral parameters $g_\parallel = 2.25$, $g_\perp = 2.04$, $A_\parallel = 175$ Oe, and $g_\perp = 2.03$, $g_\parallel = 2.24$, $A_\parallel = 185$ Oe respectively). Vacuum heat treatment at 100 °C did not affect the spectrum of a sample on which pyridine had been adsorbed, whereas inversion of the g-factors occurred in the sample on which ammonia had been adsorbed ($g_\perp = 2.26$, $g_\parallel = 2.03$). The inversion was produced by removal of the ammonia molecules and by the resulting change in the symmetry of the co-ordination sphere to that of a tetrahedron compressed along the trigonal axis. It was also found that in the case of samples containing adsorbed pyridine a change in measurement temperature from room temperature to −196 °C does not affect the ESR spectra. Hence the authors suggest[104] that the $[Cu(Py)_4]^{2+}$ complexes are formed within the sodalite cells, which "freezes" the motions of the complex and makes the spectral parameters independent of the measurement temperature.

Further developments in this work have also been reported. It was shown[83] that the behaviour of Cu^{2+} ions towards the adsorption of pyridine and ammonia is substantially the same in types Y and X zeolites, and also[86] that the specific adsorption of pyridine (unlike that of ammonia, which interacts with copper ions even at room temperature) is limited to temperatures above 120 °C. This difference is most probably due to the inability of pyridine molecules to penetrate into the sodalite cells except at high temperatures.

An ESR study of the adsorption of ammonia on CuNaY zeolite as a function of the amount of ammonia adsorbed is described in Ref. 98. Four types of complex were shown to be formed, differing in the number of ammonia molecules (five, three, and two) and in their disposition in the co-ordination sphere.

Optical spectroscopy has shown[66] that the adsorption of NH_3 on dehydrated zeolites leads to the formation of di- and tri-ammines (absorption maximum at ~15 200 cm^{-1}), with a very small number of tetra-ammines (shoulder at 17 000 cm^{-1}). Adsorption of pyridine produces di- and tetra-pyridine copper complexes (15 400 and 17 200 cm^{-1}), whereas the adsorption of large quantities of ammonia[105] produces mainly tetra-ammines (16 500 cm^{-1}). Partial desorption of the ammonia leads to the formation of complexes to which the structure $(O)_3$–Cu–NH_3 has been assigned.

Thus, whereas in the case of pyridine adsorption the structural information given by optical spectroscopy is consistent with the ESR results, pointing to the formation of $[Cu(Py)_4]^{2+}$ complexes, there is some disagreement between the two methods in determining the structure of the copper ammine complexes. The ESR measurements indicate preferential formation of the $[Cu(NH_3)_4]^{2+}$ complex [for example, Lunsford and coworkers[94] failed to detect any other ESR signals, even at very low levels of adsorption ($N_{NH_3}/N_{Cu^{2+}} \ll 1$)], whereas the optical spectra suggest that these complexes are formed only when the zeolites are saturated with ammonia.

Vansant and Lunsford[91] studied the adsorption of ammonia, methylamine, and ethylamine molecules on CuNaY zeolite. Ammonia adsorption was found to give rise to complexes containing four ammonia molecules and having the D_{4h} square coplanar symmetry, whereas only one adsorbate molecule entered into the co-ordination sphere of the copper ion after adsorption of the amines. It is interesting to note that two types of complex between copper ions and amines were detected in the sodium form of the zeolite, whereas in the calcium form only one complex was found. The difference in structure between the two types of complex in CuNaY probably involves differences in the stabilisation sites of the copper ions ($S_{II'}$ or $S_{I'}$).

Interesting results were obtained in an extensive investigation by optical spectroscopy of the adsorption of ammonia, pyridine, and ethylenediamine molecules from aqueous solutions on CuNaY zeolite[46,96,106]. The following copper ion complexes were detected: $[Cu(NH_3)(H_2O)_5]^{2+}$, $[Cu(NH_3)_2 \cdot (H_2O)_4]^{2+}$, $[Cu(NH_3)_6]^{2+}$, $[Cu(Py)_4]^{2+}$, and $[Cu(en)_3]^{2+}$. On the other hand, after adsorption of ethylenediamine from the gas phase[84] the complexes $[Cu(en)]^{2+}$ and $[Cu(en)_2]^{2+}$

have been detected by ESR and u.v. spectroscopy. [Cu.$(en)_3]^{2+}$ complexes were formed only after lengthy exposure of the sample to ethylenediamine.

The adsorption of molecules not containing nitrogen has not been studied in such detail. Leith and Leach[82] examined, in addition to the adsorption of ammonia and pyridine, also the adsorption of butene, cyclopropane, and 3,3-dimethylbutene, and they showed that the latter molecules interact with Cu^{2+} ions in S_{II} positions whereas NH_3 and pyridine molecules can interact with Cu^{2+} ions in S_I positions.

A study by ESR and i.r. spectroscopy of the interaction within zeolites between carbon monoxide molecules and copper cations in different states has been reported[99,101]. Isolated copper ions were found not to interact with CO up to 500 °C, whereas the weak magnetic associations of these ions form complexes with CO at low temperatures and oxidise it to CO_2 at temperatures above 300 °C (being reduced to Cu^{2+} by this reaction). These processes are thought to involve non-lattice oxygen. The stronger associations of copper ions, which include a bridging oxygen atom not belonging to the zeolite skeleton, oxidise the CO molecules to CO_2 and to carbonates even at low temperatures.

We should note that the ESR method can be used also to study complex formation between adsorbed molecules and univalent copper ions. The adsorption of nitric oxide on Cu^+–Y zeolites prepared by reduction of zeolites containing copper(II) has been studied in this way[85,107], and the formation of the Cu^+–NO complex has been observed ($g_\parallel = 1.89$, $g_\perp = 2.009$). The results of various studies of the complexes of copper and some other transition metals (Co, Cr, Ni, Fe) with nitrogen-containing molecules are discussed in detail in Refs.108 and 109.

III. IONS OF THE METALS FROM THE SECOND AND THIRD TRANSITION PERIODS

Relatively few papers on studies by ESR and optical spectroscopy of zeolites containing ions from the second and third transition period have been published. As far as the present writers are aware, all of them are concerned with ions from Group VIII of the Periodic Table.

1. Ruthenium

The electronic structure of the ground state of the atom is $(K)(4d)^7(5s)^1$. Ruthenium-containing type Y zeolites have been studied[110] by ESR and optical spectroscopy, and the properties of the ruthenium ions were shown to be very sensitive to the exchange conditions and to the subsequent treatment of the samples. Thus, samples exchanged in an excess of ammonia gave signals from Ru^{3+} complexes differing in the number of ammonia ligands ($g_1^A = 2.57$, $g_2^A = 2.20$, $g_3^A = 1.73$, and $g_1^B = 2.44$, $g_2^B = 2.12$, $g_3^B = 1.82$), whereas after exchange at pH ~7 only one broad band (with $g \approx 2.5$) is observed. Dehydration of the samples reduces some of the ruthenium to the metal with formation of ferromagnetic micro-crystals of an alloy of ruthenium with the iron present as an impurity in the zeolites. The formation of these micro-crystals is indicated by the appearance of a very strong ESR signal at low fields. The size of the micro-crystals depends on the exchange conditions (increasing with pH). In very finely divided crystals the adsorption of hydrogen molecules has a marked effect on the ferromagnetic properties, as shown by the substantial decrease in signal strength.

The preparation of ruthenium zeolites of types A, X, and Y by exchange methods is discussed also in Ref.111.

2. Rhodium

The electronic structure of the ground state of the atom is $(K)(4d)^8(5s)^1$. Rhodium-containing X and Y zeolites (2–80% exchange) have been studied by ESR.[110,112–114]. In type X zeolites exposed to an oxidation (O_2, 500 °C) and a reduction treatment (H_2, 150 °C) in succession, ESR signals from Rh^{2+} ions in a distorted octahedral co-ordination have been observed[110]. The adsorption of various molecules (O_2, NO, Co, NH_3) at room temperature had no effect on the ESR spectrum (i.e. complex formation was not observed). This observation, together with the co-ordination of the Rh^{2+} ions, suggests that these ions are localised in S_I sites.

Unlike the type X zeolites, in which only isolated Rh^{2+} ions are observed, type Y zeolites give rise to paramagnetic centres after an oxidising treatment ($g_\perp = 2.69$, $g_\parallel = 2.18$, $A_1 = 355$ Oe, $A_2 = 110$ Oe). These centres consist of two non-equivalent rhodium ions (called an ion pair[112]). Integral intensity measurement indicates that ~20% of the rhodium ions take part in ion pair formation.

Rhodium pairs have been shown[112–114] to act as adsorption centres for various molecules (H_2O, NH_3, O_2, CO, NO, etc.). Adsorption of water molecules causes the formation of paramagnetic associations in the large holes of the zeolite, containing at least four rhodium atoms. Storing the samples in an ammonia atmosphere at room temperature or at 100 °C also produces changes in the ESR spectra, resulting from the interaction of the rhodium pairs with ammonia.

The adsorption of CO, O_2, and NO molecules, unlike the adsorption of strongly polar molecules, leads to the formation of unstable complexes which break down under evacuation even at room temperature. The adsorption of CO molecules was found[113] to produce complexes giving an ESR signal with the parameters $g_\perp = 2.186$, $g_\parallel = 1.992$, and $A_\parallel(Rh) = 18.5$ Oe. By using labelled carbon monoxide (^{13}CO) it was shown that only one CO molecule is present in each complex, and that this molecule is covalently bound to the rhodium.

The adsorption of NO at 77 K causes the formation of nitrosyl complexes whose composition includes two molecules of nitric oxide[114].

The formation of complexes of the peroxy type following oxygen adsorption has been observed ($g_\perp = 1.943$, $g_\parallel = 2.014$). These species (called σ-complexes) were found to be very reactive towards the oxidation of various molecules, including alkenes and hydrogen[110,112].

An ESR study of the properties of rhodium ions in NaY zeolite is described also in Ref.115. In the early stages of the thermal activation of the zeolite in oxygen (at ~100 °C) the tervalent rhodium complexes $[Rh(NH_3)_5Cl]^{2+}$ initially introduced by ion exchange are found to break down, giving the paramagnetic bivalent rhodium complexes $[Rh(NH_3)_5]^{2+}$ whose ESR spectra have the parameters $g_1 = 2.09$, $g_2 = 2.06$, and $g_3 = 1.97$. At higher temperatures (500 °C) Rh^{2+} ions directly attached to the zeolite skeleton are formed. As in our experiments[112,113], these workers observed the formation of complexes with CO and O_2, but their structural interpretation is somewhat different from ours. They assume that oxygen-containing complexes are produced by the oxidation of diamagnetic Rh^+ ions, giving the bridge structure Rh^{2+}–O–O–Rh^{2+}. However, in view of the small distance between the paramagnetic Rh^{2+} ions in this structure, which should lead to substantial interaction between the unpaired electrons, we would expect the ESR spectrum to be more complex than the spectrum actually observed (charateristic of the systems with $S = 1/2$). For these reasons we consider the proposed bridge structure to be improbable.

3. Palladium

The electronic structure of the ground state of the atom is $(K)(4d)^{10}$. All the work on palladium-containing zeolites reported so far has been done on samples prepared by ion exchange between type Y zeolites and solutions of tetra-ammine complexes of bivalent palladium ions.

Naccache and coworkers[116,117] examined by ESR the state of the palladium ions and its dependence on various treatments of the sample (including the adsorption of hydrogen and carbon monoxide molecules). Oxidising treatments were shown to produce a signal in the ESR spectra of the zeolites with the parameters $g = 2.233$, $\Delta H = 16$ Oe, assigned to Pd^{3+} ions in a distorted octahedral or trigonal co-ordination (S_I or $S_{I'}$, S_{II} sites). Adsorption of hydrogen at room temperature on an oxidised sample reduced the Pd^{3+} ions to Pd^{+}, whose ESR signals have the parameters $g_\perp = 2.10$, $g_\parallel = 2.28$ and $g_\perp = 2.11$, $g_\parallel = 2.41$ respectively. It is pointed out that ~8% of the palladium ions give rise to ESR signals. The suggested localisation of the palladium ions in $S_{I'}$ sites is confirmed by X-ray diffraction results[118], which indicate that 10.6 of the 12.5 palladium ions in the elementary cell are located in $S_{I'}$ sites.

The adsorption of CO on these samples causes the appearance of an ESR signal with the parameters $g_1 = 2.192$, $g_2 = 2.061$, and $g_3 = 2.038$. By using carbon monoxide enriched in the ^{13}C isotope the components of the signal for each g-factor were shown to be split into three ($A_1 = 56$ Oe, $A_2 = 56$ Oe, and $A_3 = 60$ Oe). Hence the authors concluded[116,117] that the Pd^{+} ions form complexes with two CO molecules.

An ESR study of the adsorption of NO molecules on PdNaY zeolite is reported in Ref. 119. A signal with $g = 1.95$ was observed on oxidised as well as on reduced samples, leading to the conclusion (confirmed by i.r. spectral measurements) that the complexes formed by the Pd^{2+} ions contain one molecule of NO.

Garbowski and coworkers[120,121] reported a study of PdNaY zeolite by optical spectroscopy. Most of the spectra were complex, and had to be analysed by resolving the absorption lines into their components. The conclusion was that in the initial samples the Pd^{2+} ions were present as $[Pd(NH_3)_4]^{2+}$ complexes in the large zeolite holes, whereas after dehydration at 500 °C in a stream of oxygen the Pd^{2+} ions were converted into the C_{3v} co-ordination[122]. The same workers examined the adsorption of ammonia, pyridine, water, and nitric oxide molecules. From their optical measurements they concluded that the adsorption of water gives two types of complex: tetrahedral, in $S_{I'}$ sites, and square coplanar, in large holes. The adsorption of NO molecules led to the formation of complexes containing one molecule of nitric oxide. A study[121] of the simultaneous adsorption of CO and NO showed that these complexes can be of two types: one type (in $S_{I'}$ sites) does not interact with CO, whereas the other (in $S_{II'}$ sites) can co-ordinate an additional CO molecule to give a complex of composition $Pd(O)_3NOCO$.

IV. CONCLUSIONS

To conclude this review we shall mention an important paper by Sancier and Inami[122], who studied by ESR the reduction in hydrogen at 400 °C of Pd^{2+}NaY and Pd^{2+}CaNaY zeolites containing also iron ions. These workers noted the formation, under these conditions, of reduced forms of iron, whereas no reduction took place in zeolites not containing palladium. The effect is explained by postulating the formation (during the reduction of palladium ions) of atomic hydrogen, which subsequently migrates towards the iron ions and reduces them (the "spill-over" effect).

Our discussion of work by ESR and optical spectroscopy on zeolites containing ions of the transition elements leads to the following general conclusions. Evidently, these methods do not always allow the localisation sites of the ions in the zeolites after dehydration to be identified unambiguously, but they provide reliable data on the accessibility of the ions to adsorbed molecules of various types. The dehydration of zeolites containing ions of the transition elements is usually followed by gradual migration of the ions into S_{II}, $S_{II'}$, $S_{I'}$, and S_I sites. However, the effect is strongly dependent on the dehydration conditions and on the nature of the cation. Thus, the localisation of cations in S_I sites of faujasites is clearly observed only when low heating rates are used.

For these reasons the "centre of gravity" of the research in this area has been shifted from the determination of the localisation sites of ions in zeolites to the study of the electronic structure and of the properties of the complexes formed in the zeolite holes by the interaction of the transition metal ions with adsorbed molecules. In these complexes the ions of the transition elements often form a bond with both the adsorbed molecule and the oxygen ions from the zeolite skeleton, and their co-ordination, localisation site, and even valency can change as a function of the nature of the ligands, the concentration of adsorbed molecules, and the temperature. Another area which has attracted attention in recent years is the identification and study of ions in "unusual" valency states, which can often be stabilised in zeolites by interaction with the alumino-silicate skeleton. ESR and optical spectrosocpy methods offer a high sensitivity and a high information content, and allow these processes to be monitored even when other methods fail.

Singlet Oxygen: Methods of Preparation and Detection

N.V.Shinkarenko and V.B.Aleskovskii

An historical account of the discovery of singlet oxygen is given, its physicochemical properties are discussed, and existing methods of preparation and detection are reviewed. 171 references.

I. INTRODUCTION

15 years ago singlet oxygen was either unknown to most chemists or treated as a spectroscopic state of theoretical interest in the physics of the upper atmosphere. In recent years, however, singlet oxygen has come to the notice of a wide range of researchers. It was shown to have a high reactivity towards many organic compounds, to play an important role in the chemistry of atmospheric pollution, to be involved in the degradation of organic materials by light and oxygen, to take part in the life processes of plants and animals, to behave as a carcinogen, etc.

The first papers dealing specifically with singlet oxygen appeared in the mid-1960's, and by the year 1970 the number of such publications was over 100. According to Kasha and Khan[1] all our views on the participation of molecular oxygen in various chemical and biological systems must now be reconsidered from the standpoint of our new understanding of singlet molecular oxygen. In the Soviet literature very little has been published so far on singlet molecular oxygen. In 1965 Arbuzov referred to singlet oxygen in a review[2] of the oxidation of organic compounds, and a more recent review[3] mentions the quenching of singlet oxygen in the context of the resistance to photo-oxidation of organic compounds. The foreign literature contains a number of reviews dealing with various aspects of the singlet molecular oxygen problem[1,4-15]. In the present review we shall discuss the nature of singlet oxygen and the methods by which it can be prepared and detected.

In Fig.1 the ground state of the oxygen molecule is shown as an energy level diagram[13,16], illustrating the formation of molecular orbitals (MO) following the close approach of two oxygen atoms. Each oxygen atom has eight electrons. Four of these remain in $\sigma(1s)$ and $\sigma^*(1s)$ orbitals, while the next four move into $\sigma(2s)$ and $\sigma^*(2s)$ orbitals. The next six electrons move into three bonding MO: $\sigma(2p_x)$, $\pi(2p_y)$, and $\pi(2p_z)$. The last pair of electrons can be accommodated either on one of the π^* orbitals (if the electrons have opposite spins) or on two MO [$\pi^*(2p_y)$ and $\pi^*(2p_z)$] if the spins are parallel. The latter variant is energetically preferred, because of the large repulsion energy between two electrons in the same orbital: the two electrons are further apart when in different orbitals, and their mutual repulsion is less marked. This preferred electronic configuration is illustrated in Fig.1.

This state of the oxygen molecule is known as the triplet sigma-state ($^3\Sigma$). The higher-energy configuration, in which the last two electrons are located in the same $\pi^*(2p_y)$ orbital, is shown in Fig.2. It corresponds to the lower excited state of the oxygen molecule, which is a singlet state because the electrons are paired. This state of the oxygen molecule is denoted as $^1\Delta$ and lies 22.5 kcal mole^{-1} above the $^3\Sigma$ ground state (Table 1). This energy level was obtained by emission spectroscopy[17], the $^1\Delta \rightarrow {}^3\Sigma$ transition corresponding to a wavelength of 1269 nm (0.9772 eV). The next excited state of the oxygen molecule is 37.5 kcal mole^{-1} above the ground state[17] and has the electronic configuration shown in Fig.3: it is denoted by the symbol $^1\Sigma$. It differs from the $^3\Sigma$ state in that the last two electrons in the π^* orbitals have antiparallel spins in the $^1\Sigma$ state. In terms of group theory and of the theory of symmetry properties these three states of the oxygen molecules can be described as $^3\Sigma_g^-$, $^1\Delta g$, and $^1\Sigma_g^+$ respectively. Some of the characteristics of these three states are listed in Table 1.

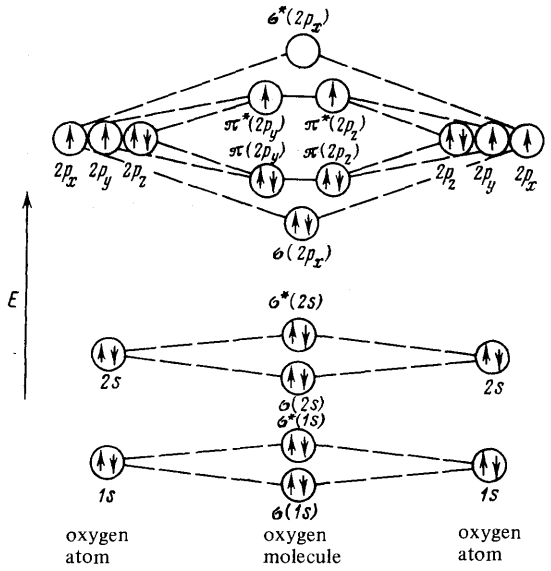

Figure 1. Normal (or triplet) $O_2(^3\Sigma_g^-)$.

The photochemical reactions of organic compounds with molecular oxygen were studied in detail in the first half of the present century. Some of these reactions are of the utmost importance in biological terms. For example, it was shown that some endoperoxides can regenerate an oxygen molecule when heated. Thus red rubrene gives a colourless peroxide when exposed to light in the air, but on being heated it becomes red again and begins to fluoresce[18]. The formal

analogy between this type of reaction and the reversible absorption of oxygen by hemoglobin is evident.

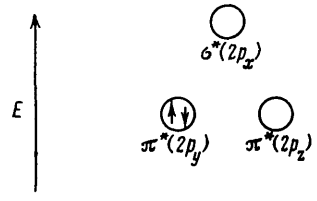

Figure 2. Singlet $O_2(^1\Delta_g)$.

Table 1. Lowest electronic states of an oxygen molecule, and their properties[1].

Electronic state	Life time, s		Relative energy, kcal mole^{-1}	Position of the 0.0 band, λ, nm	Equilibrium internuclear distance, A
	vacuum	solution			
$^1\Sigma_g^+$	7	10^{-11}	37.51	762.14	1.227
$^1\Delta_g$	2700	10^{-6}	22.53	1268.7	1.216
$^3\Sigma_g^-$	∞	∞	0	—	1.207

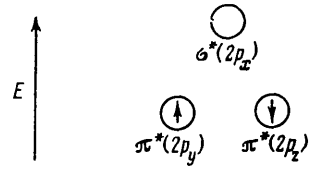

Figure 3. Singlet $O_2(^1\Sigma_g^+)$.

The classical work of Kautsky[19] in the 1930's demonstrated that photo-excitation of a sensitiser in the presence of oxygen can cause oxidation of an organic molecule physically removed from the sensitiser. He concluded that the light energy absorbed by the sensitiser (dye) is transferred to the oxygen (by fluorescence quenching of the dye) which is thus converted from its ground triplet state into one of the excited singlet states ($^1\Delta$ or $^1\Sigma$). The singlet oxygen then attacks the organic molecule, giving the oxidation product[19]. Thus Kautsky's mechanism can be summarised as

$$\begin{aligned} S &\xrightarrow{h\nu} {}^1S \\ {}^1S &\rightarrow {}^3S \\ {}^3S + {}^3O_2 &\rightarrow S + {}^1O_2 \\ {}^1O_2 + A &\rightarrow AO_2 \ . \end{aligned} \qquad (1)$$

Direct energy transfer from the sensitising dye to the organic molecule can be excluded, because the absorption bands of many organic molecules lie at wavelengths shorter than those of the dyes used as sensitisers, and therefore the energy of the excited dye molecules is insufficient to raise these acceptors into their excited states[14].

In the 1940's Terenin generalised Kautsky's model by pointing out that the total electron spin is conserved in this process. He described the energy transfer process as follows[20,21,106]:

$$S[\uparrow][\uparrow] + O_2[\downarrow][\downarrow] \rightarrow \tilde{S}[\uparrow\downarrow][\ ] + {}^1O_2[\uparrow\downarrow][\ ]$$

where the symbol ~ denotes an excess of vibrational energy.

However, Kautsky's mechanism was not accepted by most of the leading foreign workers, and for many years singlet oxygen remained of interest only to astrophysicists and to specialist gas kineticists. However, the situation changed in 1960 when Seliger[22] discovered a red luminescent emission on mixing H_2O_2 and HClO. The spectrum of this radiation, which had been first reported by Mallet 33 years previously[23], was found to consist of a narrow band at 634 nm.

Khan and Kasha[24,25] confirmed Seliger's results and observed an additional band at 703 nm. The separation of these two bands (1567 cm^{-1}) agrees within experimental error with the vibrational frequency of molecular oxygen in the ground state (1580 cm^{-1}); furthermore, the O–O bond in the hydrogen peroxide molecule was shown to remain undisturbed by the reaction

$$H_2O_2 + HClO \rightarrow O_2 + HCl + H_2O \ . \qquad (2)$$

On these grounds the authors ascribed[24,25] this radiation to an excited state of molecular oxygen. Though this assignment was later shown[26] to be only partly correct (see below), Khan and Kasha had correctly associated the luminescence with metastable, excited, singlet oxygen. Following this assignment, Kautsky's hypothesis was more widely accepted.

The same two bands were observed[26] in the radiation from a stream of gaseous oxygen exposed to an electric discharge. The chemiluminescence of the H_2O_2–HClO system was re-examined, and in addition to the bands at 634 and 703 nm a new, weak band was discovered at 762 nm, corresponding to the transition $O_2(^1\Sigma) \rightarrow O_2(^3\Sigma)$, as well as a stong band at 1270 nm, corresponding to the transition $O_2(^1\Delta) \rightarrow O_2(^3\Sigma)$.[27] Obviously, the bands at 634 and 703 nm must have the same origin whether the luminescence is produced in solution or in a gas discharge.

It has been suggested[10,26] that the bands at 634 and 703 nm are produced by a dimer consisting of two excited $O_2(^1\Delta)$ molecules, which are deactivated simultaneously and emit a single quantum of energy:

$$2O_2(^1\Delta) \rightarrow 2O_2(^3\Sigma) + h\nu \ . \qquad (3)$$

This transition produces radiation at 634 nm if both molecules of the product are in the vibrational ground state: if one of the product molecules is in the first vibrational level the radiation will be at 703 nm.

The hypothesis of simultaneous electronic transitions was not novel. The absorption bands at 634 and 580 nm in liquid oxygen, which are responsible for its blue colour, had previously been assigned to double transitions of the same type, in which the absorption of one photon causes the simultaneous transfer into excited states of two electrons in two different molecules[28,29]:

$$2O_2(^3\Sigma) + h\nu \rightleftarrows 2O_2(^1\Delta)$$

Thus, the hypothesis put foward by Arnold and coworkers[26] is consistent with earlier reports. The band at 634 nm is convenient for monitoring the concentration of $O_2(^1\Delta)$ singlet oxygen, because its intensity is proportional to the square of the concentration of $O_2(^1\Delta)$ (thus confirming the validity of the hypothesis). In addition to the double transition (3), the following transitions have also been proposed[10,26]:

$$2O_2(^1\Sigma) \rightarrow 2O_2(^3\Sigma) + h\nu_{861\,nm} + h\nu_{861\,nm}$$

$$2O_2(^1\Delta^1\Sigma) \rightarrow 2O_2(^3\Sigma) + h\nu_{478\,nm} \qquad (4)$$

All these dimers are assumed to be simple collisional complexes.

Thus singlet oxygen was rediscovered in the reaction between H_2O_2 and HClO and in a stream of oxygen exposed to an electric discharge. It was later found[30] that the oxidation products of organic molecules exposed to the H_2O_2–NaOCl system are identical to those obtained by the sensitised oxidation of the same acceptors. Excited oxygen molecules generated in a discharge upstream from the organic solution have been shown[31] to react with various substituted anthracenes and alkenes to give oxidation products identical to those of the sensitised photo-oxidation of the same acceptors. These comparisons led to the conclusion that singlet oxygen is the reactive intermediate in sensitised photo-oxidation reactions, as originally suggested by Kautsky.

In a later variant of Kautsky's experiment the sensitiser and the oxygen acceptor were placed on opposite sides of a stearic acid film[32,33]. In spite of the 500 Å separation between the sensitiser molecules and the acceptor, sensitised photo-oxidation took place as a result of diffusion of the singlet oxygen molecules through the film.

Thus Kautsky's mechanism is now universally accepted. On the other hand, up to the mid-1960's the Terenin–Schenck mechanism (called the Schenck mechanism in the foreign literature) was more widely used. Terenin[20,34] and (later) Schenk[35] proposed the following scheme for dye-sensitised photo-oxidation reactions

$$S \xrightarrow{h\nu} {}^1S$$
$${}^1S \rightarrow {}^3S$$
$${}^3S + {}^3O_2 \rightarrow [S \ldots O_2]$$
$$[S \ldots O_2] + A \rightarrow S + AO_2$$

where the metastable $[S...O_2]$ complex is the reactive intermediate which transfers oxygen to the acceptor A.

Following the demonstration[30,31] that singlet oxygen is the active intermediate in many sensitised photo-oxidations, interest in the Terenin–Schenck mechanism began to wane, but there was still no proof that a long-lived complex (as postulated in that mechanism) was not formed as a precursor of the free, singlet molecular oxygen. This important problem has been finally resolved by comparing the effectiveness of oxygen quenching of the fluorescence of pyrene excimers under low- and high-intensity irradiation respectively (using light from a nitrogen laser[36]). Under high irradiation intensity each oxygen molecule can produce 200 excited pyrene excimers, the fluorescence quenching being comparable (~91%) with the quenching observed at very much lower irradiation intensities (93%). In order to explain this effect we have to assume that each O_2 molecule has sufficient mobility to quench ~100–200 pyrene molecules, and therefore that the life time of the pyrene–oxygen complex is less than 2×10^{-10} s. These experiments exclude the possibility of complex formation between an excited pyrene molecule and oxygen, and they also exclude the existence of any excited formation (including oxygen) having a life time greater than 2×10^{-10} s.

A theoretical study of the energies of different states of the $(S...O_2)$ complex has shown[14,37] that though the $({}^3S + {}^3O_2)$ complex corresponds to a weak minimum ($\leq$300 cm^{-1}) this state has a very short life time ($<10^{-10}$ s due to its fast relaxation into lower-lying dissociative states of the complex: $[S...O_2({}^1\Delta)]$ and $[S...O_2({}^1\Sigma)]$, giving $O_2({}^1\Delta)$ or $O_2({}^1\Sigma)$. Obviously, the oxide complex is too short-lived to act as an intermediate responsible for oxygen transfer in sensitised photo-oxidation reactions. Additional evidence against the existence of oxide complexes was provided by measurements[38] of the decomposition kinetics of the endoperoxide of diphenylfuran, aimed at explaining whether oxygen transfer to other oxygen acceptors A occurs by the direct bimolecular reaction

$$DPFO_2 + A \rightarrow AO_2 + DPF$$

or with the participation of a singlet oxygen molecule

$$DPFO_2 \rightarrow DPF + {}^1O_2$$
$${}^1O_2 + A \rightarrow AO_2.$$

In these equations $DPFO_2$ is a molecule of diphenylfuran endoperoxide, A is an oxygen acceptor molecule (tetramethylethylene, cyclohexa-1,3-diene, or rubrene), and DPF is a molecule of diphenylfuran. The results convincingly favour the second mechanism (i.e. the singlet oxygen mechanism).

II. METHODS OF PREPARATION OF SINGLET OXYGEN

Singlet oxygen can be prepared by physical or by chemical methods. The physical methods of preparative value include photo-sensitisation and radio-frequency discharge. Among the chemical methods the most important are the decomposition of hydrogen peroxide by hypochlorite or hypobromite and the decomposition of some ozonides.

1. Formation of Singlet Oxygen in Photo-processes

a) Photo-sensitisation

Photo-sensitised oxidation occurs by the following scheme[39]:

$${}^1S_0 + h\nu \xrightarrow{k_1} {}^1S_1 \text{ (absorption)}$$
$${}^1S_1 \xrightarrow{k_2} {}^1S_0 + h\nu' \text{ (fluorescence)}$$
$${}^1S_1 \xrightarrow{k_3} {}^1S_0 \text{ (internal conversion)}$$
$$\left.\begin{aligned} {}^1S_1 &\xrightarrow{k_4} {}^3S_1 \\ {}^3S_1 &\xrightarrow{k_5} {}^1S_0 \end{aligned}\right\} \text{(intercombination conversion)}$$
$$\left.\begin{aligned} {}^1S_1 + {}^3O_2 &\xrightarrow{k_6} {}^1S_0 + {}^1O_2 \\ {}^3S_1 + {}^3O_2 &\xrightarrow{k_7} {}^1S_0 + {}^1O_2 \end{aligned}\right\} \begin{array}{l}\text{(energy transfer; formation}\\ \text{of singlet oxygen)}\end{array}$$
$${}^1O_2 \xrightarrow{k_8} {}^3O_2 \text{ (deactivation of singlet oxygen)}$$
$${}^1O_2 + {}^1A_0 \xrightarrow{k_9} {}^1(AO_2)_0 \text{ (formation of product)}$$

In these equations ${}^1S_0$, ${}^1S_1$, and ${}^3S_1$ are the singlet ground state, the singlet excited state, and the triplet excited state of the sensitiser S, ${}^1A_0$ and ${}^1(AO_2)_0$ are the singlet ground states of the organic molecule A and of the product AO_2, and ${}^3O_2$ and ${}^1O_2$ are the triplet state and the singlet excited state of oxygen (${}^3\Sigma$; ${}^1\Sigma$, and (or) ${}^1\Delta$ respectively).

One of the most important conclusions from studies of dye-sensitised photo-oxidation reactions is that singlet oxygen molecules can be obtained by energy transfer from the sensitiser molecules in excited triplet or singlet states[6–9]. The mechanism of the energy transfer process is assumed to involve intermediate formation of a contact pair between the sensitiser and the oxygen molecule[14,39,40] (Fig. 4). Since the ground state of the organic molecule is singlet, and that of the oxygen is a triplet ${}^3\Sigma$ state, the ground state of the contact pair (or weak complex) $S...O_2$ must be triplet[40]. Excitation of S or of O_2 produces a series of excited states of the complex: some possibilities are illustrated in Fig. 4. In addition to these states of the complex we have to consider states involving charge transfer (CT), formed by the transfer of an electron from S to O_2. For example, for the benzene–O_2 complex the charge transfer complex lies approximately

100 kcal mole^{-1} above the ground state[41]. The next lower excited state of the contact pair is the *F*-state[1,3,5], which can transfer oxygen[4] and from which transitions into the three repulsive states $^3G_0$, $^1X_1$, and $^1X_2$ can be expected. These transitions give oxygen in the ground triplet state and in two singlet states ($^1\Delta$ and $^1\Sigma$) respectively.

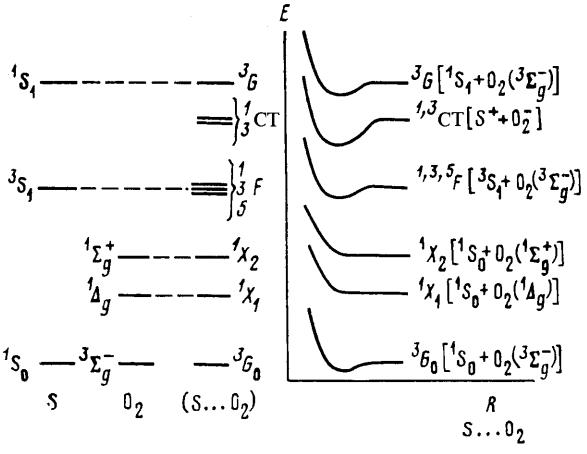

Figure 4. Energy level diagram and potential energy curves for the sensitiser, the oxygen, and the sensitiser–oxygen pair.

Quenching of triplet states by oxygen. Various mechanisms have been proposed to explain the oxygen quenching of molecules in the triplet state[19,42,43]. An analysis[14] of the energy level diagram (Fig.4) was based on the following processes for the quenching of molecules in the triplet state:

$$\begin{aligned}&(a)\ {}^1({}^3S_1+{}^3O_2)\rightarrow {}^1S_0+O_2({}^1\Sigma)\\&(b)\ {}^1({}^3S_1+{}^3O_2)\rightarrow {}^1S_0+O_2({}^1\Delta)\\&(c)\ {}^3({}^3S_1+{}^3O_2)\rightarrow {}^1S_0+O_2({}^3\Sigma)\end{aligned}\qquad(5)$$

The first two mechanisms were first suggested by Kautsky [see Ref.(1)], the third implies an enhancement of the intercombination transition in the S molecule resulting from interaction with the paramagnetic oxygen molecule. Although in principle this process can be assisted by the inhomogeneous magnetic field of the paramagnetic oxygen molecule[43], the effect has been shown[44] to be negligibly small. Furthermore, a study of the quenching of molecules in the triplet state by paramagnetic ions has shown[45] that the quenching efficiency is not correlated to the magnetic moment of the paramagnetic ions.

Another mechanism, proposed by Weiss[42], assumes electron transfer to the oxygen. In most cases this mechanism is excluded by energy considerations (see Fig.4), though it is quite probable in the case of molecules with a very low ionisation potential (amines) in a polar solvent[14].

Direct interaction between a triplet organic molecule and an oxygen molecule in the ground state is another possible quenching mechanism; however, it has been shown experimentally that even in the case of molecules undergoing photooxygenation this reaction is not involved in the quenching of the triplet molecules[14].

Calculations[46] for the aromatic hydrocarbon–oxygen contact pair, with an intermolecular distance of ~4 Å, clearly show that the transfer of energy to triplet oxygen, leading to the formation of $O_2(^1\Sigma)$ or $O_2(^1\Delta)$ (see Eqns.5*a* and 5*b*), should be far more effective (100–1000-fold) than quenching in the ground state without energy transfer (Eqn.5*c*). This is because the process involving the conversion of the smallest amount of electronic energy into vibrational energy will be the predominant one: on the other hand, intercombination transitions always involve the conversion of the largest amount of electronic excitation energy into vibrational energy.

The following unimolecular rate constants have been calculated[40] for the quenching of a molecule in the triplet state having an energy $E_T = 60$ kcal mole^{-1}:

$^1F \rightarrow {}^1X_2$ (10^{12} s^{-1}; energy transfer to $O_2(^1\Sigma)$)
$^1F \rightarrow {}^1X_1$ (10^{11} s^{-1}; energy transfer to $O_2(^1\Delta)$)
$^3F \rightarrow {}^3G_0$ (10^9 s^{-1}; enhanced intercombination conversion).

The quenching of molecules in the triplet state by oxygen has been studied in the vapour[47–50], the liquid[51–54], and the solid phase[32,55–59]. Evidence that energy transfer to the oxygen is the basic mechanism of the oxygen quenching of triplet molecules has been obtained also by ESR: the quantum yield of the formation of singlet oxygen, which is proportional to the number of triplet molecules of naphthalene produced, was shown[60] by this technique to be ~1.

Since $^1O_2(^1\Sigma)$ has an excitation energy of 37.7 kcal mole^{-1} it can be produced by using sensitisers in which the energy of the triplet excited level is 37.7 kcal mole^{-1}, whereas $^1O_2(^1\Delta)$ can be obtained by energy transfer from any sensitiser of energy >22.6 kcal mole^{-1}. The ratio $O_2(^1\Sigma)/O_2(^1\Delta)$ has been studied[40] as a function of the triplet state energy of the sensitiser. It was found that the quenching of molecules with a high triplet state energy ($E_T > 50$ kcal) produces ~10 times more $O_2(^1\Sigma)$ than $O_2(^1\Delta)$. This is because a smaller amount of electronic energy is converted into vibrational energy by the creation of a $^1\Sigma$ (as compared to a $^1\Delta$) state. In the case of molecules having a triplet state energy <37 kcal only $^1\Delta$ molecules can be formed. For intermediate values of the triplet state energy of the sensitiser molecule ($50 > E_T > 37$ kcal) the ratio $O_2(^1\Sigma)/O_2(^1\Delta)$ falls smoothly to zero (Fig.5).[14]

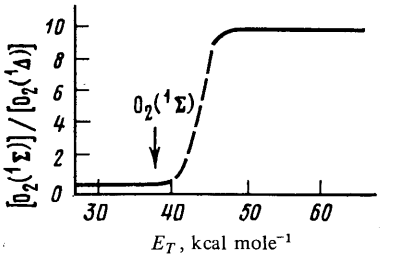

Figure 5. $O_2(^1\Sigma)/O_2(^1\Delta)$ ratio against the triplet state energy of the sensitiser.

Gollnick and coworkers[39] studied the triplet states of various types of sensitiser (dyes, aromatic hydrocarbons, carbonyl compounds). Electronic excitation of aromatic hydrocarbons and dyes give $^3(\pi,\pi^*)$ triplets, whereas carbonyl compounds (except naphthyl phenyl ketones[61] and fluorenone[62]) give $^3(n,\pi^*)$ triplets. As Table 2 shows, the triplet state energies of the sensitisers examined in that work[39] cover the range 30–85 kcal mole^{-1}.

Quenching of singlet states by oxygen (fluorescence quenching). It has long been recognised that oxygen can effectively quench the fluorescence of many organic molecules[63–68], but the mechanism of this effect was not understood. By applying theoretical calculations to the energy level diagram of the sensitiser–oxygen contact pair (Fig. 4) Kearns[14] concluded that relaxation of the excited organic molecule into a state with charge transfer (CT), i.e.

$$^1S_1 + {}^3O_2 \rightarrow (S^+ + O_2^-)$$

is the main mechanism involved in the oxygen quenching of molecules in an excited singlet state, and that the probability of quenching directly to the ground state is very much lower.

Table 2. Lowest triplet state energies of various photosensitisers[39].

Sensitiser	E_T, kcal mole^{-1}	Sensitiser	E_T, kcal mole^{-1}
Azulene	38—31	Pyrene	48.7
Anthracene	42.0	Propiophenone	74.6
Acetophenone	73.6	Rhodamine B	43
Bengal Rose	39,5—42,2	Tetrachlorofluorescein	42.2—44.1
Benzaldehyde	72.0	Tetrachloro-eosin (phloxin)	39.5—42.2
Benzene	84.5	Tetracene	29.4
Benzophenone	68.5	Thioxanthone	65.5
1-Bromonaphthalene	59.0	Triphenylene	66.6
Biphenyl	65.7	Phenanthrene	62.2
Carbazole	70.1	Flavone	62.0
Xanthone	74.2	Fluorene	67.6
Methylene Blue	34	Fluorenone	53.3
Naphthalene	60.9	Fluorescein	45.2—48.1
1-Naphthyl phenyl ketone	57.5	Quinoline	62.0
2-Naphthyl phenyl ketone	59.6	Eosin	43.2—46.0
		Erythrosin	43.1—45.8

The importance of CT states is confirmed, for example, by the much higher (100-fold) effectiveness of NO in quenching the singlet states of hexafluoroacetone[69], since NO has a higher electron affinity than oxygen.

The oxygen quenching of the fluorescence of aromatic hydrocarbons is diffusion-controlled in solution as well as in the vapour phase[69–78].

Generation of singlet oxygen by sensitisers on a solid substrate. A new method of photo-oxygenation, described by Blossey and coworkers[79], relies on the generation of singlet oxygen by a photosensitiser supported on an insoluble polymeric substrate. The sensitiser Bengal Rose was bonded to chloromethylated polystyrene through its carboxyl and (or) phenolic groups. A suspension of sensitiser-coated polymer spheres in a suitable solvent (CH_2Cl_2, $CHCl_3$, CCl_4, C_6H_6, CS_2, etc.) containing the organic compound was irradiated in the presence of molecular oxygen. The photo-oxidised product was isolated simply by filtering off the sensitiser spheres and removing the solvent by evaporation. From these experiments the authors concluded[79] that free singlet oxygen is formed with high efficiency by energy transfer from the polymer–Bengal Rose system to the oxygen. The usual problems of photo-sensitised oxydation (solubility of the sensitiser, and its separation, bleaching, regeneration, etc.) are avoided by the use of a heterogeneous method of photo-oxygenation. The sensitiser bonded to the polymer can be re-used without significant loss of effectiveness. Other (related) sensitisers on a polymer substrate were also examined (eosin, fluorescein, chlorophyllin, and hematoporphyrin), but their quantum efficiency towards the singlet oxygenation process was found to be lower than that of Bengal Rose.

Ion-exchange resins, which form strongly bound complexes with ionic sensitisers, can also be used as the solid substrate[80]. Thus, the anionic dyes Bengal Rose and eosin have been introdued into the strongly basic Amberlite IRA-400 anion exchange resin, and the cationic dye Methylene Blue into the strongly acidic Amberlite IRC-200 cation exchange resin. The sensitisers supported on a resin, like those supported on a polymer, act as effective heterogeneous photo-oxidation catalysts.

Following Kautsky's experiments, Nielsson and Kearns[81] developed several heterogeneous sensitisers with an absorption bond. They found that silica gel covered with Bengal Rose or Methylene Blue, or alumina covered with pyrene, offer the same (albeit low) photo-sensitisation efficiency as the corresponding homogeneous systems.

Triphenylmethane dyes are reported[82] to be inactive as sensitisers in solution, but to become active when bound to polymers or used in a solid environment.

An interesting solid-phase, thin-film photochemical singlet oxygen generator has been described[83]. It consists of a water-cooled tube internally coated with a thin solid film of the sensitiser (Bengal Rose), irradiated with a tungsten lamp, and a flask coated with a film of solid rubrene, which acts as a trap for singlet oxygen. An opaque screen separates the tube from the flask so as to avoid self-photosensitised oxidation of the rubrene. The choice of rubrene as a trap was dictated by its high reactivity towards $^1O_2$ coupled with total inactivity towards $^3O_2$, and also by its low volatility. Passing a stream of dry air through the whole system at 3 mmHg for 24 h converted 65% of the rubrene into rubrene peroxide. The reaction was monitored spectroscopically (in benzene, at 494 and 530 nm). However, the reproducibility of the results obtained with singlet oxygen generated by this method is not high[83].

Photo-sensitised generation of singlet oxygen by near infra-red radiation. The generation of $^1O_2$ by irradiation with near infra-red light ($\lambda < 0.9$ μm) from a xenon lamp was first reported by Nathan and Adelman[84], who used the following sensitisers: 1,1′-diethyl-2,2′-tricarbocyanine iodide, xenocyanine, and 3,3′-diethyl-9,11,15,17-dineopentylene-thiapentacarbocyanine iodide. No singlet oxygen was obtained when other sensitisers were used. The reactions were carried out in dioxan and dichloroethane solutions, using 9,10-dimethylanthracene as the acceptor (which was converted into the 9,10-endoperoxide). The progress of the reaction was monitored by the intensity of the 9,10-dimethylanthracene absorption bands at 245 and 265 nm, which are not given by the endoperoxide.

b) Formation of singlet oxygen through charge transfer complexes

This mechanism for the formation of singlet oxygen was proposed after an investigation[85,86] of the reversible absorption of u.v. light (230–400 nm) by olefin–oxygen collision complexes.

Reversible absorption by olefins and aromatic hydrocarbons in the u.v. region, due to the presence of oxygen, has been observed repeatedly in the liquid and the gas phase[43,44,87–93], and was studied in detail in our laboratory[94,95] (see Ref. 95 for a detailed bibliography on this effect). This work led to the firm conclusion that any

compound able to act as an electron donor towards oxygen (aromatic and heterocyclic hydrocarbons, alkenes, and alkanes) can form a charge transfer complex (CTC) with oxygen in which the hydrocarbon acts as an electron donor and the oxygen as the acceptor. As a result, these hydrocarbons show additional absorption in the u.v. or visible region in the presence of oxygen, consisting of a very strong band in the shorter-wave region and much weaker (~100 times) bands in the longer-wave region. The stronger band is due to absorption with charge transfer (between the hydrocarbon and the oxygen), and the weaker bands to singlet–triplet absorption by the hydrocarbon induced by the oxygen (which is forbidden by the selection rules under normal conditions). The spectrum of the original hydrocarbon is shifted towards longer wavelengths by this additional absorption.

Collisions between hydrocarbon molecules (donor, D) and oxygen molecules (acceptor) produce weak complexes (contact pairs) which have a triplet character[86]:

$$^1D_0 + O_2(^3\Sigma) \rightleftarrows {}^3[D \ldots O_2(^3\Sigma)].$$

This complex can absorb light. The result is the transfer of an electron to the acceptor (oxygen) with formation of a charge-transfer complex which can be either in the triplet or in the singlet state, since both D^+ and O_2^- are in doublet states:

$$(a)\ {}^3[D \ldots O_2(^3\Sigma)] \xrightarrow{h\nu} {}^3[D^+ - O_2^-]$$

$$(b)\ {}^3[D \ldots O_2(^3\Sigma)] \xrightarrow{h\nu} {}^1[D^+ - O_2^-]. \qquad (6)$$

In reaction (6a) both the ground state and the CT state are triplet, which makes the transition allowed according to the spin conservation rule.

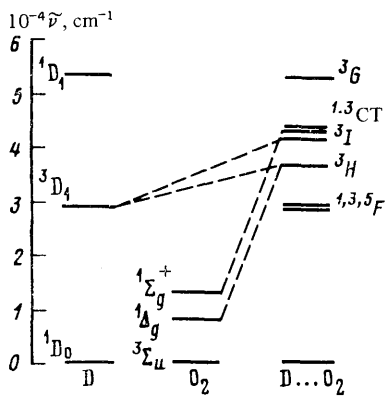

Figure 6. Energy level diagram for the donor, the oxygen, and their 1 : 1 contact pair.

The first excited singlet and triplet states of the donor and of the corresponding 1 : 1 pairs with oxygen in the ground state $O_2(^3\Sigma)$ are $^1D_1$, $^3D_1$, and ^3G, $^{1,3,5}F$ respectively (Fig. 6). The donor molecule in the first excited singlet state $^1D_1$ forms a CTC in the triplet state ^3G with oxygen in the ground state, whereas a donor molecule in the $^3D_1$ state can give quintet (^5F), triplet (^3F), and singlet (^1F) CTC states with oxygen in the ground state. If 1 : 1 pairs are formed between a triplet donor ($^3D_1$) and singlet oxygen in $^1\Delta$ or $^1\Sigma$ states, two additional states (denoted ^3H and ^3I) are created.

The CT state can interact with ^3G, obtaining its energy from the allowed transition between the ground and the singlet excited state of the donor. Similarly, ^3F can interact with ^{3}CT, thus borrowing energy from the CT transition and causing enhanced $S \rightarrow T$ absorption. It was shown[44] that the direct interaction between ^3F and ^3G states has a much weaker influence on the intensity of the $S \rightarrow T$ band than the interaction between the same states through a triplet state with charge transfer. Thus, the additional absorption observed consists of the allowed CT band, which borrows energy mainly from the allowed $^1D_0 \rightarrow {}^1D_1$ transition and also (to a much smaller extent) from the $S \rightarrow T$ band, which is strengthened by the ^{3}CT state. If this path for the internal conversion of energy from ^3G to ^3F through the ^{3}CT state is effective, the CTC in the ^3F state can produce a donor in the triplet state and molecular oxygen in the ground state:

$$^3[^3D_1 + O_2(^3\Sigma)] \rightarrow {}^3D_1 + O_2(^3\Sigma). \qquad (7)$$

An alternative mechanism includes the conversion of ^{3}CT into ^3I and ^3H states, which can then dissociate to give $^1O_2 + {}^3D_1$:

$$(a)\ {}^3CT \rightarrow {}^3I \rightarrow {}^3D_1 + O_2(^1\Sigma)$$

$$(b)\ {}^3CT \rightarrow {}^3H \rightarrow {}^3D_1 + O_2(^1\Delta). \qquad (8)$$

Reaction (7) gives singlet molecular oxygen by energy transfer from the triplet donor to the oxygen in the ground state (Kautsky's mechanism), whereas reaction (8) produces $^1O_2$ directly.

This mechanism for the formation of singlet oxygen is believed[86] to be very important in the chemistry of industrial atmospheric pollution.

c) *Direct optical excitation*

Liquid oxygen (and also gaseous oxygen at high pressure) has a series of bands in the u.v., visible, and i.r. region of the spectrum corresponding to various transitions (see above)[96,97]. The wavelength of the He–Ne laser (623.8 nm) corresponds almost exactly to the absorption band due to the $2O_2(^3\Sigma) \rightarrow 2O_2(^1\Delta)$ transition, and Evans[98] found that irradiation of a solution of 9,10-dimethylanthracene under a high oxygen pressure with light from a He–Ne laser causes photo-oxygenation of the anthracene (in the absence of a sensitiser). The quantum yield of the photo-oxidation was only 0.13, but it could be raised to ~0.6 by using a more reactive acceptor of singlet oxygen (1,3-diphenylisobenzofuran, DPBF). By using a range of different light sources Evans[98] established an approximate "action spectrum" for photo-oxidation by light of different wavelengths, and he showed that only light of wavelength corresponding to the known absorption bands of oxygen is active in promoting oxidation reactions. Though this method of generating singlet oxygen has little preparative value it is important in studies of the mechanism of various reactions involving singlet oxygen.

d) *Photolytic generation of singlet oxygen*

The photolysis of ozone is another method of producing $^1\Sigma$ and $^1\Delta$ oxygen in a gaseous system[99–104]:

$$O_3 + h\nu \rightarrow O_2[^1\Sigma \text{ or } {}^1\Delta) + O(^1D \text{ or } {}^3P).$$

From energy considerations we can establish the threshold

wavelengths for the direct production of $O_2(^1\Sigma)$ and $O_2(^1\Delta)$ by ozone photolysis. In principle the photolysis of ozone at $\lambda = 253.7$ nm can give either $O_2(^1\Sigma)$ or $O_2(^1\Delta)$ plus an atom of oxygen in the excited ^1D state, but in practice only $O_2(^1\Delta)$ is obtained[100]. Formation of $O_2(^1\Sigma)$ takes place by the following side reaction, involving energy transfer from an excited oxygen atom to molecular oxygen in the ground state[99,101,102,105]:

$$O(^1D) + O_2(^3\Sigma) \rightarrow O(^3P) + O_2(^1\Sigma).$$

The following reactions (which also take place in the system),

$$O(^1D) + O_2(^3\Sigma) \rightarrow O_2(^1\Delta) + O(^3P)$$
$$O_3 + h\nu_{253.7\,nm} \rightarrow O_2(^1\Sigma) + O(^1D)$$

are only minor sources of $O_2(^1\Delta)$ and $O_2(^1\Sigma)$.[100] It has been shown[14] that $O_2(^1\Sigma)$ can be obtained also by the photolysis of molecular oxygen from the reactions

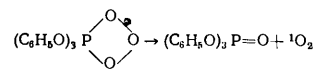
$$O_2 + h\nu_{147\,nm} \rightarrow O(^1D) + O(^3P)$$
$$O(^1D) + O_2(^3\Sigma) \rightarrow O_2(^1\Sigma) + O(^3P).$$

2. Chemical Sources of Singlet Oxygen

a) Decomposition of hydrogen peroxide

The decomposition of hydrogen peroxide according to Eqn.(2) was used in the first definite demonstration of the participation of singlet oxygen in sensitised photo-oxidation reactions[30,107–109].

In the absence of organic compounds the resulting singlet oxygen is deactivated (with chemiluminescence) to triplet oxygen[107]. By comparing the chemiluminescence bands with the emission bands of gaseous oxygen in an electric discharge and with the absorption bands of liquid oxygen it was established that the decomposition of hydrogen peroxide gives a high yield of singlet oxygen molecules[24,25,107,108,110–112]. The chemiluminescence is produced by double molecular transitions [see Eqns.(3) and (4)] as well as by the single molecular transitions



$$O_2(^1\Sigma) \rightarrow O_2(^3\Sigma) + h\nu_{760\,nm}$$
$$O_2(^1\Delta) \rightarrow O_2(^3\Sigma) + h\nu_{1270\,nm}. \qquad (9)$$

Studies of chemiluminescence[24,25,107,110] have yielded some other interesting results. Firstly, this work showed that the strongest band in the chemiluminescence spectrum (703.2 nm) results from a cooperative transition involving a pair of $O_2(^1\Delta)$ molecules, which is explained by the generation of large amounts of excited singlet oxygen during the decomposition of H_2O_2. Secondly, in solutions the chemiluminescence band at 760 nm [for the $O_2(^1\Sigma) \rightarrow O_2(^3\Sigma)$ transition] has a rotational fine structure which suggests that the radiation is from singlet oxygen molecules in gas bubbles[108] rather than from dissolved oxygen. Though the rotational structure has not been resolved in the other bands it is assumed that the whole of the radiation comes from oxygen molecules in the gas phase, because the life time of singlet oxygen in solution is very much shorter than in the gas phase (see Table 1).

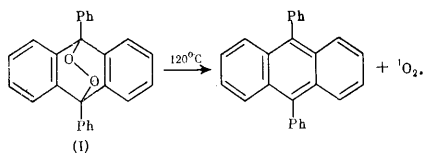
The yield of singlet oxygen during the decomposition of hydrogen peroxide is very sensitive to the nature of the solvent[113]. In methanol the yield is 70%, and high yields are obtained also in ethanol and in a methanol–t-butanol mixture. In other solvents miscible with water the yield is usually <10%.[113] This effect is not understood at present. Since photo-sensitised oxygenation is not sensitive to the solvent it follows that the nature of the solvent can influence the formation of singlet oxygen but not its reactions[7].

b) Decomposition of ozonides

One of the most convenient methods of chemical generation of singlet oxygen is the decomposition of the adduct of triphenyl phosphite with ozone, which can be prepared at −70 °C. When heated to −35 °C this compound gives singlet molecular oxygen by the reaction[114–118]:

The proof of the formation of singlet oxygen by the decomposition of this adduct rests on the observation that various oxygen acceptors can be oxidised by it to give the same products as the recognised reactions of singlet oxygen with the same acceptors. Wasserman and coworkers[119] showed by ESR spectroscopy that the decomposition of this ozonide produces $O_2(^1\Delta)$, which could be detected in the gas phase after being evolved from the solution. However, the possibility of complicating side reactions was later pointed out[120]. Tetramethylethylene (TME) was found to react with triphenylphosphiteozone at −60 °C, i.e. below the temperature at which the rate of decomposition of the adduct is sufficient to produce free oxygen in substantial amounts. Furthermore, by comparing the reactions of this adduct with TME and with 2,5-dimethylfuran (another effective acceptor of singlet oxygen) we note that TME is the more effective acceptor towards this adduct whereas in the sensitised oxidation reactions the opposite is true.

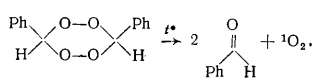
This work[120] led to the conclusion that direct transfer of O_2 from triphenylphosphiteozone (by an alternative mechanism) must be possible. The mechanism yields the same products as the reaction with free singlet oxygen, but it has a different selectivity towards various organic compounds. The study was extended to other alkenes[121], and direct transfer of O_2 from the adduct to the acceptor was again observed. In this sense the ozonides are very similar to the molecular oxides of Terenin and Schenck's mechanism[14,20,34,35].



The ozonides of 4-ethyl-2,6,7-trioxa-1-phosphabicyclo-[2,2,2]octane[122] and 1-phospha-2,8,9-trioxa-adamantane[123] have also been used as sources of singlet oxygen, which they generate at somewhat higher (and more convenient) temperatures.

c) Decomposition of endoperoxides

Various aromatic hydrocarbons (especially linear polyacenes) undergo sensitised photo-oxidation reactions in the presence of oxygen to give endoperoxides which dissociate on heating, regenerating the initial hydrocarbon and free molecular oxygen[9,124]. Theoretical considerations suggest that the oxygen generated by the dissociation of endoperoxides can be in an excited singlet state[125].



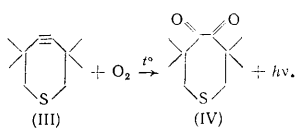
Wasserman and Scheffer[126] showed that the decomposition of 9,10-diphenylanthracene peroxide (I) in the presence of suitable acceptors of singlet oxygen can be used to promote

typical singlet oxygen reactions:

(I)

Similarly, singlet oxygen can be generated[127] by heating 3,6-diphenyl-1,2,4,5-tetroxan (II):

d) Decomposition of the O_2^- ion



The peroxide ion O_2^- is a potential source of singlet oxygen, since by losing an electron of the appropriate spin it can give either molecular oxygen in the ground state or singlet excited oxygen[14]:

$$^2O_2^- \rightarrow {}^{1,3}O_2 + e^-$$

Evidence of sensitised fluorescence has been detected[128] by adding various fluorescent dyes to a saturated solution of potassium peroxide in dimethylsulphoxide. This was interpreted[128] as evidence for the formation of singlet oxygen in this system, but other chemiluminescence mechanisms cannot be excluded, and doubts were later expressed[129] on this conclusion.

e) Thermal preparation of singlet oxygen

Turro and coworkers[130] reported that the seven-membered alkyne compound 3,3,6,6-tetramethyl-1-thia-4-cycloheptyne (III) when heated (~90 °C) in the dark in the presence of atmospheric oxygen yields the dione (IV) with chemiluminescence [Eqn.(10)]:

(III) (IV) (10)

The same product is obtained by the reaction between the compound (III) and singlet oxygen. Since atmospheric oxygen is triplet, intercombination conversion must be taking place at some stage during reaction (10). The authors conclude[130] that a reactive intermediate (probably an ionic acetylene–oxygen adduct) is formed during the reaction. They suggest that the triple bond in this adduct increases the probability of finding both the electrons from the electron pair of the oxygen molecule on the same oxygen atom, and hence it increases the probability of forming singlet oxygen by the pairing of these electrons.

Free singlet oxygen is generated by the decomposition of the acetylene–oxygen intermediate complex. In this way the starting compound is regenerated, and therefore the process can be classified as a catalytic thermal generation of singlet oxygen from triplet oxygen. This process could be very important in biological systems.

f) Other chemical sources of singlet oxygen

Peroxyacetyl nitrate (PAN), a component of smog, is easily decomposed in the presence of bases[14]:

$$CH_3\overset{O}{\overset{\|}{C}}OONO_2 + 2OH^- \rightarrow CH_3\overset{O}{\overset{\|}{C}}O^- + H_2O + NO_2^- + O_2.$$

Steer and coworkers[131] studied this reaction, and detected a weak radiation at 1270 nm during the decomposition of PAN which they assigned to the $O_2(^1\Delta) \rightarrow O_2(^3\Sigma)$ transition. They ascribed the high reactivity of PAN in chemical and biological systems to its ability to generate singlet oxygen.

Some other compounds also could be of interest for the generation of singlet oxygen. They include the monomeric adducts of oxygen with various transition metals[132–135], and also clathrate oxygen compounds[136]. It has been reported[137] that even in oxyhemoglobin singlet oxygen is formed in the light by a reaction photosensitised by heme:

$$Hem—{}^3O_2 \overset{h\nu}{\rightleftarrows} {}^1Hem^*—{}^3O_2 \rightarrow Hem + {}^1O_2.$$

Although heme does not fluoresce, and hence cannot sensitise the formation of $^1O_2$ in the normal way, its physical proximity to an oxygen atom in the oxyhemoglobin molecule appears to compensate for the short life time of the excited state[137].

3. Electrical Discharge

In this physical method of generating singlet oxygen, discovered by Noxon[138] and developed by various workers[12,111,139,140], an electrodeless microwave or radio-frequency discharge in a stream of oxygen in a discharge tube produces ~10% of $O_2(^1\Delta)$. A mass spectroscopic study of this reaction[142] has shown that the $O_2(^1\Delta)$ continues to exist beyond the discharge region. A small amount of $O_2(^1\Sigma)$ is also produced in the discharge[143], but it rapidly relaxes to $O_2(^1\Delta)$. Oxygen atoms are also formed in the electric discharge, but they can be removed by placing a film of mercuric oxide between the discharge and the observation point[144].

Ozone is another component formed in the discharge. It can react with $O_2(^1\Sigma)$ according to the equation[145]

$$O_2(^1\Sigma) + O_3 \rightarrow O_2 + O_2 + O.$$

The oxygen atoms produced by this reaction can react with a further molecule of ozone:

$$O + O_3 \rightarrow 2O_2.$$

In the absence of ozone and other gases the de-activation of $O_2(^1\Delta)$ and $O_2(^1\Sigma)$ occurs mainly through collisions with the walls of the flow system[140].

4. Incandescent Lamps as Sources of Singlet Oxygen

Khan has shown[146] that electronically excited molecular oxygen can be generated by an ordinary tungsten filament lamp. He found that the radiation from a tungsten filament lamp consists of a series of distinct peaks on a continuous background, and he noted that these peaks correspond to emission bands which had been previously assigned to simultaneous transitions of oxygen pairs. It is assumed that excited oxygen molecules are formed on the tungsten surface, and are then emitted from this surface[147].

Spectroscopic observations[146] have led to the suggestion[14] that the weak luminescence at 520–620 nm which accompanies the chemisorption of oxygen on clean tungsten surfaces[148] may also be due to radiation from excited oxygen molecules.

A relationship between the weak luminescence observed[149] at 600–800 nm during the adsorption of oxygen molecules on various solid oxide surfaces and the formation of singlet oxygen molecules is also possible.

III. METHODS OF DETECTION OF SINGLET OXYGEN

1. Gas-phase Methods

Various methods of detecting singlet oxygen in the gas phase are discussed in recent reviews[1,12,14].

a) Paramagnetic resonance

Oxygen in the $^1\Delta$ state is paramagnetic by virtue of its orbital angular momentum, and several workers[60,119,150–152] have observed and analysed the paramagnetic resonance spectrum of $O_2(^1\Delta)$ in a discharge. In particular, signals corresponding to transitions with $\Delta M = 1$ have been observed for states with a full angular momentum $J = 2$ in addition to the normal signals for the triplet ground state of oxygen. In this way it was shown that the concentration of $O_2(^1\Delta)$ is 10% of the total concentration of oxygen in the discharge. The same method has been used to demonstrate the formation of $O_2(^1\Delta)$ in the gaseous decomposition products of the triphenyl phosphite–ozone adduct[119], and the formation of $O_2(^1\Delta)$ by energy transfer from sensitisers in the triplet state[60,152].

The EPR method is specific for the $^1\Delta$ state of oxygen, because the $^1\Sigma$ state is diamagnetic.

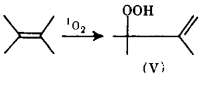
b) Emission spectroscopy

Optical radiation from the $O_2(^1\Delta)$ and $O_2(^1\Sigma)$ molecules can be detected in the gas phase[10,26,27,110,138,139,153–157]. Single molecular transitions occur at 1270 and 760 nm respectively [see Eqn.(9)]. At high oxygen pressures the cooperative (or bimolecular) radiation bands at 634 and 703 nm are easily observed [see Eqn.(3)], as well as the weaker bands at 381 and 478 nm [Eqn.(4)].

An important advantage of the emission spectroscopy method is its ability to detect both $O_2(^1\Sigma)$ and $O_2(^1\Delta)$ over a wide pressure range, whereas by the EPR method $O_2(^1\Delta)$ can be detected only at pressures of several Torr. The sensitivity of the method can be raised still further by using a reflective amplifier to detect the radiation[158].

c) Photo-ionisation

The ionisation potentials of singlet oxygen molecules in $^1\Delta$ and $^1\Sigma$ states are lower (by 1.0 and 1.6 eV respectively) than the ionisation potential of the $^3\Sigma$ ground state (12.5 eV).[159] The photo-ionisation method of detecting excited oxygen is based on this difference[160–163]. The method was used initially with monochromatic excitation[160–162], but later a large increase in sensitivity was obtained by using the resonance lines of the inert gases to ionise excited oxygen molecules[163]. For example, the krypton line at 1165 Å selectively ionises $O_2(^1\Sigma)$, whereas the argon resonance lines at 1067 and 1048 Å ionise both $O_2(^1\Delta)$ and $O_2(^1\Sigma)$, but not $O_2(^3\Sigma)$. The method has yielded valuable information on the rate constants of various reactions of singlet oxygen in the gas phase.

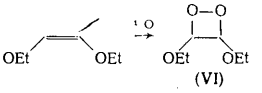


Though the photo-ionisation method is very sensitive, its applications are limited, because the method is not appropriate to systems containing organic molecules, oxides of nitrogen, or other compounds having an ionisation potential lower than 11 eV.

d) Calorimetry

The isothermal calorimetric method of detecting $O_2(^1\Delta)$ depends on the efficient deactivation of this species on a cobalt-coated platinum wire[10,110,111,164]. The heated wire is exposed to the gas stream, and the concentration of excited oxygen molecules can be calculated from the quantity of heat generated by the deactivation process. It has been shown[10,110] that a wire coated with cobalt can deactivate more than 95% of the $O_2(^1\Delta)$ present in the gas stream. The main disadvantage of this method is its lack of selectivity, since $O_2(^1\Sigma)$, atomic oxygen, and any other species in an excited state present in the gas can contribute to the heat evolution.

2. Methods of Detecting Singlet Oxygen in the Condensed Phase. Effect of the Solvent on the Life Time of Singlet Oxygen



Since the life time of singlet oxygen in the condensed phase is approximately eight orders of magnitude [for $O_2(^1\Delta)$] and ten orders of magnitude [for $O_2(^1\Sigma)$] lower than in the gas phase (see Table 1), most of the methods used to detect singlet oxygen in the gas phase are inappropriate for solutions. Chemical methods are used for solutions, but they are not always reliable. Thus, the reaction of TME with singlet oxygen produces the rearranged allyl hydroperoxide (V):[6,7,30]

(V)

The formation of this hydroperoxide is usually taken as an indication of the presence of $^1O_2$.[85,128] However, there is evidence that this allyl hydroperoxide is formed also when TME reacts with oxygen in the ground state by a chain reaction mechanism including free-radical intermediates[120,165,166].

Singlet oxygen reacts with vinyl diethers to form dioxetanes (VI):[14]

(VI)

However, the same products can be obtained from "non-singlet" oxidation reactions[167], and additional experiments are needed to exclude other possible reactions. These involve adding one or two singlet oxygen fluorescence quenchers (for example, β-carotene, or a tertiary amine such as 1,4-diazobicyclo[2,2,2]octane), and also a typical inhibitor of free-radical auto-oxidation (a substituted phenol). The role of singlet oxygen can be inferred from a comparison of the two experiments.

Of all the reactions examined only the 1,4-cycloaddition to conjugated dienes can be used as an unambiguous test of the presence of singlet oxygen, since no other reagent appears to give the same product[165].

A new method of detecting singlet oxygen in solutions, based on measurements of the life time of singlet oxygen in solutions by infrared spectroscopy, was developed by Merkel

and coworkers[168,169]. These workers found that the life time of singlet oxygen is surprisingly very sensitive to the nature of the solvent. They generated[168,169] singlet oxygen ($\sim 5 \times 10^{-5}$ M) by energy transfer from Methylene Blue triplets excited by light pulses from a ruby laser. The singlet oxygen was then determined spectroscopically by its reaction with the coloured acceptor DPBF to give a colourless product. Measurements of the bleaching rate at two different acceptor concentrations gave the life time of the singlet oxygen and the rate constant of the reaction. When the concentration of DPBF was too low for this reaction to be the main deactivation path of the $O_2(^1\Delta)$ the life time of the singlet oxygen was calculated directly.

Table 3. Solvent dependence of the life time of $O_2(^1\Delta)$.[168,169]

Solvent	Water	Heavy water	Methanol	Ethanol	Cyclohexane	Benzene	Acetone	Chloroform	Hydrogen sulphide	Carbon tetrachloride
Life time of $O_2(^1\Delta)$, μs	2	20	7	12	17	24	26	60	200	700

Table 4. Solvent dependence of the life time of $O_2(^1\Delta)$.[171]

Solvent	n-Butanol	t-Butanol	Benzene methanol (4:1)	Bromobenzene/methanol (4:1)	Pyridine	Dioxan
Life time of $O_2(^1\Delta)$, μs	19±3	34±4	26±5	23±4	33±15	32±10

The results[168,169] revealed no correlation between the life time of the singlet oxygen and properties of the solvent such as the viscosity and dielectric constant. The same conclusion was reached independently in another investigation[170]. Merkel and coworkers[168,169] also found that the life time of singlet oxygen is 10 times higher in D_2O than in ordinary water (see Table 3).

More recently, measurements of life time by flash photolysis have been reported for other solvents (see Table 4).[171]

The deuterium isotope effect has been used[168,169] as a new method of detecting singlet oxygen in solutions. By monitoring the rate of bleaching of DPBF (10^{-5} M) in H_2O/CH_3OH (1:1) and D_2O/CD_3OD (1:1) mixtures under otherwise identical conditions they noted a ten-fold increase in the effectiveness of photo-oxidation in the deuterated solvent. Since the rate constant was unaffected by the deuteration, a ten-fold increase in the life time of singlet oxygen was inferred from these observations.

Theory of Mixed Isoactive Electrolyte Solutions

Yu.G.Frolov

The basic laws of the osmotic theory of mixed isoactive solutions of electrolytes are discussed, and the possibilities of calculating the thermodynamic functions of the mixtures from data for the binary isopiestic solutions are considered. The results obtained for the salting-out effect in extraction systems are presented as an illustration of the theory. 94 references.

I. INTRODUCTION

The theory of isoactive solutions has been applied increasingly in theoretical work and in practical calculations in recent years. Work during the past 10–15 years has produced the first theory able to deal with both dilute and concentrated (up to saturation) solutions of electrolytes. This theory relies on comparisons of the properties of mixed solutions with those of the initial binary systems at constant activity of the solvent (isopiestic method). Electrolyte solutions have many common features, and it seems logical to use the properties of binary solutions to calculate the corresponding properties of electrolyte mixtures. However, in principle, the general conclusions of the theory can be applied to any system.

The theory can be said to have begun in 1936, when Zdanovskii's rule was published[1] (the fundamental relationship in this theory). However, general interest in Zdanovskii's rule became evident only in the 1960's, stimulated by discussions of its physical significance and of its role in solution thermodynamics. We should note that almost all the theoretical foundations of the theory of isoactive solutions were laid by Soviet scientists.

The general thermodynamic relationships used in the isopiestic method are discussed by Kirgintsev[2]. In this review we shall examine the limiting laws and the possibility of calculating the properties of mixed systems from data for the binary solutions.

II. LAW OF IDEAL MIXING OF ISOPIESTIC SOLUTIONS

The deviation from ideal behaviour of the solvent in a solution is usually characterised by an osmotic coefficient. In our studies of salting-out in electrolyte solutions[3–5] we have pointed out that the osmotic coefficient also describes the tendency of the solute to take up solvent (especially water). This tendency is described particularly well by the molal osmotic coefficient ϕ, defined by the expression

$$\ln a_w = -0.001\ M\nu m\varphi, \qquad (1)$$

where a_w is the activity of the solvent, M is its molecular weight, ν is the stoichiometric coefficient of the electrolyte, and m is the molal concentration of the solute.

Formula (1) is written for a binary solution. If the solution contains several solutes the formula becomes

$$\ln a_w = -0.001 M\varphi_m \sum \nu_i m_i. \qquad (2)$$

The osmotic coefficient of the mixed solution (ϕ_m) is a measure of the average tendency to take up solvent for the particular mixture of solutes. In order to determine the contribution of each component we need to consider the limiting case in which the specific interaction between the components is negligibly small, i.e. we must assume that the molecules or ions of the solute experience the same effect from the other components in the mixed solution as in a binary solution with solvent at the same activity (where the effect arises entirely from like molecules or ions). In such a solution the components have the same tendency to take up solvent as in a binary solution of the same activity, since the solvent has the same "lack of attractiveness" in the two media. The numbers of solvent molecules oriented around a given ion remain the same. Under these conditions the osmotic coefficients of a given component in the binary and in the mixed solution having the same solvent activity should be the same[3].

Thus, for this particular limiting case Eqn.(2) can be written as a sum of the contributions of the individual components to the decrease in the activity of the solvent:

$$\ln a_W = -0.001 M \sum \nu_i m_i \varphi_i^*, \qquad (3)$$

where ϕ_i^* is the osmotic coefficient of the binary solution in isopiestic equilibrium with the mixed solution. (Throughout this reivew we shall use an asterisk to denote parameters referring to isopiestic binary solutions.)

