Photochemistry of Aliphatic and Aromatic Amines

Ya.N.Malkin and V.A.Kuz'min

The luminescence spectroscopic properties and photochemical reactions of aliphatic and aromatic amines in liquid and solid solutions are examined. Attention is concentrated on the photochemical reactions of aromatic amines derived from aniline in liquid solutions. The mechanism of the photodissociation of the nitrogen-hydrogen and carbon-nitrogen bonds and the dependence of the luminescence spectroscopic properties of amines on their structure and on the positions of their energy levels in the lowest electronically excited states are discussed.
The bibliography includes 151 references.

III. Aromatic amines	1045

I. INTRODUCTION

Much attention has been devoted recently to the study of the mechanisms of the photochemical processes involving aliphatic and aromatic amines not only because of the vigorous development of fundamental photochemical studies but also because of numerous investigations in adjacent branches of science and engineering (photobiology, photodegradation, and photostabilisation of polymers, theory of photographic processes, lasers based on organic compounds). The absorption bands of amines are as a rule located in the ultraviolet and in addition amines have low oxidation potentials. In view of these properties, aliphatic and aromatic amines are convenient models for the investigation of the mechanisms of photochemical processes and, in particular, of the quenching of fluorescence via electron transfer and for the investigation of donor–acceptor interactions in exciplexes.

The need for a detailed description of the reactivities of organic compounds in terms of different classes arises from the fact that photochemical behaviour is usually classified in terms of types of reactions: photodissociation (photocleavage), photosubstitution, photoaddition, photoisomerisation, and photorearrangements, as well as oxidation-reduction reactions (electron phototransfer). However, such studies are insufficient for the understanding of the reactivities of compounds of different types, particularly since in practice the converse problem frequently arises: it is necessary to know the photochemical properties of compounds of a definite class in order to foresee all the reactions possible under the given conditions.

The aim of the present review was to examine and summarise the results of studies of the photochemical and luminescence spectroscopic properties of aromatic and aliphatic amines. For this purpose, a classification of the photochemical properties of amines is proposed on the basis of ideas concerning the elementary photochemical processes and a scheme for the disposition of the lowest electronically excited states in specific systems has been constructed. The nature of the electronically excited state through which a photochemical reaction proceeds is discussed on the basis of kinetic data for the elementary processes.

The formation of exciplexes in the degradation of the electronic excitation energy has been studied in extremely great detail.[1-3] This review deals only with the mechanisms of the photochemical reactions of amine molecules in solutions (the mechanisms of the solid-phase reactions of these compounds have been studied fairly completely[4-13]). The data on the photolysis and, in particular, the luminescence of amines in the gas phase, which have been described systematically in a monograph,[7] are invoked only insofar as they are needed for the understanding of the photoprocesses in the condensed phase.

Table 1. The luminescence spectroscopic properties of aliphatic amines.

Amine	Solvent	λ_{abs}^{max}, nm	ϵ_{max}, litre mol^{-1} cm^{-1}	λ_{fl}^{max}, nm	φ_{fl}	τ_{fl}, ns	Refs.
Trimethylamine	—	198	3720	287	0.97	45	[31]
Diethylmethylamine	hexane	—	—	292	0.64	26.0	[33]
"	tetrahydrofuran	—	—	308	0.44	42	[33]
"	ether	—	—	340	0.14	48	[33]
Triethylamine	hexane	—	—	286	0.69	--	[33]
"	tetrahydrofuran	—	—	340	—	--	[38]
"	ether	—	—	310	—	—	[38]
4-Methylpiperidine	—	207	5500	290	0.95	60	[37]
4,*N*-Dimethylpiperidine	—	—	—	—	1.0	50	[37]
N-Methylmorpholine	—	204	4150	274	0.78	66	[37]

Notation: λ_{abs}^{max} and ε_{max} are the wavelength of the maximum in the absorption spectrum and the extinction coefficient and λ_{fl}^{max}, ϕ_{fl}, and τ_{fl} are the wavelength of the maximum in the fluorescence spectrum, the quantum yield, and the fluorescence lifetime.

II. ALIPHATIC AMINES

1. Absorption Spectra

Bands of moderate intensity with a maximum at ~200 nm (Table 1) are observed in the ultraviolet absorption spectra of the simplest aliphatic amines (methyl- and ethyl-amines). Previously it was regarded as an established fact that the long-wavelength absorption band of aliphatic amines corresponds to the $n \rightarrow \sigma^*$ transition and is therefore absent from the spectra of acid solutions since the nitrogen atom in the cation has no non-bonding n electrons.[14-21] Within the framework of this type of explanation and on the basis of quantum-chemical calculations, it has been suggested[14] that the unshared electron pair in the molecules of ammonia and alkylamines is located in the *sp*-hybrid atomic orbital (AO) located along the symmetry axis of the molecule. The band corresponding to the $n \rightarrow \sigma^*$ transition in the absorption spectra of such molecules should be fairly intense.[22-31] Recent calculations[19-23] have shown that all the lowest electronically excited states of ammonia and primary amines are of the Rydberg type (Table 2) (the assignment of the long-wavelength absorption bands to the $\sigma \rightarrow \sigma^*$ and $n \rightarrow \sigma^*$ transitions in alkylamines is erroneous[31]). The simplest primary amines (methylamine and ethylamine) have a lowest Rydberg n, 3*s* state in which the predissociative decomposition of the N–H bond takes place.[23]

Table 2. The transitions for ABCO and ABCU.[39]

Transition	n	Orbital*
ABCU		
$S_1 \leftarrow S_0$	3	3*s*
$S_2 \leftarrow S_0$	3	3*p*
$S_3 \leftarrow S_0$	3	3*d*
$S_3 \leftarrow S_0$	4	4*s*
$S_4 \leftarrow S_0$	4	4*p*
ABCO		
$S_1 \leftarrow S_0$	3	3*s*
$S_2 \leftarrow S_0$	3	3*p*
$S_3 \leftarrow S_0$	4	4*s*

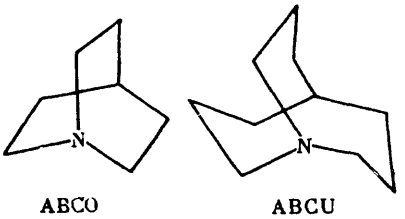
*Only the Rydberg orbitals are presented.

2. Luminescence Properties

Tertiary aliphatic amines fluoresce in the gas phase and in solution,[12,32,33] while primary and secondary amines do not. The fluorescence of the simplest tertiary amines (trimethylamine and tri-n-propylamine) under the influence of light at a wavelength of 206.2 nm takes place either in the σ^* or Rydberg state.[32] The absence of fluorescence in primary and secondary amines in the gas phase is associated with their effective deactivation via predissociation, which takes place only in compounds where hydrogen (or deuterium) is bonded directly to the nitrogen.[32-42]

In the absence of steric perturbations, the configuration of the molecules of saturated tertiary amines (in which the unshared electron pair of the nitrogen plays the role of the chromophore) in the equilibrium excited singlet state is planar (and not tetrahedral as in the ground state).[39]

The nature of the atomic orbitals in which n electrons are excited on irradiation has been determined for symmetrical amines derived from 1-azabicyclo[2,2,2]octane (ABCO) and 1-azabicyclo[3,3,3]undecane (ABCU) on the basis of the magnitude of the quantum defect (Table 2); it was found that all three long-wavelength bands are of the Rydberg type for these substances.[39-42]



ABCO ABCU

An intense bathochromic shift of the fluorescence spectra with increasing solvent polarity is characteristic of all aliphatic amines (Table 2); the long-wavelength bands of the fluorescence excitation and absorption spectra then remain

unaltered (at 77 K a shift of the above type is not observed in a frozen matrix).[42] The shift is associated, according to Muto et al.,[42] with the change in the nature of the lowest electronically excited state of amines from the Franck–Condon state, corresponding to the first absorption band of the σ* type, to the Rydberg 3s state, which is significantly stabilised under the influence of the solvent as a result of the ion–dipole interaction of the nucleus of the cation in the Rydberg 3s state with a solvent molecule. A model of the solvated Rydberg state,[42] in which the orbital of the excited amine electron passes through the closest solvent molecules has in fact been developed on the basis of the fluorescence data for aliphatic amines. Thus the solvated Rydberg state consists, according to Nakato et al.,[43] of a cation–electron pair linked by Coulombic forces.

The role of the solvated Rydberg state in the bathochromic shift of the fluorescence spectrum of diethylmethylamine in a polar solvent has been noted in a recently published communication.[33]

An *ab initio* quantum-chemical calculation of the energies of the lowest electronic transitions in trimethylamine, ABCO, and diazabicyclo[2,2,2]octane (DABCO) showed[34] that all these states are fully of the Rydberg type (no valence states with energies below 6.4 eV have been found), although it had been assumed earlier[41] that two long-wavelength bands in the absorption spectra of dialkylamines are associated with the $n \rightarrow \sigma^*$ transition. It has also been noted that in the case of saturated amines there can be no mixing of the excited valence states with the Rydberg states (at least for the amines in which excitation entails an insignificant alteration of the molecular geometry[34]).

3. Photochemical Properties

(a) Primary amines

The photochemical properties of all the aliphatic amines, except tertiary amines, are determined by the lability of their N–H bonds. Under the influence of light with $\lambda < 240$ nm, aliphatic amines in hexane decompose with formation of gaseous products and hex-1-ene. The primary step in the photolysis is the dissociation of the N–H bond:[15]

$$RNH_2 + h\nu \rightarrow R\dot{N}H + H. \quad (1)$$

The quantum yields in the photodecomposition of amines in hexane are listed in Table 3; they depend only slightly on the concentration of the amines and increase insignificantly with increased temperature.

In polar solvents (for example, in water) the dissociation of the C–N bond becomes possible because the homolytic dissociation of the N–H bond is hindered owing to the considerable solvation of the amine molecules:[16,17]

$$RNH_2 + h\nu \rightarrow \dot{R} + \dot{N}H_2. \quad (2)$$

The photodecomposition quantum yield is then found to be less than in hexane (Table 4) and the photolysis products are ammonia and alcohols. In water the yield in the photodecomposition of amines increases sharply with increasing pH.

The mechanism of the liquid-phase photolysis of aliphatic amines has been studied in greatest detail for solutions of cyclohexyl- and cyclopentyl-amines in cyclohexane and cyclopentane and also of n-hexylamine in hexane.[18] The products of the photolysis of cyclohexylamine are cyclohexylcyclohexane and ammonia and those of the photolysis of cyclopentylamine are cyclopentylcyclopentane, *N*-cyclopentylidenecyclopentylamine, and dicyclopentylamine. The primary processes occurring under these conditions can be illustrated schematically in the following manner:

$$RR'CHNH_2 \xrightarrow{h\nu} \begin{cases} \rightarrow RR'CH\dot{N}H + H; & (3) \\ \rightarrow RR'\dot{C}H + \dot{N}H_2; & (4) \\ \rightarrow RR'\dot{C}NH_2 + H; & (5) \\ \rightarrow RR'C{=}NH + H_2. & (6) \end{cases}$$

Table 3. The quantum yields in the photochemical decomposition of amines in hexane (ϕ_1) and water (ϕ_2)*.

Amine	φ_1	φ_2	Amine	φ_1	φ_2
Isopropylamine	0.100	0.049	n-Pentylamine	0.052	0.037
n-Propylamine	0.079	0.039	n-Hexylamine	0.064	0.038
Isobutylamine	0.092	0.046	n-Heptylamine	0.036	0.025
n-Butylamine	0.082	0.042	n-Octylamine	0.039	0.027
Isopentylamine	0.086	0.050			

*The amine concentration was 10^{-3} M; the irradiation was carried out at a wavelength of 230–240 nm.

Table 4. The energy levels (E, eV), the oscillator strengths (f), and the wave functions for the aniline molecule (according to the data of Kimura et al.[47]

Level	E_{calc} (gas phase)	E_{exp} (gas phase)	E_{exp} (in hexane)	f_{calc}	f^*_{exp} (in hexane)
W_1	4.72	4.40	4.32	0.021	0.028
W_2	5.42	5.39	5.31	0.174	0.144
W_3	6.42	6.40	6.32	0.416	0.510
W_4	6.86	6.88	7.06	0.505	0.570

W_6	8.05	7.87	—	0.416	0.68

*Data of Kimura and Nagakura.[55]

The relative contributions of reactions (3)–(6) for each compound are determined by the stability of the corresponding alkyl radicals. For cyclohexylamine, the principal primary photochemical process is the dissociation of the C–NH_2 bond [reaction (4)], which is followed by the interaction with the solvent:

$$NH_2 + C_6H_{12} \rightarrow \dot{C}_6H_{11} + NH_3;$$

$$2C_6H_{11} \rightarrow C_{12}H_{22}. \quad (7)$$

In the case of cyclopentylamine dissociation of the N–H bond [reaction (3)] plays the main role. On photoirradiation of n-hexylamine in cyclohexane the main product is *N*-(1-hexylidene)-n-hexylamine together with bicyclohexyl and cyclohexylamine; here too the primary photochemical process is reaction (3) involving the elimination of a hydrogen atom.[18]

The almost complete lack of data on the quantum yields of the primary photochemical processes in the photolysis of aliphatic amines in the liquid phase is noteworthy. It is

apparently due to the difficulty of the quantitative determination of the yields of the aminyl radical formed.

In contrast to the processes in the gas phase, the nature of the primary process in solutions has been little investigated: for example, it has not been established for virtually any system which of the bonds in the molecule is dissociated and what is the probability of the process; the extent of other radiative and non-radiative pathways leading to the dissipation of the electronic excitation energy in solutions of aliphatic amines are also unknown. The secondary photochemical reactions, i.e. the further reactions of the compounds arising in reactions (3)–(6) with formation of stable final products, have not been investigated in extremely great detail for aliphatic amines. The present level of knowledge is such that the nature of the final photoproducts and the relative yields can be predicted for any aliphatic amines in the usual solvents.

In the photolysis of amines in the gas phase the quantum yields in the formation of products have been measured for a series of primary photochemical processes[44–46] (one should bear in mind that only the yields in the formation of the final products were measured and the efficiency of the primary photochemical processes was inferred only from indirect data).

For example, it has been suggested[44] that methylamine undergoes photodissociation under the influence of radiation with $\lambda = 184.9$ nm:

$$CH_3NH_2 + h\nu \rightarrow CH_3\dot{N}H^* + H.$$

The quantum yield is unity and the aminyl radical formed is in an electronically excited state, decomposing further in accordance with the scheme

$$CH_3NH^* \longrightarrow H + H_2C{=}NH.$$

As a result, the quantum yield for the formation of hydrogen in the photolysis of gaseous CH_3NH_2 exceeds unity.

The quantum yields of the photochemical reaction of CH_3NH_2 in the gas phase depend strongly on the excitation wavelength[44] and the excitation of the methylamine molecule to the S_3 state entails the formation of CN and HCN via the mechanism

$$CH_3NH_2 \xrightarrow{h\nu} \begin{cases} \xrightarrow{\alpha} CH_3\dot{N}H^* + H \rightarrow H + H_2C{=}NH; \\ \xrightarrow{1-\alpha} CH_2NH^* + H_2 \rightarrow H_2 + HCN^*; \end{cases}$$

$$HCN^* \longrightarrow \begin{cases} \xrightarrow{\beta} H + \dot{C}N; \\ \xrightarrow{1-\beta} HCN, \end{cases}$$

where $\alpha = 0.59$ and $\beta = 0.44$.

As regards the photolysis of amines in the solid phase, there has been only one communication[40] stating that hydrogen atoms are ejected into the gas phase in the photolysis of frozen methylamine.

The first attempts to interpret theoretically the accumulated experimental data on the photochemical reactions of aliphatic amines and to answer the important question why the dissociation of the N–H bond in gaseous amines and not the C–N bond is most likely have been made only recently.[23] By means of non-empirical calculations, it has been possible to show[23] that the lowest excited singlet state of methylamine (the Rydberg n, $3s$ state) is capable of an adiabatic transition to the valence states of the radical products (CH_3NH + H or CH_3 + NH_2). As for NH_2, the $3s$ orbitals then lose their Rydberg character and are localised at the H atom (which leads to the dissociation of the N–H bond). In general, the transition to the Rydberg states takes place as follows: $3s \rightarrow 3s$, $\sigma^* \rightarrow 1s$.

The bond dissociation in systems of this kind thus proceeds in such a way that n, $3s$ states are converted into n, σ^* states (here σ^* refers to N–H or C–N bonds) at a certain point on moving along the reaction coordinate (i.e. on "extension" of the N–H or C–N bond). The potential energy surface of the molecule in the n, $3s$ state has a shallow minimum corresponding to such dissociation or has none at all. However, higher Rydberg states (for example, n, $3p$) have deeper minima and should be correlated with higher (usually Rydberg) states of the products. The behaviour of the molecules in the n, $3s$ state in the bond dissociation process should therefore differ from their behaviour in higher Rydberg states for which the H_2 elimination process is possible.

The potential energy surfaces for the dissociation of the N–H and C–N bonds in the n, $3s$ state for CH_3NH_2 have a minimum in the region of the Franck–Condon geometry; the dissociation of the N–H bond therefore takes place in the state to which the system is excited.

The C–N bond dissociation energy in methylamine is twice as high as the N–H bond dissociation energy.[13] However, even when the energy barrier is the same, the N–H bond should have been ruptured much more readily because this process can take place fairly effectively via tunnelling (which is feasible precisely for shallow minima of the kind which obtain in the n,$3s$ state). This in fact explains the finding that the primary photochemical process involving methylamine (and many other primary amines) in the gas phase is the dissociation of the N–H bond and this is why triethylamine (and other tertiary amines) are relatively stable on excitation by radiation with a wavelength in the region of the 0–0 band in the absorption spectrum.

(b) Secondary amines

The main products of the photolysis of ethylmethylamine in hydrocarbon solvents are hydrogen, unsaturated compounds, small amounts of methane, and a nitrogen-containing polymer.[59]

Photolysis of pure liquid diethylamine by the radiation emitted by a high-pressure mercury lamp in the absence of oxygen leads to the formation of mainly *N*-butenylidene(2-ethyl-2-butyl)ethylamine (yield in excess of 70%) and also a mixture of the *meso*-racemates of *NN*-diethyl-2,3-butylenediamine, tetraethylhydrazine and 1,3-diethyl-2,4,5-trimethylimidazoline.[20,21] The reaction mechanism involves the photodissociation of the α-hydrogen atom and the formation of the radical $CH_3\dot{C}HCNC_2H_5$. The disproportionation of this radical leads to the formation of *N*-ethylideneamine, while dimerisation produces *NN*-diethyl-2,3-butylenediamine; the interaction of these two products affords 1,3-diethyl-2,4,5-trimethylimidazoline:

$$2CH_3CHNHC_2H_5 \longrightarrow \begin{cases} \rightarrow CH_3CH{=}NC_2H_5 + (C_2H_5)_2NH; \\ \rightarrow CH_3\underset{\displaystyle CH_3\dot{C}HNHC_2H_5}{CHNHC_2H_5}; \end{cases}$$

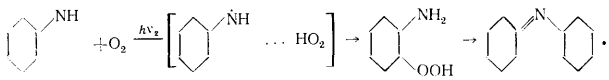
$$2CH_3CH{=}NC_2H_5 \rightarrow \underset{\displaystyle CH_2CH{=}NC_2H_5}{CH_3CHNHC_2H_5} \rightarrow CH_3CH{=}CHCH{-}NC_2H_5.$$

The presence of hydrazine among the reaction products means that the primary step in the photolysis is the abstraction of a hydrogen atom from the nitrogen, i.e. the dissociation of the N–H bond.

It is noteworthy that one cannot postulate the photodissociation of the pure compound on photoirradiation, as was done by Allan and Swan,[20] because at the given concentration

of the test substance it is in principle impossible to distinguish true photodissociation from the processes occurring on self-quenching.

The photoirradiation of solutions of amines in the presence of oxygen leads to a variety of products, which are obtained on decomposition of the hydroperoxide formed initially.[21] The excited state of the contact charge-transfer complex between the amine and oxygen arises in the first stage of photolysis[24-28] and then decomposes with formation of a hydroperoxide, which is converted into the final products:



The photoirradiation of solutions of di-n-hexylamine, dicyclohexylamine, and cyclohexyl-n-hexylamine in cyclohexane (10^{-2} M) in the absence of oxygen at 18 °C leads to the formation of the corresponding imines in preparative yields of 89–91%[28,29] (for the first compound, the product is *N*-n-hexylidene-n-hexylamine together with cyclohexylcyclohexane and n-hexylamine, while for the second compound the product is *N*-cyclohexylidenecylcohexylamine together with cyclohexylcyclohexane and cyclohexylamine). The entire photochemical reaction includes the following processes:

$$R_2NH + h\nu \rightarrow [R_2\dot{N} + H];$$
$$[R_2\dot{N} + H] \rightarrow R'CH{=}NR + H_2;$$
$$R_2NH + H \rightarrow R_2\dot{N} + H_2;$$
$$2R_2\dot{N} \rightarrow R'CH{=}NR + R_2NH.$$

In the review of von Sonntag and Schueman[12] the formation of hydrogen and imines in the photolysis of dihexylamines has been erroneously attributed to the H_2 elimination reaction.

The photoirradiation of a solution of dimethylamine in n-nonane (at a concentration in excess of 1 M) at 35 °C in the absence of oxygen leads to the formation of mainly *NNN'N'*-tetramethyldiaminomethane.[23] In addition, a small amount of methylamine and microamounts of *NNN*-triemthyldiaminomethane as well as tetramethylhydrazine are produced. The overall process mechanism includes the following stages:

$$\begin{gathered}(CH_3)_2NH + h\nu \rightarrow [(CH_3)_2\dot{N} + H];\\ [(CH_3)_2\dot{N} + H] \rightarrow H_2 + CH_3N{=}CH_2;\\ 2(CH_3)_2\dot{N} \rightarrow (CH_3)_2NCH_2N(CH_3)_2 + CH_3N{=}CH_2;\\ (CH_3)_2NH + H_2C{=}NCH_3 \rightarrow (CH_3)_2NCH_2NHCH_3.\end{gathered} \quad (8)$$

Photoirradiation of solutions of dimethylamine in chloroform and other organochlorine solvents also leads to the formation of aminyl radicals, but as a result of the photodissociation of the intermediate charge-transfer complex and not as a result of direct photodissociation:[24-26]

$$(CH_3)_2NH \cdot CCl_4 \xrightarrow{h\nu} Cl_3\dot{C} + [(CH_3)_2NH^+]Cl^-;$$
$$[(CH_3)_2NH^+] + (CH_3)_2NH \rightarrow (CH_3)_2NH \cdot HCl + (CH_3)_2\dot{N}.$$

The aminium radical-cation abstracts a hydrogen atom from the initial compound with formation of $(CH_3)_2\dot{N}$. This results in the formation of the dimer $(CH_3)_2NCH_2N(CH_3)_2$ and methylamine in this case too, but via different mechanisms.

Thus, in contrast to the photolysis of dimethylamine in the gas phase,[17,24-26] in organic solvents the recombination of aminyl radicals with formation of hydrazine derivatives takes place to an extremely significant extent. The almost complete absence of *NN*-dimethyldiaminomethane among the photolysis products means, according to the authors,[24] that the mechanism of the photolysis of dimethylamine is different to that postulated by Allan and Swan[20] and does not include the stage involving the formation of a C-centred radical (in addition, the α-aminoalkyl radical formed shows a tendency to recombine but not disproportionate). It is noteworthy that, according to the data of Kassab et al.,[23] obtained in the photolysis of a 1 M solution of dimethylamine, the photolysis products do not contain an imine having the structure R'HC = NR, while according to Hadley and Volman[30] precisely these amines are the main final photolysis products.

This discrepancy is apparently associated with the fact that at fairly high temperatures the imines are effectively converted into other products as a result of the reaction with the initial amine [reaction (8)] and also the fact that the imines investigated by Hadley and Volman[30] are less reactive in the nucleophilic addition of amines owing to the steric hindrance introduced by the bulky hexyl substituent.

The photodissociation of the N–H bond and the formation of the aminyl radical $(CH_3)_2\dot{N}$ in the photolysis of dimethylamine have been confirmed by the direct detection of this radical by EPR at 77 K[31,32] (the $CH_3NH\dot{C}H_2$ radical was not then detected).

In the photolysis of solutions of primary and secondary amines in non-polar solvents, the dissociation of the N–H bond is the main process for n-alkyl derivatives; the composition of the stable products is then determined by the reactivity of the aminyl radical formed and the concentration of the amine (i.e. the ratio of the rates of radical disproportionation and recombination) and also by the interaction of the radicals with the amine itself. In the photolysis of cyclic amines in more polar solvents, the probability of the dissociation of the C–N bond is greater, which leads to the appearance of products such as ammonia and bicyclohexyl (for cyclohexylamine).

(c) Tertiary amines

The photolysis of pure triethylamine by the light of a moderate pressure mercury lamp in the absence of oxygen leads to the formation of the *meso*-racemic mixture of *NNN'N'*-tetraethyl-2,3-butylenediamine and *NN*-diethyl-2,3-butylenediamine,[20] as well as small amounts of 1,3-diethyl-2,4,5-trimethylimidazoline and tetraethylhydrazine. The authors believe that the primary photochemical steps in this case are both the dissociation of the C–H bond with formation of the radical $CH_3\dot{C}HN(C_2H_5)_2$ and the dissociation of the C–N bond with formation of the radical $(C_2H_5)_2\dot{N}$, which is converted into diethylamine by abstracting hydrogen; diethylamine undergoes in its turn the photochemical decomposition described above.

III. AROMATIC AMINES

1. Absorption Spectra

The ultraviolet absorption spectra of the simplest aromatic amines (aniline and its derivatives) both in the gas phase and in solution have been investigated in fair detail.[47-55] The ultraviolet absorption spectra of aniline vapour clearly manifest five bands, three of which correspond to benzene absorption bands; at least two of the five bands are due to intramolecular charge transfer from the amino-group to the ring.[47]

Quantum-chemical calculations make it possible to interpret in detail the absorption spectra of aniline (Table 4). The wave functions for the excited states of aniline in the CNDO/S method were set up using singly excited electronic configurations of the π,π* aromati ccomponent of the aniline molecule and configurations with charge transfer from the orbitals of the unshared electron pair of the nitrogen atom to the antibonding orbitals of the aromatic ring (these configurations

correspond to the $l \rightarrow a_\pi$ transitions in Kasha's terminology [47,50]

Seven electronic configurations have been used to construct the wave functions $\Psi_0 - \Psi_b$: thsoe of the ground state, two charge-transfer states, and four locally excited states corresponding to the $A_{1g} \rightarrow B_{2u}$, $A_{1g} \rightarrow B_{1u}$, and $A_{1g} \rightarrow E_{1u}$ transitions in the benzene molecule. It follows from these calculations that the transition to the S_1 state in aniline corresponds to the transition to the B_{2u} state of the benzene ring; the contributions of charge-transfer configurations to this S_1 state are 22% for aniline and 36% for *NN*-dimethylaniline. The contribution of the charge-transfer configurations to the W_2 state of aniline is more than 50% (Table 4); thus the transitions in the aniline molecule cannot be regarded as simply the benzene transitions perturbed by the presence of the attached amino-group.[56]

Table 5. The calculated and experimental energies (E) and oscillator strengths (f) for the long-wavelength transitions of aniline derivatives.[47,55]

Transition	E, eV		f

$W_0 \rightarrow W_5$	7.86	7.62	0.920	0.88
$W_0 \rightarrow W_6$	7.89		0.525	

It is believed[47-49,55] that all the intense absorption bands of aniline and its simplest derivatives (*N*-methylaniline, *N*-ethylaniline, *NN*-dimethylaniline, *NN*-diethylaniline, and *N*,n-butylaniline) with energies below 6.2 eV are due to $\pi-\pi^*$ transitions (Table 5). The additional bands in the region of 230 nm in the spectra of *N*-methyl-, *N*-ethyl-, and *N*-butyl-anilines have been tentatively assigned[99] to the $n \rightarrow \sigma^*$ transition, because the bands corresponding to the $n \rightarrow \sigma^*$ transitions are characteristic of saturated aliphatic amines precisely in the region of ~200 nm[57] (see the discussion of this problem below). Despite the convincing agreement between the calculated and measured transition energies[47,55] (Tables 4 and 5), an unambiguous interpretation of the electronic states of amines remains unattainable because of the necessity for the complete separation of the contributions by the σ and π orbitals, since the amine molecules are nonplanar.[58]

On the basis of calculations[49] by the PPP method taking into account the configuration interaction (in relation to aniline, β-naphthylamine, β-aminoanthracene, vinylamine, and butadienylamine), it has been shown that the excited states of many aromatic and unsaturated amines cannot be classified as "pure" π,π^* or l,a_π states but are mixed [it has been suggested that they be designated by $S(\pi l,\ \pi^*)$ and $T(\pi l\pi)$]. With increase of the Ar–NH_2 bond length, "pure" l,a_π states can appear among the excited states of these amines†.

The increase in the size of the π system is accompanied by a decrease of the contribution of the l,a_π state to the wave functions of the lowest excited states because the vibrational structure is revealed more clearly in the absorption spectra of amines with an extensive system of π-bonds.

Furthermore, comparison of the rotational constants for the S_1 state of aniline and other benzene derivatives[68] makes it possible to establish precisely that the C–N bond in the molecule of aniline in the S_1 state is shorter by 0.08 Å than in the S_0 state, because the conjugation between the unshared electron pair in the $2p_x$ orbital and the π electrons of the ring is stronger in the S_1 state.

By measuring the absorption and magnetic circular dichroism spectra of aniline and *NN*-diethylaniline in solution in the gas phase, it has been possible to establish[52] that the absorption bands of these compounds in the range 46000 to 60000 cm^{-1} correspond to the Rydberg transitions.

The absorption spectrum of aniline vapour contains a 0–0 band, corresponding to the $S_1 \leftarrow S_0$ transition and located at 46530 cm^{-1}, as well as a vibrational progression at 490 cm^{-1}. These bands are absent from the spectra of the solutions and films at 77 K; on these grounds, there are attributed to Rydberg transitions, like the bands at 53270 and 56660 cm^{-1}. All these bands are described by the Rydberg formula

$$h\nu = 62\,170 - R/(n-\delta)^2,$$

where 62170 cm^{-1} is the first (adiabatic) ionisation potential of aniline. The quantum defect, which amounts to $\delta = 0.53$, shows that the bands belong to the *np* series.

In contrast to aniline, Rydberg transitions not only of the *p* type but also of the *s* type (corresponding to the first ionisation potential) can be clearly observed for *NN*-diethylaniline, which is associated with the fact that the highest occupied orbital in *NN*-diethylaniline has a different character—this is predominantly the *n* orbital of the substituent (the amino-group).

Thus Rydberg transitions appear at 47180 cm^{-1} in the spectrum of aniline and at ~36520, 38880, and 42000 cm^{-1} for *NN*-diethylaniline;[52] consequently the appearance of low-lying Rydberg states, due to the change in the nature of the highest occupied molecular orbitals, may be expected for aniline derivatives with electron-donating substituents (particularly in solution).

Previously it was thought to be established that the oscillator strengths of dialkylanilines,[59] corresponding to the four long-wavelength absorption bands, are proportional to

† Precisely the involvement of the l,a_π state in the establishment of the excited states explains the spreading of the absorption bands of the amines (compared with the bands in the spectra of hydrocarbons having a vibrational structure), because the change in the C = N bond length on excitation is in fact associated with these states.

$\cos^2\alpha$, where α is the angle between the plane of the amino-group and that of the benzene ring (the so-called "$\cos^2$ law"). This was deduced by Platt on the basis of the hypothesis that the dipole moment of the transition is proportional to the resonance energy, which is in its turn proportional to the overlap integral of the orbitals of the amino-group and the ring and hence to the angle α. However, the resonance energy for 5-cyano-*N*-methylindoline and all other indoline derivatives investigated is much higher than for methyl- or diethyl-aniline, although the oscillator strength of the long-wavelength transition is much lower for indoline derivatives.[59-61]

It is believed[62] that this discrepancy is caused by the mixing of the lowest charge-transfer states of these compounds with locally excited states: it has been shown that the energy of the lowest state of aniline hardly changes when the molecule is "twisted"[63] and the observed bathochromic shift of the absorption band is a consequence of the decreased energies of charge-transfer transitions. For low values of α, the mixing is slight and the usual $f \propto \cos^2\alpha$ relation is observed; for high values of α, there is a deviation from the relation caused by the contribution of the charge-transfer state.

According to Frolen and Goodman,[63] the $f \propto \cos^2\alpha$ law is valid only in the range of values of α amounting to ~30–90°; for smaller angles, one must use the formula

$$(\epsilon_{corr} - \epsilon_{min})/(\epsilon_0 - \epsilon_{min}) = \cos^2\alpha,$$

where ε_{corr} is the extinction coefficient at the maximum corrected for the non-steric influence of the substituents and ε_0 and ε_{min} are the maximum and the minimum values of ε respectively.

2. Luminescence Properties

All aromatic amines fluoresce in liquid solutions and hardly phosphoresce in frozen matrices;[62-91] examples are presented in Table 6.

The dependence of the fluorescence spectra of aniline on solvent polarity has been studied in detail and it has been shown that, with increased solvent polarity, the maximum of the fluorescence spectrum shifts from 315 nm in cyclohexane to 342 nm in water.[53] In hydroxylated solvents 1:1 complexes are formed with a hydrogen bond between the hydrogen of the hydroxyl and the unshared electron pair of aniline; an increase of solvent polarity leads to the "blocking" of the unshared electron pair of nitrogen, as a result of which the luminescence transition becomes close to the $n \rightarrow \pi^*$ type and the fluorescence quantum yield is correspondingly reduced.[65]

The fluorescent state of the β-naphthylamine molecule corresponds to the $'L_b$ state of naphthalene. The absorption band corresponding to this transition lies 6000 cm^{-1} below the band corresponding to the $'L_a$ state[148] (Table 6).

The first absorption band in the spectrum of α-naphthylamine consists of two unresolved components corresponding to transitions to the modified $'L_a$ and $'L_b$ states of naphthalene. The shoulder in the region of 30000 cm^{-1} in the absorption spectrum of its solution in cyclohexane corresponds to the transition to the $'L_b$ state.

Two features are characteristic of the luminescence properties of naphthylamines: an appreciable bathochromic shift of the fluorescence spectra in polar solvents while the fluorescence excitation spectrum remains unchanged and a significant discrepancy between the calculated and experimental fluorescence lifetimes.[148] It has been observed that the excitation of β-naphthylamine entails an increase of the dipole moment by 3.5 D, while the dipole moment of α-naphthylamine increases by 1.9–2.5 D. The increase of the dipole moment on excitation is caused by charge transfer from the nitrogen of the amino-group to the ring; the amino-group then undergoes a change in its conformation from the tetrahedral sp^3 conformation in the ground state to the trigonal sp^2 conformation in the excited state.[148] The equilibrium excited state is characterised by a greater degree of charge transfer than the Franck–Condon state, and the probability of a transition from this state is therefore greater than the probability calculated from the absorption spectra. This is why the experimental fluorescence lifetimes $\tau = \tau_{fl}/\phi$ are smaller than those calculated from the absorption spectrum.

Analogous results for α-naphthylamine have been again obtained recently and quite independently.[147] The authors investigated the kinetics of the quenching of the fluorescence and the shift of the fluorescence band as a function of solvent polarity and concluded that the $'L_a$ and $'L_b$ states of α-naphthylamine undergo an inversion in polar solvents. According to the authors,[147] the anomalous bathochromic shift of the fluorescence spectra of α-naphthylamine in polar solvents (even in frozen glasses) is associated with two mechanisms for relaxation of the Franck–Condon state: a change in the conformation of the amino-group and the relaxation of the solvent dipole relative to the increased amine dipole in the excited state, which leads to an increase of the contribution of the $'L_a$ charge-transfer state in polar solvents. The observed dependence of the bathochromic shift on solvent viscosity and temperature can be explained by the operation of the solvent dipole relaxation mechanism.

A characteristic feature of all aromatic amines, which leads to a change in their absorption spectra and to the quenching of their fluorescence, is the formation of hydrogen bonds with proton acceptors.[67] In the ground state the hydrogen bond between amines and proton acceptors is frequently very weak (for example, the equilibrium constant for the hydrogen-bonded complex between 1-aminopyrene and pyridine in hexane is 3 litre mol^{-1}); in polar solvents the hydrogen bonds are even weaker by virtue of the solvation of the amine and acceptor molecules. In the S_1 state amines form hydrogen bonds much more vigorously; the formation of a complex is manifested by the bathochromic shift of the absorption spectra.

It has been established by picosecond laser photolysis[114] that the excitation of such hydrogen-bonded complexes leads to charge transfer between the donor and acceptor and equilibrium between the locally excited donor and the charge-transfer complex (CTC) (D – H...A and $D^+ - H...A^-$) is established over a period shorter than 6 ps.

It is believed[114] that the fluorescence of amines in hydrogen-bonded complexes with pyridine is quenched as a result of the formation of short-lived non-fluorescent CTC on excitation of the hydrogen-bonded donor (amine)–acceptor (pyridine) pair.

(a) Acid–base properties in the ground and excited states

The luminescence properties of aromatic amines are closely related to their acid–base properties, namely all aromatic amines are weak bases. When aniline and aminoanthracenes are protonated, the perturbing influence of the amino-groups on the aromatic ring is reduced to a minimum and the absorption spectrum of the $C_6H_5NH_3^+$ ion in alcohol is therefore almost identical with the benzene spectrum,[69] while the spectra of the cations of aminoanthracenes are almost identical with the spectrum of anthracene.

The anilinium ion fluoresces and phosphoresces in the ether–isopentane–ethanol mixture (EPA) at 80 K and at room temperature;[22] the positions of the maxima of the 0–0 band at 80 K in EPA are illustrated below:

	Aniline	Anilinium ion

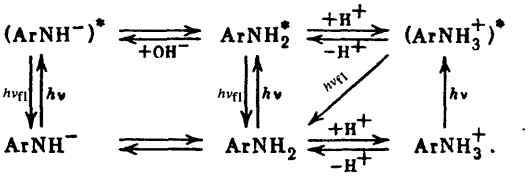
Notation: ν_{abs}, ϵ_{max}, and ν_{fl} are the long-wavelength maximum in the absorption spectrum, the extinction coefficient at the maximum, and the maximum in the fluorescence spectrum respectively, ϕ_{ISC} is the intersystem conversion quantum yield, and DHQ and THQ represent 1,2-dihydroquinoline and 1,2,3,4-tetrahydroquinoline respectively; for the significance of the remaining notation, see the footnote to Table 1.

In the S_1 state the principal properties of aniline are weakened and the anilinium ion dissociates adiabatically in the excited state at room temperature; the fluorescence of aniline itself is then observed.[69]

Aminoanthracenes and 1,2-dihydroquinolines in the excited state undergo acid dissociation: a longer-wavelength fluorescence band, corresponding to emission by the anthramide anion[87] or the corresponding anion derived from 1,2-dihydroquinolines,[88] appears in the spectrum in highly alkaline solutions.



Thus, a common feature of all aromatic amines is the weakening of the basic and intensification of the acid properties when they are excited to the S_1 state, which leads to the effective quenching of the fluorescence of amines by proton donors.[70–74]

The mechanism of the dissipation of the electronic excitation energy in the phototransfer of a proton has been studied in detail.[70–72] It has been shown in relation to aqueous and alcoholic solutions of β-naphthylamine, 3-aminopyrene, and 2-aminoanthracene that in highly acid solutions of the amines the excited states of the latter undergo effective induced deactivation by protons.[70,71] This process apparently involves the protonation of aromatic amines in the aromatic ring. At acid concentrations of 2–5 M, the appearance of a third emission band of amines (apart from the fluorescence bands of the neutral amine and the cation), which is due to the fluorescence of a carbonium ion, has been observed[71] in the range 550–580 nm. This means that the protonation process is adiabatic without loss of excitation.

The possibility of the induced deactivation by the proton of the excited states of 1- and 2-naphthylamines, formed as a result of the dissociation of their cations in the excited state, has also been noted[74] but it has been attributed to adiabatic deactivation.

The p*K* of the amines in the ground and excited states have been listed in another review[73] and will not be quoted here.

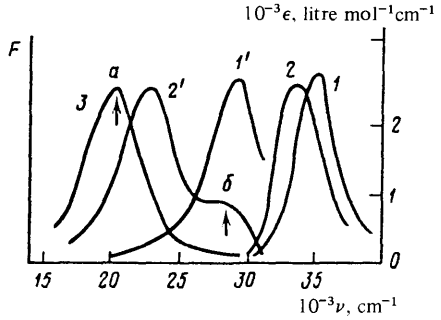


Figure 1. Absorption and fluorescence spectra of *p*-cyano-3-methyl-*NN*-dimethylaniline:[75,81] 1) and 1') in methylcyclohexane; 2) and 2') in dichloromethane; 3) in acetonitrile (the absorption spectrum in acetonitrile is close to that in methylcyclohexane and is not presented here).

(b) The luminescence properties of amine molecules with a "twisted intramolecular charge transfer state"

NN-Dialkyl-*p*-cyanoanilines (and in general anilines with electron-donating and electron-accepting substituents in the *para*-position) occupy a special place among aniline

derivatives.[62,75-86] A characteristic feature of these compounds is the two-component fluorescence of their solutions in polar solvents (Fig.1).[75] In a non-polar solvent (methylcyclohexane) there is only one "normal" fluorescence band of *NN*-dialkyl-*p*-cyanoanilines, while in more polar solvents there are two components *a* and *b*, the intensity and bathochromic shift of the long-wavelength component *a* increasing with solvent polarity.

Detailed studies of the luminescence,[76-78] luminescence spectroscopic,[79,80] and photochemical[85] properties of the above compounds led to the conclusion that a type of excited states (Fig.2), hitherto unknown, exists for these compounds—"states with twisted intramolecular charge transfer" (TICT) in the terminology adopted by Grabowski et al.[75] Quantum-chemical calculations showed that complete intramolecular charge transfer from the unshared electron pair of the $N(CH_3)_2$ group to the π^* orbital of the CN substituent[81] is possible for these compounds in the conformation where the angle α between the planes of the donor and acceptor is 90°.

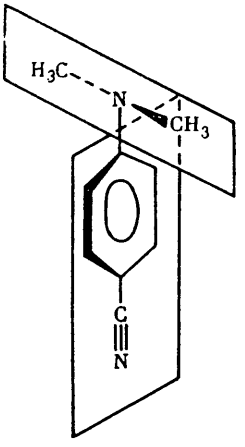

Figure 2. The "twisted state" of *p*-cyano-*NN*-dimethylaniline.

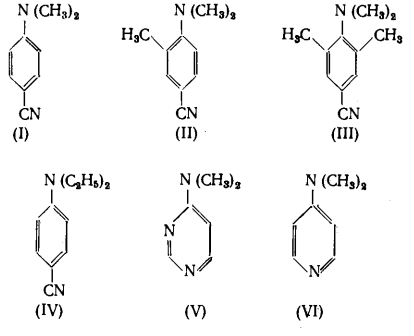
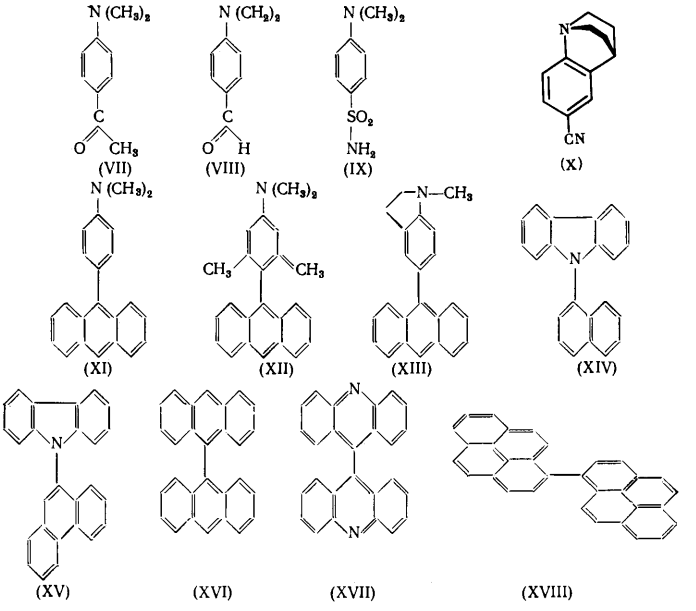
The formulae of all the compounds for which TICT has been postulated are given below.[75]





Thus, when *NN*-dialkyl-*p*-cyanoanilines are irradiated, the usual delocalised π,π^* state is initially excited, as in all other aniline derivatives. In non-polar solvents this state exhibits the usual fluorescence (the *b* band); but in polar solvents rapid $b^* \rightarrow a^*$ relaxation takes place and radiation is emitted from this TICT state (the *a* band). In solvents of moderate polarity the $b^* \rightleftarrows a^*$ equilibrium obtains and both fluorescence bands are shown.

The kinetics of the solvation by alcohol of the TICT state of *p*-dimethylaminobenzonitrile have been followed directly by the method of picosecond laser photolysis.[82] It follows from the results of these measurements that the equilibrium between the planar and TICT states in propanol is established after ~20 ps; the constant of this equilibrium has been estimated (not less than 30 in propanol and not less than 25 in butanol). A second value of the formation time of TICT state, amounting to 11 ps, has been determined from the kinetics of the quenching of the two-component fluorescence of *p*-dimethylaminobenzonitrile by oxygen[75,81] and, according to these data, the rate of formation of the TICT state does not depend significantly on the viscosity.

The most convincing proof of the role of the TICT states in the emission of the anomalous fluorescence band has been provided by structural studies.[75,81] The authors studied in detail the luminescence spectroscopic properties of various sterically hindered anilines and showed that, for compounds (II) and (III) whose *ortho*-positions relative to the amino-group contain methyl groups (in which the twisted structure is as it were "fixed"), only the *a* band is observed, while compound (I) emits both bands.

The fluorescence of compounds (I)–(III) in the TICT state must be rigorously prohibited both by steric factors (owing to the minimum overlap of the orbitals involved in the transition for the "twisted" conformation) and by the symmetry ($A_2 \leftarrow A_1$ transition in the C_{2v} point group). However, extremely low activation energies have been obtained from the temperature variation of the emission rate constant: $k_B = k_0 + k_1 \exp(-hcE/kT)$, $E \approx 120$–200 cm^{-1}. Such low values of E are associated with the occurrence of torsional vibrations, which increase the overlap between the donor and acceptor orbitals and thus increase the probability of the radiative transition.

The luminescence properties of *p*-dimethylaminobenzaldehyde (VII) and its derivatives (XVI) are even more complex.[77] Apart from the emission bands *a* and *b* associated with the TICT, the spectra of these compounds show bands due to aggregates and excimers.

In non-polar solvents the monomer of *p*-dimethylaminobenzaldehyde does not fluoresce at all in the lowest $S_1(n\pi^*)$ state and only phosphorescence in the $T_1(\pi,\pi^*)$ state is observed; in polar solvents a band *b* due to the fluorescence in the $S_1(\pi,\pi^*)$ state is observed. With increase of solvent polarity, there is a bathochromic shift of the band corresponding to the emission from the TICT state.

The fluorescence quantum yield of *p*-dimethylaminobenzaldehyde and *p*-dimethylaminoacetophenone in methyltetrahydrofuran depends on the excitation wavelength (Table 7).[84]

Table 7. The fluorescence (ϕ_{fl}) and phosphorescence (ϕ_{phosph}) quantum yields for *p*-dimethylaminobenzaldehyde (DAB) and *p*-dimethylaminoacetophenone (DAA).[84]

Amine	Solvent	φ_{fl}		φ_{phosph}
		λ_{exc} = 338 nm	λ_{exc} = 357 nm	
DAB	methyl-THF	—	0.09	0.20±0.015
DAB	propanol	0.56	0.93	0.07±0.017
DAB	methanol-water	0.98	—	0.014
DAA	methyl-THF	<0.01	—	0.44±0.05
DAA	propanol	0.32	—	0.04

The existence of several conformers of compounds (I) and (II) in the ground state follows from the discrepancy between the fluorescence excitation spectra of the two compounds and their absorption spectra. The fluorescence quantum yield of compounds (I) and (II) increases appreciably with decrease of temperature: at 77 K it is greater by two orders of magnitude than at room temperature, which is associated, according to the authors,[84] with the presence of conformers also in the TICT state, the relaxation of the initially populated planar state to form the TICT state being controlled by diffusion.

Calculations by the CNDO/S method have confirmed the existence of a whole series of conformers of compounds (I) in the ground and excited states, which are characterised by different angles of rotation of the $-N(CH_3)_2$ and $-CHO$ goups relative to the plane of the ring and by different degrees of hybridisation of the nitrogen atom, which is also responsible for the dependence of the fluorescence and phosphorescence spectra on the excitation wavelength.[86]

3. Photochemical Properties

The photochemical properties of aromatic amines are classified in this Section in terms of the type of the primary processes undergone by the amines. Four possible processes are examined: photodissociation of the N–H bond, photoionisation and formation of exciplexes, photodissociation of the C–N bond, and photorearrangements in the aromatic rings.

(a) Photodissociation of the N–H bond

Photoirradiation of solutions of primary and secondary aromatic amines in non-polar solvents leads to the rupture of the N–H bond and the formation of hydrogen atoms and aminyl radicals:

$$RNH + h\nu \rightarrow R\dot{N} + H \cdot$$

Aminyl radicals have been detected by flash photolysis in the photoirradiation of aniline and *N*-methylaniline,[89,94] 1,2-dihydroquinolines,[90–92] 1,2,3,4-tetrahydroquinolines (Fig. 3),[93] indoles,[94,96] 7-azaindolines,[97,98] and indolines.[100] The formation of hydrogen on photolysis of aniline and 1,2-dihydroquinolines has also been demonstrated mass-spectrometrically and chromatographically.[89,101]

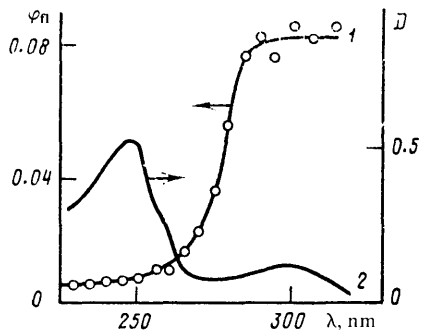


Figure 3. Dependence of the fluorescence quantum yield for a solution of 1,2,3,4- tetrahydroquinoline on the excitation wavelength (curve *1*) and the absorption spectrum of its solution in heptane (curve *2*).

The photodissociation quantum yields and the extinction coefficients of the aminyl radicals formed are presented in Table 8.

In non-polar solvents the neutral aminyl radicals are as a rule destroyed via a second order reaction in the absence of oxygen as a result of disproportionation or recombination:

$$2RN \rightarrow \text{products.}$$

The rate constants for this process are 1.5×10^9 litre $mol^{-1}s^{-1}$ for anilino-radicals in hexane[89] and 8.9×10^7 litre $mol^{-1}s^{-1}$ for 1,2-dihydroquinoline radicals.[101]

It has been shown[88,102] both experimentally and by quantum-chemical calculations that aminyl radicals are much stronger bases than the initial amines.

In aqueous and aqueous alcoholic solutions radical-cations are therefore formed in the photolysis of amines even at neutral pH:

$$RNH + h\nu \rightarrow R\dot{N} + H \underset{-H^+}{\overset{+H^+}{\rightleftarrows}} RNH^+.$$

For example, the p*K* for the equilibrium $C_6H_5\dot{N}H + H^+ \rightleftarrows C_6H_5NH_2^+$ is 7.0 ± 0.1;[88] for 1,2-dihydroquinolines, the p*K*

are as a rule higher (Table 9).