From Eqns.(2) and (3) we obtain

$$\varphi_m = \sum \nu_i m_i \varphi_i^* / \sum \nu_i m_i \text{ or}$$
$$\varphi_m = \sum y_i \varphi_i^*, \qquad (4)$$

where y_i is the ion fraction defined as $\nu_k m_k / \Sigma \nu_i m_i$. Thus ϕ_m is an additive function of composition. Therefore, under these conditions the osmotic pressure generated by a given electrolyte in a mixture is proportional to the ionic concentration of the electrolyte over the whole range of ion fractions. The postulated equality of the osmotic coefficients of the component in isopiestic solutions (i.e. Eqn.(4) has been confirmed[5] from the theoretical and experimental results

of many authors[6-15] for various mixed solutions of alkali metal and other chlorides and nitrates. Experimental results agreed within 1–2% with those calculated from data for the isopiestic binary solutions (with total salt concentrations as high as 3.0–5.0 *m*).

Hence, dividing Eqn.(3) by Eqn.(1) for isopiestic mixed and binary solutions, we obtain[3] the expression known as Zdanovskii's rule:

$$\sum_i m_i/m_i^* = 1, \qquad (5)$$

where m_i^* is the molality of the binary solution having a solvent activity identical to that of the mixed solution. Zdanovskii arrived at this rule purely empirically[1], and at first believed it to be approximate and valid in special cases only. Th law states that when isopiestic binary solutions are mixed the activity of the solvent is unchanged in the absence of specific interactions between the solutes.

Dividing (5) by the total molality or by the total ionic concentration gives, respectively,

$$\frac{1}{m} = \sum_i \frac{1}{m_i^*} x_i \text{ and } \frac{1}{\nu m} = \sum_i \frac{1}{\nu_i m_i^*} y_i, \qquad (6)$$

whence we find that the reciprocal total molality and the reciprocal total ionic concentration are additive functions of composition (x is the mole fraction).

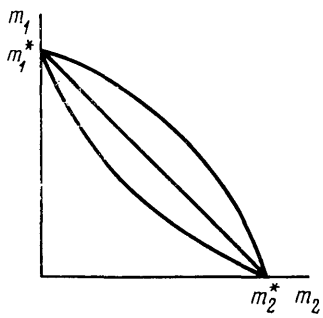

Figure 1. Isotherm–isobars of water in a ternary water–salt system.

For ternary aqueous salt systems with two dissolved electrolytes *1* and *2* Eqns.(5) and (6) take the form

$$m_1/m_1^* + m_2/m_2^* = 1 \qquad (7)$$

and

$$\frac{1}{m} = \frac{1}{m_1^*} x_1 + \frac{1}{m_2^*} x_2. \qquad (8)$$

According to these two equations Zdanovskii's rule can be expressed graphically by straight-line plots (Figs.1 and 2). Its validity has been demonstrated for a large number of systems by Zdanovskii himself and by other workers. Existing experimental information, reported from different laboratories, shows that in mixed solutions of electrolytes with a common anion the deviations from Zdanovskii's rule are usually less than 1–2%. These solutions include the halides, nitrates, and sulphates of the alkali and alkaline-earth metals, and various other salts, at concentrations up to saturation. The fullest bibliography on this topic is given in Ref.16, but it is already seriously out of date.

This discussion of the thermodynamic significance of Zdanovskii's rule allows us to generalise the rule and to conclude that it should apply not only to solutions of salts with a common anion, as had previously been assumed, but also to mixed solutions from any system[3]. This conclusion was confirmed experimentally for solutions with a common cation[3] (including mixtures of strong acids) and for systems without a common ion[17,18]. The latter systems were subsequently studied in detail in our laboratory, following a suggestion by G.I.Mikulin, as quaternary reciprocal systems.

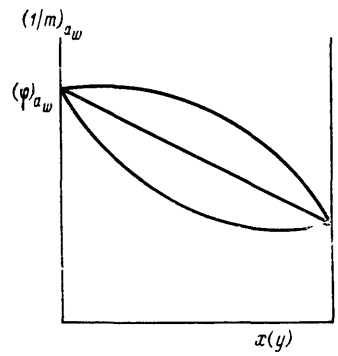

Figure 2. Reciprocal total molality and osmotic coefficient against composition of the ternary solution.

All the available results show that the only condition for the validity of Zdanovskii's rule on mixing binary solutions of electrolytes is the absence of specific interactions between the ions, so that the form of the ions and of their associations is unchanged by the conversion of the binary solution into a mixed solution. Hence no redistribution of the solvent among the components takes place when isopiestic solutions of this type are mixed. For example, large deviations from Zdanovskii's rule are observed[19,20] on mixing solutions of caesium and cobalt chlorides, because the two cations have very different affinities for the chloride ion. On the other hand, isopiestic solutions of cobalt and nickel chlorides can be mixed in exact accordance with Zdanovskii's rule, in spite of the well known chemical interaction between the cations and the anions. This is because of the similarity in properties of the cobalt and nickel ions towards the chloride ion: as a result, there is no redistribution of the chloride ions on mixing, and hence no redistribution of the water.

In the absence of specific interactions between the electrolytes it follows from Eqns.(1)–(3) that the total osmotic activity (as well as the activity of the water) is unchanged when isopiestic solutions are mixed. The total osmotic activity remains equal to the sum of the osmotic activities of the binary solutions, i.e.

$$\sum \nu_i m_i \varphi_i^* = \text{const.} \qquad (9)$$

This expression conveniently characterises the behaviour of solutes on mixing. It is formally similar to the law of constant ionic strength, but it is more strict as well as having greater generality, since it is applicable also to concentrated solutions. If the solutions being mixed have equal (or similar) osmotic coefficients the law of constant osmotic

activity (9) becomes a law of constant ionic concentration, since in this case the isopiestic binary solutions will have identical ionic concentrations and the mixing will affect neither the activity of the water nor the ionic concentration of the resulting mixed solution. This follows from Eqn.(5) for the condition

$$m_1^* = m_2^* = \ldots m_i^*.$$

The direct relationship which we have established between Zdanovskii's rule and the postulate of equal osmotic coefficients of the components in isopiestic solutions, and the resulting additivity of the properties [Eqns.(4) and (6)], suggest that the two laws are identical and are both limiting laws. Additional evidence for this statement comes from the following considerations. Constancy of the solvent activity and of the osmotic activity of the electrolytes on mixing is possible only when the excess Gibbs free energy is zero ($G_m^E i = 0$). Since the activities are related to the chemical potentials, this is a sufficient condition for constancy of the solvent activity, i.e. for the validity of Zdanovskii's rule. However, it follows from the expression

$$G_m^{Ei} = \Delta H - TS_m^{Ei} = \Delta H + T\partial G^{Ei}/\partial T,$$

(where ΔH is the enthalpy of mixing, T is the temperature, and $S_m^E i$ is the excess entropy of mixing) that, in general, we have $\Delta H = 0$ for $G_m^E i = 0$, i.e. that mixing is ideal when Zdanovskii's rule applies. Nevertheless non-ideal mixing with $G_m^E i = 0$ is possible in some cases: this occurs when a small enthalpy change can be compensated (at a given temperature) by the excess entropy term.

Thus, in general mixed solutions free from specific interactions between the dissolved components can be prepared by ideal mixing of binary solutions of the components in isopiestic equilibrium. We have proposed the term isoactive for solutions of this type[18,21].

The first evidence of the ideality of mixing in accordance with Zdanovskii's rule was obtained by Vdovenko and Ryazanov[22,23], who also formulated the analogy between Zdanovskii's rule and Raoult's law. A similar demonstration was later given by Kirgintsev[2] by introducing a new thermodynamic function (the aqueosity of the solution).

It follows that Zdanovskii's rule can no longer be treated as partial and approximate: it is a limiting expression, or, more strictly, a limiting law[24]. Hence, experimental results on mixed solutions cannot be classified as confirming (or not confirming) the generality of this law. Zdanovskii's law is entirely general, and it can be used as a standard of comparison for the properties of real solutions: in other words, the whole of the experimental information can be interpreted from the standpoint of deviations from this law. This is the essential feature common to all limiting laws. No "correction" to Eqn.(5) can increase its generality, since it introduces some indeterminacy arising from the need to determine the correction experimentally for each specific system.

III. ADDITIVITY OF THE PROPERTIES OF MIXED SOLUTIONS OF ELECTROLYTES

The ideal mixing of isopiestic binary solutions of electrolytes allows us to calculate all the thermodynamic properties of mixed isoactive solutions from the properties of the initial binaries. The difference from the calculation of the properties of ideal solutions is that the mixing of individual components is replaced (in the case of isoactive solutions) by the mixing of the appropriate binary solutions in isopiestic equilibrium with the mixed isoactive solution. Thus all the calculations begin with a determination of the so-called isopiestic concentrations m_i^* of the binary solutions, usually by a selection method relying on successive approximations[1]. The concentration dependence of the activity of the water in the binary solutions is first established from tabulated data (Fig.3). A suitable value of the activity of water is then chosen, and the corresponding concentration is inserted into Eqn.(5) (the concentrations of the components in the mixed solution m_i are assumed to be known). If the sum differs from unity the operation is repeated: when the results are satisfactorily consistent the calculated concentrations of the binary solutions will be isopiestic.

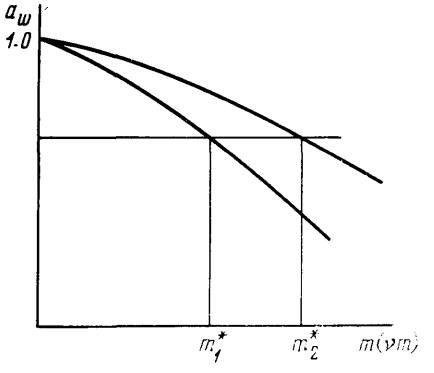

Figure 3. Determination of the isopiestic concentrations m_1^* and m_2^* for a ternary solution.

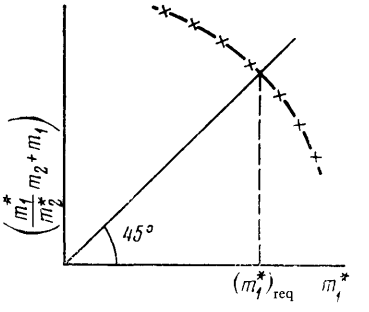

Figure 4. Graphical determination of the required value of m_1^*.

The need for selection can be avoided by using the method proposed in Ref.22. Zdanovskii's law for a ternary solution is written

$$\frac{m_1^*}{m_2^*} m_2 + m_1 = m_1^*.$$

The ratio m_1^*/m_2^* can be taken from tabulations, or alternatively we can use Fig.3 and draw a number of sections for different water activities. We then plot (Fig.4) the function $(m_1^*/m_2^*)m_2 + m_1$ against the corresponding value of m_1^*. The intersection of the resulting curve with a straight line drawn

through the origin at 45° gives the wanted value of m_1^*. The concentration m_2^* is found in a similar way. In extensive calculations it is convenient to establish the approximate $a_W = f(m_i)$ expressions and to solve them simultaneously with Eqn.(5) on a computer[25].

These methods can be used only when the isopiestic concentrations do not exceed the solubility limits of the components. If the isopiestic concentration is higher than the solubility it cannot be determined experimentally. Zdanovskii overcame this problem by graphically extrapolating the $a_W = f(m^*)$ relationships to the supersaturated solution region. In our work[25] the same result was achieved by using analytical expressions as approximations to the experimental data. If experimental values of the activity of water are available for solutions saturated with the first electrolyte, i.e. for point C lying on the m_1^S–m_{12}^S curve of Fig.5, the calculation is possible[26]. If the coordinates of this point are m_1 and m_2 we can solve Eqn.(5) for m_1^* and obtain

$$m_1^* = m_1 m_2^* / (m_2^* - m_2).$$

Therefore the quantity m_1^*, corresponding to a given activity of water, can be found if m_1, m_2, and m_2^* are known. Mikulin[27] carried out calculations of this type in his graphical–analytical treatment of data for the KCl–NaCl–H_2O, KNO_3–$NaNO_3$–H_2O, and NaCl–$CaCl_2$–H_2O systems.

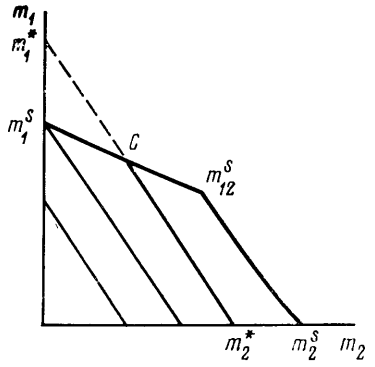

Figure 5. Determination of the isopiestic concentration beyond the solubility limit.

If the isopiestic concentrations of the binary solutions and their properties are known, the corresponding property for the multi-component isopiestic solution is easily calculated. Ideality of mixing is equivalent to zero changes in enthalpy and in volume on mixing: it follows that these properties (and others, related to them) are additive. In mixed isoactive solutions additivity is expected in relation to the isopiestic binary solutions. For example, in order to form a ternary solution of given composition the initial binary solutions have to be mixed in the appropriate proportions. According to Zdanovskii's law (5), in order to prepare a mixture of electrolytes having a common ion in which the concentration of the first electrolyte is m_1 and that of the second electrolyte is m_2 we have to mix m_1/m_1^* parts of the binary solution of electrolyte *1* and m_2/m_2^* parts of the binary solution of electrolyte *2*. The enthalpy of the resulting ternary solution will be[23]

$$H = \frac{m_1}{m_1^*} H_1^* + \frac{m_2}{m_2^*} H_2^* \quad \text{or} \quad H = \sum_i \frac{m_i}{m_i^*} H_i^*. \tag{10}$$

In a similar way we can obtain an expression for the volume:

$$V = \frac{m_1}{m_1^*} V_1^* + \frac{m_2}{m_2^*} V_2^* \quad \text{or} \quad V = \sum_i \frac{m_i}{m_i^*} V_i^*. \tag{11}$$

The additivity of the enthalpy and volume allows us to calculate other properties of the multicomponent solutions derived from these functions. For example, Zdanovskii[28] obtained a similar expression for the specific heat

$$C = \frac{m_1}{m_1^*} C_1^* + \frac{m_2}{m_2^*} C_2^* \quad \text{or} \quad C = \sum_i \frac{m_i}{m_i^*} C_i^* \tag{12}$$

and for the density (the reciprocal of the specific volume)

$$\frac{1}{\rho} = \frac{m_1}{m_1^*} \frac{1}{\rho_1^*} + \frac{m_2}{m_2^*} \frac{1}{\rho_2^*} \quad \text{or} \quad \frac{1}{\rho} = \sum_i \frac{m_i}{m_i^*} \frac{1}{\rho_i^*}. \tag{13}$$

The entropy is defined by the equation

$$S = \frac{m_1}{m_1^*} S_1^* + \frac{m_2}{m_2^*} S_2^* + \Delta S_m \quad \text{or} \quad S = \sum_i \frac{m_i}{m_i^*} S_i^* + \Delta S_m, \tag{14}$$

where ΔS_m is the ideal entropy of mixing. The equation for the Gibbs free energy therefore becomes

$$G = \frac{m_1}{m_1^*} G_1^* + \frac{m_2}{m_2^*} G_2^* + \Delta G_m \quad \text{or} \quad G = \sum_i \frac{m_i}{m_i^*} G_i^* + \Delta G_m, \tag{15}$$

where ΔG_m is a purely entropic term. When the ideality of the mixing of isopiestic solutions has been established Eqns.(10)–(15) can be used in the simplified form shown.

The equation for the change in entropy during ideal mixing of isopiestic binary solutions was obtained by Vdovenko and Ryazov by a statistical method[23]:

$$\Delta G_m = -T\Delta S_m = RT\left(\nu_1 m_1 \ln \frac{\nu_1 m_1}{\nu_1 m_1 + \nu_2 m_2} + \nu_2 m_2 \ln \frac{\nu_2 m_2}{\nu_1 m_1 + \nu_2 m_2} - \right.$$
$$\left. - \nu_{-1} m_1 \ln \frac{\nu_{-1} m_1}{\nu_{-1} m_1 + \nu_{-2} m_2} - \nu_{-2} m_2 \ln \frac{\nu_{-2} m_2}{\nu_{-1} m_1 + \nu_{-2} m_2}\right), \tag{16}$$

where the subscripts −1 and −2 denote the anions of the first and the second electrolyte. If the electrolytes *1* and *2* have no common ion the last two terms drop out of the equation.

All these expressions for thermodynamic properties per mole of solute can be written in the form[29]

$$\Phi^m = x_1 \Phi_1^{m*} + x_2 \Phi_2^{m*} + \Delta\Phi_{m.id.}^m, \tag{17}$$

where Φ_i^m are the thermodynamic functions referred to one mole of solute, and $\Phi_{m.id.}^m$ is the change in the thermodynamic functions caused by ideal mixing of the isopiestic solutions.

If the binary solutions being mixed have the same (or similar) concentration dependences of the water activity, or similar values of the osmotic coefficients under isopiestic conditions, the total ionic concentration in the mixed solution will be equal (or similar) to the ionic isopiestic concentrations in the binary solutions [see Eqns.(1) and (3)]. In this case all the equations for additive functions (Φ) again take a form similar to Eqn.(17):

$$\Phi = x_1 \Phi_1^* + x_2 \Phi_2^* + \Delta\Phi_{m.id.} \quad \text{or} \quad \Phi = \sum_i x_i \Phi_i^* + \Delta\Phi_{m.id.}. \tag{18}$$

The properties of one binary solution may have to be inferred from those of the mixed solution and of the other binary solution. For example, it is difficult (or even impossible) to determine the properties of solutions of salts undergoing hydrolysis. Hydrolysis can be suppressed by adding acid to the solution: if the mixture can be assumed to be an isoactive solution the properties of the binary solution of hydrolysable electrolyte in a hypothetical non-hydrolysed acid-free form[30] can easily be calculated by the above formulae.

The properties of isoactive systems are directly related not only to those of the isopiestic binary solutions but also to those of solutions of any concentration. This is because

when solutions with different solvent activities are mixed only redistribution of the solvent takes place between the electrolytes. "Internal" levelling of the activity occurs, increasing concentration of one component being accompanied by increase ing dilution of another. The process taking place within the solution can be described as a succession of steps: 1) dilution and concentration of the binary solutions to the isopiestic concentration levels, and 2) ideal mixing of the isopiestic binary solutions. Thus, any property of the solution can be expressed as the sum

$$\Phi_i = \Phi_i^* + \Delta\Phi_{m_i - m_i^*} \quad \text{or} \quad \Phi_i^* = \Phi_i - \Delta\Phi_{m_i - m_i^*}, \tag{19}$$

where $\Delta\Phi_{m_i^I - m_i^*}$ is the change in the function for the binary solution upon conversion from the concentration chosen for mixing to the isopiestic concentration.

It has been shown[29] that the thermodynamic functions of mixing can be calculated by expressions similar to (10)–(17):

$$\Delta\Phi_m = \frac{m_1}{m_1^*}\Delta\Phi_{m_1' - m_1^*} + \frac{m_2}{m_2^*}\Delta\Phi_{m_2' - m_2^*} + \Delta\Phi_{m.id.} \tag{20}$$

If the thermodynamic functions are calculated for one mole of electrolyte we have

$$\Delta\Phi_m^m = x_1\Delta\Phi_{m_1' - m_1^*}^m + x_2\Delta\Phi_{m_2' - m_2^*}^m + \ldots + \Delta\Phi_{m.id.}^m \tag{21}$$

Since the mixing effects during formation of isoactive solutions are determined by the solvent redistribution and by the ideal entropy changes which follow the mixing of isopiestic solutions, an appropriate term is added to Eqns.(20) and (21): in the case of functions independent of the entropy of mixing this term is zero. For example, for the enthalpy of mixing we have

$$\Delta H_m^m = x_1\Delta H_{m_1' - m_1^*}^m + x_2\Delta H_{m_2' - m_2^*}^m. \tag{22}$$

This expression was obtained by Zdanovskii and Deryabina[31] for the enthalpy change caused by the redistribution of the solvent. It is evident from Eqn.(19) that the expression for a generalised property of the mixed solution in terms of the properties of binary solutions of arbitrary concentration takes the form of Eqns.(10)–(17):

$$\Phi = \frac{m_1}{m_1^*}(\Phi_1 - \Delta\Phi_{m_1' - m_1^*}) + \frac{m_2}{m_2^*}(\Phi_2 - \Delta\Phi_{m_2' - m_2^*}) + \ldots + \Delta\Phi_{m.id.} \tag{23}$$

If the property is calculated for one mole of the electrolyte the expression becomes

$$\Phi^m = x_1(\Phi_1^m - \Delta\Phi_{m_1' - m_1^*}^m) + x_2(\Phi_2^m - \Delta\Phi_{m_2' - m_2^*}^m) + \ldots + \Delta\Phi_{m.id.}^m \tag{24}$$

Thus, if no specific interactions between the electrolytes are found in the mixed solution (as compared with the binary solutions) the properties of the mixed solution—including the functions of mixing of the binary solutions—can be calculated from the properties of the latter without further experiments.

To conclude this Section we should stress that in principle any mixed solution of electrolytes, even one in which chemical interactions are present, can be treated as isoactive if the compositions of the resulting complexes are known. The analogy with ideal associated solutions[32] is appropriate. By allowing for the chemical interaction we can compare these systems with the binary isopiestic solutions of their components. However, calculation of the thermodynamic properties of the system is possible only if the necessary data for the binary solutions of the initial components and of the resulting components are available. If complexes are formed our formulae will have limited value, since very few data are available on the properties of complex solutions (especially when the stability of the complexes is low). However, this approach offers the possibility of calculating complex formation in solutions[33].

All the arguments presented here follow from the postulate that isoactive solutions can be treated as "an ideal mixture of binary solution quasi-particles"[34]. The quasi-particles can be simple ions, complex ions, or neutral molecules, i.e. any formation known to be present in real solutions. Deviations from the limiting law are a result of the impossibility of allowing for the large number of states in which the dissolved components may exist. If allowance can be made even only for the fundamental states the mixed solutions can be "reduced" to isoactive or almost isoactive solutions. This is clearly shown by our work[35–37] on systems containing sulphuric acid, which has only a weak second dissociation though most of the thermodynamic properties of its solutions have been determined with respect to full dissociation. By ignoring the second dissociation step and treating sulphuric acid as a 1–1 electrolyte we were able to show experimentally[36,37] that mixtures of sulphuric acid and monobasic inorganic acids (nitric, perchloric, hydrochloric) or lithium or potassium hydrogen sulphates can be treated as isoactive with acceptable precision (up to ±3%). In practice, mixtures of lithium sulphate and hydrogen sulphate are also isoactive: the deviations increase with the size of the alkali metal cation. All the thermodynamic parameters of the mixed solutions mentioned above were calculated in our laboratory[37] by using this effect.

IV. ACTIVITY COEFFICIENTS OF ELECTROLYTES IN MIXED ISOACTIVE SOLUTIONS

The condition for the formation of an isoactive mixed solution from isopiestic binary solutions is ideal mixing ($\Delta G_m^E i = 0$). From this condition we can easily obtain an expression for the activity coefficients (γ) of the components in the mixed solution, which vary only as a result of changes in the overall ionic concentration. This involves comparing the chemical potentials, measured from the corresponding standard states[24]:

$$\nu_1 RT \ln a_1 = \nu_1 RT \ln a_1^* + \nu_1 RT \ln \frac{\nu_1 m_1}{\nu_1 m_1 + \nu_2 m_2}.$$

It follows that

$$\gamma_1 = \nu_1 m_1^* \gamma_1^* / (\nu_1 m_1 + \nu_2 m_2) \quad \text{or} \quad \gamma_k = \nu_k m_k^* \gamma_k^* / \sum \nu_i m_i, \tag{25}$$

Eqn.(25) is known as Mikulin's equation.

A formula of this type for 1–1 electrolytes was first proposed[38] as an approximation, obtained from McCay and Perring's[39] general differential equation. Mikulin[40] and, later, Vdovenko and Ryazanov[22], derived Eqn.(25) for mixtures of electrolytes of different valency types by an exact simultaneous solution of McCay and Perring's equations and Zdanovskii's law (5). Mikulin's equation, like Zdanovskii's law, applies with adequate precision to a very large number of different mixed solutions of electrolytes, including solutions at very high concentrations.

In order to formulate the dependence of the activity coefficient of the electrolyte on the composition at constant water activity we shall express Eqn.(25) in terms of the osmotic coefficients, using Eqns.(1), (2), and (4). We obtain[4]

$$\gamma_1/\gamma_1^* = \varphi_m/\varphi_1^* \tag{26}$$

and for a ternary solution

$$\gamma_1/\gamma_1^* = (1 - \varphi_2^*/\varphi_1^*)\, y_1 + \varphi_2^*/\varphi_1^*, \tag{27}$$

$$\frac{\gamma_1}{\gamma_1^*} = 1 - (1 - \varphi_2^*/\varphi_1^*)\, y_2, \qquad (28)$$

or in terms of the isopiestic concentrations

$$\gamma_1/\gamma_1^* = 1 - (1 - \nu_1 m_1^*/\nu_2 m_2^*)\, y_2. \qquad (29)$$

It follows from (26)–(29) that at constant water activity the activity coefficient of the electrolyte is directly proportional to both its own ion fraction and the ion fraction of the second electrolyte. The slope of the straight-line dependence is determined by the difference (or ratio) of the osmotic coefficients of the binary isopiestic solutions (or of the isopiestic concentrations). Eqns.(27)–(29) are reminiscent of Harned's rule[41], though they differ from it in having a thermodynamic foundation and hence in being applicable without exception to all isoactive solutions, i.e. to solutions in which specific interactions between the electrolytes can be neglected.

In order to convert Eqns.(28) and (29) into a form similar to Harned's rule we shall take logarithms [of Eqn.(28), say]. Series expansion of the logarithm on the right-hand side, truncated after the first term, gives

$$\ln \gamma_1 = \ln \gamma_1^* - (1 - \varphi_2^*/\varphi_1^*)\, y_2. \qquad (30)$$

From these considerations we may conclude that a linear dependence of the activity coefficient on composition is characteristic, strictly speaking, of the condition of constant solvent activity (or constancy of osmotic activity), and not constancy of the ionic strength (as required by Harned's rule). We should note that at the water activity corresponding to the intersection of the $a_w = f_1(m_1)$ and $a_w = f_2(m_2)$ plots the coefficient of y_2 is zero, and on either side of this point the coefficient has different signs.

If the osmotic coefficients in the isopiestic solutions of electrolytes being mixed are equal Mikulin's equation for the activity coefficient of one of the components becomes[3]

$$\gamma_k = \gamma_k^* = \text{const}. \qquad (31)$$

This expression follows also from Eqn.(26).

Since the condition of constant water activity in this case, is analogous to constancy of the overall ionic concentration (3), we can infer the following from Eqn.(31): if the electrolytes have equal osmotic coefficients (i.e. equal tendencies for taking up water) their activity coefficients at constant total ionic concentration will be constant (i.e. independent of the component ratio) and equal to the activity coefficient of the component in the binary solution. Eqn.(31) applies strictly, even to concentrated solutions, in the absence of specific interactions between the electrolytes (i.e. for ideal mixing of binary isopiestic solutions of electrolytes). However, the condition of equal osmotic coefficients in the binary solutions is most easily satisfied at low concentrations. We have obtained satisfactory results[3] at total molalities up to 1.5–2.0 for the following systems (which have also been studied by other workers): HNO_3–$CaCl_2$–H_2O, HNO_3–$MgCl_2$–H_2O, HCl–$CaCl_2$–H_2O, HCl–$SrCl_2$–H_2O, HCl–$MgCl_2$–H_2O, HCl–$HClO_4$–H_2O, etc.

The expression (31) is analogous to the ionic strength rule, and yet it reveals the shortcomings of that rule and the advantages of using ionic and osmotic concentrations. The ionic strength rule was confirmed by the Debye–Hückel law, and in some of the contemporary publications[42–44] the law was also compared with Zdanovskii's rule, which had previously been thought to be only an approximation. It was shown[45] that only a special case of Zdanovskii's law, corresponding to equal osmotic coefficients of the components [as in Eqn.(31)], could be compared with the Debye–Hückel law. The Debye–Hückel limiting law describes the ideal mixing of electrolyte solutions to a good approximation only at very high dilutions. The Zdanovskii limiting law also is applicable only to systems without specific interaction between the electrolytes, but its validity is unaffected by the tendency of the electrolytes to take up solvent or by the concentration of the electrolyte.

It is often necessary, especially in radioactive tracer work under industrial conditions, to calculate the thermodynamic activity of a microcomponent in the presence of a macro-component: for example, in the salting-out of micro-components during extraction and adsorption. The application of Eqn.(25) to a micro-component is greatly simplified if the concentration of the micro-component can be ignored in comparison to that of the macro-component. Under those conditions we assume that the total ionic concentration in the denominator of the right-hand side of Eqn.(25) and the isopiestic concentration of the binary solution of the macro-component are equal to the concentration of the macro-component in the mixed solution. Thus, the isopiestic concentration of the micro-component *1* (m_{01}) is determined by the initial concentration of the macro-component *2*, and Eqn.(25) becomes[4]

$$\gamma_{01} = \nu_{01} m_{01}^* \gamma_{01}^* / \nu_2 m_2. \qquad (32)$$

If in one solution substance *1* is the micro-component and substance *2* is the macro-component, and in another solution the roles are reversed, then for equal ionic concentrations of the macro-components the ratio of the activity coefficients of the micro-components in these solutions will be

$$\gamma_{01}/\gamma_{02} = \nu_{01} m_{01}^* \gamma_{01}^* / \nu_{02} m_{02}^* \gamma_{02}^*. \qquad (33)$$

Robinson and Stokes, when discussing mixed solutions of hydrochloric acid and sodium chloride, quote the following "paradoxical result: the activity coefficient of hydrochloric acid in a solution containing effectively only sodium chloride is practically equal to the activity coefficient of sodium chloride in a solution containing effectively only hydrochloric acid"[46]. The explanation of this paradox follows from Eqn.(33). The activity coefficients of the micro-components in these solutions will be similar if the products $\nu m^* \gamma^*$ have similar values. In the case of hydrochloric acid and sodium chloride solutions the ratio of these products is close to unity over a wide range of concentration.

V. THERMODYNAMIC PROPERTIES OF QUATERNARY RECIPROCAL SYSTEMS

It is obvious, from the formulation of the ideal mixing of electrolyte solutions given by Zdanovskii (see Section I), that both the probability and the magnitude of deviations from ideality will be greater if the electrolytes being mixed do not have a common ion. This is mainly the result of ion-exchange interaction in systems without a common ion. Furthermore, in systems which include a like ion the deviations cannot be calculated in terms of the properties of the binary solutions, because the transfer of the ions from one electrolyte to another is accompanied by the formation of complexes which cannot exist in the binary solutions. In systems without common ions the main interaction is ion exchange between the dissolved electrolytes, which can be described by treating the mixture of electrolytes as a system of four reciprocal binary isopiestic solutions, as suggested by Mikulin and Voznesenskaya[47].

Equilibrium in a quaternary reciprocal system is treated as an ionic exchange double decomposition reaction:

$$\underset{1}{AM} + \underset{4}{BN} \rightleftarrows \underset{2}{AN} + \underset{3}{BM}, \qquad (34)$$

Following Mikulin and Voznesenskaya[47], we shall represent a mixed solution of two electrolytes without a common ion in a composition square (Fig.6) relating the concentrations of

the components of the quaternary reciprocal system (34). We shall denote the concentrations of A, B, M, and N by n_A, n_B, n_M, and n_N respectively, and we shall take the total concentrations of electrolytes in the system to be n g-equiv per 1000 g of water. The following relationships will be used for the ion fractions in the case of electrolytes of different valency:

$$x=n_A/n;\ 1-x=n_B/n;\ y=n_M/n;\ 1-y=n_N/n.$$

The concentrations of the electrolytes AM, AN, BM, BN (point S of Fig.6) will be related by the expressions

$$n_1nxy;\ n_2=nx(1-y);\ n_3=n(1-x)y;\ n_4=(1-x)(1-y). \qquad (35)$$

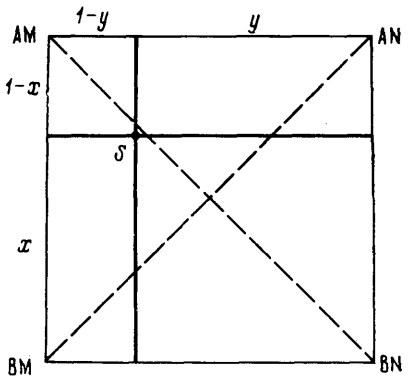

Figure 6. Relationship between the composition of the components in a quaternary reciprocal system (composition square).

We shall also use[48] the expression (4) relating the osmotic coefficient of the mixed solution (ϕ) to the osmotic coefficients in the binary solutions of the electrolytes (ϕ_i^*) at the same water activity. For a quaternary reciprocal system, allowing for the equality

$$\nu_i m_i = \frac{z_i^+ + z_i^-}{z_i^+ z_i^-} n_i = K_i n_i$$

Eqn.(4) becomes

$$\varphi = \sum_i \varphi_i^* K_i n_i \Big/ \sum K_i n_i. \qquad (36)$$

Inserting into this equation the expressions for the concentrations of the electrolytes [Eqn.(35)] we arrive at a formula for the osmotic coefficients of quaternary aqueous reciprocal systems:

$$(\varphi)_{a_w} = \lambda_1\varphi_1^* + \lambda_2\varphi_2^* + \lambda_3\varphi_3^* + \lambda_4\varphi_4^*, \qquad (37)$$

where ϕ_i^* are the osmotic coefficients of the binary isopiestic electrolyte solutions which constitute the quaternary reciprocal system (34). The coefficient λ_i (for example, in the case of electrolyte 1) is given by

$$\lambda_1 = xyK_1/[xyK_1 + x(1-y)K_2 + (1-x)yK_3 + (1-x)(1-y)K_4].$$

Eqn.(37) is valid if no chemical interactions other than ion exchange are present in the solution. It is the analogue of Eqn.(4), obtained by postulating equal osmotic coefficients of the components in the isopiestic solutions. It follows that systems of this type can be treated as quaternary reciprocal systems to which Zdanovskii's law applies. Hence, all the equations given in Section II are fully applicable to mixed solutions of electrolytes without a common ion, for example

$$\Delta H = \frac{m_1}{m_1^*}\Delta H_1^* + \frac{m_2}{m_2^*}\Delta H_2^* + \frac{m_3}{m_3^*}\Delta H_3^* + \frac{m_4}{m_4^*}\Delta H_4^*$$

etc.

On the other hand, if we start from the concentrations of two solutions of electrolytes (without common ions) being mixed, the properties of the mixture are parabolically dependent on the relative amount of one of the components. That this should not be interpreted as a deviation from Zdanovskii's law is evident from the work of Mikulin[47], though he himself states[34] that "Zdanovskii's rule applies only to mixed solutions with a common ion, but it follows from this rule that in quaternary aqueous reciprocal systems the equal water activity plots are in general parabolic". Evidently, Mikulin erroneously identifies Zdanovskii's rule not with Eqn.(5), but with the linearity of the water isotherm–isobar for two components, or with the textual formulation of the law in terms of the mixing of two binary solutions.

In order to calculate the thermodynamic functions directly we must start from the concentrations (in the mixture) of the (two) mixed electrolytes, since the concentrations of the four electrolytes in the equilibrium mixture are unknown. In order to simplify the mathematics we shall assume that the ions from all the electrolytes in the system (34) have identical charges (in absolute value): for example, that the electrolytes being mixed are both 1–1, or 2–2. Under these conditions the following equality applies to the AM(1)–BN(4)–H_2O system:

$$x=y=n_1/(n_1+n_2),$$

and Eqn.(4) becomes

$$(\varphi)_{a_w} = (\varphi_1^* + \varphi_4^* - \varphi_2^* - \varphi_3^*)x^2 + (\varphi_2^* + \varphi_3^* - 2\varphi_4^*)x + \varphi_4^* \qquad (38)$$

or

$$(\varphi)_{a_w} = Ax^2 + Bx + C. \qquad (39)$$

A similar expression was obtained earlier[47] for the reciprocal total molality.

The coefficients A, B, and C can easily be determined from the tabulated values of the corresponding osmotic coefficients of the binary solutions. In this way all the thermodynamic functions of the mixed isoactive solution formed from two solutions of electrolytes without common ions can be calculated. For example,

$$\Delta G = A'x^2 + B'x + C' + \Delta G_M^{id}, \qquad (40)$$

where

$$A' = \Delta G_1^* + \Delta G_4^* - \Delta G_2^* - \Delta G_3^*,$$
$$B' = \Delta G_2^* + \Delta G_3^* - 2\Delta G_4^*,$$
$$C' = \Delta G_4^*.$$

Satisfactory agreement between calculation and experiment is obtained for practically all the systems composed of halides and nitrates of alkali and alkaline-earth metals[17,18,49–51].

Formulae for the activity coefficients of the electrolytes (without common ions) in a mixed solution can be obtained from Eqn.(39). In our calculation[48,52] the McCay–Perring equation[39] was first converted into a form consistent with that of the expression for the osmotic coefficients:

$$\ln\frac{(\nu_1 m_1 + \nu_2 m_2)\gamma_1}{\nu_1 m_1^* \gamma_1^*} = \int_0^{\ln a_w} \left[(1-y_1)\left(\frac{\partial\varphi}{\partial y_1}\right)_{a_w} + \varphi + \varphi_1^*\right]\frac{d\ln a_w}{\ln a_w}. \qquad (41)$$

Simultaneous solution of Eqns.(39) and (41) for electrolytes with the above limitations on the stoichiometric coefficients gave

$$\ln\gamma_1 = \ln\frac{m_1^*\gamma_1^*}{m_1+m_4} - (1-x)^2\int\frac{A}{\ln a_w}\,\mathrm{d}\ln a_w.$$

From the Gibbs–Duhem equation for a binary solution we have

$$\int\frac{\varphi_i^*}{\ln a_w}\,\mathrm{d}\ln a_w = \ln a_i^*,$$

whence

$$\ln\gamma_1 = \ln\frac{m_1^*\gamma_1^*}{m_1+m_4} - (1-x_1)^2\ln\frac{a_1^*a_4^*}{a_2^*a_3^*}. \qquad (42)$$

This formula was first obtained[47] by an entirely different approach. In the case of electrolytes of any valency type the McCay and Perring equation must be solved by using the more complex expression (37).

If the coefficient of x^2 in equations of the type of (39) is zero (i.e. $A=0$) it follows that the quaternary system is not only isoactive but also additive with respect to the separate ions: for example, for the system

$$AX_2+2BY=AY_2+2BX$$

we expect to find

$$\varphi_{AX_2}^* + 2\varphi_{BY}^* = \varphi_{AY_2}^* + 2\varphi_{BX}^*. \qquad (43)$$

In this case the affinities of the two cations for the two anions (or of the two anions for the two cations) are the same. Eqn.(43) applies, for example, to the $CaBr_2$–LiCl–H_2O and $CaCl_2$–KBr–H_2O systems[53].

VI. CALCULATION OF THE OSMOTIC COEFFICIENTS AND ACTIVITY COEFFICIENTS OF SEPARATE IONS

The success of our postulate of equal osmotic coefficients for a component in mixed solutions having the same water activity (in the absence of chemical interactions) suggested the possibility of applying the same approach to separate ions. An analogy was formulated[54] between mixed solutions of electrolytes and binary solutions, which were described as mixed by treating the ions as separate components. In keeping with Eqn.(1), which features the mean ionic molal osmotic coefficient, we can introduce the concept of an osmotic coefficient of the ion and replace Eqn.(1) by an expression for the activity of the solvent in the following terms:

$$\ln a_w = -0.001Mm(\nu_+\varphi_+ + \nu_-\varphi_-). \qquad (44)$$

where ν_+ and ν_- are the stoichiometric coefficients of the ions, and ϕ_+ and ϕ_- are the osmotic coefficients of the ions. Like the osmotic coefficients of the components, those of the ions are a measure of the ability of the given species to take up water. Extending the analogy, we assumed that the osmotic coefficients of a given ion in different solutions must be equal if the activity of water in the solutions is the same and if there is no difference between the ionic interactions (in particular, the chemical interactions) in the different solutions. By adopting these hypotheses and taking an arbitrary electrolyte as standard we can easily calculate the osmotic coefficients of the ions in other solutions.

The standard electrolyte is usually chosen so that $\phi_+^0 = \phi_-^0 = \phi_\pm^0$, and therefore it is usually a 1–1 electrolyte. By comparing Eqn.(44) for a solution of the standard electrolyte with the same equation for the unknown binary solution, having an ion in common with the standard, we obtain expressions for the counter-ion in the unknown solution

$$\nu_{+2}\varphi_{+2} = \nu_{\pm 2}\varphi_{\pm 2} - \nu_-\varphi_\pm^0 \quad\text{and}\quad \nu_{-2}\varphi_{-2} = \nu_{\pm 2}\varphi_{\pm 2} - \nu_+\varphi_\pm^0 \qquad (45)$$

and for the 1–1 electrolytes

$$\varphi_{+2} = 2\varphi_{\pm 2} - \varphi_\pm^0 \quad\text{and}\quad \varphi_{-2} = 2\varphi_{\pm 2} - \varphi_\pm^0.$$

For electrolyte solutions not having an ion in common with the standard we use the scheme KCl → CsCl → CsBr.

Using a solution of potassium chloride as standard we have calculated[54] from the above expressions the osmotic coefficients of the ions in binary solutions of various alkali metal halides at concentrations between 1.0 and 2.0 *m*. As a test of the method, we also calculated the mean ionic osmotic coefficients of electrolytes not having an ion in common with the standard, using the scheme KCl → CsCl → CsBr and KCl → KBr → CsBr. The arithmetic means were compared with tabulations[46]: the deviations were found to be within 2%, confirming the correctness of our assumption of equal osmotic coefficients for ions in isopiestic solutions of these electrolytes.

These favourable results justified an attempt to calculate the activity coefficients of individual ions by Mikulin's equation. If two ternary solutions have one electrolyte in common and equal water activities the ratio of the activity coefficients of the electrolytes in the solutions is

$$\gamma_1/\gamma_1' = (\nu_1'm_1' + \nu_3'm_3')/(\nu_1m_1 + \nu_2m_2).$$

In the standard electrolyte solution $\gamma_{+0} = \gamma_{-0} = \gamma_{\pm 0}$, and therefore the expression for the ions (comparing two binary electrolyte solutions with a common ion) becomes

$$\gamma_+/\gamma_{\pm 0} = 2m_0^*/\nu m^* \quad\text{and}\quad \gamma_-/\gamma_{\pm 0} = 2m_0^*/\nu m^*, \qquad (46)$$

i.e. the ratio of the activity coefficients of the ions in the two solutions having identical water activities is equal to the reciprocal of the ratio of the ionic concentrations of these solutions.

Eqns.(46) are easily generalised for multicomponent solutions:

$$\frac{\gamma_{+m}}{\gamma_{+2}} = \frac{\nu_2m_2^*}{\sum_i \nu_im_i} = \frac{\varphi_m}{\varphi_{\pm 2}^*} \quad\text{and}\quad \frac{\gamma_{-m}}{\gamma_{-2}} = \frac{\nu_2m_2^*}{\sum_i \nu_im_i} = \frac{\varphi_m}{\varphi_{\pm 2}^*}, \qquad (47)$$

where γ_{+m} and γ_{+2} are the activity coefficients of the common ion in the mixed and the binary (e.g., the standard) isopiestic solution. For electrolyte solutions without an ion in common we can use the above scheme, which gives (for example) in the case of a $CaBr_2$ solution

$$\gamma_{Ca^{2+}} = \gamma_{\pm CaCl_2}^3(3m_{CaCl_2}^*)^3/\gamma_{\pm KCl}^2(2m_{KCl}^*)^2 \cdot 3m_{CaBr_2}^*,$$
$$\gamma_{Br^-} = \gamma_{\pm KBr}^2(2m_{KBr}^*)^2/\gamma_{\pm KCl}3m_{CaBr_2}^* \cdot 2m_{KCl}^*. \qquad (48)$$

We have calculated[53,54] the activity coefficients of the separate ions in binary solutions of various alkali and alkaline-earth metal halides. The calculations were tested by the scheme used for the osmotic coefficients, but in this case the root mean square values were obtained from pairs of results (because the osmotic coefficients of the ions are additive, and the activity coefficients are multiplicative). The deviation of the calculated mean ionic activity coefficients from the tabulated values[46] was within 1–3% for electrolytes without an ion in common with the standard (potassium chloride).

Bates and coworkers[55] used Robinson and Stokes' hydrate theory to calculate the activity coefficients of separate ions for several solutions of electrolytes. Their results are consistent with ours[54].

For $a_w \to 1$ Raoult's law gives[56]

$$\nu_1m_1^* = \nu_2m_2^* = \sum_i \nu_im_i.$$

Using this expression we find from Eqn.(47) that in very dilute solutions the activity coefficients of the separate ions are a function only of the total ionic concentration, i.e. the

rule of constant water activity becomes an ionic concentration rule[52] reminiscent of Lewis' ionic strength rule but relying on stricter thermodynamic foundations.

Assuming the sulphuric acid–lithium hydrogen sulphate–water system to be isoactive, and assuming equality of the osmotic coefficients of the ions in the isopiestic solutions, we have calculated[35] from data for binary solutions of sulphuric acid and of lithium chloride respectively the dependence of the activity of water on the concentration of lithium hydrogen sulphate (which had not been reported previously). Subsequently[37] the experimental results were compared with calculations: the deviation was less than 1% for isopiestic concentrations, thus allowing all the thermodynamic functions of the system to be calculated by the isoactive solution theory.

If the inter-ionic interactions in the solutions being compared are specific to different extents, more exact values of the osmotic coefficients and of the activity coefficients of the separate ions can be obtained by using quaternary reciprocal systems. Using Eqn.(34) to express the relationship between the osmotic coefficients of 1–1 electrolytes (including the osmotic coefficients of the separate ions) we obtain[24]

$$2\varphi^*_{AM} + 2\varphi^*_{BN} - 2\varphi^*_{AN} - 2\varphi^*_{BM} = ({}^M\varphi^*_A - {}^N\varphi^*_A) + \\ + ({}^B\varphi^*_N - {}^A\varphi^*_N) + ({}^N\varphi^*_B - {}^M\varphi^*_B) + ({}^A\varphi^*_M - {}^B\varphi^*_M) = 2A.$$

Averaging gives

$${}^A\varphi^*_M - {}^B\varphi^*_M = {}^1/_2 A, \qquad (49)$$

where A has the same significance as in Eqn.(39). In the absence of chemical specificity $A = 0$, and Eqn.(49) reduces to equality of the osmotic coefficients of the ions in isopiestic solutions.

A similar averaging is possible for the activity coefficients of individual ions[24]. In this case we write, using the same scheme, an expression relating the logarithms of the activities of the binary electrolytes having identical solvent activities, and also the corresponding expression in terms of the activity coefficients of the separate ions. The same formula for the activity coefficients of the separate ions can be obtained from Eqn.(42) by treating the ions as separate components:

$$\ln \frac{{}^A\gamma^*_M}{{}^B\gamma^*_M} = \ln \frac{m^*_{BM}}{m^*_{AM}} + \frac{1}{4} \ln \frac{a^*_{AM} a^*_{BN}}{a^*_{AN} a^*_{BM}}. \qquad (50)$$

In the absence of chemically specific interactions the expression under the logarithm in the term on the right becomes unity, and formula (50) reduces to (47).

Undoubtedly, the most accurate and general of these equations is[52]

$$\frac{\gamma_{+m}}{\gamma_{+s}} = \frac{\nu_s m^*_s}{\sum_i \nu_i m_i} e^{\Delta} = \frac{\varphi_m}{\varphi_{+s}} e^{\Delta},$$

where Δ is the integral of McCay and Perring's equation for the mixed solution. Extensive information on isopiestic equilibria in ternary solutions with a common ion is available in the literature, and therefore the quantity Δ can be evaluated easily in most cases.

VII. DEVIATIONS FROM IDEAL MIXING IN ISOPIESTIC SOLUTIONS OF ELECTROLYTES

Ideal mixing is a limiting case: all real mixing processes must deviate from ideality to some extent. Aqueous solutions of electrolytes have many features in common, and therefore there is a very large number of pairs of binary solutions which under isopiestic conditions can be mixed with deviations small enough to be ignored. However, mixing operations requiring correction for non-ideality are far from being exceptional. Nevertheless, non-ideal behaviour in mixed systems does not exclude the possibility of limiting cases: for example, in solutions which are dilute with respect to one of the components.

The isotherm–isobars of water in systems with specific interaction between the electrolytes (Figs.1 and 2) are not rectilinear. Substantial curvature of the isotherm–isobars in these systems is usually ascribed to complex formation[57–60], and the curvature is taken as a measure of the intensity of the interactions in the system[61–65]. Even the composition of any compound formed in the mixed solution can be established from the geometry of the isopiestic diagrams[59,60]. We shall examine first of all the general characteristics of the deviations from ideality.

As in the case of mixing individual components, the deviations from ideality in our case can be characterised by excess functions, activity coefficients, and empirical parameters.

Extensive investigations of ternary water–salt systems by Kirgintsev and Luk'yanov, which we have not attempted to list comprehensively among our references[61–65], have shown that the majority of curvilinear isobar–isotherms can be described by the equation

$$1/m = \frac{1}{m^*_1} x + \frac{1}{m^*_2}(1-x) + bx(1-x), \qquad (51)$$

where x is the mole fraction of one of the two electrolytes, and b is an empirical parameter depending on the activity of water and on the concentrations of the components. It follows from (51) that the reciprocal of the total molality is a quadratic function of the composition, in keeping with Robinson's treatment[66].

When $b = 0$ Eqn.(51) reduces to Zdanovskii's law (ideal mixing); when $b > 0$ the system shows positive deviations from ideal mixinge, and when $b < 0$ it shows negative deviations. Inserting Eqn.(51) under the integral in McCay and Perring's equation defines the activity coefficients of the components of the mixture. (The properties of the quantity b and its use in thermodynamic calculations are discussed in detail in Ref.2.) Since our work was based on relationships between osmotic coefficients, we proposed[17,20] that the deviations should be discussed from the standpoint of Eqn.(4). For a real mixture of two electrolytes we have

$$\varphi(a_w, y) = \varphi_1^* y_1 + \varphi_2^* y_2 + \Delta$$

or

$$\varphi(a_w, y) = \varphi_1^* y_1 + \varphi_2^* (1-y_1) + \beta_0 y_1 (1-y_1), \qquad (52)$$

where

$$\Delta = \beta_0 y_1 y_2 = \beta_0 y_1 (1-y_1).$$

This formulation of the deviations from isoactivity allows for the interactions in the system in terms of the activity of water, which is the criterion for isopiesticity of the solutions, and it permits extrapolation to zero concentration of the electrolytes in calculations of the activity coefficients of the components.

When $\beta_0 = 0$ Eqn.(52) becomes indistinguishable from the ideal mixing condition (4). If $\beta_0 > 0$ the system shows positive deviations, suggesting an increase in osmotic properties on mixing, such as would result from increased dissociation of the electrolytes in the mixture as compared with their respective binary solutions. This case is seldom met, and the deviations are usually small. Negative deviations ($\beta_0 < 0$), due to association in the mixed electrolytes, are far more common. Large negative deviations arise from complex formation. Association lowers the osmotic properties of the mixture, and in order to maintain isopiesticity with the

binary solutions the total concentration of electrolytes in the mixture must be increased.

The quantity β_0 is a measure of the interactions in the ternary solution. In general β_0 depends on the activity of water and on the concentration ratio of the electrolytes. For small values of β_0 we only need to consider the effect of water activity, but when the deviations are large we must consider also the effect of solution composition on β_0. Series expansion in powers of the activity of water gives

$$\beta_0 = -\beta_{01}(\ln a_w) + \beta_{02}(\ln a_w)^2 - \ldots \quad (53)$$

In most cases we do not need to go beyond a linear dependence of β_0 on $\ln a_w$, but in some systems a very complex relationship is observed. For example, in mixtures of nickel, cobalt, or copper chloride with lithium chloride[20] β_0 increases at first, going through a maximum, and then decreases and even changes sign: in other words, deviations from Zdanovskii's law of either sign can take place in these systems, depending on the activity of the water. Composition-independence of the parameter β_0 is recognised by the symmetry of the Δ function (Fig.7).

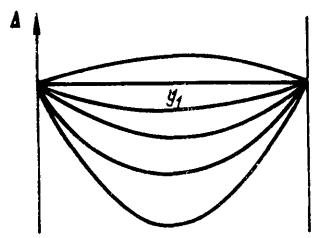

Figure 7. Deviations from isoactivity in ternary water–salt systems.

Whereas the magnitude of β_0 defines the intensity of the interaction, the position of the maximum of the Δ function gives an indication of the composition of the compounds formed in solution. We have used this method to determine, for example, the compositions of the complexes of nickel, cobalt, and copper in chloride and sulphate solutions[20,67,68]. A method of calculating the stability constant of the complex (when only one complex is formed in the solution) was also developed and applied to mixtures of nickel or cobalt nitrate and urea solutions[69]. Results consistent with other methods were obtained.

Experimental determination of Δ or β_0 allows calculation of the excess Gibbs free energies with respect to ideal mixing of the isopiestic solutions ($\Delta G_M^E i$). We have calculated $\Delta G_M^E i$ from measurements of the activity of the solvent only[21,70] by using Scatchard's method[71,73], developed for the isomolal mixing of solutions of 1–1 electrolytes:

$$\Delta G_M^{Ei} - m\partial\Delta G_M^{Ei}/\partial m = -2\Delta RTm.$$

For electrolytes of any valency type this expression becomes (putting $\Sigma\nu_i m_i = \nu_1 m_1 + \nu_2 m_2$)

$$\Delta G_M^{Ei} - \sum \nu_i m_i \frac{\partial \Delta G_M^{Ei}}{\partial \sum \nu_i m_i} = -\Delta RT \sum \nu_i m_i. \quad (54)$$

After converting (54) into

$$-\left(\sum \nu_i m_i\right)^2 \left(\frac{\partial \Delta G_M^{Ei} / \sum \nu_i m_i}{\partial \sum \nu_i m_i}\right)_{\Sigma \nu_i m_i} = -\Delta RT \sum \nu_i m_i$$

we obtain

$$\Delta G_M^{Ei} = \sum \nu_i m_i RT \int_0^{\Sigma \nu_i m_i} \frac{\Delta}{\sum \nu_i m_i} \mathrm{d} \sum \nu_i m_i.$$

Combining this equation with (52) gives

$$\Delta G_M^{Ei} = y_1(1-y_1) RT \sum \nu_i m_i \int_0^{\Sigma \nu_i m_i} \frac{\beta_0}{\sum \nu_i m_i} \mathrm{d} \sum \nu_i m_i. \quad (55)$$

In this expression the excess Gibbs free energy with respect to the isoactive solutions has the dimensions of energy per 1000 g H_2O. We write

$$\beta_0 = \beta'_{01}\left(\sum \nu_i m_i\right) + \beta'_{02}\left(\sum \nu_i m_i\right)^2 + \cdots \quad (56)$$

and, combining (55) and (56), we find

$$\Delta G_M^{Ei} = y_1(1-y_1) RT \left(\sum \nu_i m_i\right)^2 \left[\beta'_{01} + \frac{1}{2}\beta'_{02} \sum \nu_i m_i + \cdots\right] \quad (57)$$

If we retain only the first-order term (i.e. $\beta_0 = \beta'_{01} \Sigma \nu_i m_i$) we have

$$\Delta G_M^{Ei} = \beta_0 y_1(1-y_1) RT \sum \nu_i m_i = \Delta RT \sum \nu_i m_i. \quad (58)$$

Using the relationship between β_0 and b,

$$\beta_0 = -55.51 \ln a_w b\left(\frac{\nu_1 x_1 + \nu_2 x_2}{\nu_1 \nu_2}\right),$$

we obtain an expression for the excess Gibbs free energy with respect to the isoactive solution in terms of the quantity b:

$$\Delta G_M^{Ei} = -x_1(1-x_1) RTmb \cdot 55.51 \ln a_w. \quad (59)$$

In Eqn.(55) the independent variable is the total ionic molality of the mixed solution. It is sometimes convenient to use the activity of water as the independent variable. An appropriate change of variables gives

$$\Delta G_M^{Ei} = y_1(1-y_1) RT \sum \nu_i m_i \int_0^{\ln a_w} \frac{\beta_0}{\ln a_w} \mathrm{d} \ln a_w. \quad (60)$$

Allowing for the dependence of β_0 on the activity of water [Eqn.(53)] we arrive at

$$\Delta G_M^{Ei} = y_1(1-y_1) RT \sum \nu_i m_i \left[\beta_{01}(-\ln a_w) + \frac{1}{2}\beta_{02}(-\ln a_w) + \cdots\right]. \quad (61)$$

Under conditions which justify the approximation $\beta_0 = -\beta_{01} \ln a_w$ we revert to Eqn.(58).

We have used these equations to calculate the excess Gibbs free energies for alkali and alkaline-earth metal halides mixed with cobalt, nickel, and copper chlorides[20] and for alkali metal halides mixed with cobalt, nickel, and alkali metal nitrates[74]. Concurrent measurements of the termal effects in mixing (by Karapent'yants and coworkers[49,75]) have allowed the entropic contributions to be evaluated in most of the mixed solutions.

The most revealing method of expressing the deviations from isoactivity is in terms of the activity coefficients (which are thermodynamic properties of the individual components). A formula for the activity coefficients, obtained from the McCay and Perring equation (41), can be used in conjunction with the expression for the osmotic coefficients.

Eqn.(52) for the osmotic coefficient of the mixed solution can be written as a quadratic function, analogous to (39):

$$\varphi_{(a_w, y)} = Ay^2 + By + C, \quad (62)$$

where $A = -\beta_0$. The difference between this expression and (39) is that the coefficients which appear in (62) can be determined experimentally. In Eqn.(39) they are calculated from the osmotic coefficients of the binary isopiestic solutions. Thus, solution of Eqn.(41) involves operations analogous to those applied to the quaternary reciprocal systems.

By combining Eqn.(62) with the empirical relationship (53) we obtain the following formulae for the activity coefficients:

$$\ln\gamma_1 = \ln\frac{\nu_1 m_1^{\circ}\gamma_1^{\circ}}{\nu_1 m_1 + \nu_2 m_2} + (1-y_1)^2\left[-\beta_{01}\ln a_w + \frac{1}{2}\beta_{02}(\ln a_w)^2 - \cdots\right], \quad (63)$$

$$\ln\gamma_2 = \ln\frac{\nu_2 m_2^{\circ}\gamma_2^{\circ}}{\nu_1 m_1 + \nu_2 m_2} + (1-y_2)^2\left[-\beta_{01}\ln a_w + \frac{1}{2}\beta_{02}(\ln a_w)^2 - \cdots\right].$$

The function β_0 is often linearly related to $\ln a_w$ and independent of composition, allowing the terms in β_{02} to be ignored. Comparing these expressions for the activity coefficients of the components with the excess Gibbs energy [Eqn.(58)] calculated for 1000 g of water and for 1 mole of electrolyte mixture we find

$$g_M^{E_i} = \Delta\mu_1 y_1 + \Delta\mu_2 y_2 = y_1\ln\frac{\gamma_1}{\gamma_1^{\circ}} + y_2\ln\frac{\gamma_2}{\gamma_2^{\circ}}. \quad (64)$$

where $\Delta\mu_i$ is the change in chemical potential of the component with respect to the isoactive mixture of electrolytes, and γ_i and γ_i° are the activity coefficients of the i-th electrolyte in the real solution and in the model solution for which Zdanovskii's law is valid.

The advantages of using the osmotic coefficients in the integration of the McCay and Perring equation include more accurate extrapolation to the region of infinite dilutions, since when $a_w \to 1$ we have $\beta \to 0$, i.e. in the case of electrolyte solutions of any valency type the functional dependence of ϕ under isopiestic conditions tends towards Eqn.(4) at high dilutions. It was found experimentally that for $\beta_0 \leq 0.05$ the errors in the calculation of the activity coefficients are less than 1%. The deviations from the limiting expressions (39) for mixtures of electrolytes without a common ion was estimated[51] in terms of the quantities β_0' and b' by using the expressions

$$(\varphi)_{a_w} = Ax^2 + Bx + C + \beta_0' x(1-x)$$

and

$$1/m = A'x^2 + B'x + C' + b'x(1-x). \quad (65)$$

If $b' = D + Ea_w$, integration of the McCay–Perring equation together with Eqn.(65) gives the following formula for the activity coefficients:

$$\ln\gamma_1 = \ln\frac{m_1^{\circ}\gamma_1^{\circ}}{m_1 + m_2} - (1-x_1)^2\left[\ln\frac{a_1^{\circ}a_4^{\circ}}{a_3^{\circ}a_3^{\circ}} + K\ln a_w\right], \quad (66)$$

where

$$K = (D+E)/0{,}018.$$

The deviations of other thermodynamic functions from isoactivity (e.g. ΔH or ΔV) are best determined directly.

From the experimental point of view the isopiestic method of investigation is not a high-sensitivity method, because all the functions are defined in terms of the activity of the solvent, whose concentration in most cases is substantially greater than the concentration of the solutes. The sensitivity decreases markedly as the electrolyte concentration decreases. An attempt was made[77] to determine the excess enthalpy from the temperature dependence of the excess Gibbs energy, but the results had a large scatter and could only be accepted as tentative.

To conclude this Section we shall dwell on real mixed solutions of electrolytes in which one electrolyte is present at low concentration. In view of the analogy between Zdanovskii's and Raoult's laws we could expect an expression similar to Henry's law to apply to real mixed systems including the micro-component *1*. By using the Gibbs–Duhem equation, and assuming the following expression for the activity coefficient of the micro-component in the ternary solution:

$$\gamma_1 = \frac{\nu_1 m_1^{\circ}\gamma_1^{\circ}}{\nu_2 m_2} e^{l_1/\nu_1 RT}, \quad (67)$$

(where l_1 is an energy parameter depending only on the activity of the water and therefore having the significance of an excess function), we replaced[76] Zdanovskii's law (which is obtained when Mikulin's equation is used) by the expression

$$1 - \frac{m_1}{m_1^{\circ}} - \frac{m_2}{m_2^{\circ}} = -0.018\frac{m_1}{RT}\frac{\mathrm{d}\,l_1}{\mathrm{d}\ln a_w}. \quad (68)$$

This equation gives the relationship between (dm/dx) and $dl_1/d\ln a_w$, where $x = m_1/m$:

$$m\left(\frac{1}{m_2^{\circ}} - \frac{1}{m_1^{\circ}}\right) + \left(\frac{x}{m_1^{\circ}} + \frac{1-x}{m_2^{\circ}}\right)\left(\frac{\partial m}{\partial x}\right)_{a_w} = \frac{1}{RT}\frac{\mathrm{d}\,l_1}{\mathrm{d}\ln a_w}\left[x\left(\frac{\partial m}{\partial x}\right)a_w + m\right]. \quad (69)$$

From Eqn.(69) we can obtain the dependence of l_1 on a_w by using isopiestic measurements on ternary systems. It is clear from Eqn.(68) that at constant water activity the deviation from Zdanovskii's law (given by the right-hand side of the equation) is proportional to the molality of the micro-component. Denoting this deviation by bm_1 we can write

$$1/m = x_1(1/m_1^{\circ} + b) + x_2/m_2^{\circ}. \quad (70)$$

Thus the contribution of the micro-component to the reciprocal total molality remains proportional to the mole fraction, but the proportionality coefficient is no longer equal to the reciprocal isopiestic concentration, and depends also on the differential $dl_1/d\ln a_w$. This is where the analogy between our expression and Henry's law appears. The quantity b is a parameter of Eqn.(51), which reduces to Eqn.(70) when $x_1 \ll 1$. In the absence of specific interactions between the dissolved electrolytes Eqn.(67) simplifies to Eqn.(32).

VIII. SALTING-OUT IN EXTRACTION SYSTEMS

Salting-out effects provide one of the most important applications of the theory of isoactive mixed solutions of electrolytes. This was realised by Zdanovskii, Mikulin, and Kirgintsev, all of whom made important contributions in this area. Their work was aimed mainly at the salting-out of electrolytes into a solid phase, i.e. at determining the solubility of some electrolytes in the presence of others. In this review we shall confine our attention to the salting-out problem in extraction systems, where the substance to be separated is distributed between two liquid phases.

The salting-out effect is directly related to the effective concentration (activity) of the solvent. It manifests itself as a change in the activity coefficient of the component being salted out, and therefore salting-out problems can be solved like other problems in the theory of multi-component solutions. The effectiveness of the salting-out agent is determined by its tendency to become hydrated. Ionic hydration is often thought to be determined by the charge and the radius of the ion. However, this view is too simple, and we must think of hydration as the result of a large number of specific properties of the substance whose overall effect

cannot be ascribed merely to the charge and the size of the ion. In recent years the hydration propensity of electrolytes has been quantified in calculations of activity coefficients by using hydration numbers, which give a very good description of specific properties because they are, to some extent, a derived characteristic[46,78]. We know, nevertheless, that experimental values of the hydration number are strongly dependent on the method of measurement, and can vary by a large factor. Furthermore, methods of calculating salting-out effects by relying on constant parameters cannot reflect changes in hydration with concentration, which are characteristic of electrolyte solutions. Hence, these methods can give only a qualitative estimate of changes in systems containing a salting-out agent.

Harned's coefficient is often used as a criterion for salting-out effects. However, Harned's coefficient can be obtained only if experimental data are available for the multi-component system of interest. Furthermore, it is extremely sensitive to the uncertainties in the determination of the activity coefficients. For example, Vdovenko and Ryazanov[79] have shown that an error of 2% in the activity coefficients can produce deviations of up to 10% in the Harned coefficient. We should note that since the "ionic strength" concept lacks strict thermodynamic foundations all attempts at calculating the Harned coefficient theoretically must continue to be unsuccessful.

We have previously suggested[4] the use of the molal mean ionic isopiestic osmotic coefficient as a criterion of the effectiveness of salting-out agents. The osmotic coefficient is, of course, a thermodynamic parameter of the electrolyte solution which characterises its ability to take up water and embodies all the individual properties of the solution. We should stress that the osmotic coefficient takes account also of any interactions between the ions and the molecules of the dissolved electrolyte. The osmotic coefficients of binary solutions have been determined over a wide range of concentrations for most electrolytes of interest and to a high precision. They are tabulated in Robinson and Stokes' monograph[46]. The most significant advantage of the osmotic coefficient as a criterion of salting-out effectiveness is its direct relationship to the theory of mixed isoactive solutions outlined above. The osmotic coefficient, being a thermodynamic criterion of salting-out, can be used as a reference standard for the salting-out parameters given by other solution theories. By combining Mikulin's equation (25) with Eqn.(1) we obtain Eqn.(26), from which it follows that the activity coefficients of the components (or their salting-out properties) are determined exclusively by the osmotic coefficients.

To determine the efficiency of a salting-out agent we simply plot the function $a_w = f(\nu m)$ for the appropriate binary solutions (see Fig.3), which follows from Eqn.(1) and from which it is clear that the relative position of the curves is determined only by the osmotic coefficients of the electrolytes. The higher the osmotic coefficient (or the steeper the curve), the more effective will be the electrolyte as a salting-out agent. For example, magnesium chloride at low ionic concentrations is a less effective salting-out agent than nitric acid. However, the curves intersect at $\nu m \cong 3.3$, and at the higher ionic concentrations magnesium chloride becomes a stronger salting-out agent than nitric acid. This inversion of the relative effectivenss of pairs of electrolytes is encountered fairly often. We note that the plot shown in Fig.3 can be used at the same time to determine the isopiestic concentrations, which are needed to calculate the activity coefficients by Mikulin's equation in accordance with Zdanovskii's law.

Calculations of the salting-out effect (W) can be classified into three possible cases[80]. In the first case addition of the salting-out agent affects the thermodynamic activity of the substance to be separated, but saturation is not reached. The system remains homogeneous, and the concentrations in the phase are unchanged. For a non-electrolyte we can write

$$a_{ns} = m\gamma_{ns};\ a_{ws} = m\gamma_{ws},$$
$$W_a = a_{ws}/a_{ns} = \gamma_{ws}/\gamma_{ns}, \qquad (71)$$

and for an electrolyte

$$a_{ns} = \nu_+^{\nu_+}\nu_-^{\nu_-} m^{\nu}\gamma_{\pm ns}^{\nu},\quad a_{ws} = \nu_+^{\nu_+} m^{\nu_+}(\nu_- m + \nu_{-s} m_s)^{\nu_-}\gamma_{\pm ws},$$
$$W_a = \frac{a_{ws}}{a_{ns}} = \left(\frac{\gamma_{\pm ws}}{\gamma_{\pm ns}}\right)^{\nu}\left(1 + \frac{\nu_{-s} m_s}{\nu_- m}\right)^{\nu_-}, \qquad (72)$$

where a_{ws}, a_{ns}, and γ_{ws}, γ_{ns} are the activities and activity coefficients of the components with and without the salting-out agent respectively, m is the concentration of the main solute, m_s is the concentration of the salting-out agent, and ν, ν_+, and ν_- are the stoichiometric coefficients of the electrolyte, the cation, and the anion respectively.

It follows from (71) and (72) that during salting-out in a homogeneous system the salting-out effect W_a for the non-electrolyte is determined only by the change in the activity coefficients, whereas in the case of the electrolyte the change in concentration of the like ion (in our case, the anion) also has an effect. If the solutions are isoactive the activities of the main electrolyte and the salting-out effects are easily calculated by using the theory of mixed isoactive solutions to obtain the activity coefficients.

The second case relates to salting-out in a heterogeneous system, when the solution is in equilibrium with the main component in the pure state. Addition of the salting-out agent in this case does not alter the activity of the main compound, but it alters its concentration (i.e. the solubility). For a non-electrolyte we have

$$m_{ns}\gamma_{ns} = m_{ws}\gamma_{ws} \text{ and } W_m = m_{ns}/m_{ws} = \gamma_{ws}/\gamma_{ns}, \qquad (73)$$

and for an electrolyte

$$\nu_+^{\nu_+}\nu_-^{\nu_-} m_{ns}^{\nu}\gamma_{\pm ns}^{\nu} = \nu_+^{\nu_+} m_{ws}^{\nu_+}(\nu_- m_{ws} + \nu_{-s} m_s)^{\nu_-}\gamma_{\pm ws}^{\nu},$$
$$W_m = \frac{m_{ns}}{m_{ws}} = \frac{\gamma_{\pm ws}}{\gamma_{\pm ns}}\left(1 + \frac{\nu_{-s} m_s}{\nu_- m_{ws}}\right)^{\nu_-/\nu}. \qquad (74)$$

If the mixed solutions are isoactive we can easily calculate the solubility m_{ws} in the presence of the salting-out agent from Eqn.(74) after determining the activity coefficients of the main compound in the mixed solution by the above formulae. The activity coefficients of non-electrolytes and gases in solutions are inversely proportional to the solubility. If these solutes are indifferent to the salting-out electrolyte we may assume that the solubility (S_0) is proportional to the activity of the solvent, and re-write Eqn.(73) as

$$\ln\frac{S_0}{S} = \ln\frac{m_{ns}}{m_{ws}} = -\ln a_S. \qquad (75)$$

Using Eqn.(1) we obtain[81,82]

$$\lg\frac{S_0}{S} = K_\varphi \nu_s m_s \varphi_s.$$

This formula is the analogue of Sechenov's equation[83], but it differs from it by taking account both of the ionic concentration of the salting-out agent and of its affinity for the solvent (ϕ_S). The constant K_ϕ should be (in the ideal case) independent of the nature of the salting-out electrolyte.

The third salting-out case is distinguished by the fact that addition of the salting-out agent to one phase alters the concentrations of the main substance in both phases. Salting-out in extraction systems is of this type. Whereas in the

first case the concentration was constant, and in the second case the activity, in this case the constant parameter is the distribution constant of the main substance between the phases, given by the ratio of the activities in the two phases[81,82]:

$$K=\bar{a}_{ns}/a_{ns}=\bar{a}_{ws}/a_{ws} \qquad (76)$$

The salting-out effect W_D is the numerical factor by which the distribution coefficient $D=\bar{m}/m$ is increased. For the distribution of a non-electrolyte we have

$$W_D=\frac{D_{ws}}{D_{ns}}=\frac{\bar{m}_{ws}m_{ns}}{m_{ws}\bar{m}_{ns}}=\frac{\gamma_{ws}}{\gamma_{ns}}\cdot\frac{\bar{\gamma}_{ns}}{\gamma_{ws}}. \qquad (77)$$

In the case of electrolytes (assumed undissociated in the organic phase) we obtain

$$W_D=\left(\frac{m_{ws}}{m_{ns}}\right)^{\nu-1}\left(1+\frac{\nu_{-s}m_s}{\nu_-m_{ws}}\right)^{\nu_-}\left(\frac{\gamma_{\pm ws}}{\gamma_{\pm ns}}\right)^{\nu}\frac{\bar{\gamma}_{ns}}{\bar{\gamma}_{ws}}. \qquad (78)$$

Thus, in extraction systems the overall salting-out effect is determined as much by changes in the organic phase as by those in the phase containing the salting-out agent. Furthermore, in the case of electrolytes the effect of the salting-out agent is not only to increase the distribution coefficient but also to alter the shape of the extraction isotherm. Without the salting-out agent the distribution coefficient of the main substance (in the absence of dissociation in the organic phase) tends towards zero as the dilution is increased. In the presence of the salting-out agent the expression for the distribution coefficient becomes

$$D_{ws}=K\nu_+^{\nu_+}m_{ws}^{\nu_+-1}(\nu_-m_{ws}+\nu_{-s}m_s)^{\nu_-}\gamma_{\pm ws}^{\nu}/\bar{\gamma}_{ws}, \qquad (79)$$

where $m_{ws}^{\nu_+-1}=1$ for electrolytes in which the stoichiometric coefficient of the cation is $\nu_+=1$ (which is true of many electrolytes). Therefore when $m_{WS}\to 0$ the distribution coefficient D_{WS} tends towards a constant, non-zero value. This effect has great practical importance in extraction by "neutral" extractants, especially for trace amounts of electrolytes.

Since the extraction of inorganic substances is often due to chemical interaction between these substances and the extractant we can obtain[81,82] equations for the salting-out effect corresponding to different extraction mechanisms[84-86] by equating constants of the extraction reaction with and without the salting-out agent. For example, in the case of molecular extraction, and negligible dissociation in the organic phase, typical of extraction by "neutral" extractants

$$n\bar{A}+B\rightleftarrows\bar{A}_nB,$$

we have obtained the expression[80-82]

$$W_D=\left(\frac{m_{Bws}}{m_{Bns}}\right)^{\nu-1}\left(1+\frac{\nu_{-s}m_s}{\nu_-m_{Bws}}\right)\left(\frac{\gamma_{\pm Bws}}{\gamma_{\pm Bns}}\right)^{\nu}\cdot\frac{\bar{\gamma}_{A_nB_{ns}}}{\gamma_{A_nB_{ws}}}\left(\frac{\bar{a}_{Aws}}{a_{Ans}}\right)^{n}. \qquad (80)$$

This expression shows that allowance must be made for changes in the activity coefficient of the resulting complex and in the activity of the extractant caused by the addition of the salting-out agent to the extraction system. Eqn.(80) is most conveniently used in a logarithmic form[80], in which the various contributions to the overall salting-out effect are additive:

$$\lg W_D=\lg W_c+\lg W_{c.i.}+\lg W_{\gamma\pm}+\lg\bar{W}_\gamma+\lg\bar{W}_A, \qquad (81)$$

where W_C is the concentration effect, $W_{C.i.}$ is the common ion effect, $W_{\gamma\pm}$ is an effect due to changes in the activity coefficients of the electrolyte in the aqueous phase, $\bar{W}_\gamma$ is due to the change in the activity coefficients of the complex in the organic phase, and $\bar{W}_A$ is due to the change in the activity of the extractant. Analogous considerations can be applied to the factors affecting the separation of substances (see Ref.87 for a detailed discussion).

These thermodynamic arguments show that calculations of salting-out effects almost invariably reduce to calculations of changes in the activity coefficients of the main substance in the two phases, though on occasions the activity coefficients of other (interacting) components are also relevant. The other contributions to the overall salting-out effect are relatively easy to calculate. In the case of an isoactive aqueous phase the activity coefficients of the electrolytes can be calculated by the equations given above, whereas the calculation of the activity coefficients of the components in the organic phase often requires additional experiments.

The isopiestic method has been found to be useful also in studies of some properties of the organic phase. For example, experimental determination of the activity coefficients of the components in the mixed solution by the distribution method was shown[88] to be possible if the osmotic coefficients of the substance to be extracted and of the salting-out agent are not very different, especially when the solubility of water in the organic phase is appreciable.

The solubility of water in the organic phase depends not only on the nature of the diluent (extractant) but also on the nature of the substance to be extracted. Water can either decrease or increase the association of the components. However, another general feature is the influence of the water on the standard state in the organic phase in the calculation of the activity coefficients of the components. By applying the Gibbs–Duhem equation to a three-component solution we have shown[89,90] that the degree of hydration of the extractant, complex, or distributed component (m_2) is

$$h=(m_3-m_3^0)/m_2,$$

where m_3 is the concentration of water in the extract, m_3^0 is the solubility of water in the diluent, and for $m_2\to 0$ it is a measure of the effect of water on the activity of component 2 when this component is transferred from its binary solutions to solutions containing water. Furthermore,

$$\ln\frac{a_2^0}{a_2}=h \quad\text{or}\quad \ln\gamma(0)=h, \qquad (82)$$

where a_2^0 and a_2 are the activities of the second component in the pure and in the moist diluent (solvent) respectively, and $\gamma(0)$ is the zeroth activity coefficient, characterising changes of standard state. This expression was later confirmed for a large number of systems. A more detailed account of the effect of water and of ways to allow for it in calculations of the component activities in the organic phase can be found in Refs.89 and 90.

Thus, in extracts where the main contribution to the changes in the activity coefficients is that of hydration these coefficients are easily determined if h is known. An independent determination of the salting-out effect in the organic phase is thus possible.

The contributions of the components to the overall salting-out effect have been determined for several systems with different extractants and extracted substances[91-93], including acids and salts. We shall mention only one example: the extraction of nitric acid by N-dioctylamine in o-xylene[93]. Salting-out by lithium nitrate[93] is illustrated in Fig.8: the effects were determined according to Eqn.(81) for a constant initial acid concentration of 0.25 M. The activity coefficients of nitric acid in the water phase in the presence of the salting-out agent were calculated by Mikulin's equation (25), and the activity of the free extractant was assumed to be equal to its concentration. The ratio of the activity coefficients in the organic phase was determined from the extraction isotherm[94] in terms of the known activities of the acid

in the water phase. It is clear from Fig.8 that all the salting-out effects included in Eqn.(80) play a substantial role in this system. In this case large positive effects are produced by the change in the activity coefficient of the salt formed in the organic phase, due mainly to the increase in the association of the salt with concentration. The common ion effect is even more substantial. All the other effects, including the change in the activity coefficients in the water phase, are negative. Depending on the chosen system, the contributions of the various effects may differ in sign as well as in magnitude.

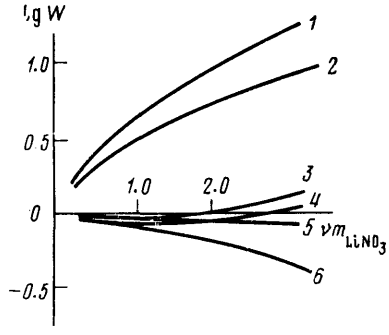

Figure 8. Salting-out effects for nitric acid in the presence of lithium nitrate: *1)* $W_{c.i.}$, *2)* W_D, *3)* $\bar{W}_\gamma$, *4)* W_γ, *5)* W_A, *6)* W_c.

--o0o---

This review shows that the theory of isoactive solutions is essentially an osmotic theory, since it operates on the osmotic properties of solutions (solvent activity, osmotic acitivities, osmotic coefficients). The validity of isoactive solution theory can no longer be doubted. Experimental studies of mixed solutions at constant activity of the solvent, and isopiestic measurements, have made a valuable contribution to the development of the theory and practice of mixed concentrated solutions.

The α-Effect in Organic Compounds of Group IVB Elements

V.P.Feshin, L.S.Romanenko, and M.G.Voronkov

A critical and systematic account is given of the results of studies of the α-effect by physical and chemical methods. The nature of the α-effect, its characteristic features, and its influence on the structure and properties of the corresponding organic compounds of Group IVB elements are discussed.
The bibliography includes 160 references.

IV. The nature of the α-effect 255

I. INTRODUCTION

The mutual influence of the atoms X and E in organic molecules containing the triatomic group $X-\overset{|}{\underset{|}{C}}-E$ does not correspond to their electronegativities and to the inductive effect of the constituents (the geminal interaction effect)[1-5]. Such an effect is shown in virtually all compounds and the atoms E and X can have both unshared electron pairs and vacant orbitals. This non-inductive interaction is usually observed when one compares the properties of the above compounds with isostructural compounds in which E = C or with homologues of type XCH_2CH_2M. We have called[5-8] the non-inductive geminal interaction of a given atom X with an atom E having vacant *d* orbitals in the $X-\overset{|}{\underset{|}{C}}-E$ system the α-effect†. At the present time the problem of the α-effect in an organic compound of Group IVB elements has attracted the attention of many investigators[9] and numerous publications have been devoted to it. Nevertheless the views on the nature of the α-effect and on the very possibility of its occurrence, based on studies using a wide variety of different physical and chemical methods, are extremely contradictory. The methods employed make it possible to observe the geminal interaction effect and to investigate its characteristics, but the majority do not permit the determination of the mechanism of the effect. Therefore almost all the existing hypotheses concerning the nature of the α-effect do not have a serious basis.

Some investigators (see below) base their views on individual experimental data which are consistent with ideas concerning the dominant inductive interaction of the atoms E and X and the problem of the occurrence of the intramolecular non-inductive interaction of geminal atoms is still regarded as controversial. There also exists a view that the α-effect is not shown in all the compounds containing the $X-\overset{|}{\underset{|}{C}}-E$ group but only in certain molecules of this type.

This indefinite state of the problem of the α-effect led us to write the present review.

†The term "α-effect" sometimes has another significance. For example, it is used in the interpretation of the anomalous reactivity of hydrazine derivatives (see, for example, Edwards and Pearson[10] and Grekov and Veselov[11]).

II. CHEMICAL MANIFESTATIONS OF THE α-EFFECT

The anomalous (i.e. inconsistent with the inductive influence of the atom E or a substituent in which it is included) properties of compounds containing the group $\overset{|}{\underset{|}{X-C-E}}$ were observed a long time ago. Thus, as early as the 1950's, it was noted that chloromethyltrimethylsilane is much more reactive in nucleophilic substitution reactions than its carbon analogue, while it is inert with respect to electrophiles (see, for example, George et al.[12] and Andrianov and Petrashko[13]). This was explained by the steric characteristics of the group $CH_2Si(CH_3)_3$ and its comparatively pronounced electron-accepting properties[14]. The electronegativity (EN) of this group, determined by the Kharash method, proved to be higher than that of the alkyl groups $n-C_6H_{13}$, CH_3, and $CH_2C(CH_3)_3$ but lower than that of the phenyl group. The expectedly high electronegativity of this group was attributed to the electronic unsaturation of the silicon atom[14]. The unusual influence of the silicon atom in compounds of the type $XCH_2Si(CH_3)_3$ (X = Cl or I) on their reactivity has been called the "α-silicon effect".[14]

In contrast to β- and γ-chloroalkylchlorosilanes, chloromethylchlorosilanes undergo the Friedel–Crafts reaction with difficulty[15-21], which indicates a reduced electron density at the chlorine atom in the group $ClCH_2Si\lesssim$. The replacement of the chlorine atom linked to the silicon atom by an alkyl group as a rule increases the reactivity of the compound. For example, $ClCH_2(CH_3)SiCl_2$ is more reactive in this reaction than $ClCH_2SiCl_3$.[21].

The relatively high reactivity of $ClCH_2Si(CH_3)_3$ in the reaction with KI (higher by a factor of 16 than for $n-C_4H_9Cl$, by a factor of 15 than for $n-C_3H_7Cl$, and by a factor of 8 than for C_2H_5Cl) was explained by the stabilisation of the transition state as a result of the interaction of the approaching iodide ion with the vacant 3*d* orbitals of the silicon atom and with the carbon atom[22-24]. It has been suggested that the leaving chloride atom thus interacts with the Si and C atoms[22,25-27]:

$$ClCH_2Si(CH_3)_3 + {}^{-}I \rightleftarrows CH_2\begin{matrix}\diagup Cl\\ \\ \diagdown I\end{matrix}Si(CH_3)_3 \rightleftarrows ICH_2Si(CH_3)_3 + Cl^{-}\ .$$

An analogous mechanism has been postulated for the reaction of chloromethyltrimethylsilane with the SCN^- ion in acetone and with the $C_2H_5O^-$ ion in ethanol[22,25,28]. The reactivity of $ClCH_2Si(CH_3)_3$ with respect to the $C_2H_5O^-$ ion is somewhat lower than that of $n-C_4H_9Cl$. However, it

would be lower still were it not for the possibility of the coordination interaction of the type indicated above[25,29]. It has been shown that $ICH_2Si(CH_3)_3$ is less reactive in the exchange with the I^- ion in ethanol than $n\text{-}C_3H_7I$.[14,25]. In the absence of coordination interaction, one would expect that iodomethyltrimethylsilane is still less reactive[25].

In bimolecular nucleophilic substitution reactions with KI and KSCN the chlorine atom in chloromethyltrimethylsilane is much more mobile than in γ-chloropropyltrimethylsilane[12,30], which is consistent with the electron-accepting properties of the trimethylsilyl group. On the other hand, in the interaction of chloromethyl- and γ-chloropropyl-trichlorosilanes with alcoholic alkali, the chlorine atom in the γ-position with respect to the silicon atom is much more mobile[31]. The discrepancy between these results has been explained by the fact that alcoholic alkali is not a reagent characterising the reactivity of the chlorine atom in the C–Cl bond in reactions of organosilicon compounds, because under the influence of alkali on chloromethyltrichlorosilane the reaction involves only the Si–C bond, while the reaction with γ-chloropropyltrichlorosilane involves both the Si–C and the Si–Cl bonds[30].

The exchange reactions between the chloromethyltrimethylgermane and KSCN, $HN(C_2H_5)_2$, and KI are faster than the analogous reactions of chloromethyltrimethylsilane, which shows that the $CH_2Ge(CH_3)_3$ group is more electronegative than $CH_2Si(CH_3)_3$. This is consistent also with the lower basicity constant of $(C_2H_5)_2NCH_2Ge(CH_3)_3$ compared with $(C_2H_5)_2NCH_2Si(CH_3)_3$.[32] The reactivity of chloromethyltrimethylstannane (in reactions of the S_N2 type) with respect to I^- and $C_2H_5O^-$ ions is higher still than those of chloromethyltrimethylsilane and chloromethyltrimethylgermane[25]. On the other hand, the electron-donating properties of the $-E(CH_3)_3$ groups become more pronounced as a function of E in the following sequence: Si < Ge < Sn.[33,34]. Consequently the observed sequence in the variation of the reactivity of compounds of the $ClCH_2E(CH_3)_3$ series (E = C, Si, Ge, or Sn) does not correspond to the inductive effect of the groups $-E(CH_3)_3$. This was explained by the fact that the nucleophilic substitution reactions involving these compounds proceed via the "bridge mechanism" described above, which is most marked in the case of chloromethyltrimethylstannane. In conformity with this, the tin atom exhibits a greater tendency than silicon and germanium atoms to expand its coordination number with formation of pentacoordinate and hexacoordinate complexes[35] and exhibits the smallest steric hindrance to nucleophilic attack because of its large atomic radius[25].

The rate constants for the reaction of chloromethyltrimethylsilane with sodium in the gas phase are greater than for neopentyl chloride and γ-chloropropyltrimethylsilane almost by factors of 15 and 5 respectively, which shows that the negative charge on the chlorine atom in chloromethyltrimethylsilane is smaller than in the compounds with which it has been compared[36].

In the reaction with 80% aqueous ethanol α-halogenoisopropyltrimethylsilanes $X(CH_3)_2CSi(CH_3)_3$ (X = Cl or Br) are much less reactive than their carbon analogues $X(CH_3)_2 \cdot CC(CH_3)_3$ and $XC(CH_3)_3$. This has been explained[37] by the enhanced electron-donating properties of the CH_3 and $C(CH_3)_3$ groups owing to the ability of their C–H and C–C bonds to participate in hyperconjugation (and not by the reduced electron-donating capacity of the trimethylsilyl group). It has also been suggested[37] that the lower reactivity of $Br(CH_3)_2CSi(CH_3)_3$ with respect to aqueous alcohol relative to $Br(CH_3)_2CH$ is caused by steric hindrance to solvation. A greater electron-accepting effect of the $Si(CH_3)_3$ group, compared with hydrogen, which would lead to the observed ratios of the rates of solvolysis of the above compounds is thought to be unlikely[37].

The rate constants for the acid-catalysed hydrolysis of triorganylsilanes $HSiR_3$ are correlated with the inductive Taft constants of the constituents R. However, the rate constant for the hydrolysis of chloromethyldimethylsilane deviates from this correlation, which has been explained[38] by the interaction of the unshared electron pair of the chlorine atom with the vacant *d* orbitals of silicon, described by the resonance structure $Cl^+CH_2=SiR_3$.

The enthalpies of the protonation reactions of the compounds $X(CH_2)_nEH_3$ (E = C or Si; X = Cl or F), calculated by the LCAO-MO method in the CNDO/2 approximation (with and without inclusion in the calculation of the vacant *d* orbitals of silicon), depend greatly on the molecular conformation for E = Si, but are insensitive to conformational changes for E = C. This indicates the occurrence of an intermolecular interaction in organosilicon compounds containing the $X-CH_2-Si$ group which is not characteristic of their organic analogues[39].

The reactivity of fluoromethyltrimethylsilane in the reaction with ethylmagnesium bromide is higher, as for the corresponding chloro-derivative, than that of γ-fluoropropyltrimethylsilane. In both compounds the fluorine atom is more mobile than in n-heptyl fluoride. It has been suggested[40] that this is caused by the "positive inductive influence" of the trimethylsilyl group, which has been shown most markedly in fluoromethyltrimethylsilane. The inertness of the fluorine atom in neopentyl fluoride has been attributed to the steric effect of the t-butyl group[40].

The numerous rearrangements involving the cleavage of the E–C bond and the migration of the substituent X from the carbon atom to the E atom have been explained by the intramolecular interaction between the E and X atoms in the molecules containing the group $X-\overset{|}{\underset{|}{C}}-E$ (E = Si, Ge, or Sn):

$$X-\overset{|}{\underset{|}{C}}-E- \rightarrow X-E+:C\overset{|}{\underset{|}{\ }}.$$

Reactions of this type are observed, for example, in the pyrolysis of organosilicon compounds containing the group $X-\overset{|}{\underset{|}{C}}-Si$ (X = halogen)[41–43]. A similar rearrangement with formation of a carbene takes place in the case of halogenomethylsilanes:

$$XCH_2SiH_3 \rightarrow XSiH_3 + :CH_2 \ (X = F, Cl, I)^{44}.$$

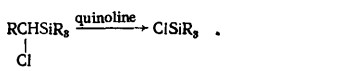
The cleavage of the Si–C bond with migration of the fluorine atom from the α-carbon atom to the silicon atom in the compound $F_2CHCF_2SiX_3$ takes place in the vapour phase at 130–210 °C (X = F) or at 310–370 °C ($X = CH_3$):[45]

$$F_2CHCF_2SiX_3 \rightarrow \left[F_2CHCF\begin{matrix}\nearrow F\\ \searrow SiX_3\end{matrix}\right] \rightarrow FSiX_3 + :CFCHF_2.$$

The α-decomposition of perhalogeno-derivatives of ethylchlorosilanes at 185 °C proceeds much more readily than the very common β-elimination[46–48]:

$$Cl_2SiCF_2CFCl_2 \begin{cases} \xrightarrow{\alpha} Cl_2SiF + :CFCFCl_2 \rightarrow CFCl=CFCl & (80\%) \\ \xrightarrow{\beta} Cl_2SiF + F_2C=CCl_2 & (7\%). \end{cases}$$

The pyrolysis of perfluoroalkyltrifluorosilanes proceeds similarly[49]. Similar reactions with liberation of dichlorocarbene are observed in the pyrolysis of Cl_3CSiCl_3 [24,47,50] and Cl_3CSiF_3.[51]

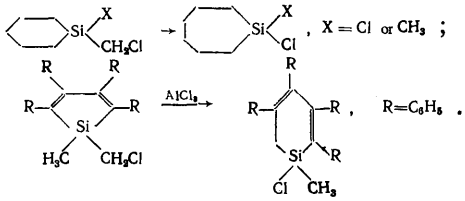


When 1,2-dichloro-2-trichlorogermyl-1-trichlorosilylethane is treated with quinoline, $GeCl_4$ is split off and not HCl. The explanation is that the germanium compounds exhibit a greater tendency towards β-decomposition than their silicon analogues[45]:

The α-elimination process is responsible for the thermal instability not only of α-fluoroalkylsilanes but also of α-fluoroalkylsiloxanes. For example, $(HF_2CCF_2SiO_{1.5})_n$ is rapidly converted into a polyfluorosesquioxane at 180–200 °C:[52]

α-Decomposition is also observed in the interaction of α-chloroalkyltrialkylsilanes with quinoline[50]:

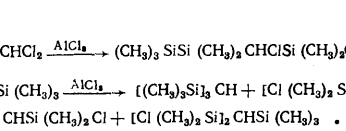
In the presence of aluminium chloride trialkylchloromethylsilanes undergo an intramolecular rearrangement[53]:



The relative ability of compounds of this type to rearrange increases in the following sequence based on varying R′:

The rearrangement proceeds via a transition state in which both substituents, R′ and Cl, are coordinated to silicon and carbon atoms[54].

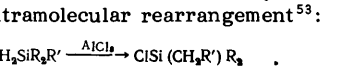
A special case of a rearrangement of this type is the expansion of the silacycloalkane ring[55] and also of the silacyclopentadiene ring[56]:



Aluminium chloride causes not a rearrangement but α-decomposition of α-chloroethylsilanes $CH_3CHClSiR_3$:[23,57]

The rearrangement of trialkyldichloromethylsilanes in the presence of $AlCl_3$ proceeds via the mechanism[23,57]

1- and 2-dichloromethylheptamethyltrisilanes also undergo a rearrangement in the presence of $AlCl_3$ with rupture of the Si–Si bond and the migration of chlorine atoms to the silicon atom[59]:



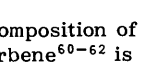
The decomposition of $F_3CSn(CH_3)_3$ with formation of difluorocarbene[60–62] is apparently due to the coordination interaction between the fluorine and tin atoms. The reactivity of the chlorine atom in trialkylchloromethylstannanes[32,60,63,64], which is higher than in the carbon, silicon, and germanium analogues, has been explained by the intramolecular coordination between the Sn and Cl atoms.

Under the influence of bases, trialkylsilylmethanols are very readily converted into the isomeric ethers[65–69]:

It has been suggested that this rearrangement takes place with formation of a bond between the silicon and oxygen atoms in the transition state; the silicon atom then becomes sp^3d-hybridised. Electron-accepting substituents at the silicon atom facilitate the rearrangement, since they promote the delocalisation of the negative charge in the three-membered transition state formed[65]. Such rearrangements are not observed for β- and γ-trialkylsilylalkanols $HO(CH_2)_n \cdot SiR_3$ ($n = 2$ or 3).[70] The thermal rearrangement of alkyl esters of α-trialkylsilylalkanecarboxylic acids, which has no analogy in organic chemistry, has been explained by a similar three-membered cyclic transition state[71].

In the pyrolysis of compounds containing the O–C–Si group the oxygen-containing group migrates from the carbon atom to the silicon atom and a carbene is evolved[72,73]:

$(C_6H_5)_2C(OCH_3)SiR_3$ is cleaved similarly[73].



The reactivity of organosilicon and organogermanium compounds of the type XCH_2ER_3 (X = O or S; E = Si or Ge) is largely consistent with the inductive influence of the ER_3 group. Thus, in a reaction with an electrophile (phenyl isocyanate) trimethylsilylmethanol is 6 times more reactive than neopentyl alcohol[74,75], more than 4 times more reactive than butanol[76], and 2.5–3 times more reactive# than methanol[74,75,77]. In its interaction with keten, trimethylsilylmethanol is 3 times more reactive than butanol[76]. The reactivity of trimethylgermylmethanol in these reactions is also significantly higher than those of neopentyl alcohol, methanol, and butanol[78]. The reactivity of alcohols of the $HO(CH_2)_nE(CH_3)_3$ series (E = Si or Ge; $n = 1–4$) in reactions with phenyl isocyanate and keten falls with increase of the number of methylene groups n and, when $n = 3$ and 4, becomes the same as that of butanol[76,78]

In the reaction with phenyl isocyanate[79] the reactivity of trimethylsilylmethanethiol is higher than that of the remaining thiols of the $HS(CH_2)_nSi(CH_3)_3$ ($n = 1–4$) series and butanol.

All these data can be accounted for by the enhanced electron-donating inductive influence of the trimethylsilyl or trimethylgermyl group which decays with increase of the number n.[76,78,79] The decrease of the nucleophilic properties of the thiyl group in mercaptans of the $HS(CH_2)_nSiR_3$ series with increase of n from 1 to 3, observed in the study of the vinylation of these compounds and confirmed by the results of potentiometric titration studies[80], can also be explained by the electron-donating influence of the trialkylsilyl group[80].

III. INVESTIGATION OF THE α-EFFECT BY PHYSICAL METHODS

The vast majority of studies on compounds containing the

grouping (E = Si, Ge, or Sn group) by various physical

The high reactivity of trimethylsilylmethanol in this reaction has also been explained[75] by the electron-accepting properties of the $CH_2Si(CH_3)_3$ group.

methods indicate the anomalous nature of their properties due to the non-inductive influence of the substituents X and E. Nevertheless some of the physical properties of these compounds are consistent with the inductive influence of the E atom (E = Si, Ge, or Sn) or more correctly of the group ER_3 incorporating it on the X atom.

On decrease of the electronegativity of the halogen atom in the sequence X = Cl, Br, I in molecules of the type XCH_2SiH_3, one should expect a decrease of their dipole moments, but in reality the dipole moments of all compounds of this type remain virtually constant. This has been explained[81] by the $(p-d)_\sigma$ or $(p-d)_\pi$ interaction of Si and X atoms not linked directly[81]. The dipole moment of the C–X bond in molecules of the type XCH_2EH_3 for E = Si is much smaller than for E = C. The difference between these dipole moments diminishes on passing from X = Cl to X = Br and I. It has been suggested[81] that this corresponds to a weakening of the interaction of the silicon and halogen atoms with decrease of the electronegativity of the halogen. Accordingly, if it is assumed that the dipole moments of the C–X bond in the XCH_2SiH_3 and XCH_2CH_3 molecules are the same, the calculated dipole moment of the SiH_3 group proves to depend on the nature of the halogen atom X.[81]

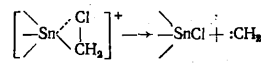
According to NMR data, the ^{29}Si atom in chloromethyltrimethylsilane is less shielded than in tetramethylsilane, which is consistent with the -I effect of the $ClCH_2$ group[82]. However, if electron-accepting substituents Y (Y = F, Cl, OR, or OCOR) are linked to the silicon atom instead of the methyl groups, the shielding of the silicon atom in compounds of the $ClCH_2SiY_n(CH_3)_{3-n}$ series proves to be greater than in the corresponding $Y_nSi(CH_3)_{4-n}$ molecules[82,83]. One of the possible explanations of the anomalous influence of the chloromethyl group on the shielding of the silicon atom in these compounds is the increase of its $(p-d)_\pi$ conjugation with the heteroatom of the substituent Y under the influence of the electron-accepting chloromethyl group[83].

According to ^1H NMR data[84], the substituents SiX_3 in molecules of the $ClCH_2SiX_3$ series influence the hydrogen atoms of the $ClCH_2$ group only via the inductive mechanism. This conclusion was reached on the basis of the ratio of the coefficients ($\rho/\rho' = 2.7$) in the correlation equations $\delta(CH_2Cl) = \delta_0 + \rho\sigma^*(SiX_3)$ for molecules of the $ClCH_2SiX_3$ (four compounds) and $ClCH_2CH_2SiX_3$ (two compounds) series, which is equal to the coefficient of the decay of the inductive influence of the substituents via the methylene group. However, it is quite evident that the small amount of experimental data makes these conclusions illegitimate.

The ^{19}F NMR spectra show that the electron density at the fluorine atom in the compounds $FCH_2Si(CH_3)_3$ is higher than in the isostructural molecules $FCH_2C(CH_3)_3$ and members of the $F(CH_2)_nSiR_3$ (R = CH_3, C_2H_5, OC_2H_5, or Cl; $n > 1$) series. These data are inconsistent with the existence of the α-effect in the fluoromethyltrimethylsilane molecule and are consistent only with the manifestation of a strong *+I* effect of the $CH_2Si(CH_3)_3$ group[85]. On the other hand, the order in which the ^{19}F NMR chemical shifts of compounds of the $Cl_nCH_{3-n}SiF_3$ series change as *n* is varied is the opposite of that expected on the basis of the inductive effect of the chlorine atoms, which has been explained by the *+M* effect of the latter[86].

The occurrence of two stretching vibration frequencies of the Si–H bond in the infrared spectra of the compounds $ClCH_2SiHRR'$ (in heptane) has been explained by the presence in solution of both molecules with intramolecular coordination between the unshared electron pair of the chlorine atom and the vacant *d* orbital of the silicon atom [the low-frequency ν(Si–H) band belongs to them] and molecules without such coordination[87]. Judging from the splitting of the ν(Si–H) line in the infrared spectra of compounds of the type $ClCH_2SiR_3$, the α-effect weakens with enhancement of the electron-accepting properties of the substituents R.[87] The steric influence of the substituents R affects to some extent the magnitude of the α-effect. The state of aggregation and the nature of the solvent also influence significantly the α-effect. It is a maximum in the gaseous state of the substance and is a minimum in the liquid state owing to its competition with the intermolecular interaction involving the vacant *3d* orbitals of the silicon atom[87].

Two bands are observed in the infrared spectra of gaseous $ClCH_2SiH(CH_3)_2$ and $BrCH_2SiH(CH_3)_2$ as well as their solutions in polar and non-polar solvents[88]. However, in this case the presence of two ν(Si–H) frequencies was explained by the existence of two rotational isomers (formed by the rotation of the $ClCH_2$ group about the Si–C bond) in which the dipole–dipole and steric interaction differ somewhat[88].



The authors own and the available literature data for the infrared and NMR spectra as well as the dipole moments of compounds of the X_3SiCH_2Y (Y = halogen) series have been analysed[89]. It was concluded that these data are consistent with an intramolecular interaction between the halogen and silicon atoms (α-effect) in halogenomethylsilanes.

It has been shown[90] that the relative basicity of the oxygen atom in the compounds $XX'X''SiOC_2H_5$, determined from the shift Δν(OH) of the stretching vibration frequency of phenol when the latter interacts with these compounds, is correlated with the sum of the Taft inductive constants of the substituents X, X', and X''. However, compounds in which one of the substituents is the chloromethyl group deviate from this correlation owing to the manifestation of the α-effect. The constant $\sigma^* = 0.54-0.57$ of the $ClCH_2$ group, calculated from Δν(OH) by means of a correlation equation, is appreciably lower than the standard value $\sigma^*_{(CH_2Cl)} = 1.05$.[84] Thus the α-effect in molecules of this type can be estimated as amounting to −0.5 of a unit on the scale of the inductive constants σ*.

The ratio of the intensities of the two lines in the ^{35}Cl NQR spectrum of the compound $ClCH_2SnCl_3$ due to the chlorine atoms in the $SnCl_3$ group is 1 : 2 and their splitting (~6%) greatly exceeds the limiting crystal [field?] splitting (1.5–2%).[91] The authors[91] attempted to explain such large splitting by the coordination interaction $Cl\overset{\frown}{-}CH_2-Sn\overset{\frown}{<}$, leading to the asymmetrisation of the tin atom, which in its turn induces the non-equivalence of the Sn–Cl bonds. Nor can one rule out the possibility of an intermolecular interaction being responsible for this non-equivalence[91]. Later preference was given to the latter explanation[92]. However, the cryoscopic distribution of the molecular weights of $ClCH_2SnCl_3$ in benzene shows that this compound is not associated[93].

It has been suggested that the intramolecular coordination interaction of the X and Sn atoms in the molecules $XCH_2SnRR'R''$ is shown in those cases where the tin atom is linked to electronegative substituents R, "capable of exciting the vacant orbitals of tin".[94,95] This interaction is weakened by the competing π-complex formation with participation of the tin atom[94]. Thus, with increase of the number *n* of electronegative substituents at the tin atom in the compounds $(ClCH_2)_{4-n}SnCl_n$ ($n = 0-4$) and $(ClCH_2)_n \cdot Sn(CH_3)_{4-n}$ ($n = 1$ or 2), a downfield shift of the proton signal of the $ClCH_2$ group is observed. The magnitude of this shift in benzene is smaller than in CCl_4, which has been explained[94] by the formation of π-complexes of the type $C_6H_6 \rightarrow SnR_4$.[94]

Rearranged fragments formed via the mechanism[94]

have been detected in the mass spectra of compounds of the $ClCH_2SnRR'R''$ series.

The broadening of the lines in the Mössbauer spectrum of the compound $ClCH_2Sn(CH_3)_3$ can be caused by the unresolved quadrupole splitting[95], in agreement with intramolecular interaction between the chlorine and tin atoms in this molecule.

The intramolecular interaction of atoms not linked directly is manifested more strongly in the solid state of a given substance, where the thermal vibrations of the molecules are considerably weakened[93]. In conformity with this, according to gas electron diffraction data and ^{35}Cl NQR spectra (at 77 K), the mutual influence of the atoms in the $ClCH_2$ group of the $ClCH_2SnCl_3$ molecule in the gaseous and solid states is not the same. Thus in the gas phase all the Sn–Cl bonds are equivalent, while the NQR spectrum of solid $ClCH_2SnCl_3$ demonstrates their significant non-equivalence (see above).

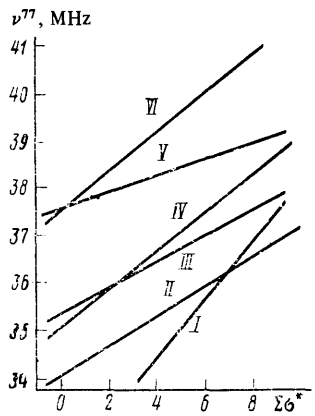


Figure 1. Correlation of the ^{35}Cl NQR frequencies (ν^{77}) of compounds of different series [*I*) $ClCH_2CRR'R''$; *II*) $ClCH_2SiRR'R''$; *III*) $Cl_2CHSiRR'R''$; *IV*) $Cl_2CHCRR'R''$; *V*) $Cl_3CSiRR'R''$; *VI*) $Cl_3CCRR'R''$] with the sum of the Taft inductive constants ($\Sigma\sigma^*$) of the substituents R, R', and R''.

The ^{35}Cl NQR frequencies of compounds of the $ClCH_2ERR'R''$ series with E = Si, Ge, or Sn are higher than for the corresponding organic analogues (E = C) [1–8,96–99] (Fig.1). The points corresponding to the organoelemental compounds $ClCH_2E(CH_3)_3$ lie appreciably above the $\nu^{77} = f(\Sigma\sigma^*_R)$ correlation straight lines plotted for compounds of the ClR and $ClCH_2R$ series[6,100]. Bearing in mind the appreciably greater electronegativity of the carbon atom compared with silicon, germanium, and tin atoms, the opposite ratio of the NQR frequencies of the corresponding organic and organoelemental compounds was to be expected. In the ^{35}Cl NQR spectra of compounds of the $Cl(CH_2)_nERR'R''$ (E = C, $n = 0$, 2, or 3 but not $n = 1$) series the NQR frequency is higher, as expected, than for the corresponding compounds with E = Si, Ge, or Sn. This also applies to the NQR frequencies of compounds of the $ClC \equiv CE(CH_3)_3$ series.

The anomalously high ^{35}Cl NQR frequencies of compounds of the $ClCH_2ERR'R''$ (E = Si, Ge, or Sn) series compared with organic analogues (E = C) are due to the intramolecular interaction between the Cl and E atoms, which we call the α-effect[1–8,96–99]. The possibility of the interaction between the chlorine atoms involved in the C–Cl bond and the silicon atom is also confirmed by a comparison of the relations between the NQR frequencies of these chlorine atoms and their number *n* in molecules of the $Cl_3CC^{35}Cl_nH_{3-n}$ and $Cl_3SiC^{35}Cl_nH_{3-n}$ series (Fig.2). Evidently, as a consequence of this interaction, the increase of the NQR frequencies with increasing number *n* in the spectra of the organosilicon compounds is much smaller than for their carbon analogues (the slope of the correlation straight line II in Fig.2 is smaller than that of line I). The replacement of the CCl_3 group in the $Cl_3CCCl_nH_{3-n}$ molecules by $SiCl_3$ leads to a significant alteration of the mutual influence of the atoms in the $Cl_n.CH_{3-n}$ group. As the chlorine atoms accumulate in this group, each becomes a weaker electron acceptor for E = Si than in the corresponding organic molecules (E = C).[101]

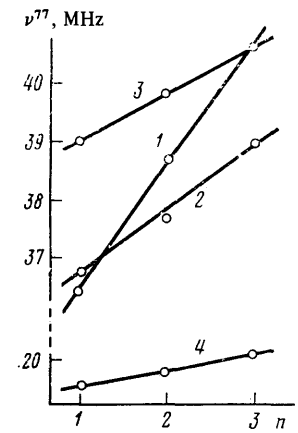

Figure 2. Relation between the ^{35}Cl NQR frequencies (ν^{77}) of compounds of the $Cl_3ECCl_nH_{3-n}$ (E = C or Si) series and the number of chlorine atoms *n*: *1*) for the chlorine atoms in the CCl_nH_{3-n} group with E = C; *2*) for the chlorine atoms in the same group with E = Si; *3*) for the chlorine atoms in the Cl_3C group; *4*) for the chlorine atoms in the Cl_3Si group.

The NQR frequencies of the chlorine atoms linked to silicon in compounds of the $Cl_3SiCCl_nH_{3-n}$ series are satisfactorily consistent with the general relation between the NQR frequencies of compounds of the Cl_2SiRR' series and the sum of the σ* constants of the substituents R. The suggested interaction between the Si atoms and the Cl atoms of the CCl_nH_{3-n} group in the $Cl_3SiCCl_nH_{3-n}$ molecules is shown only by a decrease of the sensitivity of the chlorine atoms of the Cl_3Si group to a change in the number of *n* compared with the organic analogues $Cl_3CCCl_nH_{3-n}$ (the slope of straight line IV in Fig.2 is smaller than that of line III).[101]

Analysis of the ^{35}Cl NQR frequencies of compounds of the $Cl_nCH_{3-n}SiRR'R''$ and $Cl_nCR_{3-n}SiRR'R''$ series as well as the compound $Cl(CH_3)_2SiSi(CH_3)_2Cl$ led[102] to the conclusion that the α-effect is possible only in molecules where the Cl and Si

atoms are separated by the CH_2 or $Si(CH_3)_2$ groups, because only in these cases are the NQR frequencies of the organosilicon compounds higher than those of the corresponding organic derivatives. In reality this conclusion is incorrect.

Further study of the ^{35}Cl NQR spectra of compounds of the $ClCH_2SiRR'R''$, $Cl_2CHSiRR'R''$, and $Cl_3CSiRR'R''$ series showed[5,98,99] that the ratio of the NQR frequencies in the spectra of organic and organosilicon compounds of this type is not always anomalous. For example, the $ClCH_2SiF_3$ frequency is appreciably lower than that of $ClCH_2CF_3$, as was to be expected from the ratio of the electronegativities of the C and Si atoms. The NQR frequencies of compounds of these series are satisfactorily correlated with the sum of the σ^* constants of the substituents R, R', and R'' (Fig.1). For $\Sigma\sigma^* < 7.04$, the NQR frequencies of the organosilicon compounds $ClCH_2SiRR'R''$ are higher than for the corresponding organic analogues $ClCH_2CRR'R''$, i.e. an anomalous ratio of their NQR frequencies is observed. On the other hand, for $\Sigma\sigma^* > 7.04$, the NQR frequencies of the organosilicon compounds are lower than those of the organic derivatives. This is consistent with the ratio of the electronegativities of the Si and C atoms and the inductive effect of the substituents incorporating them. The value of $\Sigma\sigma^*$ for which the ratio of the ^{35}Cl NQR frequencies of the organic and organosilicon compounds $Cl_nCH_{3-n}ERR'R''$ is reversed, decreases sharply with increase of the number of electron-accepting chlorine atoms in molecules of the given series (7.04, 1.67, and 0.25 for $n = 1$, 2, and 3 respectively).

However, the different kinds of ratios of the NQR frequencies of these compounds do not imply that there is no α-effect in the $Cl_nCH_{3-n}SiRR'R''$ molecules for some values of $\Sigma\sigma^*$, while for others the effect does exist. The mechanism of the interaction of atoms in these series of compounds must be the same for all R, because there is a satisfactory linear correlation between their ^{35}Cl NQR frequencies and the sum of the inductive constants σ^* of the substituents. These data show that the α-effect occurs in all molecules containing the $Cl-\overset{|}{\underset{|}{C}}-E$ (or $X-\overset{|}{\underset{|}{C}}-E$) group. However, its manifestation depends on the nature of the substituents linked to the atoms E and C and also on the ratio of the abilities to transmit their electronic influence in organic and organoelemental molecules. Thus the unequal manifestations of the α-effect in the organosilicon compounds $Cl_nCH_{3-n}SiRR'R''$ for different n, R, R', and R'' is caused by their appreciably lower ability to transmit the electronic influence of substituents to the chlorine atom compared with their organic analogues. The ^{35}Cl NQR frequencies of compounds of the $ClCH_2ERR'R''$ (E = Ge or Sn) series are higher than for the corresponding organic derivatives (E = C), because the abilities of these compounds (E = C, Ge, or Sn) to transmit the electronic influence of substituents to the chlorine atom are similar in magnitude (the coefficients ρ in the correlation equation $\nu^{77} = \nu_0 + \rho\Sigma\sigma^*$ are 0.58, 0.43, and 0.46 for E = C, Ge, and Sn respectively[5,99]).

Data concerning the occurrence of an intramolecular noninductive interaction in molecules containing the $X-\overset{|}{\underset{|}{C}}-E$ group (E = Si, Ge, or Sn and X = N, O, or S), obtained by infrared spectroscopy, are extremely contradictory. The nature of the variation of the basicity of the oxygen atom in molecules of the $CH_3O(CH_2)_nSi(CH_3)_3$ [103] and $CH_3O(CH_2)_nC(CH_3)_3$ series with n is the same—the basicity diminishes with increasing n.[103] The increased basicity of the oxygen atom in organic and organosilicon compounds with $n = 2$ has been explained by the effect of hyperconjugation. For compounds of the type $CH_3O(CH_2)_n \cdot Si(CH_3)_3$, the increase of basicity observed on passing from $n = 0$ to $n = 1$ and 3 is consistent with the inductive influence of the trimethylsilyl group. The basicity of the oxygen atom in the $CH_3O(CH_2)_nSiX_3$ (X = H or Cl) molecules proves to be a minimum for $n = 1$, which has been accounted for by the interaction of the oxygen and silicon atoms[103,104]. The smaller basicity of the oxygen atom in $CH_3OCH_2Si(CH_3)_3$ compared with the carbon analogue has also been explained in the same way[105]. Such interaction is manifested most effectively when there are electron-accepting chlorine atoms at the silicon atom[103].

The experimental basicity of the oxygen atom in the $[(CH_3)_3SiCH_2]_2O$ molecules proved to be smaller than was to be expected from the electron-donating properties of the trimethylsilyl group; this is caused by the superposition of the α-effect. Comparison of the basicities of the oxygen atoms shows that the α-effect in $CH_3CH_2OCH_2Si(CH_3)_3$ is stronger than in $[(CH_3)_3SiCH_2]_2O$.[106]

The lower stretching vibration frequency $\nu(C-O)$ in the infrared spectra of the compounds $XO(CH_2)_nSiR_3$ with $n = 1$ compared with their homologues ($n = 2$ or 3) and also with their organic analogues $XOCH_2CR_3$ (X = H, alkyl, or $COCH_3$) is evidently caused by the intramolecular interaction between the oxygen and silicon atoms[107].

On passing from $n = 1$ to $n = 2$ and 3, the basicity of the oxygen atom in compounds of the $(CH_3)_3Si(CH_2)_nOSi(CH_3)_3$ series diminishes. For $n = 2$ and 3, it is virtually the same and close to the basicity in $(CH_3)_3C(CH_2)_nOSi(CH_3)_3$, while for $n = 1$ it is somewhat lower than might have been expected from the electron-donating properties of the trimethylsilyl group. The latter has been explained[108] by an interaction of the type $-O-CH_2-Si$. According to other data[109] the basicity of the oxygen atom in $(CH_3)_3SiCH_2OSi(CH_3)_3$ is consistent with the inductive influence of the $(CH_3)_3SiCH_2$ group ($\sigma^* = -0.26$).

The interpretation of the infrared spectra of compounds of the $ROCOCH_3$ series and of their temperature variation led to the conclusion that the electron-donating capacity of the $R = X_3SiCH_2$ groups is reduced due to the α-effect. This effect leads to a deviation of the frequencies $\nu(C=O)$ and $\nu(C-O-C)$ for $(CH_3)_3SiCH_2OCOCH_3$ from the linear correlation of these quantities with the inductive constants σ^* of the substituents R in compounds of the $ROCOCH_3$ series and to a decrease of the frequencies $\nu(C-O-C)$ for the compounds $H_3COCOCH_2E(CH_3)_2R$ (R = CH_3, C_2H_5, or C_6H_5; E = Si or Ge) compared with $H_3COCO(CH_2)_nE(CH_3)_3$ for $n > 1$ or with $H_3COCO(CH_2)_nR$ [R = $(CH_3)_3C$ or CH_3; $n = 1-4$].[110] The acetoxy-group in compounds of the $H_3COCOCH_2Si(CH_3)_{3-n}R_n$ (R = OC_2H_5 or $OCOCH_3$) series increases the shielding of the silicon atom compared with the compounds $R_nSi(CH_3)_{4-n}$. On the other hand, according to its inductive effect, deshielding of the silicon atom would have been expected[111].

The basicity of the oxygen atom in the $H_3COCH_2EH_3$ (E = Si or Ge) molecules is lower than in the carbon analogue (E = C), which is inconsistent with the electron-donating properties of the EH_3 groups for E = Si or Ge and has been explained[112,113] by the $(p-d)_\pi$ interaction between O and E (E = Si or Ge) atoms separated by the CH_2 group.

The frequencies $\nu(C-O-R)$ and $\nu(OH)$ in the infrared spectra of the compounds $RO(CH_2)_nGe(CH_3)_3$ [R = H or $Si(CH_3)_3$; $n = 1-4$] for $n = 1$ are lower than for $n = 2-4$ and are also lower than for the carbon analogues $RO(CH_2)_n \cdot C(CH_3)_3$. This has been explained by the lability of the C–O bond caused by the α-effect. The relative basicities of the oxygen atom in molecules of the $(CH_3)_3E(CH_2)_n \cdot OSi(CH_3)_3$ (E = C or Ge; $n = 1-4$) series are consistent

with the electron-donating properties of the $(CH_2)_nGe(CH_3)_3$ groups. For $n=1$ and 2, the basicity is higher than for $n=3$ and 4.[114]

The relative basicities of the alcohols HOR, determined from the shift of the stretching vibration frequency ν(OH) of phenol, are correlated with the inductive constants σ^* of the substituents R. The basicities of the compounds $HO(CH_2)_nSi(CH_3)_3$ with $n=1$ and 2 also obey this correlation. The relative acidities of the latter likewise obey a linear correlation between the acidity of the alcohols HOR [determined from the shift of ν(OH) in the infrared spectra of their mixtures with tetrahydrofuran] and the σ^* constants of the substituents R. These data are inconsistent with an interaction between the silicon and oxygen atoms in organosilicon compounds containing the $-O-\overset{|}{C}-Si<$ group[115].

The ^{29}Si NMR chemical shifts of compounds of the $ROSi(CH_3)_3$ series are correlated with the inductive constants σ^* of the substituents R. Compounds with $R=CH_2Cl$ and $CH_2Si(CH_3)_3$ do not obey this correlation. The ^{29}Si NMR data show that the $CH_2Si(CH_3)_3$ group has a weaker electron-accepting activity when it is linked to an oxygen atom. The constant $\sigma^*[CH_2Si(CH_3)_3]$, calculated[109] from the correlation equation on the basis of the experimental quantity δ(Si) in the $(CH_3)_3SiCH_2OSi(CH_3)_3$ spectrum, is 0.15 ± 0.05.

The acidity of alcohols of the $HO(CH_2)_nSi(C_6H_5)_3$ series increases on passing from $n=1$ to $n=2$, the increase being particularly pronounced for $n=0$. The acidity of isostructural organogermanium alcohols $HO(CH_2)_nGe(C_6H_5)_3$ increases on passing from $n=2$ to $n=1$ and further to $n=0$. This sequence in the variation of the acidities of organoelemental alcohols is inconsistent with the electron-donating inductive effects of the triphenylsilyl and triphenylgermyl groups and can be explained by the $(p-d)_\pi$ interaction between the oxygen atom and the silicon or germanium atom via the methylene group. It has been suggested that such interaction is responsible also for the decrease of acidity on passing from E = Ge to E = Si and further to E = C in molecules of the $HOCH_2E(C_6H_5)_3$ series[116].

The basicity of the nitrogen atom in trimethylsilylmethylamine is higher than in its carbon analogue (by a factor of 5.69) or in γ-trimethylsilylpropylamine (by a factor of 1.5),[117] which agrees with the electron-donating effect of the trimethylsilyl group.

The basicity of compounds of the $H_2N(CH_2)_nSi(OC_2H_5)_m\cdot(CH_3)_{3-m}$ ($m=0-3$) series, determined spectroscopically, is much lower for $n=1$ than for $n=2-4$. This has been explained by the effect of hyperconjugation, which exceeds, when $n=1$, the opposite inductive effect of the silyl group[118].

Compounds of the $H_2N(CH_2)_nSi(OC_2H_5)_m(CH_3)_{3-m}$ series have also been studied by the ^{29}Si, ^{14}N, and ^{13}C NMR methods[119]. The observed increase of the shielding of the silicon atom in these compounds for $n=1$ and 2 relative to compounds of the $H(CH_2)_nSi(OC_2H_5)_m(CH_3)_{3-m}$ series has been explained by the intensification of the $(p-d)_\pi$ interaction between the silicon and oxygen atoms (in the ethoxy-group) under the influence of the electronegative group NH_2. This inductive influence decays for $n\geq3$. It has been suggested that the more pronounced shielding of the nitrogen atom in the aminomethyl derivatives (which is almost independent of the number m) compared with other members of this series ($n\geq2$) is inconsistent with the interaction between the silicon and nitrogen atoms in these molecules[119]. However, on the basis of NMR data, one can hardly draw inferences about this interaction, because the ^{14}N, ^{29}Si, etc. NMR shifts are not direct characteristics of the electron density of the indicator atom. This is evident also from the ^{14}N NMR spectra of compounds of the type $H_2N(CH_2)_n\cdot Si(OC_2H_5)_m(CH_3)_{3-m}$ investigated. For example, a change in the number m for $n=1$ does not affect δ_N and the chemical shift of the ^{14}N NMR signal in the spectrum of aminomethyltriethoxysilane differs by only 1 p.p.m. from δ for methylamine, etc.

The basicity of the amines $H_2C(CH_2)_mN(CH_2)_nSiR_3$ ($m=3-5$) for $n=1$ is lower than for $n=2$,[120-122] which is due to the α-effect in the molecules with $n=1$. The determination of the relative acidities of the hydrogen atom linked to the nitrogen atom in compounds containing the $RNHCH_2Si$ group by infrared spectroscopy[123] showed that they exhibit the α-effect. The magnitude of this effect depends on the nature of the substituent R linked to the nitrogen atom and is a maximum for R = alkyl. For $R=C_6H_5$, the α-effect is reduced owing to competition with p, π conjugation involving the aromatic ring. For $R=CH_3OC(O)$, there is no α-effect[123].

In molecules of the $R_2NCH_2E(CH_3)_3$ series, the basicity of the nitrogen atom for E = Ge is somewhat lower[32] and for E = Sn is lower by 4 orders of magnitude than for E = C.[124] The appreciably reduced basic properties of the nitrogen atom in trialkylaminomethylstannanes have been explained by the increase of the coordination number of the tin atom due to the formation of an intramolecular coordinate bond with the nitrogen atom, i.e. by the transfer of the unshared electron pair of the nitrogen atom to the vacant orbital of the tin atom with partial sp^3d character[124]. The upper limit to the strength of the intramolecular coordinate bond N → Sn ($\Delta\Delta H\cong5.5$ kcal mol^{-1}) was estimated from the decrease of basicity by means of the relations $k_1/k_2=\exp(-\Delta\Delta E/RT)$ and $\Delta\Delta F=\Delta\Delta H-T\Delta\Delta S^0$, neglecting the change in the entropy term[124]. Later[125] the authors admitted that these data and the hypothesis of the intramolecular coordination of the tin and nitrogen atoms based on them are erroneous. They found that the basicity of the amines containing the $>N-\overset{|}{C}-E<$ group increases in the following sequence of different E: C > Ge > Sn > Si.

The intramolecular coordination interaction between nitrogen and tin atoms is indicated by the retardation of the inversion of nitrogen in trialkyl(*N*-aziridinomethyl)stannanes; apart from overcoming the inversion barrier, a change in the configuration of these compounds requires the rupture of the N → Sn bond.[124]

In contrast to tetra-alkylstannanes, the ultraviolet spectra of trialkyl(aminomethyl)stannanes exhibit a slight bathochromic shift and an appreciable increase of the extinction coefficient[124], which is consistent with the N → Sn coordination. The absence of an intermolecular interaction in this case is confirmed, for example, by cryoscopic and electrothermic studies of the compound  .[124,126]

The absence of quadrupole splitting and the small changes in the chemical shifts in the Mössbauer spectra of compounds of the XCH_2SnR_3 (X = H_2N, $R_3\overset{+}{N}$, RO, F, or Cl) series[95,127] are inconsistent with intramolecular coordination in these molecules[95,128]. This may be caused by the inadequate sensitivity of the method[124].

Certain examples of the anomalous influence of the groups ER_3 (E = Si, Ge, or Sn), which are inconsistent with their inductive effect on the atom X in molecules containing the $X-\overset{|}{C}-ER_3$ fragment, have also been quoted in reviews[125-131]. This anomalous influence is usually explained by the interaction between the unshared electron pair of the atom X and the vacant *d* orbitals of the atom E.[129,131].

Thus the results presented below show that data concerning the existence of the α-effect in molecules containing the X–C–E (E = Si, Ge, or Sn) group are at present contradictory. However, one must bear in mind that many theoretical conclusions are insufficiently well-founded. Data derived by certain research methods, on the basis of which the α-effect is accepted or rejected, do not permit inferences concerning the nature of the distribution of electron density at the E and X atoms, because such data are determined by contributions from several uncontrolled factors. This applies primarily to ^{14}N, ^{29}Si, etc. NMR spectra. Furthermore, the contradictory nature of the conclusions concerning the existence of the α-effect is caused by the fact that the nature of its manifestation in molecules containing the X–C–E group depends on the electron-accepting properties of substituents linked to the C and E atoms and also on the ratio of the abilities to transmit the inductive influence of substituents to the atom X in organic (E = C) and organoelemental (E = Si, Ge, or Sn) compounds. These characteristics of the manifestation of the α-effect have usually been disregarded. The conclusions concerning the existence of the α-effect, based on a comparison of the results of studies of individual pairs of organic and organoelemental compounds, cannot therefore be regarded as reliable.

The vast majority of the available experimental data indicate a non-inductive interaction between the atoms X and E in molecules containing the X–C–E group. Systematic study of ^{35}Cl NQR spectra of compounds containing this group (E = C, Si, Ge, or Sn) showed that the α-effect exists in all these molecules but is not manifested in the same way. By analogy with these data and also bearing in mind the results obtained by other research methods, one can assume that the α-effect exists in all molecules containing the X–C–E group.

IV. THE NATURE OF THE α-EFFECT

Views concerning the nature of the α-effect in molecules containing the X–C–E group are contradictory and the majority of them do not have a convincing basis. They are based on the analysis of data obtained in the study of the corresponding compounds by physical methods which are unsuitable for the investigation of the mechanism of the mutual influence of atoms in molecules. The quantum-mechanical calculations carried out on certain molecules to elucidate the nature of the α-effect also failed to solve the problem of the mechanism of this interaction. The anomalous (inconsistent with the inductive effect of the geminal substituent) physical and chemical properties of compounds containing the X–C–E group are usually explained by the coordination interaction between the atoms X and E with transfer of electron density from the atom X to the atom E. The commonest mechanism of this transfer is $(p-d)_\pi$ conjugation of the unshared electron pair of the atom X with the *d* orbitals of the atom E through space[81,112,113,116]. The principal arguments in support of this interaction—the anomalous nature of the properties of these compounds and the possibility, in principle, of the involvement of the unshared electron pairs and vacant *d* orbitals of the corresponding atoms in the formation of chemical bonds—are merely speculative.

If the intramolecular coordination interaction in the group X–C–E does indeed occur, it is to be expected that the ECX angle should be smaller than the tetrahedral value, that the non-bonding E...X distance should approach the sum of the covalent radii of these atoms, and that the E–C and C–X bond lengths should have anomalous values. However, the experimental geometry of the $ClCH_2SiH_3$ molecule[132] does not confirm this hypothesis. The ClCSi angle in this molecule is 109.3°, the Si–C and C–Cl bond length have the "normal" values (1.88 and 1.788 Å respectively), and the distance between the Si and Cl atoms is 3.0 Å, i.e. appreciably greater than the sum of their covalent radii.

According to gas electron diffraction data[93], the $ClCH_2.SnCl_3$ molecule has the structure of a somewhat distorted tetrahedron. All the Sn–Cl bonds have the same "normal" length (2.34 Å), which is less than the sum of the covalent radii (2.39 Å). The Sn–C bond length (2.23 Å) is somewhat greater than the sum of the covalent radii of the tin and carbon atoms (2.17 Å) and the length of the Sn–C bonds in other organic derivatives of tin. The C–Cl bond (1.74 Å) is shorter than in saturated organic compounds and its length is close to that of a C–Cl bond adjoining a double bond, for example in $Cl_2C=CCl_2$ (1.72 Å). The ClCSn angle (113°) is somewhat greater than the tetrahedral value and the non-valent Sn...Cl distance (3.31 Å) is greater than the sum of the covalent radii (2.39 Å) but smaller than the sum of the van der Waals radii (3.95 Å) of tin and chlorine atoms. Although this distance is sufficient for coordination interaction between the Sn and Cl atoms, nevertheless there is no direct evidence for such coordination.

It has been suggested that the characteristics of the changes in the basicity of the oxygen atom in molecules of the $[(CH_3)_3Si(CH_2)_n]_2O$ ($n = 1-4$) series[106] and the low stretching vibration frequencies ν(C–O) and ν(HO) [107] in the compounds $XOCH_2Si(CH_3)_3$ compared with their organic analogues and other members of the $XO(CH_2)_nSi(CH_3)_3$ [X = H or $Si(CH_3)_3$] series are caused by the $(p-d)_\sigma$, $\sigma_{OC} \rightarrow d$, or $\sigma_{OH} \rightarrow d$ interactions[106,107]. The last interaction has also been postulated in the $HOCH_2Ge(CH_3)_3$ molecule[107]. The α-effect in the molecules of acetoxysilanes $H_3COCOCH_2.Si(CH_3)_2X$ has been interpreted as $\sigma_{C(O)-O} \rightarrow d$, $\sigma_{C(O)-O} \rightarrow \sigma^*_{(O)C-Si}$, or $\sigma_{C(Si)-O} \rightarrow d$ interaction[110]. The shielding of the protons of the methylene group $XCH_2Sn\lesssim$ in the molecules $XCH_2Sn(C_2H_5)_2Cl$, which is smaller than expected on the basis of the electronegativity of the tin atom, has been explained by the partial transfer of the σ-electrons of the CH_2–X bond (X = Cl or OCH_3) to the vacant 5*d* orbitals of the tin atom (σ–*d* conjugation).[133]

Analysis of the orbital interactions of the α-carbofunctional silanes XCH_2SiH_3 (X = NH_2, OH, or F) and the corresponding carbon analogues, based on the calculation of the wave functions in terms of the CNDO/2 approximation and the Mulliken analysis of the orbital populations, led to the conclusion that there exist two mechanisms of the electron-accepting influence of the second atom on the geminal heteroatom (two mechanisms of the α-effect)[134,135]: (1) interaction through space between the upper occupied molecular orbitals and low-lying antibonding orbitals ($n - \sigma + \sigma^*$), which

is reflected by the resonance structure $^{+}X-CH_2\ H-SiH_2$; the extent of this interaction diminishes in the following sequence of X: $H_2N > OH > F$; (2) interaction via bonds, which is most marked for X = F.

The sequence of the changes in the calculated (in terms of the CNDO/2 approximation without taking into account the *d* orbitals of the silicon atom) enthalpy of the reversible acid–base interaction ΔH for the compounds $X(CH_2)_nEH_3$ (E = C or Si; X = HO or H_2N; $n = 0-3$) is consistent with the sequence in the variation of the experimental basicities or acidities of these compounds determined in the gas phase. The enthalpy was calculated as the difference between the total energies *E*: $\Delta H = E_{(ROH)} - E_{(RO^-)}$ for the reaction $RO^- + H^+ \rightarrow ROH$ and $\Delta H = E_{(RNH_3^+)} - E_{(RNH_2)}$ for the reaction $RNH_2 + H^+ \rightarrow RNH_3^+$.

The basicity of the amine $H_2NCH_2Si(CH_3)_3$ is lower than for other members of the $H_2N(CH_2)_nSi(CH_3)_3$ series. On the other hand, the basicity of the alcohols $HO(CH_2)_nSi(CH_3)_3$ diminishes successively with increase of *n*. On the basis of the analysis of the orbital interactions, the unequal influences of the $(CH_3)_3Si$ group on the basicity of $H_2NCH_2Si(CH_3)_3$ and $HOCH_2Si(CH_3)_3$ have been explained by the stronger interaction of the unshared electron pair of the nitrogen atom with the Si–C bond compared with the oxygen atom, which leads to a decrease of the energy of the $n-\sigma$ orbital when the latter interacts with the antibonding σ^*_{Si-C} or σ^*_{Si-H} orbital[135]. It has been suggested[134] that the α-effect is a consequence of the high polarisability of the silicon atom, which is responsible for the existence of low-lying antibonding orbitals.

The inclusion of the vacant *d* orbitals of the silicon atom in the calculation on the XCH_2SiH_3 molecules reduces somewhat the total energy of these molecules and the energies of the individual orbitals. However, this does not alter qualitatively the tendency towards a distribution of the charges on the silicon atom and particularly on the heteroatoms of the substituents X when the latter are varied[134]. An analogous conclusion had been reached earlier[136] on the basis of *ab initio* non-empirical calculations with a contracted Gaussian basis. Furthermore, the contribution of the antibonding orbital σ^*_{Si-H} to the energy of a low-lying vacant molecular orbital is much greater than the contribution of the *d* orbitals[134].

The problem of the involvement of the vacant *d* orbitals of the atoms of non-transition elements in the formation of chemical bonds has attracted the attention of many investigators for a long time. Numerous quantum-mechanical calculations, including non-empirical calculations, have been carried out for its solution. The view (based on these calculations) that the presence of vacant *d* orbitals in the valence shells of atoms of non-transition elements hardly influences the properties of compounds incorporating them, because these orbitals are energetically so unfavourable and so diffuse that they are incapable of interacting in any way appreciably with the other valence orbitals, is nowadays gaining increasing currency (see, for example, Bochvar et al.[137] and Korol'kov[138]). In this connection it is evident that the α-effect can also be accounted for without taking into account the contribution of the vacant *d* orbitals of the atom E (E = Si, Ge, or Sn).

The α-effect in compounds containing the $X-\overset{|}{\underset{|}{C}}-E$ group is caused by the interaction of quite definite orbitals of the atoms E and X (see above). The occurrence of this non-inductive interaction between atoms and its nature can be established only with the aid of physical methods whereby one can follow the populations of these particular orbitals. One of these few methods is nuclear quadrupole resonance, which yields information about the spatial distribution of the electron density of the indicator atom. Other physical methods used to investigate the α-effect (see above) do not provide such information. The results of quantum-mechanical calculations also do not permit the elucidation of the nature of the α-effect.

According to ^{35}Cl NQR spectroscopic data for compounds of the $ClCH_2ERR'R''$ (E = C, Si, Ge, or Sn) series, the p_σ electrons of the chlorine atom, i.e. the electrons of the C–Cl bond, are involved in the interaction with the E atom of these molecules[1-8,97,139]. This follows from the higher ^{35}Cl NQR frequencies of the organoelemental compounds (E = Si, Ge, or Sn) compared with organic analogues (E = C) (see the previous Section).

The NQR frequency ν or the quadrupole coupling constant of the molecule e^2Qq are related to the number of unbalanced electrons of the chlorine atom V_p as follows (see, for example, Refs.92, 140–142):

$$e^2Qq_{mol} = e^2Qq_0 \cdot V_p = e^2Qq_0\left(\frac{N_x + N_y}{2} - N_z\right),$$

where e^2Qq_0 is the atomic quadrupole coupling constant and N_x, N_y, and N_z are the populations of the p_x, p_y, and p_z orbitals of the chlorine atom. Hence it is seen that the quantity e^2Qq can increase either with decrease of the population of the chlorine p_σ orbital (p_z orbital), involved in the formation of the C–Cl bond, or with increase of the population of the orbitals of its unshared electron pairs (p_x or p_y orbitals). The hypothesis that the populations of the $3p_x$ and $3p_y$ orbitals of the chlorine atom in organoelemental molecules are higher than in the isostructural organic molecules, where the populations of the p_x and p_y orbitals are virtually equal to 2, is unrealistic. Therefore the increase of the ^{35}Cl NQR frequency for compounds of the $ClCH_2ERR'R''$ series having E = Si, Ge, or Sn compared with organic analogues (E = C) as well as other anomalous properties of the compounds containing the $Cl-\overset{|}{\underset{|}{C}}-E$ or $X-\overset{|}{\underset{|}{C}}-E$ (E = Si, Ge, or Sn) group are caused by the decrease of the population of the p_σ orbital of the chlorine (or X) atom, i.e. by the involvement in the interaction with the E atom of the electrons of the C–Cl (C–X) bond[1-8,97,139]. This is an experimentally established fact. The participation of the p_σ electrons of the chlorine atom in this interaction is also confirmed by the comparatively low parameter of the asymmetry of the electric field gradient η at the location of the atomic nucleus of chlorine in chloromethylsilane $ClCH_2SiH_3$ ($\eta = 0.048$), which is close to the asymmetry parameter for $ClCH_2CH_3$ ($\eta = 0.035$). Consequently the hypothesis of the coordination interaction between the E and X atoms in the $X-\overset{|}{\underset{|}{C}}-E$ group with participation of the unshared electron pair of the X atom has not been confirmed experimentally.

One can only speculate in what way the E atom is involved in this interaction. According to the generally accepted view, the atoms E = Si, Ge, or Sn possess electron-accepting properties by virtue of their vacant *d* orbitals (see, for example, Refs.23, 131, 143, and 144). On this basis, one can assume that the p_σ electrons of the C–Cl (C–X) bond pass to the vacant *d* orbitals of the E atom and an electron-deficient three-centre bond is therefore formed between the

E, C, and Cl atoms[1-3]. The possibility of the formation of a three-centre bond as a result of the sharing of a single electron pair by three atomic nuclei was pointed out a long time ago by Longuett–Higgins[145]. The presence of such hypervalent bonds has been postulated in diborane[145-148], carbaboranes[149], etc. (see, for example, Refs,147, 148, and 150), but the existence of such bonds has not so far been confirmed experimentally.

In molecules containing the X–C–E group the C–X bond can also be polarised under the influence of the E atom, which should lead to a decrease of the p_σ electron density of the X atom[3]. This model of the intramolecular interaction does not conflict with the steric structure of molecules of the XCH_2ER_3 series established by gas electron diffraction[93] and microwave spectroscopy[132], since it does not require a decrease of the XCE angle relative to the tetrahedral value[2,3].

Analysis of the experimental data established a unique anomalous relation between the ^{35}Cl NQR frequencies of all compounds containing the Cl–C–E group and the charge (or, to a first approximation, the electronegativity) of the E atom[1-5]: with increase of the electronegativity (negative charge) of the E atom, the NQR frequencies of such compounds diminish (the p_σ-electron of the chlorine atom increases) and, conversely, with decrease of the electronegativity of the E atom, the NQR frequencies increase (the p_σ-electron density of the chlorine atom diminishes). Compounds with an E atom having unshared electron pairs (E = N, O, F, etc.), vacant *d* orbitals (E = Si, Ge, Sn, etc.), as well as atoms lacking either feature (E = H or C) obey this relation. The relation has been confirmed by the correlation analysis of the ^{35}Cl NQR frequencies of, for example, compounds of the $ClCH_2E^nR_{n-1}$ (*n* is the valence of the E atom) series[4]. The NQR frequencies of compounds of the $ClCH_2CR_3$ series are correlated with the inductive constants σ^* of the substituent CR_3. For $E \neq C$, such a correlation does not hold. The deviations of the NQR frequencies $\Delta\nu$ of compounds with $E \neq C$ from the above correlation are in their turn satisfactorily correlated with the electronegativity of the E atom (according to Pauling). The last correlation is obeyed by the deviations $\Delta\nu$ both for compounds with an E atom having unshared electron pairs or vacant *d* orbitals and for compounds with E = H as well as the average value of $\Delta\nu$ ($\Delta\nu_{av} = 0$) for compounds with $E^nR_{n-1} = CR_3$.

An analogous anomalous relation is shown also in the case of other physical and chemical methods for the investigation of compounds containing the X–C–E group. The anomalous properties of all these compounds (whatever the E) are due to the interaction of the E atom with the electron cloud of the C–X (C–Cl) bond, which follows from their ^{35}Cl NQR spectra. Bearing this in mind as well as the general anomalous dependence of the distribution of electron density at the X atom in the X–C–E group on the nature of the E atom, one can assume that the anomalous relation is caused by the same mechanism of the interaction of the X and E atoms whatever the E. This general mechanism can involve the electrostatic interaction of the charge of the E atom, directly through the field, with the electron cloud of the C–Cl (C–X) bond, because this interaction is almost independent of the presence of unshared electron pairs or vacant *d* orbitals in the E atom[2,4,5,139,153]. Furthermore, the electrostatic mechanism of the geminal interaction is indicated by the finding that virtually all interactions in the molecules are in fact electrostatic, the E atom influences all the C–X bonds in the given molecule in the geminal position with respect to it to virtually the same extent, etc.[5,153] The interaction of the E and Cl atoms in these molecules directly through the field has been confirmed by the ^{35}Cl NQR spectra of compounds of the $Cl_nCH_{3-n}CHClOR$ series[154,155], in which the resonance frequency of the β-chlorine atom corresponds to the inductive influence of the OR group on the latter, while the frequency of the α-atom is anomalously low. The interaction of the α- and β-chlorine atoms with the oxygen atom along the chemical bonds, the nature of the changes in their NQR frequencies would be the same. In the linear molecules Cl–C ≡ E the intramolecular interaction of the geminal Cl and E atoms takes place only along chemical bonds. The E atoms therefore influence the NQR frequency (or the quadrupole coupling constant) of these compounds in conformity with the inductive effect of the E atoms or the substituents incorporating them[4,5,139,153].

The calculated contribution $\Delta\nu$ to the ^{35}Cl NQR frequency of the interaction of the charge of the E atom with the electron cloud of the C–Cl bond directly through the field for certain molecules of the $ClCH_2E$ series agrees well with the experimental data and the quantum-chemical calculation of the charges on the E atoms in these molecules[156-158]. For example, the quantity $\Delta\nu = 4.2$–6.3 MHz (for different amounts of ionic character of the C–Cl bond, for different charges on the oxygen atom calculated for different parametrisations in terms of the CNDO approximation taking into account the error of the experimental determination of the Stark shift used in the calculation, etc.), calculated for the chloromethyl ether $ClCH_2OCH_3$, agrees satisfactorily with the deviation of the experimental NQR frequency of this ether from the linear correlation between the ^{35}Cl NQR frequencies of compounds of the $ClCH_2CR_3$ series and the inductive constants σ^* of the substituents CR_3 ($\Delta\nu_E = 4.9$ MHz). For $ClCH_2Si(CH_3)_3$, the quantities $\Delta\nu$ and $\Delta\nu_E$ are respectively 3.72 and 3.56 or 2.50 MHz, etc.[157]

The ^{35}CL NQR frequencies of compounds containing the Cl–Z–E and Cl–Z–E groups (Z = C, Si, Ge, P, etc.) obey the anomalous relation which holds for compounds containing the Cl–C–E group[2,4,5,98,139,153,159,160]. The contribution $\Delta\nu$ of the geminal interaction between the Cl and E atoms in the molecules ClZ(OR)XX′ (Z = C, Si, or Ge) is inversely related to the bulk of the central atom Z, i.e. to the distance between the E = O atom and the centre of the electron cloud of the Z–Cl bond[159]. An analogous relation has been observed also for compounds of the ClZ(OR)X series with Z = P or As.[159]. These data are also in good agreement with the electrostatic mechanism of the interaction of the Cl and E atoms in molecules containing the Cl–C–E (X–C–E) group and therefore with the electrostatic mechanism of the α-effect, which is a special case (for E = Si, Ge, Sn, etc.) of the general electrostatic effect of the geminal interaction.

The above data, obtained in the study by physical and chemical methods of compounds of Group IVB elements containing the X–C–E fragment (E = Si, Ge, or Sn; X = halogen, O, N, or S), show that in the vast majority of

cases the E atoms influence the substituent X not in conformity with the electronegativity of the E atom and the inductive effect of the group incorporating it. This non-inductive interaction of the X and E atoms has been called the α-effect. There exist most contradictory views concerning the existence of the α-effect and its nature. However, systematic studies of the ^{35}Cl NQR spectra of organosilicon compounds containing the Cl–C–Si group have shown that the α-effect occurs in all molecules of this type and that the conflicting conclusions concerning its existence arose from the fact that they were usually based on a comparison of data obtained in the study by some method of individual pairs of isostructural organoelemental and organic compounds or short series of compounds.

On the other hand, the nature of the manifestation of the α-effect depends significantly on the electron-accepting properties of the substituents linked to the C and E atoms and on the ability to transmit the inductive influence of the substituents to the indicator E atom in organic and organoelemental compounds and on the research technique employed, which may not reflect adequately the nature of the distribution of the electron density at the E and X atoms. The nature of the α-effect is usually inferred solely on the basis of the postulated possibility, in principle, that specific orbitals of the E and X atoms are involved in the formation of chemical bonds, without any experimental evidence for this hypothesis. Quantum-mechanical calculations also fail to provide a convincing explanation of the α-effect.

The ^{35}Cl NQR spectra of compounds containing the Cl–C–E group (E = C, Si, Ge, or Sn) indicate unambiguously the involvement of the p_σ electrons of the chlorine atom (the electrons of the C–Cl bond) in the interaction with the E atom. Systematic study of the ^{35}Cl NQR spectra of compounds of this type, in which the E atom has unshared electron pairs, vacant *d* orbitals, or neither one nor the other showed that their anomalous properties are caused by the electrostatic interaction directly through the field due to the charge of the E atom with the electron cloud of the C–Cl (C–X) bond, i.e. by the polarisation of the C–Cl (C–X) bond under the influence of the electric field generated by the charge of the E atom, and not by the coordination interaction between the E and Cl (or X) atoms, presupposing the transfer of electron density from the X atom to the E atom. The α-effect is only a special case of such electrostatic interaction. It is quite natural that the charge of the X atom interacts in the same way with the electron cloud of the C–E bond.

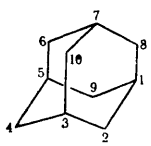
Adamantane Structures in the Chemistry of Silicon, Germanium, and Tin

V.F.Mironov, T.K.Gar, N.S.Fedotov, and G.E.Evert

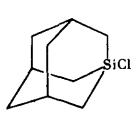
The methods of synthesis and properties of compounds with the adamantane structure containing silicon, germanium, or tin atoms in the side chain or substituting carbon atoms in the adamantane lattice are examined. The review includes studies published towards the beginning of 1979.
The bibliography comprises 177 references.

CONTENTS



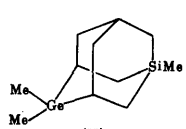
I. Introduction 262
II. Silyladamantanes 262
III. Sila-adamantanes 268
IV. Germyl- and germa-adamantanes 274
V. Stannyl- and stanna-adamantanes 275

I. INTRODUCTION



Adamantane, its analogues, and their derivatives are known to have unique physicochemical properties[1-13]. Studies designed to synthesise adamantane structures with Group IVB elements, particularly silicon, have begun to develop recently; a new field has been established in the chemistry of Group IVB elements to which more than 170 original publications have already been devoted.

Compounds of Group IVB elements having a three-dimensional skeleton comprising any atoms with the same configuration as the skeleton of carbon atoms in adamantane, which can be regarded as the unit cell of the three-dimensional carbon network in diamond, can be divided into two large classes. The first class includes compounds in which the atom of the Group IVB element is not incorporated in the adamantane skeleton. Such compounds can be called respectively silyl-, germyl-, stannyl-, and plumbyl-adamantanes. The second class includes compounds in which the atom of the Group IVB element is incorporated in the adamantane skeleton, i.e. substitutes a carbon atom. Such compounds can be called respectively sila-, germa-, stanna-, and plumba-adamantanes.

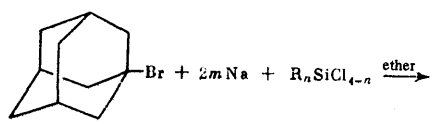


The following numbering has been adopted for the carbon skeleton of adamantane:

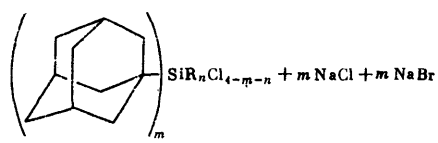
Regardless of the number of substituents, this skeleton is designated by the symbol Ad. If one or more carbon atoms in the adamantane skeleton have been substituted by atoms of other elements, then the principle of the "oxa-aza" nomenclature is used in naming such compounds. For example, compounds (I) and (II) are called respectively 1 chloro-1-sila-adamantane, and 1,4,4-trimethyl-1-sila-4-germa-adamantane:

(I)

(II)



Alphabetic symbols for such structures have not as yet been proposed, since these compounds have in most cases not been synthesised or are represented by single specimens. However, for 1,3,5,7-tetrasila-adamantanes, i.e. compounds having the skeleton of the unit cell of carborundum and frequently called carborundanes, it is reasonable to introduce a designation, since this class is already represented by numerous compounds and is nowadays widely investigated. Without taking into account the substituents, the unit cell of carborundum is designated by the symbol Cb.

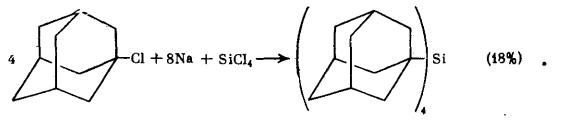


II. SILYLADAMANTANES

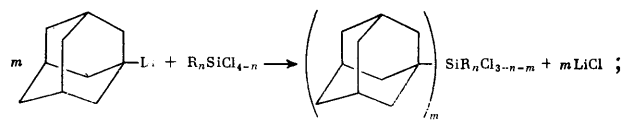
This class includes compounds having the structure AdSi$\equiv$ or AdRSi$\equiv$, where R can be any group of atoms or any element.