*The extinction coefficient was determined by comparison with the spectrum of stable 2,4,6-di-t-butylanilino-radical.
**The extinction coefficient was determined by the simultaneous measurement of the absorption spectra of the anilino-radicals at 77 K in 3-methylpentane and the determination of the amount of radicals in this spectrum with the aid of EPR spectra.[123]
***The extinction coefficient was determined by the method of Malkin et al.[98] involving the comparison of the amount of aminyl radicals formed in the direct and benzophenone-sensitised photolysis.

The aniline radical-cations formed on photolysis are destroyed in water via a second-order reaction with a rate constant of 1.5×10^9 litre $mol^{-1}s^{-1}$ apparently as a result of the formation of dimeric complexes.[89]

So far little is known about the mechanism of the photodissociation of aromatic amines, particularly about the nature of the electronically excited state in which photodissociation takes place. The main source of the difficulty in determining the mechanism is the lack of quantitative information about the efficiency of the photodissociation due to the complexity of the quantitative determination of the aminyl radicals and hydrogen atoms formed on photolysis of amines.

The nature of the photochemically active excited state in such reactions was investigated for the first time only recently: for anilines, 1,2-dihydroquinolines, and 1,2,3,4-tetrahydroquinolines, we observed[90,93,99] the dependence of the fluorescence (Fig. 4) and photodissociation quantum yields on the excitation wavelength, which permitted the conclusion that, on excitation at the wavelength corresponding to the long-wavelength band in the absorption spectrum, the photodissociation takes place in the lowest singlet state (the lowest triplet state for tetrahydroquinolines) and that, with increase of the excitation energy, a new photodissociation channel is opened—via the highest excited states.

Table 9. The excess electron density at the nitrogen atom in the amine or in the aminyl radical (q_N) and the pK of the radical-cation (according to Pirogov and Malkin.[88,102]

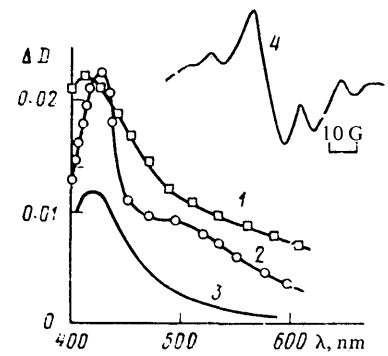

Figure 4. Absorption spectra of heptane solutions of the short-lived intermediates formed on photolysis of 1,2,3,4-tetrahydroquinoline [1) compound (XIX); 2) compound (XX)] and the absorption (curve 3) and EPR (curve 4) spectra of the aminyl radicals formed on photolysis of compounds (XIX) in vitreous 3-methylpentane matrix at 77 K.

The yield in the photochemical decomposition of aniline on photoexcitation with light at $\lambda = 254$ nm is 0.1, which is close to the quantum yield in the evolution of H_2. This shows that processes other than the dissociation of the N–H bond hardly occur in the photolysis of aniline in cyclohexane.[99]

At the present time the only question that remain obscure is whether the dissociation of the N–H bond in the highest excited states is responsible for the observed dependence on wavelength of the fluorescence quantum yields of aniline and other amines. Evidently, other photochemical processes (for example, reversible photoisomerisation of the benzene ring with formation of Dewar benzene) cannot induce this

process, because the fluorescence quantum yield of *NN*-dimethylaniline is almost independent of the excitation wavelength.[99] The dependence of the fluorescence and photochemical decomposition quantum yields of anilines and hydrogenated quinolines on the excitation wavelength is observed only in non-polar solvents and in water, while in alcohol there is no such dependence, which is apparently due to the recently observed formation of complexes between amines and alcohols.[103]

According to Köhler and Getoff[99] and Robin,[104] many amines exhibit low-lying Rydberg $n,3s$ states in the region of 40000 cm^{-1}. It appears probable that on excitation to the S_2 state, aniline (an in general all primary and secondary amines) undergo a transition onto the Rydberg potential surface, where bond dissociation takes place. A calculation[105] of the energies of the excited states of 1,2-dihydroquinolines by the CNDO/S method taking into account 40 excited configurations showed that a sharp increase of the photodissociation quantum yield takes place in the region of the $T_8(\sigma,\pi^*)$ state localised at the NH fragment (Fig.5).

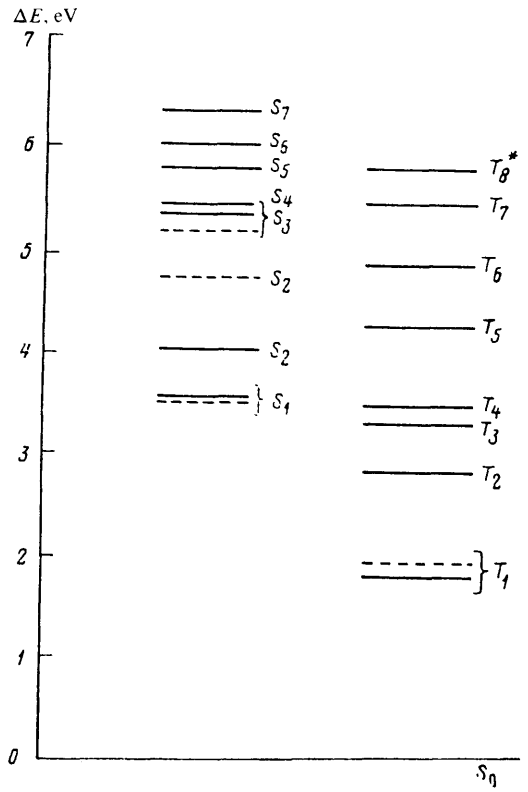

Figure 5. Energy level diagram for the electronically excited states of 2,2,4-trimethyl-1,2-dihydroquinoline (continuous line—calculation; dashed line—experiment). The σ,π^* states are marked by an asterisk; the others are π,π^* states.

The calculation demonstrated that all the electronically excited states of dihydroquinolines with energies less than 56000 cm^{-1} are delocalised over the entire molecule. The question therefore arises in what way the excitation energy of the entire π-system leads to the dissociation of the N–H bond.

There exist two different mechanisms of such a process which can be achieved, in principle, for the molecules of aromatic amines:[106,107] photodissociation in a bound state (adiabatic photodissociation) and predissociation. In the former case the electronic excitation energy, delocalised over the entire molecule, is converted into the vibrational energy of an individual N–H bond, while in the latter case it is converted into the electron ic energy of this bond. Convincing evidence for the particular photodissociation pathway in the condensed phase is at present lacking for any complex molecules (with the exception of the photodissociation of triphenylmethane[107]). For dihydroquinoline molecules, one can postulate that, when the excitation energies are below 42000 cm^{-1}, the N–H bond dissociates in a bound state via a non-adiabatic mechanism (Fig.6). Since the N–H bond dissociation energy is 3.46 eV (27890 cm^{-1}) (aniline), the rate of photodissociation via the adiabatic mechanism should be fairly low (the rate constant for the photodissociation of a C–H bond with the same strength by radiation with an energy of 54000 cm^{-1} does not exceed 10^6),[106] which is confirmed by the low dissociation yield on excitation at the wavelength corresponding to the long-wavelength absorption band (Table 10).

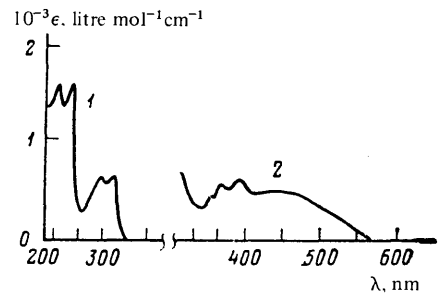

Figure 6. Absorption spectra of 1-cyano-2-hydroxy-1,2-dihydroquinoline in EPA at 77 K: 1) before irradiation with ultraviolet light; 2) after irradiation with ultraviolet light.

Table 10. The ionisation energies in vacuo (I_g) of the commonest amines.

Amine	I_g, eV	Refs.
Triphenylamine	6.68	[4]
Diphenylamine	7.25	[4]
Tetramethylphenylenediamine	6.2	[4]
Aniline	6.60	[4]
Indole	7.44	[6]
Carbazole	7.20	[151]

When the excitation energy exceeds 42000 cm^{-1}, the transition of the molecule to the repulsion state of the N–H bond and the occurrence of photodissociation via the predissociation mechanism become possible. It has been shown[106] that the repulsion state of the C–H bond (and in general the

R–H bond) is of the triplet type, i.e. the dissociation of the N–H bond can take place with an appreciable yield only in the triplet state.

Thus, for low excitation energies (less than 42000 cm^{-1}), the photodissociation of the N–H bond proceeds via the adiabatic mechanism with a low quantum yield (<0.01). When the energies are in excess of 42000 cm^{-1}, a new channel appears, leading to the dissociation of the N–H bond via predissociation, which increases the efficiency of the overall process. The nature of the increased quantum yield in the dissociation of the N–H and O–H bonds in the photoirradiation of indoles and phenols observed in a series of studies,[94,95,99,109] which involves the operation of two photodissociation mechanisms, is analogous.

(b) Photoionisation

By photoionisation we understand the direct transfer of an electron under the influence of light to the condensed phase with formation of a solvated electron.[4] Photoionisation is characteristic of compounds with a low ionisation potential (*p*-phenylenediamine and its methyl derivatives), while photodissociation predominates for amines with a relatively high ionisation potential (virtually all the remaining amines). The ionisation energy threshold J is defined by the expression

$$J = J_g - P_+ - V_0,$$

where J_g is the ionisation energy in the gas, P_+ the energy of the ionisation of the medium by the cation (radical-cation), and V_0 the energy of the interaction of the excess electron with the medium.

It follows from the data in Table 10 that the photoionisation of aromatic amines in the liquid phase can proceed via both one-quantum and two-quantum mechanisms. In non-polar solvents the differences between the energies of the one-quantum photoionisation of tetramethylphenylenediamine (TMPD) are determined by the quantity V_0 (V_0 for non-polar liquids varies from +0.6 eV for tetramethylsilane to −0.1 eV for n-hexane),[4–6] while the absolute value of the photoionisation threshold of TMPD is in the range from 4.3 eV in tetramethylsilane to 4.99 eV in n-hexane.[4] On photoexcitation of aromatic amines in non-polar solvents (other than TMPD) at the wavelength corresponding to the long-wavelength absorption band, photoionisation should therefore proceed extremely ineffectively.

It has been recently observed[113] that the photoionisation of TMPD on irradiation with light having energies in the range 42000–62000 cm^{-1} in weakly polar solvents (tetramethylsilane, 2,2-dimethylbutane, isoctane, cyclohexane, and n-hexane) leads to the formation of an electron–cation geminal ion pair, which either dissociates into the free ions or (with a significantly higher proabability) recombines to form excited TMPD, which emits recombination fluorescence.

In polar solvents the photoionisation is in general much more effective. The photoionisation of 2,7-bis(dimethylamino)-4,5,9,10-dihydropyrene in acetonitrile takes place in the fluorescent S_1 state, which is destroyed with formation of a radical-ion pair comprising the radical-cation of the amine and the radical-anion of acetonitrile; this pair subsequently dissociates into the free radical-ions (after 9 ns).[114] In benzonitrile the same compound forms an exciplex with the solvent and in this case the ionic photodissociation takes place directly in the exciplex.[115]

On the other hand, it has been shown[116] that the one-quantum ionisation of 1,6-bis(*NN*-dimethylamine)pyrene in acetonitrile proceeds via the intermediate formation of a long-lived (several microseconds) ion pair comprising the amine radical-cation and the solvated electron, which subsequently dissociates into the free ions.

In a detailed study[117] it was observed that the photodissociation of *NNN'N'*-tetramethylbenzidine (TMB) in acetonitrile, benzonitrile, and pyridine proceeds via an exciplex with the solvent, from which a radical-ion pair is formed (in the case of acetonitrile this ion pair comprises the amine radical-cation and the radical-anion derived from the acetonitrile dimer) and, in contrast to the ion pairs formed by 2,7-bis(*NN*-dimethylamine)-4,5,9,10-dihydropyrene, this ion pair is so long-lived that before dissociation it has sufficient time to react with acetonitrile to form the polymeric ion pair $TMB^+...(CH_3CN)^-$. Thus the formation of exciplexes with the solvent is a fairly general mechanism of the one-quantum photoionisation of aromatic amines in polar solvents such as acetonitrile, benzonitrile, dimethylformamide, and pyridine.

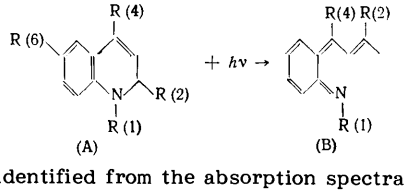
(c) Dissociation of the C–N bond in aromatic amines

In contrast to aliphatic amines, where the dissociation of the C–N bond takes place fairly frequently and has been reliably identified, there is very little reliable evidence for the dissociation of the C–N bond in aromatic amines. It has been observed[118] by EPR that the photoirradiation of TMPD in perdeuterio-3-methylpentane at 77 K leads to the formation of only one product, namely the methyl radical, as a result of the two-quantum C–N bond dissociation reaction in TMPD.

It has been demonstrated spectrophotometrically[119] that ultraviolet irradiation of frozen solutions of *NN*-dimethylaniline in EPA and 3-methylpentane at 77 K results in the formation of the anilino-radical $C_6H_5\dot{N}CH_3$ (the maxima in the absorption spectrum are at 314.0 and 400.0 nm). These bands usually overlap with the absorption bands of the dimethylaniline radical-cation. However, infrared irradiation of a solution subjected to preliminary irradiation with ultraviolet light at 77 K makes it possible to eliminate the radical-cations (as a consequence of the liberation of solvated electrons from traps and their recombination with the radical-cations) and to obtain the absorption spectrum of the anilino-radical. Thus the homolytic photodissociation of the C–N bond has been suggested as the primary photochemical reaction of *NN*-dimethylaniline.

The dissociation of the C–N bond with formation of the anilino-radical is possible also in the liquid phase;[89] thus anilino-radicals appear in the photolysis of *NN*-dimethylaniline in benzene, although the probability of this process is much less than the probability of the dissociation of the N–H bond.[89]

The photodissociation of the C–N bond has been studied in greatest detail in aromatic amines in relation to the opening of the ring of 1,2-dihydroquinolines.[120–126] The photoirradiation of solutions of 1,2-dihydroquinolines in EPA at 77 K entails the ruputre of the C–N bond and the formation of brightly coloured products with a quinonaldine structure:



(A) (B)

which were identified from the absorption spectra (Fig.6). The reverse thermal reaction takes place in the dark.

The mechanism of the formation of the quinonaldine form is apparently analogous to the mechanism of the opening of the pyran ring in pyrans, chromenes, and spiropyrans,[127–129] i.e. the excitation involves the ruputre of the C–N bond, a change in the hybridisation of the nitrogen atom, and the

rotation of both parts of the molecule about the C(3)–C(4) bond with formation of an almost planar quinonaldine structure. The probability of the dissociation of the C–N bond is determined by the nature of the substituents in the R(1) and R(2) positions and occurs only for dihydroquinolines with electron-accepting groups at the nitrogen atom.

In vitreous solutions at 77 K all the dihydroquinolines are photochemically stable. It has been observed[122] that the opening of the ring in dihydroquinolines is sensitised by triplet energy donors, which proceeds via the lowest state $T_1(\pi,\pi^*)$ having a closed or cyclic form. In contrast to the photochromic chromenes and spiropyrans, there exist no quantitative data concerning the effectiveness of the opening of the ring in dihydroquinolines on irradiation with ultraviolet light.

It is noteworthy that dihydroquinolines containing only a hydrogen atom as the substituent at the nitrogen do not undergo the ring opening reaction on photoirradiation and only the dissociation of the N–H bond takes place.[120,121] The energy level diagrams for the initial compound and the products of the N–H and C–N bond dissociation reactions of dihydroquinolines have been constructed on the basis of quantum-chemical calculations by the PPP method[126] and have made it possible to put forward the following reaction scheme:

$$(A) \xrightarrow{h\nu} (A(S_1)) \rightarrow (A(T_1)) \begin{cases} \rightarrow (B(T_1)) \rightarrow (B(S_0)); \\ \rightarrow R\dot{N}(S_0). \end{cases}$$

Calculations of the transition energies, atomic charges, and Viberg indices for the lowest singlet and triplet transitions of the *N*-acyl-substituted and unsubstituted dihydroquinolines have shown that an electron-accepting substituent at the nitrogen atom weakens the C–N bond; the photoexcitation of dihydroquinoline molecules leads to the same effect. For dihydroquinolines without substituents at the nitrogen atom, a new channel leading to the degradation of the excitation energy appears, namely the dissociation of the N–H bond, which occurs much more effectively than the dissociation of the C–N bond.

The luminescence properties of 1,2-dihydroquinolines and 1,2,3,4-tetrahydroquinolines containing hydrogen as the substituent at the nitrogen atom have been investigated in detail.[129–135] It has been observed that the first and second absorption bands in the spectra of dihydroquinolines shift in different directions under the influence of the solvent,[133] which indicates their different nature.

It has been shown by infrared spectroscopy that di- and tetra-hydroquinolines form complexes with chlorine-containing solvents in the ground state. In aqueous alcoholic solutions bands due to the $T_1 \leftarrow S_0$ transitions are observed after the introduction of KI.[129] The energies of the T_1 states of dihydroquinolines determined from these spectra are consistent with the values obtained from the phosphorescence spectra.[123]

4. Photorearrangements

The most important and most thoroughly investigated reaction of aromatic amines, which involves the benzene ring, is the photocyclisation of diphenylamines to carbazoles.[136–142]

It is known that the photoirradiation of derivatives of diphenylamine leads to the almost quantitative formation of carbazoles in almost all solvents (Fig.7).[136–138]

It follows from the experiments on the quenching of fluorescence and the sensitisation of the photocyclisation of diphenylamine and triphenylamine in hexane that the cyclisation takes place in the T_1 states of the amines via the intermediate formation of a short-lived product (E) (Table 11). Carbazole is formed from (E) as a result of the thermal elimination of two hydrogen atoms (it has been specially demonstrated that the amount of H_2 evolved is consistent with the amount of carbazole formed[139]).

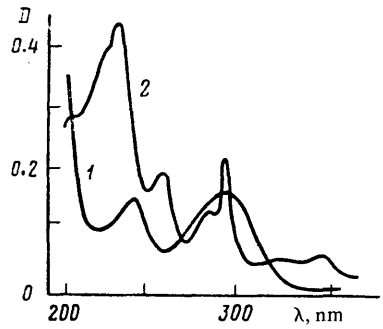


Figure 7. The conversion of *N*-methyldiphenylamine into carbazole: 1) absorption spectrum of a 2.6×10^{-5} M solution in hexane before irradiation; 2) after irradiation with ultraviolet light.

Table 11. The quantum yields in the formation of carbazole (ϕ_1) and the consumption of diphenylamine (ϕ_2) on irradiation with light at $\lambda = 253.7$ nm.[138,139]

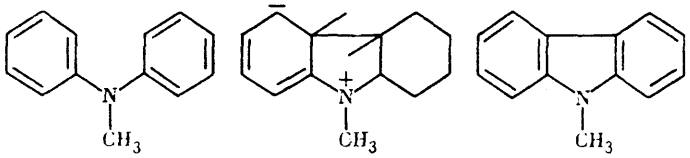
Solvent	Presence of oxygen*	φ_1	φ_2
Methyldiphenylamine			
Cyclohexane	+	0.67	0.67
Cyclohexane	—	0.06	0.06
Methylcyclohexane	+	0.67	0.67
Methylcyclohexane	—	0.06	—
n-Hexane	+	0.62	0.62
n-Hexane	—	0.06	—
Ethanol	+	0.57	—
Diphenylamine			
Cyclohexane	+	0.06	0.07
Cyclohexane	—	0.10	—
Methylcyclohexane	+	0.06	—
n-Hexane	—	0.05	—
Ethanol	—	0.10	—
Triphenylamine			
Cyclohexane	+	0.12	0.12
Cyclohexane	—	0.003	—

*The "+" and "–" signs correspond to the presence and absence of oxygen respectively.

The appreciable increase of the quantum yield of the reaction in the presence of oxygen is due to the fact that the latter appreciably accelerates the elimination of hydrogen from (E) with formation of HO_2 or H_2O_2.

The lifetimes of the T_1 state of *N*-methyldiphenylamine and triphenylamine in cyclohexane at 20 °C have been determined as respectively 1.36×10^{-8} and 8.16×10^{-8} s.[139] It has been demonstrated directly by flash photolysis[141] that *N*-methyl-4*a*,4*b*-dihydrocarbazole (D) is formed directly from *N*-methyldiphenylamine in the T_1 state and that its spectrum has an absorption maximum at 610 nm. Compound (E) is then

converted into the carbazole (P) via the elimination of a hydrogen atom.



(D) (E) (P)

The quantum yields of 4*a*,4*b*-hydrocarbazole formed from *N*-methyldiphenylamine in the T_1 state have been estimated from the dependence of the yield of carbazole and *N*-methyl-4*a*,4*b*-hydrocarbazole on the oxygen concentration on irradiation by a flash or continuously; the yields are 0.89, i.e. the T_1 state is deactivated almost exclusively via conversion into compound (E).[142]

The unusual influence of oxygen on the yield of carbazole (the dependence of the yield on the oxygen concentration passes through a maximum at O_2 concentrations of 6×10^{-4} M for *N*-methyldiphenylamine and 2×10^{-5} M for diphenylamine in hexane) is associated with the dual role of oxygen: on the one hand, it deactivates the T_1 state of diphenylamines and, on the other, it accelerates the conversion of 4*a*,4*b*-dihydrocarbazoles into carbazoles.[142]

Complete quantitative information concerning the pathways leading to the dissipation of the electronic excitation energy has been obtained for a solution of *N*-methyldiphenylamine in cyclohexane at 20 °C,[141,142] fully confirming the proposed mechanism of the conversion of diphenylamines into carbazoles via the intermediate (E).

---o0o---

The photonics of amine solutions possess in broad outline features characteristic of both aromatic and aliphatic amines, which makes it possible (despite the wide variety of structures and photochemical properties) to consider them within the framework of a single class of compounds. For all the amines in the lowest electronically excited states, the molecular geometry rearranges and undergoes a change in its electronic configuration, the two processes being associated with the intramolecular charge transfer on excitation and (or) the inclusion of the Rydberg states of the RN< fragment. This leads to an appreciable Stokes band shift in the fluorescence spectra in polar solvents, which is characteristic to a greater or lesser extent of all amines, starting from the simplest aliphatic amines and extending to indole. The main photochemical process for amines is electron transfer and the photodissociation of the N–H bond. The homolytic photodissociation of the N–H bond is the dominant process for all the primary and secondary amines in the absence of special conditions for electron transfer (polar solvents and electron acceptors).

It is essential to note that, whereas the luminescence spectroscopic properties of amines in the condensed phase have been investigated in fair detail and a fairly elegant theory, relating the electronic structure of amines to their luminescence spectroscopic properties has been constructed, the mechanism of the photochemical reactions of the same amines has been studied quite inadequately. The lack of quantitative data concerning the efficiency of N–H bond dissociation process makes it impossible to characterise the influence of the structure of the molecule on the mechanism of its photochemical reactions. This is why most difficulties are observed in the study of the many processes occurring when amine molecules absorb light in those cases where photodissociation processes are possible.

The Chemiluminescence of Organometallic Compounds

G.A.Tolstikov, R.G.Bulgakov, and V.P.Kazakov

Studies on the liquid-phase and gas-phase reactions of organometallic compounds accompanied by the emission of light are described systematically and discussed. The influence of the magnetic field on the chemiluminescence of Grignard reagents and the study of the electrochemiluminescence of solutions of organometallic compounds are examined. The ways leading to further development of the field of the chemiluminescence of organometallic compounds and certain possible applications of the phenomenon in the monitoring of industrial processes are discussed.
The bibliography includes 80 references.

I. INTRODUCTION

As a phenomenon and as a specific method, capable of yielding much information, for the investigation of the mechanisms of chemical reactions, chemiluminescence (CL) has attracted the attention of investigators in increasing numbers of fields of research. The results of studies of the chemiluminescence excited in the reactions of organic[1-4] and inorganic[5] substances have been fairly fully described in a series of special reviews and have been used to investigate the kinetics of chemical reactions,[6,7] for the analytical determination of submicroamounts of substances in solution,[5,8] and also for the elucidation of the mechanism of the transformation of the energy of chemical reactions into the energy of electronically and vibrationally excited molecules.[9] On the other hand, there have been no reviews giving a systematic account of studies of chemiluminescence involving organometallic compounds (OMC) and only isolated data are available.[10,13]

Despite the fact that the emission of light in chemical reactions involving OMC was observed more than 70 years ago,[11,12] the study of the chemiluminescence of OMC has not been developed as much as it deserves. Nevertheless, the exceptionally extensive applications of OMC involving the large-scale manufacture of various organic products,[13,14] the preparation of specially pure metals,[15] and the creation of the laser technology[16] have made it necessary to resort to physicochemical methods for the investigation of the mechanisms of the reactions of OMC. The employment for this purpose of the chemiluminescence method is especially attractive, because it is possible to record the excited states of the reaction products and intermediates (here and henceforth, unless otherwise stipulated, electronically excited states are considered) without interfering with the system incorporating chemically corrosive OMC. The potential possibility of generating chemiluminescence in the redox reactions of OMC arises from their high rates and exothermic nature. Such reactions frequently constitute the basis of organic catalytic and non-catalytic synthesis. It has been noted[17] that most of the catalytic reactions proceed via the formation of excited states of unstable intermediates. Evidently the search for new chemical reactions involving OMC accompanied by chemiluminescence will make it possible to detect such excited states from their radiative deactivation.

The studies considered in this review have been subdivided in terms of the Groups of the elements in the Periodic System and are concerned with the chemiluminescence in solution and in the gas phase. The ability of many OMC to glow in air is generally known; since the emission of light observed under these conditions includes an equilibrium component, i.e. a glow unrelated to the phenomenon of chemiluminescence, this type of light emission is not considered in this review.

II. THE CHEMILUMINESCENCE OF ORGANOLITHIUM, ORGANOSODIUM, AND ORGANOPOTASSIUM COMPOUNDS

1. The Oxidation of Organolithium, Organosodium, and Organopotassium Compounds by Oxygen

Chemiluminescence in the oxidation of an ethereal solution of C_6H_5Li has been observed by Gilman et al.[18] A glow has also been detected in the analogous reactions of solid specimens of C_6H_5Li, C_6H_5Na, and C_6H_5K.[19] The chemiluminescence spectrum in the interaction of C_6H_5Li with a saturated solution of oxygen in benzene consists of a broad band (from 320 to 600 nm) with maxima at 350 and 530 nm.[20] Even at a low concentration of butyl-lithium (10^{-3} M) the solutions have a deep brown colour, which leads to a marked distortion of the chemiluminescence spectrum as a consequence of the self-absorption by the solution.

2. The Oxidation of Butyl-Lithium by Organic Peroxides

The emission of light in the oxidation of C_4H_9Li by benzoyl peroxide (BP), lauryl peroxide, and t-butyl peroxide in toluene, heptane, and tetrahydrofuran (THF) has been investigated.[21] Two sections, which can be expressed in a linear form in terms of the variables as a second-order kinetic equation, have been differentiated in the kinetic plot of the chemiluminescence intensity in the reaction of C_4H_9Li with BP (Fig.1):

$$I^{-1/2} = (k\eta)^{-1/2}[BP]_0^{-1/2} + (k/\eta)^{1/2}\, t,$$

where k is the reaction rate constant, η the chemiluminescence yield, and $[BP]_0$ the initial BP concentration. The

rate constant k obtained from chemiluminescence measurements[20] and the results of the iodometric titration of BP agreed satisfactorily (0.3 and 0.34 litre mol^{-1} s^{-1} respectively). The chemiluminescence yield η was 10^{-12} photons per single step in the interaction of the reactants. The effective activation energy was obtained from the temperature dependence of I (on the basis of the chemiluminescence kinetics) and is 3.0 ± 0.5 kcal mol^{-1}.

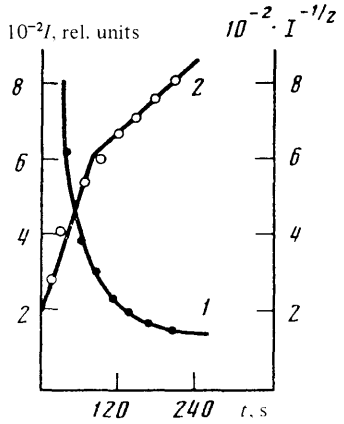

Figure 1. Kinetic curve describing the decrease of the chemiluminescence intensity (curve *1*) and its form in terms of the variables of Eqn.(1) (curve *2*);[21] $[BP]_0 = [C_4H_9Li]_0 = 10^{-2}$ M.

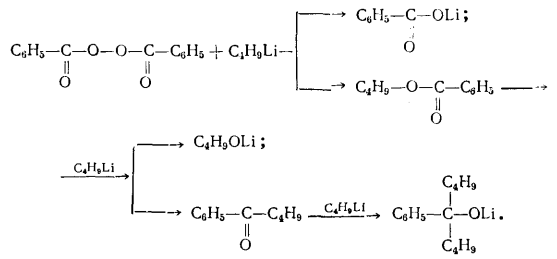
According to the results of the infrared spectroscopic and ^1H NMR analysis of the reaction products and the study of the stoichiometry of the interaction,[21] the mechanism of the complex process involving the oxidation of butyl-lithium by BP can be represented by the following consecutive reactions:



It is assumed that the source of excitation energy is the first, most exothermic stage (90–90 kcal mol^{-1}) [sic] and Panasenko et al.[21] believe that the chemiluminescence emitter is butyl phenyl ketone—the product of the second stage. The difference between the chemiluminescence and photoluminescence spectra of the suggested emitter (Fig. 2) is associated with the formation of its complex with another reaction product—lithium butoxide. Indeed, the photoluminescence spectrum of a mixture of chemically non-interacting acetophenone and lithium butoxide agrees with the short-wavelength chemiluminescence maximum (460 nm);[21] the nature of the second, long-wavelength chemiluminescence maximum has remained unelucidated. Thus the excitation of the chemiluminescence emitter occurs as a result of the transfer of the energy of the first stage of the process to butyl phenyl ketone—the product of the second stage. A more clear-cut argument in support of the proposed mechanism of the excitation of the chemiluminescence would have been the detection of an increase in chemiluminescence intensity when butyl phenyl ketone is added to the solution.

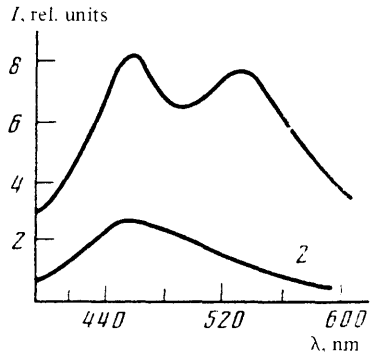


Figure 2. The chemiluminescence spectrum in the reaction of benzoyl peroxide with C_4H_9Li (curve *1*) and the photoluminescence spectrum of a mixture of acetophenone and C_4H_9OLi in heptane (curve *2*); 20 °C; $[BP] = [C_4H_9Li] = 10^{-2}$ M.

III. THE CHEMILUMINESCENCE OF SOLUTIONS OF ORGANOMAGNESIUM AND ORGANOCALCIUM COMPOUNDS

In 1905 Wedekind[22] attempted to obtain nitrotriphenylmethane by the reaction

$$3C_6H_5MgI + Cl_3CNO_2 \rightarrow (C_6H_5)_3CNO_2 + 3MgICl.$$

Although the desired product was not obtained, Wedekind observed a bright chemiluminescence arising when chloropicrin was added to a solution of the Grignard reagent (GR) in ether; the colour of the glow varied from yellow-green to pure green. In a number of his studies of this chemiluminescence, a glow was also detected in the reaction with phenylmagnesium bromide.[11,12,22] He attributed the observed glow to the phenomenon of luminescence (i.e. to a non-equilibrium emission of light), since the temperature of the system did not exceed the boiling point of ether. This first reaction of OMC accompanied by chemiluminescence was called the "Wedekind reaction". We may note that another communication by Wedekind[23] is referred in the literature to the same series of investigations, although it contains no information about chemiluminescence.

Later it was shown that a similar chemiluminescence arises in the interaction of chloropicrin and bromopicrin also with other Grignard reagents;[24] chloropicrin gave rise to a brighter glow. The iodides of Grignard reagents reacted with chloropicrin with emission of a greater amount of light than in the reaction of the chlorides. The mechanism of the chemiluminescence in the Wedekind reaction has still not been investigated. There is only no doubt that the reaction is different from that associated with the glow arising in the oxidation of Grignard reagents by oxygen, because it was observed in diethyl ether also under conditions where oxygen had been thoroughly removed.[25]

1. The Oxidation of Grignard Reagents by Oxygen

On repeating Wedekind's experiments, Heczko[26] observed the emission of light in the oxidation of Grignard reagents by oxygen. (Sometimes[27] the discovery of this chemiluminescence is erroneously attributed to Wedekind.[12]) It was assumed that the appearance of this glow requires moisture but later it was found[24,28] that the presence of moisture inhibits the glow. Subsequent investigations demonstrated that the chemiluminescence associated with the oxidation by oxygen is observed for a whole series of other Grignard reagents having different structures.[29–38] The glow in the oxidation of p-chlorophenylmagnesium bromide[30] is apparently one of the brightest among all the known chemiluminescence reactions in solution. This chemiluminescence, observed independently by Moeller[28] and Evans and Dufford,[32] has been called[24] the Moeller–Evans reaction.

There have been contradictory views concerning the influence of the nature of the Grignard reagent on its capacity for chemiluminescence and oxidation by oxygen. Moeller[28] assumed that this property is characteristic only of aromatic derivatives. According to Lifshitz,[31] the chemiluminescence is associated with the different stabilities of the etherates of aromatic and aliphatic Grignard reagents, because it has been found that all the ether-free Grignard reagents react with oxygen with emission of light; the brightness of the glow in the reactions of aromatic Grignard reagents is only a little lower than that of aromatic compounds. A systematic investigation[32] has shown that the above contradictions were associated with the influence of Grignard reagent concentrations, the optimum value of which (for the observation of the maximum brightness of the chemiluminescence) depends on their nature. Thus the concentration is 2.5 M for phenylmagnesium bromide and 0.33 M for aliphatic linear reagents such as propyl-, butyl-, and ethyl-magnesium bromides; at a concentration of 1 M chemiluminescence is not observed at all for these compounds. Apparently the author[31] dealt with less pure compounds in experiments involving the oxidation of concentrated solutions of aliphatic Grignard reagents.

Despite the lack of spectroscopic techniques available to modern investigators, the chemiluminescence intensities of various Grignard reagents observed in the old investigations (up to 1933) were compared on a quantitative basis using calibrated pyrometers. The spectroscopic characteristics of the glow were obtained either by visual observations or by a photographic procedure. This established many characteristic features of the appearance of the chemiluminescence in the reactions of Grignard reagents.[28,32–35] In the first place it was shown that the chemiluminescence in the oxidation of Grignard reagents by oxygen is a fairly general phenomenon for compounds of this class. Among the 60 Grignard reagents tested by Dufford et al.[24] 40 proved to be capable of chemiluminescence.

A list of these compounds, supplemented by the data of Evans and Diepenhorst[34] with indication of the colour and brightness of the chemiluminescence, is presented in Table 1; data for the chemiluminescence of these compounds in the reactions with chloropicrin and bromopicrin are included for comparison. The type of organic group plays a significant role in the appearance of chemiluminescence in the oxidation of Grignard reagents by oxygen. Compounds with isocyclic organic groups emit more light than those with acyclic groups. A favourable factor for both types of compounds is the presence of a direct bond between magnesium and an unsaturated carbon atom. Among isocyclic derivatives of Grignard reagents, the chemiluminescence is more intense in the reactions of compounds containing an aromatic group. The substitution of one hydrogen atom in the benzene ring by another atom or group leads to an increase of the brightness of the chemiluminescence. The position of the substituent in the benzene ring relative to magnesium is then a decisive factor:[34] The brightness of the chemiluminescence decreases in the sequence *p*- > *o*- > *n*. When the position of the substituent and the chemical nature of the group are the same, the chemiluminescence is more intense for bulkier groups. A change in the chemical nature of the substituent X in RMgX (where R is an aromatic group and X = halogen or CH_3) leads to a decrease of the brightness in the sequence chlorine > ethyl > bromine > iodine.[24,34]

Table 1. Characteristics of the reactions of Grignard reagents in ether accompanied by the brightest chemiluminescence.[24,34]

Compound	Brightness of chemiluminescence in reactions with:		
	O_2	chloropicrin	bromopicrin
p-ClC_6H_4MgBr	v.br.b	w.	nil

p-, *o*-$(CH_3)_2C_6H_3MgBr$	br.y.-wh.	–	–

Notation: v.br. = very bright; m. = moderate; b. = blue; g. = green; y.-wh. = yellow-whitish [w = weak; v.w. = very weak].

An increase of the number of substituents (more than one) in the benzene ring entails a decrease of the brightness of the flow.[35] Chemiluminescence is observed also for Grignard reagents based on naphthalene and anthracene derivatives in which the MgBr group is in the β-position.

The chemical nature of the solvent (14 different ethers, benzene, and dimethylaniline were tested) does not have a significant influence on the intensity of the glow[34] and the observed differences in brightness are caused by the different solubilities of the Grignard reagents and by the viscosity of the medium. Thus the different stabilities of the etherates of the Grignard reagents do not exert the influence suggested in earlier studies.[31,36]

The nature of the substituent and its position in the benzene ring have an appreciable influence also on the spectroscopic characteristics of the chemiluminescence. It has been found[24] that, in each of the two series of Grignard reagents C_6H_5MgCl, C_6H_5MgBr, C_6H_5MgI and *p*-$CH_3C_6H_4MgCl$, *p*-$CH_3C_6H_4MgBr$, *p*-$CH_3C_6H_4MgI$, the compounds containing chlorine give rise to a longer-wavelength (green light) chemiluminescence, while those containing iodine produce the shortest-wavelength (blue light) chemiluminescence. A similar effect has been observed also for the dihalogeno-derivatives of Grignard reagents: *p*-ClC_6H_4MgCl, *p*-BrC_6H_4MgBr, and *p*-IC_6H_4MgI. When the position of the substituent in the benzene ring relative to magnesium is varied in each of the Grignard reagents investigated, namely $CH_3C_6H_4MgCl$, $CH_3C_6H_4MgBr$,

$CH_3C_6H_4MgI$, ClC_6H_4MgBr, BrC_6H_4MgBr, and ClC_6H_4MgCl, the wavelength of the emission increases in the sequence *m*- < *o*- < *p*- (from violet to green light).[24]

When a solution of the Grignard reagent being oxidised was acted upon by ultraviolet light, a photoluminescence (PL), whose intensity increased with the degree of oxidation, was observed; the initial Grignard reagent did not exhibit a photoluminescence.[30,34,37] Neither phosphorescence nor X-ray luminescence were observed for the products of the oxidation of the Grignard reagents. As a rule, the photoluminescence spectra differed from the chemiluminescence spectra.[30,34,37] The chemiluminescence spectra of Grignard reagents containing chlorine or bromine in the benzene ring (*p*-ClC_6H_4MgBr, *p*-BrC_6H_4MgBr) consisted of a single band extending from 448 to 518 nm.[30] The chemiluminescence and photoluminescence of the Grignard reagents derived from naphthalene each contained one band with markedly different maxima.[34] A bathochromic shift of the bands has been observed in the oxidation of these Grignard reagents and has been attributed to the unusual effect of the emitted chemiluminescence as light exciting the photoluminescence of the oxidation products in a longer-wavelength part of the spectrum. The above differences between the chemiluminescence and photoluminescence spectra led to the conclusion[38] that the nature of the chemiluminescence and photoluminescence emitters is different. The bright photoluminescence occurring in the oxidation of Grignard reagents has been attributed[37] to the emission by ROMgX (where R is an aromatic group and X is a halogen).

In later investigations[20,25,27] the identification of the emitters responsible for the glow, achieved with the aid of a sensitive spectroscopic technique, showed that the chemiluminescence and photoluminescence are caused by the emission of light from the same substances but of a kind different from ROMgX. The spectroscopic characteristics have been obtained in the oxidation by oxygen of solutions of C_6H_5MgBr and *p*-ClC_6H_4MgBr in THF, diethyl ether (Fig. 3),[27] and benzene with an admixture of triethylamine.[26] The nature of this solvent does not influence the form of the spectra. The difference of the chemiluminescence spectra from those obtained previously in studies[34,37] where the emission was detected mainly in the visible region and did not coincide with the photoluminescence spectra of the oxidation products has been attributed[20] to the internal filter effect caused by the high concentrations (1 M) of the solutions of Grignard reagents. It was found that it is essential to apply corrections for this effect at low concentrations of Grignard reagents (10^{-3} M). Although Bardsley and Hercules[20] and Bolton and Kerns[27] obtained identical chemiluminescence spectra, they identified different oxidation products as the emitters. Bolton and Kerns[27] found that excited molecules of brominated biphenyls arise in the oxidation of C_6H_5MgBr and *p*-ClC_6H_4MgBr. The photoluminescence spectra of these substances, obtained by the photolysis of bromobenzene (or 1-bromo-4-chlorobenzene) in ether or by the thermolysis of benzoyl peroxide in bromobenzene, were identical with the photoluminescence spectra of the solutions after the oxidation of C_6H_5MgBr or *p*-ClC_6H_4MgBr respectively and with the chemiluminescence spectra of these Grignard reagents. However, it was not discovered which compounds are responsible for the photoluminescence in the longer-wavelength part of the spectrum, which is excited selectively by the 366 nm line in the light from the mercury lamp (instead of the 313 nm which excites both components of the photoluminescence spectrum). Bardsley and Hercules[20] suggested that the emitter is *p*-terphenyl $C_6H_5C_6H_4C_6H_5$—another product of the oxidation of phenylmagnesium bromide. According to Bolton and Kerns,[27] this identification is erroneous because Bardsley and Hercules[20] compared the chemiluminescence spectrum with an incorrect photoluminescence spectrum of *p*-terphenyl. The actual position of the photoluminescence maximum in the spectrum of *p*-terphenyl (340 nm) according to data in Berlman's book[39] differs markedly from the chemiluminescence peak/365 nm). After the oxidation of *p*-ClC_6H_4MgBr, three fractions exhibiting a blue photoluminescence were isolated[20] by chromatographic separation. The only product identified in these fractions (it is suggested that it is $ClC_6H_5C_6H_4C_6H_5Cl$) has a photoluminescence spectrum (with a maximum at 345 nm) which does not coincide with the chemiluminescence spectrum. Two other products, which were unidentified because of their small amount, exhibit a photoluminescence at 377 and 387 nm, i.e. in the region of the chemiluminescence maxima. Estimations of the quantum efficiency of the chemiluminescence[20] yielded 10^{-6} and 10^{-4} for C_6H_5MgBr and *p*-ClC_6H_4MgBr respectively.

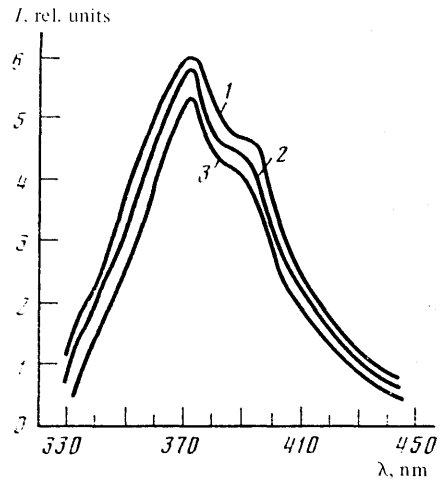

Figure 3. The fluorescence spectrum of the products of the oxidation of phenylmagnesium bromide in diethyl ether[27] with an excitation wavelength λ_e = 313 nm (curve *1*), the fluorescence spectrum of photolysed bromobenzene in ether with λ_e = 313 nm (curve *2*), and the chemiluminescence spectrum in the reaction of a solution of phenylmagnesium bromide in ether with oxygen (curve *3*).

The glow of brominated biphenyls is excited in the elementary reaction step and not as a result of energy transfer,[27] but the introduction of brightly fluorescent additives does not influence the chemiluminescence intensity. It was found that the oxidation of diphenylmagnesium is not accompanied by chemiluminescence.[27] In the same study it was also shown that the unsubstituted biphenyls formed in the oxidation of phenylmagnesium bromide (in yields up to 15%) are not excited in this chemiluminescence system. An EPR signal was detected in the oxidation of phenylmagnesium bromide,[27] which is important, since previously the formation of free radicals in the oxidation of organomagnesium compounds had been demonstrated on the basis of more indirect data: the analysis of the composition of the oxidation products and the study of the stereochemistry of the autoxidation reaction.[40]

Two mechanisms of the oxidation reaction, ensuring sufficient energy for the excitation of the chemiluminescence of brominated biphenyls (90 kcal mol^{-1}), have been proposed.[27] According to the first mechanism, the excitation takes place as a result of the reactions of free radicals:

$$C_6H_5MgX + O_2 \rightarrow C_6H_5O_2MgX \rightarrow C_6H_5^{\cdot} + MgO_2X \xrightarrow{MgX_2}$$
$$\rightarrow C_6H_5MgX + \dot{X} \rightarrow XC_6H_5MgX^{\cdot} \xrightarrow{R} R^{\cdot} + XC_6H_5MgX \xrightarrow{O_2} XC_6H_5O_2MgX \rightarrow$$
$$\xrightarrow{C_6H_5MgX} \begin{cases} \longrightarrow XC_6H_5MgX + C_6H_5OMgX; \\ \longrightarrow 2MgOX + XC_6H_5C_6H_5^{\cdot} \rightarrow XC_6H_5C_6H_5 + h\nu. \end{cases}$$

It follows from the above mechanism that the emitter is excited on interaction of the organomagnesium peroxide with the initial Grignard reagent. However, no direct evidence for the involvement of the peroxide in the generation of the chemiluminescence has been presented.[27] The low intensity of the EPR signal precluded the identification of the radicals. In order to demonstrate the involvement of the radicals in the chemiluminescence, an attempt was therefore made to investigate the influence of radical trapping agents on the chemiluminescence; the attempt was unsuccessful because of the low solubility of such agents and (or) their interaction with the Grignard reagent. The authors[27] proposed a second, alternative mechanism without the participation of free radicals:

$$C_6H_5MgX + O_2 \rightarrow C_6H_5O_2MgX \xrightarrow{C_6H_5MgX}$$
$$\rightarrow 2C_6H_5OMgX \rightarrow C_6H_5C_6H_5X^{\cdot} + MgO + MgOX;$$
$$\rightarrow C_6H_5C_6H_5X + h\nu.$$

We may note that these investigators[27] do not give preference to either of the two mechanisms.

2. The Influence of the Magnetic Field

The influence of the magnetic field on chemical reactions is regarded nowadays as a reliably established fact[41–43] although up to 1967 the existence of this effect appeared extremely doubtful.[41] The study,[44] which is apparently the first investigation in which the sensitivity of a chemical reaction to the magnetic field was observed (at any rate, this is absolutely certain in relation to reactions accompanied by chemiluminescence) is of special interest in this connection. The authors[44] thought that in a strong magnetic field there is a possibility of identical orientations of the molecules or molecular orbitals, which may result in the polarisation of the emitted light. They did not observe the polarisation of the chemiluminescence but were able to discover another effect, which consists in an increase of the intensity of the chemiluminescence when the Grignard reagent is oxidised in the magnetic field. The rapid imposition of the field induces a directional flow of a stream of solution and an increase of the brightness of the emission from the sides of the metallic crucible containing the solution. The authors[44] explained the observed phenomenon by the movement of the products of the oxidation of the Grignard reagent, which possess paramagnetic properties, towards the poles of the magnet. This effect has been clearly observed for *p*-BrC_6H_4MgBr only in strong fields (1500 G).

3. Electrochemiluminescence of Solutions of Grignard Reagents

A glow has usually been observed under severe electrolysis conditions (at potentials ranging from 100 to more than 1000 V),[44,45] with the exception of one study,[46] where, apart from the fact that electrochemiluminescence (ECL) has been detected, no other data concerning the glow of the Grignard reagent were presented. For solutions of C_6H_5MgBr or $C_6H_5CH_2MgBr$ in ether (potential 110–130 V, platinum plate electrode, current 0.02 A), the brightness of the observed ECL was so great that in the case of phenylmagnesium bromide the outline of the anode could be distinguished in a dark room at distances up to 6 m.[45]

A larger series of Grignard reagents has been investigated by Dufford et al.[44] A bright glow has been observed for Grignard reagents based on phenyl bromide (visible at 110 V), *p*-iodotoluene, and 1,4-bromochloronaphthalene (appears at a potential of 500 V); a weak glow has been found for n-lauryl bromide (visible only at a potential >1000 V) and a very weak glow has been observed for *m*-bromochlorobenzene (even at 1500 V the ECL is weaker than the chemiluminescence of this compound in its reaction with O_2) and for α-bromonaphthalene; there is no glow in the case of benzyl chloride. The glow is usually excited at the anode and more rarely at the cathode or at both electrodes. A number of compounds, for which chemiluminescence is not excited in their reaction with oxygen, emit light during electrolysis.

A glow during electrolysis has been observed reliably in all cases for compounds with a brighter chemiluminescence; however, the brightness of the emission in electrolysis and in oxidation by oxygen is a maximum for different Grignard reagents. On this basis, it has been concluded[44] that the nature of the glow is different in these processes. In contrast to this, in another study[45] it has been suggested that the mechanisms of the chemiluminescence and the ECL of solutions of Grignard reagents are identical and involve electron transer.

The electrolysis of Grignard reagents is accompanied by the precipitation of metallic magnesium, which exhibits a high catalytic activity.[44,45] One cannot rule out the possibility that this catalytic activity of magnesium influences also the chemiluminescence.

The modern interpretation of the mechanisms of electrode processes involving organomagnesium compounds includes reactions with participation of radicals (organic and organomagnesium radicals):[47]

$$R_2Mg \rightarrow R^{\cdot} + RMg^{\cdot}$$
$$RMg^{\cdot} \rightarrow Mg + R^{\cdot}$$

Consequently, there is a possibility of the excitation of the ECL of solutions of Grignard reagents in radical reactions. Admittedly these reactions reflect processes at the cathode (which is associated with the polarographic method of investigation), whereas, as stated above, the ECL is mainly observed near the anode. It is noteworthy that the glow excited at very high potentials (above 1000 V) is hardly a pure example of the classical ECL and its nature may be similar to that of the emission of light accompanying the so-called non-Faraday electrolysis.[5]

The ECL of phenylmagnesium bromide has been investigated at low potentials (starting with 10 V).[25] The electrolysis was carried out in carefully deoxygenated solutions. After a short time, the glow disappears spontaneously despite the continuous passage of current through the solution without an appreciable consumption of the Grignard reagent. Subsequently this was demonstrated successfully on the basis of the chemiluminescence which arises following the subsequent admission of air into the solution which ceased to emit light during electrolysis. One can therefore conclude that in this case the anodic emission of light is associated with the presence of impurities, containing O_2, the liberation of which takes place as a result of the slow decomposition of the impurities during electrolysis.

Thus, in order to determine the mechanism of the ECL of solutions of Grignard reagents and also to demonstrate the very fact that such a glow takes place, it is necessary to carry out additional experiments with a clear separation of the anodic and cathodic cell compartments and with determination of the compositions of the anolyte and catholyte.

4. Oxidation of Grignard Reagents by Organic Peroxides

The chemiluminescence accompanying the interaction of solutions of Grignard reagents with benzoyl, ethyl, and diacetone peroxides has been observed by Gilman and later confirmed by Dufford et al.[38] The reaction of BP with a number of Grignard reagents (C_6H_5MgBr, p-BrC_6H_4MgBr, p-ClC_6H_4MgBr) is accompanied by the emission of light with a lower intensity than in the oxidation of these Grignard reagents by oxygen.

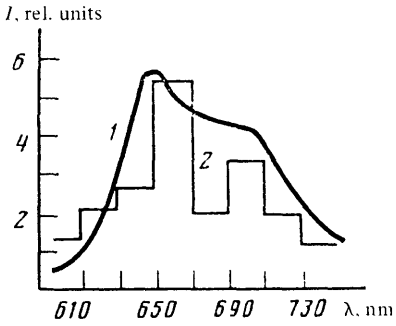

Figure 4. The fluorescence spectrum of a solution of the triphenylmethyl radical in diethyl ether (10^{-4} M) with λ_e = 447 nm (curve *1*) and the chemiluminescence spectrum in the reaction of phenylmagnesium bromide with benzoyl peroxide in ether (line 2).[48]

A detailed investigation of the mechanism of the chemiluminescence arising in the reaction of C_6H_5MgBr, ClC_6H_4MgBr, and $CH_3C_6H_4MgBr$ with BP and t-butyl peroxybenzoate in THF and diethyl ether[48] is of special interest. The reactions with diphenylmagnesium and with aliphatic Grignard reagents did not give rise to a glow. The oxidation of phenylmagnesium bromide is accompanied by a very bright (visible to the naked eye) red glow and the colour of the solution then changes from pale-brown to red. The excess peroxide produces a yellow colour owing to the formation of the triphenylmethyl radical, which was characterised by its EPR spectrum and by comparison with the spectrum of the radical synthesised independently. The radical is very stable: on storage in a sealed vessel the EPR signal remains unchanged for a month. The same radical has been identified as the chemiluminescence emitter. (Probably this is a unique case of the chemiluminescence of solutions where the radical is an emitter of the glow associated with a chemical reaction). The emitter has been identified on the basis of the identity of the chemiluminescence spectrum and the photoluminescence spectra of the products of the reaction of BP with phenylmagnesium bromide and a solution of the triphenylmethyl radical (Fig. 4). The time corresponding to a decrease of the chemiluminescence intensity by 50% depends on the nature of the solvent. The chemiluminescence emitter is excited in an elementary reaction step, since in the presence of fluorescent additives (pentacene, rubrene, and rhodamine G) the brightness of the chemiluminescence does not increase.

In order to determine the mechanism of the formation of the triphenylmethyl radical, a study has been made[48] of the reaction of deuteriated phenylmagnesium bromide with peroxide. The EPR signal of the resulting radical is three times wider than in the reaction of the protonated Grignard reagent, which the authors interpreted as evidence for the formation of the triphenylmethyl radical from one of the benzene rings of the Grignard reagent and two peroxide rings. The formation reaction of this radical is a side reaction in relation to the main interaction of the Grignard reagent with the peroxide. This is associated with the low yield of the radical compared with the yield of the stable oxidation products (the interaction of 0.1 M C_6H_5MgBr with an excess of the peroxide produces 10^{-4} M triphenylmethyl radical). However, when the reaction conditions are altered, it is possible[48] to increase the yield of the radical and hence also the chemiluminescence intensity.

5. The Interaction of Grignard Reagents with Other Substances

When a number of substances (H_2O, N_2O, H_2O_2, SO_2, CO, NO_2, H_2, N_2, NO, CO_2, and Na_2O_2) come into contact with solutions of Grignard reagents, a glow does not appear even when highly exothermic reactions take place (with Na_2O_2, H_2O_2, and H_2O).[28,31,32] The appearance of chemiluminescence in the reactions of certain Grignard reagents with benzene triozonide has been mentioned.[24] A bright-red chemiluminescence has been observed[25] in the reaction of phenylmagnesium bromide with carbon tetrachloride in diethyl ether. This extremely vigorous reaction results in the formation of the triphenylmethyl radical. However, in the absence of oxygen chemiluminescence is not observed; the autoxidation of the triphenylmethyl radical is also not accompanied by a glow.

6. The Oxidation of Organocalcium Compounds by Oxygen

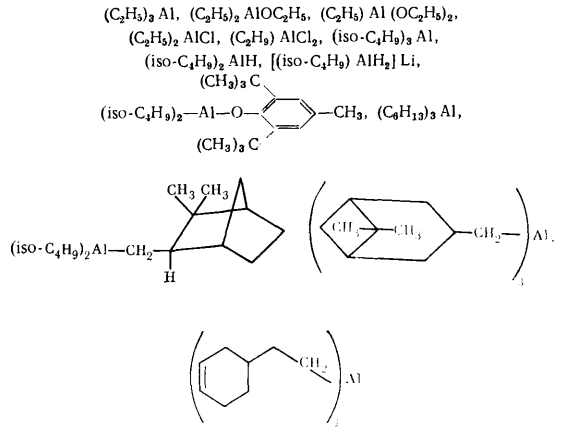
The organocalcium compound C_6H_5CaI was synthesised for the first time by Thomas and Dufford[35] and a yellow chemiluminescence was observed in its oxidation with oxygen. The not unduly high intensity of this chemiluminescence is comparable to that of the chemiluminescence in the analogous reaction of C_6H_5MgI. The alkyl derivative C_2H_5CaI does not chemiluminesce in its reaction with oxygen. A similar negative result has been obtained for organomercury[35] and organozinc[24] compounds: C_6H_5ZnBr, C_6H_5ZnI, and p-BrC_6H_4ZnBr.

IV. THE CHEMILUMINESCENCE OF SOLUTIONS OF ORGANOALUMINIUM COMPOUNDS AND THE ELECTROCHEMILUMINESCENCE OF A RHENIUM CARBONYL SOLUTION

1. Oxidation By Oxygen

The chemiluminescence in the oxidation of organoaluminium compounds (OAC) in solution by oxygen has been observed comparatively recently.[49] There is no information about the chemiluminescence of organic compounds of other Group III elements. The ability to enter into a reaction with oxygen

accompanied by chemiluminescence proved to be a characteristic property of solutions of OAC: a glow has been detected for trialkylalanes with different numbers of carbon atoms (C_2–C_6), their hydride and halogeno-derivatives, a complex of the hydride with an alkali metal, derivatives of norbornene, and other OAC:[49–51]



The kinetic plots of the chemiluminescence intensity obtained when air (or oxygen) is bubbled through solutions of the above OAC, have a feature in common: they exhibit one or several luminescence intensity maxima, which indicates the excitation of the chemiluminescence in reactions of intermediates in the oxidation of the OAC. The brightest chemiluminescence has been observed in the oxidation of the complex $[(iso\text{-}C_4H_9)_2AlH_2]Li$;[50] a bright glow has been noted in the oxidation of diisobutyl(2,6-di-t-butyl-4-methylphenoxy)-aluminium.[50]

The quenching of the chemiluminescence by oxygen and the luminescence yield for the primary emitter made it possible to postulate compounds containing the carboxy-group as the likely chemiluminescence emitters.[51] The increase of the brightness of the chemiluminescence following the replacement of the alkyl group in $(iso\text{-}C_4H_9)_3Al$ by the norbornane group is apparently associated with the high yield of ketones in the oxidation of the norbornane derivative. For certain OAC of this kind, the yield of ketones reaches 90%, while in the oxidation of alkyl derivatives ketones are side products.[13]

The brightness of the chemiluminescence in the oxidation of OAC by oxygen (in contrast to the oxidation of Grignard reagents) increases when a fluoroscent additive (9,10-dibromoanthracene) is introduced into the solution. It has been established that the increased chemiluminescence intensity is caused by the sensitising action of this additive, since the rate of oxidation and the form of the kinetic curve do not change under these conditions and the chemiluminescence spectrum coincides with the photoluminescence spectrum of 9,10-dibromoanthracene.[51] The intensification coefficients of the brightness of the chemiluminescence in the presence of identical amounts of the additive depend on the nature of the OAC and diminish in the sequence diisobutyl(isocamphenyl)aluminium (74) > trimyrtanylaluminium (27) > diisobutyl(2,6-di-t-butyl-4-methylphenoxy)aluminium (2).[50] Thus the primary chemiluminescence emitters in the oxidation of these OAC are of different kind and have different luminescence yields.

Three luminescence regions have been differentiated on the kinetic plot of the chemiluminescence intensity in the oxidation of triethylaluminium: two maxima and a long low-slope descent (Fig.5).[51] This kinetic relation indicates the occurrence of several reactions, accompanied by chemiluminescence, of the intermediates formed in consecutive stages. We may note that similar information can be found just as explicitly from the monotonic kinetic variation of the amount of absorbed oxygen, usually obtained in the study of the kinetics of the oxidation of OAC. The complexity of a more detailed interpretation of the kinetic chemiluminescence plot obtained can be understood when a simplified mechanism, reflecting the overall oxidation reaction of trialkylalanes, is considered taking into account the reactions undergone by organoaluminium peroxides:

$$AlR_3 \xrightarrow{O_2} \underset{(I)}{R_2Al(OOR)} \rightarrow R_2Al(OR) \xrightarrow{O_2} \underset{(II)}{RAl(OR)(OOR)};$$

$$RAl(OR)_2 \xrightarrow{O_2} \underset{(III)}{Al(OR)_2(OOR)} \rightarrow Al(OR)_3;$$

$$RAl(OR)(OOR) + AlR_3 \rightarrow RAl(OR)_2 + R_2Al(OR); \quad (1)$$

$$RAl(OR)(OOR) + R_2Al(OR) \rightarrow 2Al(OR)_2; \quad (2)$$

$$RAl(OR)(OOR) + RAl(OR)_2 \rightarrow 2Al(OR)_3; \quad (3)$$

$$R_2Al(OOR) \rightarrow RAl(OR)_2; \quad (4)$$

$$RAl(OR)(OOR) \rightarrow Al(OR)_3. \quad (5)$$

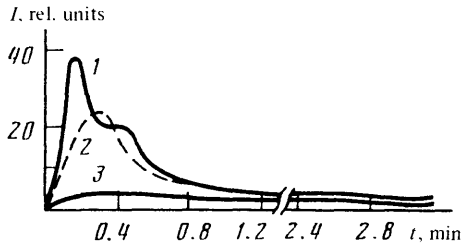


Figure 5. Time variation of the chemiluminescence intensity in the oxidation of solutions of OAC (2.9×10^{-2} M in toluene at 20 °C: *1*) triethylaluminium; *2*) the oxide; *3*) the dioxide.[51]

On the basis of data obtained by Razuvaev and co-workers[52] in a study of the dark oxidation of OAC, Tolstikov et al.[51] concluded that the chemiluminescence develops in a solution containing a complex mixture of OAC with different numbers of alkoxy-groups and organoaluminium peroxides [(I), (II), and (III)]. In order to discover the reactions accompanied by chemiluminescence, the stable oxidation products diethylaluminium ethoxide (oxide), ethylaluminium diethoxide (dioxide), and aluminium triethoxide (trioxide) were synthesised[51] by the reaction of triethylaluminium with ethanol.[51] It was shown that the interaction of these OAC in the absence of oxygen is not accompanied by chemiluminescence even in a highly exothermic reaction such as the formation of the oxide:

$$R_3Al + RAl(OR)_2 \rightarrow 2R_2Al(OR).$$

The interaction with oxygen of each of these OAC (except the trioxide) induces chemiluminescence, on the kinetic plot of which it is possible to differentiate one, two, and three luminescence regions (Fig.5) for the dioxide, oxide, and triethylaluminium respectively. The increase of the chemiluminescence intensity in this sequence is caused by the increased rate of oxidation of the OAC. The set of data

obtained, namely the dependence of the number of chemiluminescence intensity maxima on the number of alkoxy-groups in the OAC, the coincidence of the instant of the emission of the first chemiluminescence intensity peak with the dissociation of the first Al–C bond in triethylaluminium, and correlation of the effective activation energies for each of the three chemiluminescence maxima of triethylaluminium with the activation energies for the dark oxidation of triethylaluminium, the oxide, and the dioxide[52] enabled Tolstikov et al.[51] to conclude that the three regions on the kinetic plot of the luminescence intensity correspond to consecutive changes in the oxidation of the three Al–C bonds of triethylaluminium.

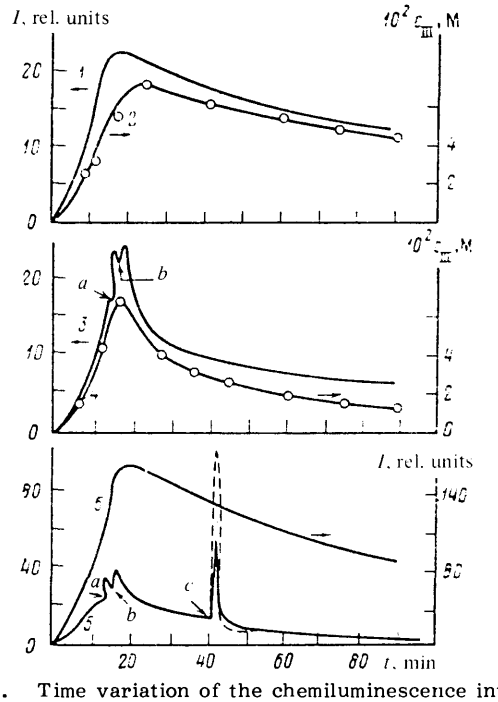

Figure 6. Time variation of the chemiluminescence intensity (curves *1*, *3*, *5*, and *6*) and of the concentration of the peroxide $Al(OR)_2(OOR)$ (III) (curves *2* and *4*) in the oxidation of a solution of the dioxide (0.3 M) in toluene at 20 °C:[51] *1*) and *2*) with constant bubbling of air; *3*) and *5*) the instants when the bubbling with air is stopped (*a*), the bubbling with argon is started (*b*), and the dioxide (continuous line) and the monoxide (dashed line) are added (*c*) are indicated; *6*) the chemiluminescence intensity after the addition of the activator (1×10^{-4} M).

The oxidation of the dioxide yielded parallel kinetic chemiluminescence intensity curves describing the analytical concentration of the organoaluminium peroxide (III) (the intermediate determined by the iodometric titration (Fig.6). The chemiluminescence intensity varies linearly with the concentration of the peroxide (III) (Fig.7). These results and also the absence of significant differences between the mechanisms of the oxidation of triethylaluminium and its alkoxy-derivatives permitted the conclusion that the appearance of chemiluminescence intensity maxima in the oxidation of all three OAC (triethylaluminium, the oxide, and the dioxide) reflects the accumulation and consumption of the corresponding peroxides (I), (II) and (III). We may note that the kinetic plot of the intensity of the chemiluminescence of triethylaluminium is the only experimental "monitor" which makes it possible to follow at the usual temperatures the formation and consumption of the highly reactive peroxides $(C_2H_5)_2AlOOC_2H_5$ and $(C_2H_5)Al(OOC_2H_5)(OC_2H_5)$, which had been previously [52,54] detected in solution only after extensive cooling of the latter.

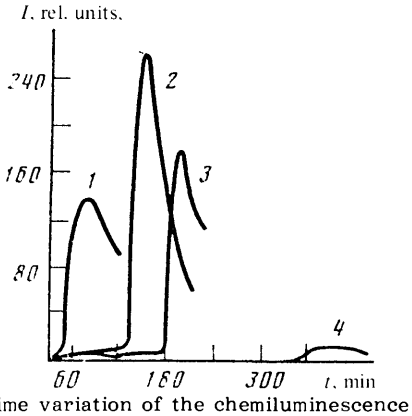

Figure 7. Time variation of the chemiluminescence intensity in the oxidation of solutions of $(C_2H_5O)_2AlC_2H_5$ in toluene in a closed volume (20 ml) under conditions of a constantly decreasing concentration of the dissolved O_2, in the presence of the 9,10-dibromoanthracene concentration [DBA] = 10^{-4} M at 20 °C, and at different initial concentrations of the dioxide (M): *1*) and *5*) 10^{-1}; *2*) 2.5×10^{-2}; *3*) 2.0×10^{-2}; *4*) 1.5×10^{-2}; curves *1–4* represent oxidation by oxygen.

The above reactions of organoaluminium peroxides are the main ones in the mechanism of the consecutive oxidation of the three Al–C bonds of trialkylalanes. In order to determine the contribution of each of these reactions to the excitation of the chemiluminescence, a more detailed study was made of the oxidation of the dioxide,[53] since this OAC has only one unoxidised Al–C bond.[55] Careful purification of this compound showed that only the activated chemiluminescence is observed in its oxidation, which is associated with the low contribution by the luminescence of the primary chemiluminescence emitter. The presence of a glow after the removal of oxygen from solution some time after the start of the oxidation of the dioxide established that the chemiluminescence is not excited in the peroxide formation stage, i.e.

$$(C_2H_5O)_2AlC_2H_5 + O_2 \rightarrow (C_2H_5O)_2AlOOC_2H_5, \qquad (6)$$

but arises in the interaction of the peroxide with the initial OAC:

$$(C_2H_5O)_2AlOOC_2H_5 + (C_2H_5O)_2AlC_2H_5 \rightarrow 2Al(OC_2H_5)_3. \qquad (7)$$

The removal of oxygen (Fig.6) leads merely to the acceleration of the decrease of the luminescence intensity, since the peroxide in consumed in the absence of the source from which it is generated [stage (6)].[51] The straight lines with the same slope $k = (1.9 \pm 0.1) \times 10^{-2}$ min^{-1} correspond to sections reflecting the decrease of the chemiluminescence

intensity and the concentration of the organoaluminium peroxide expressed in terms of semilogarithmic variables.[53] The ratios of the rate constants for the oxidation of the first, second, and third Al–C bonds in triethylaluminium are 100 : 25 : 0.96,[52,54,55] indicating the possibility of the simultaneous presence in solution of the dioxide, the oxide, and a small amount of triethylaluminium and the corresponding peroxides in the initial instant of the triethylaluminium oxidation reaction. Taking this into account as well as the chemiluminescence data for the oxidation of the dioxide and the intensification of the brightness of the chemiluminescence when the oxide and triethylaluminium are added to the solution after the removal of O_2 (Fig.6), one may conclude that the chemiluminescence in the oxidation of triethylaluminium is excited in the overall reactions (1), (2), and (3) and possibly also in the reaction

$$R_2AlOOR + R_3Al \rightarrow 2R_2Al(OR). \qquad (8)$$

The correctness of the identification of the above reactions of organoaluminium peroxides with OAC as the sources of the excitation of the chemiluminescence in the oxidation of the OAC by oxygen has been confirmed by the results of a study[56] in which chemiluminescence was observed in the interaction of triisobutylaluminium with the stable peroxide $(C_2H_5O)_2AlOOC(CH_3)_3$. The kinetic plot of the chemiluminescence intensity has a simpler form in this instance (without maxima), since the consumption of the organoaluminium peroxide is not complicated by the accumulation of the peroxide, as in the oxidation of the OAC by oxygen. It was found that oxygen plays a dual role in the chemiluminescence of OAC. On the one hand, it is essential for the excitation of the chemiluminescence as a source of peroxide and on the other it deactivates the glow.[51,53] The latter property of oxygen is manifested by the decrease of the chemiluminescence intensity when air is replaced by pure oxygen[51] and also by the presence of an induction period preceding the appearance of a brighter chemiluminescence in the oxidation of the dioxide under the conditions of the continuously decreasing concentration of dissolved O_2 (Fig.7).[53]

The addition of radical reaction inhibitors (diphenylamine or diphenylpicrylhydrazine) does not influence the chemiluminescence in the oxidation of OAC,[51] although it is known that these additives suppress the chemiluminescence in the oxidation of hydrocarbons.[3] The use of a more effective free radical trapping agent, namely the galvinoxy-radical (In),[53] induces the appearance of induction periods before the chemiluminescence is generated (when In is added before the start of the supply of O_2 to the solution) or a sharp decrease of the chemiluminescence intensity and the cessation of the absorption of O_2 (when In is added under the conditions of the excitation of the chemiluminescence) (Fig.8). On the grounds that the addition of In does not entail the complete disappearance of the chemiluminescence, the authors concluded[53] that the chemiluminescence in the oxidation of the dioxide by oxygen is excited in two types of reactions: free-radical and molecular reactions. We may note that the formation of free radicals in the interaction of organoaluminium peroxides with OAC has been unambiguously demonstrated only recently in a study[57] of the dark process.

2. Thermolysis of Organoaluminium Peroxides

Apart from the reaction with OAC, there exists another pathway for the consumption of the organoaluminium peroxide (OAP) in solution: thermal decomposition.[58–60] The possibility of the excitation of chemiluminescence in this process has been investigated[56] in relation to the thermolysis of a solution of the stable peroxide $(C_2H_5O)_2AlOOC(CH_3)_3$ in toluene free of O_2. This process is indeed accompanied by chemiluminescence, whose intensity increases with increase of temperature and the OAC concentration. At a constant temperature, the kinetic plot of the chemiluminescence intensity consists of two luminescence regions (Fig.9); in the first region the flash of chemiluminescence resulting from the addition of the OAC to the solvent is followed by a decrease of its intensity and in the second a sharp rise of the chemiluminescence intensity to a maximum followed by a prolonged descent is observed. The kinetic plot of the analytical concentration of the OAC has a simpler form (Fig.6, curve 2) i.e. yields less information.

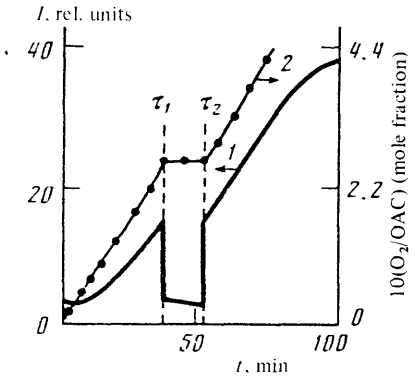

Figure 8. The influence of the addition of the inhibitor in the oxidation of a 10^{-1} M solution of $(C_2H_5O)_2AlC_2H_5$ in toluene on the chemiluminescence intensity (line *1*) and on the rate of absorption of O_2 (line *2*): [DBA] = 10^{-4} M; 20 °C; volume of solution 10 ml; [In] = 2×10^{-5} M; τ_1 = instant of addition of In; τ_2 = instant corresponding to the end of the induction period.

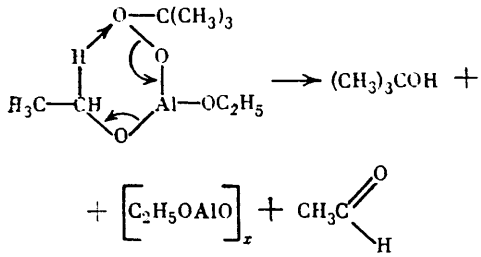
The existence of two thermolysis regions indicates the complexity of the thermolytic process, which has been interpreted in two ways in the literature concerned with the results of dark investigations: as heterolytic[57] or homolytic.[58] The second region in the kinetic plot of the chemiluminescence intensity (Fig.9), where a sharp rise has the form characteristic of the induced decomposition of organic peroxides, has been attributed[56] to the reactions of free radicals produced by the simultaneous dissociation of the O–O and Al–O bonds in the organoaluminium peroxide in conformity with the results of the study of the dark process:[58]

$$(C_2H_5O)_2AlOOC(CH_3)_3 \rightarrow (C_2H_5O)_2AlO^{\cdot} + (CH_3)_3CO^{\cdot};$$

$$(CH_3)_3CO^{\cdot} \rightarrow (CH_3)_2C{=}O + \dot{C}H_3.$$

The rate constant for the thermolysis of the OAP, calculated[56] from the slope of the linear form of the second section of the plot of the time variation of the chemiluminescence intensity (Fig.9*b*) agrees with the values $k = 7.4 \times 10^{-3}$ min^{-1} (T = 353 K) obtained[58] from dark measurements of the rate of decomposition of the same peroxide. The first luminescence region (Fig.9) has been assigned[56] to the consumption of the OAP as a result of the intramolecular oxidation of the ethyl fragment in the cyclic reactive complex, whose mechanism can be represented as follows in conformity with

the data obtained in the dark:[57]



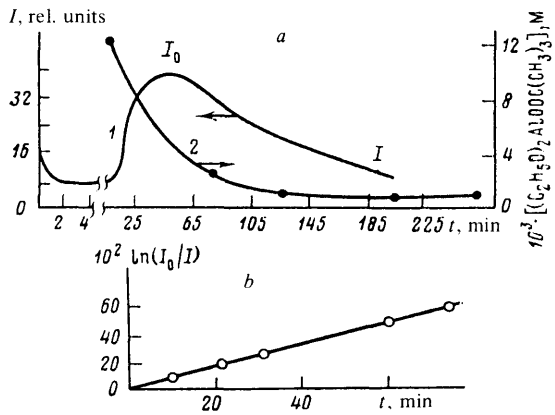


Figure 9. *a*) Time variation of the chemiluminescence intensity (curve *1*) and of the OAP concentration (curve *2*) in the thermal decomposition of the OAP (1.2×10^{-2} M) at 80 °C (the instant of the addition of the OAP to toluene heated to 80 °C was adopted as the starting point for the time readings); *b*) linear form of the I_0-I section in Fig. 9*a*.

The mechanisms presented above for the thermolysis and the homolytic and heterolytic decomposition of the OAP show that aldehydes and ketones, which frequently behave as emitters in the oxidation of hydrocarbons,[2] may be formed. The chemiluminescence spectra in the thermolysis of the OAP contain[56] three luminescence components with maxima at 430, 510, and 550 nm and, whereas the first two can be assigned to emission by excited ketones and aldehydes, the presence of the long-wavelength luminescence components indicates a more complex mechanism of the excitation of the chemiluminescence. In the presence of 9,10-dibromoanthracene the chemiluminescence spectrum corresponds to the emission by an excited activator.

The chemiluminescence data for the thermolysis of OAP show that, in the oxidation of OAC by oxygen, the chemiluminescence may be excited in reactions of two types: in the interaction with the OAC (a precursor of the OAP) or in the thermal decomposition of the OAP.

3. The Interaction of Organoaluminium Peroxides with Water

Yet another variety of the chemiluminescence of OAC has been observed recently, namely that associated with the interaction of OAP with water.[61] The addition of water to a solution of the dioxide being oxidised by oxygen intensifies appreciably the chemiluminescence. It has been shown that, among the series of highly exothermic reactions occurring in the oxidation of the dioxide by moist air in solution, only the reaction of water with the OAP—the intermediate in the oxidation of the dioxide—generates chemiluminescence.

This conclusion has been confirmed by the results of a study[56] where chemiluminescence was observed in the interaction of a stable OAP with H_2O in the absence of O_2 in the solution (Fig. 10). Two most probable mechanisms of the excitation of the chemiluminescence in the reaction of OAC with water have been proposed:[56] the recombination of the hydroperoxy-radicals with formation of an intermediate tetroxide by analogy with the chemiluminescence in the oxidation of hydrocarbons[9] and also the reaction of aluminium-containing radicals. The possibility of the formation of radicals in this system has been confirmed indirectly by the form of the kinetic plot of the chemiluminescence intensity (Fig. 10), which has a very pronounced threshold character.

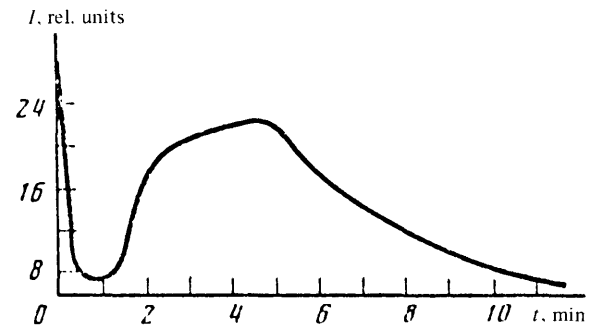

Figure 10. Time variation of the chemiluminescence intensity following the addition of H_2O to a solution of OAP in toluene after heating it for 220 min at 80 °C and then cooling (40 min) to 25 °C; $[OAP]_0 = 10^{-3}$ M; $[H_2O] = 1$ M.

The introduction of water into the system at the beginning of the oxidation of triethylaluminium or the oxide does not entail an increase in the brightness of the chemiluminescence compared with the "dry" oxidation of these OAC in view of the rapid consumption of the OAC owing to hydrolysis, as a consequence of which the OAP, namely $(C_2H_5)_2AlOOC_2H_5$ and $(C_2H_5O)_2AlOOC_2H_5$, do not accumulate in solution. There is no doubt that these highly reactive OAP should emit a brighter light in their reactions with water than in the reactions of $(C_2H_5O)_2AlOOC(CH_3)_3$ or $(C_2H_5O)_2AlOOC_2H_5$. This chemiluminescence can apparently be observed at low temperatures, where the above peroxides accumulate[52,54] in large amounts.

When water is introduced at later stages of the oxidation of triethylaluminium, a chemiluminescence flash is observed,[61] since the relatively stable peroxide $(C_2H_5O)_2AlOOC_2H_5$ has accumulated by that time as a result of the consecutive oxidation of the Al–C bonds in solution (Fig. 11). The brightness of the chemiluminescence in the reaction of this peroxide with water makes it possible to employ it for the quantitative selective determination of the OAP in solution. The generally adopted iodometric titration makes it possible to

determine up to 10^{-3} M peroxides, while 1.2×10^{-5} M peroxide in the presence of [DBA†] = 10^{-3} M can be determined from the linear dependence of the chemiluminescence intensity on the concentration of the OAP. An increase of [DBA] by an order of magnitude makes it possible to detect 10^{-6} M of the peroxide in solution.

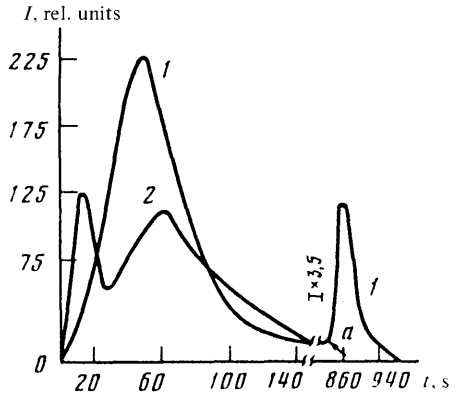

Figure 11. Time variation of the chemiluminescence intensity in the oxidation of a 1.8×10^{-2} M solution of triethylaluminium in toluene in the presence of an activator {[DBA] = 10^{-4} M}: *1*) oxidation with dry air (with addition of 10 ml of H_2O at time *a*); *2*) oxidation with moist air.

4. Oxidation of OAC Complexes with Oxygen

It has been found[62] that the addition of $Ru(bipy)_3Cl_2.6H_2O$ to the solution greatly increases the brightness of the chemiluminescence in the oxidation of OAC by oxygen. It has been established that the interaction of the ruthenium complex of the OAC with triisobutylaluminium, triethylaluminium, diisobutylaluminium hydride leads to the formation of the complex of the OAC with $Ru(bipy)_3Cl_2$ which is soluble in toluene and methylene chloride. The identity of the absorption and fluorescence spectra of the resulting complex demonstrated that ruthenium retains its oxidation state. The complex formation reaction is accompanied by the liberation of gaseous alkanes and the formation of alumino-oxanes—the products of the interaction of the water of crystallisation of the ruthenium compound with the OAC. Depending on the ratio of the amounts of the OAC and the initial ruthenium compound, the complex formed contains the initial OAC or the alumino-oxan as the ligand.

The oxidation of a homogeneous solution of the complex $[Ru(bipy)_3Cl_2(OAC)_n]$ with oxygen is accompanied by a bright-red chemiluminescence, which can be observed with the naked eye.[62] Comparison of the chemiluminescence and fluorescence spectra of the solution oxidised showed that the chemiluminescence emitter is the excited complex $[Ru(bipy)_3.Cl_2(OAC)_n]$. The difference between the forms of the kinetic chemiluminescence curves for the oxidation of the free OAC and their ruthenium complexes is not an adequate argument in support of the excitation of the chemiluminescence emitter in the elementary oxidation step or of an excitation via simple sensitisation, because of the difficulty of determining the exact composition of the ligand in the complex.

5. Electrochemiluminescence of a Rhenium Carbonyl Solution

Analysis of the data on the excitation of chemiluminescence in the redox reactions of OMC in solution permits the conclusion that the luminescence emitters are not the OMC themselves but either organic products of their reactions or the sensitisers introduced as additional species into the reaction zone. Admittedly one cannot rule out the possibility that light is emitted by excited species of the type RC–Al=O or similar formations produced when OAC are oxidised. The chemiluminescence, observed by Luong et al.,[63] in which the rhenium OMC has been reliably identified as the luminescence emitter, is therefore of special interest. The species involved in the chemical reaction and leading to the excitation of the rhenium carbonyl *fac*-$ClRe(CO)_3L$ (where L = 1,10-phenanthroline or 4,7-diphenyl-1,10-phenanthroline) were generated electrochemically. The process was carried out at platinum electrodes via cyclic electrolysis with the potential varied in the range from +1.3 to −1.3 V (in acetonitrile as the solvent). The luminescence emitter was excited by the annihilation interaction of the radical-anion and radical-cation produced by the electrochemical reduction and oxidation of the initial rhenium compound:

$$[fac\text{-}ClRe(CO)_3L]^{+\cdot} + [fac\text{-}ClRe(CO)_3L]^{-\cdot} \rightarrow 2\ [fac\text{-}ClRe(CO)_3L]^{\cdot}.$$

Comparison of the electrochemiluminescence and fluorescence spectra of the test solution showed that the luminescence emitter is the excited OMC.

V. THE CHEMILUMINESCENCE OF ORGANOMETALLIC COMPOUNDS IN THE GAS PHASE

The reactions of OAC with excited singlet molecular oxygen and with O and N atoms in the gas phase are accompanied by luminescence. Surprisingly, the gas-phase chemiluminescence of OAC has been first observed and investigated[64–66] not under laboratory conditions but in space in the vicinity of the Earth. This luminescence has been used to investigate the geophysical characteristics of the atmosphere (wind, turbulence, and molecular diffusion). For this purpose, liquid trimethylaluminium (1.1 kg)[64] or its mixture with triethylaluminium (20%)[65] was placed in a vessel containing nitrogen under a pressure of 25 atm. The OAC was evaporated in the twilight from a rocket despatched to a height of 85–160 km at a flight velocity of 1 km s^{-1}. This resulted in the formation of a chemiluminescent bluish-green cloud. The atomisation of liquid OAC proved more convenient for geophysical research than a hot mixture containing caesium nitrate and powdered metallic aluminium and magnesium.[64,65]

The luminescence quantum yield varied from 0.3 to 0.6 photons per trimethylaluminium molecule. The form of the glowing cloud resembled a cylinder 20 km long and 1.5 km in diameter. The cloud emitted an overall amount of energy of $10^{10.8}$ erg s^{-1}, which is equivalent to 2 kW; the power of the emission decreased with time in accordance with a kinetic curve having a single diffusion maximum.[64]

Simultaneously with the recording of the chemiluminescence, measurements were made of the kinetic and spectroscopic parameters of the fluorescence of the cloud excited by solar rays directed horizontally. The spectral intensity of this

†9,10-Dibromoanthracene (Translator).

fluorescence makes it possible to determine the temperature of the upper layers of the atmosphere. It was established[65] that the emitter of this chemiluminescence is AlO_2^*, emission being recorded in the form of a diffuse curve (Fig.12). The emitter is excited in the reaction of the intermediate AlO with the oxygen atoms present in the upper layers of the atmosphere: $AlO + O \rightarrow AlO_2^* \rightarrow AlO_2 + h\nu$. The presence of the intermediate (AlO) in this system has been confirmed by recording its blue-green fluorescence (Fig.12) excited by sunlight. The authors[65] put forward two possible pathways leading to the formation of AlO—via the reaction of trimethylaluminium with atomic or molecular oxygen.

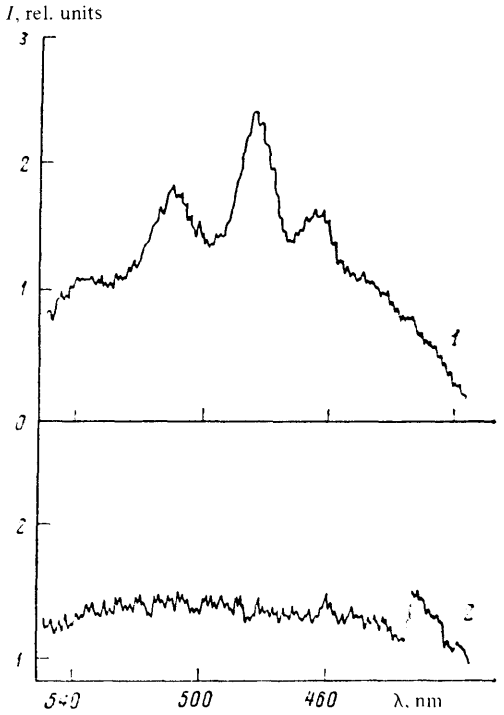

Figure 12. Emission spectra of triethylaluminium observed when the latter is sprayed from a rocket in space in the vicinity of the Earth; *1*) fluorescence spectrum excited by sunlight at a height of 138 km; *2*) chemiluminescence spectrum at a height of 92 km.

The relative contributions of the reactions of oxygen in various states to the gas-phase chemiluminescence were elucidated in laboratory investigations.[67] In these experiments pairs of OAC were introduced into an optically transparent chamber through which molecular oxygen, mixed with a carrier gas (argon) and subjected to a preliminary activation by a microwave discharge, was passed; this gas stream contains $O_2(a^1\Delta)$, $O_2(b^1\Sigma)$, and O atoms. The mixture composition was varied by removing O atoms as a result of the reaction with an HgO mirror deposited in the vicinity of the discharge unit or by introducing water vapour which selectively removes $O_2(b^1\Sigma)$. It was shown[67] that the presence of O atoms is not obligatory for the excitation of the chemiluminescence of trimethylaluminium, i.e. that the chemiluminescence in the upper layers of the atmosphere may be induced both by excited singlet oxygen $O_2(a^1\Delta)$ and O atoms. Without the preliminary activation of oxygen, a glow was not detected. Thus the chemiluminescence of OAC in the gas phase, in contrast to the liquid phase, is not excited in the reaction with molecular oxygen in the ground state.

Subsequent investigations[68,69] dealt solely with the reaction of trimethylaluminium with oxygen atoms. The absence of chemiluminescence in the reaction of trimethylaluminium with non-activated oxygen molecules was confirmed.[68] The authors[68] concluded that the recombination process of the type $AlO + O \rightarrow AlO_2^*$, proposed in earlier studies[64-66] as the excitation stage, is too slow compared with the rate of emission of light from the chemiluminescence cloud to be the source of the generation of the chemiluminescence. They suggested that the chemiluminescence emitter is AlO^* and not AlO_2^*.

A study[69] undertaken to eliminate these contradictions confirmed that the emission rate constant is indeed too high for reactions of the recombination type. However, here too AlO_2^* was identified as the chemiluminescence emitter; this was subsequently demonstrated with the aid of a high-resolution spectroscopic technique (to within 0.05 nm). In order to account for the discrepancies between the rates of emission and generation of chemiluminescence, the authors[69] postulated the existence of a second intermediate, which gives rise to AlO_2^* on reaction with O atoms:

$$RAlO + O \rightarrow AlO_2^* + R;$$

$$AlOR + O \rightarrow AlO_2^* + R.$$

The first process is believed to be energetically more favourable. In the reaction of trimethylaluminium, H_3CAlO has been suggested as an intermediate of this kind. The rate constant for the formation of the emitter via the suggested mechanism is 10^{-13} cm^3 s^{-1}.

A pink-white chemiluminescence has been observed[69] in the reaction of trimethylaluminium with N atoms obtained by activating nitrogen. The chemiluminescence spectrum consisted of well resolved bands, among which components in the red and violet parts of the spectrum predominated. The emissions due to CH and C_2 were grouped at 431.4 and 516.5 nm. Emission from Al at 507.8 and 572.6 nm was also identified. The transitions of Al(I) are manifested at 309, 394.4, and 396.1 nm.

The mechanism of the chemiluminescence, according to which all the methyl groups in the trimethylaluminium molecule are split off from the aluminium atom, was established on the basis of the spectroscopic data indicated; this results in the excitation of the residual aluminium atom. The most probable source of the excitation energy is the recombination of nitrogen atoms ($2N \rightarrow N_2$), in which 9.76 eV is evolved. The dissociation of three Al–C bonds requires an amount of energy of ~9 eV; the excitation energy of the aluminium atom is 4 eV. The following mechanism was proposed for the generation of the chemiluminescence:

$$(CH_3)_3Al + N \rightarrow AlN + 3CH_3;$$

$$AlN + N \rightarrow Al^* + N_2;$$

$$(CH_3)_3Al + 2N \rightarrow Al^* + N_2 + 3CH_3.$$

The existence of the intermediate AlN was demonstrated by means of the emission at 507.8 and 527.6 nm.[69]

Chemiluminescence has also been observed in the reactions of borine carbonyl with O and N atoms. There has been only one investigation of the chemiluminescence of organoboron compounds.[70] A technique analogous to that employed in the investigation of the chemiluminescence of OAC, supplemented by a mass-spectrometric unit for the determination of the composition and the amount of stable reaction products or

intermediates, was employed. The introduction of the complex H_3BCO into a stream of O atoms (in the absence of O_2) induced a dark-blue chemiluminescence in the range 270–390 nm. The chemiluminescence emitter was found to be BO^* (the $A^2\Pi \rightarrow X^2\Sigma$ transition) and the maximum emission was from the $v' = 4$ and $v' = 5$ levels, but emission from the $v' = 11$ and higher levels was also observed. In addition, a very weak glow of the O–H species ($A \rightarrow X$) was also manifested at 306.4 and 307.7 nm. In the presence of O_2, where the O atoms were generated by an electric discharge in an $He-O_2$ mixture, the chemiluminescence had a bright-pink colour. Its diffuse spectrum was mainly caused by the emission from BO_2^*, although here too there was also emission from BO^*.

In order to account for the observed mass spectra, the chemiluminescence, and the reaction stoichiometry, the authors[70] suggested that H_3BCO is decomposed via two possible initiation mechanisms. In the first of these O atoms remove the hydrogen atoms from the H_3B groups; the remaining fragments rapidly react with O atoms, giving rise to the highly excited BO, whose emission is in fact responsible for the chemiluminescence in the visible and near ultraviolet regions:

$$O + H_3BCO \begin{cases} \rightarrow OH + [CH_2BCO]^* \rightarrow OH + BH_2 + CO; \\ \rightarrow H_2O + [HBCO]^* \rightarrow H_2O + BH + CO. \end{cases}$$

The second possible pathway in the initiating stage involves the direct attack by the O atoms on the boron atoms with liberation of CO groups:

$$O + H_3BCO \rightarrow [H_3BO]^* + CO \begin{cases} \rightarrow BO + H_2 + H + CO; \\ \rightarrow HBO + H_2 + CO; \\ \rightarrow HBOH + H + CO; \\ \rightarrow H_2BOH + CO. \end{cases}$$

BO_2 is formed via the reaction

$$BO + O + M \rightarrow BO_2 + M;$$
$$BO + O_2 \rightarrow BO_2 + O.$$

The observed chemiluminescence is due to the last two reactions.

The interaction of H_3BCO with N atoms induces a bluish-green chemiluminescence, which could not be attributed to oxygen admixtures. The authors[70] believe that this chemiluminescence is not caused by the excitation of BN, whose radiative transitions ($^3\Pi \rightarrow X^3\Pi$) at 340–400 nm were recorded after the introduction of BCl_3 into a stream of activated nitrogen. The mechanism of this reaction is more complex than that in the H_3BCO-O system. The possibility of catalysis by one of the intermediates in the recombination reaction of nitrogen atoms has also been suggested.

The chemiluminescence in the reactions of Ni, Fe, Cr, W, Mn, and Co carbonyls with O, H, N, and inert gas (Ar, He, and Ne) atoms in metastable states has been investigated. One of the interesting aspects of the use of metal carbonyls is the gas-phase low-temperature (20–150 °C) generation of metal atoms from them in chemical reactions[71–74] on exposure to electric discharges[75–77] and on photolysis.[78–80] In all these processes some of the metal atoms are formed in an excited state, which leads to the appearance of a visually observable glow. The generation of a laser beam on the basis of Fe and Ni atoms in the ultraviolet and infrared regions of the spectrum has been achieved when the carbonyls of these metals were acted upon by discharges with a double electric pulse[75] and in the flash photolysis of $Fe(CO)_5$.[80] Only studies in which the excited states arose solely as a result of chemical reactions are examined below.

Chemiluminescence has been observed in the interaction of a number of metal carbonyls, namely $Cr(CO)_6$, $Mo(CO)_6$, $W(CO)_6$, $Fe(CO)_5$, $Ni(CO)_4$, $Mn_2(CO)_{10}$, and $Co(NO)(CO)_3$, with N atoms[71,72] and (for the first six carbonyls) also with O atoms.[72] A glow was also observed in the reactions of nickel and iron carbonyls with the inert gas (Ar, He, and Ne) atoms in metastable states. All these reactions were carried out at a reduced pressure (several mmHg) and were accompanied by emission from the excited states of the neutral metal atoms M. Metallic films were then deposited on the walls of the reactors.

The bright-blue chemiluminescence emission spectra in the interaction of metal carbonyls with nitrogen atoms consist exclusively of lines due to emission from neutral atoms.[71] In addition, an intense group of atoms has been noted[72] at 520 nm for the $Mo(CO)_6 + H$ and $Mo(CO)_6 + N$ reactions; they have been assigned to emission from Mo_2^*. On the basis of kinetic and spectroscopic reaction data, the continuous spectrum has been attributed to emission from MCO^*. The mechanism of the excitation of chemiluminescence in the reaction with N atoms includes a series of consecutive stages involving the decomposition of the carbonyls, i.e.

$$M(CO)_n + N \rightarrow M(CO)_{n-1} + NCO.$$

up to the formation of a free metal atom. The metal atoms are excited by collisions with nitrogen molecules in metastable states:

$$M + N_2^*(A^3N) \rightarrow M^* + N_2.$$

The latter are produced in a three-atom recombination reaction and have a short lifetime owing to their destruction on the walls of the reactor.

An analogous mechanism of the stepwise decomposition of the carbonyl has been proposed by Becker and Schurgers,[72] but they explain the excitation of the metal atoms by the retention of the energy, which the metals possess in the carbonyl complex, after the elimination of the CO groups. The chemiluminescence arising in the $M(CO)_n + O$ reaction, was assigned in their study to the emission from MO^*. This glow is observed for all the metals (Cr, W, Fe) investigated except for the molybdenum compound. It is suggested that the MO^* emitter is formed as a result of the direct interaction of oxygen atoms with the metal atoms formed when the CO ligands are removed from the carbonyl. Comparison of the rate constants for the overall reaction $M(CO)_n + O \rightarrow$ products with the rate constants for the reaction leading to chemiluminescence showed that a proportion (several %) of the steps in the overall reaction lead to the formation of substances in an excited state. No differences between the $M(CO)_n + H$ reaction and the $M(CO)_n + N$ (or O) reaction has been reported.[72]

The reactions of iron and nickel carbonyls with the metastable $Ar^*(^3P_2)$, $Ne(^3P_2)$, and $He(2^3S)$ atoms, obtained in a microwave discharge in a hollow cathode, are accompanied by a blue [for $Fe(CO)_5$] or reddish-blue [for $Ni(CO)_4$] chemiluminescence, readily observed with the naked eye.[73,74] The characteristic distinct spectral lines were assigned to the emission by the neutral metal atoms. The N_2 and OH^- emission bands are due to the luminescence by background impurities. The weak bands between 450 and 500 nm in the $Ne^* + Ni(CO)_4$ reaction spectrum are due to the (0,0) and (0,1) transitions of the excited CO^+ formed as a result of ionisation:

$$Ne^*(^3P_2) + CO(x, v=0) \rightarrow Ne + CO^+(A^2\Pi_i; v=0) + e^-.$$

The chemiluminescence intensity in the reactions of both carbonyls is described by linear relations as a function of the concentration of the metastable atoms X and the pressure

of the carbonyl (in the region of low pressures). Kinetic measurements showed that excited states of the metal are produced in the bimolecular process

$$X^* + M(CO)_n \rightarrow X + M^* + nCO.$$

The authors[73,74] found differences between the emission spectra of the metal atoms excited chemically and in an arc discharge.

Table 2. The chemiluminescence and electrochemiluminescence of OMC

Element	Compound	Second reagent	Medium
Li	C_6H_5Li	O_2	S, L
Li	C_4H_9Li	Benzoyl, lauryl, and t-butyl peroxides	L
Na	C_6H_5Na	O_2	S

Notation: S = solid phase, L = solution, G = gas; R = alkyl or aryl; R' = C_2–C_6 alkyls; in the reaction with O_2, R' represents in addition isocamphenyl, myrtanyl, or 3-(3-cyclohexenyl) ethyl [2-(3-cyclohexenyl)ethyl? Editor]; L = 1,10-phenanthroline or 4,7-diphenyl-1,10-phenanthroline.

VI. CONCLUSION

The summarising Table 2 shows that organic compounds of fifteen Group I–III and VI–VIII elements in the Periodic System are capable of chemiluminescence. However, we believe that chemiluminescence is a more general property of OMC, since the compounds of the majority of elements have not yet been tested in this respect and the available negative results in the literature refer to attempts to detect chemiluminescence with the naked eye. We believe that Table 2 reflects only a small proportion of the possible new chemiluminescence reactions of OMC.#

We shall now turn to the energy relations of the reactions. We may conclude that all the known light emitting reactions of OMC are highly exothermic, but by no means all highly exothermic reactions of OMC are accompanied by chemiluminescence. In the reactions with oxygen processes involving organometallic peroxides apparently play an important role in exciting the glow. However, this conclusion requires additional experimental confirmation. Thus the chemiluminescence in the reactions of compounds of Group I elements with oxygen has not been investigated at all. Whereas the involvement of intermediate peroxides in the excitation of the chemiluminescence of OAC in solution has been demonstrated fairly reliably, for Grignard reagents this is so far merely a hypothesis unsupported by experimental data.

The possibilities of the chemiluminescence method in determining the mechanism of the complex process involving the autoxidation of OMC has been demonstrated in a study of the influence of inhibitors on the chemiluminescence kinetics in the oxidation of OAC in solution. As regards the question of the involvement of free radicals in the excitation of the chemiluminescence of Grignard reagents, the available set of results obtained by the direct determination of these species by EPR in the oxidation of phenylmagnesium bromide by oxygen and in the study of the influence of magnetic fields on such luminescence can be interpreted as evidence for a free-radical mechanism. However, it is necessary to study in addition the influence on this chemiluminescence of trapping agents for free galvinoxy-radicals. It has been noted[40] that induction periods then appear in the oxidation of Grignard reagents.