1. Methods of Synthesis

Silyladamantanes with the adamantyl group linked directly to the silicon atom have been recently obtained by the Wurtz reaction independently by several groups of investigators. No and coworkers[14-18] have studied this reaction most widely:

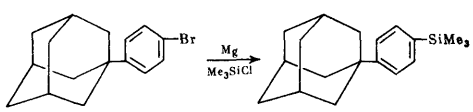


R = Et, n-Pr, n-Bu, Ph, or Me; $n = 1-3$, $m = 1-3$.



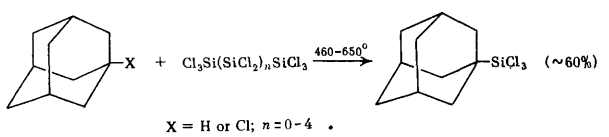
According to the authors, the reaction proceeds with high yields (50–80%) of the required products, although it is accompanied by the formation of diadamantane. The authors note that it is possible to replace only one chlorine atom in chlorosilane by the adamantyl group.

However, Roberts[19] was able to obtain tetra-adamantylsilane by the Wurtz reaction (in a low yield):



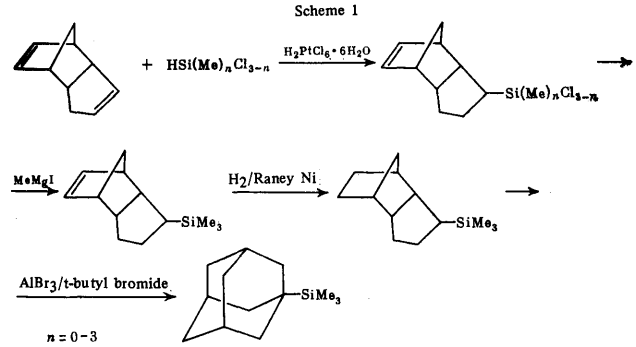
Mironov et al.[20] also investigated the synthesis of silyladamantanes using sodium and lithium, but they were able to obtain 1-trimethylsilyladamantane only in a very low yield. Roberts[19] likewise notes that trimethylsilyladamantane cannot be synthesised by the Wurtz reaction. The reported synthesis[14] of trimethylsilyladamantane by the Wurtz reaction (in 70% yield) must be regarded as erroneous. The authors of these studies claim that the melting point of their compound is 236 °C, while the true melting point of trimethylsilyladamantane proved to be ~35 °C.[21]

1-Adamantylalkyl(aryl)chlorosilanes can also be obtained from lithioadamantane[14]:



The reaction takes place readily; the main difficulty of the method consists in the multistage synthesis of the initial lithioadamantane, which is ultimately responsible for the very low yields of the desired adamantylalkyl(aryl)chlorosilanes.

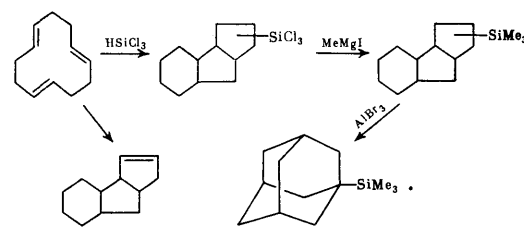
The analogous synthesis via organomagnesium compounds has not so far been used, although the possibility of preparing a Grignard reagent from 1-bromoadamantane (in 60% yield) has been reported[22]. However, the synthesis of a compound of the type AdRHal via organomagnesium compounds has proved possible[23]:



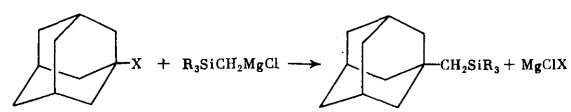
The use of organosodium synthesis has not yet permitted the preparation of trichlorosilyladamantane. This compound has been synthesised[21,24,25] by passing adamantane or chloroadamantane mixed with hexachlorodisilane or perchloropolysilanes through a quartz tube heated to 450–650 °C.

The reaction is carried out at atmospheric pressure and probably proceeds via a carbenoid mechanism, which involves the insertion of the $SiCl_2$ group in the C–Cl bond of chloroadamantane.

Yet another interesting method of synthesising trimethylsilyladamantane, in which the cyclopentadiene dimer and hydrochlorosilanes are used as the starting materials has been outlined recently[26] (Scheme 1).

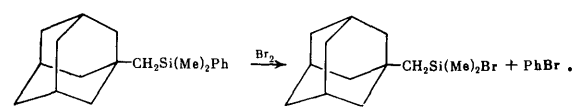


Scheme 1

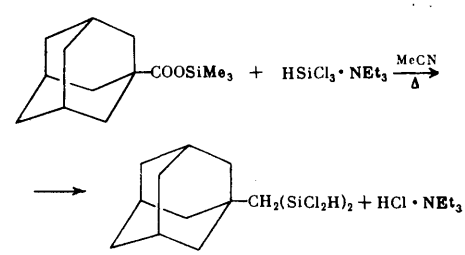


This synthesis has recently been repeated[27], but the trimethylsilyladamantane obtained had a melting point of 236 °C instead of 35 °C.

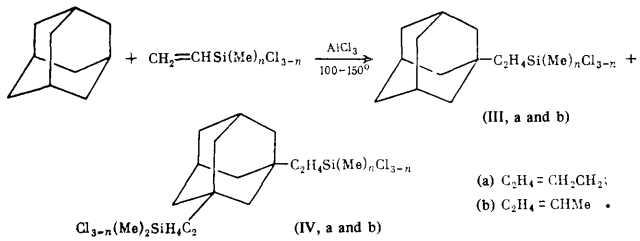
The isomerisation of a three-membered cyclic compound containing a silyl substituent also yielded trimethylsilyladamantane[28] (Scheme 2):



Scheme 2



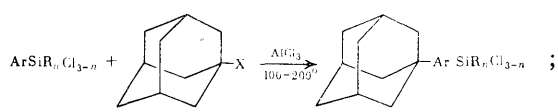
Treatment of chloro- or bromo-adamantane with Grignard reagents obtained from the corresponding α-chloromethylsilanes led to the formation of α-silylmethyladamantanes in good yields (70–80%)[29]:



In the presence of the phenyl group at the silicon atom, there is a possibility of obtaining compounds with halogenosilyl substituents:

The Benkeser reaction has also been used to synthesise α-silylmethyladamantanes, but, after treating adamantanecarboxylic acid or its trimethylsilyl ester with the "trichlorosilane–triethylamine" complex in acetonitrile, the product is 1,1-bis(dichlorosilyl)methyladamantane instead of the postulated 1-trichlorosilylmethyladamantane:

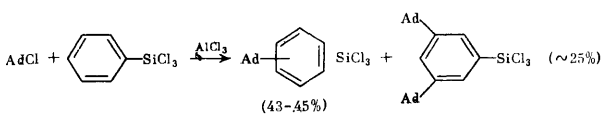
The first representatives of α- and β-silylethyladamantanes have been obtained by the Friedel–Crafts reaction[20,30–32]:



(III, a and b)

(a) $C_2H_4 = CH_2CH_2$;
(b) $C_2H_4 = CHMe$.

(IV, a and b)



This reaction results in the formation of both 1-monosilyialkylated [compound (III)] and 1,3-bis-silylalkylated [compound (IV)] adamantanes. The ratio of compounds (III) and (IV) is determined by the nature of the unsaturated chlorosilane; for example, 70% of compound (III) and 30% of compound (IV) are obtained from vinyltrichlorosilane, while methylvinyldichlorosilane gives 60% of compound (III) and 40% of compound (IV). After methylation of the mixture of isomers (III, a and b), the isomer having the normal structure (IIIa), which is crystalline, can be readily separated from isomer (IIIb) by freezing out. The silyialkylation of adamantane and 1-chloroadamantane proceeds similarly also under γ-irradiation[13]. In the alkylation of adamantane with trimethylvinyl- and dimethylvinylchlorosilanes this method is also more suitable, because in the presence of aluminium chloride the reaction mixture contains a large amount of tar and it is almost impossible to isolate the adamantane alkylation products.

The Friedel–Craft reaction can also take place between halogenoadamantanes and a number of arylchlorosilanes, despite the fact that the view that phenylchlorosilanes cannot be used in this reaction because of the ready "elimination" of the phenyl group under the influence of Lewis acids has been firmly established in the chemistry of organosilicon compounds for a long time[23,26,33–35]:

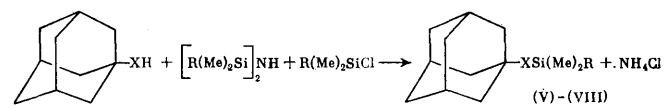
X = H or Cl; Ar = phenyl or thienyl; Ar' = phenylene or thienylene.

The best alkylation catalyst in the synthesis of adamantylthienylchlorosilanes proved to be tin tetrachloride. The highest yields of adamantyl(phenyl)trichlorosilanes[23,33] have been obtained on heating a mixture of 1-chloroadamantane and phenyltrichlorosilanes in the presence of $AlCl_3$ (in proportions of 4 : 13 : 1) for 3 h at 145–180 °C; under these conditions, up to 25% of *m,m*-diadamantylphenyltrichlorosilane is formed:

(43–45%)

1-Bromoadamantane is more reactive in this reaction than 1-chloroadamantane; in the presence of $AlBr_3$ it interacts with phenyltrichlorosilane even at 30 °C, giving rise to a 60% yield of *p,m*-adamantylphenyltrichlorosilanes[23,35,36]. The use of other catalysts ($ZnCl_2$, $SnCl_4$, and $FeCl_3$) did not lead to the desired results; the starting materials did not react or were converted into a tar.

Phenylalkylchlorosilanes of the type $ArR'Si(R)_nCl_{3-n}$ (R' = alkylene) show a greater tendency towards this reaction than phenyltrichlorosilane[36]:

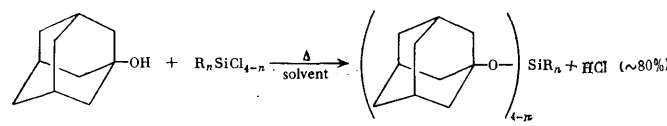


R = Cl or Me; $n = 1, 2$.

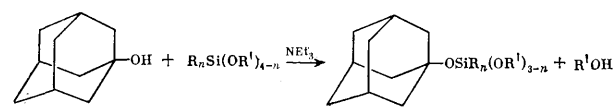
The best catalyst for the introduction of the adamantyl group into benzyltrichlorosilane is $ZnCl_2$, while the use of other catalysts ($AlCl_3$ and $FeCl_3$) leads to the formation of products with more than one adamantyl group[37].

No et al.[38] reported an unusual course of the silylalkylation of the chloride of adamantanecarboxylic acid:

Oxygen- and nitrogen-containing silyladamantanes $AdXSiR_3$ (where X = O or N) were obtained for the first time by Mironov and Fedotov[39] by silylating 1-hydroxyadamantane and adamantanecarboxylic acid on heating them with a mixture of hexamethyldisilazane and trimethylchlorosilane:



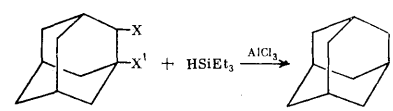
(V)–(VIII)



X = O or COO; R = Me[(V), (VI)] or H[(VII), (VIII)].

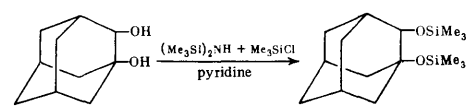
The authors note that hexamethyldisilazane alone does not silylate 1-hydroxyadamantane even on prolonged heating. It was found later[40–44] that 1-hydroxyadamantane is readily silylated by various chloro- and alkoxy-silanes (Scheme 3):

Scheme 3



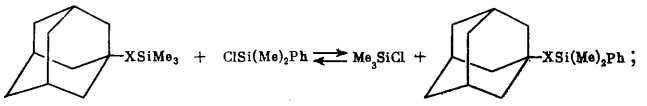
R = CH_2=CH, Ph, or MeO; $n = 0$–3;

R = alkyl, Ph, CH_2 = CH, or $ClCH_2$; R' = alkyl.



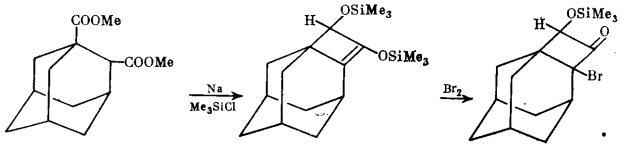
It is of interest that in the presence of Lewis acids triethylsilane reduces 1-bromoadamantane and 2-adamantanol to adamantane[45]:

X^1 = Br, X = H; X = Br, X^1 = H.

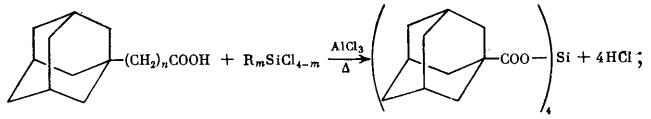


The photoinitiated oxidation of trimethylsilylketen acetal, containing the adamantyl group, to the corresponding peroxyacetate[46] and oxidation of adamantylphenylhydrosilanes with $SnCl_4$ [47] have also been described.

Exhaustive silylation of various dihydroadamantanes proceeds exclusively in pyridine:

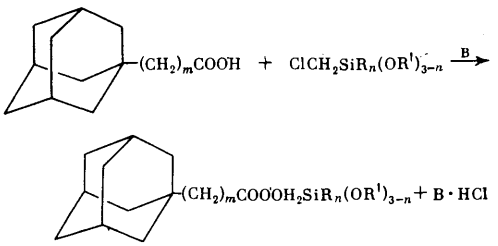


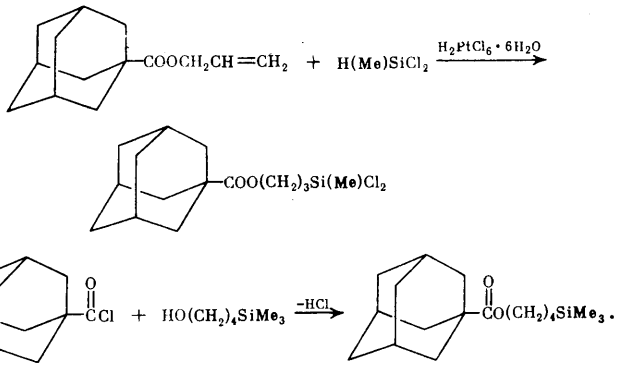
All possible isomers and conformers of bis(trimethylsiloxy)-adamantane were obtained in this way[48] and their NMR spectra were investigated. In addition, it was established that various silyl ethers of 1-hydroxyadamantane and esters of adamantanecarboxylic acid can be readily obtained by the



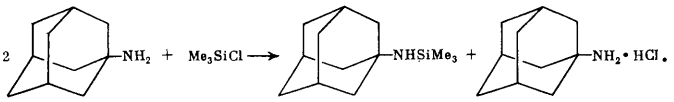
trans-silylation reaction[20,39]:

The silyl ethers of complex alcohols derived from adamantane have been obtained by a modified Ruhlman scheme[49]:



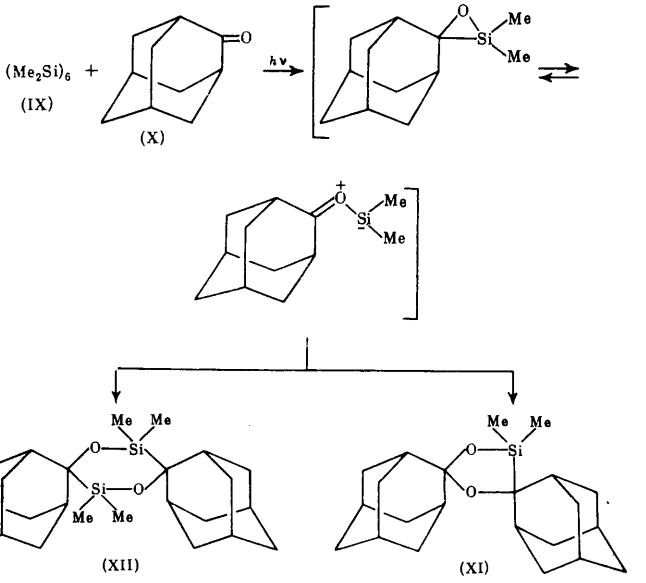


The silyl esters of adamantanecarboxylic acid are readily formed when they interact with chlorosilanes[50,51]:



The methods of synthesis of esters of adamantanecarboxylic acids and organosilicon alcohols are illustrated in Scheme 4 below[39,50-53]:

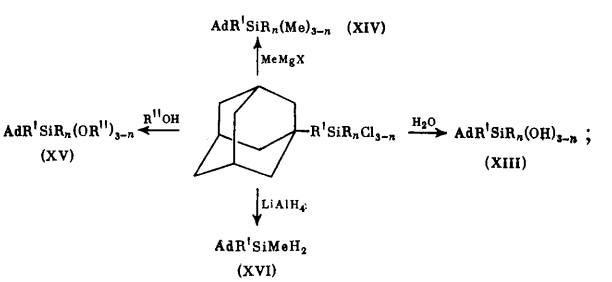
Scheme 4



Like the usual primary amines, 1-aminoadamantane is also readily silylated by trimethylchlorosilane[39]:

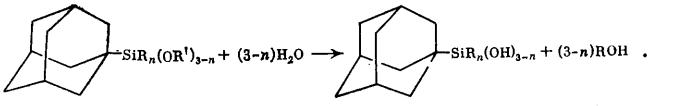
Japanese investigators[54] obtained dioxasilacyclopentanes with adamantyl groups by the reaction of dodecamethylcyclohexasilane and adamantanone in an ethereal medium under irradiation (Scheme 5).

Scheme 5



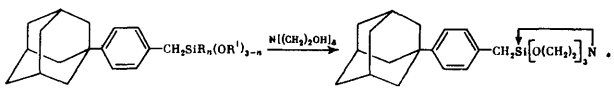
They found[54] that the interaction of compounds (IX) and (X) in the presence of alcohol lead to the formation of $EtOSiMe_2H$ (XI) and 2-ethoxydimethylsilyl-2-adamantanol.

2. Chemical Properties



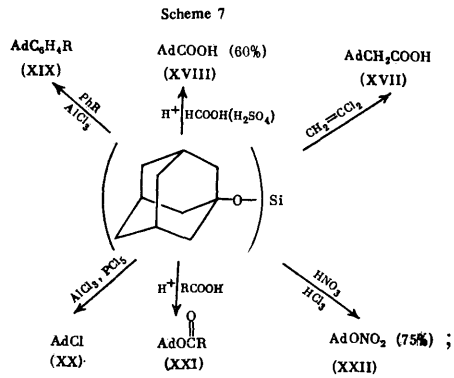
1-Adamantylalkyl(aryl)halogenosilanes are hydrolysed by water and react with alcohols, phenols, and other reagents more slowly than the usual alkyl(aryl)chlorosilanes and form compounds (XIII)[14,15,41,55,56,58], (XIV)[21,23,32,36,58], (XV)[14-16,18,36,37,55-59,61], and (XVI)[29,32,36,58] (Scheme 6).

Scheme 6



R = alkyl or aryl; R′ = alkylene or arylene; n = 0, 1, 2.

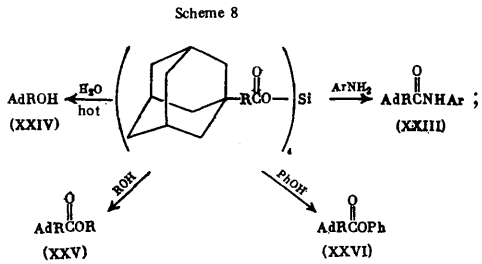
1-Adamantyl(aryl)alkoxysilanes are comparatively resistant to hydrolysis by atmospheric moisture but are readily hydrolysed on heating with dilute alkali in diethyl ether[62]:



It has been shown[37] that they are readily converted into the corresponding silatranes:

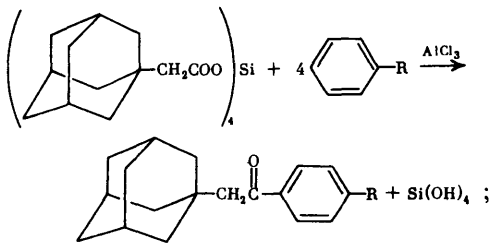
Trimethylsiloxyadamantane is resistant to hydrolysis by cold water but is readily hydrolysed by hot water[39].

The reactions of compounds containing the Ad–O–Si ≡ linkage, particularly tetra-adamantyloxysilane, are illustrated in Scheme 7. A series of adamantane derivatives have been obtained as a result: (XVII)[67], (XVIII)[66–68], (XIX)[40,41,69], (XX)[40,63–65], (XXI)[67], and (XXII)[66]:



Scheme 7

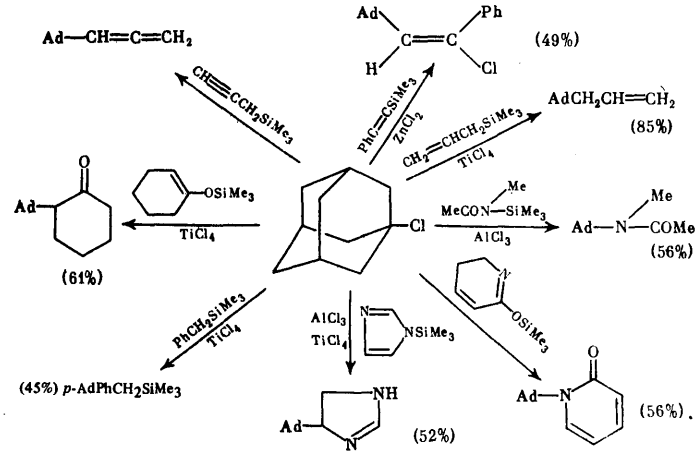
R = Me, Et, $(Me)_2CH$, or MeO.



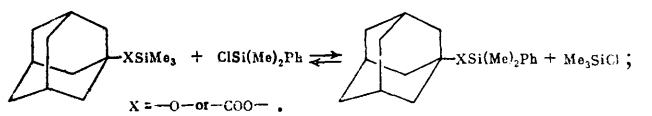
Tetra(1-adamantylcarboxy)silane and tetra(1-adamantylacetoxy)silane have also been investigated in various chemical reactions leading to the corresponding adamantane derivatives: (XXIII)[38,50,51,72], (XXIV)[70,71], (XXV)[70,73], and (XXVI)[73] (Scheme 8):

Scheme 8

Ar = Ph, *o,m*-MeC_6H_4, or $MeOC_6H_4$;
R = Me, Et, n-C_3H_7, n-C_4H_9, iso-C_4H_9, or n-C_5H_{11};
R' = OMe .

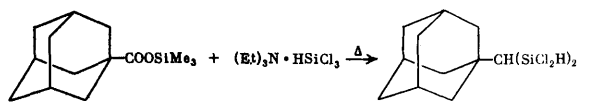


It has been established[42] that tetra(1-adamantylacetoxy)silane is less reactive in reactions with alcohols, 1-adamantanol, and phenol than tetra(1-adamantylcarboxy)silane, but is more reactive in reactions with aromatic amines. Tetra(1-adamantylacetoxy)silane undergoes the Friedel–Crafts reaction with benzene and alkylated aromatic compounds, forming the corresponding 1-adamantyl methyl ketones[42,50]:

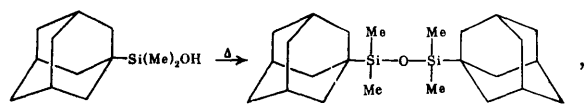


R = Me, Et or $(Me)_2CH$.

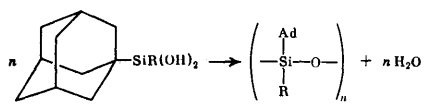
Sasaki et al.[74] achieved the interaction of various organic compounds containing trimethylsilyl groups with chloroadamantane in the presence of Lewis acid catalysts. In this way they obtained a number of organic derivatives of adamantane and in only one case a silicon-containing adamantane derivative—*p*-adamantylbenzyltrimethylsilane (Scheme 9):



Scheme 9

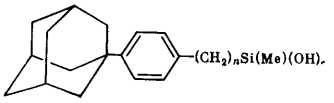


It has been found[39] that, like trimethylsilyl ethers and esters[75], the trimethylsilyl ethers of 1-hydroxyadamantane and the corresponding esters of adamantanecarboxylic acid are capable of undergoing the reversible *trans*-silylation reaction:



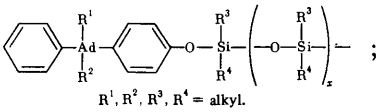
Trimethylsilyl adamantanecarboxylate enters into the Benkeser reaction[24,29]:

The study of the properties of 1-adamantylalkyl(aryl)silanols, obtained by the hydrolysis of the corresponding chloro-, alkoxy-, and acetoxy-derivatives, showed[14] that they are not appreciably dehydrated up to 80–100 °C and are fully dehydrated only at 150–200 °C after 10–15 h. Thus the thermal dehydration of 1-adamantyldimethylsilanol yields the corresponding disiloxane:



while 1-adamantylalkyl(aryl)silanediols give rise to polymers with the adamantyl group at the silicon atoms, whose molecular weights are in the range 5500–9000:

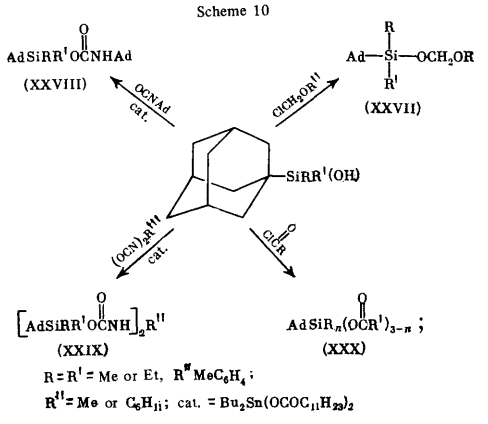
R = alkyl or aryl.



These polysiloxane polymers are resistant to the action of dilute acids and concentrated alkalies at 80–90 °C for 15–20 h.

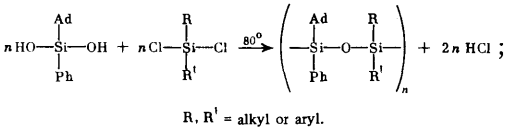
Novikov et al.[76] obtained monomers of the type

where $n = 1$ or 2, which have been used to synthesise polymers with an increased thermal stability.



Polysiloxanes containing adamantyl groups of another type have been obtained recently[77]:

R^1, R^2, R^3, R^4 = alkyl.

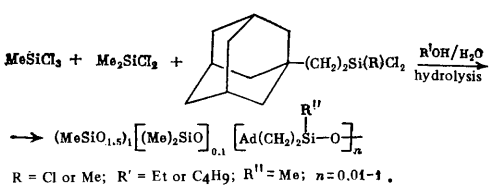


Adamantylsilanols are fairly reactive and react with various reagents, forming the corresponding derivatives: (XXVII)[14,78,79], (XXVIII)[80,81], (XXIX)[82], and (XXX)[83] (Scheme 10):

Scheme 10

R = R' = Me or Et, $R'' = MeC_6H_4$;
R'' = Me or C_6H_{11}; cat. = $Bu_2Sn(OCOC_{11}H_{23})_2$

1-Adamantyl(alkyl)arylsilanols can also undergo the polycondensation reaction with various alkyl(aryl)dichlorosilanes[14,18]:



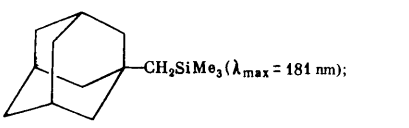
R, R' = alkyl or aryl.

The molecular weights of the polymers thus obtained are 4500–5600, which corresponds to 10–14 elementary units in the chain of the macromolecule.

Cohydrolysis of adamantylalkylhalogenosilanes with the corresponding alkyl(aryl)chlorosilanes made it possible to obtain liquid polysiloxanes—resins with the adamantyl(alkyl)-aryl groups at the silicon atom[84,85] (see, for example, Scheme 11):

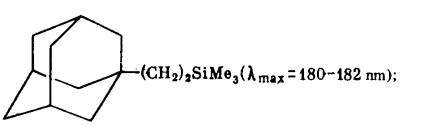
Scheme 11

R = Cl or Me; R' = Et or C_4H_9; R'' = Me; $n = 0.01$–1.



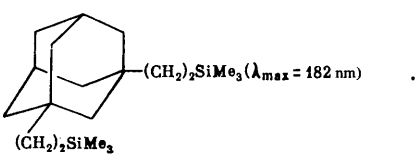
If there are aryl substituents[29] or hydrogen[47,60] in the silyl group of adamantylsilanes, they can be readily substituted by a halogen.

3. Physical Properties



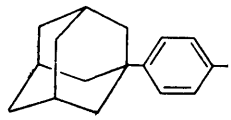
Silyl- and silylalkyl(aryl)adamantanes are as a rule crystalline substances or viscous high-boiling liquids, soluble in the majority of organic solvents. The frequencies of their absorption bands in the infrared spectra are characteristic of both the adamantane structure[86] and of the silyl and siloxane atomic groups linked to it. For example[13], β-(trimethylsilyl)ethyladamantane has a group of bands characteristic of the adamantane structure (970 and 950 cm^{-1}) and also the absorption bands of the Si–H (2120 cm^{-1}) and Si–Me (1800 cm^{-1}) groups.

There are no literature data for the NMR spectra of silyladamantanes, but it is clear that the proton spectra must contain signals due to protons of both the adamantane nucleus and the organosilicon substituents. The ^{13}C NMR spectra, in which it is possible to observe the individual signals of all types of carbon atoms in the molecule, as shown in relation to germyladamantanes[87], contain a particularly large amount of information about the structure. With the aid of ^{13}C NMR, it is possible to determine the position of the silicon-containing substituent in the adamantane skeleton. A satisfactory correlation between the chemical shifts of the ^{13}C NMR signal of the carbon atoms in the adamantane system and the inductive constants of the substituents has been established for substituted adamantanes[88]. The study of ^{29}Si and ^{13}C NMR spectra of mono- and bis-(trimethylsilyl)adamantanols[45] established that the chemical shifts of the ^{29}Si signals of 1- and 2-adamantyl derivatives occur in different regions, the position of the chemical shift being sensitive to steric interactions. This makes it possible to employ the ^{29}Si and ^{13}C NMR methods to establish the structure of any adamantyl derivative after first converting it into the corresponding trimethylsilyl derivative.

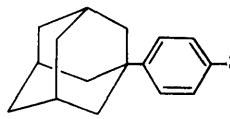


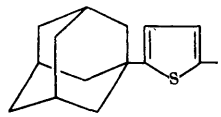
Interesting results have been obtained[89] in the study of the adsorption spectra of both adamantane itself and of silylalkyl(aryl)adamantanes in the far ultraviolet (175–200 nm). It has been established that adamantane has an intense absorption band at 180 nm. Silicon-containing substituents exert a definite influence on the main absorption band: the introduction of trimethylsilylalkylene groups causes a slight shift of the absorption band in the spectra of both mono- and di-substituted adamantanes:

CH_2SiMe_3 (λ_{max} = 181 nm);



$(CH_2)_2SiMe_3$ (λ_{max} = 180–182 nm);





$(CH_2)_2SiMe_3$ (λ_{max} = 182 nm)

$(CH_2)_2SiMe_3$

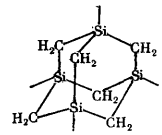
The introduction of trimethylsilylarylene groups is accompanied by a bathochromic shift.

$SiMe_3(\lambda_{max} = 196$ nm);

$SiCl_3(\lambda_{max} = 197$ nm);

$SiMe_3(\lambda_{max} = 190$ nm)

A mass-spectrometric study[32], carried out in order to determine the isomeric composition of the products of the silylalkylation of adamantane by alkenylchlorosilanes, showed that there is virtually no peak of the $(M-HR)^+$ ion in the mass spectra of all the compounds investigated, while the intensity of the peak of the $(M-R)^+$ ion is high. It is known that 1-substituted adamantanes (Ad–R) typically lose the substituent R in the form of a free radical[90,91], while 2-substituted adamantanes eliminate the MR molecule from the molecular ion[92]. Thus the substituents in all the compounds investigated were either in the 1-position or in the 1- and 3-positions. The spectra of all the mono-substituted adamantanes show the peak of the molecular ion, whose relative intensity increases with increase of the number of methyl groups attached to the silicon atom. The loss of the second substituent from the $(M-R)^+$ ion with migration of the hydrogen atom to the charged fragment, which leads to the formation of the adamantyl cation with *m/e* 135, is characteristic of all substituted adamantanes[32].

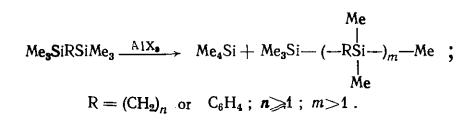


4. The Applications of Silyl- and Silylalkyl(Aryl)-Adamantanes

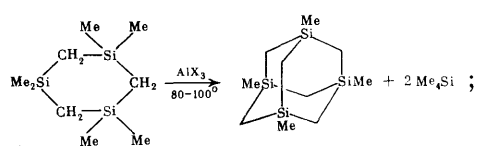
Silyl- and silylalkyl(aryl)-adamantanes have been synthesised quite recently. The study of their properties as well as the properties of polymers obtained on their bases has been initiated. Nevertheless, in view of the specificity of the properties which polysiloxane polymers acquire after the introduction of adamantyl or adamantylalkyl(aryl)groups, they are already of definite interest as substances with effective stabilities in relation to heat, light, and radiation[84,93].

III. SILA-ADAMANTANES

1. Carborundanes



Carborundanes or 1,3,5,7-tetrasila-adamantanes constitute a new class of organosilicon compounds, which have been relatively little investigated and which have extremely unusual physical and chemical properties. The molecular skeleton of tetrasila-adamantane can be regarded as the unit cell of silicon carbide–carborundum (hence the name carborundane), the rigid crystal lattice of which is free from angular and conformational strains, like the diamond lattice:



Like diamond, carborundum has exceptional chemical, thermal, and mechanical stabilities. The new class of carborundanes could not therefore fail to interest chemists working in the field of the chemistry of Group IV elements. It might have been expected, in particular, that tetrasila-adamantanes would prove to be extremely promising for the modification of siloxane polymers and for the creation of new thermally and chemically stable materials. At the beginning of 1970 there were only six papers in the literature on the synthesis and properties of carborundanes, while at the beginning of 1980 there were already about 70 original publications and six reviews[11,12,94–97]. However, one should note that the review of Frye and Klosowski[96] is very short and incomplete (the bibliography contains only 11 references), while other reviews are devoted to broader topics—heteroadamantanes[11,12,97] and carbosilanes[94,95], while the information about carborundanes is scanty and non-systematic.

(a) Methods of Synthesis of Carborundanes

There are two methods of synthesising carborundanes. They both consist in a far-reaching degradation of various methylsilanes and silcarbanes (i.e. compounds containing the $\rangle SiCH_2Si\langle$ fragment) under the influence of aluminium halides or on thermolysis. The first method is in fact a development of the reaction of Vdovin[98–100], who discovered the following new reaction in a study of the action of aluminium halides on a wide variety of bridged compounds†:

$Me_3SiRSiMe_3 \xrightarrow{AlX_3} Me_4Si + Me_3Si-(-RSi(Me)-)_m-Me$;
$R = (CH_2)_n$ or C_6H_4 ; $n \geqslant 1$; $m > 1$.

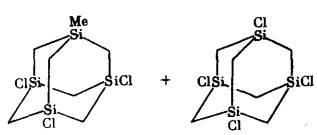
However, the amounts of aluminium halides used in the reaction was so small that it stopped at the stage involving the formation of the silmethylene oligomer[100]. Later Frye and Weyenberg[103] achieved a more far-reaching transformation of various silmethylene compounds into sila-adamantanes under the influence of increased amounts to aluminium halides (20–200% of the weight of the initial compound), for example:

X = Cl or Br.

† This reaction was found subsequently to be fairly general and to occur even when R is oxygen or nitrogen[101]. Furthermore, the reaction is fully characteristic also of the series of analogous organogermanium compounds[102].

Under the reaction conditions, some of the methyl groups at the silicon atom are substituted by the halogen X under the influence of AlX_3, so that Me_3CbX and Me_2CbX_2 are formed together with Me_4Cb. The overall yield of sila-adamantanes for X = Br was 27%.[103] Apart from the six-membered ring, $(Me_2SiCH_2)_n$, where n varies from 2 to 50, $(Me_2XSi)_2CH_2$ (X = Cl or Br), and $Me_3SiCH_2SiMe_3$ have been proposed for the synthesis of carborundanes[104]. The syntheses of sila-adamantanes from $(Me_2SiCH_2)_3$ and $AlBr_3$ (yield 27%), $(Me_2SiCH_2)_2$ and $AlCl_3$, $Me_3SiCH_2SiMe_3$ and $AlCl_3$, and $(Me_2SiCH_2)_n$ and $AlBr_3$ ($n = 4-50$) have been described as specific examples[104]. Furthermore, a mixture of $CbCl_4$ and $MeCbCl_3$ has been obtained from $(Me_2ClSi)_2CH_2$ and $AlCl_3$. The above communications[103,104] contain no data on the properties of the individual sila-adamantanes obtained (yields, melting points, etc.). Frye and Weyenberg apparently did not isolate and purify the substances synthesised. They merely state that the mixtures of sila-adamantanes can be separated by fractional sublimation or adsorption chromatography[104].

Frye's method was developed by other investigators. Thus Fritz and Kreilein[105] showed that, when the heterocycle $(Me_2SiCH_2)_3$ is heated with $AlBr_3$ at 80 °C for 24 h, 18% of Me_4Cb and 1.5% of Me_3CbBr is formed, but, on increasing the reaction time to 72 h and the temperature to 100 °C, the overall yield of desired products falls to 9.5%. Vdovin and coworkers[106] studied the rearrangement of tetramethyldisilacyclobutane under the influence of aluminium halides in greater detail than in Frye's study. They note that Me_4Cb is not formed on treatment with an equimolar amount of $AlCl_3$ at 20 °C; this requires more severe conditions ($AlBr_3$, 70 °C):



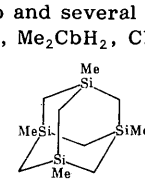
$$(Me_2SiCH_2)_2 \xrightarrow{AlBr_3} Me_4Cb + Me_3SiCH_2SiMe_3 + Me_4Si + \text{oligomers}$$

The yield of Me_4Cb is ~5% on the basis of data quoted by Vdovin and coworkers[106].

The catalytic rearrangements of disilylmethylene compounds $(Me_2SiCH_2)_n$ ($n = 2-11$) have also been studied by Mironov et al.[107]. They established that tetrasila-adamantanes can be obtained from a mixture of oligomers ($n \cong 11$) in a yield not exceeding 4%. The mixture of oligomers is readily formed when $ClCH_2SiMe_2Cl$ is treated with sodium[108] or magnesium[109].

If silmethylene compounds with Si–Cl bonds are used for the synthesis, the reaction with aluminium chloride must be carried out under more severe conditions. For example, the interaction of $(ClMe_2SiCH_2)_2SiCl_2$ with aluminium chloride begins only at 200 °C. The low-boiling products of the rearrangement consist of trimethylchlorosilane and dimethyldichlorosilane (1:2), but the yield of the tetrasila-adamantanes isolated after the reaction is only ~0.3%:

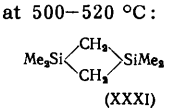
$$(ClMe_2SiCH_2)_2SiCl_2 \xrightarrow[200-215^\circ]{AlCl_3}$$



Analogous results are obtained also when the above reaction is carried out in a flow system in the gas phase. The initial chloride together with hydrogen chloride was passed over aluminium filings at 500–600 °C. The yield of sila-adamantanes was ~1% relative to the chloromethylsilane consumed[107]. It was shown experimentally that one of the causes of the low yield of products is the decomposition of the molecular skeleton of methylchlorosila-adamantanes under the influence of aluminium chloride under severe conditions.

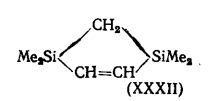
Lower methylchlorosilanes can also be used as starting materials for the synthesis of chlorocarborundanes. It is known, for example, that the first representative of the class of 1,3,5,7-tetrasila-adamantanes was obtained by Smith and Clark in 1961[110] as a result of an accidental overheating to 500 °C of an autoclave containing a mixture of trimethylchlorosilane, silicon tetrachloride, and aluminium chloride. Together with six- and eight-membered silmethylene rings, tetrachlorocarborundane ($CbCl_4$) was isolated in 0.1% yield. The substance was not obtained in an analytically pure form, but it was readily characterised with the aid of infrared and ^1H NMR spectra and by determining the molecular weight.

Much later Klosowski and Barry[111] took out a patent for a method of synthesis of sila-adamantanes which is extremely similar to that of Smith and Clark. These compounds are obtained from methylhalogenosilanes Me_nSiX_{4-n} (X = Cl or Br; $n = 1-4$) at 350–450 °C and a pressure of 70–176 atm. The catalyst consists of a mixture of aluminium halide (2.5–15%), silicon, and (or) aluminium (2.5–50% of the weight of the reagents) in order to bind the acid (probably HCl). In the examples described a mixture of Me_2CbCl_2 and $MeCbCl_3$ was obtained from Me_3SiCl, while Me_2SiCl_2 gave mainly $CbCl_4$. The overall yields (according to our calculations based on the data in the patent) are ~13–18%.



Thus Frye's method gives the best results for low-molecular-weight fully methylated silmethylene compounds, which happen to be the least available silcarbanes. Silmethylene compounds with $SiCl_2$ or $SiCl_3$ groups, which are readily obtained by direct synthesis from chloromethylsilanes $ClCH_2SiRR'R''$, are apparently relatively unsuitable for the synthesis of sila-adamantanes. On the other hand, the lowest methylchlorosilanes are converted into carborundanes only under very severe conditions and with low yields.

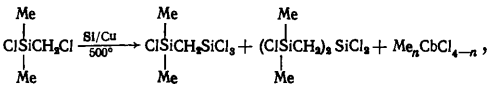
There is also another method of synthesis of tetrasila-adamantanes—the pyrolytic method. Thus the tetramethyl derivative Me_4Cb was first detected[112] in the products of the pyrolysis of tetramethylsilane at 700 °C. In subsequent years Fritz and coworkers carried out a laborious and troublesome separation of the very complex mixtures formed in the pyrolysis of Me_4Si,[113-115] $MeSiCl_3$,[116] and Me_3SiCl.[117] The authors published several large monographs and three reviews which describe in detail the methods used to separate and identify the pyrolysis products[94,95,118-121]. It is stated that the most suitable method of fractionating sila-adamantane mixtures is adsorption chromatography[104,113]. The study of the pyrolysis of tetramethylsilane led to the following results: the low-molecular-weight fraction of the reaction mixture consisted of 39 substances containing from one to three silicon atoms in the molecule and also of 12% of Me_4Cb relative to the pyrolysis reaction mixture, which corresponds to a yield of 3%.[115] In the high-molecular-weight fraction (Si_4-Si_8) it was possible to identify[118] ~60% of the compounds, among which Me_4Cb and several of its analogues are again present, i.e. Me_3CbH, Me_2CbH_2, $CbCH_2SiMe_2H$, $CbCH_2SiMe_3$, $CbCH=CH_2$, and



The remaining compounds are complex polycyclic systems of the sila-adamantane types which are described below.

Fritz and Götz[115] established that Me_4Cb is formed in the pyrolysis not only of tetramethylsilane but also of other compounds, for example the heterocycles (XXXI) at 480 °C and (XXXII) at 500–520 °C:

(XXXI)



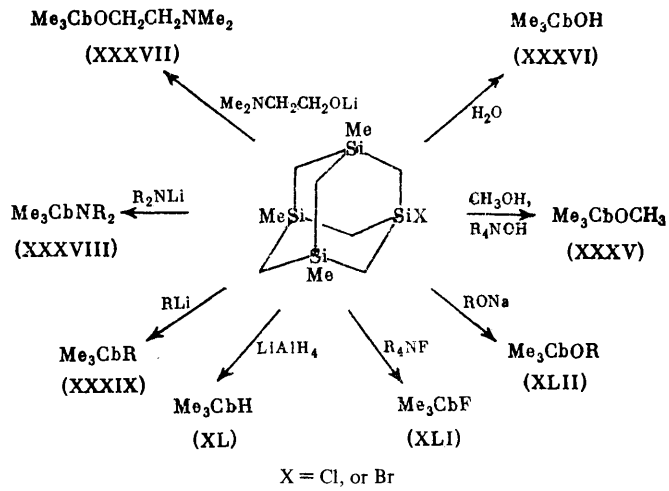
(XXXII)

According to the authors, Me_4Cb is formed via a multistage radical mechanism[115].

The pyrolysis of trimethylchlorosilane leads to a mixture of all four possible chlorosila-adamantanes: $CbCl_4$, $MeCbCl_3$, Me_2CbCl_2, and Me_3CbCl in the proportions 170 : 16 : 3 : 1.[117] The substances were characterised with the aid of ^1H NMR and mass spectrometry.

Finally yet another method of synthesising sila-adamantanes has been discovered recently. In the course of direct syntheses of silcarbanes from α-chloromethylsilanes, for example (chloromethyl)dimethylchlorosilane[122]

it was established that higher-boiling compounds as well as a non-distillable polymeric residue are always formed together with the products indicated. If the initial silane is passed over a mixture of silicon and copper powders at 500 °C, a crystalline deposit, consisting of Me_3CbCl, Me_2CbCl_2, and $MeCbCl_3$, with the dichloride predominating, is precipitated from the still residues. The overall yield of sila-adamantane is ~0.3% relative to the chloromethylsilane passed over the catalyst[107].



(b) Chemical Properties of Carborundanes

1,3,5,7-Tetrasila-adamantanes have continuously attracted the attention of investigators concerned with problems of the stereochemistry and mechanisms of the reactions involving the silicon atom as the reaction centre. The carborundane molecules incorporate four silicon atoms located in bridgehead positions. The system is rigid and free from angular and conformational strains. According to Sommer[123], such structures should be extremely inert in nucleophilic substitution reactions, because the mechanism involving an inversion of configuration cannot occur and that with retention of configuration is hindered by the rigidity of the cyclic system.

The first results of the study of the reactivity of carborundanes seemingly confirmed this hypothesis. Smith and Clark[110] noted the unusual resistance of $CbCl_4$ to the action of water and methylmagnesium chloride. The monohalides Me_3CbX also proved to be resistant to hydrolysis[124]. The reaction of Me_3CbBr with aqueous acetone takes place over a period of 9 days and the monochloride Me_3CbCl is hydrolysed only by alkali. The bromide is reduced with difficulty by lithium tetrahydroaluminate and the analogous reaction with the chloride takes place to an extent of only 10%.[124] It was found that $MeCbCl_3$ and $CbCl_4$ are only partially reduced by the $LiH–LiAlH_4$ mixture[117], while the mono-and di-chlorides do not react at all. However, it has been established that Me_3CbCl reacts with lithium derivatives of dialkylamines and dimethylaminoethanol. One should note particularly the fact that the derivatives obtained, containing the Si–N or Si–O bond in their molecule, which are usually hydrolytically unstable, in the present case were not hydrolysed even with hydrochloric acid[124].

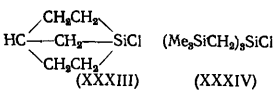
The publication of the above studies was soon followed by the appearance of the paper of Homer and Sommer[125], who claimed that their results are in sharp conflict with the established view that the reactivity of the sila-adamantane system in relation to nucleophiles is reduced. Indeed, they obtained Me_3CbOMe and Me_3CbF in high yields (86–90%) (see Scheme 12).

Scheme 12

$Me_3CbCl \xrightarrow{LiH/LiAlH_4}$ does not react (Ref.117),

$Me_2CbCl_2 \xrightarrow{LiH/LiAlH_4}$ does not react (Ref.117),

$MeCbCl_3 \xrightarrow{LiH/LiAlH_4} MeCbCl_2H + MeCbH_3$[117],

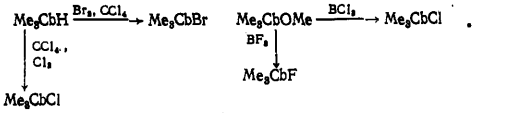


$CbCl_4 \xrightarrow{LiH/LiAlH_4} CbCl_3H + CbH_4$[117],

$Me_3CbOCH_3 + (iso\text{-}C_4H_9)_2AlH \longrightarrow Me_3CbH$[125, 127],

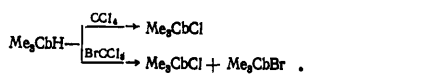
$Me_2CbCl_2 + CH_3ONa \longrightarrow Me_2Cb(OCH_3)_2$[127],

$CbBr_4 + Me_3SiCH_2Li \longrightarrow (Me_3SiCH_2)_4Cb$[105].



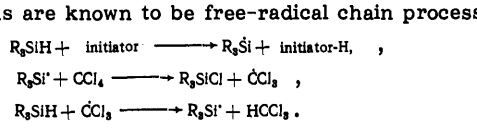
The alkylation of Me_3CbX with phenyl- and methyl-lithium was also found to be possible, although in the latter case the presence of tetramethylethylenediamine, which activates methyl-lithium, was necessary. Furthermore, Me_3CbOMe is readily reduced by di-isobutylaluminium hydride in ether, while its acyclic analogue $(Me_3SiCH_2)_3$–SiOMe reacted 100 times more slowly[125]. It is noteworthy that all these reactions with nucleophiles has been studied earlier by Sommer and coworkers in relation to acyclic optically active silicon compounds. The results of the study of the stereochemistry and mechanisms of these reactions are surveyed in a book[123] and in a review[126]. The use of data accumulated in this field enabled Homer and Sommer[125] to put forward certain hypotheses concerning the mechanism of the interaction of sila-adamantanes with nucleophiles. Subsequently these reactions were studied more thoroughly by the authors; the reactivity of the sila-adamantane system was compared with those of two model compounds (XXXIII) and (XXXIV)[127]:

The authors concluded that their results are best explained by the interaction of Me_3CbX with the nucleophiles investigated in terms of the S_N2–Si mechanism, which postulates a considerable involvement of the *d* orbitals of silicon and operates with retention of configuration. On the other hand, the reduction of Me_3CbOCH_3 by di-isobutylaluminium hydride probably proceeds via the S_Ni–Si mechanism involving a four-centre transition state[127]. All the reactions involving the nucleophilic substitution of tetrasila-adamantanes known



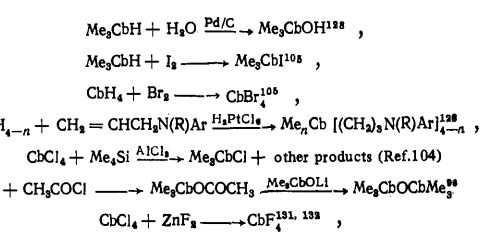
at present are surveyed in Scheme 12: (XXXVI), (XXXVII),[124] (XXXVIII),[124,128] (XXXV),[125,127] (XXXIX),[105,125,127] (XL),[124,127] and (XLI)–(XLII).[125,127]

Homer and Sommer established[129] that tetrasila-adamantanes react fairly vigorously also with certain electrophiles. For example, the halogenation of Me_3CbH takes place rapidly in the cold in scattered light, while the interaction of the methoxy-derivative with BCl_3 takes place instantaneously:



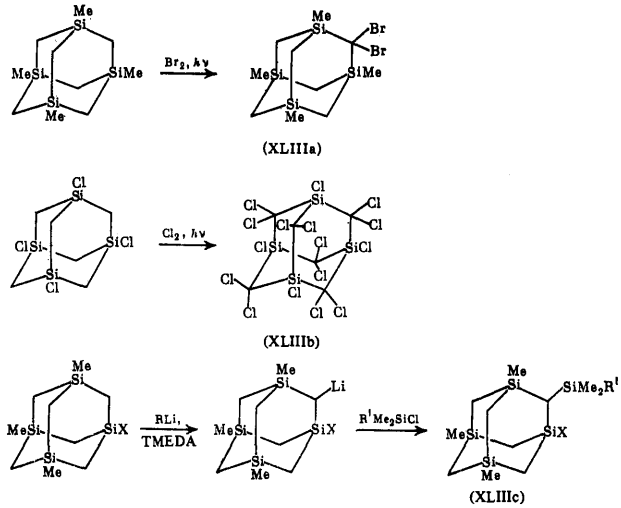
It had been shown earlier[123] that the analogous reactions with acyclic organosilicon compounds take place with retention of configuration. Evidently this type of process is not interfered with by the specific geometry of the sila-adamantane system. The interaction of Me_3CbOMe with BF_3, which goes to completion in six days, contrasts sharply with the halogenation of this sila-adamantane by boron trichloride[129]. According to Sommer's data[123], the analogous reaction of acyclic alkoxysilanes is accompanied by the inversion of configuration. This mechanism is impossible for the sila-adamantane system, so that the reaction with BF_3 proceeds, according to the hypothesis of Homer and Sommer[129], via some other pathway, least favourable as regards the nature of the reagent.

Homer and Sommer established[130] that the rigid geometry of sila-adamantanes does not hinder the formation and reactions of radicals produced from Me_3CbH under the influence of benzoyl peroxide:



Such reactions are known to be free-radical chain processes:

It has been found[130] that the compound $(Me_3SiCH_2)_3SiH$, which is an acyclic analogue of Me_3CbH, reacts much more slowly with CCl_4; consequently the radical $Me_3Cb^{\cdot}$ is formed faster than $(Me_3SiCH_2)_3Si^{\cdot}$. The selectivity of the radical $Me_3Cb^{\cdot}$ in the elimination of a halogen atom from $BrCCl_3$ proved to be approximately the same as that of other silyl radicals (this has been inferred in relation to the Me_3CbCl and Me_3CbBr formed)[130].



In conclusion certain other reactions of carborundanes may be mentioned:

In contrast to the fluorination of Me_3CbX by quaternary ammonium salts (Scheme 12), the reactions with ZnF_2 have been carried out under more severe conditions (in the absence of solvents at 100–160 °C).

Recently Fritz and coworkers[105,131] discovered a new property of carborundanes—the ability to be halogenated and metallated at the ring carbon atom [Scheme 13; (XLIIIa),[105] (XLIIIb),[131] (XLIIIc)[105]].

Scheme 13

X = Me or halogen; R = n-C_4H_9 or CH_2SiMe_3; R′ = Me or Ph; TMEDA = $Me_2NCH_2CH_2NMe_2$.

A further two trimethylsilyl groups were introduced in succession into the last compound (XLIIIb, R′ = Me) with the aid of butyl-lithium[105].

Thus the geometry of the relatively rigid ground state of the tetrasila-adamantane system does not prevent the reactions with radical reagents and the majority of nucleophiles and electrophiles and permits the synthesis of various derivatives of tetrasila-adamantanes. The chemical properties of sila-adamantanes are discussed by Frye's review[96], which summarises mainly the results of his own studies and those of his coworkers. However, attention is concentrated[96] on the mechanism of the rearrangement of silmethylene compounds to tetrasila-adamantanes under the influence of AlX_3 and also on the problem of "oxasila-adamantane" (see below).

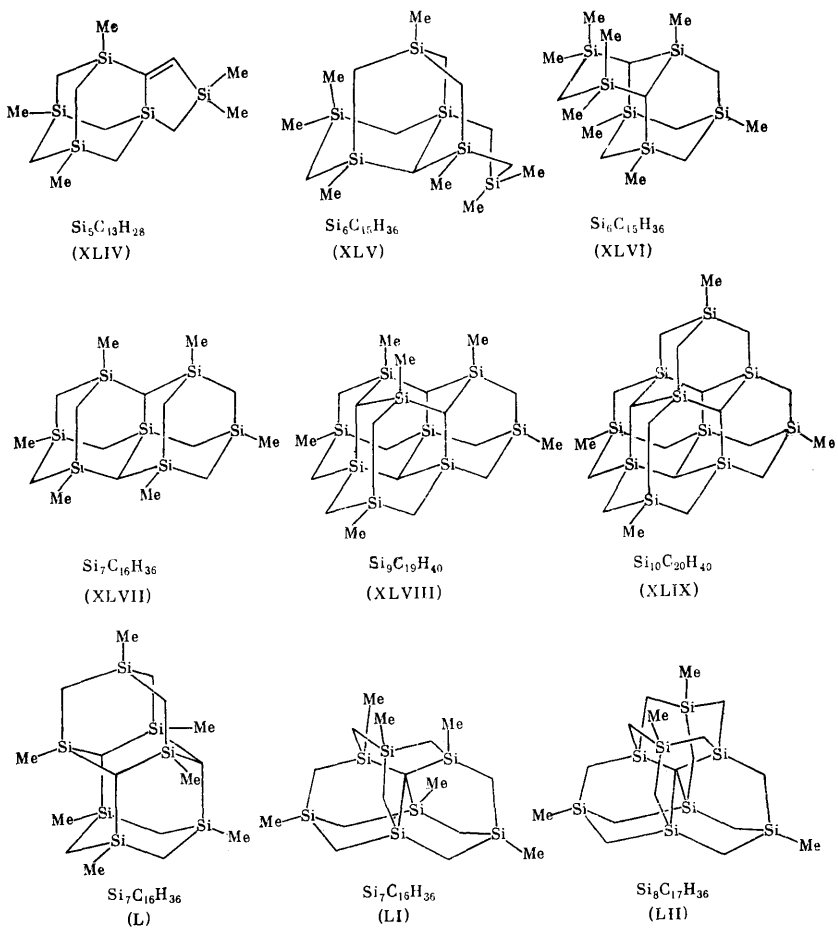
(c) Physical Properties of Carborundanes

1,3,5,7-Tetramethyl-1,3,5,7-tetrasila-adamantane and its halogeno-derivatives Me_nCbX_{4-n} are colourless crystalline readily sublimed compounds with a sharp smell. Despite their high molecular weights and frequently very high melting points, the majority of sila-adamantanes can be analysed by gas–liquid chromatography. Fritz[121] also notes the high thermal stability of Me_4Cb: at 520–540 °C this substance remains unaltered for 37 h.

Various physicochemical methods have been used to investigate the catalytic characteristics of the structure of sila-adamantanes. It has been shown by X-ray diffraction of Me_4Cb [133] that the average length of the Si–C bond in the $Si-CH_3$ and $Si-CH_2$ groups is respectively 1.889 and 1.866 Å, which is within the usual limits for the silicon–carbon bond in organic compounds of silicon. An analogous study of Me_3CbBr [134,135] led to the following results: the Si–C bond lengths are 1.84–1.90 ± 0.02 Å and the Si–Br bond length is 2.15 ± 0.01 Å. A quantum-chemical calculation of the geometrical parameters of the Me_4Cb molecule has been carried out[136].

The photoelectron spectra of the compounds CbX_4 (X = Me, H, F, or Cl) have been investigated[137,138] and it was found that the sila-adamantane molecules, like those of adamantane and urotropine, are not entirely free from strain, which is

due to the transannular SiC–SiC– and CH_2–CH_2-interactions. However, such interactions are 2–3 times weaker than in adamantane owing to the greater length of the Si–C bond compared with C–C. The changes in the spectra of the series of organosilicon compounds are induced by the inductive effect of the substituent. No influence of the $p\pi - d\pi$ interaction on the photoelectron spectra of sila-adamantanes has been observed.



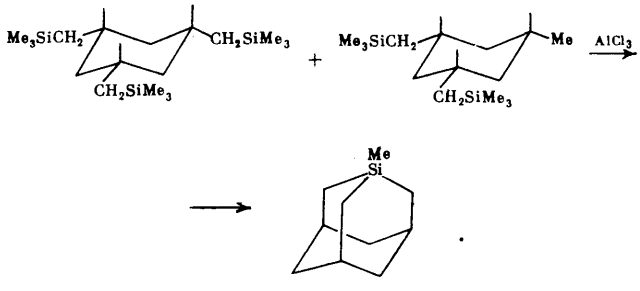
The infrared[110,124,127], ^{1}H NMR [103,105,110,115,118,124,127,131,132,139], and mass spectra[103,105,117,124,127,131] have been studied mainly in order to identify the compounds obtained. However, there has been one investigation specially devoted to the vibrational spectra of 1,3,5,7-tetramethyl-1,3,5,7-tetrasila-adamantane[140], whose author assigned the observed bands to the types of vibrations and carried out a number of calculations. The force constants obtained were compared with data for other organosilicon compounds.

The mass spectrum of $CbCl_4$, showing the presence of an intense $(M-15)^+$ peak, has been studied in greatest detail[141]. The authors noted that the appearance of this ion is probably associated with complex rearrangements of the skeleton requiring the dissociation of not less than three bonds.

Interesting results have been obtained in the determination of the basicity of Me_3CbNEt_2 in an aqueous medium and on comparing it with the basicities of other organic amines[142]. In view of the hydrolytic stability of the Si–N bond in the silylamine investigated, it was possible to achieve this for the first time. It was found that the basicity of the silylamine Me_3CbNEt_2 is much lower than those of triethyleneamine and 1-aminoadamantane. The authors[142] note that such decrease of the basicity of silylamines compared with their organic analogues is usually accounted for by the $d\pi - p\pi$ bonding in the ground state of the former, although one cannot rule out the possibility of the phenomenon, formulated by Pauling, as the neighbouring charge rule. It was shown in the above study that there is no appreciable 1,3-$(d-d)$ interaction in the molecules of sila-adamantanes in the excited state, the possibility of which for compounds with the Si–CH_2–Si group had been postulated earlier. This is confirmed by the results of a study of the ultraviolet spectra of $PhCbMe_3$ and Ph_2.$CbMe_2$; both phenyl groups in the latter compound proved to be electronically isolated, which indicates the absence of 1,3-$(d-d)$ interaction in this sila-adamantane nucleus[142].

(d) Applications of Carborundanes

Patents[104,111] recommend that Me_nCbX_{4-n} mixtures be used as mosquito repellents. It has been suggested that nitrogen-containing tetrasila-adamantanes be employed as emulsifying additives[128].



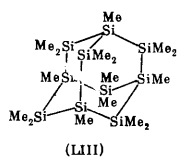
Compounds (XLIV)–(XLVII) and **(L)–(LII) according to the** data of Fritz and Marquardt[118] and compounds (XLVIII) and (XLIX) **according to the data of Fritz et al.**[113].

2. Higher Homologues of Carborundane

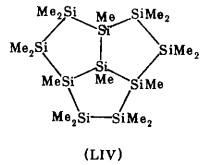
A number of higher homologues of Me_4Cb were obtained for the first time by Fritz from the pyrolysis products of tetramethylsilane[113,114,118]. Depending on the details of the steric structure, the authors separated these substances into two classes—"carborundanes" and "silascaphanes". Fritz used the latter name to designate polycyclic compounds belonging to a previously unknown class containing, together with the six-membered rings in the "chair" form, one or more rings in the "boat" form#[143]. Among the group of compounds (XLIV)–(XLIX) of the first type (see Figure), compound (XLVII), whose melting point and the relevant mass-spectrometric data[113,114] have been published and whose ^1H NMR [114] and photoelectron[138] spectra have been studied in detail, has been characterised most fully. The silascaphanes (L)–(LII) have been characterised in terms of the melting points, ^1H NMR data, and mass spectra[143]. Compound (LII) has been studied by X-ray diffraction[144].

3. Other Classes of Sila-Adamantanes

A compound with a single silicon atom in the adamantane nucleus has been synthesised recently[145]:



The structure of 1-methyl-1-sila-adamantane has been established by electron diffraction in the gas phase[146].

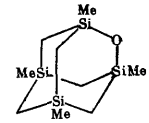


The class of sila-adamantanes includes also a group of adamantane-like compounds whose skeleton consists either of silicon atoms or of silicon and other atoms (for example, oxygen, sulphur, selenium, or phosphorus atoms). The compound $Si_{10}Me_{16}$ is of interest as a possible structural analogue of the adamantane whose skeleton consists of silicon atoms. It has been synthesised[147,148], together with other bicyclic and cellular compounds, by the reaction

$$Me_2SiCl_2 + MeSiCl_3 + Na/K \xrightarrow[C_{16}H_{34}]{THF} (MeSi)_n(Me_2Si)_m + Na(K)Cl$$

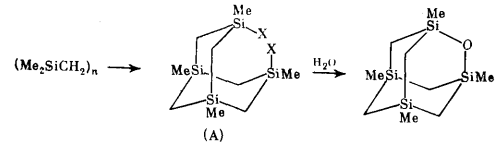
Mass-spectrometric, NMR, and infrared spectroscopic data established that the compound consists of a mixture of two postulated structural forms (LIII) and (LIV) in proportions of 3:1; the melting point of the mixture is above 360 °C.

(LIII)



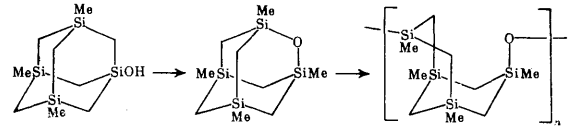
(LIV)

According to original papers, all the rings are in the boat form in silascaphanes.



However, a final conclusion concerning the structure of $Si_{10}Me_{16}$ will be possible only after careful studies and X-ray diffraction analysis.

Sila-adamantanes in which one or several carbon atoms have been substituted by oxygen, sulphur, selenium, and phosphorus atoms have now been obtained. One such compound, 1,3,5,7-tetrasila-8-oxa-adamantane (LV), has been isolated by Fritz and coworkers[112,118] from the pyrolysis products of tetramethylsilane and characterised in terms of its mass and ^1H NMR spectra.

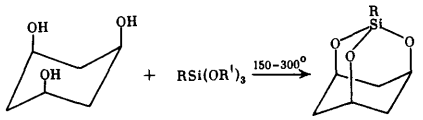


(LV)

The same compound as well as its chloro- and bromo-derivatives have been synthesised by Klosowski[149], who used Frye's method for this purpose[104]—the catalytic rearrangement of silmethylene derivatives of the type $(Me_2SiCH_2)_n (n \geq 2)$ and $(Me_2XSi)_2CH_2$ (X = Cl, Br, or Me) in the presence of aluminium halides. In his paper[149] and also in Frye's review[96] it is stated that in certain cases (these are not specified) the reaction mixture contains after rearrangement a side product having a postulated structure A, which leads to oxasila-adamantanes after hydrolysis:

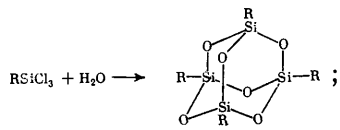
(A)

According to Frye and Klosowski[96], oxasila-adamantanes can be formed in certain cases also as a result of the rearrangement of Me_3CbOH:



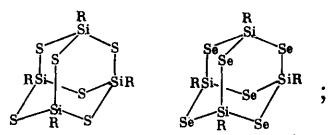
Their attempts[96] to obtain the silanol Me_3CbOH by heating $Me_3CbOCH_2CH_2NEt_2HCl$ in a highly acid medium led to a polymeric product, which may be formed as a result of the above reactions[96].

Klosowski[149] claims that the content of oxatetrasila-adamantanes in the mixture can be increased by carrying out the reaction in the presence of halogenating agents of the type of MeCOX (X = Cl, or Br) and Me_nSiX_{4-n} (X = Cl or Br, n = 1–3). It is suggested that these additives increase the yield of the products (A) and lead to oxasila-adamantanes in which one of the substituents at the silicon atom is chlorine or bromine. The authors note that, in contrast to the structure of the usual tetrasila-adamantanes, the structure of oxasila-adamantanes is apparently not free from strain, since the vibrational frequency of the Si–O–Si linkage is appreciably reduced. It is extremely likely that this structure will be readily polymerised with ring opening[96,149].



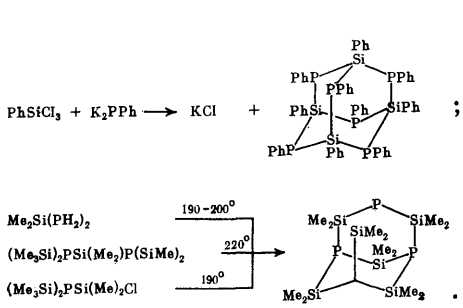
A method of synthesis of 3-substituted 2,4,10-trioxa-3-sila-adamantanes, consisting in the interaction of *cis*-phloroglucitol with trialkoxysilanes in the presence of triethylamine

on heating has been described[150,151]:



R = Me, Ph, or CH_2=CH; R' = Me or Bu.

Adamantanes of the purely siloxane type have been obtained by the hydrolysis of t-butyl and isopropyl-trichlorosilanes[152]; as a result of their high volatility, these compounds were isolated by sublimation from solid polymeric hydrolysis products. Their compositions and structures were established by elemental analysis and by molecular weight determinations (cryoscopically):



R = iso-Pr or t-Bu .

Analogous thiatetrasila- and selenatetrasila-adamantanes have been obtained under severe conditions from alkylsilanes or alkyltrichlorosilanes and hydrogen sulphide and hydrogen selenide respectively[153] and also from phenylsilane and sulphur[154].

R = Me or Et.

The crystal and molecular structures of the methyl derivative $(MeSi)_4S_6$ have been studied[155,156]. Compounds with a silicon–phosphorus adamantane nucleus have been obtained[157,158] by the reactions

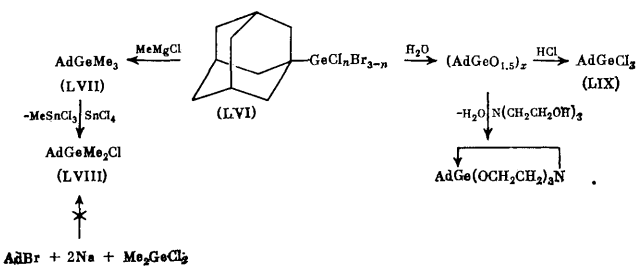
IV. GERMYL- AND GERMA-ADAMANTANES

The first representative of germyladamantanes was obtained in 1973 [19]:

$$AdX + GeX_4 \xrightarrow{Na} AdGe\ (26\%)\ .$$

However, the Wurtz reaction, used successfully in this instance, proved to be relatively unsuitable for the synthesis of other germyladamantanes.

The unexpectedly easy condensation of 1-halogenoadamantanes with trihalogenogermane etherates was discovered in 1974 [87,159]:

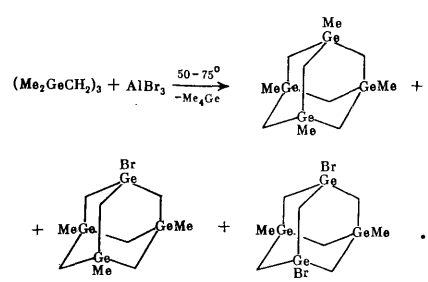


$$AdX + HGeX_3 \cdot 2Et_2O \xrightarrow[-HX]{80^\circ} AdGeX_3 + Et_2O\ ;$$

X = Cl or Br.

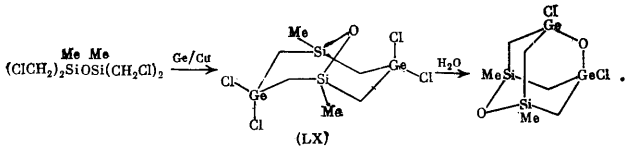
In contrast to the condensation reactions with acyclic tertiary halides, the interaction of the etherates with 1-halogenoadamantanes proceeds slowly after prolonged refluxing of the reaction mixture. This factor is the cause of the low yield of 1-tribromogermyladamantane, since the etherate $HGeBr_3$ decomposes to ethanol and $C_2H_5GeBr_3$ after prolonged heating. Use of the more stable etherate $HGeCl_3$ leads to a high yield of the product (75%). When the etherate $HGeCl_3$ reacts with 1-bromoadamantane, a mixture of chloro(bromo)germyladamantanes $AdGeCl_nBr_{3-n}$ ($n = 0-3$) is formed in ~70% yield. When the etherate of trichlorogermane is replaced in this reaction by its aminate $Et_3N.HGeCl_3$, the yield is sharply reduced (to 10%) after the same reaction time and at the same temperature[87,159].

Certain reactions of trihalogenogermyladamantanes have been carried out (Scheme 14).



Scheme 14

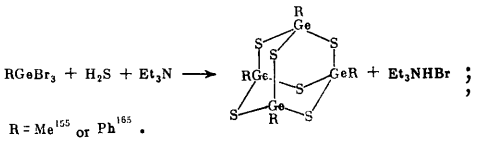
It was found[87] that the presence of the adamantyl group does not introduce significant changes into the chemical behaviour of the functional groups linked to the germanium atom. The unusually slow and incomplete reaction involving the formation of 1-adamantylgermatrane compared with the synthesis of alkyl- and phenylgermatranes by a similar method is noteworthy[160]. The reaction between compound (LVII) and $SnCl_4$ takes place very selectively, leading to the elimination of the methyl and not the adamantyl group under relatively mild conditions. Thus a compound with the Ad–Sn bond could not be obtained. In the synthesis of compound (LVIII) by an independent method via the Wurtz reaction mainly the reduction of the bromoadamantane to adamantane was observed. Traces of compound (LVIII) were detected only chromatographically.



The structure of the germyladamantanes obtained was investigated by NMR[87]. Since the proton spectrum of the adamantane group is extremely complex and cannot be interpreted, ^{13}C NMR was used to investigate compounds (LVI)–(LIX).

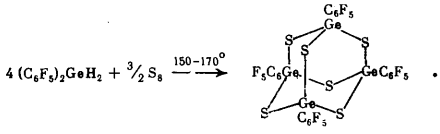
The first representatives of 1,3,5,7-tetragerma-adamantanes have been obtained by a method analogous to that for the synthesis of carborundanes[161,162]:

It was established that, with increase of temperature and the reaction time, the monobromo-derivative is formed almost exclusively, with a slight admixture of the dibromo-compound. When bis(trimethylgermyl)methane was used as the starting material, the product proved to be a mixture of all three germa-adamantanes.



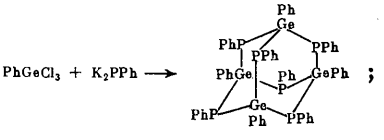
The attempts to synthesise a mixed oxasilagerma-adamantane have been reported[162-164]:

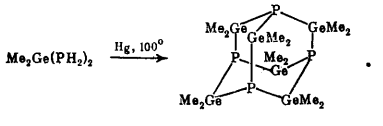
(LX)



However, the products obtained in the last reaction stage contained only traces of the required compound, which were detected mass-spectrometrically. This is probably due to the steric structure of the intermediate bicyclic compound (LX) which is unfavourable for ring closure; the compound has the "chair–boat" conformation in the crystalline state[164].

Sulphur-containing germa-adamantanes have been obtained by the reaction





R = Me[155] or Ph[165].

The adamantane-like structure of the high melting crystalline products isolated was demonstrated by mass-spectrometric, infrared spectroscopic, and ^{1}H NMR data as well as X-ray diffraction[155,165]. An analogous derivative has been synthesised by Bochkarev et al.[166]:

Two-different phosphorus-containing germa-adamantanes have been synthesised[157,167]:

V. STANNYL- AND STANNA-ADAMANTANES

An adamantyl derivative of tin was obtained for the first time simultaneously by two groups of investigators[168,169], who studied the stereochemistry of the interaction of Me_3Sn anions with different organic halogeno-derivatives:

$$Me_3SnM + AdBr \longrightarrow Me_3SnAd \ ;$$

Me = Na, K, or Li

In addition, it has been claimed[169] that not only 1-bromoadamantane but also the 2-bromo-derivative forms readily the corresponding adamantyltrimethylstannane under analogous conditions. Evidently in the case of the sterically rigid 1-adamantyl group the reaction proceeds with retention of configuration. To account for this finding, a two-stage reaction mechanism has been proposed[168,169]:

$$Me_3SnM + AdBr \xrightarrow{slow} Me_3SnBr + AdM$$

$$\downarrow \text{fast}$$

$$M = Na \text{ or } K. \qquad Me_3SnAd + MBr$$

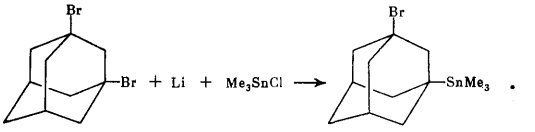
According to Koermer et al.[168], nucleophilic S_N2 substitution at the halogen atom takes place in this instance. Later Roberts[19] repeated the synthesis of Me_3SnAd with the aid of an analogous reaction. Other derivatives (Me_2SnAd_2, Ph_2. $SnAd_2$) could not be obtained by this method, but the Wurtz reaction has been used successfully[19]:

$$Ph_3SnCl + Na + AdCl \longrightarrow Ph_3SnAd \ (19\%) \ ;$$

$$SnCl_4 + Na + AdCl \longrightarrow Ad_4Sn \ (20\%) \ .$$

The compounds obtained were characterised in detail by elemental analysis, melting point measurements, infrared spectra, and NMR.