The reactions of these OMC with oxidants other than organic peroxides, accompanied by a bright chemiluminescence, have so far remained almost uninvestigated. Among new types of reactions of OMC accompanied by chemiluminescence, we may note the glow in the thermolysis and hydrolysis of organoaluminium peroxides in solutions, the annihilation electrochemiluminescence of solutions of rhenium carbonyls, and the gas-phase chemiluminescence excited in the reactions of metal carbonyls with nitrogen, hydrogen, oxygen, and inert gas atoms in metastable states. It is of interest to note the difference between the mechanisms of the chemiluminescence in the oxidation of trialkylalanes by oxygen in the gas phase and in solution. In solution the chemiluminescence is excited as a consequence of the reaction of the OAC with molecular oxygen in the ground triplet state. In the gas phase the chemiluminescence is due to the reactions of the excited singlet oxygen.

The chemiluminescence of OMC has found practical applications. The use of the gas-phase chemiluminescence of organoaluminium compounds in the investigation of the geophysical characteristics of the cosmic space in the vicinity of the Earth is of interest. The chemiluminescence in the oxidation of OAC by oxygen in solution and the glow arising when water is introduced into the system attracts interest

#This is confirmed by a study which was published during the preparation of the review for the press: R.G.Bulgakov, G.Ya.Maistrenko, V.N.Yakovlev, S.P.Kuleshov, G.A.Tolstikov, and V.P.Kazakov, Dokl.Akad.Nauk SSSR (in the press). In this investigation chemiluminescence was observed for organic compounds of metals representing all the Groups in Mendeleev's Periodic System.

because of the possibility of their use to monitor the industrial synthesis of liquid alcohols at the stage involving the preparation of alkoxides by the oxidation of trialkylalanes. Measurement of the kinetics of the variation of the chemiluminescence intensity makes it possible to follow all the main reactions in the oxidation of triethylaluminium. The introduction of water into the system incorporating the OAC undergoing oxidation makes it possible to detect reliably the onset and end of the reaction involving the oxidation of the third Al–C bond in the trialkylalane.

Summarising the data presented, it is possible to differentiate several main aspects of the further development of the research into the chemiluminescence of OMC. Firstly, we have the study of the mechanism of the non-trivial pathway involving redox reactions of the OMC with formation of excited states. This will entail the solution of the problem of the mechanism of the overall photochemical processes, the identification of the chemiluminescence emitter, the elementary step in the excitation of chemiluminescence, the chemiluminescence yield, the influence of quenching agents, etc. Secondly, it will be necessary to investigate the possibility of using chemiluminescence in the study of the mechanism of the dark process, the determination of its nature (radical or molecular), the determination of the kinetic characteristics, and the determination of the influence of inhibiting or catalytic additives on the process mechanism and kinetics. In addition, the application of chemiluminescence in the analysis of both the OMC themselves as well as other substances interacting with the OMC or present in the reaction zone may prove to be promising. Finally, a comprehensive investigation of the possibility of devising methods for the chemiluminescence monitoring of industrial processes involving OMC is essential.

Organic Reagents in Spectrophotometric Analysis

S.B.Savvin

The spectrophotometric analytical methods using organic reagents in modern chemistry are discussed. Certain new organic reagents, synthesised in recent years, are presented. New methodological procedures in spectrophotometric analysis and the possibilities of the available apparatus are examined. The advances achieved in the development of the theoretical principles of the action of organic reagents are described and a new approach to the explanation of the reactivity of organic compounds is put forward.
The bibliography includes 200 references.

V. Development of the theoretical principles of the action of organic reagents 1080

I. INTRODUCTION

The spectrophotometric methods are virtually the commonest methods in chemical analysis. Colour reactions of practical value have now been found for almost all inorganic ions. An increasing number of organic analytical methods are based on the corresponding colour reactions. The principal advantages of spectrophotometric methods is high sensitivity, universality (i.e. the possibility of determining both small and large amounts of substances), simple apparatus, and the possibility of automating the analytical procedure.

Spectrophotometric analysis is based on organic reagents (OR), whose number has been continuously increasing. At the same time the efficiency of their analytical action has increased: OR forming complexes with unusually high extinction coefficients of the order of several hundreds of thousands have appeared, which makes it possible to determine reliably 0.01 mg ml^{-1} of an element or even smaller amounts. The wide-scale automation of the methods requires the development of direct and rapid analytical procedures. This depends mainly on two factors: the selectivity and reliability of the reactions. By reliability, one understands the independence of the results of slight changes in reaction conditions and also only a slight influence of other substances present in solution on the main reaction. The most reliable results may be expected when OR interacting with the elements in acid media and not requiring the application of buffer solutions are used. The procedure employed in preparing the solution for the photometric measurements then reduces to simple dilution of the analytical solution with an acid (which, for example, makes it possible to carry out the analysis in a stream of liquid); furthermore, the possible interference associated with the hydrolysis of the ions and the formation of polymeric structures is reduced, which is especially important in the determination of certain rare and other, mainly heavy, readily hydrolysable elements such as Ti, Zr, Hf, Nb, Ta, and Pa. A series of effective OR which can be used in highly acid media have been proposed in recent years: arsenazo III and its analogues; antipyrine and its numerous derivatives; reagents of the triphenylmethane series; fluorones; azo-compounds based on pyrogallol, pyridine, and heterocyclic reagents, as well as many other groups and classes of OR.

A series of monographs[1-30] have been devoted to the theory and practice of the application of OR in photometry. These studies dealt with questions of the synthesis of the OR, their purification, and analysis,[8,12,20,27,28] the classification of the OR and the creation of an assortment of the latter suitable for individual elements,[2,7,9,12,15,20,23-25,29,30] the use of OR in spectrophotometric and luminescence measurements,[3,5,6,9,10,15,16,20,22,25] their use for the determination of organic substances[1] and anions,[21] and their application in ultra-microanalysis[4] and in extraction,[14,18] and also questions concerning the theory of the action of the OR.[2,7,8,9,20,23,24,26]

In the present review we shall confine ourselves to the consideration of the OR employed only in spectrophotometric and luminescence measurements. Attention is concentrated on azo-derivatives of chromotropic acid, because results important for the development of the theory of the action of OR have in fact been obtained in recent years precisely for these practically important OR. These results can be in many cases extended to other classes of OR.

II. PRINCIPAL CHARACTERISTICS OF THE COLOUR REACTIONS

The OR are organic compounds (monomeric or polymeric) of different classes which are used for the qualitative or quantitative determination of chemical elements and compounds (inorganic and organic) and also for the separation, concentration, masking, and other auxiliary or preliminary operations preceding and accompanying the determination of substances by any methods.[31,32]

We shall consider several principal concepts characterising the properties of the OR and their metal complexes.

1. Contrast

Contrast is one of the important characteristics of a colour reaction, although this term has not been accurately defined in analytical chemistry and it is sometimes confused with reaction sensitivity. The reaction is said to exhibit contrast when two solutions, one of which contains the OR and the other the product of the analytical reaction, differ significantly in their colour under identical conditions.

A quantitative characteristic of the contrast of a colour reaction is the difference $\Delta\lambda$ (in nanometres) between the band maxima in the absorption spectra of the reaction product (MR) and the reagent (R): $\Delta\lambda = \lambda^{MR}_{max} - \lambda^{R}_{max}$. It is assumed that the reaction exhibits a low contrast if $\Delta\lambda < 40$ nm, a moderate contrast if $\Delta\lambda = 40-80$ nm, and a high contrast if

$\Delta\lambda > 80$ nm. It is also necessary to take into account the shape of the spectrum, in particular the half-widths of the absorption bands. If the absorption spectrum of the reaction product has two maxima, then $\Delta\lambda$ is usually calculated from the positions of the band maxima in the absorption spectra of the OR and the complex differing to the greatest extent. The presence of two maxima is characteristic, for example, of the OR of the arsenazo III group.

There are several possibilities for increasing the contrast of colour reactions. It is known that contrast for a reagent of the type of ROH can be enhanced by selecting a solvent promoting the elimination of a proton from the hydroxy-groups. Such solvents can be dimethylformamide (DMF) and dimethyl sulphoxide (DMSO), which are fairly strong proton-accepting solvents. This procedure is used, for example, to increase the contrast of the reactions of phenylfluorone and its analogues.[33]

A second way of increasing the contrast of colour reactions involves the change in the structure of the OR itself—in the simplest case the introduction of suitable substituents into the OR molecule. Usually these are electronegative groups: NO_2, Cl, Br. Alizarin S and many monoazo-compounds containing the oo'-dioxyazo-group, exhibit an increase in the contrast of their reactions with the elements after the introduction of the NO_2 group.

The problem of finding new OR giving rise to contrasting reactions with the elements is more difficult and has been less thoroughly investigated. In order to solve the problem of predicting the contrast of reactions, it is necessary to find the relation between the structural and analytical spectroscopic characteristics of the reagents and their complexes with the elements. The principal difficulty in the solution of this problem consists in the lack of a clear-cut mathematical definition of the characteristics of the contrast and also of the sensitivity, selectivity, and other analytical characteristics of colour reactions. The search for new or more promising OR is therefore at present prosecuted as a rule by comparing the properties of the OR of one or several chemical classes. An example is provided by the procedure whereby the contrast of the colour reactions of OR of the group of arsenazo III can be increased. By varying the substituents in the benzene rings, while retaining the main carbon skeleton of the OR molecule, it has been possible to synthesise more than 100 new OR; some of these are characterised by a very high contrast of their colour reactions.[20] For example, Dicarboxybenzene C, containing two carboxy-groups in the *ortho*-position relative to the azo-group, gives rise to colour reactions with copper ($\Delta\lambda$ = 106 nm) and manganese ($\Delta\lambda$ = 180 nm) in experiments in aqueous organic media (solutions in acetone and propanol). In order to achieve a high contrast, two factors are used in both cases: the choice of the optimum structure of the reagent and the application of non-aqueous solvents.[34]

In order to increase the contrast of colour reactions (and also in order to improve other analytical characteristics), one employs the procedure in which the elements are determined when they form part of the composition of heteroligand and heterometal complexes, which will be discussed in greater detail below.

2. Sensitivity

A series of procedures have been proposed for the quantitative expression of the sensitivity of colour reactions.[35,36] The most universal characteristic of the sensitivity is apparently the molar extinction coefficient ε† of the analytical reaction product. It is usually assumed that, when $\varepsilon < 2 \times 10^4$, the reaction is relatively insensitive, when ε reaches $(2-6) \times 10^4$ it exhibits a moderate sensitivity, and, when $\varepsilon > 6 \times 10^4$, the sensitivity is high. There exists a limiting value of ε ($\sim 2 \times 10^5$). Although reactions with $\varepsilon > 2 \times 10^5$ are known, these are as a rule cascade reactions.

The "apparent" (or average) molar extinction coefficient is a criterion of the sensitivity of the reaction. It is calculated from the familiar formula $\varepsilon = A/cl$, where A is the optical density of the solution to be analysed, c the concentration of the substance to be determined, and l the thickness of the solution for which photometric measurements are to be made. The conditions in the determination of the element are chosen empirically by selecting the pH or masking complex-forming substances which ensure the highest selectivity. One then considers the reaction mechanism, the yield of the coloured compound (which may be less than 100%), the possibility of the formation of ternary or other complexes, and the coexistence in solution of several coloured complexes. Consequently the apparent or average molar extinction coefficient characterises the sensitivity of the analytical method and its comparison with the true molar extinction coefficients provides an idea about the extent to which the sensitivity of the method of determination is reduced compared with the sensitivity of the reaction itself.

We shall consider the possible ways of increasing the sensitivity, drawing a distinction between the sensitivity of the analytical method and the sensitivity of the reaction itself. The sensitivity of the method can be increased by concentrating the element to be determined (for example, by extraction with organic solvents) or by increasing the thickness of the solution for which photometric measurements are to be made. In the method of spot tests there exist procedures whereby one can reduce by 1–2 orders of magnitude the limit of detection of absolute amounts of the test substances;[22] this also applies to the micromethods for the quantitative determination of substances.[4]

The sensitivity of the reaction depends in the first place on the properties of the OR and on the molar extinction coefficient of the reaction products. The reaction conditions (pH, the nature of the solvent, temperature, etc.) as a rule have an insignificant influence on the sensitivity of the reaction and determine only the yield of the reaction product, which is only rarely below 70–80% under the selected optimum conditions of the determination. Nevertheless it is well known that the character of the spectral curve (the position of the maximum and the intensity and half-width of the absorption band) can change following a change in the reaction conditions (pH and the solvent). This is due to the change in the character of the interaction of the OR with the metal: under new conditions, complexes having a different composition or structure are produced. For example, four different reaction mechanisms, which operate depending on the reaction conditions have been established for certain azo-dye reagents.[37] Application of the knowledge of these mechanisms combined with the appropriate alteration of the reaction conditions lead to one of the ways of increasing the sensitivity of the colour reaction.

3. Selectivity

The concepts of the specificity and selectivity of colour reactions have been examined in a number of studies.[38–41] By the term "selectivity of an organic reagent", we understand the range of the reactive components of the mixture to be analysed which can in principle interact with the given OR, giving rise to a colour reaction; by the term "reaction selectivity" we shall understand the range of the elements interacting with the given OR under certain conditions.

†Here and henceforth the coefficients ε are expressed in litre mol^{-1} cm^{-1}.

Methods for increasing the reaction selectivity are known. In the first place they involve the variation of the pH of the medium. In conformity with the theory of analogies,[42] colour reactions in acid media with oxygen-containing OR of the type of ROH are undergone only by elements whose cations exhibit an extremely high tendency towards hydrolysis: B, Pa, Nb, Zr, Hf, U(IV), Pu(IV), Th; apart from the elements already enumerated, colour reactions are undergone also by Al, Ga, UO_2^{2+}, PuO_2^{2+}, and Sc in moderately acid solutions, by the lanthanides, VO^{2+}, Mo, and Cu in weakly acid and neutral solutions, and by Zn, Ba, Sr, Ca, and Mg in alkaline solutions. The optimum (as regards selectivity) reaction conditions are determined by the nature of the OR and other factors, and in most cases the determination of readily hydrolysable elements in strongly acid media is more selective. Thus, allowance for the nature of the ions of the element constitutes an important factor in increasing the reaction selectivity.

Another universal method for increasing the selectivity of the determination involves the application of various masking substances, including complexones.[10,17] It is noteworthy that there is also a possibility of a scheme in which the element to be determined is masked. By measuring the optical densities of the solution before and after adding the masking substances, one can estimate the interference due to the presence of other elements (for example, UO_2^{2+} is masked by potassium hexametaphosphate in its determination with an OR of the arsenazo type).[20]

A promising method for increasing selectivity, which in due course may become universal, involves the determination of the element present as part of the composition of a mixed ligand complex. The number of publications concerning the development of this application has been increasing rapidly; we shall note only one of the latest monographs.[9]

The selectivity of the determination of an element can be increased by employing extraction-photometric schemes. Here one is not dealing with preliminary extraction and subsequent determination of the element but with the employment of the OR simultaneously for extraction and for photometric measurements. The method, which it has been possible to extend to virtually all OR of different classes, even those which are readily soluble in water, consists in extracting the diphenylguanidinium salt of the corresponding inner complex by butyl or pentyl alcohol with subsequent photometric measurements on the extract without any additional operations.[43,44]

The selectivity of the OR is determined by its structure and the nature of the functional-analytical group. Since the number of the possible functional groups is limited (approximately 100 groups have been described and investigated fairly adequately), much attention has been devoted to increasing the selectivity of OR with a specific group. Thus it has been observed[45,46] that the most general method of increasing the selectivity involves the introduction into the molecule of the reagent of substituents, generating steric hindrance to the formation of a complex, in the vicinity of the chelating centre. It has been noted[46] that the principal cause of the difficulty in achieving a high selectivity for the OR is the ability of metal ions to "become adapted" to the coordination requirements of the ligands. The Schwarzenbach principle (the maximum satisfaction of the coordination requirements of the given ion) is therefore inadequate and it is necessary to impose additional conditions for structural correspondence. As an alternative, the principle of at least the minimum satisfaction of the geometrical and donor–acceptor requirements of one ion combined with the maximum possible satisfaction of such requirements for all the other metal ions has been put forward.[47]

One of the most interesting and very promising procedures for achieving a high selectivity or even specificity of the reaction is the application of macrocyclic reagents in the cavities of which can accommodate only ions with specific coordination possibilities (see, for example, West[45]). An improvement of the selectivity of the OR can be achieved also by introducing into its molecule a second complex-forming group together with the main functional-analytical group.[48,49] An even more promising procedure for the creation of selective OR involves the synthesis of reagents with heterocyclic rings containing S, P, N, and other atoms.

For example, rhodanine was proposed at one time for the precipitation of Ag, Hg, Au, and other elements. However, the low solubility of rhodanine and of the products of its interaction with the elements and the low sensitivity of the reactions precluded its wide-scale employment in photometry. At the same time, by virtue of the enhanced reactivity of its methylene group, rhodanine reacts with compounds of different classes—aldehydes, ketones, and diazo-compounds, which has served as the basis for the synthesis of a series of new OR containing chromophoric groups. For example, 5-azo- and 5-condensed derivatives of rhodanine, its five-membered analogues (thiorhodanine, thiohydantoin, selenoisorhodanine, and 3-aminorhodanine), *N*-substituted 3-aminorhodanine derivatives, and the six-membered analogue thiopropiorhodanine, have been synthesised and investigated.[50–52] In terms of sensitivity and contrast, the azo-derivatives and condensed derivatives of rhodanine and its analogues are greatly superior to rhodanine itself. The most valuable analytical reagents proved to be azo-compounds containing aminosulphophenols as the diazo-components. In contrast to the condensed derivatives, the azo-compounds are more soluble and more stable in highly acid media. As a rule, these OR also give rise to more sensitive and contrasting colour reactions with the elements, in particular with the noble metals.

An appreciable excess of alkali, alkaline earth, and nonferrous metals does not interfere with the determination of the noble metals. It is possible to determine one element of the platinum group in the presence of others. This is achieved because of the difference between the optimum conditions for their determination (concentration, nature of the acid, and temperature) and especially by virtue of the different kinetic activities of different complexes of the noble metals, which depend on the nature of the ligands and on the oxidation state of the central atom in the initial complexes. Table 1 presents the conditions in the reactions and their sensitivities for two of the most interesting OR of this series.

Yet another way of increasing the selectivity of analytical reactions, unrelated to the change in the chemical structure of the OR molecule, is based on the use of its different tautomers.

Thus there exist fairly numerous ways of increasing the selectivity of colour reactions, some of which are fairly promising. At the same time there is as yet no universal criterion which would unambiguously indicate the procedure for the specific synthesis of OR specific for each element.

In conclusion of this section, we shall quote several examples of the spectrophotometric determination of anions using OR. Carminic acid ($\varepsilon = 5.7 \times 10^3$), dianthrimide ($\varepsilon = 1.8 \times 10^4$), and alizarin S (sensitivity 0.02 $\mu g\ ml^{-1}$) are most frequently used to determine boron.[53] The reagent dibromoarsenazo II makes it possible to determine boron in 85% sulphuric acid. The reaction exhibits an appreciable contrast ($\Delta\lambda = 110$ nm), sensitivity (0.01 $\mu g\ ml^{-1}$), and selectivity.[54]

OR belonging to the group of 2,7-bisazo-substituted chromotropic acid derivatives (indirect method) are most promising for the determination of sulphate ions.[21] The determination is carried out by a reaction involving the masking by sulphates of highly sensitive colour reactions between barium and the above OR. Among the numerous OR investigated, Orthanilic K has been recommended for the photometric and titrimetric determination of sulphates. In the photometric version it makes it possible to determine sulphate ions in the concentration range 0.03–1.5 μg ml^{-1}. The determination is carried out at pH 4 in 60% acetone or alcohol.[55] Analytical methods for a wide variety of materials have been developed and successfully employed: natural and industrial waters, air and gases, electrolytes, soils, mineral rocks, etc. The reaction is highly sensitive in relation to phosphate, arsenate, thiosulphate, and fluoride ions.

Table 1. The colour reactions of some platinum elements.[50–52]

Element	Reaction conditions	$10^{-4}\varepsilon$
Reactions of sulphochlorophenolazorhodanine		
Pt	3 *M* HCl	3.2
Pt	2 *M* H_3PO_4 + 2 *M* H_2SO_4	10
Rh	14 *M* H_2SO_4 + 6 *M* CH_3COOH	3.5
Ir	10 *M* H_2SO_4 + 6 *M* CH_3COOH	4
Pd	5 *M* H_2SO_4 + 8 *M* H_3PO_4	12
Au	1 *M* HCl	5.2
Ag	pH 8–10	2
Reactions of sulphochlorophenolazothiopropiorhodanine (thiorhodanine)		
Pt	5 *M* H_3PO_4 + 2 *M* CH_3COOH	6.5
Au	3 *M* H_2SO_4 + 3.5 *M* CH_3COOH	2.5
Ag	10 *M* CH_3COOH + 1 *M* H_3PO_4	5.3

Potentiometric methods with ion-selective electrodes and photometric determinations with OR are used nowadays to determine fluorides. In photometry the indirect methods for the determination of fluorides have been almost completely displaced by the direct determination of fluorides in the form of a three-component compound. It has been found that fluorides can be determined by reactions with zirconium and one of the reagents: arsenazo III, Sulphochlorophenol S,[56,57] Xylenol Orange, or Methylthymol Blue.[58] The difference between the rates of the reactions with the reagent of different forms of zirconium (complex fluoride and hydroxide) is used to determine fluoride ions. A direct linear dependence of the optical density of the solution on the fluorine concentration has been observed in the range 0.01–0.32 μg ml^{-1} for Xylenol Orange, 0.01–0.1 μg ml^{-1} for Chlorosulphophenol C, and 0.02–1.4 μg ml^{-1} for arsenazo III.[57,58]

Phosphates are in most cases determined by means of the formation reactions of reduced heteropolyacids. However, the possibility of the formation of different forms of heteropolyacids can lead to non-reproducible results; the selectivity of the reaction is low and so is its sensitivity: $\varepsilon = (2.1–2.7) \times 10^4$. The reaction with iron(III) ions in the presence of dithizon has been suggested for the determination of phosphorus (in the form of PO_4^{3-}).[59]

III. NEW METHODS FOR INCREASING THE EFFICIENCY OF SPECTROPHOTOMETRIC ANALYSIS

It is possible to differentiate at least three procedures for increasing the efficiency of the known analytical reactions: (1) the use of reactions involving the formation of multicomponent complexes; (2) the application of non-aqueous and mixed solvents as the reaction medium; (3) the use of surfactants in different versions of the reactions. These procedures refer to both colour and luminescence reactions and sometimes make it possible to increase the sensitivity by an order of magnitude and above, to shift the selectivity in the required direction, to improve the reliability of the analysis, etc.

1. Mixed-Ligand Complex Formation

Mixed-ligand complex formation, i.e. the transition from binary to more complex complexes containing three and more components, makes it possible to improve almost all the analytical characteristics of colour reactions. This method has been widely incorporated in practical chemical analysis from the 1950's onwards and has continued to develop.[9,60]

The importance of heteroligand complexes for analytical chemistry is due to their great variety, since mixed-ligand complexes constitute the most probable form in which ions exist in solution. All these equations have been discussed in detail in a monograph.[9] Heteroligand complexes are widely used in extraction–photometric analytical methods. Compounds of organic cations with metallochromic chelates constitute the most common group of compounds in the acid dye–metal ion–organic base systems. The role of the cations in such compounds reduces to neutralising the excess negative charges on the OR due to the presence of sulphogroups[45,61] or dissociated hydroxy-groups, which are not involved in chelate formation.[62,63] Analysis of the literature data has shown that more than 40 dyes are employed as metallochromic indicators, approximately 20 organic cations are used to neutralise the excess charges, and methods are available for the determination of more than 30 metal ions.[15,18,24,64,65]

Methods have been developed for the photometric determination of metals in the form of complexes with metallochromic reagents involving the introduction of quaternary ammonium salts into such systems.[9] The contrast of the reactions increases significantly in this instance. The use of four-component and more complex mixtures leads to new possibilities for the development of photometric and extraction-photometric analytical methods.

2. Organic Solvents in Photometry

One of the new methodological procedures in photometry, which makes it possible to improve the analytical characteristics of the known reactions and also to discover new reactions, involves the employment of organic solvents which not only constitute the medium for the photometric reactions but also influence significantly the reaction mechanism. The effects observed in photometry on passing from aqueous to aqueous organic or organic media are extremely varied. The sensitivity and contrast of the colour reactions and the rate of development of the colour increase, the composition of the complexes changes, and the complexes of elements in a particular oxidation state are stabilised. The observed wide variety of effects is due to the complexity of the processes

influencing the complex formation. Solvents displace tautomeric and acid–base equilibria involving OR, solvate in different ways both the reactants and the reaction products, alter the dielectric constant of the medium and the structure of the solutions, and influence the steric configuration of the complexes.

The application of organic solvents in photometry makes it possible to extend greatly the range of OR and masking complex-forming compounds. Solvents which are most readily available and are most miscible with water are usually employed in spectrophotometry: alcohols, acetone, dioxan, carboxylic acids, DMSO, and DMF. Studies have been made of the influence of solvents on the colour reactions of the elements with OR of different classes: with azo-compounds based on heterocyclic amines,[66,67] formazans,[68,69] and compounds of the triphenylmethane series.[70]

The influence of solvents on the reactions of the elements with 2,7-bisazo-substituted chromotropic acids and also with reagents of the triphenylmethane series has been investigated in detail.[71] A sharp increase of the sensitivity of the colour reactions of Ca, Sr, and Ba with OR belonging to the class of 2,7-bisazo-substituted chromotropic acids has been observed in aqueous acetone and aqueous propanol media.[71] Thus highly sensitive colour reactions of Sr and Ba with carboxynitrazo have been observed in water–acetone mixtures containing 40 and 80 vol.% of acetone respectively ($\varepsilon \cong 1.4 \times 10^5$, $\Delta\lambda > 180$ nm for both reactions),[72] while in a mixture containing 75 vol.% of acetone the reaction of Ca with Methanilic C takes place ($\varepsilon = 0.9 \times 10^5$, $\Delta\lambda \cong 110$ nm).[73] In acetone (containing less than 5 vol.% of water) and in propanol (<0.5 vol.% of water) there is a possibility of sensitive colour reactions for Ni, Co, Mn(II), and Cu.[74] Some of them, for example the reactions with carboxybenzene [Carboxybenzene S?] are characterised by a high sensitivity and contrast ($\varepsilon \cong 1.6 \times 10^5$, $\Delta\lambda > 180$ nm).

In aqueous organic media containing acetic acid, a sharp increase of the sensitivity and contrast of the colour reactions of Al, Be, Ga, and Ti with OR based on *c*-aminohydroxyphenols has been observed.[75] In the presence of H_3PO_4 and H_2O_2, aluminium and titanium form respectively ternary complexes which are not characteristic of other elements; there is a sharp increase of the rate of development of colour. The increase of the sensitivity and contrast of the colour reactions of Be with Chrome Azurol S has been observed in water–propanol mixtures.[76]

The increase of selectivity is determined both by the properties of the solvents (mainly their solvating capacity) and by the new possibilities for masking. For example, in acetic acid media the range of elements capable of giving rise to colour reactions is much more limited than in other solvents, which itself increases the selectivity. This may be associated with the fact that many elements form stable acetates, which entails the loss of the possibility of their interaction with the OR. For example, the selectivity of the colour reactions used to determine Be, Al, and Ti can be sharply increased by employing hydrogen halides (HF, HBr, HCl) as masking-complex-forming agents, which bind many interfering elements (In, Hg, and others) in anionic halide complexes and at the same time do not interfere with the reactions of Be, Al, and Ti. As a result, it is possible to determine Al, Be, and Ti in the presence of a more than 2000-fold excess of Ga, In, Zn, Bi, and other elements.[77,78]

The colour reactions of alkaline earth metals with OR belonging to the Orthanilic, Anthranilic and Benzene group in aqueous organic media are selectively masked by certain anions. Thus in aqueous organic media the sulphates selectively mask the colour reactions of Ba and Sr with Methanilic S, while oxalates mask the reactions of Sr with carboxynitrazo, which makes it possible to determine Ca in the presence of Ba and also Sr in the presence of Ca.[72] A difference in the masking of the colour reactions of Be and Al with Chrome Azurol S is observed in aqueous propanol media, which makes it possible to determine Be in the presence of Al.[76]

Highly sensitive reactions of Ni and Mn(II) with Carboxybenzene C or of Ti with nitrobenzene have been used to determine these elements in chloroform extract after the extraction of nickel by dimethylglyoxime,[79] of manganese by diethyldithiocarbamate,[80] and of titanium by cupferron.[81] The examples quoted by no means exhaust all the possibilities for the improvement of the analytical characteristics of the colour reactions using organic and aqueous organic media.

3. Application of Surfactants

The use of surfactants in photometric analysis is not a new application, but the most interesting results, both practical and theoretical, have been obtained only in recent years. The use of long-chain ammonium and pyridinium bases, namely cetyltrimethylammonium,[82] cetylpyridinium,[83] Zephiramine,[84] and poly-hydroxyethylated ethers of alkylphenols[85] had been described earlier. Water-soluble ionogenic and non-ionogenic surfactants are most suitable for analysis.

The salts of aliphatic primary, secondary, and tertiary amines, quaternary ammonium bases, alkylpyridinium, and a number of other nitrogen-containing bases such as imidazoline, imidazole, pyrimidine, oxazoline, and others behave as cationic surfactants. Cationic surfactants such as sulphonium, phosphonium, and thiuronium compounds are known. Alkanesulphonates, alkylarenesulphonates, alkyl sulphates, and related compounds containing additional polar groups (carbamide, ester, etc.) in the chain behaves as anionic surfactants.

Hydroxyethylated aliphatic acids, glycerol esters of stearic acid, esters of triethanolamine with organic acids and alkylphenols, hydroxyethylated high-molecular-weight alcohols, block-copolymers of epoxypropane and ethylene, polyethylene derivatives of alcohols, poly(ethylene glycol) derivatives of acid amides, amines, epoxypropane, etc. belong to the group of non-ionogenic surfactants.

The introduction of cationic surfactants, particularly those containing a quaternary nitrogen atom and the cetyl group, into a metal ion–OR system (at the appropriate pH) leads to a sharp increase of the contrast and sensitivity of the reactions. Highly effective methods have been developed for the determination of Be, Sc, Y, the lanthanides, Al, Ga, In, Ti, Zr, V, Nb, Ta, Mo, W, Mn, Fe, Co, Ni, Cu, Zn, Ge, Sn, Bi, Th, U, and other elements.[86–91]

Another analytical application of surfactants involves the determination of the percentage content of the OR in their preparations. The method is based on the formation of blue ionic associated species, basic triarylmethane dyes, and anionic surfactants.

Questions concerning the theory of these reactions, which are of interest for analytical purposes, have been discussed in the literature.[88–93] The mechanisms of the interaction of different types of surfactants are different. For example, it has been established that cationic surfactants and OR of the type of Catechol Violet react at a surfactant concentration below the critical concentration for micelle formation.[89–91] It has been suggested that compounds of the type of ionic associated species are produced. However, a sharp change in the colour of the solution indicates the interaction of the cationic surfactant via the hydroxy- and carboxy-groups and not via the sulpho-groups of the OR molecule. Thus the role of the surfactants reduces to exerting an additional influence on the π-electron system of the OR by forming an associated species via the oxygen of the free hydroxy-group, which entails a bathochromic shift of the long-wavelength absorption band.

A somewhat different picture is observed on formation of chelates of phenol-carboxylic acids of the triphenylmethane series. In the absence of surfactants, the formation of metal complexes via the carboxy-groups is characteristic of these OR.[94] The addition of cationic surfactants leads to the blocking of the carboxy-groups owing to the formation of associated species and to the transformation of phenolcarboxylic acids from polyfunctional OR to monofunctional OR, because only one complex-forming group, containing the phenolic hydroxyl and the carbonyl oxygen atom of the COOH group in the o-position relative to the hydroxyl remains available. Consequently the role of surfactants in relation to phenolcarboxylic acids of the triphenylmethane series presumably does not reduce solely to influencing the π-electron system of the OR; the character of the coordination of the metal atom also changes in the presence of the surfactant. The appearance of a narrow well resolved absorption band and the high extinction coefficient of the complex are determined by the characteristics of the structure of the first coordination sphere of the metal. The strong polarising action of the metal, the asymmetry of the OR molecule, and other features of the electronic structure of the complex are apparently of decisive importance.

When non-ionogenic surfactants are used, the mechanisms of their reactions with OR as well as with the complexes produced are somewhat different. The corresponding colour reactions are observed only after the attainment of the critical concentration for micelle formation with the surfactant, i.e. the corresponding processes probably take place in the micellar phase.[92-99] Such processes, involving the displacement of the equilibrium as a result of the local concentration of substances on the surface of the micelles, are known and have been combined under the term "micellar catalysis".

The use of surfactants in combination with OR is an example of the fact that the analytical possibilities are far from being exhausted even as regards well known reagents and the application of new ideas from related branches of science can significantly improve the principal analytical characteristics of large classes of OR.

We may note that significant advances in the development of the theory of all three principal methodological procedures (the use of heteroligand and heterometal complexes, non-aqueous solvents, and surfactants in spectrophotometry) already make it possible to carry out experiments designed to improve these methods in a purposeful manner and not at random and unsystematically. This is also promoted by the fact that the principal elements of the theories of all three methodological procedures have a single physicochemical basis—comprising vigorously developing ideas concerning surface and solvation effects, phenomena associated with hydrophobic hydration, structure formation in the solvents, and the influence of these phenomena on the tautomeric and acid–base equilibria involving the OR and ultimately on the mechanisms of the complex-formation reactions.[90,91,94,100]

IV. THE CHOICE OF ORGANIC REAGENTS FOR THE DETERMINATION OF INDIVIDUAL ELEMENTS

By virtue of the advances in their synthesis, the number of OR proposed for the determination of individual elements has continuously increased and has already reached several thousands. The principal difficulty facing the analytical chemist is not the search for OR for the determination of a particular element but the selection of the best OR among many others. It is not always clear from the literature whether a newly described compound is the most effective OR for the given ion or whether the author investigated the given compound together with others, which are frequently analogues of a known OR, in order to obtain a more complete picture of the interaction of OR having similar structures with metal ions. Much attention has therefore been devoted in recent years to studies designed to obtain comparative analytical data characterising the efficacy of various OR in the determination of individual elements.

The principal characteristics which must constitute the basis of the selection of the reagents are (1) sensitivity, which can be expressed in terms of the molar extinction coefficient or with the aid of other parameters, (2) stability of the reaction product expressed in terms of the stability constant, (3) the limiting dilution or the observation limit, which are associated with the above two quantities, (4) selectivity with respect to anions, and (5) the pH necessary for the maximum yield of the complex (as a rule the more valuable OR make it possible to determine the elements in a more acid medium). The contrast of the colour reactions $\Delta\lambda$, the influence of the reagent (as the background substance) at the optimum (working) wavelength ($\varepsilon_{MR} - \varepsilon_R$ or $\varepsilon_{MR}/\varepsilon_R$ at λ_{opt}), the selectivity in relation to cations, and also the rate of equilibration, the stability of the OR and the reaction product with respect to the action of oxidants, reductants, and other external influences, the extractability of the complex, etc. are no less important characteristics.

Table 2. Examples of group reagents for the photometric and extraction-photometric determination of the elements.

Reagent	Elements
Chrome Azurol S	Be, Al, Ga, Zr, Th, Fe, V, Cu, Mn, Sn, Ti
Antipyrine C	Be, Ca, Cu, Ni, Zn, La, Ge, U(VI), Th, Al, Ga, In, Zr, Sc
Arsenazo I	U, Th, Zr, Sc, Ln, Al, Be, Ti, Nb, V, In
Arsenazo III	Th, Zr, Hf, Np, Pu, Pa, U, Sc, Ln, Pd, Ca, Pb
Arsenazo M	Ln, Cu, Pb, Ca, Sr, Th, Ba, Bi, Zr, Hf, Mg, Al, Zn, Cd, Ga, In, Mn, Ni, Ru, V
Dithizone	Pb, Zr, Cd, Hg, Ag, Cu, Bi, Pd, Mn, Fe, Co, Ni
Sodium diethyldithiocarbamate	Ti, V, Cr, Mo, Mn, Fe, Co, Ni, Cu, Ru, Pd, Ag, Os, Ir, Pt, Au, Tl, Bi
Xylenol Orange	Al, Be, V, Ga, Zr, Fe, Cd, In, Cu, Mo, Nb, Sn, Pd, Pb, Tl, Ti, Th, Bi, U
Methylthymol Blue	Al, V, Ga, Fe, In, Ln, Ca, Mg, Mn, Cu, Ni, Pb, Ti, Th, Zr, Zn
Pyridylazoresorcinol	Nb, Ta, Co, Pd, In, Ga, Ln, Cu, Zn, Cd, Tl, Sc, Th, Pb, Bi, U
Sulphochlorophenol S	Nb, Zr, Sc, Mo, Al, Ga, In, Cu, V
Thoron I	Th, U(IV), Zr, Be, Se, Pu, Np

The selectivity of the OR is one of the most important criteria of its analytical value. However, the number of specific or highly selective OR is extremely limited. The creation for each element of an assortment of OR which mutually supplement one another as regards selectivity has been increasingly considered in studies of recent years. Depending on the assumed content of other interfering elements in the object to be analysed, a specific OR is employed or, if possible, one OR is used for the separation of the element and another for its determination. For example, arsenazo III and Sulphochlorophenol S are mutually complementary OR for the determination of zirconium. Arsenazo III makes it possible to determine zirconium in the presence of niobium, molybdenum, and copper, but thorium, uranium, and the lanthanides greatly interfere with the successful outcome of the analysis. On the other hand, Sulphochlorophenol S makes it possible to determine zirconium in the presence of thorium, uranium, and the lanthanides, whereas the presence of niobium, molybdenum, and copper interferes with the analysis. Such pairs of OR can be selected

from many elements. If the solution to be analysed is complex and contains a wide range of elements or if its composition is not known beforehand, then one of the complementary OR can be employed to isolate the element to be determined (for example, by extracting zirconium together with niobium, molybdenum, and copper) and then zirconium is determined in the extract with arsenazo III; the elements isolated together with zirconium do not then interfere with the analysis.

The creation of an assortment of OR for the determination of each element makes it possible to confine oneself in analytical practice to the wide-scale employment of only some of the OR synthesised–group reagents, each of which is in principle suitable for the determination of several elements. The advantage of using a limited number of group OR in analytical practice is that they can be investigated comprehensively and a rational scheme can be selected for the determination of each element. Table 2 presents some of the most important group OR used for the spectrophotometric determination of the elements as well as the elements with which they can give the most characteristic colour reactions. The creation of a rational assortment of OR for the determination of individual elements constitutes a complex and fairly laborious task, because it is then necessary to take into account numerous factors both scientific and industrial. In the USSR such investigations are being prosecuted by several groups of investigators.[6,7,15,18–21,23–27,29,101–117]

V. DEVELOPMENT OF THE THEORETICAL PRINCIPLES OF THE ACTION OF ORGANIC REAGENTS

The studies which are being carried out on the theory of the action of OR can be as a rule assigned to three classes: (1) the determination of reliable thermodynamic and kinetic characteristics of the processes leading to a specific analytical effect; (2) the study of the mechanism of complex formation, i.e. the determination of the consecutive steps in the formation of the reaction products, and the elucidation of the structures of the OR and the final reaction products under different conditions; (3) direct study of the effect which determines the analytical value of the OR, i.e. the nature of the colour reactions in the case of OR for photometry, luminescence, etc.

The question of the structure of the OR and their complexes with the elements is the basis of all subsequent theoretical constructions associated both with the explanation of the analytical effects of the given OR and with the possibility of predicting to some extent the properties of new OR. Babko noted[16] that the structural formulae of the complexes of the elements, even those with known OR, frequently exist as a "matter of tradition" and have been copied from one communication to another without due justification. This suggests a definite lag in the development of a general theory of the action of OR compared with the advances achieved in the field of their practical application. Indeed, even the determination of the classical structural formula constitutes a non-trivial task for many OR and their metal complexes.

The first investigations of Chugaev, Feigl, Belcher, and Kulberg, some of which have been mentioned in reviews,[32,118] are well known. Alimarin's studies have made a great contribution to the development of ideas about the functional groups in OR and about the relation between the structure and properties of the latter.[119,120] Later Kuznetsov developed a series of theoretical ideas, which explain the analytical action of OR: the range of elements forming complexes with reagents having a given structure (theory of analogies),[42,121] the mechanism of solid-phase colour reactions,[122] and intramolecular dissociation (ionisation).[123,124] The theoretical principles of the extraction-photometric method for the determination of the elements in relation to water-soluble complexes have been developed.[44,125,126]

Subsequent research concerned the investigation and explanation of the mechanism of the analytical action of arsenazo III and its analogues,[127] the theory of colour reactions of hydroxylated azo-compounds,[128,129] the study of acid dissociation[130] and protonation[131] of organic reagents, the determination of the relation between the reaction conditions and the properties of both the OR and the metal cation (the protonation constant of the reagent, the solubility product of the metal hydroxide, and the pH corresponding to 50% reaction),[132] and the determination of four types of colour reactions of organic reagents with elements differing in the structure of the complexes and their spectrochemical properties.[37,132–135] The theory of the action of azo-compounds as indicators has been investigated;[136] the theoretical principles of the employment of aqueous organic solutions as media for colour reactions have been developed;[74,100,137–139] the structure and properties of mixed-ligand complexes have been investigated;[140] atomic models have been used to establish the structure of OR and their complexes;[141] the structures of several complexes have been determined by EPR;[142] a new interpretation of the concept of the functional–analytical group of the OR has been proposed;[143] the kinetics of rapid colour reactions have been studied;[144,145] a theory of the application of surfactants in spectrophotometry has been devised.[86–96]

1. Chemical and Physicochemical Methods for the Determination of the Structures of Reagents and Complexes

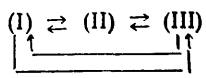
The physicochemical methods for the study of the structure of reagents and inner complexes of the elements with OR (spectrophotometry, EPR, potentiometry, and infrared spectroscopy) make it possible to obtain only indirect information about the structure of the given substance. Direct physical methods (X-ray diffraction analysis) are not applicable in all cases. Perhaps only the NMR method in its various versions, with its ever increasing instrumental capacity, may become in the immediate future a reliable and universal procedure for organic structural analysis.

The structure of the OR and its tautomeric and ionic states in the main determine the complex-formation processes and ultimately the analytical effect of the reaction. The difficulty of establishing the state of the OR and the structure of its separate forms is due to the fact that all the chemical and physical properties of OR are manifested integrally, i.e. can be caused by the simultaneous presence of a series of equilibrium forms.[146] The traditional physicochemical methods, including spectrophotometric methods, cannot always yield the required information. For example, the simplest aromatic azo-compound (azobenzene) has two stereo-forms: *cis*- and *trans*-azobenzenes.[147] These forms differ in their dipole moments and melting points; the steric differences between them have been established by crystallographic investigations. Analogous stereoisomers have been found for a series of substituted azobenzenes and azonaphthalenes.[148] Under specific conditions, one of the ionic and tautomeric forms of the reagent usually predominates. In this case the simultaneous application of spectrophotometric and potentiometric research techniques yields satisfactory results when an attempt is made to establish the sequence of stages in acid ionisation.[149] However, the data obtained must be treated as preliminary.

In general, allowance for tautomers, particularly for azo-compounds as OR, constitutes the most complex problem, which cannot always be solved by classical spectrophotometric

methods for the study of reactions. As an example, we shall consider the OR with the simplest structure—Acid Chrome Dark-Blue.[141,150] It is possible to imagine four equilibrium forms of only one ionic state of this reagent in 0.1 M H_2SO_4: (I), (II), (III), and (IV) (see below).

The existence of the reagent in the sole form (II) has been postulated[150] and the dissociation constant of this particular form has been calculated. The existence of the equilibrium (II) $\rightleftarrows$ (IV) has been postulated in another study[151] under the same conditions. Later quantum-chemical calculations demonstrated[152] that the state of the reagent in 0.1 M H_2SO_4 is described satisfactorily by the following scheme:

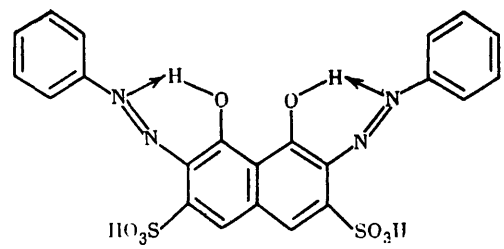


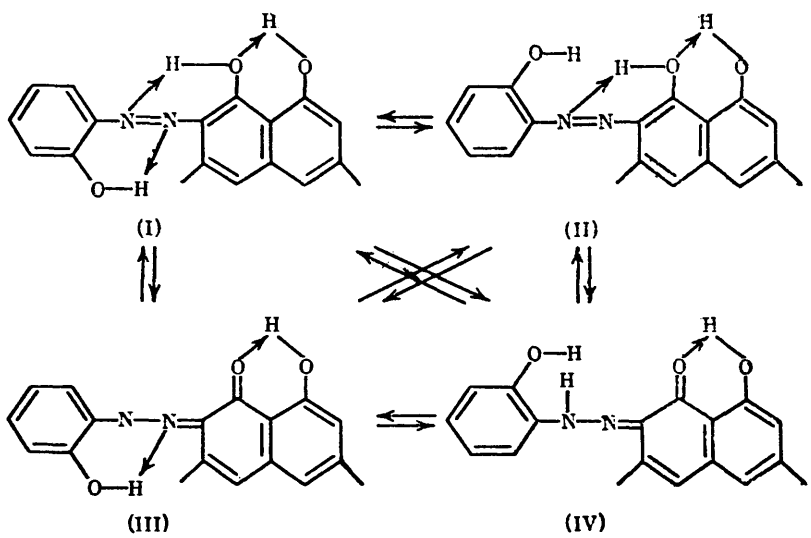
The phenomenon of tautomerism is well known but until recently such processes were considered only in isolated studies.[153,154] It was then usually assumed that the tautomeric equilibrium is almost wholly displaced towards one of the forms. Nevertheless, in determining the state and the characteristics of the reactivity of the OR, it is necessary to demonstrate in the first place the existence of one form or to estimate the concentrations of other forms, which, if they do exist, can interact with metal ions. It is known that the metal does not necessarily interact with the dominant form of the OR present in solution. The presence of metal ions can shift the equilibrium towards the formation of the complex with the form of the OR which would be less stable in the absence of the metal and would be present in solution at a low concentration. All these factors must be borne in mind in interpreting the mechanism of the complex formation reaction.

It is possible to quote a multiplicity of examples of the situation where different investigators have proposed several different structures for the same complex on the basis of the study of the latter by physicochemical methods. Other procedures, developed in recent years, which make it possible to obtain new information about the structure of the complexes and the reaction mechanisms and which have been developed in recent years, are considered below.

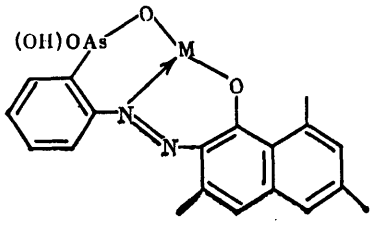
2. The Atomic Model Method

The method of atomic three-dimensional scale models, which has been used for a long time and extensively in theoretical organic chemistry, is in many instances very useful in determining the structure of OR and their complexes. For example, atomic models clearly show that, for OR which are azo-substituted derivatives of chromotropic acid, the only possible planar configuration is the *trans*-configuration of the molecule owing to the steric hindrance by the sulphogroups in the naphthalene nucleus. Thus, for example, the azo-form of the reagent, which is referred to as Benzene S, can be represented only by the following structure:



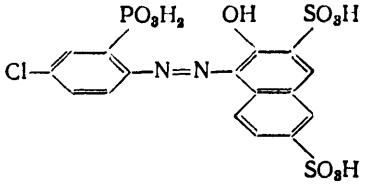


The method of atomic models made it possible to establish that the presence of bulky groups (AsO_3H_2, PO_3H_2, SO_3H, and even COOH) in the organic reagent in the o-position relative to the azo-group precludes the approach of the metal cation to the azo-group in the plane of the OR molecule and the metal ion must therefore be located somewhat above or below the plane of the molecule of the reagent.[141] For example, the structures of complexes of the type



which are usually put forward, are feasible in principle but only under conditions where the planes of the benzene and naphthalene rings have been rotated by ~25–30° and the metal atom is located above the plane of each ring. Only then is the closest contact achieved, within the limits of the sum of the average ionic radii, between the metal atom, on the one hand, and the atoms of the salt-forming groups and the nitrogen atom of the azo-group, on the other.

Three-dimensional atomic models make it possible to establish also other characteristic features of the structure of OR and their complexes. For example, it has been found[141] that, on interaction of a metal ion with chloro-phosphonazo P



the true structure of the complex having the composition MR_2 is one where the two molecules of the above OR are disposed around the metal ion with a coordination number of 6. In this case the molecule has a propeller structure; the planes of the benzene and naphthalene rings are parallel in pairs. In the molecule of the OR the angle between the planes of the two rings is 25–30°; the phosphono-groups are located on top, outside the plane of the benzene and naphthalene rings, while the metal atom is also outside these planes. Analysis of the model showed that another configuration, in which both azo-groups are in the same plane as the metal atom, can also be achieved. The above examples demonstrate the usefulness of the method of atomic models for the preliminary analysis of the possible structures and for deciding whether their existence is in principle possible or impossible.

3. Quantum–Chemical Methods for the Investigation of Colour Reactions

Quantum–chemical methods have been used for approximately 20 years in the study of complex organic reagents with specific features. They led to a way of solving certain important problems in the theory of the action of organic reagents which could not be achieved by the traditional methods available up to that time.[155–159] Thus Hückel's simple version of the quantum–chemical LCAO–MO method makes it possible to calculate the positions of the bands in the absorption spectrum of the OR and to estimate the total π-electronic energy of the system and the relative band intensities. The calculated characteristics of several structures obtained (the positions of the absorption band maxima and their intensities) have been compared with the corresponding experimental data and the structure is selected on this basis.

The LCAO method can also yield additional information about the electronic structure of the molecule of the OR and the complex: about the bond order (the amount of double bond character), about the π-electronic charges on the atoms, and about the free valence indices for individual atoms, i.e. it is possible to formulate the molecular diagram for the OR.

During recent years, extensive data have accumulated as a result of quantum–chemical studies of OR of different classes and their complexes with the elements. Apart from those already mentioned, we may also indicate several novel communications,[160–164] reviews, and monographs.[20,26,165] In the present review we would like to mention only certain features of the application of quantum–chemical methods, their scope, and the prospects for their further applications.

The structural complexity of many OR, the presence of several functional–analytical groups, and the possibility of tautomeric transformations and geometrical isomerism make the task of investigating the mechanism of the complex formation reaction and of the nature of the colour reactions extremely difficult. In calculations of the electronic and energetic characteristics of both the OR and the complexes, one therefore begins with a simplified model of these compounds. Since the S, As, and P atoms forming part of the acid groups SO_3H, AsO_3H_2, PO_3H_2, and other similar groups do not possess an unshared electron pair, their π-electron systems can be assumed to be isolated and to be virtually uninvolved in conjugation. The influence of such groups can be regarded as a perturbation, which alters the Coulombic integral of the carbon atom adjoining the group, as suggested by Wheland and Pauling.[166] The parameters of the heteroatom necessary for this purpose are calculated by Rasch's method;[167] the overlap integrals are found from tables;[168,169] the ionisation potentials are taken from Vedeneev's handbook,[170] the effective charges are calculated in accordance with Slater's rule,[171] and the interatomic distances are taken from tables.[172] The heteroatoms incorporated in the π-electron system are taken into account by introducing semiempirical parameters for the Coulombic and resonance integrals.[26]

At the present time the task which is to be performed by means of the quantum–chemical theory of the structure and action of OR is fairly limited. In the first place, it is necessary to understand the nature of many of the factors already known, for example the influence of the type of substituents, their positions, etc. Using the data obtained, it is possible to formulate certain hypotheses concerning the alteration of the structure of the given OR, which can lead to the required change in its properties: an increase in the sensitivity, selectivity, and contrast of the reaction, in the stability of the complex, etc. New OR, whose analytical value is then tested in practice, are synthesised on the basis of these postulates.

We shall consider the question of the problems of interest for the study of OR which can be actually solved by the computational methods of the quantum–chemical theory of polyatomic molecules. The most common computational method is the self-consistent field method or the Hartree–Fock–Roothaan method, which can lead to the solution of an extremely large number of problems of practical importance

when account is taken of correlation effects.[26,173,180] In calculations on polyatomic molecules mathematical difficulties arise and investigators are forced to introduce approximations of various kinds and to abandon rigorous versions of the theory in favour of semiempirical ones.[174]

Such methods are even more complex than, for example, the Hückel or the Pariser–Parr–Pople methods and their application requires a large amount of computer time; however, the development of computers makes their large-scale application feasible.

We shall consider certain conclusions which can be reached on the basis of the experience already gained in employing quantum–chemical methods for the solution of various problems associated with the structure and properties of OR. One of the first problems in the theory of OR whose solution by quantum–chemical methods has begun involves the explanation of their colour and the causes of its change on complex formation. One may say that this problem is one of the most important and, moreover, it can be best solved using quantum-chemical methods. The vast majority of OR have an extensive conjugation system and the long-wavelength bands in the spectrum are associated with the $\pi-\pi$ transitions (transitions between states of delocalised electrons)–this makes it possible to employ effectively various methods based on the π-electron approximation. The Pariser–Parr–Pople method, which, when combined with configuration superposition methods, makes it possible to simplify the problem of selecting the parameters and to carry out calculations not only for singlet but also for triplet excited states, is preferable for the calculation of the electronic spectrum.[173] As a result, it is possible to include in the investigation also luminescence spectra, which is an extremely promising feature of the analytical application of OR. The Hückel method is in principle inapplicable for this purpose.

The main difficulty in the calculations of the electronic spectra consists in the fact that, since a semiempirical method is used, it is necessary to select a system of initial parameters which would describe satisfactorily not only the spectrum of the given OR (this is not difficult to do) but would also be capable of being transferred to molecules of a specific class, which would lead to the possibility of predicting the spectroscopic properties of a large group of reagents.

By carrying out the appropriate calculations for both OR and for the complex, it is possible to find a way whereby new reagents can be sought. The construction of schemes relating the positions of the long-wavelength absorption band to the site at which the substituent is introduced in the OR molecule is useful in this connection. Examples of such schemes can be found in the literature.[174]

Using this kind of approach and comparing the wave functions for the highest occupied and lowest unoccupied orbitals of the molecules of isomeric phenolazonaphthols, Pilipenko et al.[175] concluded that the azo-derivatives of 1-naphthol should give rise to a more contrasting reaction than the azo-derivatives of 2-naphthol. The reagents synthesised confirm the above hypothesis. Theoretical analysis also led to the conclusion that the contrast of the reactions can be increased by introducing substituents into the aromatic nuclei of OR molecules and that it is useful to employ substituents which exert only an inductive influence. This led to the synthesis of an OR, namely Picramine Epsilon, whose reaction with zirconium and copper is twice as sensitive as that of Picramine P used for this purpose hitherto.[176]

Quantum–chemical calculations helped to demonstrate the likely usefulness of the synthesis of new OR containing the *oo'*-aminohydroxyazo-group and the *oo'*-carboxyaminoazo-group. These OR proved to be extremely sensitive and selective in reactions with palladium, rhodium, molybdenum, and platinum.[177] *N*-Methylanabasine-α-azo-4-cyclohexylresorcinol has been synthesised on the basis of a preliminary calculation for the photometric determination of indium.[178]

Together with the study of spectroscopic properties, quantum methods have also proved useful for other purposes. They can be used, for example, to study charge transfer in oxidation-reduction reactions. Thus, quantum–chemical studies of the electronic structures of OR as a function of the character of the substituent, resulted in the specific synthesis of new reagents: 4-arsono- and 4-phosphonophenylanthranilic acids, phosphonodiphenylamine, and diphosphonodiphenylamine, which are effective oxidation-reduction reagents for the determination of iron, chromium, and vanadium.[179]

There are as yet few examples of the specific synthesis of OR, but one should note that the number of special quantum–chemical studies whose aim is to predict new reagents is also still very small. The limited number of examples of this kind arises mainly due to the fact that analytical chemists have made little use in their investigations of quantum–chemical computational methods, particularly those where account is taken of all the valence electrons, such as CNDO, INDO, and especially MINDO/3.[180]

Attention must be drawn to the great benefit which theoretical analytical chemistry can derive from the application, together with the usual language of structural formulae, of the language of molecular diagrams based on concepts of fractional atomic charges and fractional orders. Numerous examples have shown that molecular diagrams in many respects promote the elucidation of analytical reactions. It is also significant that such molecular diagrams change comparatively little when more complex methods for their calculation are resorted to.

4. Conformational Analysis

The most important characteristic of OR and their complexes which can be successfully investigated by means of modern theoretical chemistry is the geometry of the systems. The study of geometrical parameters is particularly important, because the cause of complex formation reactions and the spectroscopic properties of complex molecules are in many respects determined by their shape and geometry.

Molecular geometry can be determined by theoretical conformational analysis based on the approximation of atom–atom pair potentials. This method, which has been examined in monographs,[181,182] is used widely to investigate the most varied organic compounds, including large biological systems. In almost all cases where it was possible to compare the results of such conformational calculations with experimental data or with the results obtained via other independent calculations it was found that the method is fairly reliable. This makes it possible to regard it as a procedure with a high predictive power.[183]

The mathematical task reduces to finding the potential energy minimum for the system by varying the interatomic distances. This problem can be solved with the aid of well known mathematical procedures. The simplicity of the expression used for the potential energy makes it possible to formulate the problem formally and to develop special computer programmes distinguished, on the one hand, by great power, and on the other hand, by a great simplicity of the representation of the initial data; this has made the methods of theoretical conformational analysis very accessible.

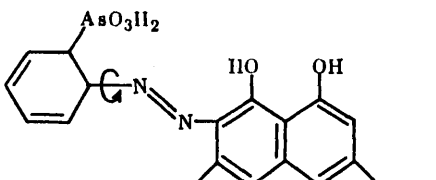
The conformations of a number of organic reagents of the arsenazo III group and related compounds have been calculated[183] and the possibility of rotation about the $C_{Ar}-N$,

N=N, C_{Ar}–AsO_3H_2, C_{Ar}–SO_3H, C_{Ar}–COOH, and C_{Ar}–OH bonds as well as the possibility of the deformation of the valence angles at the nitrogen atoms in the azo-group and the oxygen atom in hydroxy-groups have been examined. Calculations showed that the molecular skeleton of organic reagents without substituents, such as arsenazo III, is planar. The rotation about the C_{Ar}–N bond at the naphthalene nucleus leads to the appearance of stereoisomers differing in the orientation of the azo-group. Regardless of its orientation, all the isomers are energetically equivalent. The substitution of the hydrogen atoms in the 1- and 8-positions in the naphthalene nucleus by hydroxy-groups results in a sharp differentiation of the possible conformers as regards energy: the conformations in which there is a possibility of O–H...N hydrogen bonds are energetically more favourable (approximately by an amount equivalent to the energy of the hydrogen bonds formed) than the conformations in which there are no hydrogen bonds. The formation of conformers containing the O–H...O hydrogen bond (asymmetric conformations) is also possible in principle. All the possible conformations of such molecules are planar.

The presence in a system of this kind of a bulky rotating group results in a sharp increase of the complexity of the picture and renders the principal molecular conformations non-planar. The conformations in which two hydrogen bonds are formed have the lowest energy. At the usual temperatures the equilibrium mixtures can contain only those forms because they are energetically more favourable (the energy gain is 10–20 kcal mol^{-1}).

In order to elucidate the mechanism of the complex formation reaction or to interpret the experimental data for the formation of complexes by azo-reagents with the elements, it is sufficient to know merely the equilibrium geometry of the conformers; it is essential to know how rigid are particular conformations and what is the approximate energy expenditure needed for rotation about the bonds in order to attain the most favourable geometry for the formation of the complex; it is also important to estimate the feasibility of the transition from one conformation to another.

Such calculations for arsenazo I



showed[184] that the rotation about the C_{Ph}–N bond (indicated by an arrow in the schematic diagram above) is fairly free: rotation by ~30° requires an energy expenditure of ~1 kcal mol^{-1}; consequently the OR can readily undergo a change in conformation on complex formation. The barrier to the transition to a neighbouring (relatively unstable) conformation is also low and amounts to 4–5 kcal mol^{-1}.[183,184]

Conformational maps[182] from which one can infer the "softness" or "hardness" of the OR molecule and the energies of the transitions from one conformation to another can also be obtained from the calculations. It was found that, despite the abundance of the possible conformations, as a rule only one conformer is present under the conditions of analytical reactions (we shall not consider here tautomeric transformations and the possibility of the simultaneous presence of several tautomeric forms) and its structure is nearly planar (the deviation of the benzene ring from the plane of the naphthalene ring ranges from 0° to 30° depending on the substituents). The possible conformations of the OR are fairly soft. This means that the same functional group, for example, the *o*-arsonazo-*o'*-hydroxy- or *o*-phosphonoazo-*o'*-hydroxy-group, can satisfy the coordination requirements of many metal cations which can in principle interact with it.

This is one of the most important conclusions reached with the aid of conformational analysis. The selectivity of the reagent can be inferred from its softness or hardness. The OR of the arsenazo I and arsenazo III groups are known to be unselective; they interact with many elements, which in fact was to be expected in view of the softness of the conformations of the reagents of this group.

Similar conformational analysis has not so far been carried out for OR of other groups. If it is confirmed that the softness or hardness of the conformations of the OR is directly related to its selectivity, then conformational analysis of compounds of different classes will possess predictive power and will become one of the methods for the theoretical search for specific selective or group reagents. The knowledge of the geometry of the OR and its complexes is essential also for the subsequent quantum–chemical calculation.

5. Estimation of the Reactivities of Organic Reagents

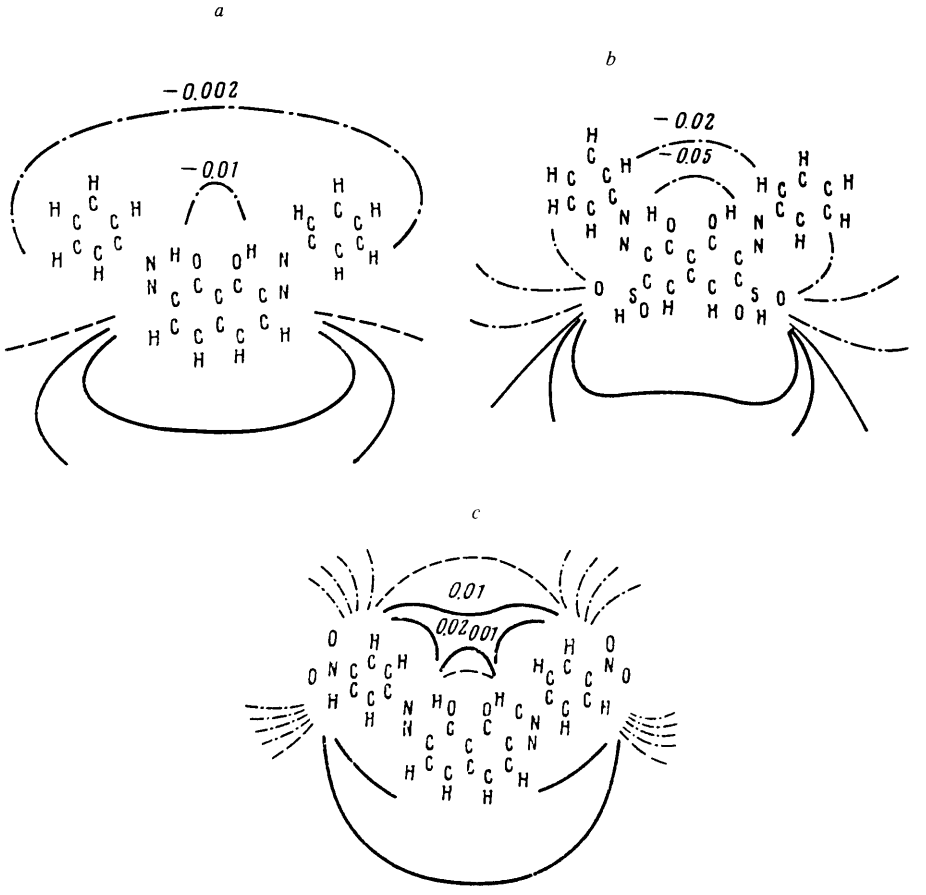
In recent years quantum–chemical methods have been used in the study of the reactivities of OR and of the mechanisms of complex formation reactions. As a rule, the complex formation reaction, especially in its first stage where the metal cation or any other inorganic or organic ion is still comparatively remote from the molecule of the OR, has a distinct electrostatic character. This involves the mutual approach of the charged species and the molecule of the OR, which can be both charged and electrically neutral, but, by virtue of its steric structure and the complex distribution of charges within it, it gives rise to an inhomogeneous electrostatic field along its immediate periphery. The electrostatic field can promote the approach of the metal ion to the reaction centre or conversely can hinder its movement, whereupon the reaction becomes impossible or is retarded. Thus arises the problem of investigating the electrostatic field around the molecule at distances of the order of magnitude equivalent to 2–3 atomic dimensions.

The solution of this problem does not apparently require an especially accurate calculation and the treatment can be restricted to approximations of the type of point charges calculated by the CNDO, INDO, and certain other methods. The methods based on the π-electron approximation are naturally inapplicable in this instance. We shall quote certain model examples demonstrating the dependence of the electrostatic field of the OR molecules on the substituent.

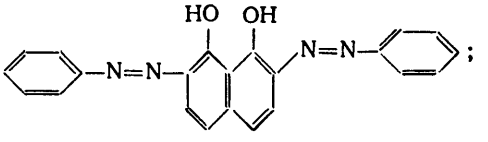
The Figure shows maps of the molecular electrostatic potential calculated for different 2,7-bisazo-substituted 1,8-dihydroxynaphthalenes.[183–185] The distribution of the electrostatic fields in these molecules either facilitates or hinders nucleophilic or electrophilic reactions. In reagents of the group of 2,7-bisazo-substituted chromotropic acid (or 1,8-dihydroxynaphthalene) it is possible to differentiate several functional–analytical groups. We shall consider one of them—the peridihydroxy-group. In the model OR illustrated in Fig.*b* the negative electrostatic potential in the vicinity of the given reaction centre has increased compared with the model reagent in Fig.*a* by a factor of 5 solely as a result of the introduction of two sulpho-groups into the naphthalene nucleus. This model OR is close to a real reagent, namely to a reagent based on chromotropic acid. Naturally the sulpho-groups exert only a weak influence on the distribution of the π-electron density on the atoms incorporated in the conjugation chain of the molecule. This also applies to the

oxygen atoms in the functional–analytical group of the model OR.

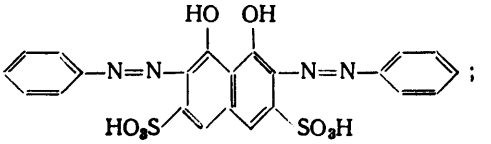
The introduction of nitro-groups in the *p*-positions in the benzene rings of the model OR (Fig.*c*) reverses the sign of the electrostatic potential. The π-electron density on the atoms forming part of the composition of the functional–analytical group hardly changes under these conditions. At the same time the experimental data show unambiguously a sharp alteration of the reactivity of the OR after the introduction of sulpho-, nitro-, amino-, and other groups even



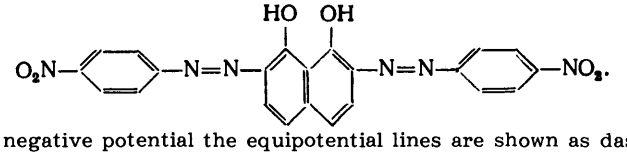
The molecular electrostatic potentials of OR (section in the plane of the molecule): *a*) model reagent of the type of Benzene S without sulpho-groups in the naphthalene nucleus:



b) the Benzene S reagent



c) a model reagent of the type of Benzene S with nitro-groups in the *p*-positions in the benzene rings:



In the region of the negative potential the equipotential lines are shown as dash-dot lines. In the region of the positive potential they are shown as continuous lines; the zero potential lines are indicated by a series of dashes; the numerals denote the potential in e/A^{-1}.

into parts of the molecule remote from the functional–analytical centre. Thus the observed change in the reactivity of the OR can be attributed solely to a change in the molecular electrostatic potential in the immediate (1–3 Å) environment of the functional–analytical centre of the OR.

This comparatively new approach to the theoretical study of the reactivity of the OR can also be used to study their interaction with metal cations to form chelate compounds. The initial structures of the reactants (the structures of the reagents and of the form of the metal under the given conditions) and the structure of the final reaction products have so far been investigated by different procedures; the possible structures of the reaction intermediates have sometimes been discussed. Maps of the molecular electrostatic potentials of the reagents make it possible to follow to some extent the pathway (more precisely the likely site of attack) traversed by the metal ion towards the OR molecule. This may make it possible to specify more precisely the structure of the complex in those cases where there are several sites at which the metal ion can be attached in principle. One cannot rule out the possibility that the selectivity of the OR, the rates of its reactions, and its other analytical characteristics depend to some extent also on the distribution of the molecular electrostatic potential.[185]

In conclusion of the brief survey of the applications of the quantum–chemical methods in the solution of the problems of the theory of the action of OR, we may note that the use of quantum–chemical research techniques has not introduced radical changes into the principal postulates of the theory of the action of OR. On the other hand, during the first decade after the introduction of these methods into the working arsenal of analytical chemistry, it has been convincingly demonstrated with their aid that the theoretical ideas constructed on the basis of traditional research techniques are correct. In the same stage quantum–chemical methods made it possible to obtain much new information about the structure of OR which might have been obtained, albeit with much difficulty, also by means of traditional methods.

The second, modern stage in the application of quantum–chemical methods in analytical chemistry (which began approximately in 1970) is characterised by the possibility of obtaining new information (detailed characteristics of the electronic structures of OR, their electrostatic potential fields, and their reactivities), which cannot be obtained in principle by traditional methods. One can also imagine a transition in the immediate future to a third stage, which will make it possible to predict specific syntheses of OR with specified properties.

6. Kinetics of Colour Reactions

The study of the rates of rapid chemical reactions is important both for the theoretical and practical aspects of analytical chemistry. Certain chemical reactions, which have been regarded for a long time as rapid, are retarded so much under certain conditions that this can introduce significant errors into chemical analysis. It is important to take into account the retardation of the reaction in the development of automatic schemes for the continuous control of industrial processes, for example, in analysis in a stream of liquid. Hitherto few studies have been made on new practical possibilities for increasing sensitivity and selectivity which might be realised if it were possible to employ as analytical forms the reaction intermediates whose principal spectroscopic characteristics can be measured either with the aid of high-speed spectrophotometers or by the application of external influences which arrest or retard the reaction at a specific stage.

However, the mechanisms of the majority of the chemical reactions of analytical importance still remain unelucidated. Even if the composition and structure of the initial reactants and of the analytical product are known, as a rule nothing is known about the structure of the intermediates produced in the interaction of the cation of the given element with an OR having a fairly complex structure.

Until recently, colour reactions were divided into slow and "instantaneous". The kinetics of the latter reactions were hardly investigated, although the rapid reactions might have been in fact of greatest interest for the understanding of the process mechanism because in such cases the mechanism of the formation of complexes operates in a pure form (slow reactions are usually complicated by the hydrolytic process, by the dehydration of metal ions and OR molecules, and other side reactions).

The advances in the study of rapid reactions achieved in related fields of chemistry stimulated the application of the newly developed methods also to the study of analytical colour reactions. Procedures have appeared in recent years for the investigation of the reaction kinetics which make it possible to investigate reactions with a half-reaction time ($t_{1/2}$) ranging from 10^9 to 10 s.[186] It was established in almost all cases that colour reactions are not simple single-stage reactions but proceed with formation of at least one or several intermediates. The study of the reactions of aluminium with Xylenol Orange and Aluminocrezone[187] established that the former reaction proceeds in accordance with a kinetic second-order equation and the latter in accordance with a first-order equation.

In the study of the complex formation reaction between gallium and Methylthymol Blue[188] the formation of the intermediate $Ga(OR)_2$ in the course of the formation of the final complex GaOR was established. It was shown that the process is of first order with respect to both the metal and the OR. Its rate-limiting stage involves the interaction of the complex $Ga(OR)_2$ with the $Ga(H_2O)_n$ cation. The same reagent enters into a first-order reaction with nickel[189] and lanthanium.[190] The slow reaction of arsenazo III with zirconium has also been investigated.[191]

In the case of rapid reactions, the kinetic spectrometric method is very useful in the analysis of a mixture of substances involving complex reactions but differing as regards the formation or decomposition of the complexes. The flow version of the method has been used for the analysis of alkaline earth and certain transition elements.[192] The kinetic method for the quantitative determination of individual lanthanides in the presence of other lanthanides employs the reaction of complexone III (EDTA) with the coloured complexes formed by the lanthanides with Xylenol Orange, it proceeds in accordance with the following scheme:

$$LnX + EDTA \rightleftarrows LnEDTA + X,$$

where Ln is the lanthanide ion, X is the anion of Xylenol Orange, and EDTA represents ethylenediaminetetraacetic acid. In relation to the coloured complex LnX, the above reaction is of first order; in the series of lanthanides the rate of attainment of 50% reaction varies from 236 s^{-1} to 30 s^{-1}.[193] The method developed makes it possible to determine certain lanthanide elements in the presence of a tenfold excess of other lanthanides.

The reaction of UO_2^{2+} with arsenazo III, widely used in analytical chemistry, has also been investigated by spectroscopic-kinetic methods.[144,194] The absorption was measured on a specially designed spectrophotometer with electronic scanning of the spectrum, which ensures the recording of optical absorption spectra in the range 230–800 nm and also the recording of kinetic curves at any wavelength. Analysis of the absorption spectra and of the kinetic curves obtained under different

conditions (concentration, pH of the medium, the presence of other substances in solution, temperature, etc.) permits definite conclusions about the mechanism of the complex formation. It was found that the order of the reaction of UO_2^{2+} with arsenazo III is close to unity; the rate of reaction is proportional to the concentration of one of the components; the determining factor is the concentration of the active, ionised form of the OR. This means that, although the direct interaction of the uranyl ion with the undissociated form of the OR cannot be ruled out, the main process, which determines the rate of reaction, is the interaction of the uranyl ion with the active and especially the dissociated form of the OR.

More complete information about the mechanism of a complex colour reaction can be derived from the study of the absorption spectra of the reaction products recorded by the given apparatus in the course of the reaction. This makes it possible to follow the variation of the concentrations of the individual substances involved in the reaction, i.e. one can obtain their kinetic curves and one can calculate the rate constant for each elementary stage. The constants obtained in this way then have an entirely concrete significance and are not conventional (overall). It is fairly difficult to carry out such an experiment, since it requires, in particular, a high accuracy of the measurements and the ability to resolve unambiguously the complex spectral curves into simple components and also the ability to choose the optimum reaction conditions which will ensure that the reaction proceeds via an unambiguous mechanism. It is likewise essential to have at ones disposal a clear-cut scheme for the interpretation of the results.[184,185]

---oOo---

Some information about the state and prospects for the development of a branch of science can be obtained by a numerical scientific study of publications. The number of communications devoted to the investigation and general analytical employment of OR varies according to different data from 600 to 1300 per annum, while the annual number of publications on the analytical chemistry of inorganic substances is of the order of 4300–4700.[196,197] The available literature data[198] have shown that different branches of analytical chemistry have undergone one of three types of evolution at different times: regression, saturation, or growth. According to statistical data, studies in the field of OR have not yet reached the stage of saturation and are in the growth stage. The fraction of publications on OR constitutes, according to some data,[197] about 30% of the total number of communications on analytical chemistry.

The main bulk of the applications of OR are in photometry. Photometric analysis is one of the commonest methods. The publications on the photometry constitute ~30–35% of all the publications devoted to analytical chemistry.[199,200] More than half of all the analyses in industry, in agriculture, in medicine, and in the monitoring of the pollution of the environment are performed by spectrophotometric methods. There is reason to believe that in the immediate future (20–30 years) spectrophotometry will become the most important method of chemical analysis. This is indicated by the new ideas and developments in the field of the automation of analysis and analytical apparatus (the flow-injection system and chemical sensors) and also by the advances in the synthesis of new OR.

The synthesis of new highly effective OR is at the present time largely determined by the level of development of the theory of the action of such reagents. This is associated with the fact that the semiempirical search, which has been hitherto the main basis for the creation of new OR, has been virtually exhausted. Theoretical ideas already exist which make it possible to synthesise structural analogues of the known reagents by introducing functional-analytical and other groups or by slight modification of the main carbon skeleton of the molecule of the prototype reagent. This is a reliable way of altering and improving the properties of OR. However, the expected and subsequently observed effects, although satisfactory and sometimes considerable, are not fundamental in the sense that they make it possible to obtain OR specific to some chemical element or to achieve a sharp increase, for example, by an order of magnitude, in the sensitivity of the reaction.

A characteristic feature of the theoretical developments in the last 10–15 years, associated with the application of quantum-chemical and other theoretical research techniques, consists in the search for specific syntheses of new classes and groups of OR with properties specified beforehand. There is reason to believe that this procedure will lead to the creation of new and highly effective OR.

Advances in the Field of Organoelemental Polymers

V.V.Korshak and N.M.Kozyreva

This review deals with organoelemental polymers containing the elements of various Groups in the Periodic System. The major role of these polymers in many fields of modern technology and national economy is demonstrated. The methods of synthesis of organoelemental polymers used at present and the prospects for the development of this field in the future are considered. It is shown that the heterounit structure of the polymer is a common phenomenon in the chemistry of macromolecular compounds, characteristic also of organoelemental polymers. It has been established that the presence of stable isotopes in polymer macromolecules is one of the causes of the appearance of the heterounit structure.
The bibliography includes 113 references.

INTRODUCTION

The chemistry of organoelemental polymers as an independent branch of polymer science has been formulated only in the last forty years. It is characterised by rapid development, which can be accounted for by the possession by organoelemental polymers of valuable qualities such as, for example, high thermal stability, chemical stability, incombustibility and many other specific properties, which make them irreplaceable in practical applications; they have therefore found extensive applications in a number of fields of modern technology.

A.N.Nesmeyanov has pointed out that one of the most important ways of creating new polymers is to employ for their synthesis different elements of Mendeleev's Periodic System.[1] The chemistry of organoelemental compounds is a science of the boundary between inorganic and organic chemistry, which is undoubtedly its positive aspect, since it makes it possible to obtain polymeric compounds combining useful qualities characteristic of compounds of most branches of chemistry.[2] Because of this, many elements of the Periodic System, capable of forming various polymeric compounds, have been the object of chemical research and some of the polymers obtained have already found practical applications in a number of branches of modern technology.[3]

Thus organoelemental macromolecular compounds such as numerous organosilicon polymers, polymers based on various metals and their derivatives, poly(phosphonitrilic chloride) and its various modifications, phosphorylated polystyrene, a series of organoboron compounds, particularly those containing carbaborane groups, and many polymers, and copolymers of fluorinated ethylenes are being manufactured at present on an industrial scale and have found a wide variety of applications.

The concept of organoelemental compounds has been put forward by Nesmeyanov and has been accepted by many investigators.[4]

The history of the chemistry of organoelemental compounds began with the investigations of Andrianov,[5] who obtained in 1937 for the first time organosilicon polymers, and demonstrated their practical value; since that discovery, the field of organoelemental macromolecular compounds has begun to develop.

Undoubtedly one of the most important trends in the future progress of polymer science will be a wide-scale employment of elements of the Periodic System for the synthesis of various polymers;[6] the number of elements used for this purpose increases every year. At the present time 75 elements have already been employed in the synthesis of various macromolecular compounds.[6-8] Among the 106 elements known at present, only the noble gases (6 elements) and the 12 elements belonging to Groups I and VII of the Periodic System, which are univalent and can only play the role of terminating groups, are incapable of producing polymers. Thus, the remaining 88 elements are capable of functioning as chain-forming elements, giving rise to polymeric macromolecules.

Table 1. Elements entering into the composition of the organoelemental polymers synthesised.

Period	Groups									
	I	II	III	IV	V	VI	VII	VIII

7	—	—	—	—	—	—	—	—	—	—

Lanthanides: Ce, Pr, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, and Lu.
Actinides: Th and U.

These elements give rise to bifunctional and polyfunctional atoms and groups. The formation of polymeric macromolecules with a homochain structure is fairly common with elements such as boron, carbon, silicon, phosphorus, sulphur, germanium, arsenic, selenium, tin, antimony, tellurium, bismuth, and polonium (in all, 13 elements). Among these elements of the Periodic System, carbon is distinguished by an exceptional ability to form unusually long chains in carbochain polymers, while the remaining elements enumerated above can produce homochain polymers

to a much lesser extent. However, in contrast to this, the number of elements able to participate in the formation of heterochain polymers is very considerable and such compounds include more examples than homochain polymers.

Table 2. The bonds introduced into the composition of organoelemental polymers.

Bond	Bond	Bond
				
		
		
		
heating to a temperature exceeding 350 °C, polysiloxanes readily depolymerise, forming cyclic siloxanes. The Si–C bonds then remain unchanged, while the Si–O bonds are ruptured. This difference in behaviour can be explained by the mechanism of the accompanying reaction in which the bonds are rearranged via the formation of an intermediate compound.[13] This reduces the energy barrier to the rupture of the Si–O bond and a cyclic siloxane is formed in accordance with the equation

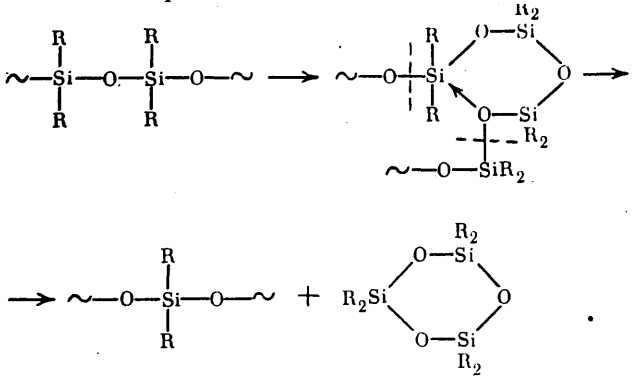

Table 4. The bond energies in heterochain organoelemental polymers.[11,12]

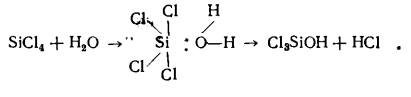
Bond	E_b, kcal mol^{-1}	Bond	E_b, kcal mol^{-1}
B–O	119,3	As–O	64.5
B–N	104,3	Al–C	61.6
B–C	100,0	C–S	61.5
P–O	81,7	Si–S	60.9
C–O	79,0	Si–C	57.6
Si–O	89,3	As–C	54.6
Sb–O	71,0	N–O	37.0
C–N	66,0		

Many other reactions of silicon compounds can be explained in the same way, i.e. by the transition of silicon to a quinquevalent state, as happens, for example, in the hydrolysis of silicon tetrachloride:[15]



However, there are also other ideas concerning the mechanism of these reactions.[16] The bond energies listed in Tables 3 and 4 refer to the homolytic type of bond dissociation reactions. However, bond dissociation reactions of the heterolytic type are encountered among organoelemental compounds much more frequently than those of the homolytic type and it is therefore necessary to take into account the "ionic bond energy", which is characteristic of the reactions which proceed as follows:

$$AB \rightarrow A^- + B^+.$$

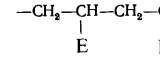
Thus, one can understand why the Si–H bond, for which the homolytic bond dissociation energy is 76.0 kcal mol^{-1}, while the ionic bond dissociation energy is 222.9 kcal mol^{-1}, is more stable in heterolytic reactions than the Si–Cl bond, for which the above energies are respectively 91 and 190 kcal mol^{-1} and the overall energy, amounting to 281 kcal mol^{-1}, is lower than the overall energy in the former case, where it is 298.9 kcal mol^{-1}.[15]

The bonds between the elements in organoelemental polymers are of a different character for different elements. It is possible to arrange the elements in three groups depending on the type of bond characteristic of them,[17] as can be seen in Fig. 1.

III. METHODS OF SYNTHESIS OF ORGANOELEMENTAL POLYMERS

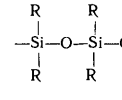
Organoelemental polymers can be synthesised by means of reactions involving both the polycondensation and polymerisation of the corresponding monomers and via a series of direct modification reactions of various polymers. This results in the formation of polymers of the following three types:

(1) carbochain polymers with an organic main chain of the macromolecule and organoelemental side groups (E):



(2) heterochain polymers containing carbon atoms in the main chain together with those of other elements:

(3) heterochain polymers with an inorganic main chain and organic side groups, such as, for example, polysiloxanes, etc.:



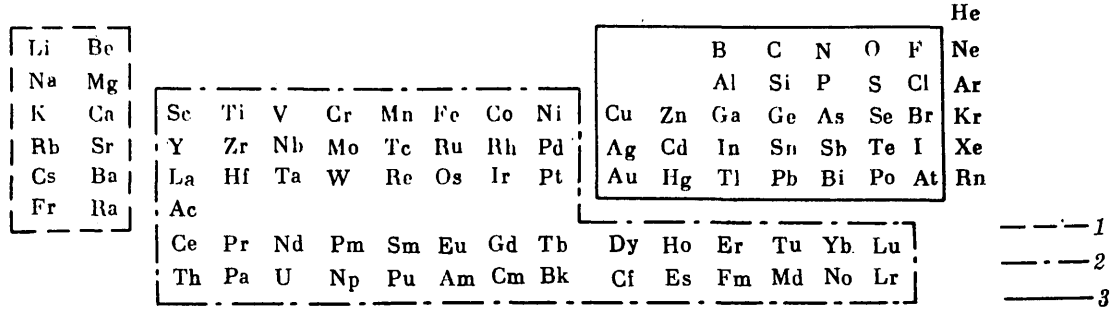


Figure 1. Distribution of the elements in groups as a function of the character of the bond between the atoms: 1) ionic bond type; 2) *d* orbital bond type; 3) covalent bond type.

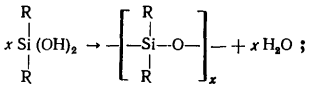
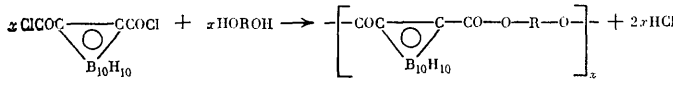
A characteristic feature of organolemeental polymers is the fact that whereas bonds of the $s-p-\sigma$ and $\sigma-\pi$ types are most characteristic of organic compounds, in organoelemental compounds there are also d orbital π-bonds: $d_\pi-p_\pi$ and $p_\pi-p_\pi$, where one or several free electron pairs of the atoms are bound directly to the atom of the element having unoccupied p_π or d_π low-energy orbitals and a suitable symmetry. There are also other types of interaction, which has been demonstrated in relation to numerous new types of compounds belonging to the groups of metallocenes, hydrides, carbaboranes, coordination polymers, etc.

Apart from the elements of the Second Period in the Periodic System, i.e. carbon, nitrogen, and oxygen, bonds of the p_π type are rarely encountered for other elements. Bonds involving $d_\pi-p_\pi$ orbitals are more common in organoelemental compounds, but such bonds are incapable of polymerisation. As a result of this, linear organoelemental polymers are usually synthesised by the polycondensation of bifunctional monomers or by the polymerisation of heterocycles. The advances in the synthesis of organoelemental polymers have been described in a series of reviews and monographs.[4,9-11,14-24]

Several different types of reactions have been used to synthesise organolemental polymers.

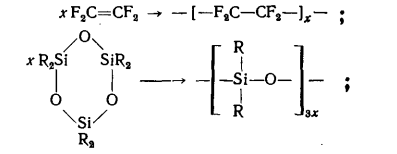
1. Polycondensation of monomers having two and more identical or different functional groups, for example:[25,26]

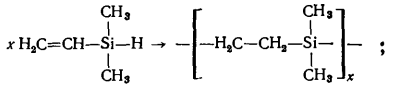


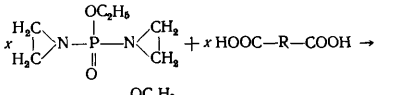


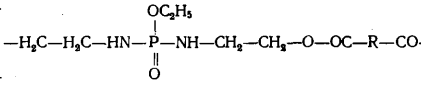
In this case heterochain organoelemental polymers are produced. Two versions of the reaction are then possible, namely "equilibrium" and "non-equilibrium" polycondensations differing in the magnitude of the equilibrium constant,[20,21] which is less than 10^3 for equilibrium polycondensation and more than 10^3 for non-equilibrium polycondensation.

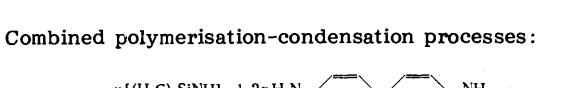
2. Polymerisation of monomers having double bonds or heterocycles and also the migration copolymerisation of the hydrides of silicon and other elements, for example:



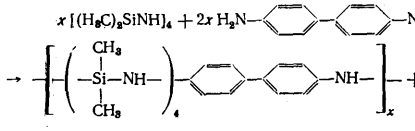








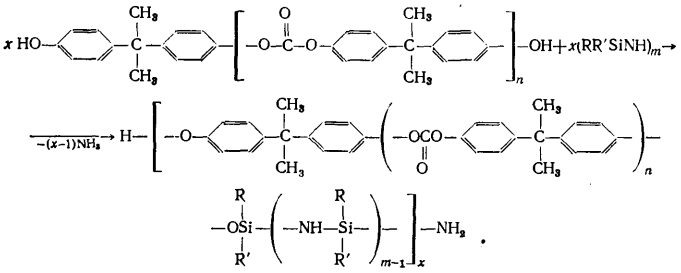
3. Combined polymerisation-condensation processes:



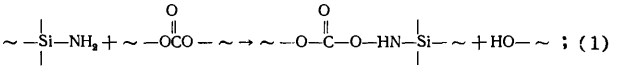
The reaction proceeds not only with the opening of the silazane ring (polymerisation) but also with evolution of ammonia (polycondensation).[27]

The studies[28-35] in which polymers with inorganic and organic molecular chains were obtained by combined polymerisation-condensation processes are of interest. Such polymers can be synthesised from organocyclosilazanes having the general formula $[RR'SiNH]_3$ and diamines or diols. The reaction proceeds both in the presence and absence of catalysts with evolution of ammonia and formation of Si–N bonds in the macromolecular chain. The products exhibit a high thermo-oxidative stability and, depending on the structure of the cyclosilazanes and diols are either solid rubber-like substances with high elasticity or viscous liquids.

The products of the interaction of organocyclosilazanes with oligocarbonate-diols have been described:[28]



The polymers were obtained by reactions in solvents and in bulk. The reaction in bulk proceeds at a much higher rate but side reactions reduce the molecular weight of the polymer and lead to a less ordered structure of the latter owing to the degradation of the polycarbonate and silazane blocks and the appearance of urethane and isocyanate groups in the macrochain via the following mechanisms:



(1)

(2)

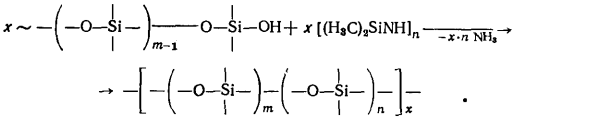
At higher temperatures the side reaction

(3)

plays a notable role.

The shift of the equilibrium in reaction (2) to the right, which entails an increase in the concentration of OH groups capable of reacting with the less reactive NH groups in the linear sections of the chain, gives rise to the possibility of condensation reactions leading to the additional evolution of ammonia.

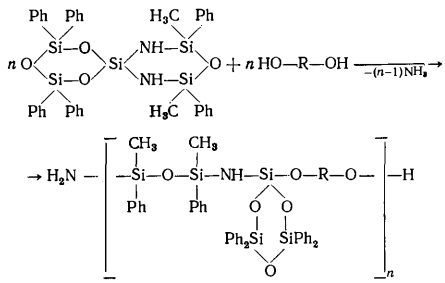
Not only organic diamines and diols but also organosilicon diols can be used in the reactions with diorganocyclosilazanes. Results of practical interest have been obtained by the reaction of $\alpha\omega$-dihydroxypolydimethyl(methylvinyl)siloxanes and dimethylcyclosilazanes:



The rubbers based on such polymers are superior as regards their physicomechanical parameters after thermal ageing to the rubbers based on industrial raw rubber.[29]

Polycarbonate-silazasiloxane block copolymers have been described.[30] They contain not only polycarbonate and silazasiloxane blocks but also urethane groups and have a branched structure.

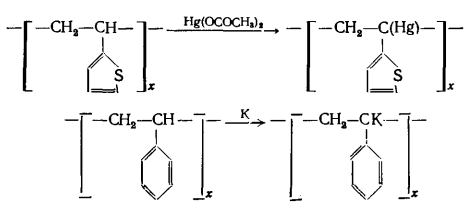
In connection with the different reactivities of the Si–N and Si–O bonds in relation to hydroxy-compounds,[31,32] studies of the polycondensation of organo-spiro-bicyclosilazasiloxanes with organic and organosilicon diols of different structure are of interest. In the ideal case the reaction proceeds via the scheme



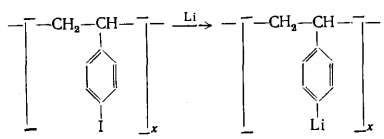
Polymers soluble in organic solvents and cross-linked polymers have been obtained. The block copolymers of organocyclosiloxanes with diols are of great practical interest for the development on their basis of thermostable greases, thermoplastic materials for the storage of information,[33] compositions for coatings,[34,35] etc.

4. The modification of polymers by treatment with metals and their compounds leads to the formation of various organoelemental polymers:

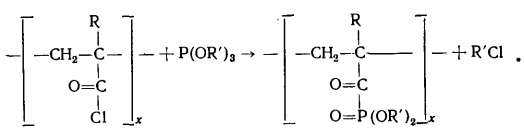
(a) By substituting hydrogen atoms in the polymer chain,[36,37] for example:



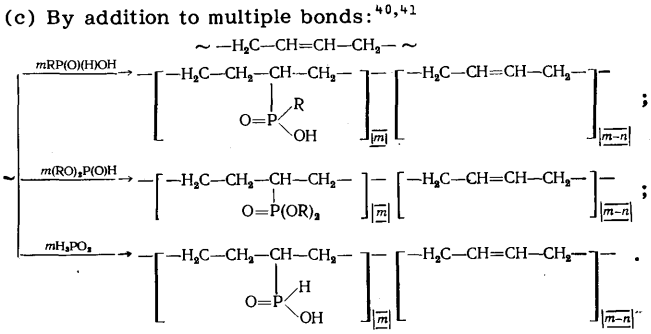
(b) By substituting iodine atoms in poly-p-iodostyrene:[38]



or by substituting chlorine atoms in the polymer:[39]

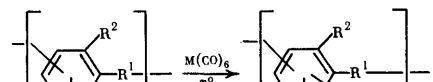


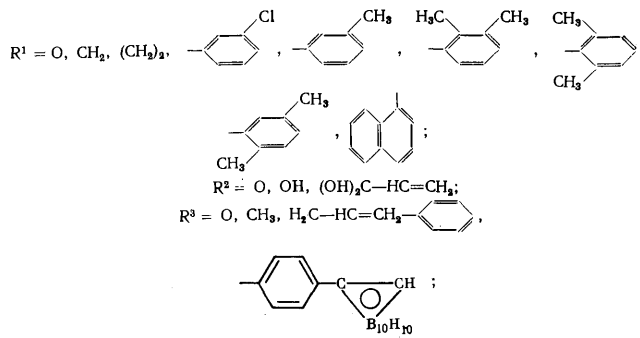
(c) By addition to multiple bonds:[40,41]



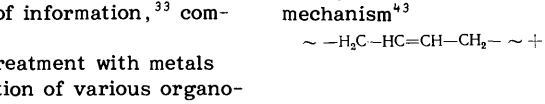
(d) By the π-complex formation reaction involving polymers.

π-Arenemetal tricarbonyl polymeric or oligomeric complexes have been obtained via the following mechanism:[42]





Polymeric π-complexes of metals are obtained via the mechanism[43]



The reactions of the chlorides of *o*-, *m*-, and *p*-carbaboranedicarboxylic acids with cellulose lead to the formation of the corresponding cellulose esters which are able to produce a residue on heating with a high "coke content".[44]

There exist also a wide variety of other modification reactions leading to the formation of organoelemental polymers. They all result in the formation of heterounit polymers.

IV. THE HETEROUNIT STRUCTURE OF ORGANOELEMENTAL POLYMERS

The concept of the heterounit structure of polymers is equally applicable to organoelemental polymers, as it is in fact to all other macromolecular compounds, being a general phenomenon in this field of chemistry.[45,46] The syntheses of polymers involve various side reactions leading to the formation of anomalous units and hence to the appearance of heterounit polymers. Various reactions and other causes responsible for the formation of anomalous units in the polymerisation and polycondensation of monomers and also in the modification of polymers are presented below. The statistical distribution of isotope atoms, which occurs in all polymers, should be added to this factor. As a result, a more correct formula for real polymers is as follows:

$$-[-(M)_{|m|}-(A)_{|n|}-]_x-\ ,$$

where M is the normal unit, A the anomalous unit and *m* and *n* are coefficients indicating the statistical distribution of anomalous units of different kinds. On the other hand, the formula usually employed, i.e.

$$-[-M-]_x-$$

is idealised and is never really valid.

The formation of heterounit polymers as a result of various side reactions proceeds differently depending on the character of the latter. This is clearly seen when the

characteristics of the polycondensation, polymerisation, and modification reactions are compared (Figs.2, 3, and 4). Each of these reactions involves numerous chemical transformations of different kinds which results in many different anomalous units and heterounit structures of different types. Fig.2 presents the set of polycondensation reactions, including numerous reactions leading to a heterounit structure.[45] Fig.3 presents the set of all the possible polymerisation reactions, including normal reactions and those resulting in a heterounit structure.[45] Finally, Fig.4 presents the set of modification reactions, including those resulting in a heterounit structure,[45] which happens mainly in incomplete substitution processes.

Figure 2. The set of polycondensation reactions.

An important feature of organoelemental polymers, which is frequently encountered in practice, is the possibility of the formation of both linear and branched or three-dimensional polymers. This difference is determined by the functionality of the initial monomer or oligomer.[50] It is therefore necessary to distinguish the following types of functionality, namely the possible functionality Φ_p, the practical functionality Φ_{pr}, and the relative functionality Φ_r. When the possible functionality $\Phi_p = 2$, a linear polymer is produced whereas in the case where the values of the possible functionality are greater than 2 the product is a branched or a three-dimensional polymer.[51]

V. STABLE ISOTOPES AS A CAUSE OF THE HETEROUNIT STRUCTURE OF ORGANOELEMENTAL POLYMERS

Among the causes giving rise to a heterounit structure of polymers, mention should be made of the presence of stable isotopes of polymer-forming elements, which are distributed statistically in the macromolecular chain. The influence of isotopes has been demonstrated particularly strikingly in relation to the copolymers of ethylene, propene, and styrene by comparing them with their deuteriated analogues.[46-48] The copolymers have the following structures:

$$-\left[-(-CH_2-CH_2-)_{\overline{m}}-(-CD_2-CD_2-)_{\overline{n}}-\right]_x-$$

$$-\left[-\left(-CH_2-\underset{CH_3}{CH}-\right)_{\overline{m}}-\left(-CD_2-\underset{CD_3}{CD}-\right)_{\overline{n}}-\right]_x-$$

$$-\left[-\left(-CH_2-\underset{C_6H_5}{CH}-\right)_{\overline{m}}-\left(-CD_2-\underset{C_6D_5}{CD}-\right)_{\overline{n}}-\right]_x-.$$

In all the cases investigated, a distinctive effect of the content of hydrogen isotopes on the properties of the polymers was observed.

Table 5 lists the stable isotopes of the elements used to synthesise polymeric structures.

Table 5. The stable isotopes of polymer forming elements.[49]

Element	Stable isotopes	Relative distribution, %
Hydrogen	H, D	H (99.984), D (0.016)
Boron	^{10}B, ^{11}B	^{10}B (18.8), ^{11}B (81.2)
Carbon	^{12}C, ^{13}C	^{12}C (98.9), ^{13}C (1.1)
Nitrogen	^{14}N, ^{15}N	^{14}N (99.6), ^{15}N (0.4)

VI. SURVEY OF POLYMERS IN TERMS OF GROUPS IN THE PERIODIC SYSTEM

The organoelemental polymers known at the present time are divided into two large groups depending on the structure of the main chain—homochain and heterochain polymers.[9,11] Among homochain polymers, the group with the largest number of representatives is that of carbochain polymers. Homochain polymers based on other elements are extremely few in number and are not quite so important. However, we may mention that homochain polymers of the following eight elements are known at the present time: C, B, Si, Ge, P, S, Sb, and Se.

Heterochain polymers based on a large number of elements in the periodic system are a much more important class of organoelemental polymers. Almost all the elements are capable of forming heterochain polymers. Various polymers of the elements in the Periodic System, starting from Group I and extending to Group VIII, are now known. Heterochain polymers containing the following Group I elements have been described: H, D, Li, Na, K, Cu, and Ag. Among them, the copper and hydrogen compounds are of practical importance. Polymers containing isotopes of various elements are of considerable interest for the understanding of the characteristic features of the reactions and properties of polymers.[46-49] Thus polymers containing a heavy hydrogen isotope (deuterium) are important for the explanation of the heterounit structures of a series of polymers. "Heavy" polymers in which the hydrogen has been fully or partly substituted by deuterium have been obtained with the aid of this procedure. The properties of such "heavy" polymers differ significantly from those of their hydrogen analogues.[46-49] "Heavy polyethylene", "heavy polypropylene", and "heavy polystyrene" have been obtained in this way:[46-49]

$$-\left[-CD_2-CD_2-\right]_x- \quad -\left[-CD_2-\underset{CD_3}{CD}-\right]_x- \quad -\left[-CD_2-\underset{C_nD_5}{CD}-\right]_x- .$$

Heterochain organoelemental polymers containing the following Group II elements are known: Be, Mg, Zn, Ca, Ba, Cd, and Hg. Homopolymers and copolymers of metal-containing alkali and alkaline earth metal (Ca, Sr, and Ba) monomers have been described.[52-54] Magnesium compounds have found particularly extensive applications in organic synthesis.

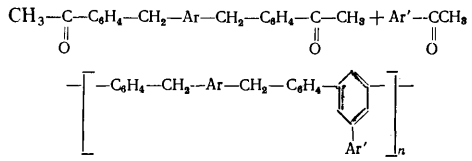
Polymers containing B, Al, Ga, Ce, and Tl are known for Group III elements. Polymers containing boron and aluminium have attracted particular attention among them. The formation of coordination polymers as well as a wide variety of condensation reactions leading to the formation of macromolecular compounds are characteristic of Group III elements.