According to Roberts' hypothesis[19], the Wurtz reaction takes place in this instance via a radical mechanism involving electron transfer from sodium to R_3SnX and AdX:



$$R_3SnX + Na^{\cdot} \longrightarrow R_3Sn^{\cdot} + NaX \ ;$$

$$AdX + {}^{\cdot}Na \longrightarrow Ad^{\cdot} + NaX \ ;$$

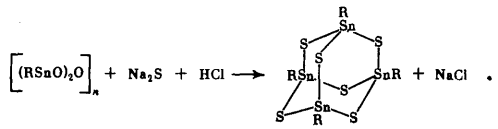
$$R_3Sn^{\cdot} + Ad^{\cdot} \longrightarrow R_3SnAd \ .$$

It has been stated[19] that the process is accompanied by side reactions involving the dimerisation of the radicals with formation of Ad_2 and R_3SnSnR_3. The attempts to synthesise 1-adamantyltrichlorostannane by refluxing 1-chloroadamantane and $SnCl_2$ in diglyme (with and without the addition of amine salts as catalysts) were unsuccessful: mainly the reduction of chloroadamantane to adamantane was observed[87].

3-Bromo-1-trimethylstannyladamantane has also been synthesised[170]:

Certain chemical properties of adamantyl derivatives of tin have been investigated[19,171], mainly in reactions with electrophiles. The tetra-adamantane compound proved to be extremely inert with respect to bromine and $HgCl_2$. However, the same reagents interact vigorously with monoadamantyl derivatives:

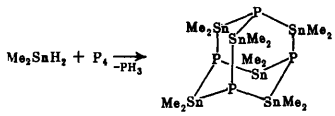
$$Me_3SnAd + X_2 \longrightarrow Me_2XSnAd \ ;$$



$$Me_3SnAd + HgCl_2 \longrightarrow Me_2ClSnAd \ ;$$

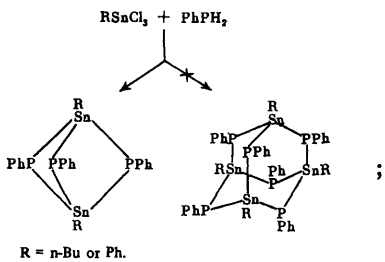
X = Cl or Br.

Triphenyladamantyltin reacts with bromine exclusively with the dissociation of the tin–phenyl bond.



The physical properties of adamantylstannanes have so far been studied inadequately. Roberts[19] quotes the wavelengths of the infrared absorption bands of Me_3SnAd and Ph_3SnAd as well as ^{1}H and ^{13}C NMR data for the compounds synthesised (certain features of the proton spectra are also discussed). Several sulphur-containing adamantane-like compounds of tin have also been obtained. Komura and Okawara[172] investigated the reactions of methyl-, n-propyl-, and n-butyl-tin oxides with sodium sulphides in hydrochloric acids. The reaction of

the n-butyl compound yielded a product soluble in benzene, which made it possible to determine its molecular weight and to study some of its chemical properties:



Later this compound was suggested as a stabiliser of PVC.[173] The methyl derivative (R = Me) obtained from $MeSnCl_3$ and Na_2S has an analogous structure[174] However, the adamantane-like structure of the compound obtained was established by X-ray diffraction much later[175].

Selenium- and tellurium-containing stanna-adamantanes $Me_4Sn_4X_6$ (X = Se or Te), whose structure was confirmed by infrared spectroscopic NMR, and X-ray diffraction data, were synthesised from $MeSnBr_2$ and NaHX.[176] A novel hexakis(dimethylstannyl) tetraphosphide has been obtained recently[177]:

It is noteworthy that the attempt to synthesise another phosphorus-containing stanna-adamantane was unsuccessful[155], although the analogous reactions with organosilicon and organogermanium compounds led to products with the adamantane structure:

R = n-Bu or Ph.

---o0o---

During the preparation of the manuscript for the press, new reports on the chemistry of silicon-containing adamantanes were published. Among the new syntheses of silyladamantanes, the involvement of dihalogenoadamantanes and arylsilanes in the Friedel–Crafts reaction[178,179] as well as the interaction of adamantane with methylchlorosilane under the influence of lithium[180] should be mentioned. Polymers have been obtained from silyladamantanes; they exhibit improved thermal and radiation stabilities[181]. The structure of 1-methyl-1-sila-adamantane has been established by gas electron diffraction[182,183]. Studies on tin-substituted adamantanes are being continued: the methods of synthesis are being improved and the physicochemical properties (^{13}C NMR spectra) and the chemical behaviour of these compounds are being investigated[184].

Reports of the synthesis of a new inorganic high-strength fibre from silicon carbide, suitable for the preparation of a wide variety of compound materials, have recently begun to appear in the literature[185,186]. The technology of the preparation of this fibre consists in the spinning of thread from a polymeric oxygen-free organosilicon product and its subsequent thermal carborundation[187–189].

Fluorine-containing Halogenomethylenephosphoranes

V.V.Tyuleneva, E.M.Rokhlin, and I.L.Knunyants

The methods of synthesis of fluorine-containing halogenomethylenephosphoranes, their stability, and their applications in the Wittig reaction in order to obtain fluorine-substituted olefins are examined.
The bibliography includes 80 references.

I. INTRODUCTION

Phosphorus ylids are widely used in organic synthesis[1-7], mainly in order to obtain various unsaturated compounds by the Wittig reaction. In recent years phosphorus ylids containing fluorine or fluorinated residues in the methylene group have been used on an increasing scale. The properties of fluorine-containing phosphorus ylids and the methods of their generation depend on the relative positions of the fluorine atoms and the carbanionic centre of the methylene group.

Fluorine-containing halogenomethylenephosphoranes, which are the subject of the present review†, constitute a special group of such phosphorus ylids.

Fluorine-containing mono- and di-halogenomethylenephosphoranes (I, a–h) are apparently insufficiently stable for their isolation in a pure form.

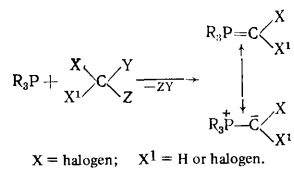
$R_3P{=}CFX$ (I)

R	Ph	Ph	Ph	Ph	n-Bu	n-Bu	Me_2N	Me_2N
X	H	F	Cl	Br	F	Cl	F	Cl
	(Ia)	(Ib)	(Ic)	(Id)	(Ie)	(If)	(Ig)	(Ih)

These compounds are obtained by different methods and are used without isolation in the "carbonyl olefinating" Wittig reaction. Two cases are then possible.

(1) The phosphorus ylid is generated in the presence of the reagent (carbonyl compound) involved in the subsequent reaction (reaction *in situ*).

(2) The phosphorus ylid is generated and then, without its isolation, the carbonyl compound is added to the reaction mixture ("the olefinating solution").



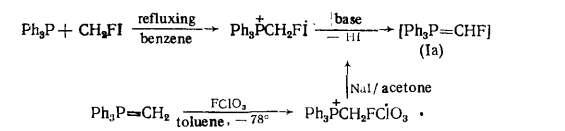
The superiority of a particular method depends not only on the method of generation and stability of the ylid but also on the nature of the reagent, mainly on its reactivity in reactions with the ylids and with the initial compounds from which the ylid is obtained.

Usually, even when the ylids are generated in a preliminary step, there is no certainty that the reaction mixture actually contains the ylid. Although, on subsequent interaction with the reagent, the final products which should have been obtained from the phosphorus ylid are indeed formed, nevertheless in certain cases the ylid is absent from the mixture or is present in very insignificant amounts. This is sometimes confirmed by spectroscopic data (see below), but, even if such evidence is lacking, in their subsequent exposition it will be arbitrarily assumed that the "olefinating solution" does contain the phosphorus ylid.

† In writing this review, the authors used the automated information searching system for the chemistry of organofluorine compounds—AIPS "FTOR" [All-Union Institute of Scientific and Technical Information (VINITI),

II. SYNTHESIS

Regardless of the reaction mechanism, the methods of synthesis of mono- and di-halogenomethylenephosphoranes are based as a rule on the interaction of a tertiary phosphine with some source of a mono- or di-halogenomethylene fragment:



X = halogen; X^1 = H or halogen.

Such sources of halogenomethylenes can be methylene halides, haloforms, carbon tetrahalides, derivatives of halogenoacetic acids, and certain other compounds.

1. Interaction of Tertiary Phosphines with Methylene Halides

Fluoroiodomethane readily alkylates triphenylphosphine to form a stable phosphonium salt[8]. A particularly pure iodide can be obtained by the fluorination of methylenetriphenylphosphorane with subsequent replacement of the anion on treatment with sodium iodide[9]. The dehydroiodination of this salt by BuLi,[8,10] iso-PrNLi,[8] t-BuOK,[11] or the adduct PhLi.LiBr [9] leads to fluoromethylenetriphenylphosphorane (Ia):

(1)

The deuterated ylid $Ph_3P{=}CDF$ has been obtained similarly[12].

2. Interaction of Tertiary Phosphines with Haloforms

The stable fluoroiodomethyltriphenylphosphonium iodide# is formed from triphenylphosphine and fluorodi-iodomethane and is then converted under the influence of the zinc–copper couple into fluoromethylenetriphenylphosphorane (Ia)§ :[8,10]

It may be that in this process the "positively charged" iodine atom is initially attacked by the phosphine with subsequent "anionic exchange" in the phosphonium salt (see below).

§ The phosphorus ylid (Ia) is probably formed as a complex with zinc iodine[8].

$$Ph_3P + CHFI_2 \xrightarrow[CH_2Cl_2]{60^\circ} Ph_3\overset{+}{P}CHFI\ \bar{I} \xrightarrow[DMF]{Zn/Cu,\ 0^\circ} \underset{(Ia)}{[Ph_3P{=}CHF]}\ . \qquad (2)$$

In the presence of strong bases haloforms give rise to dihalogenocarbenes, which can add to a tertiary phosphine to form the corresponding phosphorus ylid. Thus chlorofluoromethylenetriphenylphosphorane (Ic) has been obtained from dichlorofluoromethane and triphenylphosphine in the presence of t-BuOK:[13–16]

$$CHFCl_2 \xrightarrow[-KCl,\ -Me_3COH]{+Me_3COK} [:CFCl] \xrightarrow{+Ph_3P} \underset{(Ic)}{[Ph_3P{=}CFCl]}\ . \qquad (3)$$

It was not possible to obtain by a similar procedure difluoromethylenetriphenylphosphorane (Ib) from chlorodifluoromethane (the initial triphenylphosphine was recovered unchanged)[13]. It has been suggested that the diflurocarbene formed reacts preferentially with t-BuOH and not with Ph_3P. Nor was it possible to obtain analogously difluromethylenetributylphosphorane (Ie) [13] and chlorofluoromethylene-tributylphosphorane (If).[13,14]

3. Interaction of Tertiary Phosphines with Carbon Tetrahalides

The accumulation of electron-accepting halogen atoms in the carbon tetrahalide molecules makes possible the attack by the tertiary phosphine on the "positively charged" halogen. This results in the formation of a halogenophosphonium salt, which can be converted into a trihalogenomethylphosphonium salt by "anion exchange":[17,18]

$$R_3P + CX_4 \rightarrow R_3\overset{+}{P}X\ \bar{C}X_3 \xrightarrow{\bigcirc} R_3\overset{+}{P}CX_3\ \bar{X}\ .$$

In the reaction with mixed fluorine-containing carbon tetrahalides the less electronegative atom of the other halogen is attacked rather than the fluorine atom, which results in the formation of fluorine-containing quaternary phosphonium salts.

Thus the reaction of triphenylphosphine with dibromodifluoromethane yielded the stable bromodifluoromethyltriphenylphosphonium bromide[19,20]. Trichlorofluoromethane does not react with triphenylphosphine under mild conditions, while under more severe conditions a complex mixture of substances is formed[21]. However, the reaction with tris(dimethylamino)phosphine yields readily the stable dichlorofluoromethyltris(dimethylamino)phosphonium chloride[18,22]:

$$Ph_3P + CF_2Br_2 \longrightarrow Ph_3\overset{+}{P}CF_2Br\ \bar{Br}\ ;$$
$$(Me_2N)_3P + CFCl_3 \longrightarrow (Me_2N)_3\overset{+}{P}CFCl_2\bar{Cl}\ .$$

Dehalogenation of phosphonium salts leads to fluorine-containing halogenomethylenephosphoranes. The reaction frequently takes place without the isolation of the phophonium salts, the tertiary phosphine taken in excess serving as the dehalogenating agent. The corresponding ylids (I, b and d) have been obtained in this way from triphenylphosphine and dichlorodifluoromethane[23,24], dibromodifluoromethane[23–29], and tribromofluoromethane[30]:

$$2Ph_3P + CFXY_2 \xrightarrow[\text{diglyme or triglyme;}\ -Ph_3PY_2]{70^\circ} \underset{(I,\ b\ and\ d)}{[Ph_3P{=}CFX]}\ . \qquad (4)$$

X	F	F	Br
Y	Cl	Br	Br

The ylid (Ig) is formed similarly from tris(dimethylamino)phosphine and CF_2Br_2:[26,29]

$$2(Me_2N)_3P + CF_2Br_2 \xrightarrow[\text{triglyme},\ -(Me_2N)_3PBr_2]{20^\circ} \underset{(Ig)}{[(Me_2N)_3P{=}CF_2]}\ . \qquad (5)$$

However, in many instances a multistage synthesis is more convenient: the interaction of equimolar amounts of the phosphine and carbon tetrahalide yields a phosphonium salt, which is then dehalogenated by treatment with a second mole of the phosphine (another tertiary phosphine can be used at this stage). "Olefinating solutions"—sources of difluoromethylenetriphenylphosphorane[20,31], difluoromethylenetris(dimethylamino)phosphorane (Ig),[20,31] and chlorofluoromethylenetris(dimethylamino)phosphorane (Ih) [18,32,33]—have been obtained in this way:

$$R_3\overset{+}{P}CF_2Br\ \bar{Br} + R_3P \xrightarrow[-R_3PBr_2]{} \underset{(I,\ b\ and\ g)}{[R_3P{=}CF_2]}\ ; \qquad (6)$$

$$(Me_2N)_3\overset{+}{P}CFCl_2\ \bar{Cl} + R_3P \xrightarrow[-R_3PCl_2]{} \underset{(Ih)}{[(Me_2N)_3P{=}CFCl]}\ ; \qquad (7)$$

R = Ph or Me_2N.

It must be emphasised that in reality these solutions may not contain phosphorus ylids, although their interaction with carbonyl compounds does yield the products of the Wittig reaction. Thus, after refluxing an acetonitrile solution of equimolar amounts of Ph_3P and bromodifluoromethyltriphenylphosphonium bromide for 6 h, only the initial phosphonium salt was detected by ^{19}F NMR, while difluoromethylenetriphenylphosphorane was not found; nevertheless, on treatment with a carbonyl compound, the Wittig reaction takes place successfully[20]. Evidently the dehalogenation of the phosphonium salt by triphenylphosphine is reversible, the equilibrium being strongly displaced towards the initial compounds. In the presence of a carbonyl compound the phosphorus ylid (Ib) is removed from the reaction, which shifts the equilibrium towards the final products:

$$Ph_3\overset{+}{P}CF_2Br\ \bar{Br} + Ph_3P \rightleftharpoons \underset{(Ib)}{[Ph_3P{=}CF_2]} + Ph_3PBr_2$$
$$\Big| \diagdown C{=}O \qquad (8)$$
$$\downarrow\ \diagup$$
$$\diagdown C{=}CF_2 + Ph_3PO\ .$$

The $(Me_2N)_3\overset{+}{P}CF_2Br\ \bar{Br} + (Me_2N)_3P$ [20] and $(Me_2N)_3\overset{+}{P}CFCl_2\ \bar{Cl} + Ph_3P$ [18] systems behave similarly. On the other hand, when dichlorofluoromethyltris(dimethylamino)phosphonium chloride is acted upon by $(Me_2N)_3P$, an exothermic reaction is observed even in the absence of the third component and the resulting solution does not exhibit an "olefinating" activity¶.[18] Evidently in this case the equilibrium is displaced to the right; in the absence of a carbonyl compound, the resulting ylid (Ih) is removed from the reaction as a result of decomposition[18,33]:

$$(Me_2N)_3\overset{+}{P}CFCl_2\ \bar{Cl} + (Me_2N)_3P \rightarrow \underset{(Ih)}{[(Me_2N)_3P{=}CFCl]} + (Me_2N)_3PCl_2\ .$$
$$\Big|\ \longrightarrow \text{decomposition products}$$

Trihalogenomethylphosphonium salts can be dehalogenated successfully even by metals. Thus the interaction of $CFCl_3$ with triphenylphosphine and zinc in the presence of carbonyl compounds leads to the formation of the products of the Wittig reaction[21,33]. This probably involves the formation of a quasi-complex organometallic compound+, which dissociates into $ZnCl_2$ and the phosphorus ylid (Ic):

$$Ph_3P + CFCl_3 + Zn \xrightarrow[DMF]{60^\circ} \left[\begin{array}{c} ZnCl \\ | \\ Ph_3\overset{+}{P}{-}CFCl\ \bar{Cl} \end{array}\right] \qquad (9)$$
$$\Big\uparrow \qquad \Big\uparrow$$
$$\diagdown C{=}CFCl \xleftarrow[-Ph_3PO]{+\ C{=}O} \underset{(Ic)}{[Ph_3P{=}CFCl]} + ZnCl_2\ .$$

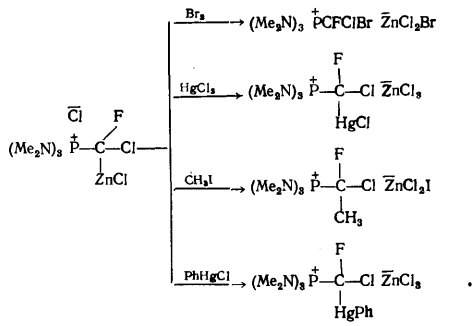
¶ When the reaction is carried out *in situ* (in the presence of a carbonyl compound), the same system gives rise to the products of the Wittig reaction with high yields[18].

+ Similar quasi-complexes of non-fluorinated ylids with mercury(II) chloride are known[34–37].

The formation of the ylid (Ib) is postulated when metals act on a mixture of triphenylphosphine and CF_2Br_2 [29] or on bromodifluoromethyltriphenylphosphonium bromide[28,38]:

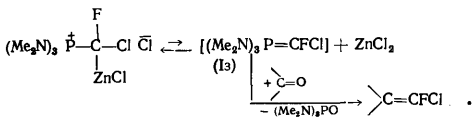
$$Ph_3P + CF_2Br_2 + Zn \xrightarrow[AcNMe_2]{100-110^\circ} \underset{(Ib)}{[Ph_3P{=}CF_2]} + ZnBr_2 \quad ; \qquad (10)$$

$$Ph_3\overset{+}{P}CF_2Br\ \bar{B}r \xrightarrow[-HgBr_2]{+Hg} \underset{(Ib)}{[Ph_3P{=}CF_2]} \quad . \qquad (11)$$



The ylid (Ig) has been obtained similarly[29]:

$$(Me_2N)_3P + CF_2Br_2 + Zn \xrightarrow{AcNMe_2} \underset{(Ig)}{[(Me_2N)_3P{=}CF_2]} + ZnBr_2 \quad . \qquad (12)$$



The action of Group IIB metals (zinc, cadmium, and mercury) on dichlorofluoromethyltris(dimethylamino)phosphonium chloride has been studied in particular detail. This entails the formation of an exceptionally stable "olefinating solution" containing a quasi-complex organometallic phosphonium salt#, [32,33] for example:

$$(Me_2N)_3\overset{+}{P}CFCl_2\ \bar{C}l + Zn \xrightarrow[THF]{60^\circ} (Me_2N)_3\overset{+}{P}{-}\underset{ZnCl}{\overset{F}{C}}{-}Cl\ \bar{C}l \quad . \qquad (13)$$

The structure of the quasi-complex salts obtained was confirmed by ^{19}F and ^{31}P NMR and also by chemical reactions[32]:

On treatment with carbonyl compounds, the quasi-complex salts undergo the Wittig reaction, probably as a result of the reversible dissociation into the ylid and a metal salt[32,33]:

In the synthesis of a phosphorus ylid from a trihalogenomethylphosphonium salt the trihalogenomethyl anion can evidently also act as a dehalogenating agent. It has been shown[19,39,40] that trihalogenomethylphosphonium salts serve as convenient sources of trihalogenomethyl anions and dihalogenocarbenes in the presence of alkali metal fluorides, for example:

$$Ph_3\overset{+}{P}CF_2Br\ \bar{B}r \xrightarrow{+\bar{F}} Ph_3PFBr + [\bar{C}F_2Br] \xrightarrow[-Br^-]{} [:CF_2] \quad .$$

In the presence of benzoyl fluoride the product of the Wittig reaction, namely 3-bromotetrafluoro-2-phenylpropene (yield 57%), was obtained in addition to ω-bromo-ω,ω-difluoroacetophenone (yield 9%). [39] It is suggested that this involves the intermediate formation of the ylid (Ib) as a result of the dehalogenation of the phosphonium salt by the anion $\bar{C}F_2Br$:

$$Ph_3\overset{+}{P}CF_2Br\ \bar{B}r \xrightarrow[-Ph_3PFBr]{+KF} [\overset{+}{K}\bar{C}F_2Br] \xrightarrow[-KBr,\ -CF_2Br_2]{+Ph_3\overset{+}{P}CF_2Br\ \bar{B}r} \underset{(Ib)}{[Ph_3P{=}CF_2]} \quad ;$$

$$[\overset{+}{K}\bar{C}F_2Br] + PhCOF \xrightarrow{-KF} PhCOCF_2Br \quad ;$$

$$PhCOCF_2Br + \underset{(Ib)}{[Ph_3P{=}CF_2]} \xrightarrow{-Ph_3PO} \begin{matrix} Ph \\ \diagdown \\ C{=}CF_2 \\ \diagup \\ BrCF_2 \end{matrix} \quad .$$

The "conserving" influence of mercury(II) chloride on non-fluorinated phosphorus ylids is also known[36].

The presence of the phosphorus ylid (Ib) was confirmed by the reaction with trifluoroacetophenone[39]:

$$\underset{(Ib)}{[Ph_3P{=}CF_2]} + PhCOCF_3 \rightarrow \begin{matrix} Ph \\ \diagdown \\ C{=}CF_2 \\ \diagup \\ CF_3 \end{matrix} \ (33\%) \quad .$$

The ylid (Ib) has also been obtained from CF_2Cl_2 under the influence of triphenylphosphine and KF.[15]

The formation of the ylid (Ib) from equimolar amounts of dibromodifluoromethane, triphenylphosphine, and butyllithium was described in 1960 (without experimental details) (the intermediate formation of difluorocarbene was postulated):[41]

$$CF_2Br_2 \xrightarrow[-LiBr]{+BuLi} [:CF_2] \xrightarrow{+Ph_3P} \underset{(Ib)}{[Ph_3P{=}CF_2]} \quad .$$

However, in a later study[13] this result could not be reproduced.

4. The Interaction of Tertiary Phosphines with Derivatives of Trihalogenoacetic Acids

The decarboxylation of trihalogenoacetate salts is frequently used to generate dihalogenocarbenes[40,42]. Decarboxylation in the presence of tertiary phosphines leads to the formation of the corresponding phosphorus ylids. Thus difluoromethylenetriphenylphosphorane has been obtained from lithium[43-46], sodium[43-54], or potassium[44] chlorodifluoroacetate and triphenylphosphine:

$$Ph_3P + ClCF_2COOM \xrightarrow[\text{diglyme, DMF, } N\text{-methylpyrrolidone, etc.}]{80-180^\circ} \underset{(Ib)}{[Ph_3P{=}CF_2]} + MCl + CO_2 \quad ; \qquad (14)$$
$$M = Li, Na \text{ or } K.$$

The analogous reaction with tributylphosphine led to difluoromethylenetributylphosphorane:[51,55]

$$Bu_3P + ClCF_2COONa \xrightarrow[DMF \text{ or } N\text{-methylpyrrolidinone}]{180^\circ} \underset{(Ie)}{[Bu_3P{=}CF_2]} + NaCl + CO_2. \qquad (15)$$

Chlorofluoromethylenetriphenylphosphorane§,[14,16,46,54] bromofluoromethylenetriphenylphosphorane,[30] and chlorofluoromethylenetributylphosphorane[14] have been obtained similarly:

$$Ph_3P + X_2CFCOOM \xrightarrow[triglyme]{80-90^\circ} \underset{(I,\ c \text{ and } d)}{[Ph_3P{=}CFX]} + NaX + CO_2 \quad ; \qquad (16)$$
$$X{=}Cl, Br;\ M{=}Li, Na$$

$$Bu_3P + Cl_2CFCOONa \xrightarrow[triglyme]{85^\circ} \underset{(If)}{[Bu_3P{=}CFCl]} + NaCl + CO_2 \qquad (17)$$

It is sometimes suggested[40,47] that these reactions proceed via the intermediate formation of a dihalogenocarbene:

$$Y{-}\underset{F}{\overset{X}{C}}{-}\overset{O}{\overset{\diagup\!\!\diagdown}{C}}_{OM} \xrightarrow[-MY,\ -CO_2]{\Delta} \left[\begin{matrix} X \\ \diagdown \\ F \end{matrix}\!\!>\!C:\right] \xrightarrow{+R_3P} \left[R_3P{=}C\begin{matrix} X \\ \diagup \\ F \end{matrix}\right] \quad .$$

However, there is important evidence against the "carbene" mechanism. Thus the reaction of chlorofluorocarbene generated from dichlorofluoromethane and t-BuOK with an equimolar mixture of triphenylphosphine and tetramethylethylene leads to almost identical yields of a substituted cyclopropane (II) and the phosphorus ylid (Ic) (the yield of the latter was determined from the results of the Wittig reaction with trifluoroacetophenone):[14,16]

$$CHFCl_2 \xrightarrow[-Me_2COH,\ -KCl]{+Me_2COK} [:CFCl] \xrightarrow{Me_2C{=}CMe_2+Ph_3P} \underset{F\quad Cl}{Me_2C{-}\overset{\diagup\!\!\diagdown}{C}{-}CMe_2} + \underset{(Ic),\ (19\%)}{[Ph_3P{=}CFCl]}$$
(II), (14%)

Consequently tetramethylethylene and triphenylphosphine have comparable reactivities in reactions with dichlorofluorocarbene. However, the decarboxylation of sodium dichlorofluoroacetate in the presence of tetramethylethylene and triphenylphosphine results in the formation of only the phosphorus ylid (Ic) and the cyclopropane (II) is not detected§. The authors[14,16] therefore concluded that the phosphorus ylid is not formed via the halogenocarbene in the present instance. Evidently the trihalogenoacetate behaves in this reaction like carbon tetrahalides (see above), giving rise to the betaine (III) on interaction with phosphine and the betaine is then decarboxylated to give the phosphorus ylid:

$$Ph_3P + Cl_2CFCOONa \xrightarrow{-NaCl} \underset{(III)}{[Ph_3\overset{+}{P}CFCl\overline{CO}O]} \xrightarrow{-CO_2} \underset{(Ic)}{[Ph_3P{=}CFCl]} .$$

Analogous evidence in support of the formation of the betaine $Ph_3\overset{+}{P}CF_2\overline{CO}O$ when difluoromethylenetriphenylphosphorane (Ib) is generated has been adduced by other workers[43]. It has also been shown that the presence of triphenylphosphine accelerated the decarboxylation of sodium chlorodifluoroacetate[43].

Naturally, the mode of reaction should depend on the nucleophilic activity of the tertiary phosphine and on the nature of the halogen atoms in the trihalogenoacetate. The latter affects both the ease of the nucleophilic attack by the phosphine on the halogen atom and the ease of decarboxylation. Nor can one rule out the possibility that in various specific instances the reaction mechanism is different (the "carbene" or "phosphobetaine" mechanism).

In the synthesis of difluoromethylenetriphenylphosphorane (Ib) it is also possible to use trimethyltin trifluoroacetate as the initial trihalogenoacetate[56]:

$$Ph_3P + CF_3COOSnMe_3 \xrightarrow[-Me_3SnF,\ -CO_2]{150^\circ,\ NaI} \underset{(Ib)}{[Ph_3P{=}CF_2]} .$$

The interaction of methyl trihalogenoacetates with a tertiary phosphine in the presence of nucleophiles capable of demethylating esters is a variety of the method of synthesis of fluoromethylenephosphoranes described. Thus difluoromethylenetriphenylphosphorane is formed when methyl chlorodifluoroacetate is acted upon by triphenylphosphine and the complex of LiCl with hexamethylphosphoramide (HMP):[57]

$$Ph_3P + ClCF_2COOMe \xrightarrow[\sim 80^\circ,\ \text{triglyme}]{LiCl\cdot 2(Me_2N)_3PO} \underset{(Ib)}{[Ph_3P{=}CF_2]} . \qquad (18)$$

The ylid (Ib) could be formed via two pathways: via the difluorocarbene (a) or via the phosphonium salt (IV)¶ and the phosphobetaine (V)† (b):

a) $ClCF_2COOMe \xrightarrow[-MeCl]{+LiCl} ClCF_2COOLi \xrightarrow[-LiCl,\ -CO_2]{} [:CF_2] \xrightarrow{+Ph_3P} \underset{(Ib)}{[Ph_3P{=}CF_2]}$

b) $Ph_3P + ClCF_2COOMe \rightarrow \underset{(IV)}{[Ph_3\overset{+}{P}CF_2COOMe\overline{Cl}]} \xrightarrow[-MeCl]{(LiCl)}$

$\rightarrow \underset{(V)}{[Ph_3\overset{+}{P}CF_2\overline{CO}O]} \xrightarrow{-CO_2} \underset{(Ib)}{[Ph_3P{=}CF_2]}$

§ In the absence of triphenylphosphine the cyclopropane (II) was obtained in 37% yield[14,16].

¶ It has been shown[58,59] that, on heating (90–120 °C in DMF), the salt $Ph_3\overset{+}{P}CH_2COOMe\overline{Br}$ decomposes into MeBr, CO_2, and the ylid $Ph_3P{=}CH_2$.

† From the point of view of stoichiometry, the reaction should take place, in principle, in the presence of catalytic amounts of LiCl regardless of its mechanism. However, an excess of the complex of LiCl with HMP was used[57], evidently in order to increase the rate of reaction [the resulting ylid (Ib) was used in the Wittig reaction *in situ*].

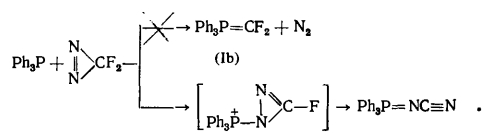
Since the presence of triphenylphosphine does not accelerate the decomposition of methyl chlorodifluoroacetate, the "carbene" mechanism (a) is more probable[57].

The chlorofluoro-substituted phosphorus ylid (Ic) has been obtained from methyl dichlorofluoroacetate and triphenylphosphine in the presence of NaH and methanol under mild conditions, possibly via chlorofluorocarbene[60]:

$$Ph_3P + Cl_2CFCOOMe \xrightarrow[\substack{25-30^\circ;\\ \text{heptane or}\\ \text{benzene}}]{NaH/MeOH} \underset{(Ic)}{[Ph_3P{=}CFCl]} . \qquad (19)$$

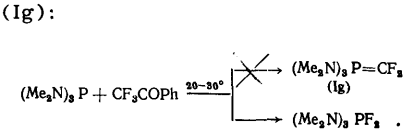
5. Other Methods of Synthesising Fluorine-Containing Halogenomethylenephosphoranes

On interaction with triphenylphosphine, the usual source of chlorofluorocarbene—dichlorofluoromethylphenylmercury—gives rise to chlorofluoromethylenetriphenylphosphorane:[15]



$$Ph_3P + PhHgCFCl_2 \xrightarrow[\text{xylene}]{80^\circ} \underset{(Ic)}{[Ph_3P{=}CFCl]} + PhHgCl . \qquad (20)$$

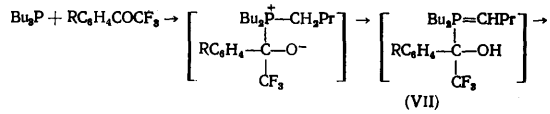
It has been claimed[61] that difluoromethylenetriphenylphosphorane is formed when trifluoronitrosomethane interacts with ammonia and triphenylphosphine. Difluorodiazomethane is then postulated as an intermediate:

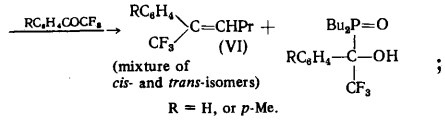


$$CF_3NO \xrightarrow[-H_2O]{+NH_3} [CF_3N{=}NH] \xrightarrow[-NH_4F]{+NH_3} [\overline{C}F_2{-}\overset{+}{N}{\equiv}N] \xrightarrow[-N_2]{+Ph_3P} \underset{(Ib)}{[Ph_3P{=}CF_2]} .$$

However, no evidence has been produced in support of the formation of the ylid (Ib).[61]

The ylid (Ib) cannot be obtained from difluorodiazirine (difluorocyclodiazomethane) and triphenylphosphine[62]:





Mark[63] reported the synthesis of difluoromethylenetris-(dimethylamino)phosphorane and its ethyl analogue $(Et_2N)_3P{=}CF_2$ by the reaction of the corresponding phosphorus acid triamides [tris(dialkylamino)phosphines] with trifluoroacetophenone. These phosphorus ylids have been described[63] as stable distillable liquids. However, it was shown later[64] that in fact the reaction products are not phosphorus ylids but tris(dialkylamino)difluorophosphoranes, whose structure was demonstrated rigorously by spectroscopic data and by specific synthesis[62,64,65]. The properties of tris(dimethylamino)-difluorophosphorane agree fully with those of the compound described by Mark[63], who incorrectly attributed to it the structure (Ig):

Only traces of the ylid (Ig) were detected in the reaction medium by mass spectrometry[64].

Tributylphosphine reacts differently with difluoroacetophenone (and *p*-methyltrifluoroacetophenone); the reaction yields the olefins (VI) probably via the phosphorus ylids (VII):[66]

Other trialkylphosphines react similarly[66].

III. PROPERTIES

As already mentioned, fluorine-containing mono- and di-halogenomethylenephosphoranes (I, a–h) have not been isolated in a pure state#. When different methods of synthesis are used, the reaction mixtures frequently contain different compounds, which are in principle capable of interacting both with the phosphorus ylid (reversibly or irreversibly) and with other reagents. All this causes extreme difficulties in the determination of reliable data on the comparative stabilities and reactivities of fluorine-containing halogenomethylenephosphoranes, despite the extensive experimental results which have been accumulated. However, since these compounds have already assumed a fairly considerable importance and are widely used in the synthesis of fluorine-containing olefins by the Wittig reaction, it is necessary to describe the available data concerning their stabilities. In the first place we shall consider the use of fluorine-containing halogenomethylenephosphoranes in the Wittig reaction.

1. Stability of Fluorine-Containing Halogenomethylenephosphoranes

When the stabilities of compounds (I) are considered, one must not overlook the fact that in practice one is not dealing with a phosphorane as such but with a reaction mixture containing different components. In each case attention must therefore be directed not only to the nature of the ylid but also to the method of its synthesis.

(*a*) *Fluoromethylenetriphenylphosphorane* $Ph_3P=CHF$ (*Ia*). The phosphorus ylid (Ia), obtained in the form of a lemon-yellow solution in tetrahydrofuran (THF) on dehydroiodination of a phosphonium salt by PhLi [(Eqn.(1)], is readily attacked by nucleophiles and decomposes. In its synthesis it is necessary to add slowly, with very thorough stirring, a solution of PhLi to fluoromethyltriphenylphosphonium iodide and to maintain a fairly low temperature (<–50 °C) to avoid self-condensation§ [9] (see also Vanderhaar et al.[30]). Nevertheless this ylid can be generated in solution in the absence of a carbonyl compound and then used in the Wittig reaction[9]. The use of BuLi in a mixture of THF and hexane also leads to a relatively stable solution of the ylid (Ia) (it does not decompose at 0 °C for 40 min but does decompose at 28 °C).[8]

The "olefinating solution", obtained by the dehalogenation of fluoroiodomethyltriphenylphosphonium iodide with the zinc–copper couple in dimethylformamide (DMF) [Eqn.(2)], apparently contains the complex $Ph_3\overset{+}{P}CHFZnI\ \bar{I}$ and not the free ylid (Ia). The solution is relatively unstable—after 90 min at 0 °C it loses almost completely its "olefinating" capacity and is therefore used in the Wittig reaction *in situ*[8].

(*b*) *Difluoromethylenetriphenylphosphorane* $Ph_3P=CF_2$ (*Ib*). Under the conditions of its synthesis by the "halogenoacetate" method [Eqn.(14)], the ylid (Ib) is unstable and can be used in the Wittig reaction only *in situ* in solvents such as diglyme, DMF, and *N*-methylpyrrolidinone. The attempts to use dimethyl sulphoxide as the solvent were unsuccessful, evidently as a result of the interaction of the ylid (Ib) with Me_2SO (dimethyl sulphide was isolated from the reaction product in 84% yield)[43].

When triphenylphosphine reacts with dibromodifluoromethane or bromodifluoromethyltriphenylphosphonium bromide in diglyme, triglyme, or acetonitrile [Eqns.(4) and (6)], stable "olefinating solutions" are formed (they do not decompose in 60 h at 70 °C).[20,26] Their stability can be explained by the reversibility of the formation of the ylid (Ib) and the appreciable shift of the equilibrium [Eqn.(8)] to the left. However, in DMF it is impossible to obtain a stable solution—probably as a consequence of the interaction of the solvent with dibromotriphenylphosphorane Ph_3PBr_2, which shifts the equilibrium to the right[20].

(*c*) *Chlorofluoromethylenetriphenylphosphorane* $Ph_3P=CFCl$ (*Ic*). In contrast to the difluoroylid (Ib), the chlorofluoroylid (Ic) is comparatively stable under the conditions of its synthesis from triphenylphosphine and sodium dichlorofluoroacetate [Eqn.(16)]. After the evolution of CO_2 (after heating for several hours at 80–90 °C in triglyme), a solution with "olefinating" activity was obtained; however, the yields in the Wittig reaction were nevertheless higher when the ylid was employed *in situ*.[14,16]

When chlorofluoromethylenetriphenylphosphorane was generated under mild conditions from methyl dichlorofluoroacetate, Ph_3P, and NaH [Eqn.(19)][60] or from $CHFCl_2$, Ph_3P, and t-BuOK [Eqn.(3)],[13,14,16] relatively stable "olefinating" solutions are also formed.

(*d*) *Bromofluoromethylenetriphenylphosphorane* $Ph_3P=CFBr$ (*Id*). The solution obtained by the reaction of triphenylphosphine with tribromofluoromethane in diglyme or triglyme at 70 °C [Eqn.(4)] does not lose its "olefinating" capacity after 21 h at 37 °C.[30]

(*e*) *Tributyldifluoromethylenephosphorane* $Bu_3P=CF_2$ (*Ie*) *and tributylchlorofluoromethylenephosphorane* $Bu_3P=CFCl$ (*If*). The tributyl-substituted ylids (Ie) and (If) are apparently less stable than the corresponding triphenyl ylids (Ib) and (Ic).[13,14,16] Tributyldifluoromethylenephosphorane[51] and tributylchlorofluoromethylenephosphorane[14] can be generated by the "halogenoacetate" method [Eqns.(15) and (17)] and used in the Wittig reaction *in situ*; however, the attempts to obtain them from a haloform, a phosphine, and t-BuOK [as in Eqn.(3)] proved unsuccessful[13,14,16]. It has been suggested[13] that the ylid (If) reacts with t-BuOH under the reaction conditions.

(*f*) *Difluoromethylenetris(dimethylamino)phosphorane* $(Me_2N)_3P=CF_2$ (*Ig*). The "olefinating" solutions which behave as sources of the ylid (Ig) are prepared by treating dibromodifluoromethane [Eqn.(5)][26] or bromodifluoromethyltris(dimethylamino)phosphonium bromide [Eqn.(6)] with tris(dimethylamino)phosphine in triglyme[20,31]¶. These solutions are stable at room temperature (they hardly decompose after 300 h),[26] probably as a consequence of the establishment of a dynamic equilibrium, which ensures the virtual absence of the ylid from the mixture[20] (see above).

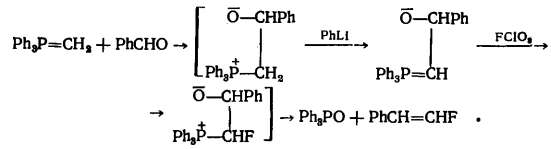
Dichloromethylenetriphenylphosphorane $Ph_3P=CCl_2$ has been isolated in the form of a yellow powder; its structure was demonstrated spectroscopically[67].

§ Schlosser and Zimmermann[9] do not give any details.

¶ The report of the isolation of the ylid (Ig) in a pure form[63] was erroneous (see above).

(g) Chlorofluoromethylenetris(dimethylamino)phosphorane $(Me_2N)_3P=CFCl$ *(Ih).* When Ph_3P reacts with dichlorofluoromethyltris(dimethylamino)phosphonium chloride in benzonitrile [Eqn.(7)], a very stable "olefinating" solution is formed (it does not decompose after 500 h at room temperature or after 24 h at 60 °C). On the other hand, if tris(dimethylamino)phosphine is used instead of triphenylphosphine, the above system can be used in the Wittig reaction only *in situ*[18]. These results can be explained by the different equilibrium positions[18,33] (see above).

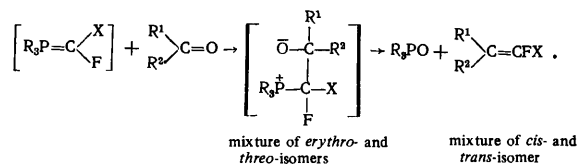
The quasi-complex salts obtained when dichlorofluoromethyltris(dimethylamino)phosphonium chloride is acted upon by metals [Eqn.(13)] are usually very stable[32,33]. The organozinc phosphonium salt does not decompose in THF after 10 h at 60 °C or after 30 days at room temperature; the solution in PhCN is less stable (2 h at 60 °C). The analogous cadmium derivative decomposes after 2 h at 60 °C in THF and after 1 h in PhCN. The mercury derivative is particularly stable (it does not decompose after 83 h at 60 °C in PhCN).



2. Fluorine-Containing Halogenomethylenephosphoranes in the Wittig Reaction. The Synthesis of Fluoro-olefins

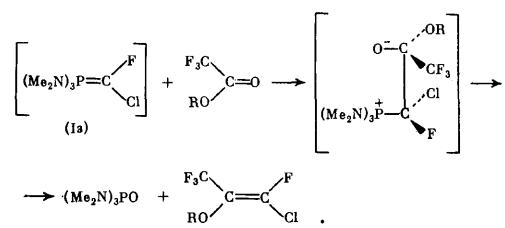
The synthesis of olefins by the Wittig reaction is the principal application of phosphorus ylids[1,2,4,6]. Fluorine-containing halogenomethylenephosphoranes are also widely used to synthesise fluoro-olefins from carbonyl compounds†.

The important role of fluoro-olefins as "key" compounds in organofluorine chemistry is known. Despite the abundance of methods for the synthesis of fluoro-olefins, the expansion of this field with the aid of the Wittig reaction is important.



The ease of the Wittig reaction depends on the nucleophilic properties of the ylid and the electrophilic properties of the carbonyl compound[1,2]. The introduction of a halogen into methylenephosphorane apparently reduces somewhat its nucleophilic reactivity[4], but it is nevertheless sufficient for interaction with aldehydes and also with ketones having electron-accepting fluoroalkyl groups. The conversion of inactive ketones into olefins is achieved with much more difficulty. The method of enhancing the nucleophilic properties of the ylid based on the introduction of electron-donating groups at the phosphorus atom has been used recently on an increasing scale. The employment of tris(dimethylamino)-phosphoranes $(Me_2N)_3P=CFX$ instead of triphenyl derivatives $Ph_3P=CFX$ makes it possible in a number of instances to convert into olefins also inactivated ketones. Equilibrium mixtures containing the phosphorus ylid in very low amounts are frequently used in the Wittig reaction instead of the "pure" halogenomethylenephosphoranes; only under the influence of a carbonyl compound does the ylid react with the latter and the equilibrium is displaced to the right. Such "olefinating" systems include mixtures of trihalogenomethylphosphonium salts with tertiary phosphines (see above) and quasi-complex organometallic phosphonium salts (see above). This form of the ylid usually ensures the stability of the "olefinating" agent, but reduces its reactivity.

Apart from using fluorine-containing phosphorus ylids in order to obtain fluoro-olefins, it is possible to apply also another procedure, which likewise involves the Wittig reaction. This is the SCOOPY method (α-substitution plus carbonyl olefination via β-oxido-phosphorus ylids)[4,71-73]. The method is based on the conversion with the aid of a strong base of the phosphobetaine formed from the phosphorus ylid and the carbonyl compound into a "β-oxido-phosphorus ylid", which reacts with an electrophile to form a new α-substituted phosphobetaine; the decomposition of the latter leads to a substituted olefin. For example, when "β-oxido-phosphorus ylid" is fluorinated with subsequent decomposition of the α-fluorophosphobetaine, an α-fluoro-olefin is formed[71]:

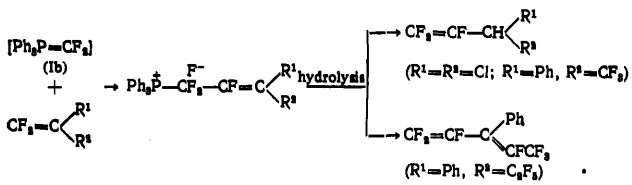


Thus, in terms of its results, this reaction is equivalent to the Wittig reaction with fluoromethylenephosphorane.

In reactions of monofluoro-, chlorofluoro-, and bromofluoro-methylenephosphoranes with aldehydes and asymmetric ketones there is a possibility of the *cis-trans* isomerism of the final products#. In contrast to the reactions with non-fluorinated active phosphorus ylids, which are frequently stereoselective[2,3,11,73,74], the reactions with halogenomethylenephosphoranes as a rule yield *cis*- and *trans*-olefins in approximately equal amounts[8,9,11,12,14-16,18,21,30,32,60]:

mixture of *erythro*- and *threo*-isomers — mixture of *cis*- and *trans*-isomer

Only the interaction of chlorofluoromethylenetris(dimethylamino)phosphorane with fluorocarboxylate esters proved to be stereoselective—mainly the *Z*-isomers of alkylpolyfluoroalkenyl esters are then formed[18,32] (see below). Evidently only one of the diastereoisomeric intermediate phosphobetaines is formed under these conditions:



(Ia)

The synthetic applications of fluorine-containing halogenomethylenephosphoranes are virtually limited to the Wittig reaction. However, there are data (without experimental details)[38] showing that difluoromethylenetriphenylphosphorane, generated by treating bromodifluoromethyltriphenylphosphonium bromide with mercury [Eqn.(11)], reacts with fluoro-olefins to form allylphosphonium salts—the products of the "vinyl" substitution of the fluorine atom in the olefin.

† Fluoro-olefins are also obtained from phosphorus ylids without fluorine and from fluorocarbonyl compounds[68,69]. An interesting pathway leading to fluoro-olefins arises from the reaction of phosphorus ylids with halogenocarbenes[70]: $Ph_3P=CR^1R^2 + :CF_2 \rightarrow Ph_3P + R^1R^2C=CF_2$.

For the mechanism and stereochemistry of the Wittig reaction, see Refs.2–4 and 73–77.

Hydrolysis of these salts leads to the cleavage of the C–P bond and the formation of olefins or dienes:

Methods for the introduction of the =CHF, $=CF_2$, =CFCl, and =CFBr groups with the aid of the Wittig reaction are examined below:

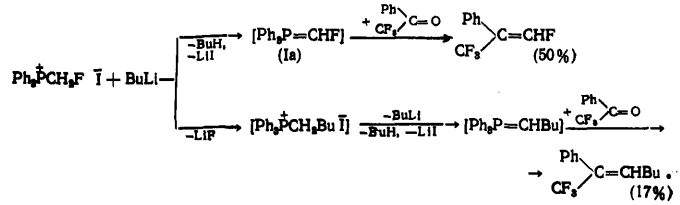
(*a*) *The introduction of the =CHF group.* α-Fluoro-α-hydro-olefins are obtained from fluoromethylenetriphenylphosphorane, generated either by the dehydrohalogenation of a fluoromethyltriphenylphosphonium salt [Eqn.(1)][8,9,11] or by the dehalogenation of a fluoroiodomethyltriphenylphosphonium salt [Eqn.(2)].[8,10] The reaction involves aldehydes (aliphatic and aromatic)[8–11] and ketones (activated and non-activated)[8,10]:

$$[Ph_3P{=}CHF] + RCHO \rightarrow RCH{=}CHF + Ph_3PO$$
(Ia) — mixture of *cis*- and *trans*-isomers (~ 1 : 1)

R = n-C_5H_{11}, n-C_6H_{13}, Ph, *m*-ClC_6H_4, or *m*-$CF_3C_6H_4$ (~ 20 °C, THF or CH_2Cl_2, yield 25–65%);
R = n-C_6H_{13}, Ph, or C_6F_5 (0 °C, DMF, yield 52–65%);

$$[Ph_3P{=}CHF] + \underset{R^1}{\overset{R}{\rangle}}C{=}O \rightarrow \underset{R^1}{\overset{R}{\rangle}}C{=}CHF + Ph_3PO$$
(Ia)

$RR^1 = -(CH_2)_5-$; Ph, Me (~20 °C, THF/hexane, yield 48–69%); RR^1 = $PhCF_3$ (0 °C, DMF, yield 80%).



A deuterated olefin was obtained similarly (yield 48%):[12]

$$[Ph_3P{=}CDF] + PhCHO \xrightarrow[THF]{20^\circ} PhCH{=}CDF .$$

A 17-fluoromethylene-substituted steroid has been formed from the 2-tetrahydropyranyl ether of 3β-hydroxo-17-oxo-5-androstene (yield 16%).[9] The attempts to obtain by this method fluoromethylene-substituted sugars from the corresponding ketones were unsuccessful[15].

In the case of non-activated ketones best results are obtained by generating the ylid (Ia) from a fluoromethylphosphonium salt [Eqn.(1)] and, in the case of aldehydes and trifluoroacetophenone, from a fluoroiodomethylphosphonium salt [Eqn.(2)] using the ylid *in situ* in a DMF solution[8].

When BuLi is used to dehydrohalogenate a phosphonium salt in accordance with Eqn.(1), the resulting "olefinating" solution is made to react with a carbonyl compound and the mixture is then treated with potassium t-butoxide; without such treatment, the yields of olefins are reduced[8]. It has been suggested that the betaines produced as intermediates in the Wittig reaction form stable complexes with lithium salts, which hinders their cyclisation to oxaphosphetans preceding the cleavage to the final product—an olefin and a phosphine oxide (cf. Schlosser and Christmann[78]). However, in certain cases the yield of the product of the Wittig reaction is reduced as a consequence of its interaction with t-BuOK. Another cause of the reduced yield of the fluoro-olefin is the formation of a butylolefin as a side product[8]:

Since it has been shown that the entire butyl-lithium is consumed before the ketone is added, the source of the butyl group in the side reaction is apparently a butyl-substituted phosphorus ylid.

It must be emphasised that in many cases it is more convenient to synthesise α-hydrofluoro-olefins by the selective reduction of the corresponding α,α-difluoro-olefins[29] or α-chloro-α-fluoro-olefins[15] and not by the Wittig reaction.

(*b*) *The introduction of the* $=CF_2$ *group.* α,α-Difluoro-olefins are usually obtained from difluoromethylenetriphenylphosphorane, but tributyldifluoromethylenephosphorane and difluoromethylenetris(dimethylamino)phosphorane are also used.

Difluoromethylenetriphenylphosphorane is usually generated from $ClCF_2COONa$ and Ph_3P [Eqn.(14)][43–54] and is used *in situ* in the Wittig reaction§. This ylid gives rise to satisfactory yields of α,α-difluoro-olefins on reaction with aldehydes[45,47,50] and activated ketones[43,52]:

$$[Ph_3P{=}CF_2] + RCHO \xrightarrow[N\text{-methylpyrrolidinone, etc}]{80-180^\circ} RCH{=}CF_2 + Ph_3PO ;$$
(Ib) — (50–75%)

R = n-C_6H_{13}, Ph, *p*-$MeOC_6H_4$, or *p*-FC_6H_4, ;

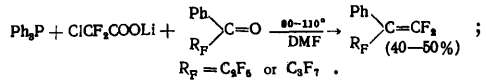
$$[Ph_3P{=}CF_2] + \underset{CF_3}{\overset{R}{\rangle}}C{=}O \xrightarrow[\text{diglyme, DMF; etc.}]{75-148^\circ} \underset{CF_3}{\overset{R}{\rangle}}C{=}CF_2 + Ph_3PO ;$$
(Ib) — (60–85%)

R = n-Bu, C_6H_{11}, $PhCH_2$, Ph¶, *p*-FC_6H_4, *p*-MeC_6H_4 or *p*-$MeOC_6H_4$.

In the reaction with *p*-dimethylamino-ω,ω,ω-trifluoroacetophenone the yield of the olefin *p*-$Me_2NC_6H_4C(CF_3){=}CF_2$ is only 16%.[43]

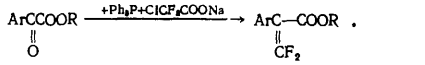
In many instances the products include, apart from α,α-difluoro-olefins, the products of their reactions in the presence of the F^- anion†. The use of lithium chlorodifluoroacetate instead of the sodium salt usually suppresses these reactions, since LiF is less reactive with respect to fluoro-olefins than NaF.[43,44] Thus the olefin *p*-$ClC_6H_4C(CF_3){=}CF_2$ (yield 32%) and the product of the addition of hydrogen fluoride *p*-$ClC_6H_4CH(CF_3)_2$ (yield 37%) have been obtained from *p*-chlorotrifluoroacetophenone, $ClCF_2COONa$, and Ph_3P in diglyme; in the reaction with the lithium salt in DMF the yield of the olefin increases to 64%.[43]

In the reaction with ketones containing perfluoroalkyl groups the isomerisation of the terminal fluoro-olefin to an internal fluoro-olefin is frequently observed[44], for example:



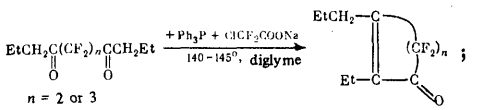
$$[Ph_3P{=}CF_2] + \underset{CF_3CF_2}{\overset{Ph}{\rangle}}C{=}O \xrightarrow{-Ph_3PO} \underset{CF_3CF_2}{\overset{Ph}{\rangle}}C{=}CF_2 \xrightarrow{400^\circ F} \underset{CF_3CF}{\overset{Ph}{\rangle}}C{-}CF_3 .$$
(Ib)

§ A mixture of a phosphine, an acid salt, and a carbonyl compound is heated in the solvent until the evolution of CO_2 ceases. When large amounts of the reactants are used, it is more convenient to add the salt solution dropwise to a heated solution of Ph_3P and the carbon compound[43,50]. When a lithium salt is used, the yield of the α,α-difluoro-olefin is increased[45].

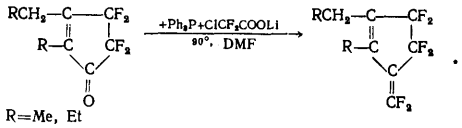


¶ The best yield of 2-phenylpentafluoropropene (80%) was obtained when the ylid (Ib) was generated from methyl chlorodifluoroacetate [Eqn.(18)].[57]

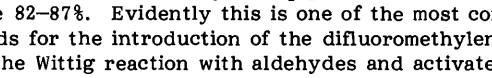
† It has been suggested[43,44] that the F^- anion is generated on decomposition of the ylid (Ib) or directly by the decarboxylation of $ClCF_2COOM$. The yield of the olefin *p*-$O_2NC_6H_4CH{=}CF_2$, formed from *p*-nitrobenzaldehyde, in only 2%, while the yield of the addition product HF–*p*-$O_2NC_6H_4CH_2CF_3$ is ~20%.[50]



However, the use of a lithium salt suppresses the isomerisation[43,44]:

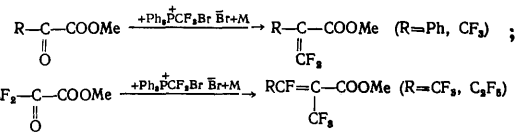


In contrast to aldehydes and activated ketones, cyclohexanone[51] and acetophenone[52] do not react with difluoromethylenetriphenylphosphorane, evidently owing to the insufficiently pronounced electrophilic properties of the carbonyl carbon[43]. The esters of aromatic α-ketoacids enter into the Wittig reaction, forming the esters of α-aryl-β,β-difluoroacrylic acids[54,79,80]:



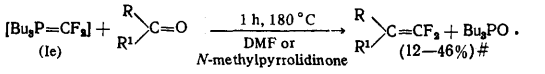
When the ylid (Ib) was generated by the "halogenoacetate" method, it was not possible to achieve the Wittig reaction with the diketones $PhCO(CF_2)_nCOPh$ (n = 2 or 3).[46] In the reaction with the analogous dipropyl-substituted diketones the ylid (Ib) induces their cyclisation to unsaturated ketones[46]:

Fluorocyclopentorones undergon the Wittig reaction (in contrast to the corresponding cyclohexanones) and give low yields of difluoromethylenecyclopentenes[46]:



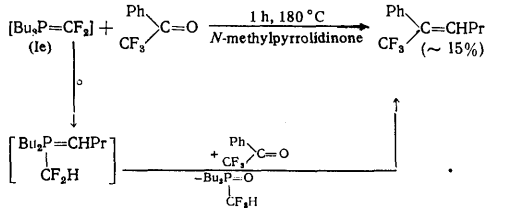
When another method of synthesis of the ylid (Ib) is used, namely from Ph_3P and CF_2Br_2 [Eqn.(4)], it is possible to involve also diketones in the Wittig reaction[28]:

This method of generation of the ylid (Ib) has been used successfully in the reactions with PhCHO,[23,24,29] PhCH=CHCHO,[29] $PhCOCF_3$,[20,25] p-$ClC_6H_4COCF_3$,[25] $PhCOC_2F_5$,[25] m-$BrC_6H_4COCF_3$,[25] and m-$BrC_6H_4COC_2F_5$;[25] the yields of olefins are 82–87%. Evidently this is one of the most convenient methods for the introduction of the difluoromethylene group in the Wittig reaction with aldehydes and activated ketones. However, particularly severe requirements are then imposed on the dryness of solvents[29].



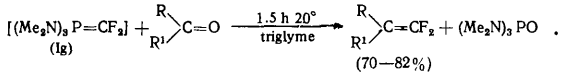
In the reaction with aldehydes the method of generation of difluoromethylenetriphenylphosphorane from Ph_3P, CF_2Br_2, and zinc [Eqn.(10)] is even more convenient. α,α-Difluoro-olefins are readily obtained by this procedure from n-C_6H_{13}.CHO, n-$C_{10}H_{21}CHO$, and PhCHO (yields ~80%), as well as PhCH=CHCHO (yield 33%);[29] there is then no need for especially thorough drying of solvents. In the reaction with PhCOMe the yield of difluoro-olefin does not exceed 5%.

The esters of α-substituted perfluoroacrylic acids and their isomerisation products have been obtained by the interaction of the esters of α-ketoacids with bromodifluoromethyltriphenylphosphonium bromide and a metal[28]:



Difluoromethylene-substituted sugars have been prepared by treating the corresponding oxo-derivatives with triphenylphosphine, dichlorofluoromethane, and KF.[15] The intermediate formation of the ylid (Ib) in the reaction of bromodifluoromethyltriphenylphosphonium bromide with KF and PhCOF was described above.

Since difluoromethylenetriphenylphosphorane does not as a rule enter into the Wittig reaction with non-activated ketones, the corresponding difluoro-olefins must be synthesised using other more active difluoromethylenephosphoranes. The use of tributyldifluoromethylenephosphorane, generated by the "halogenoacetate" method [Eqn.(15)], for this purpose has been described[51,55]:



The reaction is carried out *in situ* with cyclohexanone, benzophenone, and methylketones MeCOR (R = C_5H_{11}, Ph, 2-furyl, or 2-thienyl). In the reaction with heptanal the yield of the olefin n-$C_6H_{13}CH=CF_2$ is only 7%.[51]

In the interaction with trifluoroacetophenone the carbonyl oxygen is replaced by the butylidene group and not the difluoromethylene group, probably as a consequence of the isomerisation of the ylid (Ie):[43,51]

α,α-Difluoro-olefins could not be obtained either by treating phenyl α-pyridyl ketone, p-benzoquinone, hexachloroacetone, and camphor with tributyldifluoromethylenephosphorane[51].

The most convenient source of the difluoromethylene group in the Wittig reaction with non-activated ketones is evidently difluoromethylenetris(dimethylamino)phosphorane generated from dibromodifluoromethane [Eqns.(5) and (6)].[20,26,29,31]§ The enhanced nucleophilic activity of the ylid (Ig), induced by the electron-donating influence of the dimethylamino-groups, ensures high yields of difluoro-olefins from cyclohexanone, diethyl ketone, acetophenone, and propiophenone[20,26]:

The reaction can be carried out *in situ* or with preliminary generation of the "olefinating solution"[20,26]. However, one should use very thoroughly dried solvents[29].

This method is evidently unsuitable for the Wittig reaction with activated fluorine-containing ketones, because fluoroketones react with tris(dimethylamino)phosphine[64].

The ylid (Ig), generated from $(Me_2N)_3P$, CF_2Br_2 and zinc [Eqn.(12)] has been used successfully in reactions with aldehydes. The yield of 1,1-difluoro-oct-1-ene from n-$C_6H_{13}CHO$ is 77%. β,β-Difluoro-α-methylstyrene is formed in ~40% yield from acetophenone[29]. Careful drying of the solvent is not required.

#In a later communication it is stated[26] that the yields do not exceed 10%.

§For a description of the equilibrium in the $(Me_2N)_3\overset{+}{P}CF_2Br\ \overline{Br} + (Me_2N)_3P \rightleftharpoons (Me_2N)_3P=CF_2 + (Me_2N)_3PBr_2$ system, see above.

(c) *The introduction of the group =CFCl.* Chlorofluoromethylenetriphenylphosphorane and chlorofluoromethylenetris(dimethylamino)phosphorane are widely used in the synthesis of α-chloro-α-fluoro-olefins by the Wittig reaction.

When the ylid (Ic) is generated by the "halogenoacetate" method [Eqn.(16)][14,16] or its modification Eqn.(19)], aldehydes and activated ketones are successfully "olefinated" with formation of a mixture of *cis*- and *trans*-isomers of chlorofluoro-olefins (in proportions of ~1 : 1):

$$[Ph_3P{=}CFCl] + RCHO \xrightarrow[\text{ether}]{\text{triglyme or petroleum}} RCH{=}CFCl + Ph_3PO \quad (25\text{—}63\%)$$
(Ic)

R = n-Bu, Ph, *p*-ClC_6H_4, *p*-$MeOC_6H_4$, or *o*-$MeOC_6H_4$;

$$[Ph_3P{=}CFCl] + \underset{CF_3}{\overset{R}{\diagdown}}C{=}O \xrightarrow[\text{triglyme}]{90^\circ} \underset{CF_3}{\overset{R}{\diagdown}}C{=}CFCl + Ph_3PO \quad (30\text{—}70\%)$$
(Ic)

R=n-Bu, C_6H_{11}, $PhCH_2$, Ph, *p*-ClC_6H_4, *p*-FC_6H_4, *p*-MeC_6H_4, *p*-$MeOC_6H_4$;

$$[Ph_3P{=}CFCl] + \underset{R_F}{\overset{Ph}{\diagdown}}C{=}O \xrightarrow[\text{triglyme}]{90^\circ} \underset{R_F}{\overset{Ph}{\diagdown}}C{=}CFCl + Ph_3PO \quad (41\text{—}42\%)$$
(Ic)

R_F=C_3F_8, n-C_3F_7.

Non-activated ketones enter into this reaction with difficulty, so that there is sufficient time for the decomposition of the ylid (Ic).[14,16] It has been shown[60] that the reactivity of carbonyl compounds in relation to chlorofluoromethylenetriphenylphosphorane decreases in the sequence *p*-ClC_6H_4. .CHO > PhCHO > $PhCOCF_3$ > PhCOMe. Benzophenone could not be "olefinated" and the reactions with acetophenone, cyclopentanone, and cyclohexanone gave only small yields of the corresponding olefins[14,16,60]. Nor was it possible to make 1,2-dialkylhexafluorocyclohex-3-enones to undergo the reaction[46].

The esters of α-aryl-β-chloro-β-fluoroacrylic acids were obtained from the esters of aromatic α-ketoacids[54]:

$$Ar{-}\underset{\underset{O}{\|}}{C}{-}COOR \xrightarrow{+Ph_3P+CCl_2FCOONa} Ar{-}\underset{\underset{CFCl}{\|}}{C}{-}COOR .$$

When the ylid (Ic) is generated from Ph_3P, $CHFCl_2$, and t-BuOK [Eqn.(3)], which requires milder conditions than the synthesis by the "halogenoacetate" method, chlorofluoromethylenecyclopentane is formed from cyclopentanone in 27% yield[14,16]. The report that benzophenone was made to undergo the reaction[13] was not confirmed[14,16]. Olefins have also been obtained by this method from benzaldehyde and from activated ketones[14,16]:

$$[Ph_3P{=}CFCl] + \underset{XCF_2}{\overset{Ph}{\diagdown}}C{=}O \xrightarrow[\text{heptane}]{20^\circ} \underset{XCF_2}{\overset{Ph}{\diagdown}}C{=}CFCl + Ph_3PO \quad (30\text{—}50\%)$$
(Ic)

X = F or Cl .

Yet another method of synthesising chlorofluoromethylenetriphenylphosphorane, namely from Ph_3P, $CFCl_3$, and zinc (60 °C in DMF) [Eqn.(9)], also makes it possible to introduce into the Wittig reaction only aldehydes (heptanal and benzaldehyde) and an activated ketone (trifluoroacetophenone)[21,33]; the yield of the product from cyclopentanone is only 4%.[21]

Ketosugars were converted into chlorofluoromethylene derivatives on treatment with the ylid (Ic), generated from dichlorofluoromethylenephenylmercury in accordance with Eqn.(20).[15]

Chlorofluoromethylenetris(dimethylamino)phosphorane is apparently very convenient for the synthesis of α-chloro-α-fluoro-olefins by the Wittig reaction[18,32,33]. This ylid is generated by the dehalogenation of dichlorofluoromethyltris-(dimethylamino)phosphonium chloride on treatment with a tertiary phosphine [Ph_3P or $(Me_2N)_3P$—Eqn.(7)][18,32,33] or a metal [Eqn.(13)].[32,33]

The phosphorus ylid (Ih) is much more reactive than its triphenyl-substituted analogue (Ic), which makes it possible to carry out the Wittig reaction for non-activated ketones. At the same time the methods for the generation of this ylid ensure the formation of very stable "olefinating solutions" (see above). All this, together with the availability of the initial compounds, makes the use of chlorofluoromethylenetris(dimethylamino)phosphorane in the Wittig reaction particularly promising.

The reaction with aldehydes (heptanal and benzaldehyde) under mild conditions (60 °C, DMF) afforded chlorofluoro-olefins in quantitative yields[32].

The ylid (Ih), generated by the dehalogenation of the phosphonium salt by Ph_3P or Zn/Cu, successfully "olefinates" activated ketones[18,32,33]:

$$(Me_2N)_3P{=}CFCl + \underset{CF_3}{\overset{R}{\diagdown}}C{=}O \xrightarrow[\text{THF, triglyme, or PhCN}]{0\text{–}60^\circ} \underset{CF_3}{\overset{R}{\diagdown}}C{=}CFCl + (Me_2N)_3PO; \quad (75\text{—}100\%)$$

R = Ph or CF_3.

In dehalogenation by tris(dimethylamino)phosphine, fluoroketones cannot be introduced into the reaction, since they are cleaved[18,64]. However, this method (together with dehalogenation by a metal) is most convenient for reactions with non-activated ketones. The yield of the olefin from acetophenone is 56–70%;[18,32] the reaction does not take place with benzophenone and that with cyclopentanone gives an 18% yield of the olefin[32].

The reactions of the ylid (Ih) with the esters of fluoroacids, leading to alkyl fluoroalkenyl ethers, are of particular interest[18,32]¶:

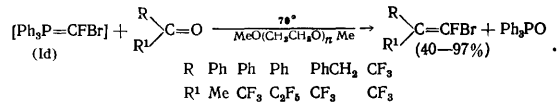
$$\underset{(Ih)}{[(Me_2N)_3P{=}CFCl]} + \underset{RO}{\overset{R_F}{\diagdown}}C{=}O \xrightarrow[\text{or PhCN}]{\text{triglyme}} \underset{RO}{\overset{R_F}{\diagdown}}C{=}C\overset{F}{\underset{Cl}{\diagdown}} + (Me_2N)_3PO; \quad (21\text{—}90\%)$$

R_F=CF_3, HCF_2, $ClCF_2$, C_2F_5 or C_3H_7; R=Me, Et or iso-Pr.

The best results were obtained with methyl trifluoroacetate; methyl dichlorofluoroacetate and *N*,*N*-dimethyldifluoroacetamide do not enter into the reaction[32].

In contrast to the interaction with aldehyde and ketones, the reaction with esters is stereoselective—the Z-isomers are mainly formed[18,32].

The use of tributylchlorofluoromethylenephosphorane in the Wittig reaction is much less convenient than that of the ylids (Ic) and (Ih). The tributyl-substituted phosphorus ylid is more reactive in reactions with carbonyl compounds than the triphenyl-substituted ylid, but the instability of the ylid (If) precludes its wide-scale employment[14,16]. Nevertheless, when the ylid (If) was generated by the "halogenoacetate" method [Eqn.(17)], chlorofluoromethylenecyclopentane was obtained in 25% yield by the reaction with cyclopentanone (85 °C, triglyme, *in situ*); when the triphenylylid (Ic) is used under the same conditions, the yield of the olefin is only 9%.[14,16]



(d) *The introduction of the group =CFBr.* α-Bromo-α-fluoro-olefins are obtained by the Wittig reaction with the aid of bromofluoromethylenetriphenylphosphorane generated from triphenylphosphine and tribromofluoromethane [Eqn.(4)].[30]† The reaction can be carried out either *in situ* or

---

¶These unsaturated ethers polymerise when an attempt is made to isolate them, but their formation has been rigorously demonstrated with the aid of NMR.[18,32]

†The use of the "halogenoacetate" method [Eqn.(16)] is less convenient[30].

with preliminary preparation of a stable "olefinating" solution. The ylid (Id) reacts fairly readily even with non-activated ketones. The Wittig reaction results in the formation of bromofluoro-olefins in the form of mixtures of *cis*- and *trans*-isomers (in proportions of ~1 : 1):

(Id) (40—97%)

R	Ph	Ph	Ph	$PhCH_2$	CF_3
R^1	Me	CF_3	C_2F_5	CF_3	CF_3

It is clear from the data presented that fluorine-containing halogenomethylenephosphoranes are highly reactive intermediates, which can be used successfully in the synthesis of fluoro-olefins and related compounds by the Wittig reaction. The use of a wide variety of methods for their generation and the introduction of different kinds of groups at the phosphorus atom permit a specific regulation of the stability and nucleophilic activity of these intermediates.

Oxidative Dehydrodimerisation and Cyclisation Reactions of Unsaturated Hydrocarbons in the Presence of Oxide Catalysts

E.A.Mamedov

The review is devoted to a comparatively new type of heterogeneous-catalytic processes—oxidative dehydrocoupling and cyclisation reactions of hydrocarbons with unsaturated bonds. The catalysts used in these processes and the rules governing their selection are examined. A systematic account is given of data on the kinetics and mechanisms of the reactions. Certain general characteristics of processes of this type are formulated and the problem of the selection of catalysts is discussed on their basis.
The bibliography includes 143 references.

I. INTRODUCTION

Oxidative dehydrodimerisation and cyclisation of unsaturated hydrocarbons constitute a comparatively new type of processes within the large class of heterogeneous catalytic reactions involving molecular oxygen. The first reports, demonstrating the possibility of these processes in principle, appeared in the patent literature in the middle 1960's and immediately attracted the attention of investigators.

The interest in the reactions under consideration is due to the possibility of processing numerous hydrocarbons with a mobile hydrogen atom in the α-position relative to the unsaturated bond. By specific catalytic synthesis, it is possible to obtain symmetrical dehydrodimers and in many instances the products of the subsequent reactions, which have practical applications. With the aid of these processes, it is possible to obtain, for example, diallyl and benzene from propene, *p*-xylene from isobutene, bibenzyl and *trans*-stilbene from toluene, and *p*-terphenyl from α-methylstyrene.

A number of advantages arise from the reactions being carried out in the presence of molecular oxygen compared with the familiar dehydrocyclodimerisation[1] and dehydrocyclisation[2] of paraffins and olefins. As a result of the oxidation of the eliminated hydrogen, these reactions are exothermic and the degree of conversion of the initial substance is not limited by the equilibrium conditions. The absence of carbon deposition ensures the stable operation of the catalyst and hence the continuity of the process. Finally, the oxidative version of the reaction is characterised by a narrower set of products, which greatly facilitates the isolation and purification of the required substances.

Apart from their applied importance, the oxidative dehydrodimerisation and cyclisation reactions of unsaturated hydrocarbons are of theoretical interest as an additional and convenient model for the application and refinement of the postulates of the theory of oxidative-reductive and acid–base catalysis.

Taken together, all these factors stimulated the publication during the last decade of a comparatively large number of patents and communications devoted to the above type of reactions. Among these, there have been reviews[3-5], which, however, suffer from being incomplete and one-sided. They describe mainly the compositions of catalysts found empirically and the conditions of the oxidative dehydrodimerisation and aromatisation reactions of the lower olefins. Considerably less attention has been devoted to the principles of the selection of catalysts and the problems of the reaction mechanisms, the principal data on which have been obtained very recently. Nor do they discuss the position occupied among other oxidative heterogeneous catalytic processes by dehydrocoupling reactions and the limits of the applicability to the latter of the special relations which have accumulated for total and partial oxidation reactions of hydrocarbons. The elimination of these gaps was one of the aims of the present review, which is based on studies published in the last 10–12 years.

II. OXIDATIVE DEHYDRODIMERISATION AND CYCLISATION OF OLEFINS

The principal products of the oxidative dehydrodimerisation and aromatisation of propene are hexa-1,5-diene and benzene and those obtained from isobutene are 2,5-dimethylhexa-1,5-diene and *p*-xylene. This difference from the thoroughly investigated reactions involving the partial oxidation of propene and isobutene to the corresponding unsaturated aldehydes and acids and oxidative dehydrogenation of *n*-butenes and isopentene to butadiene and isoprene is due to the differences between the compositions of the catalysts employed.

1. Process Catalysts

Table 1 presents the known catalysts of the oxidative dehydrodimerisation and cyclisation reactions of olefins. The vast majority of them consist of metal oxides. The use of noble metals, for example silver[6,7] and palladium[8], for this purpose has not developed owing to their high cost and the lack of significant advantages over oxide catalysts. For a number of technological reasons, it is difficult to carry out the process in the presence of melts of metals such as bismuth and tin[9] or salt melts of the type of lithium iodide[10].