The homochain polymers of boron, whose main chian consists only of B–B bonds, constitute a group of polymers with a small number of representatives, which can apparently be accounted for by their tendency to oxidise and hydrolyse.[55,56] Depending on the molecular weight, the polymers are colourless or yellow or brown powders. Some polymers are soluble in organic solvents, but no solvents have been found for the majority of them. The thermal stability of the polymers with B–B bonds does not exceed 200 °C. Heterochain boron compounds with B–C bonds have not found practical application because of the considerable tendency of the B–C bond to hydrolyse and, in aliphatic compounds, to oxidise.

Polymers containing polyhedral borane groups have appeared only in the last 15–20 years. The information available in the patent literature indicates their possible use as protective coatings on glass, wood, metals, and other surfaces.[57] In compositions with other polymers, they can be used as thermostable rubbers[57] or as highly effective rocket fuel.[58]

The discovery of carbaborane was the first step towards the creation of a new field of the chemistry of organoboron polymers containing carbaborane fragments. Carbaborane-containing polymers are obtained by both polymerisation and polycondensation methods. However, the polycondensation method of synthesis has come to be most widely used. Among the carbaborane-containing polymers of the polycondensation type, polyphenylenes,[59-63] phenol-formaldehyde polymers,[64-67] polyesters, polyamides,[68-76] and polysiloxanes[77-87] have been most thoroughly investigated at the present time.

Polyphenylenes, the first stage in the synthesis of which can be represented schematically in the following manner have been described:[59,60]



where Ar = *o*-, *m*-, or *p*-carbaboranylene and Ar' = phenyl, benzyl, or *o*-, *m*-, and *p*-carbaboranyl.

It has been noted[59,60] that the polycondensation reactions of the above compounds proceed unambiguously and are accompanied by the formation of dyphone and also linear and cyclic polyvinylene fragments. The oligophenylenes synthesised contain *o*-, *m*-, or *p*-carbaborane groups in the main macromolecular chain and in some cases also in the side chain and are highly soluble in many organic solvents. All the carbaborane-containing oligophenylenes have low molecular weights (MW = 1100–4600) and their softening temperatures are in the range 150–220 °C; at 400–500 °C in an inert atmosphere in the course of 4 h or in a pressing process involving heating to 400–450 °C (and a pressure of 1000 kg cm^{-2}), they are converted into infusible and insoluble three-dimensional polymers as a result of their interaction via terminal acetyl and ketyl groups. Polyphenylenes with *o*-, *m*-, and *p*-carbaborane fragments in the main chain exhibit an enhanced adhesion to glass fibre, which amounts to 250–350 kg cm^{-2}, and have been recommended as thermostable binders for glass plastics.[60]

Oligophenylenes containing carbaborane fragments in the side chain have been obtained.[59,62] The authors noted that the introduction of carbaborane fragments into the side chain of polyphenylene increases the thermal stability of the latter, but this effect is smaller than for the polyphenylenes containing carbaborane groups in the main macromolecular chain.

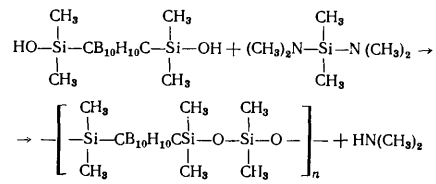
In order to simplify the synthesis of polyphenylene with *o*-carbaborane frgaments, the more readily available ethyl ketal or acetylbiphenylyl-*o*-carbaborane has been used instead of 4-acetylbenzyl-*o*-carbaborane, the synthesis of which is technologically complex.[61,63] The oligophenylenes obtained were less soluble in organic solvents but their thermal stability proved to be greater.

Studies on the synthesis and properties of carbaborane-containing phenol-formaldehyde oligomers of the resol type have continued in recent years.[64,65] The chemical reactions occurring in resols and resites based on 1,2-bis(4-hydroxyphenyl)-*o*-carbaborane on heating under various conditions have been studied. It has been established that in the temperature range 50–200 °C the formation of resol structures proceeds via the usual mechanism not involving the *o*-carbaborane groups. Above 200 °C, significant chemical transformations of the *o*-carbaborane fragments of resites take place and the degree of conversion depends on the heating conditions (in air or *in vacuo*). The high-coke residue from *o*-carbaborane-containing resites its due to the oxidation of the B–H bond in the *o*-carbaborane nuclei, which has been confirmed by X-ray diffraction and EPR data.[64–66] Adhesives with a high strength and thermal stability have been obtained from *o*-carbaborane-containing resol oligomers.[67]

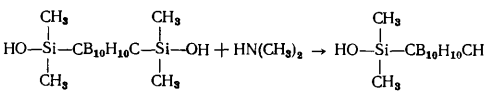
There has been an increase of interest recently in the study of the properties of the polyesters and polyamides with carbaborane fragments obtained previously.[68–76] The structural-chemical transformations of *o*- and *m*-carbaborane-containing polyarylates on isothermal heating in the temperature range 225–235 °C have been investigated by infrared spectroscopy. It has been established that processes involving the rupture of the ester linkage, changes in the carbaborane fragments (a change in the B–H bond and the appearance of the B–O–B bond), and the formation of cross-linked structures take place at a temperature as low at 225 °C. A comparative study of the thermal stabilities of polyarylates with various structures has been carried out.[70] Problems concerning the chemical stability of polyamides with carbaborane-containing fragments and their anti-friction properties have been examined.[71–76]

The most numerous and best investigated class of carbaborane-containing polymers is that of carbaboranesiloxane polymers. Investigations of the synthesis of *m*-carbaborane-containing polysiloxanes of the "Dexsil" type and of their properties are being continued vigorously. The difficulty of the synthesis and vulcanisation of these polymers, in which a high thermal stability is combined with elasticity, prevents their practical application.

A new method of synthesis of linear "Dexsils" is based on the condensation of an *m*-carbaborane-containing disilanol with a reactive silane, for example, bis(*NN'*-dimethylamino)-dimethylsilane or bis(*NN'*-dimethylcarbamato)dimethylsilane, under mild conditions:

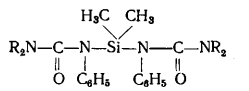


The side reaction

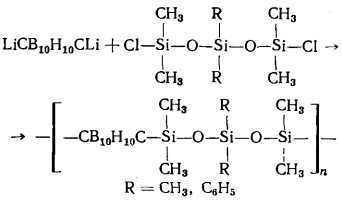


prevents the formation of "Dexsils" with higher molecular weights.

"Dexsils" with molecular weights in excess of 25000 have been synthesised using stable bis(ureido)silanes as reactive silanes:[77,78]



Another, very convenient method of synthesis of "Dexsils" directly from *m*-carbaborane via the following mechanism has been proposed:[79]



However, the molecular weights of the polymers thus obtained are low.

Studies have been made of the thermal, thermo-oxidative, and hydrolytic stabilities of poly-*m*-carbaboranylene-siloxanes.[80,81] The practical value of poly-*m*-carbaboranylenesiloxanes, in which a high thermal stability (up to 500 °C) is combined with excellent fire resistance (oxygen index 62), has been noted in Peters' review.[82] These polymers have found extensive applications as liquid phases in gas chromatography for the separation of organosilicon and

organic substances[83] and for the analysis of polycyclic aromatic hydrocarbons.[84]

Adhesive compositions, capable of being used for a long time at 600 °C and of withstanding a temperature of 1200 °C for brief periods, have been produced on the basis of *m*-carbaborane-containing polysiloxanes.[85] Poly-*m*-carbaboranylenesiloxanes are used for the coating of conductors and other articles which have to withstand a temperature of ~300 °C[82,86] and also as lubricating materials for high-temperature nuclear equipment.[87]

Thus the literature data published in recent years permit the conclusion that boron-containing polymers and particularly carbaborane-containing polymers have attracted the attention of investigators. The study of the properties of these polymers and their modifications and the search for new simpler ways of synthesising them are of particular interest.

Polymers containing the following Group IV elements have now been synthesised: C, Si, Ti, Ge, Zr, Sn, and Pb. This group of polymers has the greatest number of representatives: polymers containing carbon and silicon are of particular importance in practice.

The continued interest in the creation of new materials with a set of valuable properties, some of which are characteristic of organosilicon polymers (frost resistance, thermal stability, permeability, etc.) has stimulated further development of studies on the synthesis and properties of polyorganosiloxanes and copolymers based on them.[88]

The polydiethylsiloxane rubber, which has been studied in detail recently,[89,90] has extremely interesting properties. The properties of various block copolymers containing fragments of the polydiethylsiloxane chain as a flexible block have attracted attention. Polycarbonate-siloxanes, polycarbonate-urethane-siloxanes, polysulphone-siloxanes, and polyarylate-siloxanes have been most thoroughly investigated and have been adequately described.[91,92]

Polyorganosiloxanes containing metal atoms in the polymer chain have found extremely varied practical applications.[93] Polyaluminoorgano-siloxanes are used as catalysts of the hardening of various organosilicon oligomers.[93] Polystannoorganosiloxanes are employed as hydraulic liquids, thermostable coatings, inhibitors of the oxidation of siloxane liquids, and modifying agents for rubber mixtures based on siloxane raw rubbers.[93] Polytitano-organosiloxanes, polyvanadium-phenylsiloxanes, and polyzirconium-aluminophenylsiloxanes are effective catalysts of various processes.[93] A technology for the industrial manufacture of many polymers has been developed.[94]

Among polymers containing Group V elements, extremely numerous and practically important products with elements such as N, P, As, Sb, and Bi are encountered. Among them the nitrogen and phosphorus compounds are especially important. The introduction of a phosphorus atom into the macromolecules of various polymers makes it possible not only to imporve their important properties such as thermal stability and colour fastness,[95] fire resistance,[96] hydrophilicity,[97] and physicomechanical indices but also to synthesise polymeric materials capable of ion exchange as well as polymers possessing oxidation-reduction properties and biological activity.[98]

Phosphorus-containing polymers can be synthesised by polymerisation, polycondensation, and chemical modification methods. The copolymerisation of unsaturated organic monomers with an organophosphorus monomer is one of the promising ways of obtaining organophosphorus polymers, which permits an extensive modification of the properties of various polymeric materials.

Organophosphorus monomers enter into the free-radical copolymerisation reaction with virtually all the usual vinyl monomers and the introduction of small amounts of phosphorus frequently imparts new and valuable qualities to the polymers. The diene, methacrylate, and styrene derivatives of phosphorus are of greatest interest for copolymerisation.[99]

Depending on the chemical nature of the fragments incorporated in the copolymer chain, the copolymers of phosphonodienes are plastics or rubber-like materials and, by virtue of the presence of polar phosphoryl groups, they exhibit an improved adhesion to glass, metals, and other surfaces. When phosphonodienes are introduced into a copolymer, the most significant effect is manifested in the improvement of the fire resistance of the material. Methods for the preparation of transparent colourless, incombustible organic glasses have been developed on the basis of copolymers of methyl methacrylate and phosphono-2,3-dienes.[99]

The introduction of phosphorus-containing groups into the polymer chain leads to the self-stabilisation of polymers.[100] The introduction of such groups via the copolymerisation of the monomers has not so far become of great practical importance. However, this procedure has significant advantages in special methods for the processing of polymers, in particular for the formation of poly(vinyl chloride) materials from solution.[101]

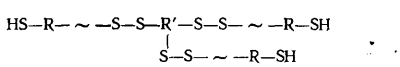
The most important feature in the chemical modification of polymers involves the introduction of phosphorus-containing groups via polymer-analogue reactions.[41,102] Phosphorylation of synthetic rubbers increases their thermal stability and lowers their combustibility.[100] Phosphorylation of chlorosulphonated polyethylene greatly improves its technological properties and strength parameters.[100] The study of the phosphorylation reactions of chloromethylated polystyrene and the copolymers of styrene with aromatic vinyl compounds has shown that the polymers obtained possess ion-exchange properties, effective mechanical properties, and improved porosity and thermal stability.[100] The phosphorylation of polymers at the stage in which degradation processes develop gives rise to a secondary stabilisation of the polymeric products and improves their operating characteristics.[100]

There has been an apprecialbe growth of interest in the last decade in polyphosphazenes—polymers with inorganic main molecular chains consisting of alternating phosphorus and nitrogen atoms in organic or organoelemental frameworks surrounding the phosphorus atom. The interest in these polymers is due to their high thermal stability and fire resistance,[104] their effective elastic properties,[105] and their improved resistance to degradation by oxidants and reductants.[95]

The use of polyphosphazenes for medical purposes, which has been developing in two directions, is of great interest. The first application involves the study of their biological compatibility and thrombogenic properties in order to elucidate the possibility of using such polymers in surgery. Thus the high stability of polyfluoroalkoxyphosphazene as regards clotting, compared with ftoroplast-4 [a type of PTFE] and polyethylene for medical purposes has been demonstrated.[106] In combination with the constancy of its physicomechanical and mechanical properties after prolonged contact with a medium close in composition to that of blood, this renders this polymer extremely promising for the manufacture of articles used in vascular surgery. The other type of research on polyorganophosphazenes for medical purposes involves the synthesis of polyphosphazenes as carriers of medicinal drug molecules and as absorbable surgical materials.[107]

For Group VI elements, polymers containing O, S, Cr, Se, Mo, W, and U are known; the most important of these are oxygen- and sulphur-containing polymers. The great interest of investigators in sulphur-containing polymers and their increasing practical use are associated with their valuable properties and the ready availability of the raw materials combined with the simple methods of their synthesis.

Interesting representatives of sulphur-containing polymers are polysulphide oligomers containing sulphur in the main chain. The majority of industrial polysulphide oligomers have a weakly branched structure with terminal SH groups:



The presence of such end groups, which are readily oxidised under mild conditions makes it possible to employ these oligomers as a basis for the preparation of composite materials (materials for hermetic seals, mastics, and casting compositions).[108]

The different operating conditions for hermetic materials of different brands are striking. Thus the minimum operating temperature varies from −30° to −60 °C, while the maximum operating temperature varies from +80° to +140 °C. The difference between the minimum operating temperatures of hermetic materials can be accounted for by the recipe specifying their composition. The maximum operating temperature usually depends on the presence, type, and amount of the modifying additive, the type of vulcanising agent, and the filler. Polysulphide oligomers are non-toxic, burn with difficulty, and are non-explosive. Hermetic materials based on them do not have a harmful effect on man.[109]

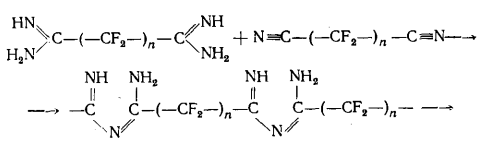
Among the polymers containing Group VII elements, compounds with F, Cl, Br, I, and Mn are known, those containing fluorine and chlorine being most widely used. Many fluorinated plastics play an important role in the development of modern technology.

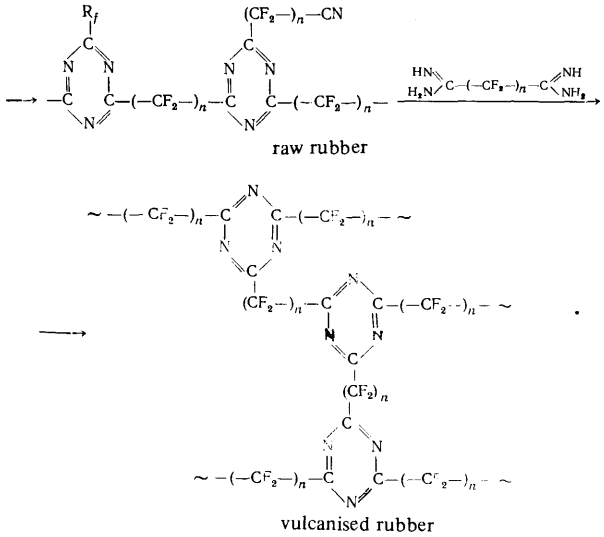
Carbochain fluorine-containing polymers are most widely used at the present time. Among them, polytetrafluoroethylene (PTFE) is the most thermostable polymer. It is resistant to the action of oxygen up to comparatively high temperatures, but it is a high-melting crystalline material and becomes ealstic only at temperatures close to the decomposition temperature. Despite its unique properties, the making of articles from PTFE is fairly difficult. Methods based on sintering an mechanical treatment are largely employed.

In order to obtain elastomers from fluorinated hydrocarbons, it is necessary to disturb the regularity of the structure of the polymer chain in order to rule out or diminish crystallisation. For this purpose, various "hinged" groups are introduced by copolymerising PTFE with fluorinated or non-fluorinated monomers. Tetrafluoroethylene copolymerises effectively with both fluorinated and non-fluorinated monomers, forming numerous copolymers with a wide range of valuable properties. In recent years it has been possible to create a series of tetrafluorethylene copolymers which, whilst retaining many of the valuable properties of PTFE, can be worked with the aid of the usual equipment.[110]

The introduction of the triazine ring into chains of perfluorinated polymers makes it possible to increase the thermal stability of the raw rubber and gives rise to the possibility of obtaining rubbers whose vulcanisation network has a thermal stability not inferior to that of the main chain. Methods are known for the introduction into some of the triazine rings of perfluorinated groups with functional substituents, which can be employed for vulcanisation.[110]

The starting material for the preparation of perfluoroalkylenetriazine rubbers consists of the dinitriles of perfluorinated dicarboxylic acids:





raw rubber

vulcanised rubber

According to literature data the rubbers produced from triazine raw rubbers retain a fairly tensile strength after heating for a long time. Perfluoroalkylenetriazine raw rubbers are resistant to the action of strong acids, but are decomposed by bases, including ammonia.

Apart from the triazine ring, other heterocyclic systems can be introduced into the polymer chain; oxadiazoles, benzimidazoles, thiadiazoles, pyromellitimides, etc.

Perfluorinated rubber-like polymers based on olefin oxides can be synthesised from diiodo-derivatives in the presence of mercury on irradiation with ultraviolet light. The resulting elastomer has excellent low-temperature properties and a high thermal stability:[110]

Despite the interesting properties of this elastomer, it is only a model compound, because of the difficulty of obtaining the initial diiodo-derivatives. A method of synthesis suitable for practical application has not yet been found.

Fluorinated olefins are usually copolymerised with tetrafluoroethylene or vinylidene fluoride in an aqueous emulsion and it is also possible to carry out the process in a solvent.

At temperatures up to 200–250 °C, the structure of the raw fluororubbers does not undergo appreciable changes for a long time. In terms of their resistance to organic liquids, particularly at high temperatures, the rubbers prepared from the raw fluoro-rubbers are appreciably superior to the rubbers obtained from all other sources. In view of the extremely wide range of applications of raw fluoro-rubbers (materials for hermetic seals), their most important parameter is the residual compressive deformation. Because of this, investigators have concentrated their efforts on improving this characteristic.

Group VIII elements of the Periodic System which have entered into the compositions of polymers synthesised are iron, cobalt, and nickel. The three elements form part of various thermostable coordination polymers whose properties are determined by the chemical nature of the ligand and the metal forming the coordination centre.

The infusibility and insolubility of the majority of the coordination polymers restrict their wide-sclae application. Studies designed to obtain metal complex iron, cobalt, and nickel polymers without their conversion into a three-dimensional structure, which ensures the retention of solubility by the polymers, are therefore of great interest.[111,112] The polymeric complexes synthesised contain metal carbonyl

fragments in the polymer chain, are soluble in organic solvents, and are capable of forming strong films and coatings with a high degree of adhesion to glass and metals. After the films have been subjected to a heat treatment, they undergo structure formation and an increase in strength and the polymer acquires at the same time new properties. Thus the decomposition of the iron tricarbonyl complex in the polymer matrix involves the formation of a metallic phase and the film acquires ferromagnetic properties.[113]

Metal-containing polymers have found applications in a wide variety of fields: an application associated with the improvement of various properties of polymers and compositions based on them and an application based on the appearance of new properties due to the presence of the metal in the main chain or a side chain.[21]

It is thus clear that the development of the fields of organoelemental polymers has now placed at the disposal of polymer science a considerable number of organoelemental polymers, many new examples of which are being added each year.

---o0o---

In conclusion of the discussion of the advances in the synthesis and investigation of organoelemental polymers, we may conclude that a new major field of polymer science has now arisen and is developing vigorously.

At the present time this field embraces a large number of organoelemental polymers, for the synthesis of which 75 elements of Mendeleev's Periodic System have been used and the number of polymers of this type increases rapidly. Organoelemental polymers are substances with a wide range of specific properties which depend both on their composition and on their chemical structure.

As a result of the wide-scale application of the elements of the Periodic System in the synthesis of polymers, not only a quantitative growth and the appearance of many new qualitative changes in the structure of the groups forming the polymer macromolecules but also the appearance of a new set of properties have been observed.

The considerable advances in the synthesis and study of groups of organoelemental polymers such as polysiloxanes, polymetallosiloxanes, phosphorus-containing polymers (including polyphosphazenes), organoboron (including various polycarbaboranes), organosulphur, and coordination polymers of the chelate type (including polyferrocenes), as well as polymers incorporating various fluorocarbons and their copolymers must be specially emphasised.

Organoelemental polymers include a large group of thermostable polymers, a series of substances with valuable biological properties, and also substances with a high electrical conductivity and semiconducting properties, a high elasticity, and an oustanding strength and hardness.

The main task of the investigators concerned with polymers is the expansion of the range of organoelemental macromolecular compounds, the development of new and improvement of existing methods of synthesis of such substances, and the study of their properties with the aim of their practical application.

Kinetics and Mechanism of the Catalytic Cyclotrimerisation and Polycyclotrimerisation of Isocyanates

A.K.Zhitinkina, N.A.Shibanova, and O.G.Tarakanov

The available literature data concerning the kinetics and mechanism of the cyclotrimerisation and polycyclotrimerisation of isocyanates in the presence of catalysts of various kinds are presented and analysed in this review. Attention has been concentrated on studies published during the last ten years. A number of features characterising the kinetics of the cyclotrimerisation of isocyanates have been deduced from the information about the process presented here. The mechanism of the reaction in the presence of basic catalysts is examined.
The bibliography includes 263 references.

I. INTRODUCTION

Among the numerous reactions of isocyanates, their cyclotrimerisation (CT) and polycyclotrimerisation reactions have found extensive applications at the present time. This can be accounted for by a number of factors, namely the high thermal stability, fire resistance, and resistance to the action of organic solvents of corrosive media of isocyanurate-containing polymeric materials and the large assortment and availability of catalysts of the cyclotrimerisation of isocyanates, which permit the specific synthesis of the polymers under mild conditions.

The CT reaction of isocyanate groups is used in polymerisation processes in the preparation of coatings, films, varnishes, elastomers, adhesives, and various resins.[1-9] However, the greatest number of advances in this field concern the preparation of polyisocyanurate-containing foam plastics,[10-50] which have been finding increasing applications as thermostable, fire resistant, thermally insulating, electrically insulating, sound proofing, and constructional materials in applied fields such as building, refrigeration technology, instrument making, transport, shipbuilding aeroindustry, space technology, etc.[29,30,51-53]

Despite the fact that the cyclotrimerisation of isocyanates was achieved more than a century ago,[54-56] their study and practical utilisation were not resumed until the end of the 1960's and the beginning of the 1970's. Numerous communications devoted both to the study of the CT and cocyclotrimerisation reactions of isocyanates[57-117] and to the synthesis of various materials based on them[1-53] have now been published. The majority of the studies concerning the CT reactions were undertaken to investigate the efficiency of various kinds of catalysts in this process; many fewer studies have dealt with the reaction kinetics and mechanism. The data published in the above communications are frequently contradictory. At the same time the great interest in this process, associated with the practical possibilities for its utilisation in the formation of new materials, requires the analysis and survey of the data concerning it which have now accumulated. The existing reviews[8,41-43,58,62,63,118-129] do not contain sufficiently complete information about this question.

The cyclotrimerisation of isocyanates in the absence of a catalyst takes place slowly at 373 K. In order to carry it out under milder conditions and to ensure process selectivity, a large assortment of both acid and basic catalysts is used at the present time. The acids are fairly weak catalysts of the above process and are effective only at elevated temperatures.[41,130] The basic catalysts of the cyclotrimerisation of isocyanates known at the present time are tertiary amines,[5,12,15,32,50,59,84,95,100,115,131-138] phosphines and phosphites[5,96-98,139,140] metal alkoxides,[95,102,142,141-144] metal carboxylates[4,5,9,56,59,60,62,82,83,101,102,108,109,115,118,125,145,146] metal oxides,[77,110] quaternary ammonium bases as well as their alkoxides and carboxylates[8,95,147-150] hydrides,[111] cobalt, iron, and tin acetylacetonates,[79,80] organometallic compounds,[61,112,113,145,146,151-154] combined catalysts (amine/epoxide, amine/aldehyde, amine/imine, amine/alkylene carbonate, amine/alcohol, amine/epoxyalkane/proton donor, amine/carboxylic acid, amine/metal carboxylate, amine–organometallic compound, alkali metal carboxylate/oligoether, and amine/metal alkoxide),[6-8,21,25,29,31,34,45-50,74,88,91-95,104,116,118,120,128,150,155-160,161-171] and other catalysts (aminoimides, sulphonium zwitter-ions, alkali metal salts of aminoacids and glycine amide, as well as their combinations with other catalysts).[24,172-179] Among the entire enormous assortment of the catalysts quoted, alkali metal and alkaline earth metal carboxylates, quaternary ammonium carboxylates (and also alkoxides or phenoxides), certain tertiary amines, namely mono- di- and tri-substituted dialkylaminoalkylphenols and *NN'N"*-tri(dialkylaminoalkylene)-*sym*-hexahydrotriazines, as well as certain combined catalysts and catalytic systems are at present of greatest practical importance.[8,10-40,45,46,128,148-150,161-168,180-182]

II. CATALYSIS BY TERTIARY AMINES AND CATALYTIC SYSTEMS BASED ON THEM

The relative catalytic activities of various tertiary amines in the CT reaction of isocyanates have been estimated.[50,95,136] A number of investigators have noted in this connection that, in the presence of aliphatic or alicyclic tertiary amines, the formation of cyclic trimers from isocyanate is observed only

at elevated temperatures.[84,137] Even in the presence of an amine active in the urethane-formation process, such as triethylenediamine (TEDA), the formation of only the phenyl isocyanate (PIC) dimer has been observed.[94] In the presence of an alcohol or a urethane and an amine, an increase of the yield of the trimer has been noted, which led Kogan to propose a mechanism for the cyclotrimerisation of an isocyanate in a system of this kind via the formation of a dimer and allophanate:[84]

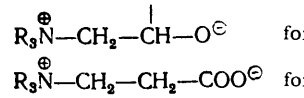
$$PhNCO + C_2H_5OH \begin{cases} \xrightarrow{\sim 293\ K} PhNHCOOC_2H_5; \\ \xrightarrow{398\ K} PhNHCON(Ph)COOC_2H_5 + (PhNCO)_2; \\ \xrightarrow[398\ K]{amine} (PhNCO)_3 + PhNHCOOC_2H_5. \end{cases}$$

Subsequent studies have established, however, that the formation reaction of the isocyanate dimer is independent of the CT process[62,79] and that the formation-dissociation reaction of the allophanate is coupled with the CT process.[50]

The most active tertiary amines in relation to the CT reaction of isocyanates proved to be mono-, di-, and tri-(dialkylaminoalkyl)phenols as well as symmetrical tri(dialkylaminoalkyl)hexahydrotriazines, which have found fairly extensive applications in real processes designed to synthesise polyisocyanurate-containing materials.[31-40] Early investigations[92,94,95] already established, however, that compounds such as olefin oxides, aldehydes, alkyleneimines, and 2-methylimidazole are effective cocatalysts of the CT reaction of isocyanates in the presence of tertiary amines. It has been shown[80] that ethylene carbonate and β-propiolactone can function as cocatalysts in analogous systems and alkylene sulphides have also been used for this purpose in other investigations.[72,73] Ketones (isobutyl methyl ketone and acetone), ethers (dioxan, tetrahydrofuran, and the dimethyl ether of diethylene glycol), esters (ethyl acetate), as well as acrylonitrile do not activate appreciably the CT reaction of isocyanates in the presence of tertiary amines,[94] although subsequently the acceleration of the CT reaction of 2,4-tolylene diisocyanate (2,4-TDI) in the presence of a number of ethers, including epoxides, was observed.[134,136] However one should note that in this case ethers behaved more like a second solvent (they were introduced in a large excess relative to 2,4-TDI), influencing the properties of the medium and the specific solvation of the reactants. The data in Table 1 as well as the efficiencies of various types of catalysts in the CT reaction of isocyanates, quoted by Behrendt and Joel,[50] show that, in the presence of an epoxide, the catalytic activities of all the amines investigated increase. The basicity of the amine is not then the only decisive factor; the process is also influenced by the structure of the substituents at the nitrogen atom.[136]

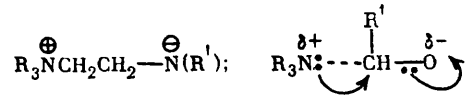
The relative efficiences of all the cocatalysts in the CT reaction of phenyl isocyanate in the presence of triethylenediamine have been estimated[94] and it has been established that low-molecular-weight olefin oxides and aldehydes are much more effective cocatalysts than their higher homogogues. The cocatalytic activity series of olefin oxides has been established: epoxyethane > epoxypropane > epoxybutane > epichlorohydrin > styrene oxide > 1,2-epoxyhexane > 1,2-epoxyoctane. It has also been demonstrated that *N*-methylethyleneimine is itself a catalyst of the CT reaction of isocyanates, but in combination with TEDA its activity increases. This also happens when it is combined with an epoxyalkane.[94] Having estimated the dependence of the rate of the CT reaction of 2,4-TDI on the catalyst, cocatalyst, and monomer concentrations, Beitchman[92] showed that, with increase of the concentration of each ingredient of the catalytic mixture, the rate of reaction increases too and in all cases the reaction obeys a formal first order kinetic equation. By analogy with the hypothetical structures of the zwitterions formed in the CT reactions of isocyanates in the presence of tertiary amines, proposed by Jones and Savill,[88] i.e.

for the amine/epoxyalkane combination,



for amine/propiolactone,

he suggested, in discussing the possible mechanism of the observed cocatalytic effect of various compounds in the above reactions, that the catalytic structures



are active for the amine/imine and amine/aldehyde combinations. Bearing in mind the presence of an induction period in the CT reaction of an isocyanate in the presence of amine/cocatalyst systems and the absence of autocatalysis by the reaction product (the isocyanate dimer and trimer), Beitchman also suggested that the observed autocatalysis is associated with the formation of an intermediate transition compound at a constant concentration and that it may comprise a catalyst–isocyanate complex with one or two isocyanate molecules, in conformity with the following mechanism:

$$C + I \rightleftarrows CI,$$
$$CI + I \rightleftarrows CI_2,$$
$$CI_2 + I \rightleftarrows C + T,$$

where C = TEDA/cocatalyst, I = isocyanate, and T = trimer.

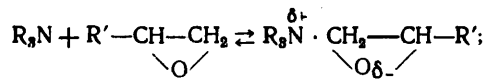
Table 1. The relative activities of tertiary amines in the cyclotrimerisation of isocyanates.[95,136]

In chlorobenzene (4 *N* PIC solution Ref.95)		2,4-TDI (0.35 mole), in bulk, in the presence of epoxypropane (0.03 mole) (Ref.136)			
catalyst	relative rate of CT	catalyst	amount of amine, mole	τ up to T_{max}, min	pK_a of amine
2,4,6-Tri(dimethylaminomethylene)phenol (I)	1.0	triethylenediamine	0.0022	6.0	8 6
(I) + diglycidyl ether of bisphenol (A) (1 : 1)	1.2	*NNN'N'*-tetramethylbutylenediamine	0.0035	30.8	10.6
NN'N''-Tri(dimethylaminopropylene)-*sym*-hexahydrotriazine (II)	2.4	pyridine	0.0025	75.0	5.29
(II) + diglycidyl ether of bisphenol (A)	7.7	*N*-methylmorpholine	0.0023	**	7.41
Triethylamine + epoxypropane	*	2-methylimidazole	0.012	**	—
2-Hydroxypyridine	*	—	—	—	—

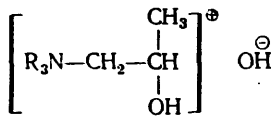
*The reaction was not observed for 30 min.
**The reaction was not observed for 120 min.

Subsequently several studies of the kinetics of the CT reactions of isocyanates in the presence of an amine/epoxide system, which were also designed to elucidate the role of the cocatalysts and the possible process mechanism, were carried out.[6-8,74,120,136,155-158,163,164,168,169,183] Various hypotheses

were put forward concerning the mechanism of the catalytic action of epoxides in this system. Together with the structure of the zwitter-ion proposed previously[94] and discussed in a later investigation,[145,184] the following features were considered: the complex of the epoxide with the amine formed as a result of the partial redistribution of charges without the opening of the epoxide ring:[74]

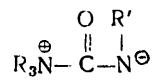


the complex of the epoxide with the isocyanate;[135,136] the product of the interaction of the tertiary amine, the epoxide, and water (traces of which are as a rule present in the catalytic systems):[6,8,94]



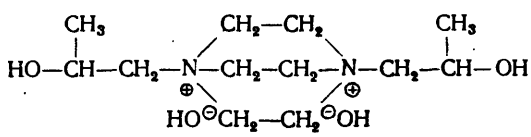
(III)

the complex of 3C* with the isocyanate trimer, where C* is a compound with an active centre initiating the CT reaction of the isocyanate, which can consist either of a zwitter-ion or a product of type (III).[120,155–158] Unfortunately, none of the proposed structures has been demonstrated experimentally. However, it has been confirmed quantitatively that, in the presence of an amine/epoxide system, the rate of cyclotrimerisation of isocyanates varies in proportion to the change in the concentrations of both ingredients,[74] although it has been shown[136] that the proportionality between the rate of the CT reactions of isocyanates and the epoxide concentration is not maintained in all solvents. On the basis of this factor and bearing in mind also the negative result of the Auerbach test for the presence of quaternary ammonium compounds and the constant content of the epoxy-groups in the course of the reaction, the authors explain the cocatalytic effect of epoxides (as well as that of several ethers) by the formation of a complex with the isocyanate. The proposed mechanism of the catalysis of the given reaction presupposes the direct interaction of the tertiary amine with the isocyanate to form a zwitter-ion having the following structure:[135,136]



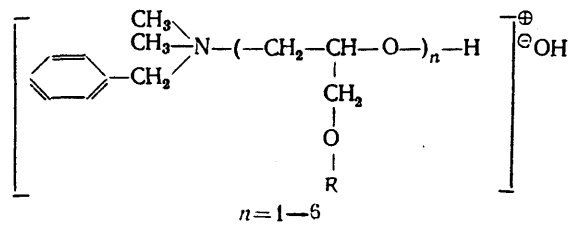
However, one should note that the constant concentration of epoxy-groups in the course of the CT reaction is not apparently an unambiguous indication that there is no possibility of interactions in the system involving the opening of the epoxide ring and the formation of active products, because the concentration of the latter may be extremely low compared with the initial concentration of the epoxide.

The hypothesis of the possible formation of a product of type (III) in the amine/epoxide catalytic system was put forward in an early study by Beitchman,[94] who showed that the product of the interaction of TEDA, epoxypropane, and water, for which he proposed the structure



is an effective catalyst of the cyclotrimerisation of TDI. In the case where TEDA and epoxypropane were thoroughly dried and the CT reaction was carried out in a tube *in vacuo*, the formation of a trimer was not observed over a period greater than 4.5 h. Taking this finding into account, the author presumes that the presence of traces of moisture in the amine/epoxide catalytic system is essential for the formation of an active catalytic complex. However, the CT reaction of the isocyanate in the presence of a product of type (I) retained an induction period,[94] which is evidence that the formation of this product is not a sufficient condition for the effective initiation of the process.

In later studies[6,8] it was also shown that under conditions excluding the access of moisture to the dimethylbenzylamine/glycidyl phenyl ether catalytic system, the CT reaction of 2,4-TDI is not observed. These workers also noted the disappearance of epoxy-groups in the interaction of equimolar amounts of benzyldimethylamine, glycidyl phenyl ether, and water. The appearance of the absorption band due to the hydroxy-group was then noted in the infrared (IR) spectrum. The authors proposed the following structure for the products isolated under these conditions:



$n = 1—6$

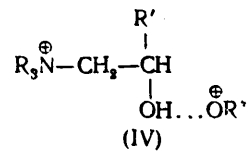
It was shown that their catalytic activity in the CT reaction of 2,4-TDI and poly(diene diisocyanates) is much greater than the catalytic activity of the amine/epoxide binary system. However, here too the reaction had an induction period. The comparatively high catalytic activity of quaternary ammonium hydroxides in the CT reaction of isocyanates had also been noted earlier.[95] In connection with the results described, catalysts of this kind at one time found practical application in the synthesis of polyisocyanurate materials.[148,149,181,185–187]

The dependence of the rate of the CT reaction of isocyanates on the preliminary contact time between the components of the amine/epoxide system has been reported.[188] In the same communication it is also noted that the presence of a third component—a proton donor—is essential for the formation of an active intermediate compound in the above system. Subsequently it was observed[182] that the interaction of tertiary amines (TEDA, etc), epoxyalkanes, and proton donors (PD) such as alcohols, phenols, or any other compounds with a mobile hydrogen atom (urethane, allophanate, urea, and biuret)[150,189] lead to products of the type of alkoxides (phenoxides) of quaternary ammonium bases, which are much more active catalysts of the cyclotrimerisation of isocyanates than the initial binary catalytic systems and are more active than adducts based on tertiary amines, epoxides, and water.

The dependence of the kinetics of the CT reaction of an isocyanate on the duration of the preliminary interaction of the components of the amine/epoxide and amine/epoxide/PD catalytic systems and also on the type of PD was first investigated in several studies.[163,164,168,190] In the investigation of the kinetics of the CT reaction of phenyl isocyanate

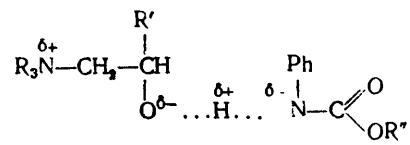
in chlorobenzene in the presence of the 2-methyltriethylenediamine/glycidyl phenyl ether (GPE) catalytic system, it was established that, with increase of the preliminary contact time between the components of the catalytic system and also with increase of its moisture content, the rate of the CT reaction of phenyl isocyanate increases while the induction period shortens.[163,168,190] It has also been observed that, after the preliminary interaction of the amine, the epoxide, and PD such as alcohols and phenol, the activity of the catalytic system investigated in the CT reaction of an isocyanate increases by more than two orders of magnitude, while the induction period is sharply reduced under these conditions. The interaction then terminates after 2–48 h depending on the reaction conditions, the reactant concentrations, and the type of PD, while the active adducts formed are stable during storage in the absence of moisture. It has been observed in addition that the products of the primary and secondary reactions of an isocyanate with alcohol or water (urethane, allophanate, urea, and biuret) can also play the role of active PD in the catalytic system investigated.[163,168] The character of the dependence of the rate of the main reaction and of the reciprocal of the induction period on the treatment time (and hence on the activity) of the amine/epoxide/PD catalytic system is identical in all cases, which indicates the decisive role of the initiation stage in the overall process kinetics. It has also been shown that the duration of the induction period and the rate of reaction depend on the concentration of each of the three components of the catalytic system, i.e. the involvement of all three components is obligatory for the formation of the active products. In the presence of carefully purified components of the amine/epoxide binary mixture the CT reaction of phenyl isocyanate was not observed for several hours.[168] Subsequently the authors studied in detail the role of the PD in the catalysis of the CT reaction of isocyanates by the amine/epoxide system.[150] It has been established by argentimetric titration[150,168] that the concentration of the epoxy-groups decreases with time in the 2-methyl-TEDA/epoxide/PD system; the rate of change of their concentration increases with increase of the amount of PD and when methanol is replaced by phenol. It has been established by dielectrometric and potentiometric titration methods[150,163] that the epoxy-rings are opened during the interaction in the 2-methyl-TEDA/epoxide/PD system and 1:1:1 molecular complexes are formed, their polarity being greater than that of the initial components and their basicity being at the level of that of quaternary ammonium bases. According to IR spectroscopic data,[164,169] the above interaction is accompanied by appreciable changes in the PD structure, particularly by an intense ionisation of the O–H and N–H bonds respectively. Thus it has been shown that the role of the PD in the catalytic system investigated consists in the fact that it is capable of opening the epoxide ring in the presence of a tertiary amine and forms part of the composition of the product—the active catalyst of the CT reaction of isocyanates.

Analysis of studies in the field of the polymerisation of epoxy-compounds in the presence of tertiary amines and alcohols[191–200] which are, in principle, not associated with the cyclotrimerisation of isocyanates but are devoted to the investigation of the interaction in ternary amine/epoxide/alcohol systems, has shown that products of the type of tertiary ammonium alkoxides (phenoxides), which are in fact the effective catalysts of the polymerisation of epoxides, are formed in such systems. Studies in this field[197–199] have shown that the interaction in the amine/epoxide/alcohol system entails the disappearance of epoxy-groups and the appearance of hydroxy-groups with an absorption band at 3280 cm^{-1}, which have been identified[195] as the OH groups in the catalytic complex having the following structure:



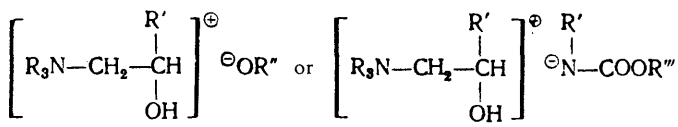
(IV)

The rate of interaction in the amine/epoxide/alcohol system does not depend directly on the basicity of the amine but is to a large extent determined by the steric structure of the latter.[136] It has been suggested[150,168] that analogous reactions take place in the catalytic systems for the cyclotrimerisation of isocyanates based on amines and olefin oxides in the presence of a proton donor. The structure of the products formed in the case of an alocohol as the proton donor is then assumed to be analogous to that of complex (IV) and in the case of a urethane as the proton donor the product is believed to be a complex having the following structure:



(V)

The study of the probability of the formation of donor–acceptor complexes in the amine/epoxide/PD system by the semiempirical quantum-chemical LCAO-MO SF method in terms of the CNDO/BW approximation has shown[201] that compounds of types (IV) and (V) should be formed as transition compounds in the formation of ionic tetraalkylammonium compounds:



(VI) (VII)

It has been established[150,183] that the concentration of adducts of types (VI) and (VII) is proportional to the rate of trimerisation of PIC (the partial order of the reaction with respect to the catalytic adduct is unity). In this case the adduct based on urea proved to be the most active. The adduct based on phenol also showed an enhanced activity. The increase of activity on passing from water and methanol to phenol can be accounted for by the increase of the polarity and basicity of the catalytic adduct formed.[150] The relatively high catalytic activity of the system based on urea can apparently be explained by the fact that water and the products of its interaction with isocyanate exert different influences on the processes investigated, depending on their concentration in the system. In small amounts, they can behave as effective PD cocatalysts, while an increase in their concentration can lead to an appreciable decrease of the rate of cyclotrimerisation of isocyanates.[8,144]

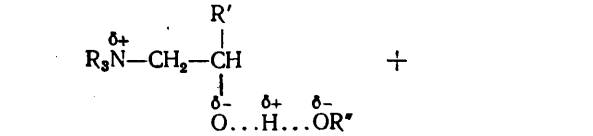
In a weakly polar solvent (for example in chlorobenzene) the form of the kinetic curves for the cyclotrimerisation of PIC in the presence of compounds of the type of quaternary

ammonium alkoxides corresponds to a quasi-unimolecular first-order reaction up to a conversion of ~90% with an induction period whose duration is determined by the concentration and structure of the catalysts. At the end of the induction period, the rate of reaction is close to the maximum value and the concentration order with respect to the monomer is then two.[150]

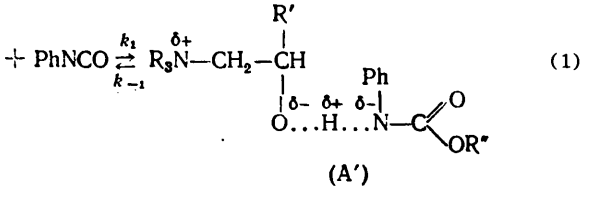
The kinetics of the cyclotrimerisation of isocyanates in the presence of basic catalysts are significantly influenced by acid inhibitors.[150] Presumably, the induction period in the reaction investigated is determined by two factors, namely by the action of the inhibitor and by the slow initiation.

According to the results obtained, the hypothetical process mechanism proposed by Zhitinkina et al.[168] is as follows (Scheme 1):

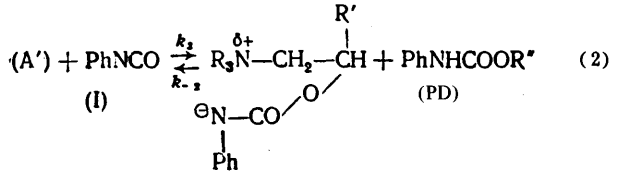
Scheme 1



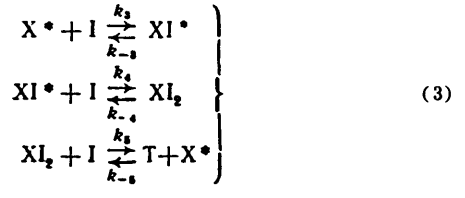
(A)



(A′) (1)



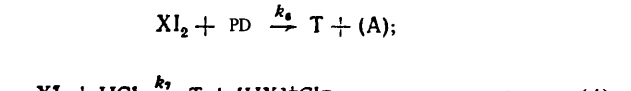
(X*) (2)



(3)

where X* is the initiator.

According to this scheme, the interaction during the induction period between the catalyst and the isocyanate leads to the formation of the initiator X*, which is much more active than the initial catalyst. Stage (2) can then apparently include also more complex interactions between the initial catalytic complex and the isocyanate (or the products of their reactions). On the other hand, when the initial catalyst, obtained from a tertiary amine, an olefin oxide, and a urethane, is used as a proton donor, the process must be regarded as starting with stage (2). The chain termination in stage (3) can then occur as a result of the proton donor present in the system or other impurities (mainly acid ones), for example, HCl:

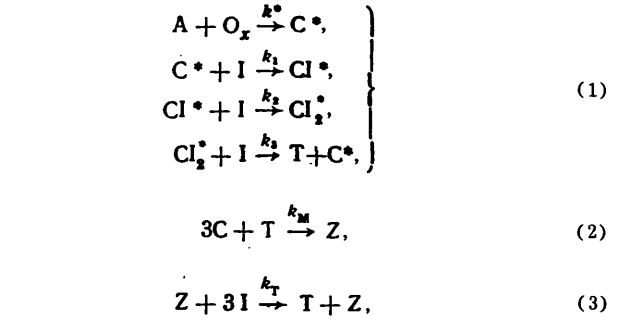


(4)

However, Korzyuk et al.[169] were not able to establish a correlation between the rate of cyclotrimerisation of the isocyanate and the concentration of the quaternary ammonium catalyst. In their study of the kinetics of the cyclotrimerisation of PIC in a mixed solvent (chlorobenzene/dimethyl sulphoxide) by IR spectroscopy, they observed that the reaction consists of two stages and begins under conditions without an induction period. The proportionality between the catalyst concentration and the rate of formation of the trimer is then observed only for the first stage of the process. According to the authors, the observed two-stage nature of the reaction is associated with the rearrangement of the catalyst during the reaction. However, presumably in the systems investigated the anomalous kinetics can be due to the possible interaction of the monomer with dimethyl sulphoxide.[145,146,154]

In the series of studies devoted to the kinetics of the cyclotrimerisation of isocyanates in the presence of an amine/epoxide catalytic system (CS), a special place is occupied by a number of investigations.[120,155–158] In their study of the kinetics of the cyclotrimerisation of *m*-chlorophenyl isocyanate (*m*-Cl-PIC) in dioxan in the presence of the epoxypropane/triethylenediamine catalytic system, the authors found that the trimer obtained in the presence of the TEDA/epoxypropane catalytic system accelerates the cyclotrimerisation of the isocyanate (in contrast to the trimer obtained in the presence of TEDA alone). When it is introduced into the reaction mixture simultaneously with the catalytic system, the trimer does not accelerate the reaction, while, after it has been kept together with the catalytic system beforehand, it does accelerate the cyclotrimerisation of *m*-Cl-PIC and shortens the induction period. From these findings and also taking into account the fact that they found the order of the reaction to be 1–3 with respect to the active centre C* and 2.6 with respect to the monomer, the authors proposed a template mechanism of the catalysis of the cyclotrimerisation of isocyanate. According to this mechanism, the trimer formed plays the role of a template on which three active centres are grouped. This structure of the template catalyst is believed to enable the simultaneous coordination of three isocyanate molecules on the catalyst. Thus the process proceeds via the mechanism (Scheme 2)

Scheme 2



(1)

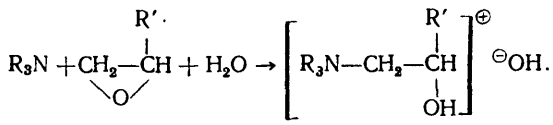
(2)

(3)

where A is the amine, O_x the epoxyalkane, and C* the active centre. The first stage is the formation of the trimer (seed) and the second stage involves the formation of the template catalyst Z, capable of rapidly coordinating three monomer molecules with formation of the final product.

The modelling of the proposed kinetic scheme on an analogue computer makes it possible to attain qualitative agreement between the principal calculated and experimental features of the reaction kinetics. The authors believe that the set of data which they obtained for the CT reaction of isocyanates definitely constitutes evidence in support of the view that a reactive product is formed on a catalyst of the template type consisting of the trimer molecule containing three active centres.[120,155-158]

However, one should not fail to note certain contradictions concerning the proposed mechanism. In the first place the accelerating role of the trimer in the cyclotrimerisation of isocyanates has not been confirmed in a number of studies.[94,136,137,147,150] One of the main features identifying the operation of the proposed mechanism is believed[158] to be a reaction order ranging from 1 to 3 with respect to C*. However, in order to calculate the concentration of C* at the instant of the reaction, the authors employ the effective rate constant k_{eff} for the formation of active centres from the amine and the epoxide, obtained by extrapolating the constants k_{eff} characterising the rate of the above reaction in aqueous dioxan to pure dioxan. In their study of the kinetics of the formation of active products from TEDA and epoxypropane (EP) in aqueous dioxan, the authors assume that the role of water in this process consists in altering the dielectric constant of the medium and in the possible solvation of the reactants (TEDA). On the other hand, the studies on the reactions occurring in the polymerisation of epoxides[191-200] and also other investigations[6,163,168,201] permits at the present time the unambiguous claim that the interaction in the amine/epoxide system with opening of the epoxide ring does not take place at all in the absence of at least traces of a PD. Water is an effective PD in systems of this kind and participates directly in the reaction, entering into the composition of the product (like alcohols and other PD):



When account is taken of this finding, one should apparently exercise cuation in using the k_{eff} obtained by means of the extrapolation described above, particularly in relation to a reaction system containing an isocyanate and possible active admixtures (for example, water and urea). The rate of accumulation of active centres in such a system is probably determined not only by the concentrations of the epoxide and the amine but also by the presence of a third coreactant, the participation of which is obligatory for the formation of active centres with the opening of the epoxide ring.[6,150,163,168]

It follows from the experimental data[158] that the preliminary maintenance of the trimer in contact with the TEDA/EP catalytic system leads merely to a decrease of the induction period in the CT reaction of *m*-Cl-PIC but not to its disappearance. At the same time, it appears evident that, on formation of a template catalyst under these conditions, the reaction should begin without an induction period.

On the other hand, it is known that, under certain conditions (temperature, catalyst), the stable isocyanurate ring can be cleaved on treatment with epoxides to form 2-oxazolidinones.[202] One cannot rule out the possibility that the observed effect of the trimer in the given process[120,155-15] is associated with reactions of this kind.

Naturally one of the confirmations of the template mechanism of the CT reaction of isocyanates may be the experimental detection of a complex catalyst of the template type.

Quantum-chemical calculations by the LCAO-MO SCF method in terms of the CNDO/BW approximation have shown that the structural characteristics of the components of the amine/epoxide catalytic system and of the trimer indicate a low probability of the formation of a template catalyst owing to steric hindrance.[201]

III. CATALYSIS BY TIN, ZINC, ANTIMONY, PHOSPHORUS, AND ARSENIC COMPOUNDS AND METAL NAPHTHENATES AND ACETYLACETONATES

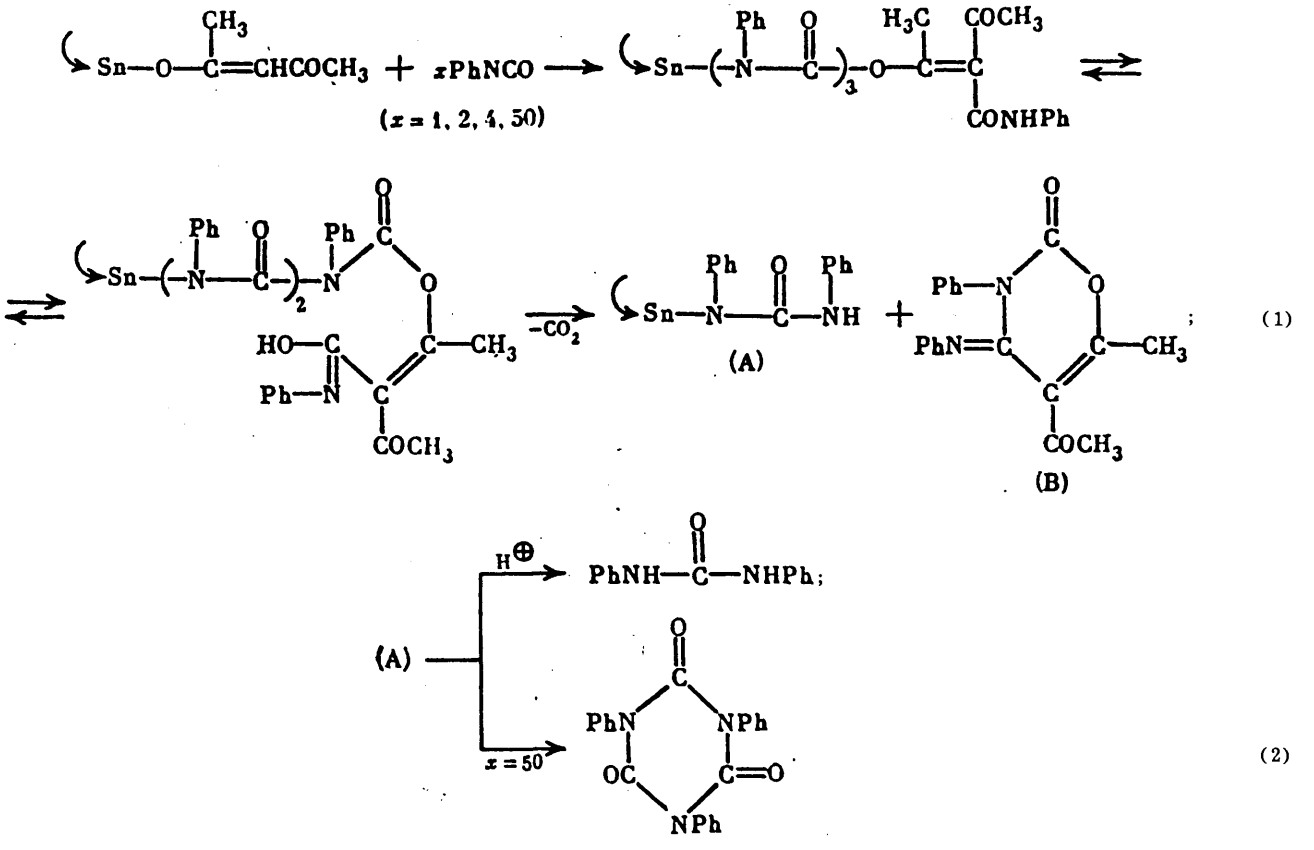
Virtually all the studies on the above types of catalysts[61,77-80,118,145,146,151-155] involved merely an estimate of the catalytic activity of compounds of this kind in relation to the cyclotrimerisation of isocyanates and certain ideas about the mechanism of this reaction under the conditions investigated. A distinctive feature of all the proposed mechanisms of the CT reaction of isocyanates in the presence of such catalysts is catalysis with the aid of "insertion" reactions.[61]

The catalytic activity of antimony and arsenic trialkoxides in the cyclotrimerisation of isocyanates has been reported.[77] In the presence of antimony tri-n-butoxide and arsenic triisobutoxide, the authors obtained high yields of the trimers of PIC, *o*-methoxyphenyl and ethyl isocyanates, hexamethylene diisocyanate, and *m*-nitro- and *m*-chloro-phenyl isocyanates. It was also observed that tri-n-butylantimony diethoxide and triisobutylantimony diacetate as well as the dioxides are active catalysts of the cyclotrimerisation of isocyanates. The more basic oxides of trialkylantimony and trialkylarsenic showed a higher catalytic activity in the cyclotrimerisation of isocyanates. The author suggested that catalysis by the test compound entails the initial formation of a stoichiometric complex of the isocyanate with the catalyst, which subsequently reacts with the excess isocyanate to form the trimer. The suggested complex has been isolated after the reaction of antimony tri-n-butoxide with a slight excess of PIC and has been characterised in terms of its elemental composition and by IR spectroscopy. The product exhibited a catalytic activity in the cyclotrimerisation of the isocyanate.

The cyclotrimerisation of 2,4-TDI in the presence of iron acetylacetonate as the catalyst has been observed.[79,80] The author showed that the dimerisation of the isocyanate is in this case an independent process. It was found that the initial rate of dimerisation decreases from the maximum value almost to zero at the equilibrium concentration of the dimer and the trimerisation process under these conditions does not correspond to equilibrium, the activation energy amounting to 44.2 kJ mol^{-1}.

In their study of the reaction of PIC in the presence of β-dicarbonyl complexes of tin, Wakechima et al.[151] proposed a mechanism of the catalysis involving "insertion" reactions, i.e. with insertion of the isocyanate in the Sn–O bond (Scheme 3). The products formed under these conditions in the first stage can undergo various transformations depending on the $PhNCO/Sn(acac)_2$ ratio:

Scheme 3



(1)

(2)

The occurrence of "insertion" reactions in the cyclotrimerisation of isocyanates in the presence of catalysts containing the Sn–S and Sn–O bonds (oxides and alkoxides) has been indicated in several studies.[61,155,203] In their investigation of the cyclotrimerisation of PIC and ethyl isocyanate in the presence of catalysts having the structure

$Sn(OR)_2$, where $R=C_2H_4N(CH_3)_2$ (A);

$C_2H_4OCH_3$ (B); C_2H_5 (C); $C(CH_3)=CH-COCH_3$ (D);

$C(CH_3)=CHCO_2C_2H_5$ (E);  (F)

Wakechima and Kijima[152] found that these compounds are active catalysts of the cyclotrimerisation of isocyanates. The highest activity was noted for compound (A) and the lowest for compound (F). Hence it was concluded that the nucleophilic properties of the oxygen atom are important in the catalysis of the cyclotrimerisation of isocyanates by bivalent tin compounds. The above workers also showed that compounds of quadrivalent tin such as $Sn(OC_4H_9)_4$ and $n\text{-}C_4H_9Sn(OS_4H_9)_3$ hardly catalyse the cyclotrimerisation of PIC under the same conditions. In their investigation of the interaction of isocyanates with quadrivalent tin oxides and alkoxides, Tiger et al.[155] found that in their presence the isocyanate is slowly converted into the trimer. Various isocyanates can then give rise to mixed isocyanurates. Hence the authors concluded that the cyclotrimerisation in the presence of R_3SnX proceeds via the consecutive insertion of the isocyanate between Sn(IV) and the counterion (X), affording initially a carbonate and then 1 : 2 (allophanate) and 1 : 3 adducts (Scheme 4):

Scheme 4

$$(C_4H_9)_3SnX + RNCO \rightleftarrows \underset{\text{(VIII)}}{(C_4H_9)_3Sn\cdot NRCOX}; \quad (1)$$

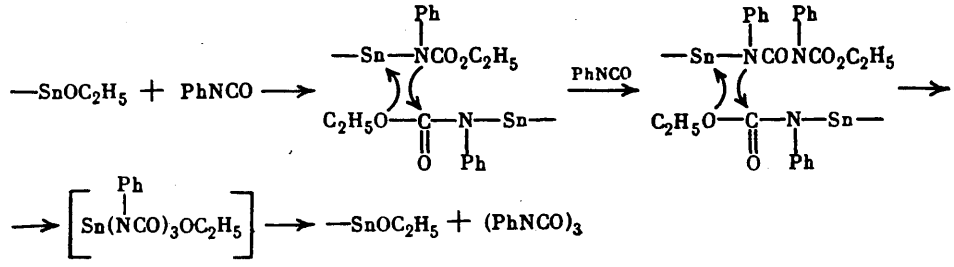
$$\text{(VIII)} + R'NCO \rightleftarrows \underset{\text{(IX)}}{[(C_4H_9)_3Sn\cdot NR'CONRCOX]}; \quad (2)$$

$$\text{(IX)} + R'NCO \rightleftarrows \underset{\text{(X)}}{[(C_4H_9)_3SnNR'CONR'CONRCOX]};$$

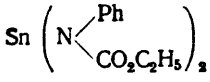
$$\text{(X)} \rightarrow (C_4H_9)_3SnX + T. \quad (3)$$

However, instances of the direct formation of a product of type (IX) could not be observed. In all cases the hydrolysis of the products yielded only the carbamate and the trimer, whence it was suggested that the allophanate reacts very rapidly with subsequent conversion into the carbamate.

In contrast to this, the mechanism of the catalysis of the cyclotrimerisation of isocyanates by bivalent tin compounds, involving the four-centre intermolecular interaction



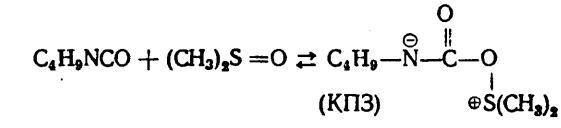
has been proposed[152] on the basis of the change in the yield of the hydrolysis products. The authors believe that the proposed reaction pathway is confirmed by the weakening of the nucleophilic attack by the nitrogen atom in



compared with  .

Two groups of catalysts in the cyclotrimerisation of aromatic and aliphatic isocyanates have been investigated:[145,146,154] the first group $[(C_4H_9)_3Sn]_2O$, $Ti(C_4H_9)_4$, and $Zr(OC_4H_9)_4$, while the second includes lead, zirconium, and cobalt naphthenates. It was shown that the catalysts of the first group are effective in the cyclotrimerisation of aromatic isocyanates and are almost ineffective in that of aliphatic isocyanates. The addition of polar solvents [dimethylformamide(DMF) and dimethyl sulphoxide(DMSO)] to the isocyanate in proportions of 1 : 1 leads to a sharp acceleration of the cyclotrimerisation of PIC in the presence of catalysts of the first group, while in the presence of those in the second group the cyclotrimerisation of PIC is accelerated even after the addition of a small amount of DMF or DMSO. In the case of C_4H_9NCO the addition of polar solvents hardly accelerates the cyclotrimerisation in the presence of catalysts of the first group. On the other hand, the addition of small amounts of, for example, DMSO leads to an appreciable acceleration of the cyclotrimerisation of C_4H_9NCO by catalysts of the second group, although the overall process remains slower than in the case of PIC. Under these conditions, there is an optimum in the rate of cyclotrimerisation of C_4H_9NCO (in the presence of catalysts of the second group) as a function of the content of DMSO in the system at the concentration of the latter 5–10 times greater than that of the catalyst.

An explanation of the observed facts follows from the consideration of complex formation in isocyanate–solvent and isocyanate–catalyst systems. It was shown[145,146,154] that, compared with PIC, C_4H_9NCO interacts only weakly with DMSO and that the concentration of the charge–transfer complex (CTC) (which is more active than the initial monomer) formed under these conditions is very low.



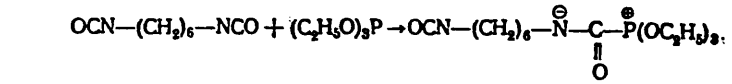
This in fact accounts for the absence of an increase in the rate of cyclotrimerisation of aliphatic isocyanates in the presence of polar solvents.

On the basis of the appreciable increase of the rate of cyclotrimerisation of isocyanates (both aromatic and aliphatic) in the presence of small amounts of DMSO in catalysis by compounds of the second group, the authors suggested that very low concentrations of the charge-transfer complex are effective in complex formation with the metal, which results in the formation of a catalytic complex of the isocyanate with the metal of the catalyst. In their study of complex formation in the isocyanate–cobalt naphthenate system by the spectrophotometric method, they found[146] that both PIC and C_4H_9NCO form a complex with the catalyst having the composition [NCO]/[Co] = 3. They demonstrated at the same time that, in the complex formation reaction with the metal, the NCO group in the aliphatic isocyanate is a much weaker ligand than that of PIC. As a result of this, in the reaction of the aliphatic isocyanate the DMF or DMSO present at high concentrations can compete with the isocyanate in the complex formation reaction with the catalyst metal, causing thereby an increase in the induction period of the CT reaction. On the other hand, in the case of PIC, which forms complexes with the catalysts of the second group much faster and with a much higher equilibrium constant, the observed rate of cyclotrimerisation is much higher under the same conditions.

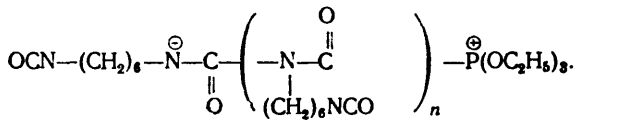
The cyclotrimerisation of organic isocyanates in the presence of organozinc compounds ($RZnNR'_2$ or $RZnOR'$) has been described.[113] Davydov et al.[106] and Cherednikova[118] investigated the cocyclotrimerisation of chlorohexyl isocyanate (CHIC) and PIC in the presence of zinc octanoate in toluene at 353–383 K and showed that CHIC is more reactive than PIC. The kinetic cyclotrimerisation curves were S-shaped: the rate of reaction increased to a maximum at the end of the induction period and then began to decrease slowly (for 30–50% conversion of the monomer). The results were interpreted by the authors from the standpoint of the template mechanism of catalysis, although the accelerating role of the PIC trimer had been demonstrated only after it had been kept in contact with the catalyst at 353 K. The formation of a stable complex of the catalyst with the PIC trimer under the conditions indicated is unlikely.

The catalytic action of certain phosphorus compounds on the cyclotrimerisation of isocyanates has been reported in a number of communications.[97,98,105,140] The active catalysts of this reaction are tertiary phosphines.[105] Trialkyl phosphites (TAP) are also vigorous nucleophiles which catalyse the formation of cyclic isocyanate dimers and trimers.[97,140] According to the authors, the polymerisation of diisocyanates initiated by TAP involves the nucleophilic attack by the phosphorus atom of the phosphite on the carbon atom of the

isocyanate group—the most electrophilic centre of the molecule:



This results in the formation of a dipolar ion; the addition of subsequent isocyanate molecules is to the anion:



The autocyclisation of the macroanion in the trimer stage can be achieved spontaneously with the regeneration of trialkyl phosphite.

IV. CATALYSIS BY ALKALI METAL AND QUATERNARY AMMONIUM CARBOXYLATES

Although alkali metal and quaternary ammonium carboxylates are nowadays used perhaps most extensively in practical systems for the preparation of isocyanurate-containing polymers and various materials based on them,[10,21,25,44-47,204] there have been comparatively few studies on the kinetics of this process and on its mechanism in the presence of catalysts of this kind.[9,62,101,102,125,128,147,161,166-168,205,206] Until recently it was believed that alkali metal carboxylates are weak catalysts of the cyclotrimerisation of isocyanates and are effective only at elevated temperatures.[136] They were therefore used most often in combination with other catalysts of the cyclotrimerisation of isocyanates.[21,25]

The characteristics of the cyclotrimerisation of aromatic isocyanates have been investigated in relation to PIC in solution in DMF in the presence of lithium acetate.[9,62,108,109,125] The conversion of PIC into a trimer took place over a period of ~3 h at 333 K. It was established that the reaction is of second order with respect to the isocyanate and of first order with respect to the catalyst. In the initial stages of the reaction, the authors observed, together with the formation of the trimer, the formation of the PIC dimer (as an independent parallel process), which at the end of the reaction was fully converted into the trimer. It has also been shown that the PIC dimer in solution in DMF at 333 K reacts rapidly to form the trimer when the reaction is catalysed by lithium acetate. The authors suggest that the interaction of the PIC dimer with lithium acetate entails the formation of catalytically active compounds capable of converting the dimer into the monomer and the trimer.[62,125] On the grounds of general considerations, the authors suggest that the active centre in the CT process is in this case the product of the addition of PIC to lithium acetate, i.e. the lithium salt of a substituted urethane.[62]

Tne cocatalytic effect of linear oligoethers in the cyclotrimerisation of isocyanates in the presence of alkali metal acetates (alkoxides, phenoxides) has been observed,[45] and it has been suggested that it be used in the synthesis of isocyanurate-containing foam plastics. Subsequently the same workers carried out a series of studies on the kinetics of the CT reaction of isocyanates in the presence of alkali metal acetates in various oligoethers and also of their low-molecular-rate analogues (glymes) as cocatalysts[44,128,161,162,165,190,206] and of the complex formation reaction in alkali metal acetate/oligoether (or glyme) systems.[44,167,168] They also carried out investigations designed to elucidate the role of oligoethers in the catalysis of the CT reaction of isocyanates by alkali metal acetates.[128,161,165,168]

The cocatalytic effect of compounds containing the ether linkage (diethylene glycol, triethylene glycol, and polyoxypropylenetriol with a molecular weight of ~3000) in the CT reaction of isocyanates (2,4-TDI) in the presence of potassium acetate as the catalyst was characterised quantitatively for the first time by Medved' and co-workers.[161,162] It has been shown that the activity of the AcOK/cocatalyst catalytic systems depends on the concentrations of both the catalyst and the cocatalyst and also on the equivalent ratio [−O−]/[AcOK]. With increase of this ratio, the rate of the CT reaction increases, while the induction period diminishes. Taking into account the data obtained for the heat of reaction of AcOK with the polyoxypropylenetriol (~21 kJ mol^{-1}; AcOK), the authors put forward the hypothesis that the observed cocatalytic effect of linear oligoethers in the process investigated is due to the specific solvation of the potassium ion by the polyether (analogously to the reaction of glymes and cyclic polyethers, namely crown-ethers, in solutions of alkali metal salts),[207-214] as a result of which the catalyst can pass from the state of contact ion pairs to one of solvate-separated ion pairs, whose activity is much higher, for example in relation to the anionic polymerisation of various monomers.[215-226]

In subsequent investigations[44,128,165,166,168,227-229] more detailed studies were made of the influence of various oligoethers on the kinetics of the CT reaction of 2,4-TDI[44,165,166,168] and of the nature and structure of the complexes formed in the AcOM/oligoether systems (where M = alkali metal).[128,227-229] It was established that AcOK in the form of solutions in methanol or ethylene glycol behaves as a very weak catalyst of the cyclotrimerisation of 2,4-DTI under the conditions investigated (298 K, in bulk) (the reaction was not observed in the course of at least 2 h).[168] The addition of even small amounts of polyethers based on epoxyethane (EE) or epoxypropane leads to a sharp increase of the rate of reaction (the process takes place over a period of several minutes). The study of the kinetics of the cyclotrimerisation of 2,4-TDI in the presence of the AcOK/polyether catalytic system established that the dependence of the rate of reaction on the equivalent ratio [−O−]/[AcOK] is represented by curves with saturation [a plateau] for a specific value of [−O−]/[AcOK], which depends on the structure and molecular weight of the polyether. It was established that oligoethers based on EE are much more effective cocatalysts in the process investigated than oligoethers based on EP; the effectiveness of the catalyst is also influenced by the molecular weight and functionality [the number and nature of functional groups (Translator)].[128,166,168] Dimethyl ethers of glycols (glymes) also accelerate the cyclotrimerisation of isocyanate in the presence of AcOK, but their activity is lower than that of their analogues having higher molecular weights—linear oligoethers based on EE (Table 2).[128,168]

According to Gerard et al.[213] and Davydova et al.,[230] the relative capacities of various compounds containing ether linkages for complex formation with alkali metal salts (NaCl, KI, CsCl) decrease in the sequence dibenzo-18-crown-6 > poly(ethylene oxide) (MW ≅ 18 000) > glyme 8 > glyme 7 > glyme 6 > glyme 5. On formation of complexes of the ligands considered with metal cations, appreciable heat changes are observed;[230] the entropies are then in most cases negative and reflect the restriction of the mobility of the ligand molecules. An important feature of the complex formation reaction of polyethers with metal salts is the decrease of the electrostatic interaction between the counterions, as a result

of which the ions are separated.[128] Since the majority of ionic catalysts are present in the polymerisation mixture in the form of ionic associated species and contact ion pairs, coordination to polyethers converts them into solvate-separated ion pairs or free ions. At the same time it is known that the catalytic activity of separated ion pairs in ionic polymerisation is higher by 2–5 orders of magnitude than that of contact ion pairs[215] and is close to the activity of free ions. Instances of the employment of glymes and cyclic polyethers as activators in the polymerisation of styrene,[216] α-methylstyrene,[217] propylene sulphide,[218] olefin oxides,[219] lactones,[220] butadiene,[215] and certain other monomers are known.

The study of the complex formation reaction between AcOK (in solution in methanol) and various linear oligoethers and glymes by calorimetric and conductimetric methods established[128,167,168] that, at a concentration in excess of 0.1 M, AcOK is present in methanol in the state of contact ion pairs and their aggregates. The addition of oligoethers to dilute AcOK solutions (10^{-3}–10^{-4} M) decreases their limiting equivalent conductance, which is a consequence of the increase of the bulk of the potassium ion and the decrease of its mobility as a result of its coordination to the polyether (the Stokes radius increases from 2.9 Å to 8.45 Å). The addition of oligoethers to a concentrated AcOK solution in methanol (0.5 M) entails partial separation of the ions and the disruption of the ionic aggregates, as a result of which the electrical conductivity of the solution increases somewhat. It has also been established[227–229] that linear polyethers based on EE and EP in solutions in methanol form partly dissociated coordination-saturated complexes via the donor–acceptor interaction of the oxygen in the ether linkage of the polyether with the potassium cation. The interaction of AcOK with polyethers is accompanied by a heat change, whose magnitude depends on the characteristics of the polyether: polyoxyethylenediols > polyoxypropylenediols (with the same degree of polymerisation) > polyoxypropylenetriols (with the same equivalent weight). The composition of the complexes depends on the molecular weight of the polyethers, i.e. on its content of electron-donating groups, namely ether linkages. Polyethers with a sufficiently high molecular weight (for example, MW ≥ 1000 for polyoxypropylenediols) can interact with two and more cations.[227–229] The interaction of polyethers with AcOK is characterised by comparatively low equilibrium constants:[229] for oligoethers based on EE, these values are greater by a factor of 2–3 (~250 litres per mole of AcOK) than for oligoethers based on EP (~100 litre $mole^{-1}$) with the same degree of polymerisation, which agrees with the data of other workers on the complex formation reactions of potassium thiocyanate with linear polyethers.[230]

It has been established[227] that the presence of ether linkages is a necessary but not a sufficient condition for the effective complex formation between the potassium ion and electron-donating ligands and for the corresponding cocatalytic effect of the latter in the cyclotrimerisation of isocyanates. Thus polyfurit, dioxan, and dibutyl ether do not solvate K^+ and do not accelerate the cyclotrimerisation of 2,4-TDI in the presence of potassium acetate. Evidently the solvating capacity of ligands of this kind is determined not only by their chemical structure but also by the conformation of their molecules. According to Gluck et al.,[231] the conformation of poly(ethylene oxide) is a helix with a repeat period of 19.3×10^{-10} m; in structured complexes poly(ethylene oxide) consists of a non-planar zig-zag with a repeat period of 11.75×10^{-10} m;[232] the conformation of polyfurit is a planar zig-zag, while dioxan has the chair conformation.[233] Only the first conformation ensures the possibility of the simultaneous involvement of two and more neighbouring electron-donating groups in the interaction with the metal cation by virtue of the high flexibility of the chain in poly(ethylene oxide) and poly(propylene oxide) and their polydentate structure.

The $\Delta H - \Delta S$ relation for the complex formation reactions of AcOK with polyoxyethylene and polyoxypropylene oligoethers is linear and is described by the equation[229]

$$-\Delta H = -0.36\,\Delta S + 1.85,$$

This relation is a common feature of donor–acceptor interactions.[234] The relation $-\Delta H = f\{[-O-]/[AcOK]\}$ has the form of curves with saturation for all the AcOK/oligoether systems investigated,[227,228] analogously to the situation demonstrated for the dependence of the rate of cyclotrimerisation on the same ratio [–O–]/[AcOK],[44,128,168,232] which indicates a direct relation between the complex formation reaction in the catalytic systems investigated and the catalytic activity of the latter in the cyclotrimerisation of isocyanates. This is also indicated by a number of other features common both to the complex formation reaction and to the cyclotrimerisation kinetics in the presence of the AcOK linear oligoether catalytic system: the high heats of reaction and the high equilibrium constants characterising the complex formation in the catalytic systems based on AcOK and oligooxyethylenes, compared with the catalytic systems based on AcOK and oligooxypropylenes, and the correspondingly higher catalytic activity of the former systems in the cyclotrimerisation of 2,4-TDI (Table 2), as well as the absence of interaction (and hence of the cocatalytic effect in the CT reaction) of polyfurite, dioxan, and dibutyl ether with AcOK, etc.

Table 2. Parameters of the complex formation reactions [$-\Delta H$(kJ/mol AcOK) and K_p (litre^n mol^{-n})] of various electron donors (ED) with AcOK and their cocatalytic activities in the cyclotrimerisation of 2,4-TDI.[168]

ED	MW	[–O–]/[AcOK] at V^1_{max} and ΔH_{max}	$-\Delta H$, kJ/mol AcOK	K_p, litre^n mol^{-n} [2]	Relative V_{max} for CT
Diglyme	134	—	15	42	1.0
Tetraglyme	222	20	33	66	1.4

[1] V_{max} and ΔH_{max} are the maximum rates of cyclotrimerisation of 2,4-TDI and the enthalpy of complex formation respectively.
[2] n is the number of moles of the electron donor in the complex.
[3] PEO does not contain OH groups.
[4] POPD-500 was synthesised from diethyleneglycol and contains ~12% of hydroxyethyl groups.

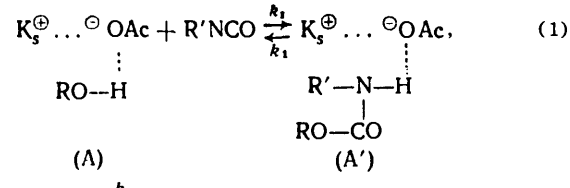
A study[235] using the potassium salts of aminoacids as catalysts of the cyclotrimerisation of isocyanates in the synthesis of isocyanurate-urethane foam plastics dealt with the principal rules governing the influence of linear oligoethers on the catalytic activity of systems, observed by

Denisov et al.[44] and Zhitinkina et al.[168] Thus, for the same content of the oligoether by weight in the composition, the replacement of oligooxyethylenediol-200 by oligooxypropylenediol-200 leads to an increase of the foaming time of the composition by a factor of 2 (from 35 to 68 s). An increase of the equivalent ratio $[-O-]/[K^+]$ diminishes the above parameter.

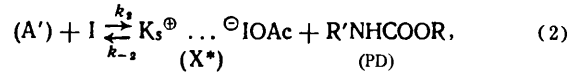
The cocatalytic effect of linear oligoethers based on EP and EE has been used[236] to establish highly effective catalytic systems suitable for the synthesis of isocyanurate-urethane foam plastics with effective physicomechanical parameters, thermal stability, and fire resistance.[45-47]

Analysis of data[44,128,166,168] on the kinetics of the cyclotrimerisation of isocyanates in the presence of the AcOK/oligoether catalytic systems has shown, however, that the complexes formed are not apparently the "true" initiators of this reaction, since the induction period persists (at sufficiently low catalyst concentrations). At the end of the induction period, the reaction begins at a rate close to the maximum and obeys a formal kinetic first-order equation. The order of the reaction with respect to the catalyst is unity.[168] On the basis of the factors indicated, a hypothetical mechanism of the cyclotrimerisation of isocyanates in the presence of catalytic systems of this kind has been put forward[166,168] in the following way (for systems containing ROH, Scheme 5):

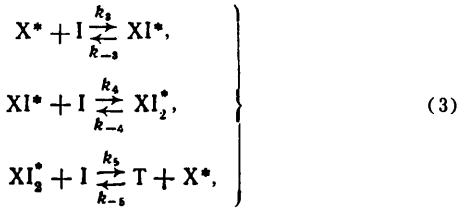
Scheme 5



(1)



(2)



(3)

(4)

or

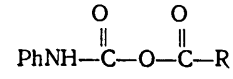
(5)

The chain termination in stage (3) of this system can apparently be due to cyclisation in the presence of a proton donor with regeneration of the initial catalyst. It is also possible that stage (2) involves more complex interactions.

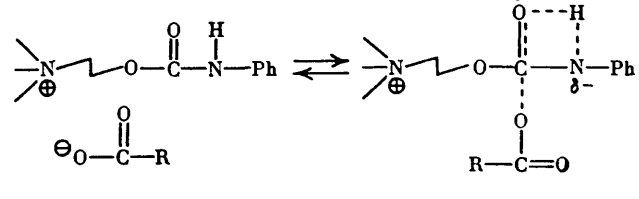
The kinetics of the cyclotrimerisation of PIC in the presence of various catalysts, including quaternary ammonium carboxylates, have been described recently.[147,205] The authors reported[205] that, in the presence of a quaternary ammonium carboxylate, the reaction is of first order with respect to the isocyanate at low degrees of conversion: at high degrees of conversion, the reaction deviates from the first order. However, in the next study[147] by the same workers involving the cyclotrimerisation of PIC in diglyme, it was stated that the reaction is of second order with respect to the monomer in the presence of a catalyst of the same type. In addition they established that the rate of reaction in the presence of a quaternary ammonium carboxylate (the DABCO TMR product) varies non-linearly under these conditions with the concentration of the catalyst and the order of the reaction with respect to the catalyst is close to two. For other types of catalysts, the order of the reaction is unity.[147] Thus fairly contradictory data have been obtained. Unfortunately, the information quoted in these communications concerning the kinetics of the cyclotrimerisation of PIC was obtained using commerical catalysts (DABCO TMR; APCI). There are no data concerning their exact structure and purity, which precludes the analysis of the results from the standpoint of the influence of various factors.

It has been established[147] that the PIC trimer does not have an accelerating effect on the cyclotrimerisation in the presence of the catalysts investigated (in the presence of the trimer, the rate of cyclotrimerisation is actually somewhat lower). The author showed that, in the presence of a quaternary ammonium carboxylate (DABCO TMR), the rate of cyclotrimerisation of PIC diminishes with increase of temperature. Since the catalyst itself does not lose its activity after being thermostatted at 323 K, they suggest that this effect is associated with the depolymerisation of the growing chain in the stages preceding cyclotrimerisation. In a study of the influence of the catalyst structure on the rate of cyclotrimerisation of PIC, Bechera[147] established that, among compounds of the given type, the catalysts with primary OH groups are more effective than catalysts with secondary OH groups while the latter are more effective than catalysts with tertiary OH groups. On the other hand, an increase of the number of OH groups in the catalyst leads to a decrease of the rate of cyclotrimerisation of PIC. It has also been established that, with increase of the basicity of the carboxylate anion, the activity of the catalyst rises, while the addition of a carboxylic acid to the catalyst reduces the rate of cyclotrimerisation of PIC. The authors do not attempt to interpret the latter fact in any way.

At a low concentration or at a low activity of the catalyst the induction period persists. In the case of substituted quaternary ammonium benzoates, its duration is inversely proportional to the basicity of the carboxylate anion. It is believed[147] that the induction period is due to the slow formation of an activated catalyst as a result of the addition of an isocyanate molecule to the OH group and that this product exhibits a somewhat higher catalytic activity than the initial catalyst in the cyclotrimerisation of PIC. In their study of the structure of the product of the addition of PIC to hydroxyethyltrimethylammonium nitrobenzoate (in equivalent proportions) by IR and NMR spectroscopy, the authors observed the presence of the absorption band of the urethane carbonyl group and the absence of free NCO groups and of the mixed anhydride of carbamic acid:

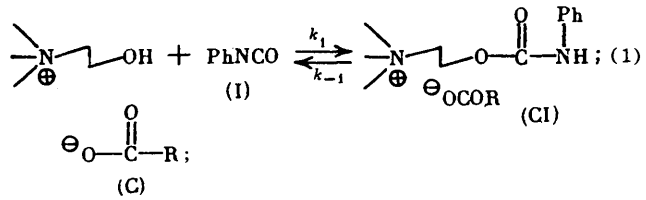


On the other hand, the presence of a very "acid" proton was revealed by the NMR spectra. On the basis of the results obtained, they represented the structure of the isocyanate-activated catalyst in the following way:

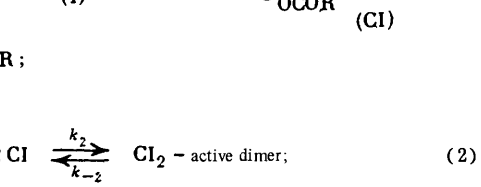


However, in an attempt to explain the observed second order of the reaction with respect to the catalyst, the authors assumed further that this product forms a very active dimer in the initiation stage and put forward the following mechanism for the cyclotrimerisation of isocyanate in the presence of ROH (Scheme 6):

Scheme 6



(1)



(2)

(3)

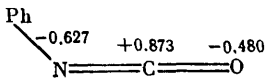
(5)

It is fairly difficult to imagine the nature of such a dimer, which was in fact stated by the authors themselves.

V. SOME FEATURES OF THE KINETICS OF THE CYCLOTRIMERISATION OF ISOCYANATES AND THE PROPOSED PROCESS MECHANISM

Isocyanates belong to the class of unsaturated compounds with cumulated double bonds,[237-240] which determines their reactivity in relation to various compounds, including their reactivity in relation to one another. The electron density in the NCO group is distributed in such a way that the nitrogen and oxygen have electron-donating properties, while carbon has electron-accepting properties. Quantum-chemical calculations of the distribution of electron density in isocyanates, carried out by the CNDO/BW method with optimised geometry, which agree qualitatively with non-empirical calculations,[241] have shown that the nitrogen atom carries a larger negative charge than the oxygen atom:

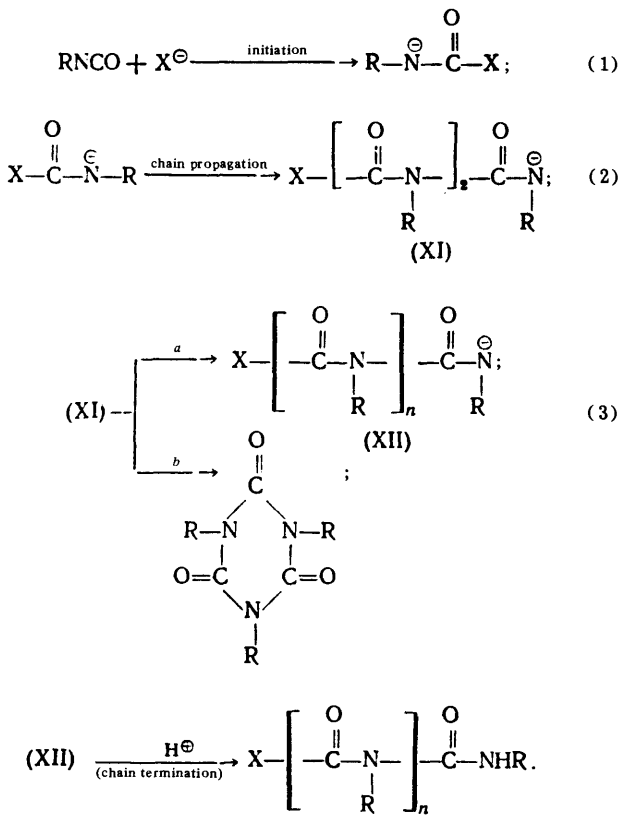


From the C=O (635 kJ mol^{-1}) and C=N (375 kJ mol^{-1}) bond energies quoted by Fedotova et al.,[242] one can assume that the addition to the N=C bonds is easier. The results of studies on the EPR spectra of the radicals formed on γ-irradiation of isocyanates and ρn their interaction with active hydrogen atoms confirm this.[243] All subsequent studies devoted to the synthesis of linear homopolymers of isocyanates,[244-247] their copolymers,[64-71] and cyclic trimers indicate the preferential cleavage of the N=C bond.

A number of studies have been devoted to the elucidation of the causes of the anionic polymerisation of isocyanates preferentially via the N=C bond,[241,248] in which it was shown, from quantum-chemical calculations, that at the instant of interaction with nucleophiles the N=C bond undergoes an intense polarisation (compared with the C=O bond), which explains its high reactivity in such processes.

The CT reaction of isocyanates was first considered as a special case of anionic homopolymerisation in two studies.[249,250] In the presence of typical catalysts of anionic polymerisation (sodium cyanide and others) at 173–253 K a linear polymer with a polyamide structure was obtained in a high yield (MW = 10^4–10^5) and the trimer was isolated as a side product. The authors proposed a general stepwise mechanism for the polymerisation of isocyanates under the influence of anions, in which the cyclotrimerisation reaction is a special case (Scheme 7):

Scheme 7



(1)

(2)

(3)

Pathway *a* responds to a low temperature and a low catalyst concentration and pathway *b* to a high temperature and a high catalyst concentration.

There is at present no doubt about the ionic character of the polymerisation of isocyanates.[60] Even under the influence of γ-radiation (^{60}Co) the process proceeds via a radical mechanism.[251] Cyclic trimers of aliphatic and aromatic isocyanates have been obtained by the anionic electroinitiated polymerisation.[252-254] The typical features of the cyclotrimerisation of isocyanates via the anionic mechanism are as follows. The activity of the isocyanates in cyclotrimerisation depends on the donor–acceptor properties of the substituents adjoining the NCO groups: isocyanates with electron-accepting substituents (aromatic) are more reactive than isocyanates with electron-donating substituents (aliphatic).[58,60,145] In a series of substituted phenyl isocyanates, those containing electron-accepting substituents in the *para*-position cyclotrimerise faster than the unsubstituted

PIC, while isocyanates with electron-donating substituents in the *para*-position cyclotrimerise more slowly.[60,95]

The high positive Hammett constant ρ for substituted isocyanates[59,95] shows that electron-accepting substituents increase k_{cat}, i.e. the activation process involves the electrophilic carbon centre of the isocyanate group. The initiation of the cyclotrimerisation of isocyanates as a result of the influence of nucleophilic groups on the electrophilic carbon atom of the isocyanate is also indicated by the increase of k_{cat} in the CT reaction with increase of the nucleophilicity of the catalytic centre, which has been recently demonstrated.[60,147,205]

It has been frequently noted in studies on the kinetics of the cyclotrimerisation of isocyanates in the presence of various kinds of catalysts at fairly low catalyst concentrations that the reactions investigated in many cases have an induction period, whose duration depends on the concentrations of the catalyst, the cocatalyst, the isocyanate, and the nature and polarity of the solvent. Inadequate attention has apparently been devoted to the study of the causes of the induction period in the cyclotrimerisation of isocyanates and of the relation between this factor and the overall process mechanism. Analysis of the data examined suggests that the appearance of the induction period in the cyclotrimerisation of isocyanates is due to the slow initiation, on the one hand, and the possibility of the action of an inhibitor, on the other.

It is known[150,255] that strong acids (for example, HCl) are effective inhibitors of the cyclotrimerisation of isocyanates at moderate temperatures. At the same time, the possibility of the presence of traces of HCl in isocyanates (which is almost always the case) is as a rule disregarded in kinetic studies. This may be the reason why a non-proportional dependence of the rate of cyclotrimerisation of the isocyanate on the catalyst concentration is sometimes observed at inhibitor concentrations comparable to those of the catalysts.[132] However, one should note that in the vast majority of experiments the reaction is of first order with respect to the catalyst.[60,62,74,94,118,125,128,136,137,144,150,168,172]

When the CT reaction of isocyanates is carried out in highly polar media (DMF, DMSO), an induction period is as a rule not observed, which indicates an increase of the rate of initiation in solvents of this kind. The study of the dependence of the rate of cyclotrimerisation of isocyanates on the dielectric constant of the medium[60] has demonstrated agreement with the Kirkwood equation.[256] This shows that the charge separation in the polymerisation active centre formed as a result of initiation is greater than in the initial reactants. On the other hand, it has been demonstrated that the rate of cyclotrimerisation of isocyanates cannot be unambiguously determined by properties of the solvents such as the dielectric constant and the dipole moment.[60,136] The electron-donating capacity of the solvent and the specific solvation of the reactants by the solvent also have a considerable influence under these conditions.[60,128,168]

The orders of the reaction of isocyanates observed in various experiments with respect to the main monomer ranged from zero[137] to two[60,147,150] and above,[155–158] depending on the type of catalyst used, the solvent, etc. In most cases the kinetic curves for the reaction obey a formal first-order kinetic equation.[62,74,94,136,150,168,172]

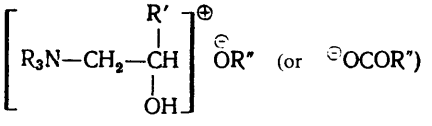
In non-polar and virtually non-solvating solvents (benzene, chlorobenzene), with the initiation as the slow stage limiting the rate of the main reaction, it has been noted that the order of the CT reaction of isocyanates with respect to the monomer is preferentially unity in terms of time and 2 in terms of concentration.[150,163,168] The above relations and also the finding that at the end of the induction period the reaction begins close to the maximum rate show apparently that initiation, involving the interaction of the catalyst with the isocyanate, leads to the formation of an initiator which is much more active than the highly polar initial catalyst.

In principle, when one considers the most effective catalysts of the cyclotrimerisation of isocyanates or the catalytic systems recommended at present for practical use, it is easy to see that they are all ion pairs with separated charges, in which the cation is to a considerable degree localised:

1. The alkali metal carboxylate (alkoxide)/oligoether systems consisting of solvate-separated ion pairs:[44,168]

$$M_s^{\oplus} \ldots {}^{\ominus}OCOR$$

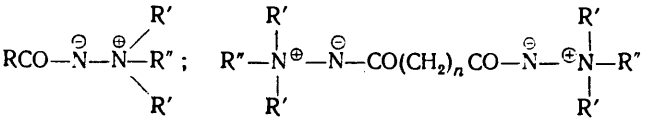
2. Quaternary ammonium derivatives obtained from tertiary amines, epoxyalkanes, and PD (water, alcohols, phenols, and carboxylic acids):[147,150,163,168,205]



(XIV)

Analysis of the structures of compounds of type (XIV) by means of quantum-chemical calculations[201,257] has shown that the anion in such compounds has a considerable capacity for free migration.

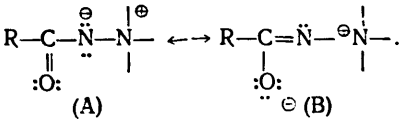
3. Aminoimides:[173–175]



(XV)

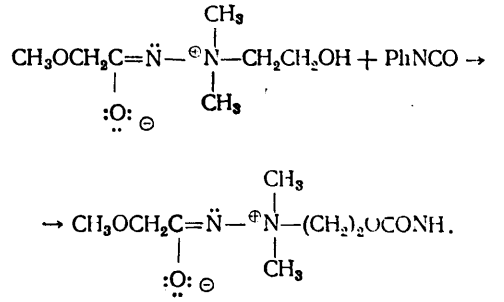
R, R′ = Alk; R″ = CH_2—CH(OH)—CH_3 or CH_2CH_2OH

The most active are the derivatives with primary OH groups. Acylamine imides are zwitter-ions having the following resonance structure:[173]

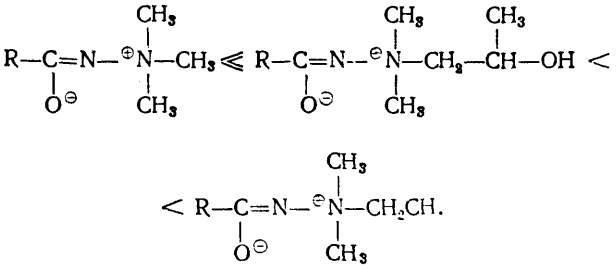


(A) (B)

From IR spectroscopic data, preference is given to structure (B). The authors have shown that the interaction of dimethyl-2-hydroxyethylaminomethoxyacetimide with PIC in acetonitrile leads to the formation of a carbamate:

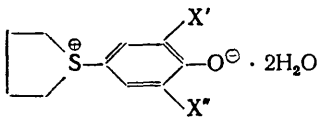


The authors believe that the carbamate promotes the induced polarisation of the isocyanate via the formation of a hydrogen bond and explain by its formation the higher catalytic activity of hydroxyl-containing acylaminoimides compared with the alkyl-substituted derivatives:



Unfortunately experimental kinetic data are not quoted in the relevant study,[173] which makes it impossible to infer the principal kinetic characteristics of the CT reaction of isocyanates in the presence of catalysts of this kind.

4. Sulphonium zwitter-ions:[159,160]



X', X'' = H, R

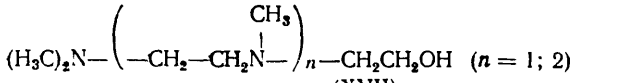
According to the data of Kresta et al.,[160] the CT reaction of PIC in acetonitrile in the presence of a catalyst of this kind is of first order with respect to the catalyst and of second order with respect to the monomer. At 298 K in the presence of this catalyst, a cyclic trimer is obtained in a quantitative yield; 93% of the trimer and 7% of a linear polymer are formed at 248 K and 64% of the trimer and 36% of the linear polymer are formed at 233 K. An important factor which determines the activity of the catalyst in the cyclotrimerisation of isocyanates is the nucleophilicity of the anion. With increase of the electron density of the oxygen atom in cyclic sulphonium zwitter-ions, the catalytic rate constant for cyclotrimerisation increases. Analogous results have been obtained by other workers[147] in the cyclotrimerisation of PIC in the presence of quaternary ammonium carboxylates as catalysts. At the same time, it has been shown[60] that the presence of bulky substituents in the anion of catalysts of the type of MOR does not exert a significant influence on the rate of cyclotrimerisation of PIC.

The characteristics noted above and others observed in the study of the kinetics of the cyclotrimerisation of isocyanates are the reason why there are at present no clear-cut ideas about the mechanism of this process despite the fairly large amount of experimental data. Generally speaking, all the hypotheses put forward concerning this question reduce to the consideration of two main process mechanisms: the insertion mechanism (or the mechanism of "insertion reactions) involving the M–X bond, where X = O, N, S,[61,155,203] or N–H,[84,87] and the mechanism involving addition to the anion.[41,86,94,136,168,258]

The template polymerisation mechanism has also been proposed for the cyclotrimerisation of isocyanates.[155–158]

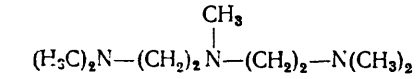
When ionic catalysts, which as a rule consist of ion pairs dissociated to different extents[128,147,168,205] or zwitter-ions,[159,160,173] are used for the cyclotrimerisation of isocyanates (which normally takes place at moderate or elevated temperatures), one should apparently consider polymerisation in the presence of separated ion pairs. In order to achieve the process involving free anions, the latter must be stabilised under these conditions.[41,215] The charge separation in the initial catalysts of the cyclotrimerisation of isocyanates of the type (XIII)–(XVI) is apparently a necessary but not a sufficient condition for effective catalysis via attack on the carbonyl component of the NCO group. Additional activation of the reactants is necessary, for example, the polarisation of the monomer and the catalyst by employing highly polar solvents or powerful solvating agents, which promotes the interaction of the catalyst with the isocyanate in the initiation stage.

In the study of the cyclotrimerisation of PIC in DMF in the presence of sodium ethoxide ($NaOC_2H_5$), it has been establisned[141–143] that in the presence of carbamates the rate of reaction increases in proportion to their concentration. The authors explained the cocatalytic effect of urethane by the polarisation of the NCO groups (as for hydroxyl-containing acylimides). The authors showed that, in the presence of carbamates the quantity ρ for the cyclotrimerisation of isocyanate diminishes under the conditions investigated. The authors suggest that the polarisation of the NCO groups then proceeds to an extent such that the inductive effect of the substituents in the aromatic ring of the isocyanate is less pronounced. However, the coordination interaction between the isocyanate and the urethane has not been observed.[259] The variation of the catalytic activity of hydroxyl-containing quaternary ammonium carboxylates in the catalysis of the cyclotrimerisation of isocyanates had also been attributed to the cocatalytic effect of the carbamate groups.[147,205] The recently observed catalytic activity of a series of tertiary amines having the structure



(XVII)

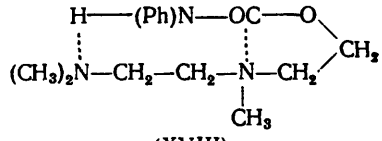
in the cyclotrimerisation of isocyanates has been explained by the same effect[172] on the basis of the fact that amines of the type



are ineffective under these conditions. However, it has been shown that dimethylethanolamine is also ineffective, like amines of the type

It has likewise been established that the cyclotrimerisation of isocyanates in the presence of catalysts of this kind in toluene is of first order with respect to the catalyst and the monomer and is characterised by the presence of an induction period, whose duration is inversely proportional to the catalyst concentration. Catalysts with primary OH groups are much more active than those with secondary hydroxyls; an increase of the number of substituents with OH groups at the same nitrogen atom returns the cyclotrimerisation of the isocyanate (analogously to the situation which obtains for quaternary ammonium carboxylates).[117] In the presence of an alcohol, the formation of a urethane in the presence of the catalysts indicated above always precedes the cyclotrimerisation and, under conditions where there is a slight excess of isocyanates (2 : 1), this is followed by the formation of the allophanate and cyclotrimerisation is observed only on further increase of the excess of isocyanate. The product of the addition of trimethylaminoethylethanolamine to PIC has been isolated and characterised[172] with the aid of infrared spectra and the following structure has been

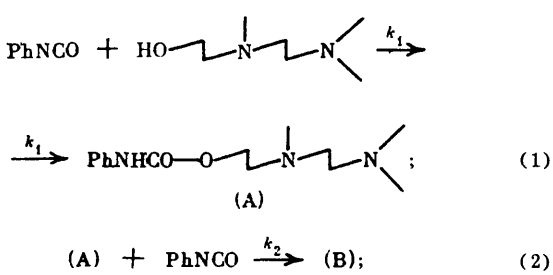
attributed to it:



(XVIII)

Since the urethane-formation reaction in the presence of catalysts of type (XVII) is of first order with respect to the alcohol and is almost independent of the isocyanate concentration, the authors believe that the complex (XVIII), formed rapidly in the presence of ROH, interacts with the alcohol, which entails the formation of a urethane and the regeneration of the catalyst. However, it is fairly difficult to imagine such interaction. It appears more probable that under these conditions the alcohol competes with the urethane in the complex formation reaction with the amine, forming the catalytic complex $R_3N.R'OH$ (in conformity with the general mechanism of the catalysis of the urethane-formation reaction by tertiary amines[260]), which then interacts comparatively rapidly with the isocyanate, forming the urethane. The trimerisation reaction is regarded as the consecutive addition of the isocyanate to the N–H bond in the complex (XVIII) (Scheme 8):

Scheme 8



(A)

$$(A) + PhNCO \xrightarrow{k_2} (B); \quad (2)$$

$$(B) + PhNCO \xrightarrow{k_3} (C); \quad (3)$$

$$(C) + PhNCO \xrightarrow{k_4} T + (A). \quad (4)$$

Bearing in mind that the product (A) is formed very rapidly, this scheme cannot, however, account for the induction period in the CT reaction with a subsequent high rate of the latter. In this connection, the authors, noting that the nature of the induction period is unknown, expressed the view, which conflicts with Scheme 8, that the induction period may be caused by the slow formation of a "synergistic intermediate complex". The possibility of the inhibition of the CT reaction by slowly reacting impurities is also allowed.