The simple metal oxides are as a rule relatively ineffective as regards the formation of diolefinic and aromatic hydrocarbons. Among the last number of specimens investigated

Table 1. Catalysts for the oxidative dehydrodimerisation and aromatisation of olefins.

Catalyst	Method of preparation of catalyst	Reaction conditions*	Conversion of olefin, %	Selectivity, %		Refs.
				w.r.t. diolefin**	w.r.t. aromatic products	
Metallic Ag with added alkaline earth metal oxides	decomposition in a stream of air at 220 °C of silver carbonate deposited from aqueous suspension	500°; $C_3H_6 : O_2 = 39 : 1$; $t_c = 0.56$ s	1.1	61.9	—	6,7
Metallic Bi, Sn, and their alloys in the liquid state	–	593°; C_3H_6 : air = 1 : 2; t_c = 0.2—3 s	16.6	22.4	54.4	9
Fused 98% LiI + 2LiOH mixture	–	480°; iso-$C_4H_8 : O_2 = 4.2 : 10$; t_c = 0.1—5 s	36.5	—	68.8	10
Bismuth oxide	decomposition of the hydroxide at 550 °C in 24 h	575°; C_3H_6 : air : He = 2 : 5 : 10, t_c = 2.1 s	28.5	57.0	5.4	12, 13
Indium oxide	decomposition of the hydroxide at 560°	480°; $C_3H_6 : O_2 = 5 : 1$ t_c = 1.2 s	—	22.6	40	14
Thallium oxide	decomposition at 500° of the hydroxide deposited from nitrate solution by sodium hydroxide	520°; $C_3H_6 : O_2 = 10 : 1$ t_c = 4 s	—	78.0	—	14
Lead oxide deposited on Al_2O_3	repeated impregnation of the carrier *in vacuo* with a solution of the nitrate salt; heat treatment at 700°	493°; $C_3H_6 : O_2 = 15.7 : 1$; pressure —3.2 atm; t_c = 0.04 s	5.6	76	—	15, 16
Bismuth–tin oxide catalyst; Bi : Sn = (1–9) : (9–1) (best 1 : 1)	heat treatment of a mixture of individual oxides at 540° for 16 h	470°; $C_3H_6 : O_2 = 1.4 : 1$; t_c = 3 s	24.5	—	61.5	19, 20
Bismuth–tin oxide catalyst (Bi : Sn = 2 : 3)	heat treatment of a mixture of bismuth nitrate and tin dioxide at 750° for 28 h	575°; C_3H_6 : air : He = 2 : 5 : 10, t_c = 1.1 s	18	24.2	27.5	22
Bismuth–phosphorus oxide catalyst (Bi : P = 2 : 1)	deposition from an acidified solution of bismuth nitrate and ammonium phosphates, drying, and heat treatment at 500°	500°; $C_3H_6 : O_2 = 1 : 1.6$; t_c = 1.0 g s ml^{-1}	85.8	—	44.9	25
Bismuth–phosphorus oxide catalyst (Bi : P = 2 : 1 with addition of 0.6% Na_2O)	joint deposition at pH 6; heat treatment of dried deposit at 600°	550°; $C_3H_6 : O_2 = 5.6 : 1$; t_c = 0.36 s	6.9	47	—	28
Bismuth–titanium oxide catalyst (Bi : Ti = 1 : 1)	heat treatment of a mixture of oxides	550°; $C_3H_6 : O_2 : N_2 = 1 : 2 : 8.1$; t_c = 2.0 s ml^{-1}	81.9	—	29.1	11, 30
Bismuth–titanium oxide catalyst (Bi : Ti = 4 : 3)	heat treatment of a mixture of bismuth nitrate and titanium oxide at 750°	575°; C_3H_6 : air : He = 2 : 5 : 10; t_c = 1.2 s	20.2	26.8	24.6	22
Bismuth–titanium oxide catalyst (Bi : Ti = 2 : 1)	evaporation of a solution of bismuth nitrate and titanium dioxide in dilute nitric acid, drying, and heat treatment at 500°	575°; C_3H_6 : air : He = 2 : 5 : 10; t_c = 2.1	22.0	38.4	17.5	13
Bismuth–zinc oxide catalyst [Bi : Zn = (1–3) : (3–1)]	heat treatment of a mixture of bismuth nitrate and zinc acetate at 600° for 4 h	585°; $C_3H_6 : O_2 = 5.6 : 1$; t_c = 0.36 s	3.3	58.5	—	23
Mixture of bismuth and indium oxides on a carrier (Bi : In = 7 : 3)	–	500°; iso-$C_4H_8 : O_2 = 1 : (0.3—1)$; t_c = = 1—15 s	26.2	10.5	50.3	33
Bismuth–antimony oxide catalyst (Bi : Sb = 1 : 1)	heat treatment of a mixture of oxides in air at 600° for 4 h	585°; $C_3H_8 : O_2 = 5.6 : 1$; t_c = 36 s	10.0	50.0	—	23
Bismuth and antimony oxides on a carrier promoted with Na, Cu, or Zr oxides	–	420°; iso-$C_4H_8 : O_2 = 4 : 1$; t_c = = 0.45 s	32.0	65.0	—	34
Bismuth–nickel oxide catalyst (Bi : Ni = 1 : 1)	mixing and heat treatment of individual oxides at 540°	470°; C_3H_6 : air . $H_2O = 1 : 4 : 3$; t_c = 7.5 s	51.2	25.3	46,5	35
Bismuth–copper oxide catalyst (Bi : Cu = 1 : 1)	heat treatment of a moistened mixture of oxides at 540°	470°; iso-C_4H_8 . air : $H_2O = 1 : 4 : 3$; t_c = 7.5 s	51.5	30.5	45,6	35
Bismuth–iron oxide catalyst (Bi : Fe = 1 : 1)	decomposition of a mixture of bismuth and iron nitrates	575°; C_3H_6 : air : He = 2 : 5 : 10; t_c = 1.1 s	16.1	20.7	14.6	22
Bismuth–iron oxide catalyst (Bi : Fe = 2 : 1)	heat treatment of a mixture of oxides at 600–700° for 4 h	586°; $C_3H_8 : O_2$ = 5; 7 : 1; t_c = 0.36 s	6.8	49.0	9.8	36
Bismuth–cadmium oxide catalyst (Bi : Cd = 5 : 3.5 with added lead and magnesium oxides)	heat treatment of a moistened and dried mixture of oxides at 540° for 16 h	500°; C_3H_8 (iso-C_4H_8) : air : H_2O = = 1 : 8 : 2; t_c = 4.3 s	20.0 (17.0)	—	55.2 (56.3)	37
Bismuth oxide deposited on alundum with added 2.8% K_2O	successive impregnation of the carrier with solutions of bismuth nitrate and potassium hydroxide, drying at 120°, and heat treatment at 550°	550°; $C_3H_6 : O_2 : N_2 = 10.8 : 1 : 71.5$	12.0	77.0	—	44
Bismuth–zirconium oxide catalyst (Bi : Zr = 2 : 3)	decomposition of a mixture of bismuth nitrate and zirconium oxide	575°; C_3H_6 : air : He = 2 : 5 : 10; t_c = 1.1 s	18.0	28.0	14.8	22
Bismuth–niobium catalyst (Bi : Nb = 1 : 1)	heat treatment of a mixture of bismuth nitrate and niobium oxide	575°; C_3H_6 : air : He = 2 : 5 : 10; t_c = 2.1 s	2.6	28.2	27.8	13
Bismuth–tungsten oxide catalyst (Bi : W = 2 : 1)	heat treatment of a mixture of bismuth nitrate and tungsten trioxide	575°; C_3H_6 : air : He = 2 : 5 : 10; t_c = 2.1 s	14.4	6.1	19.9	13
Bismuth arsenate $BiAsO_4$ (monazite)	evaporation of a mixture of solutions of bismuth nitrate and the ammonium salt of a hydroxy acid with subsequent heat treatment	500°; $C_3H_6 : O_2 : N_2 = 1 : 2 : 8.1$; t_c = = 2 g s ml^{-1}	69	—	33.8	11, 30
Bismuthyl sulphate $(BiO)_2SO_4$	decomposition of bismuth sulphate in air at 600°	500°; $C_3H_6 : O_2 : N_2 = 1 : 2 : 8.1$; t_c = = 2 g s ml^{-1}	61	—	10.1	11, 30
Manganese and sodium oxides (Mn : Na = 1 : 2) on Al_2O_3, SiC, and aluminosilicate carriers	fusion of manganese dioxide with Group IA and IIA metal oxides or decomposition of a mixture of acetates, oxalates, and formates	638°; $C_3H_6 : O_2 = 1 : 1$; t_c = 0.05 s	—	54.5	—	47, 48
Mixture of manganese and sodium oxides (Mn : Na = 1 : 2.3) on alumina	impregnation of the carrier with solutions of manganese and sodium acetates	627°; $C_3H_6 : O_2 = 4 : 1$; t_c = 0.1—5 s; HBr introduced into gas phase	9.0	7.4	46.6	49
Tin–cadmium oxide catalyst (Sn : Cd = 0.33 : 1)	evaporation of a mixture of cadmium oxide and a solution of metallic tin in nitric acid followed by heat treatment of the deposits at 400° for 6 h	570; iso-$C_4H_8 : O_2 = 1 : 2$; t_c = 3 s	62.5	13.4	65.5	50

*t_c = reaction time.

**The diolefin should be understood as hexa-1,5-diene in the oxidation of propene and 2,5-dimethylhexa-1,5-diene in the oxidation of isobutene.

***The main aromatic products of the conversion of propene and isobutene are benzene and *p*-xylene respectively.

by Seiyama[11], bismuth, cadmium, zinc, and tin oxides proved to be comparatively selective in the oxidative dehydroaromatisation of propene. Analogous data have been published for bismuth oxide[12,13]. The selectivity with respect to the desired products reaches 60% in the presence of the above catalysts for a degree of conversion of the initial olefins of 28%. Indium and thallium oxides are also relatively selective[14] in the presence of a large excess of the olefin in the initial mixture. In the presence of these catalysts the overall selectivity with respect to diallyl and benzene is 60–80% for a conversion of propene less than 1%. Lead oxide has similar parameters[15–17].

Almost all the individual oxides mentioned above exhibit a low activity but a comparatively high selectivity. An additional characteristic feature of lead and thallium oxides is instability of activity due to the reduction of lead oxide to the inactive metal[17] and the volatility of thallium (I) compounds formed in the catalytic process[18]. Two-component oxide systems are more active in oxidative dehydrodimerisation and aromatisation reactions of the lower olefins. The largest group consists of catalysts based on bismuth oxide. Combinations of the latter with the oxides of tin[19–24], phosphorus[25–29], titanium[13,22,30,31], zinc[23,32], indium[33], antimony[23,24], nickel[35], copper[34,35], iron[22,35,36], cadmium[30,37], lead[37], manganese[38], and a number of other metals are effective.

The increased activity of complex oxides compared with simple oxides is apparently associated with the formation of definite catalytically active compounds. In the study of the phase compositions of bismuth–tin[39–41], bismuth–iron[36], and bismuth–titanium[42] oxide catalysts, the existence in the latter of bismuth pyrostannate ($Bi_2Sn_2O_7$), orthoferrite ($BiFeO_3$), and pyrotitanate ($Bi_2Ti_2O_7$) respectively was observed. The catalysts exhibit the maximum activity for approximately the above ratios of the elements. The data of the present author and his coworkers[41], illustrated in Fig. 1, show that the rate and selectivity of the formation of the products of the oxidative dehydrodimerisation and aromatisation of propene in the presence of bismuth–tin oxide catalysts vary in parallel with their content of the $Bi_2Sn_2O_7$ phase. A similar variation has also been established for specimens with an identical ratio of bismuth and tin obtained by different methods and differing in phase composition as a result[43].

When other metal oxides are introduced into bismuth oxide, a change in the composition of the reaction products is sometimes observed together with an increase of the overall activity. Thus, when zinc oxide[32], tin dioxide[40], and indium oxide[33] are used as the second component, the fraction of aromatic hydrocarbons increases significantly compared with pure bismuth oxide, in the presence of which the main reaction product is a diolefinic hydrocarbon.

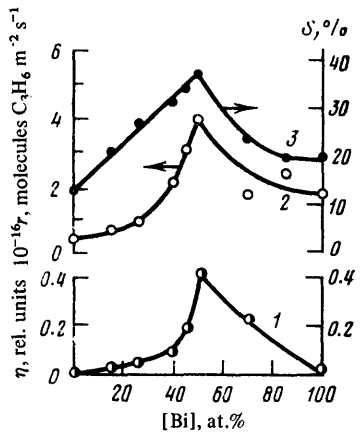

Figure 1. The influence of the composition of bismuth–tin oxide catalysts on the relative content η of the $Bi_2Sn_2O_7$ phase (curve *1*), the rate *r* (curve *2*), and the selectivity *S* (curve *3*) in the overall formation of diallyl and benzene[41].

Small amounts of added alkali metal oxides cause an appreciable increase of the selectivity of bismuth-containing catalysts in olefin dehydrodimerisation and aromatisation reactions[24,28,34,44,45]. Thus, according to a patent[44], the introduction of 2.8% of potassium oxide into deposited bismuth oxide increases the selectivity with respect to hexa-1,5-diene from 70 to 77% for the same degree of conversion of propene. Small amounts of alkali metal oxides have a similar influence on the catalytic properties of tin dioxide[11,30]. Fig. 2 shows that the maximum selectivity in the formation of benzene is observed in the presence of 5 at.% of sodium oxide in tin dioxide. These amounts of sodium oxide are uniformly dispersed on the surface of tin dioxide and do not form a chemical compound with the latter[5]. In the presence of more than 5 at.% of sodium dioxide, the uniformity of the distribution breaks down and the compound Na_2SnO_3, completely inactive in the oxidative reaction of propene, is

formed[5]. For this reason sodium bismuthate, while fairly selective, is apparently characterised by a low activity compared with bismuth oxide[46].

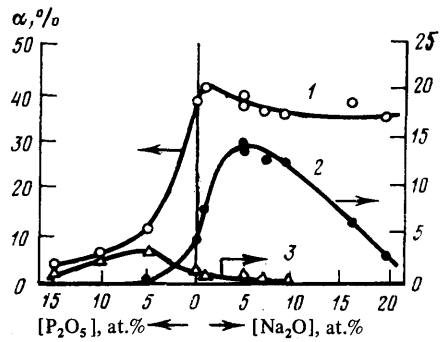

Figure 2. The promoting influence of sodium and phosphorus oxides on the catalytic properties of tin dioxide: *1*), *2*), and *3*) degrees of conversion of propene into carbon dioxide, benzene, and acrolein respectively[11].

In conclusion of the brief consideration of bismuth-containing catalysts, one must note that the introduction of zirconium[22], niobium[13], tungsten[13], arsenic[11,30], sulphur[11], and aluminium[30] compounds into bismuth oxide does not improve significantly and in some cases actually impairs its catalytic properties.

Among other oxide systems, mention should be made of the sodium–manganese oxide system[47–49]. While exhibiting a satisfactory selectivity with respect to the oxidative dehydrodimerisation and aromatisation products (50–55%), these catalysts have a low activity even at high temperatures: at 627 °C the degree of conversion of propene in their presence does not exceed 5–10%. The tin–cadmium oxide system is more active[50]. Thus, in the presence of the oxide catalyst with the composition Sn/Cd = 0.4, the degree of conversion of isobutene reaches 65–67% for a selectivity in the formation of *p*-xylene of 58–65%.

Attempts have been made to use "heterogenised" metal complex catalysts in the oxidative dehydrodimerisation of propene[51,52]. It was shown that, in the presence of palladium- and iron-containing complexes deposited on a natural silicate mineral, diallyl and benzene are formed at lower temperatures (200–300 °C) and in larger amounts than in the presence of bismuth oxide. However, here it is necessary to solve the problem associated with the stability of the activity of catalysts of this kind.

It has been suggested in a number of patents[53–56] that the reactions be carried out in the absence of gaseous oxygen and that the hydrogen split off in the dehydrodimerisation and aromatisation of the olefin be combined with the oxygen of the oxide, i.e. that the catalyst be used as an oxidant. It appears difficult to assign this version of the process to oxidative heterogeneous-catalytic reactions and to specify a clear-cut boundary between them and dehydrocyclodimerisation processes[1]. This review therefore deals only with processes carried out in the presence of molecular oxygen.

Thus the foregoing permits the conclusion that the catalysts of oxidative dehydrodimerisation and aromatisation reactions of olefins differ appreciably in their qualitative composition from the known partial oxidation catalysts containing as a rule molybdenum, tungsten, vanadium, antimony, arsenic, and tellurium oxide compounds. From this standpoint, the report[57] that the uranium–antimony catalyst, which is extremely effective in the partial oxidation and oxidative dehydrogenation reactions of olefins, is active in the dehydrodimerisation reaction appears unexpected[58,59].

2. Certain Characteristics of the Selection of Catalysts

The catalytic activities of a large number of simple and complex oxides with respect to the total oxidation of hydrocarbons are known[60–62] to be determined by the binding energy of the surface oxygen—the smaller the bond strength, the higher the rate of oxidation. The situation is more complex in partial oxidation processes whose most important characteristic is selectivity with respect to a specific substance. It has been shown for a number of reactions[60,63,64] that the selectivity with respect to mild oxidation products increases with increasing energy of the oxygen–catalyst bond.

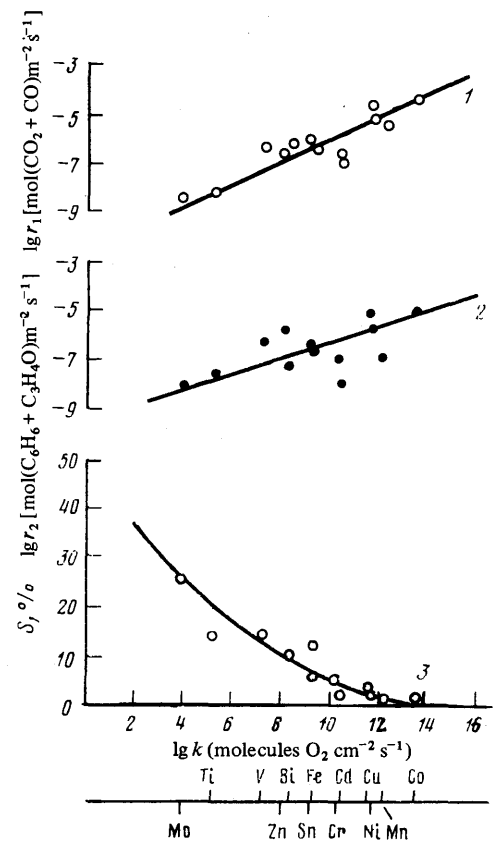

Figure 3. Dependence of the rate of total oxidation r_1 (curve *1*) and the rate r_2 (curve *2*) and selectivity S (curve *3*) in the allyl oxidation of propene[11] in the presence of simple oxides on the mobility of the surface oxygen, i.e. on the rate constant for the homomolecular exchange of oxygen k.[102]

An attempt to test the possibility of the existence of correlations of this kind for the oxidehydroaromatisation of propene was undertaken by Seiyama[11], who used the heats of formation of the individual oxides as a measure of the strength of binding of oxygen in them. When these quantities were compared with the rates of extensive and mild (acrolein + benzene) oxidative conversion of propene, it was found that the oxides can be divided into two groups, differing, according to the author, by the type of oxygen isotope exchange occurring in them. This factor as well as the considerable scatter of the points are apparently caused by the fact that the heats of formation of the oxides characterised their bulk-phase and not surface properties. It is more correct to use for this purpose the heats of desorption of the equilibrium oxygen[65] or the rates of homomolecular oxygen isotope exchange[66]. Fig. 3 shows that in the latter case the subdivision of oxides into two groups disappears and the correlation is more clear-cut.

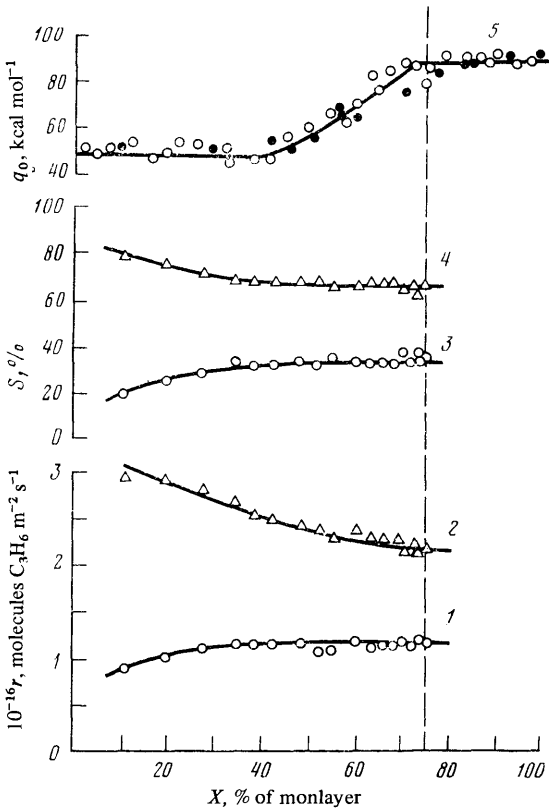

Figure 4. The influence of the degree of reduction X of the surface of the bismuth–tin oxide catalyst on the rate r and the selectivity S in the formation of diallyl (curves 1 and 3) and carbon dioxide (curves 2 and 4) and on the binding energy of oxygen q_0 (curve 5). The stationary state of the catalyst is indicated by a dashed line[69].

Fig. 3 also shows that the catalytic activity with respect to partial oxidation increases with increase of the mobility of surface oxygen to a smaller extent than in the case of total oxidation. As a result, the selectivity with respect to the overall formation of acrolein and benzene falls with decrease of the strength of binding of oxygen to the catalyst. It may be that this behaviour is caused by the fact that in the rate-limiting stage of the total oxidation reaction a larger number of oxygen–catalyst bonds are broken than in dehydroaromatisation, which is similar to the explanation used for the extensive and mild oxidation reactions of hydrocarbons[67,68].

A test of the validity of the above correlations for complex oxide catalysts of the oxidehydrodimerisation of olefins is at present difficult owing to the lack of data for the binding energies of surface oxygen in such catalysts. The possibility of the existence of correlations of this kind is supported by the results of a comparison of the relations presented in Fig. 4 between the catalytic activities and the binding energies of oxygen, on the one hand, and the degree of reduction of the bismuth–tin oxide catalyst, on the other[69]. Evidently the removal of weakly bound oxygen from the surface during the catalytic process reduces the selectivity of the total oxidation reaction and increases that with respect to diallyl - the product of the mild conversion of propene.

The problem of the way in which the strength of binding of oxygen to the catalyst influences the rate of partial oxidation of olefins to unsaturated aldehydes, on the one hand, and the rate of dehydrodimerisation, on the other, is also important. However, the relation between these quantities has not so far been discovered. One cannot rule out the possibility that different forms of surface oxygen participate in the reaction.

The dependence of the mode of oxidative transformation of olefins on the acid—base properties of the catalyst has been studied in greater detail. For many simple[11] and bismuth-,[30] zinc-,[70] cadmium-,[70] and tin-containing[71] binary oxides, it has been established that an increase of the acidity of the catalyst entails a decrease of the rate and selectivity of the formation of propene dehydrodimerisation and aromatisation products and of the increase of the yields of acrolein. The electronegativity of the metal cations[11,70], the strengths of the acid centres found by titration with *n*-butylamine[30,72], and the activity in the isomerisation involving the double bond in but-1-ene[71] are used as characteristics of the acid properties. Table 2 presents as an example, data[30] whereby one can follow the above relation between the selectivity in the oxidehydroaromatisation and partial oxidation reactions of propene and the acidity determined with the aid of Hammett indicators for bismuth-containing oxide catalysts.

Table 2. Selectivity in the allyl oxidation reactions of propene and the acid strength of bismuth-containing catalysts {500°; $[C_3H_6] = 9$ vol.%; $[O_2] = 18$ vol.%; conventional contact time 1.0 g s ml^{-1}}.[30]

Catalyst	Selectivity, %		Acid strength H_0
	benzene	acrolein	
$2Bi_2O_3 \cdot P_2O_5$	49.0	0	+7.1—+6.8
$BiAsO_4$	33.8	5.8	+6.8—+4.0
$BiPO_4$ (high-temperature form)	26.9	6.6	+6.8—+4.0
$Bi_2O_3 \cdot 2TiO_2$	18.0	0.3	+7.1—+6.8
$(BiO)_2SO_4$	10.1	4.0	+6.8—+4.0
$BiPO_4$ (monazite form)	9.1	38.6	+1.5—−3.0
$(BiO)_2MoO_4$	0	66.1	+3.3—+1.5
$Bi(BiO)(MoO_4)_2$	0	91.7	+1.5—−3.0
$Bi_2(MoO_4)_3$	0	94.9	+1.5—−3.0

This general relation makes it possible to regulate the acid–base and hence catalytic properties of the catalyst by promoting it with oxides of different kinds; this is clearly illustrated in Fig. 2. The introduction of an alkali metal oxide into tin dioxide in amounts ensuring the homogeneity of the system increases the selectivity of the oxidehydrocyclisation of propene, while the addition of an oxide having acid properties (P_2O_5) suppresses this reaction and stimulates the partial oxidation of the olefin to an aldehyde.

In explaining the correlation between selectivity and acidity, it has been suggested that[5,30] the oxidehydrodimerisation of propene proceeds, like oxidation to acrolein, via an intermediate allyl compound, which either carries a weak positive charge or is neutral. As a result of the localisation on an "acid" adsorption site, regarded as a Lewis acid, of the electron of the allyl radical, the latter becomes similar to a cation and sensitive to the addition of an oxygen anion. At sites with a lower acid strength the intermediate compounds are of a more "radical type", which favours their dimerisation. Within the framework of this hypothesis, the promoting effect of basic and acid oxides on the catalytic properties of tin dioxide discussed above can be accounted for by a change in the electronic state of the centre for the adsorption of olefin (Sn^{4+}) via the $Sn^{4+}–O^{2-}–M^{n+}$ linkage in accordance with the electronegativity equalisation principle[11].

Simultaneously with the change in the electronic state of the allyl fragment, the strength of the bond between the allyl fragment and the catalyst surface can apparently also vary as a function of the electronegativity of the adsorption centre[70–72]. On specimens with a reduced acidity, a lower bond strength and an increased mobility of allyl radicals is expected, which increases the probability of their recombination. Conversely, when allyl compounds are bound strongly to the surface there is a greater number of chances of conversion into acrolein or total oxidation products.

It is suggested that the activity of the catalyst in the test reaction involving the migration of the double bond in but-1-ene can be used as a measure of the relative strength of the olefin–catalyst bond[73]. This can be done if the isomerisation is carried out with participation of aprotic centres (the ratio of the *cis*- and *trans*-isomers of but-2-ene formed should be two[74]) under conditions close to those in oxidative catalysis[75]. While maintaining these conditions, it proved possible[71] to show that, with intensification of the isomerising capacity of the catalyst and hence with the strengthening of the bond between the adsorbed olefin and the catalyst, the rate of dehydrodimerisation of propene falls and that of its partial oxidation increases; the results of this study are presented in Fig. 5.

For an unambiguous test of the above relations, it is necessary to compare the selectivity not with the overall acidity, as was done in the studies mentioned above, but with acidity of a definite type, in particular with the strength and concentration of the acid Lewis centres. However, the methods for the determination of the acidity of the surface oxides available at present[76] preclude a reliable solution of this problem. Furthermore, the acidity parameters determined by the traditional titration and base adsorption methods correspond to conditions very remote from those in catalytic reactions.

Thus the features described show that catalysts of the oxidative dehydrodimerisation of olefins must have weakly basic properties ensuring a moderate strength of the binding of allyl complexes to the centre of the catalyst and their adequate mobility. Furthermore, the catalysts should not contain components causing the oxidation of the above complexes to unsaturated aldehydes. It has been shown[77] that highly charged ions of electronegative elements such as molybdenum, tungsten, vanadium, tellurium, antimony, etc. play the role of such components.

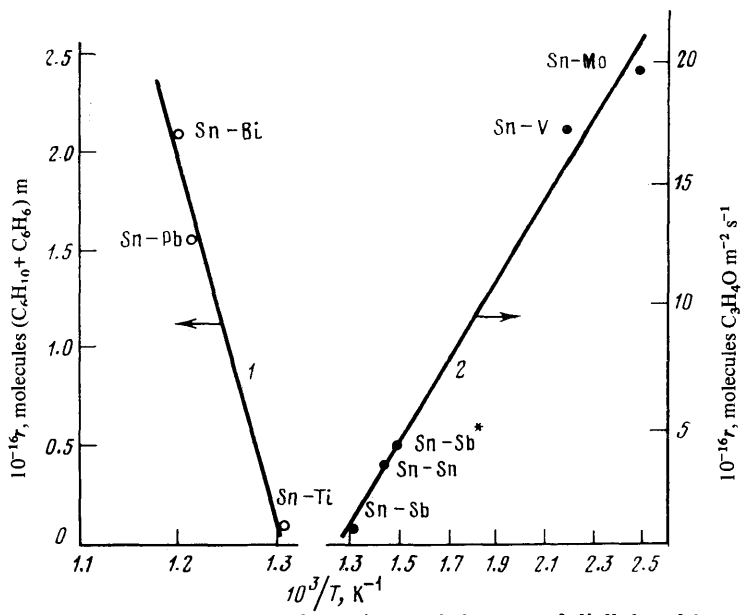

Figure 5. Dependence of the rates of formation r of the sum of diallyl and benzene (line *1*) and acrolein (line *2*) on the isomerising capacity of tin-containing oxide catalysts (on the reciprocal of the temperature $1/T$ corresponding to the attainment of the specified rate of isomerisation of but-1-ene)[71].

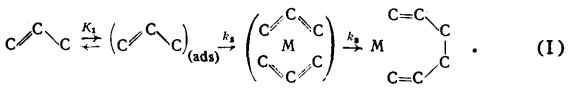
These two requirements are satisfied by the oxides of non-transition elements located in the lower left-hand section of the Periodic System. These include zinc, gallium, cadmium, indium, tin, thallium, lead, bismuth, etc. (zinc and cadmium are usually regarded as non-transition elements, because they do not in fact exhibit a variable valence and do not form compounds in which the *d* shell is unfilled[78]). The oxides of all these elements exhibit weakly basic or amphoteric properties and are active to different extents in the oxidative dehydrodimerisation and aromatisation reactions of lower olefins. A considerable proportion of them is also characterised, according to Sokolovskii and Bulgakov[79], by nearly optimum nucleophilic properties of oxygen required to abstract the proton from the olefin and form an allyl complex. The boundary of elements potentially active in the above processes runs along the diagonal drawn through aluminium, germanium, antimony, and polonium. The main product of the oxidative transformation of propene on pure antimony tetroxide[80] and certain antimony-containing oxide catalysts[57,81] is acrolein, while diallyl and benzene are formed in smaller amounts.

Alkali and alkaline earth metal oxides exert a positive influence on the selectivity of the processes when they are introduced in small amounts into the catalyst.

A considerable proportion of the oxides of the elements enumerated above are also incorporated in the set of catalysts recommended by Trimm[82,83]. The author assumes that diallyl is formed by the dimerisation of two allyl radicals linked to the same metal ion whose characteristic valence states differ by two charge units.

3. Kinetics and Mechanisms of the Reactions



A relatively small number of studies devoted to the kinetics and certain problems of the mechanism of the oxidation of lower olefins to diolefinic and aromatic hydrocarbons are described in the literature. Kinetic studies have been made on the oxydehydrodimerisation of propene on individual thallium[18] and indium[84] oxides. For low degrees of conversion of the hydrocarbon, the main products are hexa-1,5-diene and carbon dioxide, while in the presence of indium oxide acrolein is also formed. Under these conditions, the rates of formation of diallyl and CO_2 are proportional to the concentrations of propene and oxygen raised to a power of 0.4–0.5 and the reactions are inhibited by diallyl and acrolein.

The author described the kinetic data[18,84] by the Langmuir–Hinshelwood equation. According to the model which they adopted, the rate-limiting stage in the process is the formation of hexadiene by the interaction of two molecules of propene and the dissociated oxygen, all adsorbed on the surface. Propene, diallyl, and acrolein are adsorbed competitively at the same sites, while oxygen is adsorbed at other sites. The catalytic centres are tervalent thallium or indium ions, capable of forming π-complexes with the olefin.

In the oxidation of isobutene to 2,5-dimethylhexa-1,5-diene on the same indium oxide, it was shown that the reaction is of first order with respect to the olefin and has a fractional order (0.8) with respect to oxygen[85,86]. This result, as well as the weak adsorption of isobutene on the catalyst, forced the authors to postulate that in the case of isobutene two gas-phase molecules of the latter interact with the dissociatively adsorbed oxygen. In other respects the reaction mechanism does not differ from that adopted for reaction with propene.

The individual kinetic parameters of the reactions under consideration have been determined for a number of bismuth-containing catalysts. Thus, on simple bismuth oxide, the state of dehydrodimerisation of propene is directly proportional to the partial pressure of the hydrocarbon and is independent of the oxygen concentration[12]. It has also been shown that the reactions on the bismuth–iron[87] and bismuth–tin[39] oxide catalysts are of first order with respect to the propene. For the latter catalyst, the reaction was found to be of first order also with respect to oxygen.

The kinetics of the process in the presence of the bismuth–tin catalyst were investigated in greater detail by Seiyama et al.[88], who studied the oxidative dehydrodimerisation of C_3–C_4 olefins under conditions where the products are dehydrodimers and carbon dioxide formed simultaneously. It was found that the rate of dimerisation is proportional to the partial pressure of the hydrocarbon raised to a power of 1.5–2.0 and is independent of the oxygen content in the mixture. The order of the extensive oxidation reaction was found to be close to unity with respect to the olefin and to have a fractional value (~0.5) with respect to oxygen. The authors interpreted[88] the results of the kinetic measurements within the framework of the Langmuir–Hinshelwood scheme for an ideal adsorbed layer, as in the study of Trimm and Doerr[84]. It was assumed that the adsorption of the olefin involves the formation of a π-complex which interacts weakly with the hydrogen atom in the α-position relative to the unsaturated bond and in the vicinity of an oxygen atom on the catalyst surface. Next, the above hydrogen atom is abstracted and a complex of the metal ion with two allyl radicals is formed via the mechanism

(I)

Since the reaction order is nearly two with respect to the olefin and the reaction rate constant varies in opposition to the dissociation energy of the olefin C–H bond in the allyl position (Fig.6), the authors had to assume that the rate-limiting stage is surface dimerisation (k_2). The equation

$$r_{C_6H_{10}} = k_2\left(\frac{K_1 p_{C_3H_6}}{1 + K_1 p_{C_3H_6}}\right)^2 \qquad (1)$$

which follows from this mechanism describes satisfactorily the experimental data obtained on two specimens of the bismuth–tin catalyst. The activation energy for the process on a highly selective specimen is lower by 20 kcal mol^{-1} than on a specimen with a low selectivity, which has been attributed to the presence on the surface of the former of more active centres for the allyl–hydrogen cleavage of propene[5].

Appreciably different kinetic characteristics of the oxidative dehydrodimerisation of propene have been obtained recently in the presence of a bismuth–tin oxide catalyst[89]. These are in the first place a negative variation of the rate of formation of diallyl with the partial pressure of oxygen in the reaction mixture, illustrated in Fig.7*b*, and in the second place the observation that an increase of temperature entails an appreciable decrease of the reaction order with respect to the olefin (from 2.0 at 450 °C to 1.2 at 530 °C). It may be that the discrepancies with the data of Seiyama et al.[88] are caused by the significant differences between the methods of preparation of the specimens, which frequently determine the phase composition and surface properties of the catalyst.

The observed relations can be accounted for by the following scheme[89]

$$\begin{aligned} Z + O_2 &\xrightarrow{k_1} ZO_2 \,, \\ Z + ZO_2 &\underset{}{\overset{K_2}{\rightleftarrows}} 2ZO \,, \\ ZO + C_3H_6 &\xrightarrow{k_3} C_3H_5ZOH \,, \\ C_3H_5ZOH + C_3H_6 &\xrightarrow{k_4} C_6H_{10} + H_2O + Z \end{aligned} \qquad (II)$$

(here Z denotes a reduced site on the catalyst surface). Under the conditions investigated, the following kinetic equation of the fractional-rational type corresponds to this scheme:

$$r_{C_6H_{10}} = \frac{k'k''p^2_{C_3H_6}}{k'p_{C_3H_6} + k'p_{O_2}}, \qquad (2)$$

where $k' = K_2k_3^2/2k_1$ and $k'' = k_3k_4/(k_3 + k_4)$. Eqn.(2) describes the experimental data satisfactorily (Fig.7). Other forms of kinetic equations, particularly those of the Langmuir–Hinshelwood type, give a poorer agreement with experiment[90].

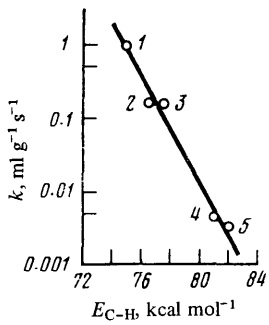


Figure 6. Dependence of the rate constant for the oxide-hydrodimerisation of olefins k on the dissociation energy E of the C–H bond in the methyl group: *1*) but-1-ene; *2*) *cis*-but-2-ene; *3*) *trans*-but-2-ene; *4*) isobutene; *5*) propene[88].

Scheme (II) presupposes that diallyl is formed by the interaction of a gas-phase propene molecule with a surface compound of the allyl type. This mechanism, which may be referred to as of the "impact" type, does not rule out the possibility of the operation of mechanism (I), which involves the stage of the surface dimerisation of allyl radicals. Furthermore, the two mechanisms can coexist. The contribution of mechanism (I) to the overall rate of the process will be evidently determined by the mobility of the allyl compound on the surface, which can depend on the reaction conditions and on the nature of the catalyst. In particular, the acid–base properties of the catalyst can play a significant role in this process[30,71].

In the interpretation of kinetic data in terms of the above mechanism, it is assumed that the oxidative dehydrodimerisation of the olefin proceeds via the formation of a π-allyl complex. This hypothesis is based on the following facts. In the presence of certain oxide catalysts[25,84], the oxide-hydrodimerisation of propene is accompanied by the formation of acrolein, which is known to proceed via an intermediate allyl compound[91]. On the bismuth–tin oxide catalyst, allyl chloride and bromide are converted into benzene in the presence of oxygen, while 2-bromopropene undergoes total oxidation[92]. Finally, the composition and structure of the diolefinic and aromatic hydrocarbons formed are not inconsistent with the allyl mechanism[93].

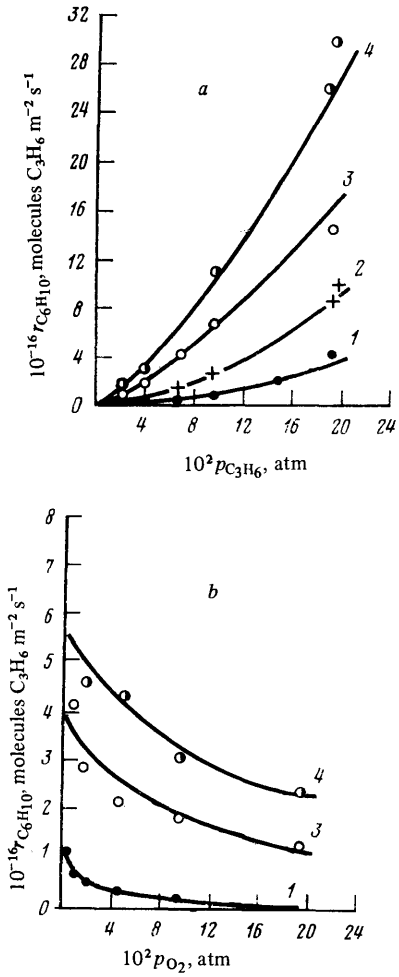

Figure 7. Dependence of the rate of formation of diallyl r on the partial pressures p of propene (*a*) and oxygen (*b*) at different temperatures (°C): *1*) 450; *2*) 485; *3*) 500; *4*) 530. The continuous curves were calculated by Eqn.(2) and the circles represent experimental data[89].

Attempts to demonstrate directly the existence of π-allyl complexes on the surface of the oxidative dehydroaromatisation catalysts have been made. Two forms of propene adsorbed on zinc oxide have been found[94–96] by infrared spectroscopy. At room temperature mainly a π-complex is formed, which is converted at higher temperatures (70 to 125 °C) into a π-allyl surface compound. The ability of zinc oxide to form allyl surface compounds of the radical-like type in the adsorption of propene has been confirmed by EPR[97].

The presence of allyl radicals has been detected also in the gas phase over manganese oxide[47,98,99] and zinc oxide[99] catalysts. It has been established by mass spectrometry that the radical concentration increases with temperature. On the other hand, the latter does not affect the significantly smaller content of free radicals over bismuth molybdate, which is a typical catalyst of the partial oxidation of olefins. These results have been explained[99] in terms of the ideas, described above, concerning the influence of the acid–base properties of the surface of the solid on the electronic structure of the adsorbed compound[11]. It is assumed that the allyl compound on a surface with acid properties (bismuth molybdate) is cationic and readily combines with the surface oxygen to form an unsaturated aldehyde. On the other hand, basic surfaces (manganese and zinc oxides) lead to the formation of free radicals.

On the basis of the results of the oxidation of propene labelled with radioactive carbon in the methylene group, it has been concluded[100] that hexa-1,5-diene is formed in the presence of a silver catalyst via an intermediate compound of the allyl type. However, the lack of data for the isomerisation of propene, the rates and mechanism of which depend on the type of catalyst[101], casts doubt on the validity of the above conclusion. In the case of rapid isomerisation, the mechanism presupposing the formation of a π-complex operates. A choice can apparently be made between these mechanisms on the basis of the results of the oxidative dehydrodimerisation of propene labelled with radioactive carbon and deuterium in different positions.

Another important factor in the mechanism of oxidative reactions involves the question of which forms of oxygen are responsible for the conversion of the hydrocarbon via a particular pathway. In the presence of many oxide catalysts the oxidative dehydrogenation[103,104] and partial oxidation[105,106] reactions of lower olefins, for example, proceed via an oxidation-reduction mechanism involving the oxygen of the surface layer of the catalyst. On the other hand, in the complete oxidation of the same hydrocarbons, the associative mechanism, which does not rule out the involvement in the reaction of forms of oxygen different from that of the oxide, makes an appreciable contribution.

Table 3. Comparison of the rates of the catalytic reaction and of the reduction and oxidation of the bismuth–tin oxide catalyst in the stationary state[107].

Reaction	Temp., °C	Mixt. compn., vol.%		$10^{-16}r$, molecules $m^2 s^{-1}$			
		C_3H_6	O_2	C_3H_6	O_2	C_6H_{10}	CO_2
Catalysis	450	0.67	0.38	1.8	5.16	0.29	4.05
Reduction	450	0.70	—	1.49	—	0.40	2.01
Oxidation	450	—	0.40	—	3.59	—	—
Catalysis	500	0.66	0.40	3.25	8.45	0.62	6.09
Reduction	500	0.67	—	2.45	—	0.65	3.52
Oxidation	500	—	0.38	—	3.69	—	—

Using the data of Gamid-zade et al.[107], the rates of the oxidative dehydrodimerisation and extensive oxidation of propene under the conditions of simultaneous and separate interactions of propene and oxygen with the bismuth–tin oxide catalyst are compared in Table 3. The satisfactory agreement between the rates of formation of diallyl in the catalytic and reduction processes shows that the oxide-hydrodimerisation proceeds via a multistage mechanism involving the separate interaction of the reactants with the catalyst surface. The main bulk of carbon dioxide is also formed from the catalyst oxygen. At the same time, the significantly higher rates of the total oxidation of propene in the catalytic process compared with the rates in the reduction process show that, under the conditions investigated, there is a considerable contribution of the combined mechanism, which diminishes with increase of temperature. It is important to note that the rates of the catalytic reaction and its individual stages have been compared for a catalyst in the stationary state. Under the conditions investigated, the stationary surface area was reduced by 70–80% and was characterised by the absence of weakly bound oxygen (Fig. 4).

The oxygen in the surface of the bismuth–tin oxide catalyst is apparently also involved in the oxidative dehydroaromatisation of propene to benzene. This was shown in a study by a pulsed method of the interaction of propene with the catalyst in the absence of gaseous oxygen[40,108].

The operation of the oxidation-reduction mechanism may be expected on the bismuth–phosphorus[109] and bismuth–titanium[110] oxide catalysts, for which a qualitative correspondence between the catalytic and reduction processes has been established. In the interaction of propene with the individual oxides of bismuth[12,111–113], tin[40,80,113], zinc[113], and indium[113] the same products are obtained (diallyl, benzene, and carbon dioxide) as under the conditions of the catalytic reaction. These findings show that a definite proportion of the products of the oxidative dehydrodimerisation and total oxidation of propene are formed with direct participation of the oxygen of the above catalysts. However, the final conclusion concerning the validity of the oxidation-reduction mechanism or lack of it could be arrived at only on the basis of a comparison of the rates of the catalytic reaction and the separate interactions of the components of the reaction mixture with the catalyst having the stationary composition, as has been done for the bismuth–tin oxide catalyst[107]. Furthermore, this procedure would permit a test, to some extent, of the possibility of the occurrence of the reaction via a heterogeneous-homogeneous mechanism.

It is known[114] that many catalytic reactions, initiated on the surfaces of solids and then transferred to the gas phase, proceed via a radical-chain mechanism. In particular, it has been suggested[115] that both reactions occur simultaneously in the oxidation of propene on certain oxide catalysts. One of these leads to the formation of acrolein via a purely heterogeneous mechanism. The second, homogeneous reaction is initiated by a surface hydroperoxide, formed via the addition of molecular oxygen to the allyl compound.

On this basis, one can assume that hexa-1,5-diene is formed via the gas-phase dimerisation of intermediate radical species (for example, allyl radicals) generated by the catalyst surface. The occurrence of oxidative dimerisation and aromatisation of propene becomes appreciable at high temperatures in excess of 450 °C. Under these conditions, there is a possibility of a weakening of the allyl–catalyst bond and of an increase of the probability of the transfer of allyl to the gas phase. This is supported by the detection of the allyl radical in the gas phase over zinc oxide and manganese oxide catalysts[98,99], which was mentioned above. However, data concerning the involvement of the allyl radical in the formation of diallyl have not so far been obtained. Furthermore, the allyl radicals generated by a pyrolytic procedure exhibit an absolute indifference to the

nature of the catalyst. When they interact with catalysts of the oxidehydrodimerisation and partial and extensive oxidation of olefins, only acrolein is formed[116]. The equality of the rates of the catalytic and reduction processes established for the bismuth–tin oxide catalyst also constitutes evidence against the heterogeneous-homogeneous mechanism, because the surface reduction of oxides usually proceeds via a heterogeneous mechanism[117].

Together with diolefins, aromatic hydrocarbons are formed on many of the known catalysts: benzene is formed from propene and xylenes are formed from butenes[25,93]. The relative content of aromatic hydrocarbons in the reaction products depends both on the chemical nature of the catalyst and on the reaction conditions. It has been noted that, on individual bismuth[12,13], thallium[18], and lead[15–17] oxides, hexa-1,5-diene is formed preferentially, whereas on catalysts of the type of zinc oxide[11], tin dioxide[11,40], and bismuth phosphate[25], the formation of aromatic hydrocarbons is more appreciable. An increase of the yield of the latter with a simultaneous decrease of selectivity with respect to diolefins is also promoted by an increase of contact time[45,84], which shows that hexa-1,5-diene is converted into aromatic hydrocarbons in successive stages.

It has been suggested[45,93] that benzene is formed via the oxidative dehydrogenation of hexa-1,5-diene to hexatrienes, the conversion of hexatrienes into cyclohexa-1,3-diene, and oxidative dehydrogenation of the latter to the aromatic compound. This mechanism is supported by the results of the oxidation of hexa-1,5-diene and cyclohexa-1,3-diene, which are converted respectively into a mixture of benzene with hexa-1,3,5-triene and benzene[93]. Furthermore, in the presence of many catalysts[12,13,22], the products include, together with diallyl and benzene, also cyclohexa-1,3-diene, which is the only cyclic diolefin detected.

Trimm and coworkers[84,85] put forward a somewhat simplified mechanism for the aromatisation of hexadienes having excluded from consideration the hexatriene formation stage. Having failed to detect hexatrienes among the reaction products, the authors suggest that the hexadiene localised on the catalyst surface is converted into cyclohexa-1,3-diene, which can then migrate to the catalytic centre, ensuring the formation of benzene. However, the absence of trienes from the reaction products cannot serve as an adequate justification for their exclusion from the formal reaction mechanism. One can assume that, by virtue of their high reactivity, the hexatrienes formed undergo readily and rapidly thermal "cycloisomerisation" to cyclohexadienes[118], as happens in the C_6-dehydrocyclisation of paraffinic hydrocarbons[2].

Indeed, Vaabel' et al.[119,120], who studied in detail the reactions of hexa-1,5-diene, cyclohexene, cyclohexa-1,3-diene, and benzene in the presence of the bismuth–tin oxide catalyst, showed that the hexatriene formed under the conditions of the oxidative dehydrodimerisation of propene cyclises and aromatises at a high rate. They also established that the pathway followed in the cyclisation of hexa-1,5-diene via cyclohexene cannot be the main one.

The facts described suggest that the oxidative dehydroaromatisation of olefins is a complex consecutive reaction, whose mechanism can be represented as follows in the case of propene:

$$\text{propene} \xrightarrow{1} \text{hexa-1,5-diene} \xrightarrow{2} \text{hexa-1,3,5-triene} \xrightarrow{3}$$

$$\text{cyclohexa-1,3-diene} \xrightarrow{4} \text{benzene}.$$

All the oxidative dehydrogenation stages (*1*, *2*, and *4*) are catalytic, while the cyclisation stage (*3*) is thermal, by analogy with the dehydrocyclisation process[2].

III. OXIDATIVE DEHYDRODIMERISATION OF OTHER HYDROCARBONS WITH MULTIPLE BONDS

The oxidative dehydrodimerisation and aromatisation of lower olefins is a special case of the more general type of reactions, which apparently extend to a wide range of compounds containing multiple bonds.

Reports of the vapour-phase heterogeneous-catalytic dehydrodimerisation of a number of compounds have been published mainly in the patent literature. Thus American investigators have patented[44,121,122] a procedure, which is feasible in principle, for the oxidative dehydrodimerisation of substances having the general formula YCRR'H to compounds of the type $(YCRR')_2$, where $Y = CH_2=CH$, Ph, CN, COOH, COOR, CO, or $CH_2=CX$ (X = halogen, alkyl, or allyl) and R and R' = hydrogen, C_1–C_6 alkyl groups, or aryl groups. The oxides of bismuth, chromium, iron, and a number of other elements, promoted by alkali metal compounds, have been suggested as catalysts. However, specific example of the processes described in the patents are confined to propene.

Among the substances enumerated above, alkyl derivatives of aromatic compounds have been studied in greatest detail. In particular, a relatively large number of patents are devoted to the selection of catalysts and the development of methods for the oxidative dehydrodimerisation of toluene to bibenzyl and stilbene.

Catalysts which are effective in the oxidehydrodimerisation reactions of lower olefins are also active in the oxidative dehydrocoupling of mono- and di-substituted benzenes. These include catalysts based on bismuth and antimony oxides with promoting additives[34,123], lead oxide on a carrier[15,16], the bismuth–tin oxide catalyst[124,125], the bismuth–iron oxide catalyst[125], and a number of others. The activity of noble metals and their oxides, hydroxides, and halides deposited on a zeolite or an aluminosilicate in these processes has also been reported[126].

The catalytic properties of the bismuth–tin oxide system have been studied in greatest detail. It has been shown[127] that the $Bi_2Sn_2O_7$ phase is formed in the course of the preparation of the catalyst, its content increasing with increasing heat-treatment temperature. At the same time the activity of the catalyst in the oxidative dehydrodimerisation of toluenes is found to increase. However, the bismuth pyrostannate phase is unstable in the atmosphere of the reaction medium at high temperatures. At 600 °C it is converted into the α-Bi_2O_3, γ-Bi_2O_3, and $Bi_{12}SnO_{20}$ phases. The bismuth–tin oxide catalysts retain a constant activity only in the course of the first three hours of operation, after which the activity and selectivity of the catalyst decrease slowly owing to coke deposition. After regeneration with air, the catalysts fully recover their properties[128].

The maximum selectivity in the formation of bibenzyl and stilbene (45%) is observed at 500 °C. With increase of temperature, the selectivity falls due to the oxidative dealkylation of toluene to benzene. With increase of the conventional contact time and the oxygen/toluene ratio in the mixture, the selectivity with respect to stilbene increases and that with respect to bibenzyl falls. These results show that stilbene is formed from bibenzyl via its oxidative dehydrogenation[128].

Oxidative dehydrodimerisation reactions of alkyl derivatives of aromatic hydrocarbons proceed much more selectively in the presence of molecular iodine. The latter arrives on the catalyst layer together with oxygen as part of the initial mixture[129–131] or is formed directly in the reaction zone as a result of the action on the catalyst by the components of the

reaction mixture, as happens in the familiar catalyst of the Shell Company (a mixture of LiI, LiOH, and Li_2SO_4 melts)[132]. For example, when melts of lithium and lead iodides are used, it is possible to achieve the dehydrocoupling of toluene to stilbene, of toluene and propene to naphthalene, and of isopropylbenzene to *p*-terphenyl[133].

It has been suggested in a number of patents[16,122,134,135] that hydrogen split off in the dehydrodimerisation of alkyl derivatives of aromatic hydrocarbons be combined with the oxygen of the metal oxides. Among the latter, mention is made of the individual and deposited oxides of bismuth, cadmium, lead, and arsenic. During the reaction, the oxides are reduced and periodic reoxidation is necessary.

Benzene apparently undergoes vapour-phase oxidative dehydrodimerisation with much more difficulty. There has been only one report of a study[126] in which noble metals were used as catalysts for this purpose. There is absolutely no information about the ability of oxides to catalyse the oxidative conversion of benzene into biphenyl. This may be explained by the fact that the dissociation energy of the C–H bond in the benzene ring (102 kcal mol^{-1}) is significantly higher than in the methyl groups of toluene and propene (83 kcal mol^{-1}).[136] In other words, the formation of phenyl radicals $C_6H_5^{\bullet}$ is energetically less favourable than that of benzyl radicals $C_6H_5CH_2^{\bullet}$, which are believed[137] to behave as intermediates in the oxide-hydrodimerisation of toluene. Furtherfore, as a consequence of the delocalisation of the π-electronic charge of the ring or the C=C bond with participation of a partially vacant orbital, the benzyl and allyl radicals exhibit an increased stability[138], which should also favour their dimerisation. The formation of the benzyl radical on the surface of zinc oxide in the adsorption of toluene has been demonstrated spectroscopically[139].

The high reactivity of lower olefins and toluenes in oxidative dehydrocoupling reactions compared with benzene indicates the possibility of the involvement in such reactions of a large number of hydrocarbons having a mobile hydrogen atom in the α-position relative to the unsaturated bond. Here one should expect the occurrence of the following consecutive stages: the abstraction of the above hydrogen atom following the adsorption of the hydrocarbon on the surface of the appropriate catalyst, dimerisation of the molecular fragments, oxidative dehydrogenation of the dimer, and, its subsequent cyclisation and aromatisation, provided that this is allowed by the structure of the compound formed.

IV. CONCLUSION

The study of heterogeneous-catalytic dehydrodimerisation and cyclisation reactions in the presence of molecular oxygen was begun comparatively recently and so far embraces a limited number of catalysts and a narrow range of hydrocarbons. Certain aspects of the conversion of substances on the surface of catalysts and the mechanisms of the action of the latter remain unelucidated. Nevertheless, the results obtained show that these reactions are fairly complex and represent a set of consecutive stages.

Oxidative dehydrodimerisation reactions of hydrocarbons are accompanied by a number of side reactions involving total and partial oxidation. The discovery of the principal features of reactions of the above type is therefore of interest for the theory of oxidative catalysis as a whole.

By virtue of the involvement of oxygen, oxidative dehydrodimerisation processes differ from the dehydrocyclodimerisation reactions of lower paraffins and olefins[1], which have been thoroughly investigated and have much in common with oxidative heterogeneous catalytic processes. In the first place the common features of their mechanisms should be noted. As shown in this review, the oxidative dehydrodimerisation of lower olefins on oxide catalysts proceeds via a mechanism involving the separate interaction of the reactants with the surface of the catalyst. A considerable proportion of the total oxidation products are formed via a combined mechanism, whose contribution to the overall rate of reaction diminishes with increase of temperature. The conversion of olefins on many oxide catalysts of the partial oxidation reaction proceeds similarly[103–106].

The similarity of the mechanisms is also manifested in the reaction kinetics. Both in the partial oxidation[91] and oxidative dehydrodimerisation[88] of lower olefins, the rate-limiting stage involves the dissociation of the C–H bond in the allyl position. Furthermore, with increase of the oxygen content in the reaction mixture, the selectivity with respect to the mild reaction product (diallyl) increases and that with respect to the extensive oxidation products increases[89], as has been observed in the oxidation of ammonia and a number of organic substances[140,141].

An increase of the binding energy of the surface oxygen on oxide catalysts leads to a decrease of the rate and an increase of the selectivity of the partial oxidation[60,61]. Similar relations have been established for the oxidehydroaromatisation of propene on simple oxides[11]. As a consequence of this, the mode and rate of conversion of olefins on dehydrodimerisation catalysts depend on the strength of binding of oxygen and the degree of surface coverage by the latter. The features observed for the bismuth–tin oxide catalyst show consistently[69,107] that a necessary condition for the selective action of the catalyst is the absence of weakly bound oxygen from its surface. In the stationary state the surface of the catalyst is characterised by a high degree of reduction and the presence of energetically homogeneous oxygen with a relatively high binding energy (90 kcal mol^{-1}). It is of interest to note that this quantity is close to the binding energy of oxygen in the stationary state on a number of selective partial oxidation catalysts[142,143].

Finally, one can postulate that the binding energy of oxygen is not the only factor determining the selectivity of oxide catalysts in oxidative dehydrodimerisation of olefins. In order to obtain a high selectivity in the presence of strongly bound oxygen, specific activation of the hydrocarbon molecule is apparently necessary, as in the mild oxidation processes[106]. It is not fortuitous that the bismuth–tin oxide catalyst, which consists of a combination of metal cations on which highly reactive allyl compounds are formed and stabilised, catalyses effectively the oxidehydrodimerisation of propene. The extension of the range of catalysts investigated will permit a comparison of the selectivities with the binding energies of oxygen and will provide a more unambiguous answer to this question.

The factors enumerated permit the conclusion that the oxidative dehydrodimerisation of unsaturated hydrocarbons is a typical example of the large class of heterogeneous-catalytic reactions with participation of molecular oxygen and that the principal relations determined previously for partial and total oxidation reactions of hydrocarbons are applicable to this process. This must be taken into account in selecting catalysts.

At the same time there is a considerable difference in the approaches to the solution of the problem of the selection of catalysts for the oxidative dehydrodimerisation and partial oxidation of olefins. This follows from the opposite variation of the activities of the oxide catalysts in these reactions with

their acid–base properties[30,70–72] and is associated with the type of conversion of the allyl type intermediates. The oxidation of the latter to unsaturated aldehydes requires the presence on the catalyst surface of Lewis acid centres with an enhanced strength and of electrophilic oxygen, which is achieved by combining amphoteric and acid oxides[79]. On the other hand, effective dimerisation requires weak acid centres and the absence of electrophilic oxygen. Such properties are characteristic of the oxides of weakly basic and amphoteric elements, combinations of which should apparently be sought as a basis for catalysts of the oxidative dehydrodimerisation of unsaturated hydrocarbons. The majority of the catalysts discussed in this review are consistent with this postulate.

The Nature of the Primary Photochemical Step in Spiropyrans

A.S.Kholmanskii, A.V.Zubkov, and K.M.Dyumaev

The mechanisms of the photocolouring reactions of spiropyrans are considered and the vibrational mechanism for the dissociation of the $C_{(2)}$-O bond in spiropyrans is analysed taking into account the relative positions of the π,π^* and n, π^* levels. The nature of the photochemically active state in spiropyrans has been established by examining the electronic nature of the low-lying excited states in organic molecules with heteroatoms. A mechanism is proposed for the photocolouring of spiropyrans, which explains the dependence of the efficiency of the $C_{(2)}$-O bond dissociation reaction in spiropyrans on their structure. The bibliography includes 63 references.

I. INTRODUCTION

The photochromic transformations of spiropyrans (SPP) are based on a reversible intramolecular photochemical reaction. In view of the enormously wide variety of structures existing in spiropyrans[1] and the ease with which the coloured form of spiropyran can be detected, the above compounds constitute a convenient model for investigating the nature of the primary photochemical step in organic molecules with heteroatoms and its dependence on the medium and the nature of the molecule. At the same time one should note that, by virtue of their unique properties, the photochromic spiropyrans are extremely promising for practical application in various branches of science and engineering[1-4].

The overall process involving photochromic transformations of spiropyrans belonging to one of the best known subclasses—spiropyrans of the indoline series—can be represented schematically as follows[1]:

(A) (B) (1)

In the initial form of SPP the indoline and benzopyran fragments of the molecule are linked by the spirocarbon $C_{(2)}$ atom with tetrahedral sp^3-hybridisation of atomic orbitals; these

fragments are therefore orthogonal relative to one another. This was confirmed by the X-ray diffraction analysis of a single crystal of 3,3-dimethyl-8′-nitro-1-phenylspiro[indolino-2,2′-(2′*H*-1-benzopyran)].[5] Henceforth 1,3,3-trimethylspiro[indolino-2,2′-(2′*H*-1-benzopyran)] will be designated by SP_1 (see Table). The orthogonality of the indoline and benzopyran fragments of the SPP is responsible for the orthogonality of the π-electron systems of these fragments and hence justifies the assumption, to a first approximation, that the properties of the indoline and benzopyran components of the SPP are independent[1].

The coloured state of the SPP obtains following the heterolytic dissociation of the $C_{(2)}$–O bond when the hybridisation of the spirocarbon atom changes to the sp^2-type[1]. This results in the formation of planar molecules with delocalised π electrons of the indoline and benzopyran components, giving rise to an intense absorption band in the visible part of the spectrum. Merocyanine dyes can serve as a model of the coloured form of spiropyran[1]. The complex dependence of the form of the long-wavelength absorption bands of the coloured form of SPP with an electron-accepting substituent in the benzopyran component (for example, SP_2 and SP_3) on the solvent and temperature can be explained by the existence of a series of stereoisomers of form B.[1,6–12] In view of the small height of the energy barrier to the transition between the stereoisomers at room temperature, thermodynamic equilibrium is established between them in solution in less than 10^{-7} s.[6]

In a number of studies devoted to the photochromic transformations of SPP at low temperatures[8,12] and at room temperature (with the aid of laser nanosecond spectroscopy)[6,9,10], it has been established that the formation of the coloured forms of SP_2 and SP_3 proceeds via a stage involving the formation of an unstable isomer X, which is a molecule of the SPP with a ruptured $C_{(2)}$–O bond but with an unaltered molecular geometry.[12]

The coloured form of the SPP is formed when the SPP is acted upon not only by ultraviolet light at a wavelength in the region of the absorption spectrum of the initial form of the SPP but also under the influence of ionising radiation[1]. Fairly extensive data concerning the mechanism of the photocolouring of the SPP under the influence of ultraviolet light in the wavelength range 300–405 nm (this region contains the first and second absorption bands of the initial form of the SPP due to electronic transitions of the π–π* type which are localised mainly in the benzopyran component of the SPP[1]) have now accumulated, while the number of studies devoted to the photolysis of SPP under the influence of light with $\lambda < 300$ nm is so far small[1,9,13]. Analysis and interpretation of the results of the study of the photolysis of SPP by light with $\lambda < 300$ nm is complicated by the fact that, in addition to the high-energy electronic transitions localised mainly in the benzopyran component of the SPP, light at this wavelength excites also the electronic transitions in the indoline component. On the other hand, the redistribution of the electronic excitation energy of the indoline component via different channels (emission and dissipation within the indoline component, transfer to the benzopyran component) has been little investigated[1]. It has been suggested[13] that, transfer of the electronic excitation energy from the indoline to the benzopyran component of the SPP may cause the production of form B. In this sense the photocolouring of the SPP by light absorbed by its indoline component is apparently related to the photosensitised colouring of SPP.

The main question concerning the mechanism of the formation of the coloured form of SPP is how the electromagnetic radiation energy absorbed by the benzopyran component of the SPP is transformed into the $C_{(2)}$–O bond dissociation energy[1]. Tasks of practical importance, involving the discovery and explanation of the laws governing the variation of the spectral-kinetic characteristics of the photochromic transformations of spiropyrans as a function of their structure and external conditions, are closely related to the solution of this problem.

The quantum yields of the photocolouring ($\phi_{AB}^{u.v.}$) and photodecolorisation ($\phi_{BA}^{u.v.}$) of spiropyrans A with different substituents under the influence of ultraviolet light.

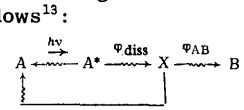
Note. The radiation yields G_B of the coloured forms of the spiropyrans SP_2, SP_3, SP_4, SP_8, and SP_{18} in polystyrene at −77 K under the influence of γ-rays are respectively 0.07, 0.4, 0.25, 0.06, and 0.13.

The aim of the present review to analyse the existing ideas concerning the mechanism of the photocolouring of spiropyrans and their generalisation on the basis of the analysis of the nature of the electronically excited states of spiropyrans.

II. THE VIBRATIONAL MECHANISM OF THE DISSOCIATION OF THE $C_{(2)}$–O BOND



Studies have been made[13,14] on the dependence of the relative quantum yield of the fluorescence of unsubstituted chromenes and SP_2 as well as the relative fluorescence yield (ν) of SP_3 in trimethylpentane at 77 K on the wavelength of the exciting light λ_e. By analysing the vibrational absorption bands of chromenes and SP_2, the authors[13,14] established that the relative fluorescence quantum yield of the above compound decreases significantly with excitation of increasingly higher vibrational levels and that an even greater decrease of the fluorescence yield is observed when chromenes and SP_2 are irradiated with light at the wavelength

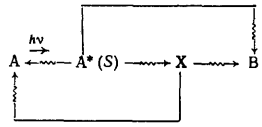
corresponding to the second absorption band. The decrease of the relative fluorescence quantum yield is explained[13,14] by the competition between the photochemical $C_{(2)}$–O bond dissociation process and the internal transition from the excited to the zero-point vibrational level, from which there is a radiative transition to the ground state.

The finding that the competition of the photochemical process is particularly pronounced on excitation of sequences of vibrations at the frequencies corresponding to the antisymmetric vibrations of the –C–O–C– group is consistent with this explanation. Three possible explanations of the vibrational mechanism of the photocolouring of SPP have been proposed[13,14]. The first applies to the case where the potential energy curve for the first excited singlet state has a "small" minimum, so that the $C_{(2)}$–O bond is ruptured after the excitation of only the first vibrational level of the S_1 state. In the second case it is assumed that the potential energy curve for an unbound excited state intersects the potential energy curve for the S_1 state near its first vibrational level. The third explanation can be used when the $C_{(2)}$–O bond is dissociated in the triplet state and the absorption of even only one vibrational quantum is sufficient for the transition of the molecule from the S_1 state to the T_0 state.

For the indoline SPP with a nitro-group in the 6′-position, a study was made of the dependence of ν on λ_e in 3-methylpentane at 77 K. The nature of this dependence is different than for the fluorescence quantum yields of chromenes and SP_2. The value of ν corresponding to SP_3 irradiated with light at $\lambda_e = 372.5$ nm was assumed to be unity; with decrease of λ_e to 323 nm, it diminishes slightly—to ~0.8; a further decrease of λ_e down to 269 nm no longer altered the above quantity. In order to account for such dependence of ν on λ_e, the authors[13] invoke the transfer of energy from the indoline component of the molecule to the benzopyran component in addition to the vibrational mechanism of the dissociation of the $C_{(2)}$–O bond. They believe that the constancy of ν starting with $\lambda = 323$ nm can be explained by the fact that at $\lambda < 323$ nm the indoline component of the molecule begins to absorb; however, since the phosphorescence of the indoline component itself is not then observed, it is suggested that the electronic excitation energy is transferred from the indoline to the benzopyran fragment, as a result of which a constant value of ν for the benzopyran component is established. In the absence of energy transfer from the indoline fragment of the molecule, ν for the benzopyran component should decrease with diminution of λ_e from 372.5 to 323 nm by an amount greater than that observed as a consequence of the competition of the photochemical $C_{(2)}$–O bond dissociation process[13].

Thus, ν for SP_3 decreases by 20% when λ_e falls from 372.5 to 269 nm, while the quantum yields of the photocolouring of this SPP under the influence of light at wavelengths of 365 and 313 nm (in 1-propanol-2-propanol mixture at 153 K) are 0.6 and 0.3 respectively[8]. It follows from these results that, firstly, the quantum yield of the photocolouring reaction (ϕ_{AB}) and the quantum yield of the photochemical $C_{(2)}$–O bond dissociation reaction (ϕ_{diss}) are different quantities. In the general case it is necessary to take into account the possibility of the reverse process—the formation of the initial form A after the dissociation of the $C_{(2)}$–O bond, i.e. the photocolouring reaction must be represented schematically as follows[13]:

(2)



Secondly, the parallel variation of the quantum yield of the photocolouring and phosphorescence of SP_3 with λ_e shows that in this case the observed relations cannot be explained solely by vibrational mechanism of the $C_{(2)}$–O bond dissociation process and it appears that this mechanism cannot be the main mechanism of the photocolouring reaction ensuring the high values of ϕ_{AB} observed.

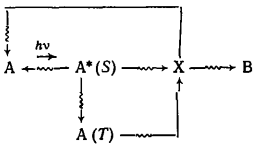
Indeed, the vibrational mechanism of the dissociation of the $C_{(2)}$–O bond does not take into account the nature of the electronic transition excited by light and the specific features of the electronic transition determine the efficiency of the photophysical and photochemical processes in organic molecules with heteroatoms[15,16]. Since the nature of the electronic transition actually helps to elucidate the dependence of the efficiency of intramolecular processes on the molecular structure, the vibrational mechanism of the photocolouring reaction is unsatisfactory. One should also note that, whereas in the case of chromenes the photochemical process may be the only one competing with the internal transition, on passing to the SPP with an indoline fragment, one cannot rule out the possibility also of other channels leading to a redistribution of the electronic excitation energy apart from the photochemical processes and fluorescence; in particular, one can postulate the occurrence of conformational vibrations of the molecule as a whole. The study of the vibrational mechanism of the photocolouring of the SPP should not therefore be limited to the measurement of the fluorescence or phosphorescence quantum yield; the parallel measurement of the photocolouring yield is also necessary.

III. THE RELATIVE POSITIONS OF THE LOWEST π,π^* AND n,π^* LEVELS AND THE MECHANISM OF THE PHOTOCOLOURING OF SPIROPYRANS

An attempt has been made in a number of studies[6,8–11,17–26] to explain the dependence of the photocolouring of the SPP on their structure by considering the relative positions of the lowest electronically excited states of the SPP[11,26] and also by determining the states in which the $C_{(2)}$–O bond dissociates and form B is produced[6,8–11,17–25]. The majority of these studies were mainly devoted to the elucidation of the involvement of triplet states in the photochemical colouring of the SPP. Studies have shown[18–20,22,27,28] that sensitised photocolouring due to the triplet–triplet transfer of energy from a triplet donor to the SPP is observed for all the SPP investigated, including SP_1 and SP_3. On the other hand, it was found[1,10] that the involvement of the triplet states in the direct photocolouring of the SPP is not observed for all SPP structures.

The spiropyrans SP_1 and 6′- or 7′-methoxy-SP_1 do not show an influence by oxygen on the photocolouring process[17] and exhibit neither phosphorescence[13,26] nor triplet–triplet absorption bands[8,17]. On this basis, one can assume that, on direct photoexcitation of SPP of this kind, the formation of form B takes place mainly from the excited singlet state and can be represented by the following scheme[10,11]:

(3)



The involvement of the triplet states in the direct photocolouring of SP_3 is indicated by the presence of short-lived absorption bands due to the T_0–T_1 transition, the kinetics of the changes in which are correlated with the kinetics of the increase in the intensity of the absorption by the coloured form of the SPP[8,9,23,24]. Attempts have been made in a number of studies[21,25,28] to demonstrate the presence of the photochemically active (PCA) triplet state of the SPP with the nitro-group in the benzopyran part of the molecule by

investigating the kinetics of the photocolouring of the SPP in the presence of a triplet energy acceptor.

It has been established[21,25] that, in the presence of anthracene[25], 9-fluorenone, or benzil[21], the efficiency of the colouring of the SPP in solutions by light with $\lambda = 365$ nm is reduced. The authors of the above investigations believe that this is caused by the deactivation of the triplet PCA states of the SPP as a result of energy transfer from the SPP to the triplet energy acceptor. Calculations have shown that 83% of the coloured molecules are formed via the triplet states in the case of SP_8[25] and 20% in the case of SP_{15}[21].

However, it has been found[28] that the efficiency of the colouring of 8′-bromo-6′-nitro-SP_1 by light with $\lambda = 405$ nm is independent of the presence in solution of added anthracene (at a concentration up to 10^{-2} M). Furthermore, dissolved oxygen, which is an effective quenching agent for triplet states, does not exert an appreciable influence on the final yield of the coloured SPP molecules[1,8,21,28]. These results throw doubt on the possibility of explaining the observed decrease in the efficiency of the photocolouring of nitro-substituted SPP in terms of the quenching of their triplet states by triplet energy acceptors such as anthracene, 9-fluorenone, and benzil. If account is taken of the fact that the given compounds can show electron-accepting properties and hence there is a possibility of the phototransfer of an electron from the SPP[29–33], then one cannot rule out the probability of a chemical interaction between them and the SPP, which can lead to a decreased efficiency of the formation of coloured SPP molecules. When the SPP–anthracene system is irradiated with light at a wavelength of 365 nm, it is apparently necessary to take into account also the absorption of the initiating light by the molecules of anthracene itself.

Studies of the photocolouring and phosphorescence of SP_3 in polymeric matrices [polystyrene and poly(methyl methacrylate)] between room temperature and 75 K led to the conclusion that under these conditions the photocolouring process takes place to the extent of 100% via triplet states[20]. Thus, scheme (2) can be represented in the following general form for an SPP with a nitro-group:

(4)

As regards the electronic nature of the triplet state under consideration, the results of a number of studies[20,25,26,34,35] have shown that the triplet PCA state and the phosphorescent state of these SPP are the same triplet state of the π,π^* type. The measured energies of the triplet PCA and phosphorescence states can differ as a consequence of the influence of the medium and temperature[25]; furthermore, the dissociation of the $C_{(2)}$–O bond in the triplet state can occur at vibrational levels above the zero-point level, while emission takes place only from the zero-point vibrational level of the lowest triplet state. This may explain the fact that the triplet PCA level of SP_3 in poly(methyl methacrylate) lies above the phosphorescence level[20].

Thus analysis of the literature data shows that the photocolouring of the SPP with electron-accepting substituents in the benzopyran part can take place via the triplet state. Since the population of the lowest triplet state depends on the intercombination transition, the probability of which in heteroatomic molecules is very sensitive to the relative positions of the π,π^* and n,π^* levels[15,16,36], an attempt was made[26] to elucidate the qualitative dependence of the photochromic properties of the indoline SPP on the relative positions of the singlet and triplet π,π^* and n,π^* levels. A study was made[26] of the absorption and emission spectra of two groups of SPP. The first group consisted of SPP which are non-photochromic at room temperature (of the type of 6′-bromo-SP_1 and SP_2) and SPP with a nitro-group in the 7′-position of the naphthopyran component. The second group incorporated SPP with a pronounced photochromism at room temperature—SP_3 and SP_{23}. The authors determined the relative positions of the singlet and triplet levels of the π,π^* and n,π^* types. It was found that even if levels of the n,π^* type are present in the SPP of the first group, they lie above the $^1(\pi,\pi^*)$ level. For the SPP of the second group, at least one of the $^1(n,\pi^*)$ or $^3(n,\pi^*)$ levels lies between the $^1(\pi,\pi^*)$ and $^3(\pi,\pi^*)$ levels.[26] This should increase the probability of an intercombination transition for the SPP of the second group by 2–3 orders of magnitude compared with the first group[26].

On the basis of the results, it has been suggested[26] that the photochromism of the SPP at room temperature is closely related to the intercombination transition and that the colouring of the SPP with a distribution of π,π^* and n,π^* levels of the kind found, for example, in SP_3 takes place mainly via the triplet state. The observed dependence of the photochromic properties of the SPP on the relative positions of the π,π^* and n,π^* levels can be used, according to the authors[26], to explain the dependence of the photochromic properties of the SPP on their structure. This approach was also used in a study[11] of the photochromism of the SPP of the phenanthridine and diazapyrene series.

Despite the fact that the authors[11,26] were able to explain satisfactorily the dependence of the photochromic properties of the SPP on their structure, we believe that their findings are not general and do not reflect the fundamental processes responsible for the photochromism of the SPP. Indeed, the dissociation of the $C_{(2)}$–O bond is primarily an electronic process, which hardly depends on the temperature of the surrounding medium. However, the stability of the coloured form of the SPP is independent of this temperature. In the case of 6′-bromo-SP_1 and SP_2 a decrease of temperature results in their being photocoloured with an efficiency comparable to that of the photocolouring of SP_3 and SP_{23}.[1]

Apart from this, the mechanism proposed[26] for the photocolouring of the SPP does not take into account, like the vibrational mechanism of the dissociation of the $C_{(2)}$–O bond, the specific features of the electronic states in which the $C_{(2)}$–O bond is dissociated. This mechanism does not therefore permit an explanation of the change in ϕ_{AB} for the SPP as the nitro-group moved from the 6′-position to the 7′- or 8′-position or following the introduction into the benzopyran component of yet another substituent, in addition to the nitro-group; as noted above, within this series of the SPP there is a fairly considerable change in the contribution of the colouring process involving the triplet state. Furthermore, ϕ_{AB} exhibits an appreciable sensitivity also to λ_e.[1]

It is also noteworthy that the positions of the n,π^* levels are usually determined very approximately[36] in view of the low intensity of the band due to the n,π^* transitions and the superposition on the latter of the significantly more intense band of the π–π^* transitions. For example, the following sequence of low-lying excited levels has been determined for SP_3 in toluene: $S_0 < {}^3(\pi,\pi^*) < {}^3(n,\pi^*) < {}^1(\pi,\pi^*) < {}^1(n,\pi^*)$ while in another study[25] the following sequence was obtained for SP_8: $S_0 < {}^3(\pi,\pi^*) < {}^3(n,\pi^*) < {}^1(n,\pi^*) < {}^1(\pi,\pi^*)$. Therefore the rate of the intercombination transition for SP_8 should apparently be not lower than the rate of the intercombination transition for SP_3 and, according to the postulates developed

by Belaits and Platonova[26], the value of ϕ_{AB} for SP_8 should be not less than for SP_3. However, in reality the values of ϕ_{AB} for these SPP in toluene at room temperature under the influence of light with $\lambda = 365$ nm are 0.59 for SP_8 and 0.76 for SP_3.[1]

Thus the mechanism of the photocolouring of the SPP proposed on the basis of the consideration of only the intercombination transition and the SPP does not reflect, like the vibrational mechanism of the dissociation of the $C_{(2)}$–O bond, the entire specific features of the primary photochemical step in the photochromic transformations of the SPP.

IV. THE PHOTOCHEMICALLY ACTIVE STATE OF SPIROPYRAN AND THE MECHANISM OF THE DISSOCIATION OF THE $C_{(2)}$–O BOND

The photochemically active state of spiropyran is an excited state in which the $C_{(2)}$–O bond is dissociated. Heiligman-Rim et al.[12] explained for the first time the dissociation of the $C_{(2)}$–O bond by a redistribution of the electron density as a result of the excitation of the electronic transition in the benzopyran component of the SPP. They assumed that the mechanism of the photocolouring process consists of two stages: (1) the delocalisation of two σ electrons as a consequence of the redistribution of electron density on excitation of the electronic transition in the naphthopyran component of SP_2; (2) the change in molecular configuration.

Ring opening leads to the formation of a high-energy unstable merocyanine isomer (isomer X, see above), in which there is a partial retention of the configuration of the initial form of the SPP[12]. The authors[12] suggest that this configuration can be associated with the *cis*-isomer in which the steric repulsion is balanced by the attraction of nitrogen and oxygen atoms with unlike charges. This treatment of the photocolouring of the SPP appears to us reasonable on the whole; it has been confirmed, in particular, by the results of the study of the second stage of the process (see above).

The next stage in the development of ideas concerning the mechanism of the dissociation of the $C_{(2)}$–O bond was reached in studies[13,18,22,25,34,35,37] in which the absorption spectra of spiropyrans and compounds modelling the indoline and benzopyran components of the SPP were investigated. Their aim was to discover in which part of the SPP molecule a particular electronic transition is localised; hypotheses were put forward concerning the electronic nature of the photochemically active transition in the SPP.

The following models of the indoline component were adopted: indole[18,22], 2-hydroxy-1,3,3-trimethyl-2-phenylindoline[13], and 1,2,3,3-tetramethylindoline[25]. Different chromenes, for example, unsubstituted 2,2-diethyl-2*H*-chromene[22], 2,2-dimethyl-2*H*-chromene, or 2,2-dimethyl-5,6-benzo-2*H*-chromene[13], and substituted chromenes[25,34,35,37] were chosen as models of the benzopyran component. Comparison of the absorption spectra of the model compounds with those of solutions of the SPP permitted the conclusion that the electronic transitions, localised mainly in the indoline component of the SPP, give rise to absorption bands in the wavelength range $\lambda < 300$ nm[13,18,22,25]; mainly the absorption bands due to the electronic transitions in the benzopyran component of the SPP are distributed in the region $\lambda > 300$ nm[13,18,25,34,35,37].

However, although the absorption spectra of the model compounds make it possible to infer in which part of the SPP the particular electronic transition is largely localised, it has been noted[18,25] that the overall absorption spectra of compounds modelling the indoline and benzopyran components of the SPP agree with the absorption spectra of the SPP only to a first approximation and the difference between the intensities of the component bands is fairly large. This result shows that in practice the electronic systems of the indoline and benzopyran components of the SPP interact[1].

The electronic transition localised in the indoline component of the SPP is a π–π^* transition[15]. The following information is available about the nature of the transitions localised in the benzopyran component: in the spectrum of an SPP without substituents in the benzopyran fragment the absorption bands at 313 and 324 nm are caused by the π–π^* transition[13]; following the introduction of a bromine atom in the 6′-position of the SPP, a long-wavelength absorption band appears, whose dependence on the solvent polarity is characteristic of bands due to an n–π^* transition[22], while the extinction coefficient corresponds to a π–π^* transition. The author[22] denotes this transition as follows:

$$\overset{n\text{——}\pi^*}{\underset{\text{—O—}}{}}$$

emphasising thereby the electron-donating role in the latter of the oxygen heteroatom. In the SPP with a condensed benzene ring in the benzopyran component two π–π^* transitions correspond to two absorption bands in the range $\lambda > 300$ nm.[13,26]

When an electron-accepting substituent, for example, the nitro-group, is introduced into the benzopyran component of the SPP, an intense absorption band appears in the range 330–360 nm, which has been ascribed to the π–π^* transition[13,18,25,34,35,37]. It has been noted[22] that this band masks the absorption band due to the transition

$$\overset{n\text{——}\pi^*}{\underset{\text{—O—}}{}}$$

and n–π^* (the latter transition involves the nitro-group). It has been emphasised[13,18,25,34,35,37] that the excitation of the π–π^* transition in the benzopyran component with a nitro-group as a substituent leads to an increase of the positive charge on the oxygen heteroatom in the first excited singlet state.

The PCA transition in SPP with a nitro-group has been identified[22] as a n–π^* $\underset{\text{—O—}}{}$ transition. Bearing in mind that this transition involves charge transfer from the oxygen heteroatom to the benzene ring, the author[22] explained the observed decrease of ϕ_{AB} by a shift of the nitro-group from the 6′-position (*para*-position relative to the oxygen heteroatom) to the 7′- and 8′-positions. However, it is believed[25] that the PCA transition in SP_8 is a π–π^* transition and that the long-wavelength absorption band of the initial form of the given SPP corresponds to it. One should also note that the low-lying $S_{\pi\pi^*}$ and $T_{\pi\pi^*}$ states of the SPP have been assigned[25] to states involving charge transfer from the oxygen heteroatom to the benzopyran ring.

A further development and generalisation of the ideas concerning the PCA transition in the SPP has been achieved in studies[38,39] where the dependence of the electronic absorption spectra of the initial forms and the ϕ_{AB} of the spiropyrans on their structure was investigated. A study has been made[38] of the spectral-kinetic characteristics of 20 indoline SPP under identical conditions. The absorption spectra in solution in ethyl acetate of a series of spiropyrans having characteristic structures and substituents are illustrated in Fig. 1. In order to interpret them, the authors[38] analysed the available literature data for the absorption spectra of the SPP themselves and compounds with a structure similar to that of the benzopyran component of the SPP.

It follows from the results of the study of the nature of the electronic transitions in the SPP described above[13,18,25,34,35,37] and from their relation with the photochromic transformations of the SPP[12,22,25] that the long-wavelength absorption band in the spectra of the SPP with an electron-accepting substituent in the benzopyran component is associated with the electronic π–π^* transition localised mainly in the benzopyran

component. The nature of the electronic transitions in the SPP can be analysed on the basis of the fact that molecules with a structure similar to that of the benzopyran component of the SPP belong to the $(\sigma\pi nl)$-type according to the orbital classification of the electronic states of organic molecules with heteroatoms[16]. In such molecules there is a possibility of electronic transitions of the type $n-\pi^*$, $\pi l-\pi^*$, and $\pi l-\pi^*\pi_n^*$ and of the states S_0, $T_{n\pi^*}$, $S_{n\pi^*}$, $T_{\pi l,\pi^*}$, $S_{\pi l,\pi^*}$, $T_{\pi l,\pi^*\pi_n^*}$, and $S_{\pi l,\pi^*\pi_n^*}$.[16] The $\pi l-\pi^*$ and $\pi l-\pi^*\pi_n^*$ transitions represent linear combinations of the one-electron transitions $\pi-\pi^*$, $l-\pi^*$, and $\pi-\pi_n^*$; in the last two transitions the electron of the l orbital of the oxygen heteroatom passes to the π^* orbital of the π system and the π electron of the π system passes to the π_n^* orbital of the electron-accepting substituent. The excitation of the $\pi l-\pi^*$ and $\pi l-\pi^*\pi_n^*$ transitions therefore leads to charge transfer from the oxygen heteroatom to the benzene ring or from the benzopyran ring to the electron-accepting substituent. Thus the $\pi l-\pi^*$ and $\pi l-\pi^*\pi_n^*$ transitions can be characterised as transitions with intramolecular charge transfer (ICT).[16]

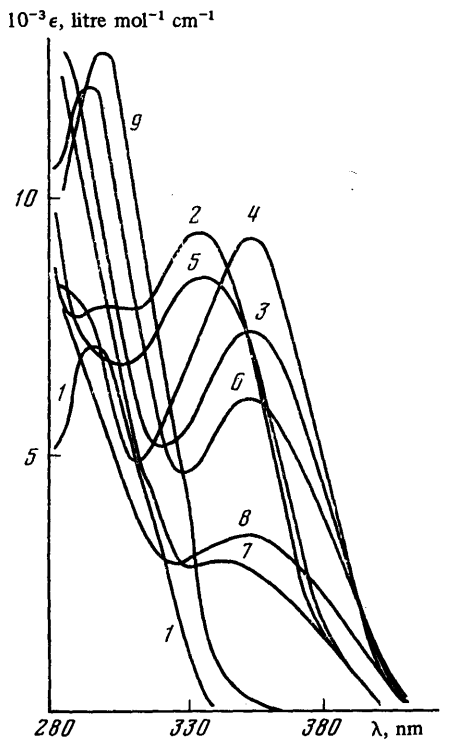


Figure 1. The absorption spectra of the initial forms of spiropyrans in solution in ethyl acetate: 1) SP_1; 2) SP_3; 3) SP_6; 4) SP_8; 5) SP_{11}; 6) SP_{17}; 7) SP_{18}; 8) SP_{20}; 9) SP_{23}.

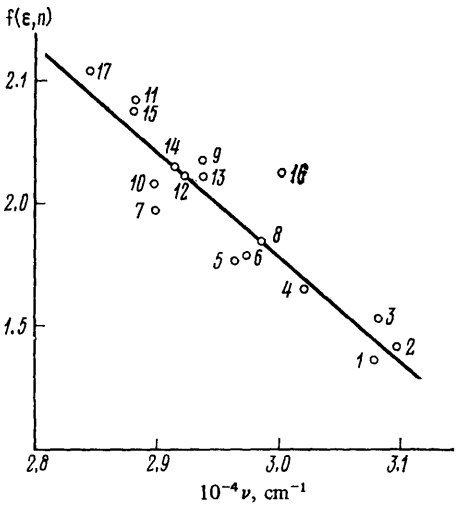
By virtue of their specific features, the $\pi l-\pi^*$ and $\pi l-\pi^*\pi_n^*$ transitions are apparently closely related to processes which result in the dissociation of the $C_{(2)}-O$ bond; consequently, these transitions can be classified as photochemically active. In the SPP without an electron-accepting substituent in the benzopyran component the $\pi l-\pi^*$ transition must be regarded as a PCA transition. The $\pi l-\pi^*$ transition in 6'-bromo-SP_1 has been designated[22] as $n-\pi^*$ (–O–). It is believed[20] that two transitions are localised in the benzopyran component of SP_1: $n-\pi^*$ and $\pi-\pi^*$ and that the $n-\pi^*$ transition is due to electron transfer from the oxygen heteroatom to the π system of the benzene ring.

On the other hand, if there is an electron-accepting substituent in the benzopyran component of the SPP, then the PCA transition is mainly of the $\pi l-\pi^*\pi_n^*$ type. The corresponding absorption band should have an intensity comparable to that of the $\pi-\pi^*$ transition band and should be located in the long-wavelength part of the absorption spectrum of the initial form of the SPP. In the absorption spectra of the SPP with a nitro-group, this band can be readily identified by comparing such spectra with the absorption spectrum of SP_1 (Fig. 1).

An important characteristic of the PCA transition is the positive charge of the oxygen heteroatom arising on excitation of this transition. It can be determined from the dipole moments of the excited and ground states of the molecule.



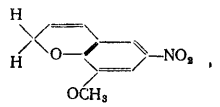


Figure 2. Dependence of the position of the long-wavelength absorption maximum of the initial form of 1,3,3-trimethyl-6'-nitrospiro[indolino-2,2'-(2'*H*-1-benzopyran)] on the universal interaction function $f(\varepsilon,n)$; solvent: 1) hexane; 2) heptane; 3) cyclohexane; 4) carbon tetrachloride; 5) benzene; 6) toluene; 7) chloroform; 8) ethyl acetate; 9) acetone; 10) dichloroethane; 11) pyridine; 12) ethyl methyl ketone; 13) dibutyl phthalate; 14) acetonitrile; 15) dimethylformamide; 16) ethanol; 17) dimethyl sulphoxide.

For quantitative estimates of the above quantities, we employed the theory of solvatochromism[40]. Fig. 2 illustrates the dependence of the shift of the ICT band of SP_3 on the universal interaction function $f(\varepsilon,n)$, which is directly related to the macroscopic characteristics of the medium—the dielectric constant ε and the refractive index n. Assuming a parallel orientation of the dipole moments of both states of the molecule, it is possible to determine the dipole moment of the molecule in the excited electronic state (μ_e)[40]

$$\mu_e = \mu_g - Chcr^3/2\mu_g \qquad (6)$$

from the slope of the linear plot of the solvatochromic shift C, the dipole moment of the molecule in the ground state μ_g, and the radius of the Onsager cavity in the solution r. Here h is the Planck constant and c the velocity of light *in vacuo*. The quantity r was assumed equal to the van der Waals radius of the molecule and was determined with the aid of X-ray diffraction data[5] ($r = 0.6$ nm for SP_3). It is known[41] that the quantity μ_g for the compound is 4.02 D. On this basis, we adopted $\mu_g = 4$ D in order to estimate μ_e for the benzopyran component of SP_8. It was found that $C = -2.2 \times 10^3$ cm^{-1}. Having substituted the selected and determined values of r, μ_g, and C in Eqn.(6), we obtain $\mu_e \cong 15$ D.

Thus the change in the dipole moment of the SP_3 molecule ($\Delta\mu$) on excitation of the photochemically active transition is ~11 D. This is in good agreement with the experimental[42] change in the dipole moment of the *p*-nitrophenol molecule in the S_0-S_1 transition, which amounts to 9 D (it is known[22] that nitrophenols constitute a fairly satisfactory model of the benzopyran component of the SPP with a nitro-group). On the basis of the value of $\Delta\mu$ and on the assumption that the dipole moment of the SP_3 molecule in the $S_{\pi l,\pi^*\pi_n^*}$ state arises from the unlike charges located on the oxygen heteroatom and on the nitro-group, it is possible to estimate the positive charge on the oxygen heteroatom. For a distance between the charges of 0.6 nm, the charge is found to be 0.38 e (where e is the electronic charge). This value agrees very well in its turn with the positive charge on the oxygen atom in the excited singlet state for the *t*-butyl ether of *p*-nitrophenol $(CH_3)_3C-O-Ar-NO_2$, which has been determined experimentally[43] and has been found to be 0.4 e.

It follows from the above results that the excitation of the PCA transition in the SPP does indeed lead to decreased electron density at the oxygen heteroatom in the lowest excited singlet state compared with the ground state. Since a structure of the "electron donor–Ar–electron acceptor" type, for which it is known that both the lowest excited singlet and triplet states are π,π^* states with ICT, can be identified in the benzopyran component of the SPP with an electron-accepting substituent, it appears that the $T_{\pi l,\pi^*\pi_n^*}$ state of the SPP with a nitro-group also involves ICT. This is supported by the finding that the lowest triplet state of the SPP is a π,π^* state (see Section III), and also by analogy with *p*-nitroaniline whose lowest triplet state has been shown[44] to be a π,π^* state with ICT.

Thus the low-lying excited singlet and triplet states of the SPP are highly polar states in which the positive charge is located on the oxygen heteroatom. An increase of the positive charge on the oxygen heteroatom leads to the polarisation of the $C_{(2)}-O$ bond and hence to its weakening. The subsequent redistribution of the electronic excitation energy among the vibrational degrees of freedom of the SPP molecule can apparently be inferred from the available data[16] concerning the mechanism of the distribution of the vibronic excitation energy in heteroatomic organic molecules.

In the study of the vibronic spectra of polyatomic organic molecules the phenomenon of the localisation of the vibronic excitation energy at specific atomic groups was observed[16]. It consists in the fact that the redistribution of energy among the vibrational degrees of freedom takes place primarily at the site of the so-called active vibrations of the molecule (these are, for example, the vibrations of the >C=O, –O–H, etc. groups). Subsequently, the energy of the active vibrations is redistributed among other vibrational degrees of freedom of the molecules of the test compound and the solvent. The active vibrations in the molecule constitute, in particular, the channels through which the selective photodissociation of the molecule takes place[16]. In the case of the SPP the active vibrations are apparently those involving the oxygen heteroatom. This hypothesis is consistent with the finding that the excitation of, for example, antisymmetric –C–O–C– vibrations leads to a higher probability of the dissociation of the $C_{(2)}-O$ bond in the excitation of any other vibrations of the SPP molecule in the excited state[13].

Thus, the mechanism of the dissociation of the $C_{(2)}-O$ bond can be represented as follows[38]: as a result of the excitation of the photochemically active transitions, localised mainly in the benzopyran component, a redistribution of electron density takes place in the SPP, which entails some increase in the positive charge on the oxygen heteroatom and the $C_{(2)}-O$ bond is polarised; in the subsequent redistribution of the electronic excitation energy among the vibrational degrees of freedom (preferentially with respect to active vibrations) the $C_{(2)}-O$ bond is ruptured. This mechanism of the dissociation of the $C_{(2)}-O$ bond can operate not only for spiropyrans but also for chromenes, which are known[13,45,46] to exhibit photochromism.

As mentioned in the introduction, the dissociation of the $C_{(2)}-O$ bond leads to the formation of an unstable configuration of the SPP molecule, i.e. the so-called X-isomer, which in the case of the SPP with an electron-accepting substituent in the benzopyran component and SP_2 has been detected by nanosecond laser photolysis at room temperature[9,10] or by low-temperature spectrophotometry[8–12]. Since the molecule in the states corresponding to the X-isomer can either return to its initial (closed) state or can give rise to the relatively stable coloured form of the SPP, it follows that ϕ_{AB} for the SPP are in the general case not greater than the quantum yield of the $C_{(2)}-O$ bond dissociation reaction [see Scheme (2)], The efficiency of the conversion of the X-isomer into the coloured form B apparently depends, like the efficiency of the dissociation of the $C_{(2)}-O$ bond, on the type and degree of the redistribution of electron density on excitation of the electronic transition in the benzopyran component of the SPP.

V. DEPENDENCE OF THE QUANTUM YIELD OF THE REACTION INVOLVING THE PHOTOCOLOURING OF SPIROPYRANS ON THEIR STRUCTURE

The ideas concerning the nature of the PCA transition, developed by two of the present authors[38,39], make it possible to explain the dependence of the efficiency of the dissociation reaction of the $C_{(2)}-O$ bond in spiropyrans on their structure. As shown in the previous Section, the PCA transition in the SPP involves intramolecular charge transfer and the corresponding absorption band can be characterised as the charge transfer band (CTB) involving charge transfer from the oxygen heteroatom to the benzopyran ring. It is known[40] that the dipole moments of transitions with ICT ($|\mathbf{D}|$) are correlated with the changes in the molecular dipole moment in the transition, i.e. the following relation holds[40]:

$$|\mathbf{D}| \sim |\Delta\mu|. \qquad (7)$$

Since the quantity $|\mathbf{D}|$ characterises the probability of the electronic transition and can be determined from the intensity of the absorption band corresponding to the given transition, it follows that, by virtue of Eqns.(7), it is possible to compare the intensity of the long-wavelength absorption band of the initial form of the SPP with the positive charge on the oxygen heteroatom and hence with the efficiency of the SPP photocolouring reaction.

In order to discover the relation between the intensity of the long-wavelength absorption band of the initial form of the SPP and their structure, one may resort to the available data for the dependence of the CTB intensity on the structure of aromatic compounds with electron-accepting substituents.

1. The addition of an electron-accepting substituent (NO_2, CHO, etc.) to an aromatic system leads to the appearance of an absorption band corresponding to charge transfer from the aromatic ring or from an electron-donating group conjugated with it to an electron-accepting substituent[16,47].

2. The CTB in the spectra of aromatic compounds with a nitro-group correspond to a transition which is polarised along the $C-N_{nitro}$ bond[47,48].

3. The intensity of the CTB depends on the degree of conjugation of the electron orbitals of the electron-donating and electron-accepting groups with the π system of the aromatic rings[16]. The degree of conjugation of the nitro-group with the π system of the aromatic rings can vary as a function of the steric and electronic (mesomeric and inductive) effects of other substituents[40,47,49]; the angle θ between the plane of the nitro-group and that of the aromatic rings can vary correspondingly[47,49].

4. The absorption spectra of *o*- and *m*-nitrophenols are similar and differ significantly from the absorption spectrum of *p*-nitrophenol[40,50]—their CTB have undergone a bathochromic shift[50,51].

5. The presence of two electron-donating substituents and one electron-accepting substituent or of one electron-donating substituent and two electron-accepting substituents in a polysubstituted benzene leads to the appearance in the absorption spectrum of a CTB which represents a superposition of the CTB of the two electron-donating groups so that of the one electron-accepting substituent or of the CTB of the single electron-donating substituent on that of the two-electron-accepting substituents[50,52].

Using the data presented, we shall attempt to explain the variation of ϕ_{AB} for the SPP (see Table) as a function of the wavelength of the exciting light and the SPP structure. In the first place one should note that in weakly polar and non-polar solvents the quantity ϕ_{AB} reaches a maximum value following irradiation of nitro-substituted SPP by light at wavelengths of 365 and 405 nm, which excite mainly the $\pi l-\pi^*\pi_n^*$ transition ($\phi_{AB}^{405}=0.45$ for SP_8 in ethyl acetate at 293 K[38]). The values of ϕ_{AB}^{313} are lower than the corresponding ϕ_{AB}^{365} (see Table). The lower value of ϕ_{AB}^{313} compared with ϕ_{AB}^{365} can apparently be caused by the fact that the light with $\lambda=313$ nm excites the $\pi-\pi^*$ transition in the indoline component of the SPP in addition to the $\pi l-\pi^*\pi_n^*$ transition. On the other hand, the excitation of the indoline component of the SPP can lead to the dissipation of energy through the conformational vibrations of the indoline component[22] and hence to a decrease of ϕ_{AB} for the SPP. Furthermore, the lower value of ϕ_{AB}^{313} for nitro-substituted SPP compared with ϕ_{AB}^{365} can be explained by the fact that the light with $\lambda=313$ nm begins to excite in the benzopyran component of the SPP a transition with an energy greater than that of the PCA transition. The $C_{(2)}-O$ bond dissociation will occur at vibrational levels lying above the electronically excited states. This is indicated, for example, by the strong competition of the photochemical processes with internal conversion to the S_2 states of chromenes and SP_2,[13] as well as the formation of coloured forms of SP_3[9,22] and 6′-methoxy-SP_1[9] under the influence of light at wavelengths of 254 nm[22] and 265 nm[9-22]—this light can excite the S_0-S_3 transition in the benzopyran component of the SPP[25]. However, the excitation of these transitions, which are not photochemically active, does not apparently entail a redistribution of the electron density in the molecule necessary for the stabilisation of form B, and the efficiency of the formation of the coloured form of the SPP from the S_2 and S_3 states is therefore lower than the efficiency of their formation from the S_1 PCA state. This can explain the lower value of ϕ_{AB}^{265} compared with ϕ_{AB}^{365} for SP_3 in petroleum ether[22]. However, unambiguous conclusions are difficult to arrive at, because, as stated in Section I, the indoline fragment of the molecule absorbs in this region, which complicates the interpretation of the results.

As regards SP_2, the PCA transition in the naphthopyran component can only be the $\pi l-\pi^*$ ($2p_z-\pi^*$)[15] transition and its relative contribution to the excitation of the naphthopyran component is smaller than the contribution of the corresponding transition to the excitation of the benzopyran component in view of the more extensive π system in the former case[16]. Light at wavelengths of 313 and 365 nm therefore excites mainly the $\pi-\pi^*$ transitions in the naphthopyran component[13]. These causes also apparently account for the decrease of the values of ϕ_{AB}^{313} and ϕ_{AB}^{365} for SP_2 compared with the corresponding values for the nitro-substituted SPP and ϕ_{AB}^{313} for SP_1 (see Table).

Since the intensity of the $n-\pi^*$ transitions is lower by ~1–2 orders of magnitude than the intensity of the $\pi-\pi^*$ transitions[36], the influence of the $n-\pi^*$ transitions on ϕ_{AB} can be appreciable only in the "tail" of the band corresponding to the PCA transition. Probably for this reason the quantity ϕ_{AB}^{365} for SP_{23} is significantly smaller than ϕ_{AB}^{313}. Indeed the frequency of the $n-\pi^*$ transition, due to the CHO group, is independent of the size of the aromatic π system and amounts to 27000 cm^{-1} (370 nm)[53] and the extinction coefficient at the maximum of the band due to the $n-\pi^*$ transition is 50–60 litre $mole^{-1}$ cm^{-1} for benzaldehyde[47], i.e. amounts to half the extinction coefficient for SP_{23} at 365 nm. On the other hand, light with $\lambda=313$ nm excites mainly the PCA transition in SP_{23} and the value of ϕ_{AB}^{313} for SP_{23} is therefore comparable to ϕ_{AB}^{313} for the SPP of the type of SP_3 (see Table) and Fig.1.

Thus, in relation to the SPP of different structures, it is seen that the successful formation of the coloured form of the SPP under the influence of light requires the excitation of a PCA transition of the type of $\pi l-\pi^*\pi_n^*$.

The variation of ϕ_{AB}^{365} over the series of nitro-substituted SPP can be accounted for by employing the known relations governing the variation of the intensity of CTB in the spectra of aromatic compounds with their structures, which are also presented at the beginning of this Section. Taking these data into account, we shall divide all the nitro-substituted SPP without condensed rings in the indoline part of the molecule into two groups. The first group includes the SPP in the benzopyran component of which it is possible to distinguish a structure corresponding to a substituted *p*-nitrophenol (see Table, SP_3-SP_{16}). The second group includes the SPP whose benzopyran components can be modelled by substituted *m*- and *o*-nitrophenols ($SP_{17}-SP_{20}$). According to the data presented above, the greatest intensity of the band dissociated with charge transfer from the oxygen heteroatom to the nitro-group will occur in the spectra of the SPP of the first group; this is confirmed by the absorption spectra illustrated in Fig.1. Accordingly, the quantity ϕ_{AB}^{365} for this group of compounds is greater than the corresponding quantum yield for the second group.

The variation of ϕ_{AB}^{365} within the groups can also be explained on the basis of the considerations described above. For example, the introduction of the OCH_3 group in the 8′-position (SP_8, SP_9) should reduce the probability of the ICT from the oxygen heteroatom to the nitro-group and hence to a decrease of ϕ_{AB}^{365} compared with ϕ_{AB}^{365} for SP_3, because there is a possibility of a competing charge transfer from the electron-donating OCH_3 group to the nitro-group. Apart from this factor, which leads to a decrease of ϕ_{AB}^{365}, when the OCH_3 or OC_3H_7 group is introduced into the 7′-position (SP_5, SP_6, and SP_7), the steric effect of the substituents will be manifested, leading to the rotation of the nitro-group relative to the plane of the benzene ring and hence to a decrease of the intensity of the PCA transition and the associated band, i.e. to an additional decrease of ϕ_{AB}^{365} (see Fig.1 and Table).

The introduction into the 8′-position of substituents with a weak electronic effect should not influence appreciably the CTB. The insignificant difference between the CTB for SP_{11} and SP_3 (Fig.1) as well as the insignificant decrease of ϕ_{AB}^{365} for SP_{11}, SP_{12}, and SP_{13} compared with ϕ_{AB}^{365} for SP_3 (see Table) are consistent with this. The appreciable decrease of ϕ_{AB}^{365} for SP_{14} following the introduction of a bromine atom in the 8′-position compared with ϕ_{AB}^{365} for SP_3 is apparently caused by the influence of the heavy bromine atom.

The presence of the heavy atom is known[54,55] to be capable of influencing the efficiency of both the intercombination transition and of the non-radiative deactivation of the triplet states of the molecule. The bathochromic shift of the long-wavelength CTB after the introduction in the 7′- or 8′-position of substituents with an appreciable electronic effect is consistent with the available data (see above).

The decrease of ϕ_{AB}^{365} for SP_{20} by a factor greater than 2 compared with that for SP_{18} in conjunction with the small difference between the intensities of the CTB in the spectra of these spiropyrans (Fig.1) may be associated with the fact that in the case of SP_{20} the band associated with the charge transfer from the oxygen heteroatom to the nitro-group is overlapped by the band associated with the charge transfer from the chlorine atom to the nitro-group.

According to X-ray diffraction data for the SP_{18} single crystal[5], the angle θ (see above) in this SPP is 54°. Since the extinction coefficient at the maximum of the band due to the charge transfer from the aromatic rings to the nitro-group is proportional to $\cos^2\theta$,[47,49] it follows that the angle θ for SP_3 can be estimated from θ for SP_{18} and the extinction coefficients at the CTB maxima for SP_3 and SP_{18}. The estimate yields a value of θ close to zero. This result is consistent with the available data for the influence of various substituents in nitrobenzene[47,49] on θ. In particular, in the absence of substituents the angle θ in nitrobenzene is zero and the band associated with the charge transfer from the benzene ring to the nitro-group has its maximum intensity[47,49]. The decrease of ϕ_{AB}^{365} for SP_{16} in dioxan almost by a factor of two compared with ϕ_{AB}^{365} for SP_8 is apparently caused by the mutual steric influence of the nitro-groups in the 5′- and 6′-positions.

The decrease of the values of ϕ_{AB}^{365} for SP_{21} and SP_{22} by more than an order of magnitude compared with ϕ_{AB}^{365} for SP_3 is probably caused by the fact that, when the benzene ring is condensed with the indoline component, the energy levels of the latter are lowered so much that, firstly, this component begins to absorb light with $\lambda = 365$ nm (i.e. the situation observed on irradiation of SPP of the type of SP_3 with light at $\lambda = 313$ nm obtains) and, secondly, the deactivation of the excited states of the benzopyran component by energy transfer to the indoline component becomes possible.

Thus the satisfactory correlation between the ϕ_{AB} for the SPP and the intensity of the long-wavelength absorption band in their spectra as a function of their structure indicates the validity of the identification[38,39] of the long-wavelength absorption band of the initial form of the SPP with the CTB band due to a PCA transition of the type of $\pi l - \pi^*\pi_n^*$ and the validity of the mechanism of the SPP photocolouring reaction based on this finding.

VI. THE MECHANISM OF THE RADIATION-INDUCED COLOURING OF SPIROPYRANS

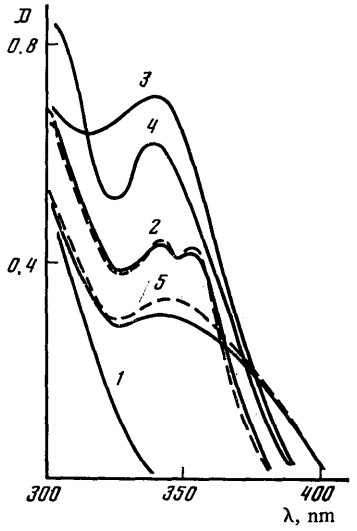
The first studies on the radiolysis of spiropyrans in frozen solutions were carried out by Hirshberg[56,57], who established that the coloured form of the SPP produced on irradiation with fast electrons is identical with form B, which arises when the SPP is irradiated with ultraviolet light[56]. Further studies of the radiolysis of the SPP in polymers [in polystyrene, poly(methyl methacrylate), polyvinylcarbazole[22,29,39,58]] and benzene solution[7,59,60] showed that the colouring of the SPP on radiolysis takes place mainly as a result of electronic energy transfer from the matrix to the SPP via a triplet–triplet mechanism.

This result permits the conclusion that the colouring of the SPP on radiolysis proceeds mainly via the chemically active triplet state which has been shown in Section IV to be the $T_{\pi l,\,\pi^*\pi_n^*}$ state. Thus the intramolecular dissociation of the $C_{(2)}$–O bond and the formation of the coloured form of the SPP on radiolysis should in essence be of the same type as in the photoexcitation of the SPP and its efficiency should therefore be greater the more effective the population of the chemically active SPP state. This hypothesis is supported by the finding that the variation of the radiation yield of the coloured forms of the SPP (G_B) under the influence of γ-rays at 77 K proved to be similar to the analogous variation of ϕ_{AB} for the SPP (see Table). Consequently, the dependence of the efficiency of the radiation-induced colouring of the SPP on their structure can apparently be explained in terms of the ideas developed in Sections IV and V.

Indeed, it follows from a comparison of the absorption spectra of the initial forms of the SPP in polystyrene (Fig.3) that there is a correlation between the intensity of the CTB and the radiation yield of form B of spiropyrans analogous to the correlation between the intensity of the CTB in the spectrum of a solution in ethyl acetate and the radiation yield of the photocolouring process (G_B).

The influence of substituents on the efficiency of the population of the chemically active triplet state of the SPP on radiolysis can be traced in relation to SP_8. As stated in Section V, apart from the chemically active transition with charge transfer from the oxygen heteroatom to the nitro-group ($\pi l - \pi^*\pi_n^*$ transition), in this SPP there is a possibility of an analogous transition with charge transfer from the electron-donating OCH_3 group to the nitro-group ($\pi l' - \pi^*\pi_n^*$ transition), associated with a band which should undergo a bathochromic shift relative to that of the $\pi l - \pi^*\pi_n^*$ transition. The absorption spectra of the SPP presented in Fig.1 shows that the shift can be by ~2000 cm^{-1}. Since the $\pi l - \pi^*\pi_n^*$ and $\pi l' - \pi^*\pi_n^*$ transitions are of the same electronic type, presumably the $S_1 - T_0$ splittings for these transitions are likewise similar[15,16,36]. Then the sequence of the lowest electronic levels for SP_8 is as follows: S_0, $T_{\pi l',\,\pi^*\pi_n^*}$, $T_{\pi l,\,\pi^*\pi_n^*}$, etc. This sequence of triplet levels leads to an effective

deactivation of the chemically active $T_{\pi l,\,\pi^*\pi_n^*}$ level and hence to an appreciable decrease of G_B for SP_8 compared with G_B for SP_3. Indeed our estimates of the radiation yields of forms B showed that G_B for SP_8 is almost an order of magnitude smaller than for SP_3 (see Table).



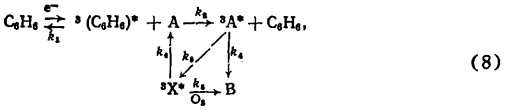


Figure 3. Absorption spectra of polystyrene films of identical thickness with added spiropyrans at equal concentrations at room temperature (continuous lines) and at 77 K (dashed lines): 1) SP_1; 2) SP_2; 3) SP_3; 4) SP_4; 5) SP_{18}.

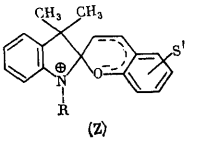
Analogous results for the dependence of the efficiency of the radiation-induced colouring of the SPP on their structure were obtained in a study of the pulse radiolysis of benzene solutions of indoline SPP (compounds SP_3^*, SP_8^*, and SP_{14}^*), having benzopyran components similar to those of SP_3, SP_8, and SP_{14} respectively[7,58,59,60]. Kryukov and Vannikov[60] published a mechanism of the colouring of the SPP on radiolysis:



where $^3X^*$ is the triplet state of the X-isomer of the SPP. The rate constants for the formation of form B in a solution through which helium is bubbled have the following values (s^{-1}): $k_4 \geq 10^8$ and $k_8 \cong 10^4$, while in the presence of oxygen we have $k_4 \geq 10^8$ and $k_8 \cong 1.5 \times 10^6$.[59,60] It has been noted[59,60] that the ratio of the rapid and slow stages in the formation of form B depends greatly on the SPP structure. For example, the ratio of the optical densities of form B at the maximum of its long-wavelength absorption band $D^1_{\lambda max}/D^2_{\lambda max}$ ($D^1_{\lambda max}$ was measured immediately after a 40 ns pulse and $D^2_{\lambda max}$ was measured after 1 μs) is 0.6 for SP_3^*, 0.3 for SP_{14}^*, and 0 for SP_8.[60] The absence of a rapid stage in the reaction involving the formation of form B for SP_8 can be explained by the fact that the chemically active $T_{\pi l,\,\pi^*\pi_n^*}$ ($^3A^*$) state is effectively deactivated as a consequence of the internal transition to the $T_{\pi l',\,\pi^*\pi_n^*}$ state, which is chemically inactive.

It has been noted[60] that the method of pulse radiolysis is preferable for the investigation of the mechanism of the formation of the coloured form of the SPP from the triplet states of the initial form of the SPP compared with the method of sensitised photocolouring of the SPP in view of the fact that the introduction of high concentrations of triplet energy donors introduces an uncertainty into the interpretation of the processes occurring in the system.

A short-lived absorption band in the region of 450 nm has been discovered[59] and assigned to the triplet–triplet transition of the intermediate, which is a *cis*-cisoid isomer of the SPP (X-isomer) in the triplet state. At the same time the ground state of the X-isomer was not manifested optically in the wavelength range from 450 to 650 nm[59] (the absorption band due to the S_0–S_1 transition of the X-isomer is in the range 440–460 nm[6,9–11]).

The establishment of the triplet states of the initial forms of the SPP in the photolysis of single crystals of nitro-substituted SPP at low temperatures has been observed[61,62] by EPR. The author[61] attributed the observed EPR signals to the EPR spectrum of a radical pair with an average distance between the paramagnetic centres of 0.26 nm. It has been suggested[29,61] that the radical pairs are formed as a result of an intramolecular electron phototransfer from the indoline component of the SPP to its benzopyran component and can be represented schematically as follows:

(Z) (9)

The distance between the nitrogen and oxygen heteroatoms of the indoline and benzopyran components, determined by X-ray diffraction[5], is 2.3 Å. Bearing in mind that the difference between this quantity and the average distance between the paramagnetic centres in a triplet radical pair can be due to the steric delocalisation of the interacting electrons and the inaccuracy of the description of their interaction by the point dipole moment[63], it appears that the mechanism of the formation of these pairs proposed by the present authors[29] does indeed operate. It is noteworthy that it has also been suggested[15,29] that the intermediate Z is involved in the photocolouring of the SPP. We may point out that generally speaking the triplet state of the X-isomer, to the triplet–triplet absorption of which a short-lived band at 450 nm has been ascribed[59,60], may be similar to Z in its nature.

Aspartame and Its Analogues

L.A.Pavlova, T.V.Komarova, Yu.A.Davidovich, and S.V.Rogozhin

The results of studies on the biochemistry of the sweet taste are briefly reviewed. The methods of synthesis of "aspartame"—a sweet dipeptide—are considered, its structural analogues are described, and quantitative estimates are made of the degree of sweetness relative to sucrose. Attention is concentrated mainly on problems of the relation between the structure of the substance and its taste in the series of aspartyl derivatives.
The bibliography includes 118 references.

I. INTRODUCTION

After the accidental discovery by Schlatter and coworkers[1] in 1969 of the sweet taste of the methyl ester of α-L-aspartyl-L-phenylalanine, numerous studies devoted to the synthesis and applications of "aspartame" (this was the name given to this sweet preparation, first manufactured on an industrial scale by the American G.D.Searle Company[2]) have been published. The study of the structural analogues of aspartame from the standpoint of their taste merits no less attention. Studies on these lines have been prosecuted on a wide scale since 1969 until today and have made a considerable contribution to the theory of the sweet taste. The problem of the relation between structure and taste, the solution of which will permit a specific search for new intensely sweet compounds, its particularly urgent[3].

The increased interest in sweet peptides is justified also from the practical point of view. The need for synthetic flavours designed to replace sucrose continuously increases[4,5]. Many representatives of the series of dipeptide esters are superior to sucrose as regards the intensity of the taste by factors of hundreds and thousands. Their application would make it possible to reduce sharply the calorie content in view of the small amount of substance required. The assimilation of such products is unrelated to insulin. By virtue of these properties, sweet peptides (together with other low-calorie natural and synthetic sweet substances) can be used in low calorie diets and are recommended primarily for patients suffering from obesity and sugar diabetes[4-9].

Being indifferent to microorganisms, sweet dipeptides such as aspartame are particularly convenient for pharmaceutical use (for example for the sweetening of medicines, which is extremely important for the treatment of children[10-12], particularly since aspartame is safe for both children and adults[13]). From the medical point of view, aspartame has yet another important advantage over sucrose: it does not stimulate the development of dental caries[5].

When aspartame is used in combination with sucrose, glucose, cyclamate, or saccharin, a synergistic effect is produced, as a result of which the consumption coefficients of both mixture components are reduced[5]. Furthermore, it has been observed that the addition of a small amount (2–3 wt.%) of aspartame or some of its analogues to saccharin fully masks its unpleasant flavour[12].

Among the most widely used synthetic sweeteners employed abroad at the present time (particularly in the USA), aspartame is superior as regards its taste[4,5]. The metabolism and potential toxicity of aspartame have been thoroughly investigated[14,15]. This preparation has withstood numerous tests for toxicity and carcinogenic properties and is contraindicated only for patients suffering from phenylketonuria[2,5]. It has been noted that aspartame influences the pH of human whole saliva and tends to alter the concentration of lactic acid in it[16].

Aspartame is convenient for use in a wide variety of dietary compositions[5]. The only limitation is its lability with respect to hydrolysis in strongly acidic and neutral-alkaline media, particularly on heat treatment[5,17]. Methods have been proposed for the modification of labile dipeptide esters which eliminate this disadvantage. One of the ways of reducing the hydrolytic lability of sweetening agents consists in binding the molecules responsible for the sweet taste to macromolecules, for example, dextran[18,19] or the soya-bean protein extract[20]. Such molecular aggregates are obtained when aqueous solutions of both components are dried together (in the required proportions) by spraying or sublimation. It is then important to find the optimum size of the aggregate, since an increase of molecular size hinders the attainment of the required contact with the receptor and can lead to an appreciable decrease of the degree of sweetness. Another way is to synthesise compounds with a structure similar to that of aspartame but without a tendency towards hydrolysis and the formation of diozopiperazine derivatives in aqueous solutions[21]. (These compounds are considered in Section 4 of the present review.)

Thus the importance of synthetic peptide flavours is evident. The problem arises of the development of the most rational and economical syntheses of the best examples of the compounds under consideration, which would make them sufficiently readily available at least for therapeutic purposes.

II. CERTAIN ASPECTS OF THE BIOCHEMISTRY OF THE SWEET TASTE

Before considering the methods of synthesis and the structure–taste relations for the enormous number of compounds obtained on the basis of the aminoacids, it is useful to describe briefly the problems of the theory of the sweet taste.

The taste reaction is a complex phenomenon which has been inadequately investigated. The perception of taste arises as a result of the interaction of the molecules of the substance stimulating the taste (tastant) with the corresponding chemoreceptor. The human sensor systems incorporate several types of the so-called taste buds, i.e. sensitive sections of the tongue. It has been established[22] that the receptors responsible for the sweet taste are located

mainly in the front part of the tongue in mushroom-shaped buds. The buds contain taste cells, in the membranes of which chemoreceptors are believed to be distributed[23,24].

The protein forming complexes with sugars and apparently behaving as a receptor responding only to sweet substances[25–29] has been isolated from the epithelial tissues of animal tongues and was subsequently investigated. The primary chemoreception processes were investigated at the molecular level for the first time by Beidler[30–32], who established, in particular, that physical processes of the type of adsorption underlie the interaction of the tastant with the active centres of the plasmatic membrane of the tast cell, this hypothesis was subsequently confirmed[33].

The wide variety of sweet substances having completely different compositions, constitutions, and geometric structures interfered for a long time with the discovery of the principal distinctive features common to all sweet compounds and enabling the receptor to recognise them. A specific common feature of sweet molecules was discovered by Shallenberger and Acree[34], who specified the concept of contact between the tastant and the receptor, having established that such contact is achieved via hydrogen bonds formed within specific sections of the molecule of the tastant and the active centres of the receptor. They claim[34] that a sweet substance must have two polar functional groups, one of which behaves as a proton donor and the other as a proton acceptor; they designated them by AH and B. In order to achieve two-point binding of the molecule to the receptor via hydrogen bonds, the distance between the atoms or groups of atoms A and B in the molecule must correspond to the distance between the active centres of the receptor. It has been established[34] that it amounts to ~3 Å.

Although this theory is in fact imperfect, it is nevertheless valid in relation to different classes of compounds with a sweet taste. The mechanism of the interaction of the receptor–sweetener pair was refined on the basis of data obtained in the study of the taste of aminoacid stereoisomers[35–39]. The fact that many D-aminoacids are sweet, while their L-isomers are tasteless or bitter indicates the stereospecificity of the chemoreceptor and leads to the conclusion that there exists a third contact between the tastant and the receptor. By calculating the interaction energy in the tastant–receptor model system, it was shown[40] that this type of interaction represents hydrophobic binding. Consequently, apart from the AHB polar system, the tastant molecule should contain a hydrophobic region (it will be designated by X) oriented appropriately[41].

The degree of hydrophobic binding to the receptor apparently determines the intensity of the taste. Deutsch and Hansch[42] and Holthae and Kier[41] demonstrated the existence of this correlation in relation to alkyl-substituted 2-amino-4-nitrobenzenes. It will be shown below, in relation to specific examples, how great is the influence of the hydrophobic properties and the geometric form of the substituents in the side chain in the series of aspartame analogues on the intensity of the taste of these compounds. It has been suggested that the third binding region X in the series of dipeptide esters is located at the centre of a branched substituent in the side chain; for example, this is the centre of the benzene ring in the case of aspartame[43].

It has been suggested[44–46] that the more exact the correspondence of the surface features of the tastant molecule and the "working" surface of the receptor, the more readily is the required contact between them attained and the stronger the perception of the taste. The external form of the "sweet unit" can thus serve approximately as a model of the active receptor surface[46]. One of the preferred conformers of aspartame, which is capable of binding to the receptor without steric hindrance, was chosen as a model[44–46] (Fig. 1a). The authors claim that this model surface of the receptor is consistent with the shape of the molecules of sweet substances of different types, which can be useful for the prediction of the taste of new structural analogues of aspartame and other compounds.

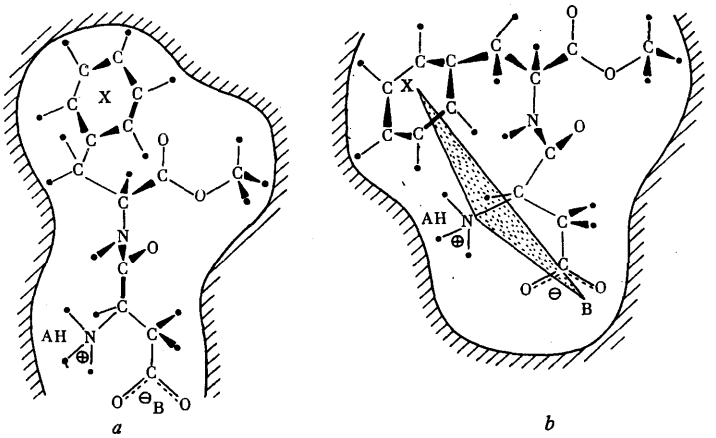

Figure 1. The suggested conformation of the aspartame molecule and of the active site of the taste receptor according to the data of Lelj et al.[44] (a) and Heijden et al.[43] (b).

Another aspartame conformer was selected as a model of the receptor by Heijden et al.[43] (Fig. 1b). According to the authors[43], only for this structure of the sweet dipeptide can the identity of the taste be influenced by the dimensions and geometrical shape of the side chain and of the terminal ester group, which ensure the maximum coupling with the receptor when the correspondence between the surfaces is satisfactory; furthermore, the structural data for this conformer agree best with the calculated A–B–X distances. Yet another model of the hydrophobically binding part of the receptor, obtained on the basis of structural data for the sweetest diesters of α-aspartylaminomalonic acid, has been proposed[47]. The contradictions between different authors as regards the topology of the taste receptor are due to the fact that their conclusions are based on calculations for individual static conformations of aspartame (or other sweet compounds) without taking into account the structural changes in the course of the interaction with the receptor. More accurate data can be obtained by the direct investigation of receptor–dipeptide ester complexes.

Despite the available data[24,40,48–53], the mechanism of the interaction of the tastant with the receptor required further thorough investigation. One cannot rule out the possibility that certain enzymes are involved in the perception of taste[24,54].

III. METHODS OF SYNTHESIS OF ASPARTAME

The methyl ester of α-L-aspartyl-L-phenylalanine has an intense sweet taste, being 150–180 times sweeter than sucrose. One of its component aminoacids (phenylalanine) is an unsubstituted natural aminoacid.

Numerous studies have been carried out on the methods of synthesis of aspartame. The most attractive procedure in view of its ease and the low cost of the starting material is

the method based on the aminolysis of the inner anhydride of aspartic acid. The anhydride of aspartic acid with the amino-group protected by groups usually employed in peptide synthesis (benzoxycarbonyl, t-butoxycarbonyl, o-nitrophenylsulphenyl, formyl, etc.[55–60]) and the anhydride in the form of different salts[61–66] are used equally widely. The aminolysis is carried out in organic solvents, aqueous organic mixtures, and water (at a specific pH)[59].

The aminolysis of the salts of aspartic acid anhydride can be carried out selectively with the preferential formation of the α-isomer by reducing the temperature, by employing an excess of the amino-component, and by introducing various additives into the reaction mixture[61]. These additives can be (1) acids (acetic acid[61], carbon dioxide[62–64], and orthophosphoric acid[65]); (2) mixtures of weak acids and lower aliphatic alochols[62]; (3) mixtures of strong acids and alcohols[66,67]. Aqueous solutions of inorganic bases have been used for the same purpose as additives in the aminolysis of the *N*-benzoxycarbonylanhydride of aspartic acid[68].

The above group of methods is characterised by general advantages and disadvantages: on the one hand, there is the evident simplicity and low cost of the method of synthesis and, on the other hand, the problem of freeing the main product from undesirable (in the given synthetic scheme) impurities, primarily the corresponding β-isomer, which is difficult to separate from the main product and has bitter taste[69–71].

The problem of separating the α- and β-isomers having opposed tastes is solved in different ways, which are based on the following factors: (1) on the different solubilities of their salts with strong inorganic acids[58,72,73] or with aromatic acids[74] (the α-isomer salts are usually less soluble in aqueous and aqueous organic media than the corresponding salts of the β-isomer); (2) the reduced reactivity of the β-isomer in the reaction with ketones. On treatment with acetone, the α-isomers of aspartame and some of its analogues readily form the corresponding 4-imidazolidinones, which are readily soluble in acetone; the β-isomers, which do not react, remain insoluble[75,76]. The latter method suffers from the following disadvantage: in order to isolate aspartame in a free form, the fairly stable 4-imidazolidinone must be hydrolysed at an elevated temperature, whereupon there is a possibility[77] of the partial decomposition of the labile aspartame.

A novel method has been proposed for synthesising aspartame, which has been recommended as an industrial procedure; it is based on the interaction of the *N*-protected aspartic acid with the amino-component in the form of an ester of an *N*-carbonylaminoacid[78]. The main disadvantage of this method is the necessity to work with phosgene at elevated temperatures (this imposes certain requirements on the apparatus) and also the inevitable formation of the β-isomer as a side product.

Aspartame has been obtained[79] by the interaction of the *N*-protected aspartic acid with formaldehyde and subsequent aminolysis of the oxazolidinone, which, in view of its inadequate reactivity, reacts with the amino-component only at an elevated temperature (50 °C). A method has been developed for the synthesis of sweet α-aspartyl derivatives using the *N*-carboxyanhydride of a β-*O*-protected derivative of aspartic acid[80]. A bottleneck in this procedure is the stage involving the aminolysis of the *N*-carboxyanhydride, which is achieved in the pH range 9–12 and under these conditions there is a possibility of the hydrolysis of the ester group.

Aspartame has also been synthesised[81] by a non-traditional method from the dichloride of maleic acid. It is important to note that this yields only the DL–L-form. It has been suggested that aspartame be obtained from (*S*)–4-vinylazetidin-2-one,[82] but the method is inconvenient owing to the instability of the intermediates.

Naturally the classical methods of peptide synthesis (the carbodi-imide, mixed anhydride, or activated esteer methods) have also been used to obtain aspartame and its analogues[83–85]. Their advantages and disadvantages are well known[86]. A version of the synthesis of aspartame using the convenient condensing agent trifluoroacetoxysuccinimide has been described[87]. This reagent ensures the rapid and complete conversion of the *N*, β-*O*-disubstituted carboxy-component into the corresponding α-*N*-hydroxysuccinimide ester, which readily undergoes aminolysis.

Modified methods for the removal of the protecting groups in the course of the synthesis of free dipeptide esters with a sweet taste have been put forward[88–90]. It has been reported[91] that the manufacture of aspartame by an enzymatic method from racemic aminoacids, which are the most convenient and economical starting material, has been stablished in Japan[91].

Table 1. The relative degrees of sweetness (RS) of aspartame, its isomers, and analogues[1].

Compound	RS*

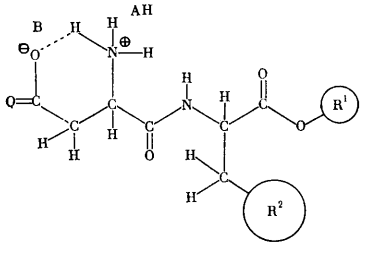
IV. RELATION BETWEEN THE STRUCTURE OF A SUBSTANCE AND ITS TASTE IN THE SERIES OF ASPARTAME ANALOGUES

1. Esters of α-aspartyl-containing Dipeptides

Mazur et al.[1] achieved the synthesis of a large series of aspartame analogues (~50 compounds) and reached the first conclusions concerning the structure—taste relation for aspartyl-containing derivatives. The following requirements must be met for a given substance to have a sweet taste: (1) unsubstituted amino- and carboxy-groups must be

present with a specific distance between them; (2) a specific configuration of the asymmetric carbon atom is necessary; (3) an ester group must be present at the C-end of the dipeptide. The authors[1] assumed that, even if only one of these requirements is infringed, the sweet taste disappears (Table 1). Later it was shown that these conditions are not obligatory for the retention of the sweet taste in the series of aspartyl-containing compounds.

When the α-aspartyl residue was replaced by other aminoacids, even one with a similar structure such as **glutamic** acid, not a single sweet dipeptide was obtained[1]. The explanation is apparently that, for the interaction with the receptor, it is important that that AHB system should be planar, i.e. in the given instance that the amino- and carboxy-groups of the N-terminal aminoacids should form a planar cyclic zwitter-ionic form[44,48] (Fig.2). This condition can be fulfilled only when the *N*-terminal aminoacid is aspartic or aminomalonic acid. As regards the second part of the aspartame molecule, the latter can undergo various changes to a greater extent. For example, phenylalanine can be replaced by L-tyrosine or L-methionine without loss of the sweet taste.



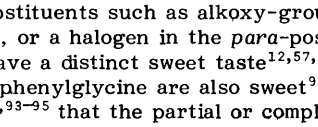


Figure 2. The esters of sweet α-aspartyl-containing dipeptides.

In order to test the requirements imposed on the stereochemistry of the molecule, L–D, D–L-, and D–D-isomers of aspartame were synthesised; they all proved to be bitter. Schlatter[84] showed that the sweet taste does not disappear fully in the DL–DL-, DL–L-, and L–DL-modifications, although the degree of sweetness of these compounds is lower than that of the L–L-isomer.

The data of Mazur et al.[1] demonstrate the influence of the size of the C-terminal ester group on the intensity of the sweet taste, namely the intensity of the sweet taste decreases with increase of the size of the ester group. This shows that variations in the size of the molecule are not unimportant for the taste receptor and confirm the validity of the conclusions of Heijden et al.[43]

Mazur and coworkers[83] extended the list of sweet dipeptides by discovering that these include also the esters of L-α-aspartyl-L-threonine, L-α-aspartyl-*S*-alkyl-L-homocysteine sulphone. The aspartame analogues obtained by introducing substituents such as alkoxy-groups, the hydroxy-group, or a halogen in the *para*-position of the benzene ring have a distinct sweet taste[12,57,83]. The esters of L-α-aspartylphenylglycine are also sweet[92]. It has been observed[10,57,78,93–95] that the partial or complete hydrogenation of the benzene ring in compounds having the general formula

R^1=Alk

R^2=H, OH, OAlk, or Hal

has a favourable effect on the intensity of the sweet taste.

In their study of the contribution of different structural elements to the sweet taste of dipeptide esters, Mazur et al.[95] established that the C-terminal aminoacid can be aliphatic and showed that the intensity of the sweet taste of compounds of the type

varies with the size, form, and hydrophobic properties of the group R [95,96] (Table 2). It was noted that the methyl esters of L–L-dipeptides of this kind do not have a sweet taste as long as the number of carbon atoms in the chain of R does not reach four.

Table 2. The esters of α-aspartyl-containing dipeptides* of the type

*L–L-configuration.

In the series of α-aspartylalanine and α-aspartyl-*C*-alkylglycine esters, the sweetest dipeptides proved to be those with the L–D-configuration[85,95,97] (Table 3). These compounds are distinguished by the following feature: if the C-terminal ester group R^1 is sufficiently large, as in the case of the n-propyl or isopropyl esters, the group R^2 must be small in order to obtain an intense sweet taste; with increase of its size, the degree of sweetness diminishes[85,95] (Table 3).

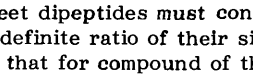

Table 3. The esters of α-aspartylalanine and α-aspartyl-*C*-alkylglycine*:

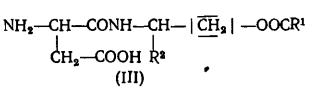
*L–D-configuration.

In general, all sweet dipeptides must contain two hydrophobic groups with definite ratio of their sizes[48] (Fig.2). It has been shown[98] that for compound of the type

there is a possibility (without loss of sweet taste) of certain combinations of the substitutents R^1 and R^2, which can be aliphatic, alicyclic, or aromatic. It has been noted[99] that the salts of such compounds with certain acids, for example, with malic, citric, etc. acids, are particularly sweet. It has also been recommended that aspartame be used in combination with citric acid[100,101]. The intensification of the taste of dipeptide esters in the presence of citric acid had been observed earlier[10]. Presumably in this case Beidler's hypothesis[23] that the conformation of the membrane of the taste cell varies with the pH of the medium, which can intensify the sweet taste in the presence of the tastant, is valid in this case.

In their search for hydrolytically stable aspartyl derivatives, Miyaoshi et al.[21] synthesised compounds of a new type. In order to rule out the possibility of the formation of substituted dioxopiperazine, they introduced an additional methylene group in various positions along the peptide chain and obtained two types of compounds with an L–D-configuration:

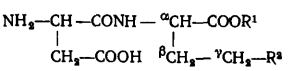


(I)

(II)

Although the length of some of these compounds is similar to that of the n-propyl ester of L-α-aspartyl-D-alanine, the relative sweetness of which amounts to 170 units, the rearrangement of the molecule induced undesirable changes in the structure, which led to a decrease of the level of sweetness to 20 units.

Compounds of type (III), obtained with an increase in chain length, as in compounds (I), with a simultaneous transformation of the terminal carboxy-group, proved more successful:



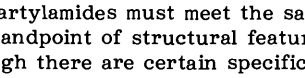
(III)

Eleven *O*-acyl-2-(L-α-aspartylamino)-D-alkanols (III) proved sweeter than sucrose by a factor of 100 and more[21]. The structural requirements which must be met by these compounds as regards the dimensions of the hydrophobic groups R^1 and R^2 are the same as for the dipeptide esters. The configuration of the 2-aminoalkanol esters must correspond to the D-form of the aminoacids; none of the *O*-acyl-2-(α-L-aspartylamino)-L-alkanols proved to be sweet. *N*-(L-α-aspartyl)-*O*-cyclobutyl-D-alaninol is 220 times sweeter than sucrose and, in contrast to aspartame, withstands boiling in aqueous solution at pH 4 and 7 for 1 h without appreciable changes in the taste[21].

The structure–taste relations for α-aspartyl derivatives of hydroxyaminoacids have been investigated[102–104]. The esters of L-α-aspartyl-L-β-(*erythro* and *threo*)-hydroxynorleucine, -*O*-actyl-L-serine, -D-serine, -D-threonine, and -D-allothreonine have been synthesised and their taste compared with that of the corresponding dipeptide esters without a hydroxy-group[103]. It was observed that the introduction of the hydroxy-group has different effects on the taste of the L–L- and L–D-dipeptides: it reduces the sweet taste in the series of L–L-peptide esters and intensifies it in the series of the L–D-isomers. For example, the esters of L-α-aspartyl-D-serine and L-α-aspartyl-D-threonine proved to be sweeter than the corresponding esters of L-α-aspartyl-D-alanine and L-α-aspartyl-D-α-aminobutyric acid. It was also found that the *threo*- and *erythro*-isomers differ in the intensity of the taste[103]. Whereas in the series of the esters of the L–L-dipeptides the sweetest derivatives were the methyl esters[1], among the hydroxy-analogues with the L–D-configuration the n-propyl and isobutyl esters are sweetest[102,103].

The replacement of the methyl group in the side chain in the series of *O*-acyl-*O*-2-α-L-aspartylamino-D-alkanols[21] by the hydroxymethylene group increased the level of sweetness in one case, while in the remaining cases it caused a decrease.

The branching of the side chain by the introduction of even one methyl group in the β- or γ-position resulted in bitter compounds in the series of both hydroxy- and deoxy-derivatives of dipeptide esters[103]:

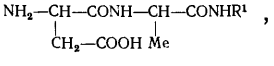


The above data show that the presence of a free or substituted hydroxy-group (depending on its location in the side chain) prevents the hydrophobic binding of the molecule to the receptor only in some cases.

In order to investigate the influence of the nature of the side chain on the intensity of the sweet taste of the esters of aspartyldipeptides, Brussel et al.[104] synthesised a series of structurally similar analogues based on *S*-alkyl-L-cysteine, *O*-alkyl-L-serine, *O*-acyl-L-serine, and asymmetric aminomalonic diesters. The dimensions of the dipeptide side chain were determined on molecular models of these compounds and the characteristics of the shape of the chain were investigated in each specific case. The authors[104] concluded, like Mazur et al.[95], that the intensity of the sweet taste of all the compounds obtained depends on the hydrophobic properties, dimensions, shape, and steric characteristics of the side chain. It has been shown clearly[104] that the degree of branching of the group R^2 in the side chain is not the only important feature, a specific geometrical position of the branching point on the side chain being more significant.

These facts show that the group R^2 of the side chain of the dipeptide ester actually interacts with the hydrophobically binding site of the receptor[43]. This conclusion is valid only in relation to L–L-dipeptides; the hydrophobic binding of the L–D-dipeptides to the receptor is possible only for the C-terminal ester group (because of the different steric dispositions of the substituents at the asymmetric carbon atom of the D-aminoacid), while in *N*-L-α-aspartyl-*O*-acyl-D-aminoalkanols this is possible only for the acyl group. This in fact explains the earlier observation[85,95,97,103] that the degree of sweetness of α-aspartyl derivatives with the L–D-configuration increases with the size of the ester group and with decrease of the bulk of the side chain.

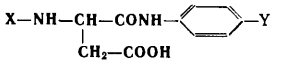
2. α-Aspartylamides



Having synthesised a series of α-aspartylamides, Mazur[105] showed for the first time that the ester group is not an obligatory element in sweet derivatives of aspartic acid; this was later confirmed in relation to aspartylacylaminoalkanols[21], which is not surprising, since the transformations of the terminal carboxy-group in L–L-dipeptides do not involve the main part of the molecule—its glucophore, which is intrinsically involved in the interaction with the receptor. This is why α-aspartylamides must meet the same requirements (from the standpoint of structural features) as dipeptide esters, although there are certain specific differences. To retain the sweet taste, it is necessary that the methyl group be present in the α-position:

Furthermore, when optically active amines are used as the starting materials, steric similarity to L–L-dipeptides must be maintained.

In the series of α-aspartylphenylalkylamides the introduction of a halogen in the *para*-position of the benzene ring as well as hydrogenation of the latter did not intensify the sweet taste[105], as had been observed for dipeptide esters. The aromatic component of aspartylphenylalkylamides can be replaced by an aliphatic chain, as in the case of dipeptide esters. The chain length of the sweetest compounds corresponds to seven carbon atoms; its decrease or increase leads to less sweet or tasteless derivatives. As was to be expected, the form of the chain influences the intensity of the taste. The sweetest α-aspartylamide is α-aspartyl-α,δ-dimethylpentylamide, being 100 times sweeter than sucrose; compounds sweeter than aspartame have not been discovered among them.



A group of sweet L-α-aspartyl-D-alanylamides of the type

where R^1 = Bu, iso-Bu, s-Bu, or cyclo-Hex, were later synthesised[106]. The level of their sweetness is approximately equal to that of aspartame (they are 100–125 times sweeter than sucrose)[106].

It is of interest to note that the presence of the α-amide linkage in all the known derivatives of aspartic acid is necessary for a sweet taste. If the amide group is alkylated or replaced by an ester group, the taste changes to bitter or disappears respectively; this transformation apparently alters the conformation of the compound so much that a three-point interaction with the receptor becomes impossible[48].

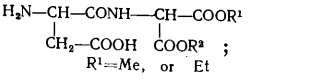
*Bitter.

**Sweet product; a quantitative estimate of the RS is not given in the original communications.

3. *N*-Acyl-α-aspartyl Derivatives

The discovery of a sweet taste in certain *N*-acyl derivatives of aspartic acid was quite unexpected[107]. The sweet taste of one of these, namely trifluoroacetyl-L-α-aspartylanalide (No.1 in Table 4), was discovered accidentally[107] (like the taste of aspartame) and could not be explained from the standpoint of the existing ideas concerning the necessity for the presence of a free amino-group in all sweet α-aspartyl derivatives. Not until 1978 was it suggested[46] that the AHB system is mainly required to fix the molecule on the active surface of the receptor. Consequently a single hydrogen bond formed by the carboxy-group may be sufficient to retain the molecule, provided that it is sterically compatible with the receptor surface[46].



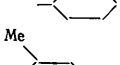
Lapidus and coworkers[107–111] noted the following features characteristic of *N*-acyl-L-α-aspartylanilides (Table 4). The introduction of a single halogen atom (except iodine) or the cyano-group in the *para*-position of the benzene ring of the anilide intensifies the degree of sweetness of the substance. The introduction of a halogen in the *ortho*- and *meta*-positions or the introduction of two halogen atoms does not lead to sweet derivatives. The introduction of substituents such as the methyl, trifluoromethyl, and hydroxy-groups in the *para*-position in the ring also has a negative influence on the taste. Among all the acyl groups tested, only the trifluoroacetyl and trichloroacetyl groups are capable of forming sweet derivatives. These two groups are apparently approximately equivalent as regards their influence on the intensity of the sweet taste (cf. Nos.6 and 10 in Table 4). Comparison of the tastes of individual *N*-acylaspartylanilides (Nos.6 and 10 in Table 4) and their analogues with free amino-groups (No.11 in Table 4) shows that the level of sweetness falls sharply following the removal of acyl groups (from 3000 to 12 units).

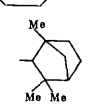
As in the series of dipeptide esters, the derivatives of D-aspartic acid lack sweetness entirely[107]. The introduction of the trifluoro- or trichloro-acetyl group into the amino-group of aspartame did not entail either an intensification or a weakening of the taste[107,108,111]. One should note that the synthesis of the *N*-trifluoroacetyl derivatives of aspartame is much simpler than that of aspartame itself; it is achieved in a single stage by the aminolysis of the *N*-trifluoroacetylanhydride of aspartic acid and there is no need to remove protecting groups. Unfortunately, the papers of Lapidus and coworkers[108–111] do not contain information about the methyl ester of *N*-trifluoroacetyl-L-β-aspartyl-L-phenylalanine as a possible side product, although one cannot absolutely rule out its formation when the ring of the corresponding inner anhydride of aspartic acid is opened.

4. The Esters of α-Aspartylaminomalonic Acid

The asymmetric diesters of α-aspartylaminomalonic acid, synthesised by Japanese investigators[112–116], are outstanding among all known sweet compounds by exhibiting the highest level of sweetness. In general aminomalonic acid is unique in the sense that it forms particularly sweet derivatives, occupying either *N*- or C-terminal positions in the dipeptide. For example, the closest analogue of aspartame—the methyl ester of DL-aminomalonyl-L-phenylalanine—surpasses it as regards the intensity of its sweet taste (156–237 units)[112].

Analysis of experimental data[112–116] showed that the ester groups of the aminomalonate must differ significantly from one another in size (Table 5). The sweetest compounds obtained are those in which one of the ester groups is OMe. Specific requirements must be met by the second ester group, since it is responsible for the hydrophobic binding to the receptor. When the R^2 groups in compounds of the type





are replaced, the intensity of the sweet taste increases in the following sequence of R^2: aliphatic alkyl < cycloalkyl < cycloalkyl monosubstituted in the 2-position < phenyl. The

introduction of a substituent into any position in the cyclohexyl ring other than the 2-position or an increase of the number of substituents reduce the degree of sweetness[47].

Since all the compounds obtained were racemic mixtures with respect to the aminomalonic residue, it is still not clear which optical isomers in fact exhibit a sweet taste. In order to predict the taste of dipeptide esters, their projection formulae have been compared[117] with those of sweet and non-sweet standards, namely aminoacids, and it was concluded that, in the group of α-aspartylaminomalonic esters, the L–L-isomers should be sweet. This hypothesis has been confirmed by literature data[118].

Table 5. Derivatives of the aminomalonic acid.

L-α-Asp-DL-Ama-OR^1 (OR^2)			
R^1	R^2	RS	References

As regards the methyl ester of aminomalonylphenylalanine, some workers[117] believe that the D–L-isomer is sweet, since its conformation agrees best with the receptor model, while others[118] give preference to the L–L-isomer by analogy with aspartame. Studies in this field are being continued and, as soon as the optically pure forms of the above dipeptides are isolated, the discrepancies will be resolved.

---o0o---

It has been shown that the assortment of sweeteners based on aminoacids is fairly wide, their advantages over glucose are in certain aspects incontrovertible, and it may be hoped that in due course universal flavouring agents, meeting most successfully the requirements imposed on synthetic sucrose substituents, will be selected from the above large list and incorporated in the food industry.

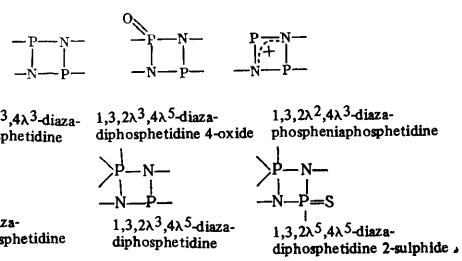
Diazadiphosphetidines

A.F.Grapov, L.V.Razvodovskaya, and N.N.Mel'nikov

The methods of synthesis and certain chemical properties of four-membered rings containing alternating nitrogen and phosphorus atoms with different degrees of coordination are examined. Attention is drawn to studies on the structure of diazadiphosphetidine rings by ^{31}P NMR and X-ray diffraction.
The bibliography includes 108 references.

CONTENTS



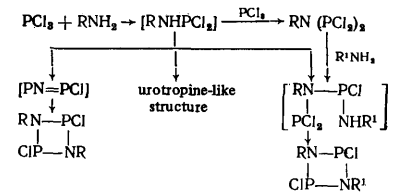
I. Introduction 324
II. Synthesis of diazadiphosphetidines 324
III. The structure of the diazadiphosphetidine ring 332

I. INTRODUCTION

Phosphorus forms extremely readily four-membered cyclic compounds with other atoms. Rings are known in which there are alternating phosphorus and sulphur, phosphorus and silicon, phosphorus and boron, phosphorus and aluminium, and phosphorus and transition metal atoms. The derivatives of four-membered nitrogen- and phosphorus-containing heterocycles are particularly numerous and important[1-6]; compounds of this class were discovered a long time ago by Michaelis[7,8]. Since the publication of Kirsanov and Zhmurova's report in 1959 concerning the synthesis of dimeric trichlorophosphazoaryls[9], a new period has begun in the study of four-membered nitrogen–phosphorus heterocycles, mainly with phosphorus(V) atoms.

Considerable advances have been made in recent years in the development of methods for the synthesis and investigation of the structure (by ^{31}P and ^{19}F NMR and X-ray diffraction) and reactivity of four-membered heterocycles with phosphorus(III) atoms and also with phosphorus atoms having other types of coordination.

There is no unanimity concerning the nomenclature of compounds of this kind, but according to the IUPAC nomenclature[10] they should be referred to as diazadiphosphetidines:



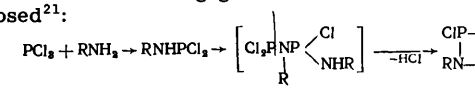
In 1970 we published a review on the chemistry of four-membered rings with alternating nitrogen and phosphorus atoms[11]. The present review includes the literature for the period from 1969 to the first half of 1978 inclusive.

II. SYNTHESIS OF DIAZADIPHOSPHETIDINES

1. Diazadiphosphetidines with Phosphorus(III) Atoms

One of the most universal methods of synthesis of diazadiphosphetidines is the reaction of amines or their hydrochlorides with PCl_3, alkyl- and aryl-dichlorophosphines, phosphoramidodichloridites, and alkyl phosphorodichloridites.

The synthesis of 1,3,2λ³, 4λ³-diazadiphosphetidines from PCl_3 can proceed via two pathways depending on the reaction conditions—in the presence of an excess of PCl_3 or with equimolar proportions of the reactants:



This mechanism has been confirmed by the results of a number of studies. The reaction of anilines or their hydrochlorides with an excess of PCl_3 at temperatures up to 30 °C leads to bisdichlorophosphinoalkyl(aryl)amines[12,13]. When bisdichlorophosphinoarylamines are heated to 100–150 °C, PCl_3 is split off and an unstable iminochlorophosphine, which rapidly dimerises, is apparently formed[14]. It has been recommended[15] that diazadiphosphetidines be synthesised from a mixture of arylamine hydrochloride and PCl_3 by refluxing for several hours in a suitable solvent, for example in *sym*-tetrachloroethylene. The interaction of phosphorus trichloride with methylamine yields a compound with a urotropine-like structure, while the reaction with sterically hindered higher alkylamines produces the corresponding diazadiphosphetidines[16-19].

The reaction of one mole of PCl_3 with three moles of lower alkylamines leads to a mixture of bisdichlorophosphinoalkylamine and 1,3-dialkyl-2,4-dichlorodiazadiphosphetidine, which are difficult to separate, but the cyclic compounds obtained in the reactions with propyl- and t-butylamines can be readily isolated by distillation. When PCl_3 interacts with t-butylamine or its hydrochloride, the reaction mixture contains t-butyl phosphoramidodichloridite in addition to the diazadiphosphetidine[19]. The reaction of PCl_3 with four-moles of t-butylamine gives rise only to a diazadiphosphetidine which is asymmetric with respect to the phosphorus atoms[20]:

$$2PCl_3 + 8t\text{-}C_4H_9NH_2 \rightarrow \begin{matrix} t\text{-}C_4H_9N\text{——}PCl \\ | \quad\quad | \\ t\text{-}C_4H_9NHP\text{—}NC_4H_9\text{-}t \end{matrix} + 5t\text{-}C_4H_9NH_2 \cdot HCl .$$

When this reaction was carried out in the presence of an excess of t-butylamine, the complete aminolysis product was isolated[20]. Since t-butyl phosphoramidodichloridite condenses to the corresponding diazadiphosphetidine in the presence of triethylamine, the following general reaction mechanism can be proposed[21]:

This course of the reaction is promoted by the presence of bulky substituents at the nitrogen atom[20]. Alkyl phosphorodichloridites can be made to undergo a similar reaction with PCl_3:

$$ROPCl_2 + ArNH_2 \rightarrow \begin{matrix} ROP{-}NAr \\ | \quad | \\ ArN{-}POR \end{matrix}.$$

It is noteworthy that Mitsunobu and Mukaijama[22], who obtained these compounds for the first time, attributed to them the structure of alkyl phenyliminophosphites and that their true structure was demonstrated by Kawashima and Inamoto using ^{31}P NMR and mass spectrometry[23].

The interaction of *N,N*-dialkylphosphoramidous dichlorides with aniline yielded 2,4-dianilino-1,3-diphenyldiazadiphosphetidine[24,25]:

$$R_2NPCl_2 + C_6H_5NH_2 \rightarrow \begin{matrix} C_6H_5NHP{-}NC_6H_5 \\ | \quad | \\ C_6H_5N{-}PNHC_6H_5 \end{matrix}.$$

Sulphonamides can be used in this reaction instead of aniline. Thus the reaction with tolunene-4-sulphonamide in pyridine gave a high yield of 2,4-bis(dimethylamino)-1,3-bis(toluene-4-sulphonyl)diazadiphosphetidine[26]:

$$ArSO_2NH_2 + (CH_3)_2NPCl_2 \rightarrow \begin{matrix} ArSO_2N{-}PN(CH_3)_2 \\ | \quad | \\ (CH_3)_2NP{-}NSO_2Ar \end{matrix}.$$

Asymmetric diazadiphosphetidines substituted at the nitrogen atoms are also synthesised by the reaction of bis-(dimethylaminochlorophosphino)methylamine or bis(dichlorophosphino)methylamine with t-butylamine[15,27]:

$$(CH_3)_2N{-}P(Cl){-}N(CH_3){-}P(Cl){-}N(CH_3)_2 \quad (CH_3\text{ on }N) + 3t\text{-}C_4H_9NH_2 \rightarrow \begin{matrix} (CH_3)_2NP{-}NC_4H_9\text{-}t \\ | \quad | \\ t\text{-}C_4H_9N{-}PN(CH_3)_2 \end{matrix}.$$

The reactions of diamides with dichlorophosphines or with PCl_3, which proceed via a similar mechanism, are similar to the above. When the bis(dimethylamide) of t-butylphosphonus acid was allowed to react with t-butyldichlorophosphine in the presence of triethylamine, the product was a phosphonamidous chloride, which was converted by phenyllithium into a mixture of the *cis*- and *trans*-isomers of 2,4-di-t-butyl-1,3-dimethyldiazadiphosphetidine[28]:

$$t\text{-}C_4H_9P(NHCH_3)_2 + m\ t\text{-}C_4H_9PCl_2 \xrightarrow{(C_2H_5)_3N} \rightarrow \begin{matrix} CH_3 \\ | \\ N \\ / \quad \backslash \\ t\text{-}C_4H_9P \quad PC_4H_9\text{-}t \\ | \quad\quad | \\ NHCH_3 \quad Cl \end{matrix} \xrightarrow{C_6H_5Li} \begin{matrix} t\text{-}C_4H_9P{-}NCH_3 \\ | \quad | \\ CH_3N{-}PC_4H_9\text{-}t \end{matrix}.$$

This mixture could be resolved into the individual isomers. The same method was used to obtain 1,3-di-t-butyl-4-chloro-2-methyl- and 1,3-di-t-butyl-2,4-dimethyl-diazadiphosphetidines[29].

It is noteworthy that the reaction of methylphosphonous di(t-butylamide) with PCl_3 takes place stereospecifically and leads to only the *cis*-isomer[29].

The considerable successes in the synthesis of diazaphosphetidines with phosphorus(III) in recent years have been associated with the application of trimethylsilylated amines. It has been shown[14,20,30] that heptamethyldisilazane and hexamethylphenyldisilazane react with PCl_3 in 1:1 proportions to form methyl- and phenyl-bisdichlorophosphinoamines. In the presence of an excess of the disilazanes, the reaction proceeds to 2,4-dichloro-1,3-dimethyl- or 2,4-dichloro-1,3-diphenyl-diazadiphosphetidines:

$$PCl_3 + RN[Si(CH_3)_3]_2 \rightarrow (Cl_2P)_2NR \xrightarrow{RN[Si(CH_3)_3]_2} \begin{matrix} ClP{-}NR \\ | \quad | \\ RN{-}RCl \end{matrix}.$$

The reaction of lithium t-butyltrimethylsilylamide with PCl_3 yielded 1,3-di-t-butyl-2,4-dichloro-1,3,2λ^3,4λ^3-diazadiphosphetidine[20,21]:

$$t\text{-}C_4H_9N(Li)Si(CH_3)_3 + PCl_3 \xrightarrow[-SiCl(CH_3)_3]{-LiCl} \begin{matrix} ClP{-}NC_4H_9\text{-}t \\ | \quad | \\ t\text{-}C_4H_9N{-}PCl \end{matrix}.$$

The lithium derivatives of *N,N*-dimethyl- and *N'*-trimethylsilylhydrazine are readily converted into the corresponding diazadiphosphetidines by reaction with *N*-t-butyl-*N*-methylphosphoramidous dichloride[31]:

$$(CH_3)_2NN(Li)Si(CH_3)_3 + Cl_2PN(CH_3)C_4H_9\text{-}t \xrightarrow[-Si(CH_3)_3Cl]{-LiCl,} \rightarrow \begin{matrix} t\text{-}C_4H_9 \\ \diagdown \\ NP{-}NN(CH_3)_2 \\ | \quad | \\ CH_3 \quad CH_3 \\ | \quad | \\ (CH_3)_2NN{-}PN \\ \diagup \\ C_4H_9\text{-}t \end{matrix}.$$

In the thermolysis of *N,N',N'*-tri-isopropyl-*N*-trimethylsilylphosphorodiamidous chloride, chlorotrimethylsilane is split off and a mixture of the *cis*- and *trans*-isomers of a substituted diazadiphosphetidine is formed[32]:

$$\begin{matrix} Cl\ Si(CH_3)_3 \\ | \quad | \\ (iso\text{-}C_3H_7)_2NP{-}NC_3H_7\text{-}iso \end{matrix} \xrightarrow[-Si(CH_3)_3Cl]{\Delta} \begin{matrix} (iso\text{-}C_3H_7)_2N{-}P{-}NC_3H_7\text{-}iso \\ | \quad | \\ iso\text{-}C_3H_7N{-}PN(C_3H_7\text{-}iso)_2 \end{matrix}.$$

Coordination-unsaturated aminoiminophosphines have been used successfully in the synthesis of diazadiphosphetidines. For example, *N,N',N'*-tris(trimethylsilyl)aminoiminophosphine and *N,N*-di-isopropyl-*N'*-trimethylsilylaminoiminophosphine dimerise to the corresponding diazadiphosphetidines[33,34]:

$$RR'NP{=}NSi(CH_3)_3 \rightarrow \begin{matrix} RR'NP{-}NSi(CH_3)_3 \\ | \quad | \\ (CH_3)_3SiN{-}PNRR' \end{matrix}.$$

N,N,N''-Tris(trimethylsilyl)-*N'*-methylhydrazinoiminophosphine, which exists in solution and in the gas phase as the monomer, dimerises to the diazadiphosphetidine after the removal of the solvent[34]:

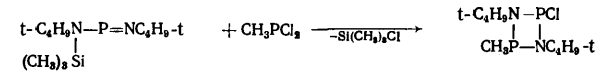
$$[(CH_3)_3Si]_2NNP{=}NSi(CH_3)_3 \quad (CH_3\text{ on }N) \xrightleftharpoons[\text{solution or gas phase}]{\text{solid phase}} \begin{matrix} [(CH_3)_3Si]_2N{-}P{-}N{-}Si(CH_3)_3 \\ | \quad | \\ (CH_3)_3SiN{-}PNN[Si(CH_3)_3]_2 \\ | \\ CH_3 \end{matrix}.$$

Certain other syntheses of diazadiphosphetidines apparently also involve the intermediate formation of aminoiminophosphines, for example, in the reaction of bis-*N,N*-dimethylphosphorodiamidous chloride with the sodium salt of hexamethyldisilazane[35-37]:

$$[(CH_3)_2N]_2PCl + NaN[Si(CH_3)_3]_2 \xrightarrow{-NaCl} [(CH_3)_2N]_2P{-}N[Si(CH_3)_3]_2 \xrightarrow{-(CH_3)_3NSi(CH_3)_2} \rightarrow [(CH_3)_2N{-}P{=}NSi(CH_3)_3] \rightarrow \begin{matrix} (CH_3)_2N{-}P{-}NSi(CH_3)_3 \\ | \quad | \\ (CH_3)_3SiN{-}PN(CH_3)_2 \end{matrix}.$$

Arenesulphonamides react via a similar mechanism with substituted phosphorodiamidous chlorides in the presence of pyridine[26]:

$$ArSO_2NH_2 + C_5H_5N \rightleftarrows ArSO_2\bar{N}H + C_5H_5\overset{+}{N}H \xrightarrow{(RR^1N)_2PCl} \rightarrow ArSO_2NHP(NRR^1)_2 + Cl^- \xrightarrow[-HNRR^1]{C_5H_5N} [ArSO_2N{=}PNRR^1] \rightarrow \begin{matrix} ArSO_2N{-}PNRR^1 \\ | \quad | \\ RR^1NP{-}NSO_2Ar \end{matrix}.$$



The thermal decomposition of phosphorous trianilide (110 °C, toluene) involves the elimination of one aniline molecule and the formation of the corresponding diazadiphosphetidine[38]:

$$(C_6H_5NH)_3P \rightarrow [C_6H_5N{=}P{-}NHC_6H_5] \rightarrow \begin{matrix} C_6H_5N{-}PNHC_6H_5 \\ | \quad | \\ C_6H_5NHP{-}NC_6H_5 \end{matrix}.$$

The formation of diazadiphosphetidines in the transamination of phosphorous triamides with substituted benzamidines belongs to the same group of reactions[39]:

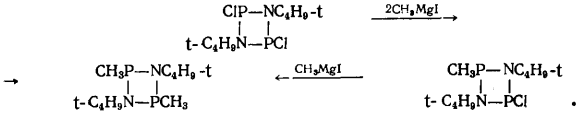
$$C_6H_5C(NR)(NH_2) + (R_2N)_3P \rightarrow \begin{matrix} C_6H_5C{-}N{-}PNR_2 \\ \| \quad | \quad | \\ RNR_2NP{-}NCC_6H_5 \\ \quad\quad\quad\quad \| \\ \quad\quad\quad\quad NR \end{matrix}.$$

4-Chloro-2-methyldiazadiphosphetidine has been obtained by the reaction of *N,N'*-di-t-butyl-*N*-trimethylsilylaminoiminophosphine with methyldichlorophosphine[29]:

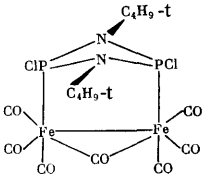
As a rule, $1,3,2\lambda^3,4\lambda^3$-diazadiphosphetidines are formed as mixtures of the *cis*- and *trans*-isomers, although certain diazaphosphetidines with bulky substituents at the nitrogen atoms are obtained in the *cis*-form[35]. After prolonged heating in 1,2-dichlorobenzene at 100 °C, the isomeric composition of the mixture changes towards an increase of the amount of the *trans*-isomer. Thus pure *cis*-2,4-bisdimethylamino-1,3-bistrimethylsilylaminodiazadiphosphetidine is converted into a mixture containing 30% of the *cis*-isomer and 70% of the *trans*-isomer[35].

^{31}P NMR is a convenient method for the determination of the *cis*- and *trans*-structures of diazadiphosphetidines. The signal in the region of ~−100 p.p.m.corresponds to the *cis*-isomers while in the case of the *trans*-isomers the signal shifts downfield (to between −180 and −220 p.p.m.)[23,33,35].

In the series of 1,3- or 2,4-di-t-butyl derivatives the ^{31}P NMR signal also shifts markedly downfield. The ^{31}P NMR signal of *cis*-1,3-di-t-butyl-2,4-dichlorodiazadiphosphetidine is at −210.9 p.p.m.[20] The ^{31}P NMR spectra of 2,4-di-t-butyl-1,3-dimethyldiazadiphosphetidine contain signals with chemical shifts of −210.7 p.p.m. (*cis*-isomer) and −281.7 p.p.m. (*trans*-isomer)[40].



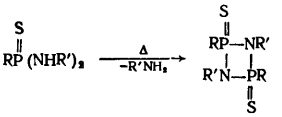
The following group of methods of synthesis of $1,3\text{-}2\lambda^3,4\lambda^3$-diazadiphosphetidines consists of reactions involving the substitution of halogen atoms by nucleophiles or electrophiles. 2,4-Dichlorodiazadiphosphetidines exchange[41] chlorine atoms for fluorine on treatment with SbF_3:



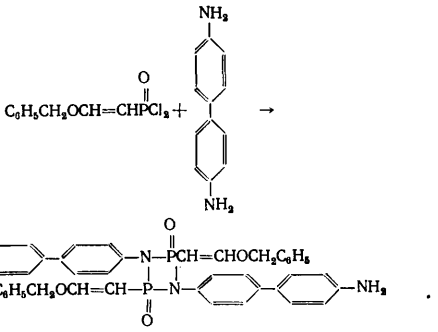
Chlorine atoms are also readily substituted by different nucleophiles. Thus, when 1,3-di-t-butyl-2,4-dichlorodiazadiphosphetidine is treated with an excess of dimethylamine, a mixture of the corresponding *cis*- and *trans*-isomers is formed[15]. The reaction with diethylamine or t-butylamine yields only the *cis*-isomer. Following the interaction with two moles of dimethylamine, the product of the substitution of only one chlorine atom was obtained[15]:

1,3-Di-t-butyl-2,4-dichloro-1,3,2,4-diazadiphosphetidine and 1,3-di-t-butyl-2-chloro-4-methyl-1,3,2,4-diazadiphosphetidine react with methylmagnesium iodide to form 2,4-dimethyldiazadiphosphetidine[29]:

As phosphorus(III) derviatives, diazadiphosphetidines form complexes with metal carbonyls. The interaction of iron nonacarbonyl with 1,3-di-t-butyl-2,4-dichlorodiazadiphosphetidine in tetrahydrofuran (THF) yielded a derivative of iron heptacarbonyl[42]:

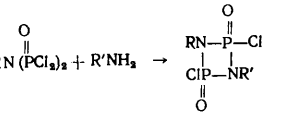


Relative to the initial diazadiphosphetidine, the ^{31}P NMR spectrum of this compound shows an upfield shift of the signal from −207 p.p.m. to +17 p.p.m.[36]

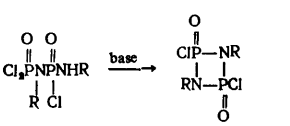


The complexes obtained from a single molecule of 2,4-bisdimethylamino-1,3-bistrimethylsilyldiazadiphosphetidine and two molecules of chromium or molybdenum pentacarbonyl have the *trans*-arrangement of the substituents[36]. Relative to $1,3,2\lambda^3,4\lambda^3$-diazadiphosphetidine, the ^{31}P NMR spectra of these compounds show a shift of the signal from −107.6 p.p.m. to −155 and −131 p.p.m. respectively[42].

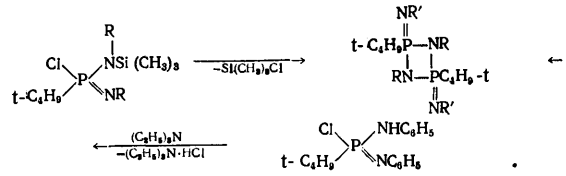
2. Diazadiphosphetidines with Tetracoordinate Phosphorus Atoms



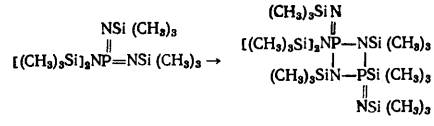
The traditional method of synthesis of diazadiphosphetidines with phosphorus(V) atoms is the pyrolysis of the di- and triamides of phosphorus acids[11]. This method has been used to obtain isomeric 1,3-diethyl-2,4-diphenyl- [43,44] and 1,2,3,4-tetraphenyl-$1,3,2\lambda^5,4\lambda^5$-diazadiphosphetidine 2,4-disulphides[45]:



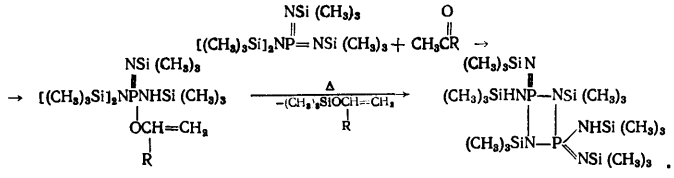
The second traditional method involves the reaction of phosphorus acid dichlorides with primary amines or anilines[11]. It has been used[46] to synthesise 1,3-bis[4-(4-aminophenyl)-phenyl]-2,4-bis(benzyloxyvinyl)-$1,3,2\lambda^5,4\lambda^5$-diaza -diphosphetidine 2,4-dioxide:



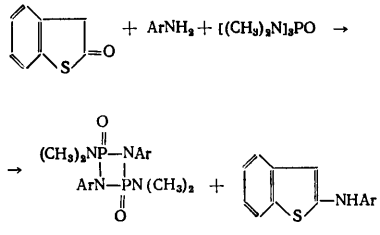
By developing this reaction, a method has been devised for the synthesis of asymmetrically 1,3-disubstituted diazadiphosphetidine 2,4-dioxides by the cyclisation of *N*-alkyl-(aryl)-*N,N*-bis(dichlorophosphono)amines under the influence of primary amines[19,27]:



The reaction with thiophosphono-derivatives proceeds with much more difficulty. In all cases mixtures of *cis*- and *trans*-isomers are formed. Acyclic diphosphazans can be converted into diazadiphosphetidines under the influence of bases[20]:

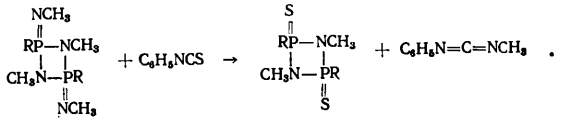


Derivatives of diazadiphosphetidine 2,4-di-imide have been obtained from substituted phosphonamidimidic chlorides[47]:

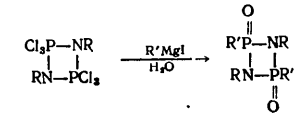


2,4-Diaminodiazadiphosphetidine 2,4-di-imide, fully silylated at the nitrogen atoms, is formed on dimerisation of the corresponding aminodi-iminophosphorane[48]:

In order to obtain hexakis(trimethylsilyl)diazadiphosphetidine, tetrakis(trimethylsilyl)aminodi-iminophosphorane is treated with acetone or acetophenone with subsequent elimination of trimethylsilyl vinyl ether and dimerisation *in vacuo* on heating[49]:

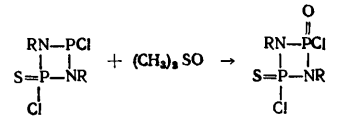


An interesting method for the synthesis of 1,3-diaryldiazaphosphetidine 2,4-dioxides involves the interaction of 2-oxodihydrobenzo[*b*]thiophen and anilines in hexamethylphosphoramide[50]; the yield of the final products is 70–80%:

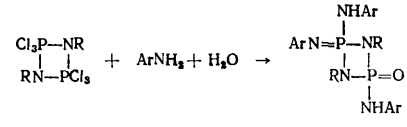


Other methods for the synthesis of diazadiphosphetidine 2,4-dichalcogenides, 2,4-di-imides, and 2,4-imidoximes involve addition or substitution reactions with the phosphorus atoms of the diazadiphosphetidine ring. Reactions involving the addition of sulphur, selenium, tellurium[29,35,40] and trimethylsilyl azide as well as the oxidation of 1,3,2λ^3,4λ^3-diazadiphosphetidines by nitrogen oxides or dimethyl sulphoxide lead to the corresponding diazadiphosphetidine 2,4-disulphides, 2,4-diselenides, 2,4-ditellurides, 2,4-di-imides, and 2,4-dioxides in high yields.

The conversion of diazadiphosphetidine 2,4-di-imide into the corresponding diazadiphosphetidine disulphide on treatment with phenyl isothiocyanate is unusual; even if the individual *cis*- and *trans*-isomers of the di-imide are introduced into the reaction, the final product is a mixture of isomers[47]:



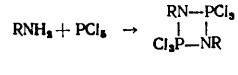
The reaction of 1,3-diphenyl- or 1,3-di-*m*-tolyl-hexachlorocyclodiphosphazanes with ethyl- or phenyl-magnesium iodide and subsequent decomposition with water yielded the corresponding diazadiphosphetidine 2,4-dioxides (yield 48–69%)[51].



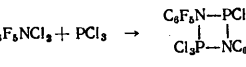
Ethylmagnesium iodide reacts similarly with 1,3-di-*o*-chlorophenyl- and di-*o*-tolyl-hexachlorodiazadiphosphetidines, but, apart from the corresponding dioxides, small amounts of 1,3-di-*o*-chlorophenyl-2,2,4,4-tetraethyl-2,4-dihydroxydiazadiphosphetidine and 2,4,4-triethyl-4-hydroxy-1,3-di-*o*-tolyldiazadiphosphetidine 2-oxide are formed in small amounts[51].

The synthesis of diazadiphosphetidines 2,4-dichalcogenides asymmetric with respect to the phosphorus atoms has been described[20,51].

1,3,2λ^3,4λ^5-diazadiphosphetidine sulphides are readily oxidised by dimethyl sulphoxide to a mixture of the *cis*- and *trans*-isomers of diazadiphosphetidine 2-oxide 4-sulphides asymmetric with respect to phosphorus[20]:



Diazadiphosphetidine 2-imide 4-oxides have been obtained by the aminolysis of hexachlorodiazadiphosphetidines by anilines in the presence of moisture[52]:



3. Diaxadiphosphetidines Containing Pentacoordinate Phosphorus Atoms

The Kirsanov reaction continues to play a notable role in the synthesis of 1,3,2λ^5,4λ^5-diazadiphosphetidines. Hexafluorodiazadiphosphetidines have been obtained by this method[53,54]:

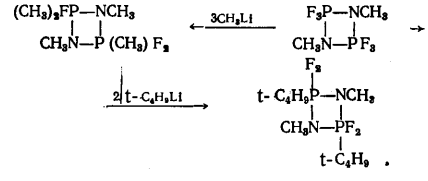
Another interesting method for the synthesis of compounds of this kind is oxidative imination of phosphorus trichloride by *N*,*N*-dichloroperfluoroarylamines[55]:

The most interesting and important results in the study of the chemistry of diazadiphosphetidines with phosphorus(V) have been obtained in relation to fluorinated derivatives and polycyclic compounds containing the diazadiphosphetidine fragment.

Schmutzler and coworkers developed a number of novel methods for the synthesis of fluorodiazadiphosphetidines. The reaction of alkyl(aryl)tetrafluorophosphoranes or

dialkyl(diaryl)trifluorophosphoranes with heptamethyldisilazane constitutes a convenient method of synthesising fluorinated diazadiphosphetidines[56,57]:

$$RPF_4 + 2CH_3N[Si(CH_3)_3]_2 \rightarrow \begin{matrix} RF_2P{-}NCH_3 \\ | \quad | \\ CH_3N{-}PF_2R \end{matrix} + 4Si(CH_3)_3F \ .$$



An asymmetric diazadiphosphetidine has also been obtained by this method[58]:

$$CH_3PF_2 + CH_3N[Si(CH_3)_3]_2 + C_6H_5N[Si(CH_3)_3]_2 \rightarrow \begin{matrix} CH_3F_2P{-}NCH_3 \\ | \quad | \\ C_6H_5N{-}PF_2CH_3 \end{matrix} \ .$$

Instead of disilazanes, one can use the lithio-derivatives of alkylamines[59]:

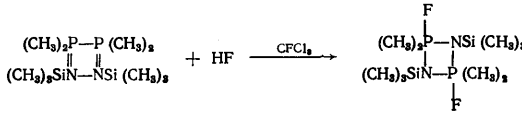
$$2RNLi_2 + 2R_2PF_3 \rightarrow \begin{matrix} R_2FP{-}NR \\ | \quad | \\ RN{-}PFR_2 \end{matrix} + 4LiF \ .$$

On reaction with organometallic compounds, hexafluoro-1,3-dimethyldiazadiphosphetidines exchange fluorine atoms for alkyl groups[57-59]:

It is of interest that, when a mixture of 1,2,3,4-tetramethyl- and 1,3-dimethyl-2,4-diphenyl-2,2,4,4-tetrafluorodiazadiphosphetidines is heated, a disproportionation reaction takes place and a compound asymmetric with respect to phosphorus is formed[58]:

$$\begin{matrix} F_2(CH_3)P{-}NCH_3 \\ | \quad | \\ CH_3N{-}P(CH_3)F_2 \end{matrix} + \begin{matrix} F_2(C_6H_5)P{-}NCH_3 \\ | \quad | \\ CH_3N{-}P(C_6H_5)F_2 \end{matrix} \rightarrow \begin{matrix} F_2(C_6H_5)P{-}NCH_3 \\ | \quad | \\ CH_3N{-}P(CH_3)F_2 \end{matrix} \ .$$

Appel et al. quite unexpectedly obtained a diazadiphosphetidine by the hydrofluorination of silylated bisiminophosphorane in trichlorofluoromethane[60]:



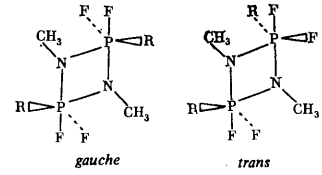


Table 1. The chemical shifts (δ, p.p.m.) of the *gauche*- and *trans*-isomers of 2,4-dialkyl-2,2,4,4-tetrafluoro-1,3-dimethyl-1,3,2,4-diazadiphosphetidines between −60° and −70 °C.[56]

Alkyl	CH_3	CH_2Cl	$CHCl_2$	CCl_3
gauche	−51.2	−56.9	−64.8	−59.0
trans	−47.4	−53.1	−62.1	−60.7

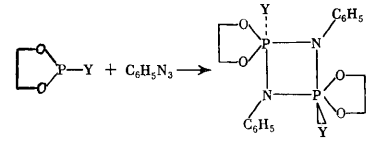
The signals in the ^{31}P NMR spectra of diazadiphosphetidines with phosphorus(V) are located in the region of 82.5–38.3 p.p.m., depending on the environment around the phosphorus atom[54]. It is noteworthy that, in a series of compounds of the type $(RF_2PNCH_3)_2$, the spin–spin coupling constant is directly related to the electronegativity of the ligand R:[61]

R	$(C_2H_5)_2N$	C_6H_5	C_6F_5	CCl_3
J_{P-P}, Az	140	111	80	125

Tetrafluorodiazadiphosphetidines can exist as *gauche*- and *trans*-isomers:

In the solid state they exist as the *trans*-isomers, while in solution there is equilibrium between the *gauche*- and *trans*-forms as a result of the pseudo-rotation at the phosphorus atom[56,57]. The *gauche*–*trans* equilibration process is rapid on the NMR time scale and the presence of the signals of the two isomers in the ^{31}P NMR spectra can be detected only at low temperatures (between −40° and −60 °C) (Table 1). It is noteworthy that in the series of 2,4-dialkyltetrafluorodiazadiphosphetidines the percentage content of the *trans*-isomer increases with increase of the degree of branching of the alkyl group (Table 2)[56,57].

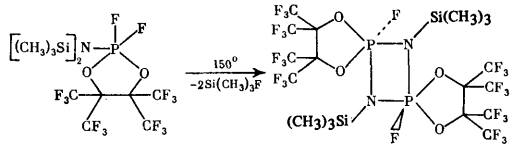
Table 2. The ratio of the *gauche*- and *trans*-isomers of 2,4-dialkyl-2,2,4,4-tetrafluoro-1,3-dimethyl-1,3,2λ^5,4λ^5-diazadiphosphetidines[56,57].



Alkyl	CH_3	C_2H_5	iso-C_3H_7	t-C_4H_9	CH_2Cl	$CHCl_2$	CCl_3
Content of *trans*-isomer, %	47	56	61	92	57	71	76

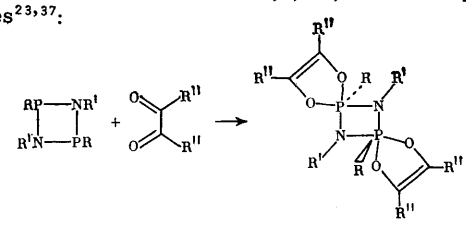
The thermal decomposition of hexahalogenodiazadiphosphetidines does not take place unambiguously. On heating, hexachloro-1,3-diethyldiazadiphosphetidine splits off methyl chloride and is convered into a polymer[62,63]:

$$x \begin{matrix} CH_3N{-}PCl_3 \\ | \quad | \\ Cl_2P{-}NCH_3 \end{matrix} \xrightarrow[48\ h]{200°} 2x\,CH_3Cl + (NPCl_2)_{2x} \ .$$

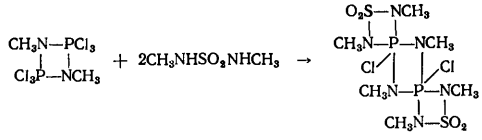


Its hexafluoro-analogue gives rise to a tetramer on heating in a sealed tube at 130 °C; in addition, a salt with the composition $(CH_3N)_4P_3F_6^+PF_6^-$ has been isolated from the residue[62-64].

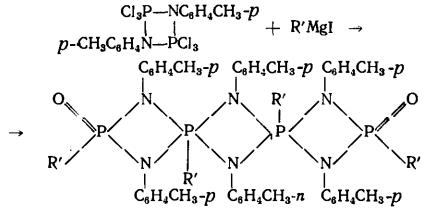
Kabachnik, Gilyarov, and Tikhonina[65-68] carried out a detailed study of the conditions governing the formation of the diazadiphosphetidine ring from cyclic phosphites—derivatives of ethylene glycol, 1,2-propylene glycol, and catechol—under the conditions of the Staudinger reaction. It was shown that the amides of glycol phosphites react with phenyl azide to form phosphoramidimidates, while esters, thioesters, and fluoride are converted into tricyclic dispirodiazadiphosphetidines:



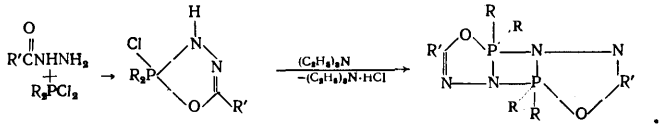
The presence of two signals in the ^{31}P NMR spectra, whose chemical shifts differ by 0.47–0.63 p.p.m., has been explained by the presence of two isomers, whose formation is caused by the pseudorotation at the phosphorus atom in solution.



The same tricyclic system has been obtained[69] on heating bis(trimethylsilyl)aminoperfluoropinacolyldifluorophosphorane at 150 °C:

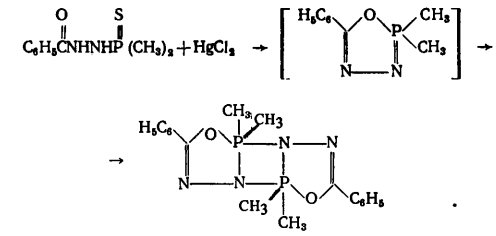


Tricyclic dispiro-1,3,2λ⁵,4λ⁵-diazadiphosphetidines are also formed when α-diketones add to 1,3,2λ³,4λ³-diazadiphosphetidines[23,37]:

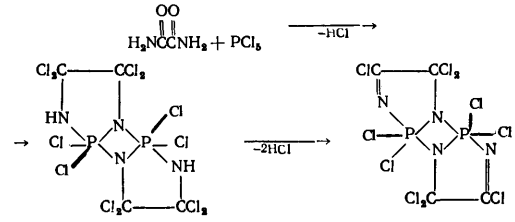


or on interaction of hexachloro-1,3-dimethyldiazadiphosphetidine with 1,3-dimethylsulphamide[70]:

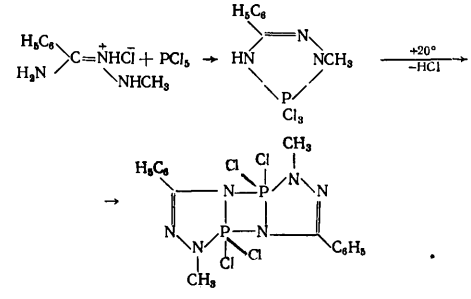
or in the reaction of hexachloro-1,3-di-*p*-tolyldiazadiphosphetidine with ethyl- or phenyl-magnesium iodide[51]:



Interesting studies on the synthesis of condensed heterocyclic systems containing the diazadiphosphetidine ring have been carried out by Kabachnik and coworkers[65,66,69] and by Schmidpeter and coworkers[71–73]. As a result of the reaction of the chlorophosphoranes $(CH_3)_nPCl_{5-n}$ ($n = 0–2$), trichlorodiphenylphosphorane, and the chlorides of dimethyl- and diphenyl-phosphinic acids with acylhydrazines and subsequent treatement of the resulting 2-chloro-1,3,4,2-oxadiazaphospholines with triethylamine yielded the dimeric 1,3,4,2-oxa-azaphospholes. The latter constitute a tricyclic system with a diazadiphosphetidine fragment[71–73]:

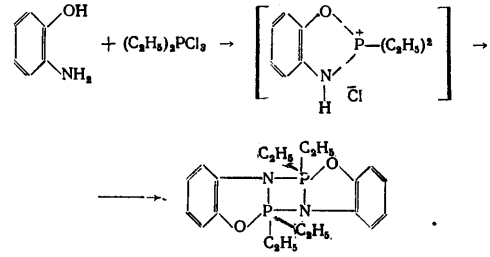


The halogen atoms at the phosphorus atom can be substituted by alkoxy- or phenoxy-groups.

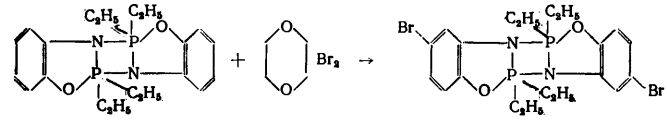


The same tricyclic system has been obtained on treating *N*-benzoyl-*N'*-dimethylphosphinothionylhydrazine with mercury(II) chloride and triethylamine. The reaction proceeds via the intermediate formation of 1,3,4,2-diazaphosphole with subsequent cyclodimerisation[74]:

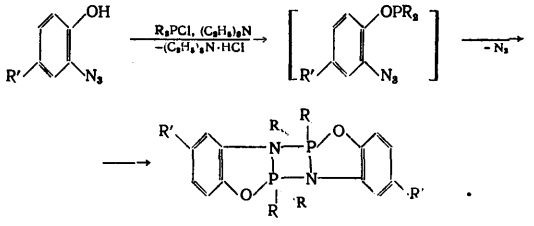
Tricyclic systems with a similar structure, containing the diazaphosphetidine fragment, have been obtained by the interaction of oxamide with an excess of PCl_5 in dichloroethane at 50–55 °C:[75]



or by treating the hydrochloride of *N*-methylbenzamidrazone with PCl_5. When the reaction is carried out at 0°C, 3,3,3-trichloro-1,2,4-3λ⁵-triazaphosphole is formed. The latter splits off hydrogen chloride at 20 °C and is converted into a cyclic dimer[76]:

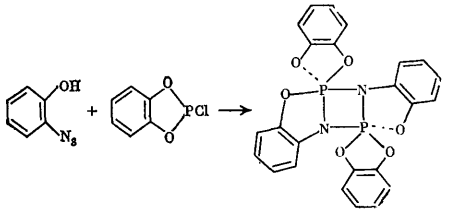


When *o*-aminophenol is treated with PCl_5 or R_2PCl_3, dimeric 1,3,2-oxazaphospholes are formed[65,77,78].

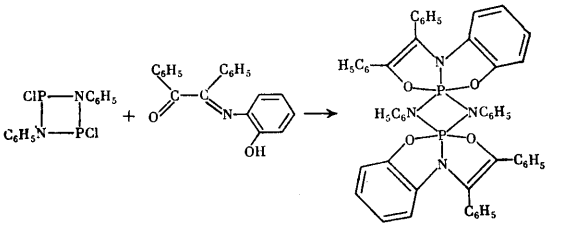


The hydrochloride of benzo-1,3,2-oxazaphosphole has been isolated as an intermediate in the reaction with chlorodiethylphosphorane. On treatment with triethylamine it is converted into the corresponding cyclic product[65]:

The *P,P,P',P'*-tetrachloro derivatives readily undergo reactions involving the substitution of chlorine atoms by alkoxy- and phenoxy-groups. The *P,P,P',P'*-tetraethyl derivatives is brominated by dioxan dibromide in the benzene ring[65]:



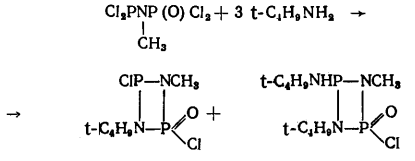
The same pentacyclic system has been obtained by the reaction of *o*-azidophenols with dialkylphosphorochloridites, dialkylchlorophosphines, and tetra-alkylphosphorodiamidous chlorides[65,66,79]:



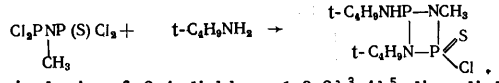
The first stage is carried out at 0 °C and the second (after separating triethylamine hydrochloride) at 20 °C.

When the phosphorochloridite of catechol is introduced into the reaction, a nonacyclic system is formed[66]:

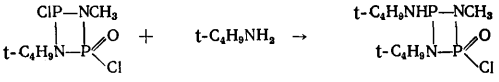
The same system has been obtained also by interaction of *o*-aminophenol with *o*-phenylenedioxytrichlorophosphorane[66].



The reaction of 2,4-dichloro-1,3-diphenyl-1,3,2λ³,4λ³-diazadiphosphetidine with *o*-hydroxyphenyliminodibenzoyl leads to a pentacyclic phosphorane[80]:

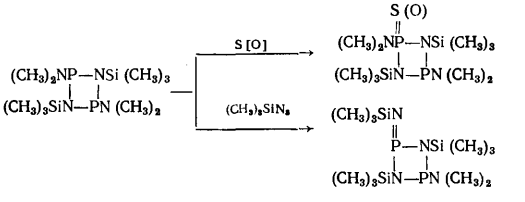


Its ^{31}P NMR spectrum has only one signal at −50.5 p.p.m., which agrees with the fact that the initial diazadiphosphetidine is in the *cis*-form and that substitution at both phosphorus atoms takes place stereospecifically[80].

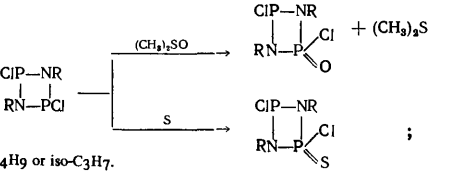


4. Diazadiphosphetidines Containing Tervalent and Tetracoordinate or Pentacoordinate Phosphorus Atoms

When *N*-(dichlorophosphino)-*N*-(dichlorophosphinoyl)-methylamine reacts with three moles of t-butylamine, a mixture of diazadiphosphetidine 4-oxides, differing in the degree of substitution of chlorine atoms at phosphorus(III), is formed. When *N*-(dichlorophosphino)-*N*-(dichlorothiophosphinoyl)methylamine is treated with t-butylamine, a 10 : 1 mixture of isomers of diazadiphosphetidine 2-sulphide is produced[27]:

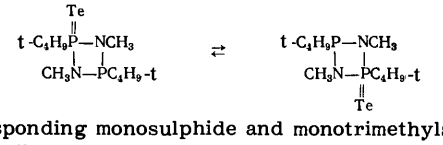


The aminolysis of 2,4-dichloro-1,3,2λ³,4λ⁵-diazadiphosphetidine 2-oxide and 2-sulphide (as mixtures of isomers) by t-butylamine results in the substitution of a chlorine atom at phosphorus(III) and the isomeric composition of the products is altered: the cause of the latter phenomenon is hitherto unknown[27]:

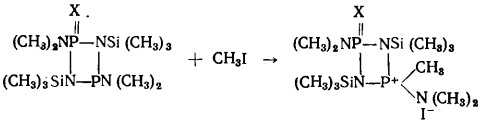


The coordination-unsaturated *N*,*N*,*N*′-tris(trimethylsilyl)-aminoiminophosphine undergoes the (2 + 2)-cycloaddition reaction with tetrakis(trimethylsilyl)aminodi-iminophosphorane and gives rise to a substituted 1,3,2λ³,4λ⁵-diazadiphosphetidine[81]. Structural data suggest that the unshared electron pair at the phosphorus atoms in diazadiphosphetidines has an appreciable amount of *s* character[82,83]. Diazadiphosphetidines containing two phosphorus(III) atoms combine under mild conditions with one mole of sulphur, selenium, or tellurium, giving rise to the corresponding asymmetric diazadiphosphetidine 4-sulphides, 4-selenides, or 4-tellurides[29,34,83,84].

2,4-Bisdimethylamino-1,3-bis(trimethylsilyl)-1,3,2λ³,4λ⁴-diazadiphosphetidine can be oxidised selectively by sulphur, oxygen, or trimethylsilyl azide[29]:

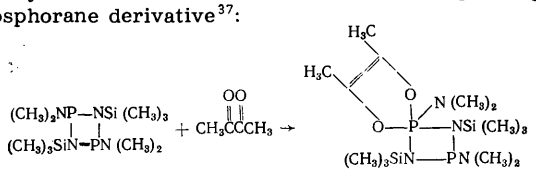


The isopropyl and *s*-butyl derivatives of 1,3,2λ³,4λ³-diazadiphosphetidines undergo controlled oxidation by dimethyl sulphoxide and sulphur with formation of diazadiphosphetidine 2-oxides and 2-sulphides[20]:

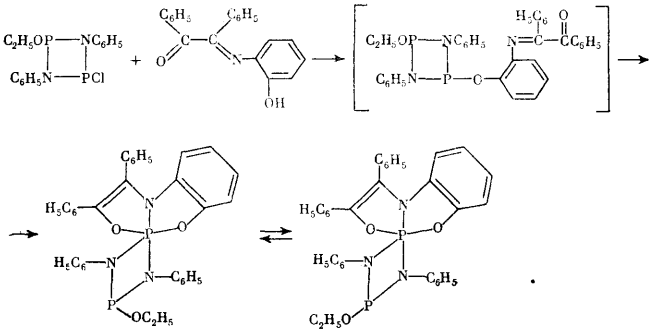


R = t-C$_4$H$_9$ or iso-C$_3$H$_7$.

These compounds are thermally stable and can be purified by vacuum distillation.

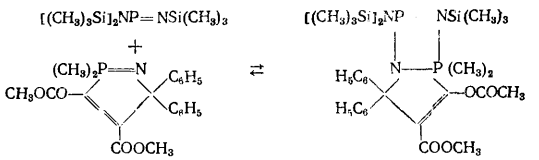


A study of the temperature variation of the ^{1}H and ^{31}P NMR spectra of *cis*-2,4-di-t-butyl-1,3-dimethyl-1,3,2λ³,4λ⁵-diazadiphosphetidine 4-telluride demonstrated the existence of the dynamic equilibrium[84]

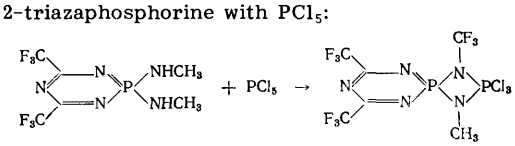


The corresponding monosulphide and monotrimethylsilylimide are readily alkylated by methyl iodide and give rise to derivatives of 1,3-diaza-2-phosphonia-4-phosphetidine[35]:

The reaction of 2,4-bis(dimethylamino)-1,3-bis(trimethylsilyl)-1,3,2λ³,4λ³-diazadiphosphetidine with 1 mole of diacetyl results in the formation of the corresponding monophosphorane derivative[37]:



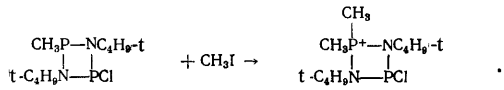
A similar reaction was observed also in the case of *o*-hydroxyphenyliminodibenzoyl[80]:



The tricyclic product exists as a mixture of *cis*- and *trans*-isomers. The chlorine atom is probably initially substituted and this is followed by intramolecular cycloaddition[80].

The addition of an azaphosphole (a cyclic product) to aminoiminophosphine yielded a bicyclic adduct, which exists in chloroform solution in equilibrium with the initial compounds. At 70 °C the equilibrium is 60% displaced to the left[91]:

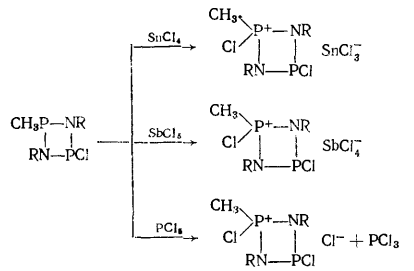
A spiro-compound containing six- and four-membered rings has been obtained[85] by the reaction of 2,2-bis(methylamino)-1,3,5,2-triazaphosphorine with PCl_5:



5. Diazaphosphenia- and Diazaphosphonia-phosphetidines

2-Choro-4-methyl-1,3,2,4-diazadiphosphetidine reacts with aluminium chloride to form a zwitter-ionic phosphenium salt—a new representative of the class of substances containing dicoordinate phosphorus ions:

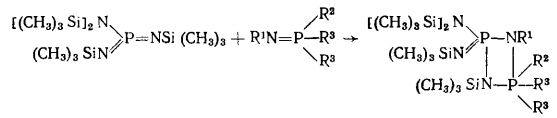
The phosphenium salt is insoluble in ether, pentane, and benzene, but is readily soluble in CH_2Cl_2 and CH_3CN. In its ^{31}P NMR spectrum the doublet with a chemical shift of −252.0 p.p.m. ($^2J_{P-P} = 36$ Hz) is due to the dicoordinate phosphorus atom[29,86], while the doublet with a chemical shift of −201 p.p.m. refers to the phosphorus(III) atom.



The reaction of 2,4-dimethyl- or 2-chloro-4-methyl-1,3,2,4-diazadiphosphetidine with electrophilic alkyl halides (methyl iodide or bromide, ethyl bromide) leads to cyclic phosphonium salts containing phosphonium and phosphine phosphorus atoms[29]:

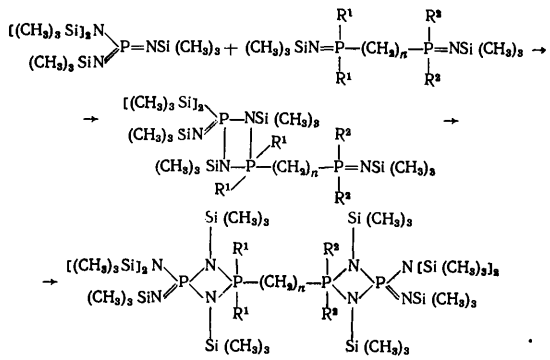
Cyclic diazaphosphoniaphosphetidine salts have also been obtained by the alkylation of 2,4-bis(dialkylamino)-1,3-bis(trimethylsilyl)-1,3,2λ³,4λ⁵-diazadiphosphetidines with an excess of methyl iodide at −70 °C. Their isomeric composition was investigated by ^{31}P and ^1H NMR; the reaction products are in most cases pure *cis*-isomers; after they have been heated at 100–130 °C for three days, the *trans*-isomer predominates in the mixture[35].

The ^{31}P NMR spectra of diazaphosphoniaphosphetidines show two signals: in a low field due to the phosphorus(III) atom and in a high field due to the phosphorus(V) atom[29]. The ^{31}P NMR spectra of methylphosphoniaphosphetidine iodides, which are mixtures of *cis*- and *trans*-isomers, contain four signals: −26.2—−33.8 p.p.m. (P^{IV}), −86.5—−97.6 p.p.m. (P^{III}), and $J_{P-P} = 33$–38 Hz for the *cis*-isomer and −50.6—−54.3 p.p.m. (P^{IV}), −120.7—−137.6 p.p.m. (P^{III}), and $J_{P-P} = 20$–33 Hz for the *trans*-isomer[35].



Diazoniaphosphetidine salts are also formed in the reaction of 1,3-di-t-butyl-2-chloro-4-methyl- or 2,4-dimethyl-1,3,2,4-diazadiphosphetidines with Lewis acids ($SbCl_5$, $SnCl_4$, and PCl_5). In all cases 1 : 1 adducts are formed initially and these then rearrange to the salts; the PCl_4^- anion decomposes under these conditions to PCl_3 and Cl^-: [86]

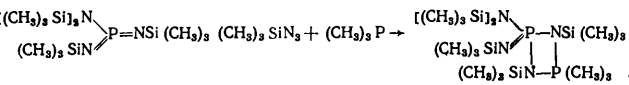
The ^{31}P NMR spectra of these compounds contain doublet P^{IV} signals in the range between −70 and −80.0 p.p.m.



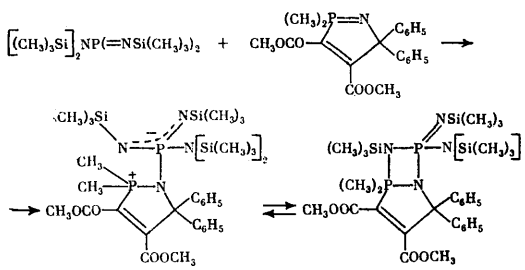
6. Diazadiphosphetidines with Tetracoordinate and Pentacoordinate Phosphorus Atoms

Diazadiphosphetidines with phosphorus(IV) and phosphorus(V) atoms are obtained mainly by the (2 + 2)-cycloaddition of phosphine imides to *N,N,N',N'*-tetrakis(trimethylsilyl)aminodi-iminophosphorane[33,87,88]:

A number of other phosphine imines[89] as well as labelled [^{15}N]*N*-methyltris(dimethylamino)phosphine imide[90] have been introduced into this reaction. The above cyclisation

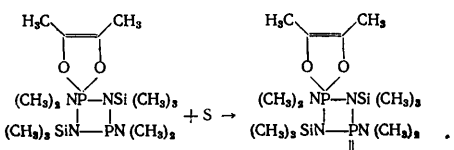


principle has been transferred also to alkylenebisphosphine imides[88]:



N-t-Butyltriphenylphosphine imide and tris(dimethylamino)-*N*-trimethylsilylphosphine imide do not undergo this reaction even after heating for many hours.

For the silylated methylenebis(methylphenylphosphine imide), it is possible to achieve a controlled addition, to isolate the asymmetric product, and then to convert it into a symmetrical alkylenebis(diazadiphosphetidine). 1,4-Butylene derivatives give rise to symmetrical products only[90].



An interesting modification of the reaction involves the heating of the adduct of trimethylsilyl azide and silylated aminodi-iminophosphorane with trimethyl- and triphenylphosphines[88]:

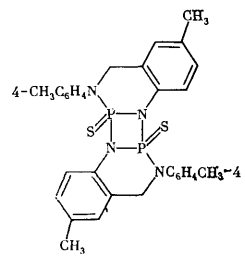
The reaction of azaphosphole with aminodi-iminophosphorane yielded a bicyclic adduct resulting from (2 + 2)-cycloaddition:

On heating in solution, the adduct is reversibly converted into a dipolar ion[91]. A diazadiphosphetidine with a P=S group has been synthesised[37] by the addition of sulphur to the corresponding phosphorus(III) derivative:

III. THE STRUCTURE OF THE DIAZADIPHOSPHETIDINE RING

The structure of the diazadiphosphetidine ring has been investigated by various physicochemical methods, but X-ray diffraction analysis proved to be the most informative.

The structure of 1,3-di-t-butyl-2,4-dichloro-1,3,2λ^3,4λ^3-diazadiphosphetidine has been investigated by X-ray diffraction[92]. The P–N bond length is 1.689 Å, which corresponds to the bond length in dimethylphosphoramidous dichloride (1.69 Å) and indicates partial p_π–d_π bonding[93]. The chlorine atoms are in the *cis*-configuration. The ring in the molecule is not planar, its atoms deviating in succession from the plane of the ring by 0.045 Å. In the molecule of *trans*-1,3-bis(trimethylsilyl)-2,4-di[bis(trimethylsilyl)amino]-1,3,2λ^3,4λ^5-diazadiphosphetidine the P–N bond length (1.727 Å) [33] approaches that of a single P–N bond in $H_3\overline{N}PO_3^2{}^-Na^+$ (1.77 Å).[94] The angles are the same in both molecules: ∠N–P–N = 82.5° and ∠P–N–P = 97.5°.



The results of X-ray diffraction studies on several diazadiphosphetidine dioxides and disulphides are presented in Table 3. It is noteworthy that the P...P and N...N distances in diazadiphosphetidine molecules are in the ranges 2.48–2.562 Å and 2.22–2.26 Å, which is less than the sum of the van der Waals radii (3.60 and 3.10 Å). These data indicate the occurrence of the transannular P...P and N...N interaction[95]. The stronger P...P repulsion explains the acute angle at the phosphorus atoms[96].

Table 3. The bond lengths and angles in 1,3,2λ^3,4λ^3-diazadiphosphetidines and 1,3,2λ^5,4λ^5-diazadiphosphetidine 4-oxides and 4-sulphides.

Formula	P–N bond length, Å	Angle, °		Refs.
		N–P–N	P–N–P

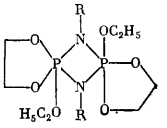
(C$_6$H$_5$P(S)–NC$_6$H$_5$)$_2$**	1.695	81.9	98.1	[45]
(ClP(S)–NCH$_3$)$_2$**	1.67	84	96	[100]

*Non-planar ring.
**Planar ring.

In a polycyclic molecule the P–N bond lengths in the diazadiphosphetidine fragment are unusually large and nonidentical, although the ring is planar and the P–N–P (91°) and N–P–N (89°) angles approach the right angle[97]:

In the molecules of diazadiphosphetidine with phosphorus(V) one P–N bond is axial and the other is equatorial[11].

The results of the determination of the bond lengths and angles in 1,3,2λ^5,4λ^5-diazadiphosphetidines obtained by different investigators are listed in Table 4.



The molecule of *trans*-2,4-diethoxy-2,4-bis(ethylenedioxy)-1,3-di-*p*-tolyl-1,3,2λ^5,4λ^5-diazadiphosphetidine has a centrosymmetric structure and the mutual orientation of

the dioxaphospholan ring and the central four-membered nitrogen-phosphorus ring corresponds to the *trans*-configuration. Two nitrogen–phosphorus bonds occupy axial and equatorial positions in the trigonal bipyramid at the phosphorus atom. The dioxaphospholan ring also has the axial-equatorial configuration, i.e., of the two ring bonds, one P–O bond is axial (1.678 Å) and the other is equatorial (1.635 Å). For the axial-equatorial arrangement of the rings, the existence of the *cis*-isomer becomes impossible.

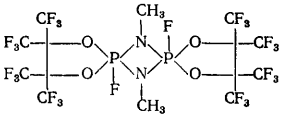


Table 4. The bond lengths and angles in planar $1,3,2\lambda^5,4\lambda^5$-diazadiphosphetidines.

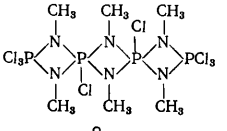
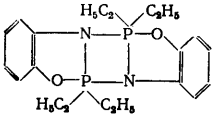
Formula	P–N bond length, Å		Angle, °		Refs.
	axial	equatorial	N–P–N	P–N–P	
$[(CCl_3)F_2P{-}NCH_3]_2$	1.742	1.621	79.9	100.1	[61,94]
$(F_3P{-}NCH_3)_2$	1.735	1.595	77.2	102.9	[105]
$[(C_6H_5)F_2P{-}NCH_3]_2$	1.750	1.631	79.8	100.2	[105]
$[(C_6H_5)F_2P{-}NCH_3]_2$	1.78	1.64	80.6	99.4	[107]
$[(C_6H_5)_2FP{-}NCH_3]_2$	1.779	1.654	78.6	101.8	[108]



The geometrical characteristics of the diazadiphosphetidine ring are as follows: axial P–N bond length 1.785 Å, equatorial P–N bond length 1.652 Å, ∠N–P–N = 79.7°, and ∠P–N–P = 100.3°; the ring is ideally planar[101]:

Similar data were obtained for tricyclic dispirodiazadiphosphetidines:



(axial P–N bond length 1.787 Å, equatorial P–N bond length 1.626 Å, ∠N–P–N = 84.1°, and ∠P–N–P = 95.9° [102]) and

(axial P–N bond length 1.75 Å and equatorial P–N bond length 1.64 Å [103]).

The bicyclic phosphabenzoxazole system in the molecule of the dimeric 2,2-diethyl-2-phosphabenzoxazole is planar and forms a dihedral angle of 1.2° with the plane of the four-membered ring. The axial and equatorial P–N bond lengths (1.812 and 1.681 Å) are close to those obtained for other $1,3,2\lambda^5,4\lambda^5$-diazadiphosphetidines, while the N–P–N valence angle is reduced and the P–N–P angle is increased by 4–5°. This finding as well as the appreciable distortion of the trigonal-bipyramidal coordination of the phosphorus atom can be explained by the fact that it is included in two rigid planar rings—the diazadiphosphetidine and oxazaphosphole rings[104]:

Advances in the Study of *s-cis-trans*-Isomerism—Stereochemistry of Carbonyl Derivatives of Five-membered Heterocycles

V.N.Sheinker, A.D.Garnovskii, and O.A.Osipov

Results obtained on the stereochemistry of carbonyl derivatives of five-membered heteroaromatic systems—furan, thiophen, selenophen, tellurophen, pyrrole, and azoles—are summarised and systematised. Factors responsible for the stereochemical behaviour of conformationally non-rigid *s-cis-trans*-isomers of carbonyl derivatives of five-membered hetaryls are isolated. A list of 287 references is included.

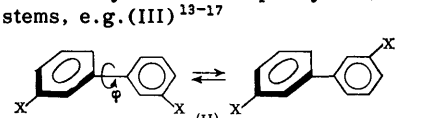
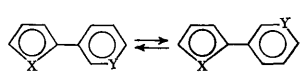
I. INTRODUCTION



An important problem in the present-day stereochemistry of organic compounds is *s-cis-trans*-isomerism[1-3], involving the appearance of conformationally non-equivalent structures as a result of restricted rotation of molecular fragments about a single bond situated between two multiple bonds. The conjugation of double bonds through a single bond raises the energy barrier to rotation about the latter and increases significantly the latter's double-bonded character (the situation is analogous to *cis-trans*-isomerism, which is the reason for the fundamental similarity in the terms used for the isomers).

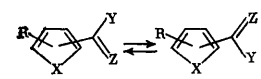
The phenomenon of *s-cis-trans*-isomerism, discovered[4] in butadiene systems



s-cis (*a*) (I) *s-trans* (*b*)

has proved to be widespread in aliphatic[1,2,5], aromatic[1,6-10], and heterocyclic[3,11-18] systems. Both planar structures, characterised by maximum conjugation, can be realised in butadiene and other aliphatic systems of type (I).[19] With conjugated aromatic systems like biphenyl (II)[6,7] and heteroaromatic systems, e.g. (III)[13-17]

X,X-*cis* ($0° < \varphi < 90°$) (II) X,X-*trans* ($180° < \varphi < 270°$)



X,Y-*cis* (III) X,Y-*trans*

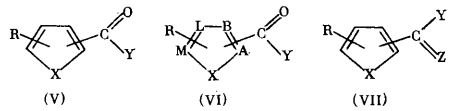
steric hindrance gives rise to non-planar structures corresponding to the optimum balance between conjugation and repulsion interactions. Unsymmetrical structures (II) and (III) may also give rise to *s-cis-trans*-isomerism. Finally, this can occur also in systems in which an aromatic or a heteroaromatic ring is conjugated with an unsaturated acyclic fragment, e.g. C=Z, where Z = C<, O, S, Se, N−, P<−†.

† Henceforward we shall arbitrarily apply the term "conformationally mobile" to such fragments.

This type of isomerism arises in aromatic systems only on the introduction of a second substituent into the ring (*ortho* or *meta* to the C : Z group).[3,20] With heterocycles, in contrast, introduction of a single conformationally mobile group is sufficient for the appearance of two isomers (IV), owing to diminution in the symmetry of the molecule to C_s and C_1:

X,Z-*cis* (IV) X,Z-*trans*

Among isomers of C : Z-containing heterocycles a most important place is occupied by carbonyl-containing derivatives (IV: Z = O), which have been investigated intensively by almost all current physical, physicochemical, and quantum-chemical methods (>80% of all the papers considered in the present Review have been published during the past decade).



The reason for such heightened interest in the stereochemistry of carbonyl derivatives of five-membered heteroaromatic systems is that they form a convenient model for establishing general laws and elucidating the factors that explain various aspects of *s-cis-trans*-isomerism. Furthermore, knowledge of conformational transitions in such systems is necessary to establish the mechanism of several chemical[21] and photochemical[22] processes, and also to explain the biological action of preparations based on them[23,24]. Carbonylfurans have been used as internal and external standards in dynamic carbon-13 nuclear magnetic resonance spectroscopy for accurate temperature measurement[25].

However paradoxical it may appear, this particular type of isomerism has been inadequately discussed in well known monographs[2,5,6,8,26-28].# Yet progress in the study of *s-cis-trans*-isomerism and the huge quantity of publications make a review of this topic necessary.

The present Review gives a critical analysis of results on the *s-cis-trans*-isomerism of carbonyl-substituted five-membered heteroaromatic systems—furan, thiophen, selenophen, tellurophen, and pyrrole (Va-e), azoles (VI) and their

This problem is raised in certain reviews[3,5,18,29-32].

arylated derivatives—as well as structural analogues of carbonyl compounds (VII)

(V) (VI) (VII)

(V)–VII): (a) X = O; (b) X = S; (c) X = Se; (d) X = Te;
(e) X = NR′ (where R′ = H, Alk, Ar);
R = n-Alk, Ar, cyclo-C_4H_4, NO_2, Hal, CO.Y;
Y = H, Alk, Ar, Het, OH, OR″ (where R″ = Alk, Ar), Cl, NH_2;
(VI): A, B, L, M = N;
(VII): Z = CH.R″′ (where R″′ = H, Alk, Ar, Het), N.OH, N.Ar.

Attention is paid to the influence of the nature of the heterocycle, the character and the position of the conformationally mobile group and the substituent R in the heterocycle, the medium, and complex formation on the stereochemistry of systems of types (V)–(VII).

II. METHODS OF INVESTIGATION OF *s-cis–trans*-CONFORMERS

Vibrational Spectroscopy

In many cases analysis of vibrational spectra is an extremely effective method for establishing the presence of a conformational equilibrium[2,6,7,32-34]. It is usually assumed in such investigations that the normal vibration frequencies of the conformers differ somewhat owing to kinematic or dynamic factors. On such a hypothesis the main criteria of the presence of a mixture of conformers in liquids, solutions, or gases are complication of the spectra, variation in relative band intensities with temperature and solvent polarity, and simplification of the spectrum ("freezing" of the bands) in the liquid–crystal transition[6,34].

In the infrared, *s-cis–trans*-isomerism in carbonyl derivatives (V) and (VI) is usually indicated by a carbonyl absorption doublet ν_{CO} in the range 1660–1790 cm^{-1}. However, the nature of this doublet has been a matter of controversy. For 2-furaldehyde and 2-formylpyrrole it is explained by the presence of *s-cis–trans*-isomers[35-43], Fermi resonance[44-48], and also molecular association[42-51]. The doublet in the infrared spectrum of 2-formylthiophen is attributed mainly to Fermi resonance[52-54], although other workers[41] ascribe it to conformational equilibrium.

Thus existing data do not permit unambiguous interpretation of the behaviour of ν_{CO} nor definite conclusions on the conformations of carbonyl derivatives of five-membered heterocycles. Theoretical analysis of vibrational spectra[45, 48,55,56] has helped to explain the differences in the spectra of conformers and to give a more profound interpretation of the modes of vibration of each. Calculation has shown[56] that the doublet in the range 1670–1710 cm^{-1} is indeed due to the presence of both conformers, the ν_{CO} vibration being composite: the position of the carbonyl group affects not only the 1680- and 1700-cm^{-1} vibrations (X,O-*cis* and X,O-*trans*) but also the absorption at 1570 cm^{-1}, which is due to a fragment of the heterocycle ($\nu_{C(2):C(3)}$).

Frequency assignments for furaldehyde in other infrared regions, also used[40] for the study of *s-cis–trans*-isomerism, have been refined[55,56]. The integral absorption band intensities necessary to determine the state of conformational equilibrium were found[55,56]. The ratio of the conformers cannot[55] be evaluated solely from the experimental intensity ratio of ν_{CO} bands in the infrared spectra of furaldehyde.

The above discussion shows that, although infrared spectral data can be used to assess *s-cis–trans*-isomerism in a series of carbonyl derivatives of five-membered heteroaromatic systems, reliable results can be obtained only by combining empirical and calculated values for the vibrational spectra.

Dielectric and Electro-optical Investigations

Several dielectric and electro-optical investigations have been made on conformational equilibrium in the above systems. However, even in this case the solution depends on the choice of additive scheme, so that the use of group moments for aromatic substituents may not always be successful[57-59].

In connection with this the dipole moment of the aldehyde group was determined[60] for compounds of the furan series on the assumption that furaldehyde exists only in the O,O-*cis*-form. Dipole moments have been calculated theoretically[61-63] for both isomers of a series of aldehydes.

The controversial aspect of the vector calculation of dipole moments for heterocyclic aldehydes is to allow for the moment of interaction between heteroatom and carbonyl oxygen, first introduced for furaldehyde[64]. Values from 0 to 0.3 D have been assigned to this quantity[65-67].

A contradictory explanation has been given for dielectric results for carbonyl derivatives of thiophen (V: X = S, Y = R = H)[68], selenophen (V: X = Se, Y = R = H)[59,69,70], tellurophen (V: X = Te, Y = R = H)[71], and benzimidazole (VI: X = NAlk, A = L = M = CH, B = N, R = cyclo-C_4H_4).

Application of the Kerr effect has also led to opposite conclusions[58,68] concerning the preferential conformation of furaldehyde. These discrepancies are due both to difference in the valency–optical scheme used and to disagreement in the experimental results.

In several cases the above contradictions are due mainly to incorrect choice of vector additive and valency–optical schemes for the theoretical calculation of dipole moments and anisotropy of polarisability of the molecules of carbonyl derivatives of five-membered heteroaromatic systems. Therefore a definite advance in the use of dielectric measurements and the Kerr effect to assess the *s-cis–trans*-isomerism of these systems was determination of the polarisability tensors for several fundamental heterocycles[74-76] and the construction of valency–optical and vector–additive dipole schemes for calculating azole molecules[77-79]. Finding the formyl group moments for 2-furaldehyde and 2-formylthiophen from independent data was of great value[80,81].

Thus the limitations of the dielectric and electro-optical methods are inherent in their very foundations, in the problem of choosing adequate group moments and polarisability tensors. Since a correct solution of such a problem is often difficult or even impossible, the results may not agree and may differ from those obtained by other methods. However, with a right choice of these quantities a simultaneous application of the methods may be extremely fruitful for solving problems of conformational analysis.

Resonance Spectroscopy

Nuclear magnetic resonance spectroscopy has recently become one of the most widely used methods for investigating *s-cis–trans*-isomerism. It was first shown[82] that the conformations of 2-formyl derivatives of five-membered heterocycles can be assessed from the stereospecific spin–spin coupling constants in the ^1H n.m.r. spectra. It was later

found possible[83] to determine the position of the *s-cis–trans*-isomeric equilibrium and its thermodynamic parameters from such spectra. Unfortunately, errors were made in the detailed investigations[83], which led to a wrong conclusion on the ratio of the stable conformers. Nuclear magnetic resonance (^{1}H), together with stereospecific constants, chemical shifts, the Overhauser effect, and shift reagents, has been used to investigate the structure of carbonyl derivatives of furan[36,55,82–89], thiophen[85,88–96], selenophen[84,89], pyrrole[97,98], tellurophen[71,95,99], and azoles[100–104]. Isolated results have appeared on the application of carbon-13 and fluorine-19 n.m.r. in the conformational analysis of carbonyl derivatives of five-membered heterocycles[105–107]. However, the possibilities of n.m.r. spectroscopy are also limited, since its use presupposes either the availability of stereospecific hyperfine coupling constants, adoption of a definite model of diamagnetic shielding, or measurements at temperatures below the coalescence point. The postulates necessary also in application of the Overhauser effect and shift reagents restrict the use of these methods. The work is greatly complicated by increase in the order of the n.m.r. spectrum and sparing solubility of the compound. Nevertheless, n.m.r. spectroscopy is one of the most promising methods of investigation in the conformational analysis of *s-cis–trans*-isomers.

Use of electron spin resonance spectroscopy becomes possible for heterocyclic aldehydes only when they generate radical-anions[12,108,109]. The range of such compounds is limited, and the position of conformational equilibrium in the radical system differs from that for the neutral molecule.

The conformations of carbonyl derivatives of five-membered heterocycles have been analysed not only by the above main methods of investigation but also on the basis of data of microwave spectroscopy[110–113] (in the gas phase), ultrasonic[114] and dielectric[103,115] relaxation, X-ray examination[116–120] (of the crystalline phase), and electronic spectra[121–124].

Quantum-chemical Methods

The *s-cis–trans*-conformations of carbonyl derivatives of five-membered heterocycles (mainly aldehydes) have been widely assessed by quantum-chemical methods. Furaldehyde[5,62,63,123,125–129] has been investigated in the greatest detail by the Pariser–Parr–Pople, INDO/2, and extended Hückel methods, although the conclusions concerning realisation of a particular conformer obtained from the calculations are contradictory. A similar situation obtains in the assessment from quantum-chemical calculations of conformers of formylpyrrole[63,123] and formylthiophen[93,130,131].

Such a discrepancy in the conclusions concerning the configurations of carbonyl derivatives of five-membered heterocycles can be explained by the very small energy difference between the two conformers, hundredths of an electron-volt; i.e. the result may change depending on the approximations and the method of calculation. The role of *d*-orbitals in calculations on the conformations of the 2-formyl-thiophen and -selenophen is equally debatable[93,123,130].

Application of the comparatively simple extended Hückel method of calculation[132,133] led to important conclusions also on *s-cis–trans*-isomerism and barriers to internal rotation in heteroaromatic aldehydes[134,135].

The results in the present section can be summarised by emphasising the inconsistency of individual conclusions reached by different physicochemical methods on the conformations of carbonyl derivatives of five-membered heterocycles. Therefore only those results are reliable that coincide for different methods and produce a single, internally consistent picture in series of compounds with variation in heterocycles, substituents, and conformationally mobile groups.

III. FACTORS INFLUENCING THE POSITION OF CONFORMATIONAL EQUILIBRIUM§

Among factors responsible for the conformation of carbonyl-substituted five-membered heterocycles we have isolated the structure of the hetero-system with the exocyclic substituent, the medium, and intra- and inter-molecular interactions.

1. Structure of *C*-Carbonyl-substituted Heterocycles

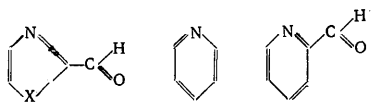
(a) Substituents Attached to the Carbonyl Group (COR)

Aldehydes (R = H). No generally accepted view can be found on the most stable conformers of the simplest 2-formyl derivatives of five-membered heterocycles: the position of conformational equilibrium determined by different methods even under closely similar conditions often varies so widely that all the data available are insufficient to determine which form is the most stable and predominant.

The situation is especially characteristic of 2-furaldehyde: whereas it has been stated[42,64,83] that the O,O-*trans*-form is energetically the most advantageous, other workers[85,88,95,106,136,137] regard the O,O-*cis*-conformer as the most stable. More unambiguous conclusions have been reached on the structure of 2-formylthiophen, which most investigators[85,88,90–96,110,111,138–142] regard as existing solely in the form of the S,O-*cis*-conformer. Yet the agreement between experimental and calculated dipole moments led to the conclusion[140] that thiophen-2-aldehyde exists as a non-planar S,O-cisoid structure with a non-coplanarity angle of 35°, and other workers[68] assume the existence of an equilibrium mixture of conformers containing up to 27% of the S,O-*trans*-form.

2-Formylselenophen is regarded[59,70,84] as conformationally a more rigid system than 2-formylthiophen. The Se,O-*cis*-isomer is the more stable[59,69,70,95,143], although the conformational mixture may contain a considerable percentage of the *trans*-form[84,143].

Nuclear magnetic resonance and infrared spectroscopy[99], and also dipole moments[59,144], suggest that 2-formyltellurophen exists in solution as a mixture of two conformers, with a lower content of the *trans*-form than in the case of furaldehyde. However, even with this aldehyde shift reagents reveal exclusively the Te,O-*cis*-conformer[95]. Thus, despite appreciable discrepancies in the results, the X,O-*cis*-conformers are the most stable in 2-formylhetaryls containing



§ In most cases the solvents in which investigations have been made are not stated in the present Review if change in them does not lead to fundamentally different results. The solvents mainly used in the work cited were as follows: tetrachloromethane, benzene, and dioxan in dielectric measurements; tetrachloromethane, chloroform, dichloromethane, dioxan, and mineral oil in infrared spectroscopy; and tetrachloroethylene, chloroform, methanol, dichloromethane, tetrachloromethane, and acetonitrile in radiospectroscopy.

elements of subgroup VI*b* as heteroatom¶, the content of this form diminishing in the sequence—selenophen > thiophen > tellurophen > furan.