From the standpoint of a more complete explanation of the majority of the characteristics of the kinetics of the cyclotrimerisation of isocyanates in the presence of basic catalysts which have been observed and described here, the scheme proposed in a number of studies[60,163,168] is apparently more favourable. It can be represented in the following general form (taking into account the possible inhibition) (Scheme 9):

Scheme 9

$$A + I \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} X^* \text{ — initiation;} \quad (1)$$

$$\left.\begin{aligned} A + I &\xrightarrow{k_2} N, \\ X^* + I &\xrightarrow{k_2'} N', \end{aligned}\right\} \text{ inhibition;} \quad (2)$$

$$\left.\begin{aligned} X^* + I &\underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} XI^*, \\ XI^* + I &\underset{k_{-4}}{\overset{k_4}{\rightleftarrows}} XI_2^*, \end{aligned}\right\} \text{ chain propagation;} \quad (3)$$

$$XI_3^* + I \underset{k_{-5}}{\overset{k_5}{\rightleftarrows}} T + X^* \text{ — chain transfer;} \quad (4)$$

$$\left.\begin{aligned} XI_2^* &\xrightarrow{k_6} T + A, \\ XI_2^* + PD &\xrightarrow{k_7} T + A', \\ XI_2^* + Inh &\xrightarrow{k_8} T + N, \end{aligned}\right\} \text{ chain termination;} \quad (5)$$

Inh = inhibitor; N, N′ = inactive compounds.

Without taking into account the effect of the inhibitor and for conditions in a quasi-stationary process, where

$$k_1 > k_{-1};\ k_{-3} \ll k_3 \simeq k_4 \gg k_1;\ k_5 \gg k_6 \simeq k_7,$$
$$[A_0] = [A] + [X^*] + [XI^*] + [XI_2^*],$$

the above scheme can be described by the equations

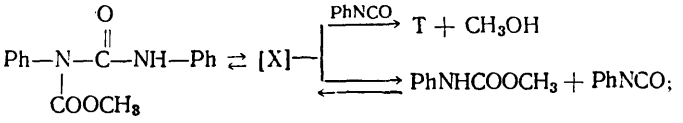
$$-\frac{d[I]}{d\tau} = k_{cat}\,\frac{[A_0][I]^2}{1 + B[I]};\quad B = \text{const};$$

$$\frac{[I_0] - [I]}{[I]\,[I_0]} + B \ln\frac{[I_0]}{[I]} = k_{cat}\,[A_0]\cdot\tau = k_{exp}\tau.$$

According to the results of Kresta and Hsieh,[60] the experimental results agree well with the latter equation. Scheme 9 includes, in principle, two kinetic chains: with regeneration of the initiator (X*) and with regeneration of the initial catalyst (A). Presumably the preferential realisation of one of them (depending on the reaction conditions and the type of catalyst) and the associated changes in the relative values of the constants for the individual stages of the process do in fact lead to differences between the observed characteristics of the CT reactions of isocyanates (different reaction orders with respect to the monomer, the presence or absence of the induction period, etc). When the rate of termination can increase during the reaction (for example, as a result of an increase in the concentration of active impurities and an increase of temperature), the reaction should be retarded according to the above scheme and there should be a corresponding increase of the reaction order with respect to the monomer (from first to second). Certain kinetic data indicate such features of the cyclotrimerisation of isocyanates.[147] However, the question of the structure of the initiator and of the interactions leading to its formation remains obscure.

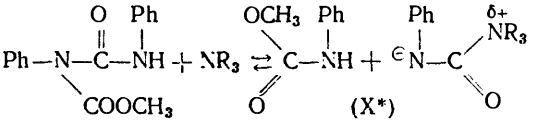
Examination of the kinetic data for the cyclotrimerisation of isocyanates reveals the striking fact that in many cases the reaction is accelerated in the presence of proton-donating compounds (alcohols, urethanes, and hydroxyl-containing catalysts),[84,141–143,147,172,173,205] even when highly basic catalysts are employed. In the presence of tertiary amines (TEDA) at moderate temperatures the cyclotrimerisation of isocyanates takes place only in the presence of an alcohol, urethane, or allophanate in the system.[137,171] Another feature which has been observed by some investigators consists of facts indicating that the reaction preceding cyclotrimerisation[84,172] or coupled with it[137,171] involves the formation-dissociation of the allophanate.

In the presence of 2-methyltriethylenediamine the cyclotrimerisation of PIC in chlorobenzene was not observed at 353 K for 2–3 h;[137,171] when methyl αγ-diphenylallophanate (MDA) was introduced into this system, PIC trimerised at a high rate. It has also been shown that in the presence of 2-methyltriethylenediamine and MDA the cyclotrimerisation of PIC begins with an induction period, the duration of which is inversely proportional to the MDA concentration and depends only slightly on the isocyanate concentration. The rate of the main reaction under these conditions is proportional to the concentrations of the catalyst and MDA and is independent of the concentration of the monomer. It was established that two coupled reactions take place in the system: the dissociation of the allophanate and cyclotrimerisation with a common induction period, whose nature the authors explain by the influence of the inhibitor on the intermediate (X) formed from the allophanate:



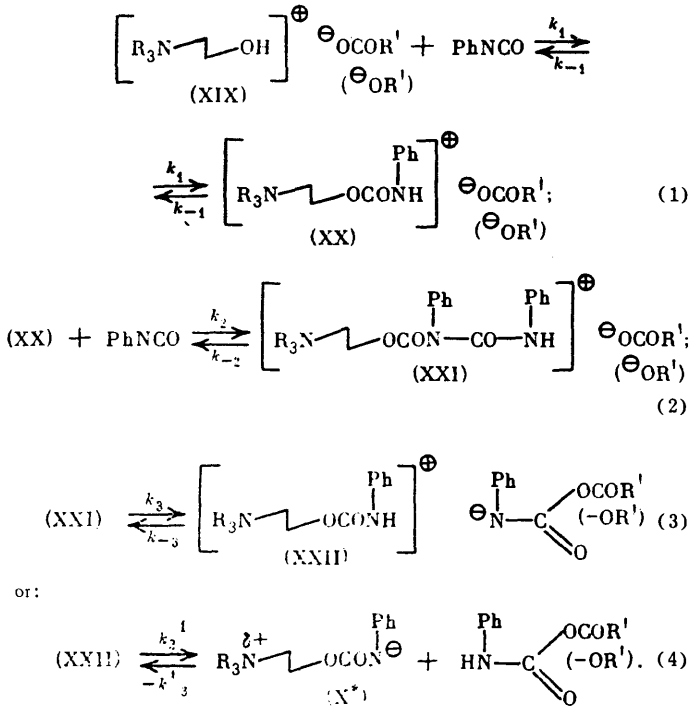
The action of the inhibitor precisely on the product (X) is caused, in their view, by the fact that the induction period persists even in the presence of a high content of MDA, which is known to exceed the possible content of the inhibitor.

On the other hand, one can assume that the formation of active polymerisation centres (X*) in systems of this kind is coupled with the allophanate dissociation step via the interaction of the catalyst with its active (possibly tautomeric) form:



Since this stage is apparently extremely slow (bearing in mind the reversibility of the process) and limits the rate of cyclotrimerisation of the isocyanate, the latter is almost independent of the isocyanate concentration but should be proportional to the MDA and catalyst concentrations. On the other hand, the possibility that the inhibitor acts on the active centres just as much as the initial catalyst cannot be ruled out in this case either. The appearance of active polymerisation centres of the type (X*) can lead to the cyclotrimerisation of isocyanates at a higher rate than that observed at the end of the induction period of the reaction. From the standpoint of the possible involvement of the allophanate in the initiation step of the cyclotrimerisation of isocyanates (via the interaction of its active form with the catalyst), it is apparently possible to explain also other instances of the influence of hydroxyl-containing agents (or urethanes) on the kinetics of this reaction; presumably in the presence of hydroxyl-containing quaternary ammonium carboxylates (alkoxides) the following interactions take place in the initiation process (Scheme 10):

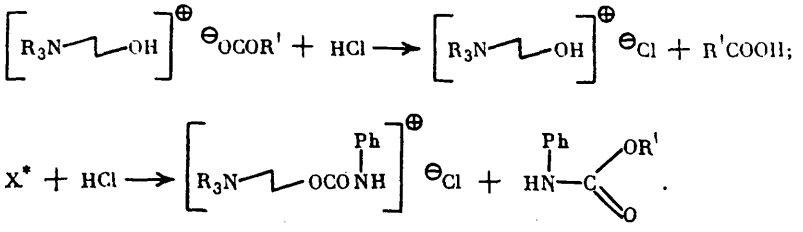
Scheme 10



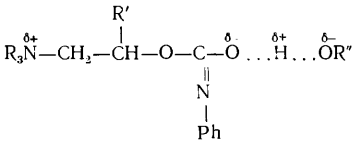
Stages (2) and (3) can then involve additional interactions.

The separated ion pair (XXII), which is more polar than the initial catalyst, or the dipolar anion (X*) initiates the CT process at a high rate in conformity with stages (3) and (4) (Scheme 9). Chain termination may be caused under these conditions by the regeneration of products of the type (XIX) or (XX) in the cyclisation stage and also by the inhibition of the active centres by impurities. With increase of temperature, the probability of such termination also increases, which may lower the rate of cyclotrimerisation of isocyanates.[132] The shift of equilibrium in stages (2) and (3) (Scheme 10) to the left should also diminish the rate of the main process.

In terms of Scheme 10, it is possible to explain also the decrease of the activity of catalysts of this kind when the primary hydroxy-groups are replaced by secondary hydroxy-groups and following an increase of the number of OH-containing substituents. The addition of carboxylic acids to such systems should entail the formation of associated species with the anion[261] and hence a decrease of the activity of the catalyst. Strong acids (HCl) can apparently convert into an inactive form both the initial catalyst and products of type (X*), inhibiting thereby the cyclotrimerisation of the isocyanate:



Analogously, it is possible to account for the catalytic activity in the cyclotrimerisation of isocyanates of a number of hydroxyl-containing amines[172] and acylaminoimides,[173] as well as the activity of carbamates as cocatalysts in the cyclotrimerisation of isocyanates in the presence of C_2H_5ONa.[141-143] The possibility of the dissociation of a urethane in the presence of products of type (III), which has been established recently,[8] also constitutes a precondition for the formation of initiators of type (X*) in systems containing a urethane (allophanate) and a strong base. One cannot rule out the possibility that products of this kind are formed also in reactions involving the possible interaction of the isocyanate trimer with an epoxide in the presence of catalysts (strong bases) or with the product of the addition of the epoxide to the catalyst of type (III)–(V), and ultimately lead to the formation of oxazolidinones[202] or products having the tentative structure[262]



The study of the above characteristics of the kinetics and the proposed mechanism of the CT reaction of isocyanates from the standpoint of conformational ideas[263] is undoubtedly of great interest.

The data presented in this review indicate the great variety of catalysts and catalytic systems used in the cyclotrimerisation of isocyanates and also the existence of different points of view on the mechanism of this reaction. Analysis of the data available on this question established that the most effective catalysts of the cyclotrimerisation of isocyanates are ion pairs with separated charges in which the active centre is the anion, the counterion being fairly well localised.

The Reactivity of 1,3,2-Diheterophosphacyclanes Containing a Pentacoordinate Phosphorus Atom

N.A.Polezhaeva and R.A.Cherkasov

Studies on the reactivity of λ^5-1,3,2-diheterophosphacyclanes obtained during the last ten years are examined and described systematically. Data concerning new prototropic and elementotropic processes involving derivatives of pentacoordinate phosphorus are presented. Attention has been concentrated on the elucidation of the influence of the incorporation of a phosphorus(V) atom in the ring on the reactivity of phosphoranes in reactions of various types. The role of phosphorus(V) compounds as intermediates in reactions of phosphorus compounds involving different types of coordination of the phosphorus atom is demonstrated.
The bibliography includes 176 references.

I. INTRODUCTION

The study of the relation between the structure and reactivity of 1,3,2-diheterophosphacyclanes containing tricoordinate[1] and tetracoordinate[2] phosphorus atoms revealed the specific features of the chemical behaviour of these organophosphorus compounds (OPC) associated with the inclusion of a phosphorus atom in the cyclic molecular skeleton. The reactivity of five-membered cyclic OPC of the above type has been found to be particularly unusual, which was manifested in the kinetic, synthetic, and stereochemical results of the reactions involving them.

In the present review an attempt is made to give a systematic account of the survey of the literature data on the reactivity of heterocyclic compounds of pentacoordinate phosphorus containing in the cyclic fragment, together with the phosphorus(V) atom, two other identical or different heteroatoms (O, N, S), namely λ^5-1,3,2-diheterophosphacyclanes. In a number of instances data on the reactivities of acyclic phosphorus(V) compounds and 1,2-heterophosphacyclanes with a similar ligand environment around the phosphorus atom are adduced for comparison.

In the review literature available hitherto attention has been concentrated on the structural[3-5] and to a lesser extent the synthetic[6-8] chemistry of compounds of pentacoordinate phosphorus. Although modern ideas about the structure, the ligand reorganisation processes, and the role of intermediates of the phosphorane type in the chemical reactions of OPC have been developed precisely in relation to λ^5-1,3,2-diheterophosphacyclanes,[9] the relation between the structure and reactivity of these OPC has been studied systematically only for a few examples.[10] During 1970–1980, new experimental data were obtained which deepened our knowledge about the chemical behaviour of compounds of pentacoordinate phosphorus. New types of phosphoranes were synthesised; some of them are stable models of the intermediates formed in reactions of compounds with different types of coordination of the phosphorus atom. New types of prototropic and elementotropic tautomeric systems, including phosphorotropic systems, containing the phosphorus(V) atom have been discovered. Data concerning the mechanisms of nucleophilic substitution reactions at a pentacoordinate phosphorus atom have been obtained for the first time. New possibilities for the employment of phosphorus(V) compounds in organic synthesis have been demonstrated.[11] The "hydroxyphosphorane concept", which is a compilation of empirical rules governing the structure and character of the ligand and valence isomerisation of the phosphorane molecules, has been developed further.[12]

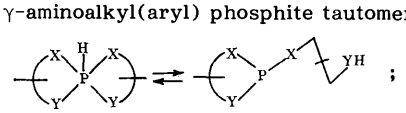
These and other results of the studies during the last ten years are included in the present review. The synthetic and stereochemical aspects of the chemistry of λ^5-1,3,2-diheterophosphacyclanes are used only to the extent that they are necessary for the elucidation of the characteristics of the reactivity of OPC of this type.

II. HYDROPHOSPHORANES

Information about the methods of synthesis and the chemical properties of hydrophosphoranes obtained in the early stages of the development of the chemistry of these compounds of pentacoordinate phosphorus, containing a P–H bond, are presented in the relevant reviews[13-15] and are not included in the present review. The principal characteristic features of the tautomeric processes involving such compounds and the results of the study of their reactivity obtained during recent years are considered here.

1. The Phosphate–Phosphorane Tautomerism

The isolation of the first spirophosphoranes and somewhat later of monocyclic phosphoranes with a P–H fragment (see Pudovik et al.[1] and Arbuzov and Polezhaeva[10] and the literature quoted therein) made it possible to establish the existence of the hydrophosphorane–γ-hydroxyalkyl(aryl) phosphite or γ-aminoalkyl(aryl) phosphite tautomeric equilibrium:



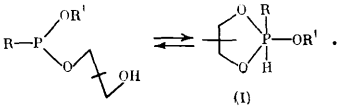
X, Y = NR, O .

The position of this equilibrium depends on the structure of the compound, the medium, and temperature. The phosphorane form is more characteristic of spirocyclanes substituted at the carbon atoms, those containing a secondary amino-group, and unsaturated and aromatic systems. A decrease of temperature promotes an increase of the content of the phosphorus(V) isomer. The introduction of substituents at the endocyclic nitrogen atom in λ^5-oxazaphospholans shifts the equilibrium towards the phosphite.[10,16]

The ease of the phosphorus(V) → phosphorus(III) transition is determined to a large extent by the nature of the endocyclic heteroatoms. For X = Y = O, the equilibrium is displaced towards the spirophosphorane even at room temperature, particularly in the case of substituted rings.[17] For asymmetrically substituted rings, two and sometimes three phosphorus(III) forms can exist in equilibrium with the hydrophosphorane.

Although a correlation between the polarity of the solvent and the content of the phosphite form at equilibrium has not been observed, it has been established that basic solvents shift the equilibrium towards phosphorus(III), while acid solvents shift it towards phosphorus(V).

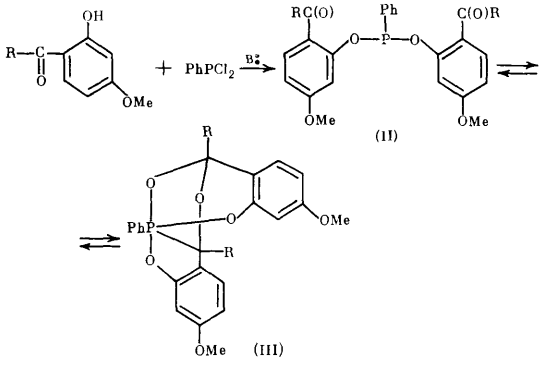
An analogous equilibrium for monocyclic phosphoranes has been detected by ^{31}P NMR; in this case too a decrease of temperature favours the formation of the phosphorus(V) form:



(I)

Hydrophosphoranes of type (I) are interesting because they are intermediates in many reactions of derivatives of tervalent phosphorus with proton-donating reagents (see Pudovik et al.[1] and the literature quoted therein) and also serve as the starting compounds for the synthesis of alkylspirophosphoranes with a P–R bond.[18]

The type of tautomerism described is characteristic mainly of hydrophosphoranes, but the observation of the phosphite–phosphorane tautomerism in the phenylphosphonite (II)–polycyclic phenylphosphorane (III) system has been reported:[19]



(II)

(III)

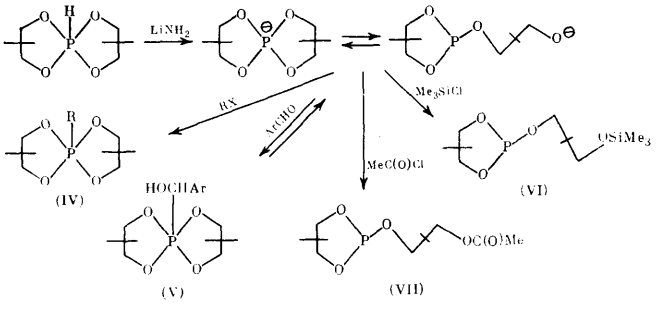
When the polycyclic phosphorane (III) is dissolved in $CHCl_3$, the equilibrium is established in 1 h at 25 °C.

The reactivity of hydrophosphoranes is determined mainly by the phosphite–phosphorane equilibrium and the presence of a fairly mobile P–H proton in the phosphorane isomer. The electrophilic properties of the pentacoordinate phosphorus atom, which predetermine the behaviour of spirophosphoranes and in general of phosphorus(V) derivatives as Lewis acids, play a significant role. In the phosphorus(III) form the reactions can involve one of two nucleophilic centres—the tricoordinate phosphorus atom and the YH(XH) group.

Estimation of the acid properties of hydrophosphoranes[20] demonstrated a decrease of the H-donating capacity following the replacement of endocyclic oxygen atoms by the NH group [apparently as a consequence of the greater $(p-d)_\pi$ donor capacity of the nitrogen atom compared with oxygen[20]] and on transition from spirocyclic to monocyclic hydrophosphoranes. The reactivity of hydrophosphoranes in the reaction with diphenyldiazomethane increases in parallel with the enhancement of the acid properties.[20]

The ease of the abstraction of the P–H proton on treatment of hydrophosphoranes with various metallating agents (metal hydrides and amides and organometallic compounds) is also determined by the structure of the phosphorane.[21,22] Whereas a proton can be abstracted from hydrophosphoranes which are derivatives of pinacol by metal amides (but not hydrides), hydrophosphoranes containing an endocyclic or exocyclic carbonyl group are deprotonated even by diethylamine

According to ^{31}P NMR data, the metallic derivatives of hydrophosphoranes are O anions and not P anions (the $^1J_{PH}$ doublet disappears and the signal of tricoordinate phosphorus appears).[21] However, a dual reactivity is characteristic of these compounds. Their alkylation by alkyl halides, alkenyl halides, and alkyl sulphates gives rise to a product with a spiran structure (IV). In the reactions with aromatic aldehydes the products are α-hydroxyalkylspirophosphoranes (V) which are thermally unstable and on heating regenerate the initial spirophosphorane and the aldehyde. The phosphoranes (V) can be formed also without the participation of metals (see below). Silylation and acylation involve the terminal oxygen atom of the phosphite group and lead to the phosphites (VI) and (VII) respectively.[21] We may note that the reactions of the hydrophosphoranes themselves with acyl chlorides in the presence of tertiary amines also lead to γ-acetoxyalkyl phosphites (VII),[23] while acylation of λ^5-oxazaspirophospholans by acetic anhydride ruptures both P–N bonds:[24]



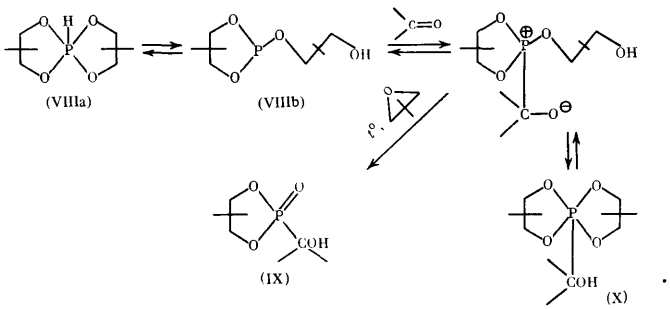
(IV) (V) (VI) (VII)

An analogy with dialkyl phosphites is manifested in these reactions: metallation takes place at the oxygen atom and the subsequent reactions with electrophiles can proceed via both the oxygen and phosphorus atoms.

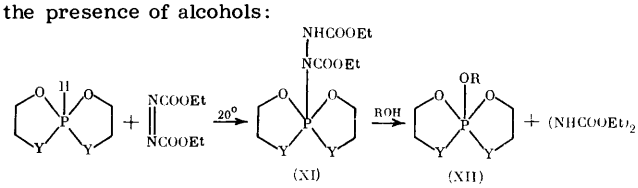
Like dialkylphosphorous acids, hydrophosphoranes interact with aliphatic aldehydes,[21,25] activated ketones, and animals[23,26] and add to electrophilic unsaturated systems.[27,28]

As already stated, although the α-hydroxyalkylspirophosphoranes formed on addition of hydrospirophosphoranes to aldehydes can be isolated, they are unstable and readily decompose. It has been suggested[26] that these reactions involve the nucleophilic addition of the phosphorus(III) atom of the form (VIIIb) to the carbon atoms of the carbonyl group; the dipolar ion, whose formation is promoted by an excess of the carbonyl reagent, is stabilised in two ways:

the elimination of the epoxide leads to cyclic α-hydroxyphosphonates (IX), while cyclisation gives rise to spirophosphoranes (X):



Imines are less reactive in the addition reactions of hydrospirophosphoranes than the aldehydes with a similar structure;[28] in the presence of alcohols cyclic enamines oxidise hydrospirophosphoranes to the corresponding pentaoxaspirophosphoranes.[29] The oxidation products (XII) are obtained ultimately also on interaction with azodicarboxylic ester in the presence of alcohols:

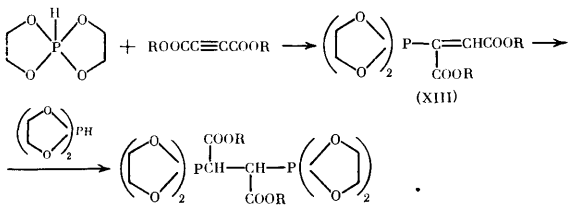


It has been suggested[30] that the adduct (XI) is formed initially, but it is unstable and has not been isolated.

The reactions of hydrospirophosphoranes with aldehydes, ketones, and imines are reversible and their thermodynamically controlled products are phosphoranes with an exocyclic P–C bond. Like the interaction with phenyl azide[31] and with certain other unsaturated systems,[23,25,28,29] these reactions are characteristic only of the hydrophosphoranes which are in equilibrium with the phosphite form; in the absence of the latter, there is no reaction.

In the general case the reactivity of λ^5-1,3,2-diheterophospholans with P–H bonds in reactions with electrophiles depends to a large extent on the nature of the heteroatoms attached to the phosphorus atom. Spirophosphoranes containing even one 1,3,2-oxazaphospholan ring are more reactive than tetrahydroxyspirophosphoranes.[28]

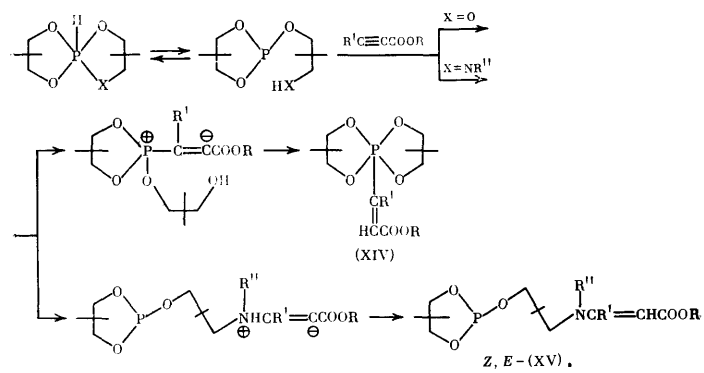
The nature of the endocyclic heteroatom of hydrospirophosphoranes influences also the synthetic result of the reactions involving addition to acetylenic reagents. Tetrahydroxyhydrophosphoranes readily add to acetylenedicarboxylate esters and proprionates with formation of vinylphosphoranes (XIII).[32] The adduct (XIII), which exists in the form of two stereoisomers, which can be separated by crystallisation, combines with a second molecule of hydrophosphorane at an elevated temperature:



It is striking that the P–C bond in the vinylphosphorane is fairly labile and is readily broken on treatment with an alcoholic solution of sodium alkoxide.[33] This can be accounted for by the high electrophilicity of the phosphorus-(V) centre.

If the spirophosphorane contains even one endocyclic P–N bond, then the reaction products are the stereoisomeric phosphites (XV). However, ring-substituted λ^5-oxazaphospholans and λ^5-dioxaphospholans form compounds of pentacoordinate phosphorus of type (XIV). It has been suggested[34] that the phosphite formed is involved in the addition process (Scheme 1); hydrophosphoranes which are not in equilibrium with the phosphorus(III) isomer are inert in such reactions.

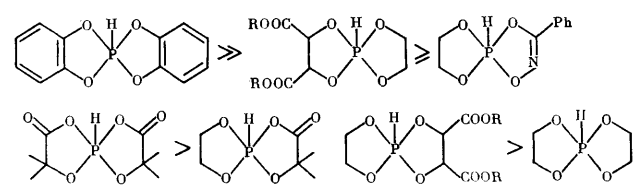
Scheme 1



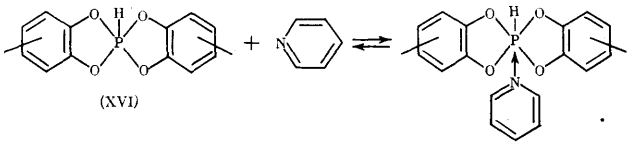
The mechanism presented in Scheme 1 is supported by the fact that alcohols do not react with these acetylenic compounds, whereas secondary amines readily add to them. The interaction of the γ-aminoalkyl cyclic phosphite isomer therefore involves the terminal amino-group like the addition of amines, while the oxa-analogues add as a result of the nucleophilic attack by the tervalent phosphorus atom on the β-carbon atom of the acetylenic group.[32–34]

Vinylphosphoranes of types (XIII) and (XIV) combine with a second hydrospirophosphorane molecule slowly, while the addition of dialkyl phosphites (in the presence of bases) is rapid. This difference has been attributed[33] to the different nucleophilic properties and steric hindrance of the phosphorus centres of the addends. In the addition of vinylphosphoranes, the nucleophile is subjected to a β-directing effect [in relation to phosphorus(V)], as in the analogous reactions of the vinyl derivatives of tricoordinate and tetracoordinate phosphorus. Only the vinylphosphorane obtained from propiolic acid esters (XIV, R' = H) combines with amines at the α-carbon atom.[33] Presumably the β-directing effect under conditions involving competition between the electron-accepting substituents in compound (XIV) is more pronounced for the alkoxycarbonyl group than for the spirophosphoranyl group.

Numerous data demonstrating the manifestation of the Lewis acidity of the phosphorus atom in hydrophosphoranes have been obtained. The following series, based on the weakening of this acidity, which agrees with the decrease of the overall electron-accepting capacity of the substituents in λ^5-diheterophospholan rings, have been found:[22]



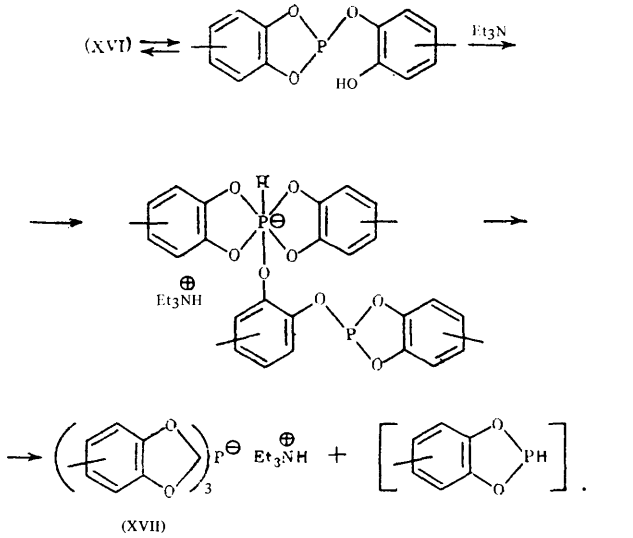
The Lewis acidity of hydrophosphoranes predetermines their capacity for coordination to bases, which increases the coordination number of the phosphorus atom to six:[35]



(XVI)

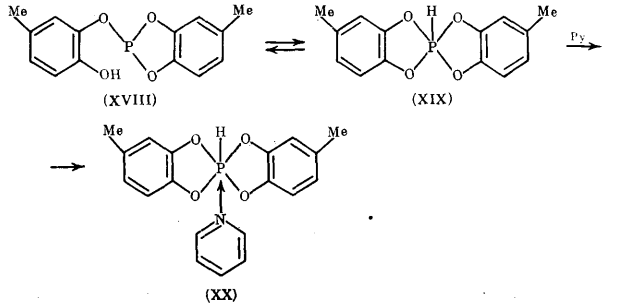
According to ^{31}P NMR data, the reversible reaction of compound (XVI) with pyridine leads to compounds of hexacoordinate phosphorus, whose content in the equilibrium mixture increases with increase of temperature. An analogous phenomenon obtains also when other spirophosphoranes without the P–H fragments are used, but in these cases it is less marked.[36]

The interaction of substituted dibenzohydrospirophosphoranes (XVI) with bases stronger than pyridine (triethylamine, triethylenediamine, and diisopropylamine) leads to the phosphoranes (XVII) as a result of the interaction of the two tautomeric forms of the hydrophosphorane:[37]



(XVII)

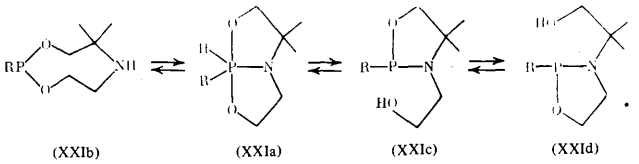
The above data indicate the ability of hydrophosphoranes to be involved in a tautomeric equilibrium with γ-hydroxyalkyl(aryl) phosphites, on the one hand, and (in basic media) with derivatives of hexacoordinate phosphorus, on the other. The presence of both types of equilibria has been established in the (XVIII) ⇌ (XIX) ⇌ (XX) system:[36]



(XVIII) (XIX) (XX)

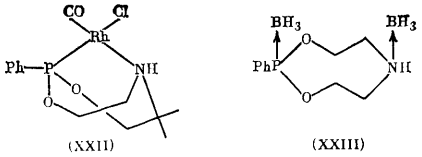
With increase of the amount of pyridine, the equilibrium shifts towards the "phosphorate" (XX).

Tautomerism involving the formation of the forms (XXI, b–d) is potentially possible for the bicyclic hydrophosphoranes (XXIa):



(XXIb) (XXIa) (XXIc) (XXId)

Only the phosphorane (XXIa), which has been found to be involved in the P–H P–D deuterium exchange, has been detected in solution;[38–40] the form containing a phosphorus-(III) atom has been identified in the gas phase by photoelectron spectroscopy.[41] Bicyclohydrophosphoranes combine with phenyl azide.[42] They react with transition metals to form complexes in which the coordinated ligand can exist in a monodentate or bidentate monocyclic phosphite form of type (XXII).[43–46]

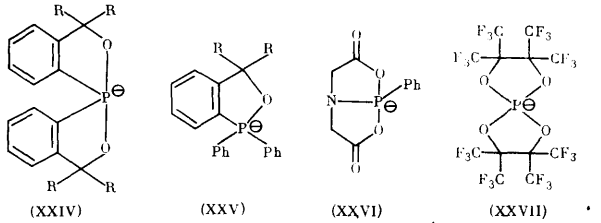


(XXII) (XXIII)

The adduct (XXIII), containing two molecules of the complex-forming agent, has been obtained by the interaction of (XXIa, R = Ph) with $Me_2S.BH_3$.[42]

2. Phosphoranide Anions

As pointed out above, the deprotonation of hydroxyspirophosphoranes results in the formation of phosphoranide anions, which may be involved in a tautomeric equilibrium with phosphite-alkoxides.[47,48] This method of generating stable cyclic phosphoranide anions has been used[48–52] for the synthesis of stable cyclic anionic systems (XXIV)–(XXVII) from the corresponding hydrophosphoranes; the bases employed were butyl-lithium[50,51] or triethylamine:[48,52]

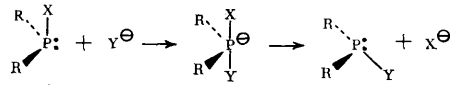


(XXIV) (XXV) (XXVI) (XXVII)

R = Me, CF_3

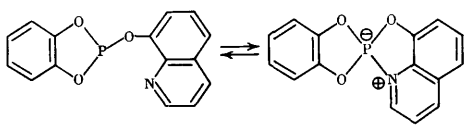
X-Ray diffraction (XRD) data for the anion (XXVII) have shown that it has the structure of a distorted trigonal bipyramid (TBP) with the unshared electron pair (LEP) in the equatorial (*e*) position and with a large difference between the lengths of the axial (*a*) P–O bonds (1.77 and 2.02 Å).[48]

Species of the type of phosphoranide anions have been postulated as unstable intermediates in bimolecular nucleophilic substitution reactions at a tricoordinate phosphorus atom:[1,53]



The isolation and identification of stable phosphoranide anions is of fundamental importance for the understanding of the mechanisms of nucleophilic substitution at the atoms of not only tricoordinate[1] but also tetracoordinate[2] and pentacoordinate (see Section VII) phosphorus atoms, which, at least in cyclic OPC, can proceed via a stage involving the formation of intermediates with an increased, compared with the initial phosphorus compound, coordination number of the central atom.

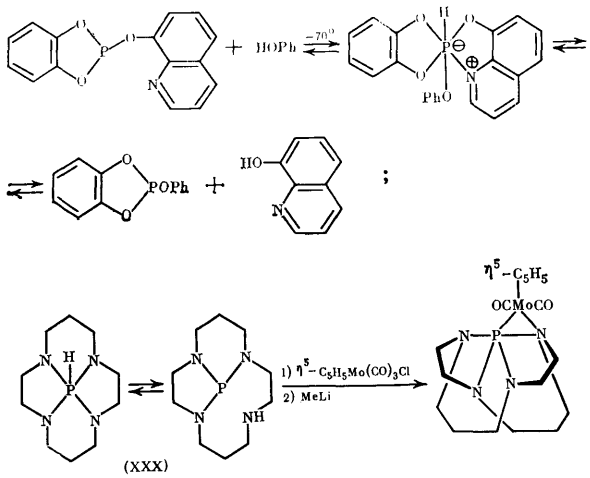
A phosphoranide centre can be formed also intramolecularly:[54]



(XXVIII) (XXIX)

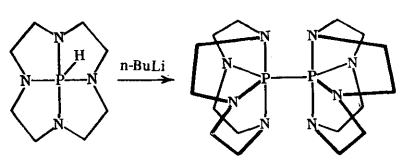
The equilibrium (XXVIII) ⇌ (XXIX), detected by ^{31}P NMR, is strongly displaced towards the form (XXVIII). Intermolecular nucleophilic substitution in this system takes place via an intermediate with a hexacoordinate phosphorus atom.[55]

Unusual polycyclic phosphoranides have been synthesised by the reaction of the hydrophosphorane (XXX) with transition metal compounds.[56] According to XRD data, the phosphorus ligand in these compounds is bidentate and is coordinated to the metal atom via both the phosphoranide and amine centres.

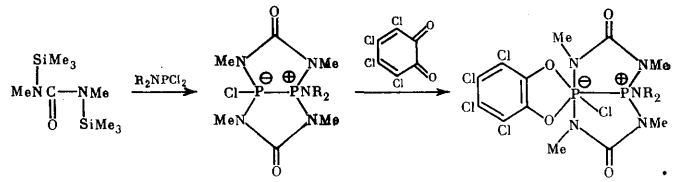


(XXX)

We may note, incidentially, that the first diphosphorane compound with a P(V)–P(V) bond has been obtained from a polycyclic hydrophosphorane:[57]



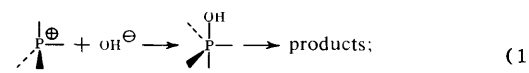
Compound (XXXI) contains a direct bond between the phosphonium and phosphoranide phosphorus atoms. The interaction with chloranil results in the formation of a "phosphoniaphosphorate"—the first compound with a P(IV)–P(VI) bond:[58]



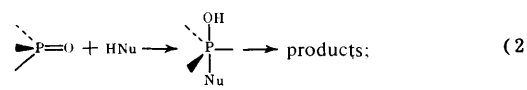
(XXXI)

III. HYDROXYPHOSPHORANES. THE PHOSPHATE–PHOSPHORANE TAUTOMERISM

The development of the chemistry of hydroxyphosphoranes is closely related to modern ideas concerning the mechanism of nucleophilic substitution reactions at a tetrahedral phosphorus atom [$S_N2P(IV)$], which are based on the rules associated with the hydroxyphosphorane concept—intermediates having a TBP structure with a pentacoordinate phosphorus atom are formed in these processes (see Cherkasov et al.[2] and the literature quoted therein). The character of such intermediates determines to a large extent the reactivity of phosphorus(IV) compounds and the synthetic and stereochemical results of nucleophilic substitution reactions. On hydrolysis of phosphonium salts [Eqn.(1)] or solvolysis of phosphoryl compounds by proton-containing nucleophiles [Eqn.(2)], the above TBP intermediates should have the hydroxyphosphorane structure:



(1)



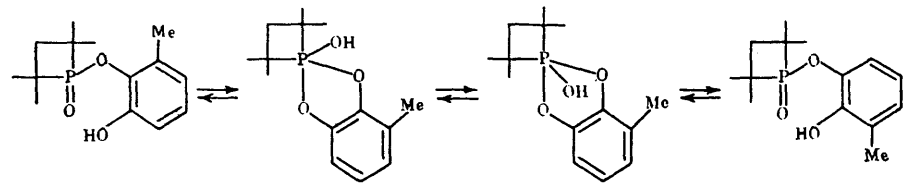
(2)

Nu = nucleophile.

The identification of the hydroxyphosphoranes and the study of their properties are therefore of decisive importance for the demonstration of a two-stage mechanism of the nucleophilic substitution reactions at phosphorus(IV), including biochemical phosphate transfer processes.[2,59,60]

Nevertheless, until the end of the 1970's, the demonstration of the formation of hydroxyphosphoranes in the nucleophilic reactions of phosphorus(IV) remained an unsolved problem. The first unambiguous evidence for the formation of hydroxyphosphoranes was obtained in the study of the interaction of cyclic phosphoryl compounds with proton-containing nucleophiles[2] and the hydroxyphosphoranes were trapped directly and successfully characterised in a study of the isomerisation of γ-hydroxyalkyl(aryl) esters of cyclic quinquevalent phosphorus acids (see Cherkasov et al. and the literature quoted therein[2]). Methods for the synthesis of stable hydroxyphosphoranes were subsequent developed.

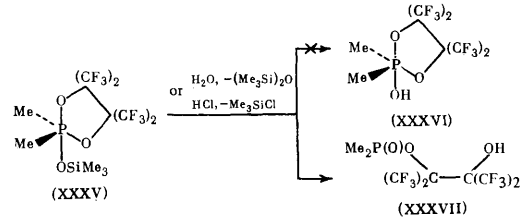
The 5-hydroxy-2-methylphenyl ester of the cyclic four-membered phosphinic acid (XXXII) shows signs in solution of a dynamic equilibrium due to the isomerisation (XXXII) ⇌ (XXXIV) involving the intermediate formation of the hydroxyphosphoranes (XXXIII, a and b):[61]



(XXXII) (XXXIIIa) (XXXIIIb) (XXXIV)

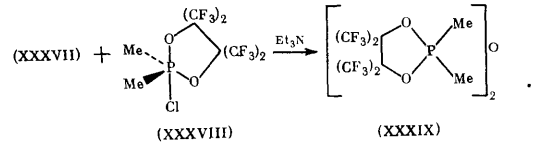
The activation energy for the isomerisation process is 17 kcal mol^{-1}. The concentration of compounds (XXXIII) is insufficient for their direct detection by NMR, but the possibility of their formation has been demonstrated by the reaction of a mixture of compounds (XXXII) and (XXXIV) with diazomethane: the methyl ester of the acid (XXXIII) was obtained in 5% yield. It is striking that the activation barrier to the isomerisation of the acyclic analogues (XXXII) is 24 kcal mol^{-1} for diphenylphosphinate and 28.3 kcal mol^{-1} for diphenylphosphinothioate, which reflects the well known sequence in the decrease of the energy of the TBP on passing from acyclic to monocyclic and spirocyclic structures[2] and the lower stability of mercaptophosphoranes compared with hydroxyphosphoranes.[62]

In this connection we may also note that, when the monocyclic siloxyphosphorane (XXXV) is acidified or cautiously hydrolysed, the product is not the hydroxyphosphorane (XXXVI) but the isomeric γ-hydroxyalkyl phosphinate (XXXVII):[63]



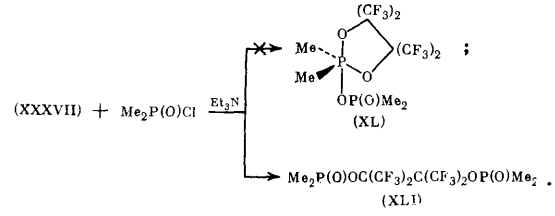
(XXXV) (XXXVI) (XXXVII)

However, it is of interest that the reaction of the phosphinate (XXXVII) with the chlorophosphorane (XXXVIII) proceeds with transfer of the reaction centre and leads to the anhydride of the hypothetical P(V)–OH acid (XXXIX):



(XXXVII) (XXXVIII) (XXXIX)

However, the acyclic chloride of dimethylphosphinic acid converts compound (XXXVII) into the symmetrical bisphosphinate (XLI) and not into the mixed anhydride (XL):[63]

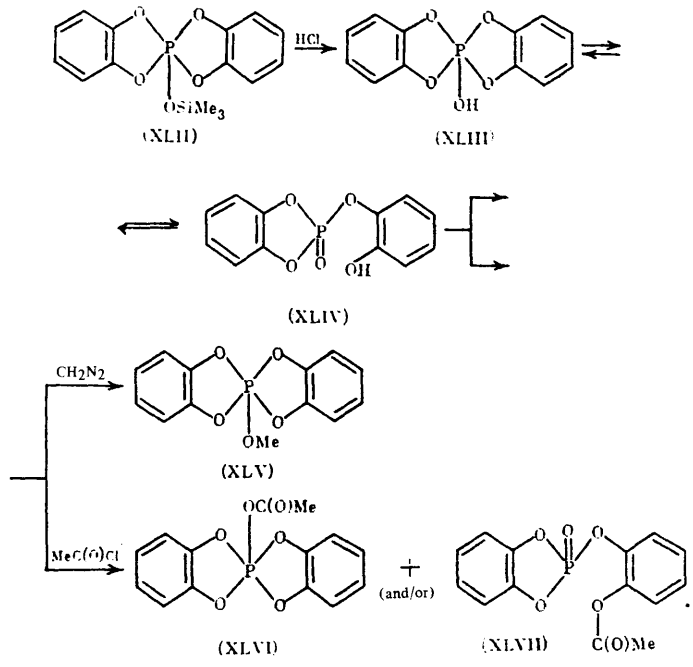


(XL) (XLI)

The formation of hydroxyphosphoranes has been postulated also in other reactions of γ-hydroxyalkyl(aryl) esters of phosphorus(IV) acids.[2]

These results indicate the possibility of the existence of a fairly mobile phosphate–phosphorane equilibrium involving hydroxyphosphoranes, which has been demonstrated for the first time by Ramirez et al.[64] and by Chang Bui Cong et al.[65] The product of the desilylation of bis(phenylenedioxy)siloxyphosphorane (XLII) has the structure of the phosphate (XLIV) in the crystalline state[66] [cf. the hydrolysis of the siloxyphosphorane (XXXV) to the phosphinate (XXXVII) [63]]. However, in acetonitrile at −48 °C the ^{31}P NMR spectrum showed two signals due to the phosphorus nucleus: the hydroxyphosphorane (XLIII) [$\delta(^{31}P) = 27.0$] was found together with the phosphate (XLIV) [$\delta(^{31}P) = +6.7$] in equilibrium with the latter and its amount was greater than that of the phosphate—the ratio P(IV) : P(V) = 1 : 1.5. The content of the phosphorus(V) form increases in the more basic acetone (3 : 1 at −48 °C):

Scheme 2



(XLII) (XLIII) (XLIV) (XLV) (XLVI) (XLVII)

Treatment of the (XLIII) ⇌ (XLIV) mixture with diazomethane affords a qualitative yield of the methoxyphosphorane (XLV); acetylation leads to a mixture of the acetyl derivatives of the phosphorane (XLVI) (20%) and the phosphate (XLVII) (80%) (Scheme 2). However, one should note that the synthetic result of the acetylation of compound (XXXV) or the (XLIII) ⇌ (XLIV) mixtures does not reflect the contents of the phosphorus(IV) and phosphorus(V) forms in the solutions: the reactions can proceed with transfer of the reaction centre [this has been confirmed

particularly strikingly by the reaction (XXXVII) + (XXXVIII) → (XXXIX) or may be subject to thermodynamic control. It has been established that the acetoxyphosphorane (XLVI) can be partly isomerised to the phosphate (XLVII) under the influence of the HCl evolved in the reaction.[66]

In the general case an increase in the content of the phosphorus(V) form in the hydroxyphosphorane–phosphate equilibrium is promoted by a decrease of temperature, by an increase of the basicity of the medium, and by the enhancement of the electron-accepting properties of the dioxyalkylene(arylene) substituent.

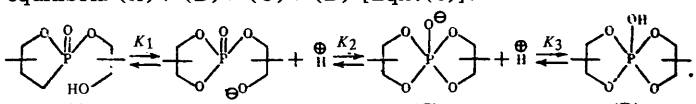
The intensity of the hydroxyphosphorane signal in the ^{31}P NMR spectra of the P(V) ⇌ P(IV) mixture begins to increase with decrease of temperature in those cases where individual lines correspond to each of the two forms P(V) and P(IV) [slow, in terms of the NMR time scale, equilibria of the type (XLIII) ⇌ (XLIV) and (LVI) ⇌ (LVIa) (Table 1)]. The averaged signal of the two equilibrium structures appears in rapid equilibria [hydroxyphsophorane (XLVIII) ⇌ (LI)]. A decrease of temperature entails a successive upfield shift of the resonance peak until the attainment of a fixed position in the region characteristic of hydroxyphosphoranes[67] (Fig.1).

The opening of the five-membered ring and the formation of phosphtate isomers are catalysed by acids. On the other hand, the introduction of bases into the P(V) ⇌ P(IV) mixture favours the hydroxyphosphorane structure up to formation of stable hydrogen-bonded complexes or salts of hydroxyphosphoranes, which can be isolated.[65–68]

However, the structure of the cyclic skeleton of the molecules of hydroxyphosphoranes is of decisive importance for the increase of their stability. Hitherto stable hydroxyphosphoranes have been identified only for a series of spirocyclic phosphoranes made up of five-membered oxa- and dioxa-phospholan rings (the effect of the five-membered ring).[12,69] NMR evidence has been adduced for the formation of relatively unstable acyclic,[70] monocyclic,[71] and condensed bicyclic hydroxyphosphoranes[72] (Table 1).

The stability of hydroxyphosphoranes increases sharply up to the formation of the sole P(V) form in solutions after the introduction of electron-accepting oxo-groups [compounds (LII), (LIII), (LV), and (LVIII)] or trifluoromethyl groups [compounds (LVII) and (LIX)]. A significant stabilisation of hydroxyphosphoranes is ensured by the presence of geminal dimethyl, bis(trifluoromethyl), and diphenyl fragments in rings (the Ingold–Thorpe effect[2]).

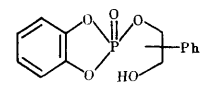
The estimation of the factors controlling the relative amounts of the forms involved in the hydroxyphosphorane ⇌ γ-hydroxyalkyl(aryl) phosphate equilibrium reduces, other conditions being equal, to the analysis of the sequence of equilibria (A) ⇌ (B) ⇌ (C) ⇌ (D) [Eqn.(3)]:[67]



(3)

The position of the hydroxyphosphorane–phosphate equilibrium is largely determined by two equilibrium constants—the dissociation constant K_1 and the cyclisation constant proper K_2, i.e. $K = K_1K_2$.[67] The determination of the thermodynamic parameters of the ring closure stage (B) ⇌ (C) (K_2) for compounds (XLVIII)–(L) with hydroxyacid ligands showed that the P(IV) form is slightly preferable for the cyclic oxo-compound (XLVIII) (ΔG^0 = +0.08, Table 2), whereas the spiran forms are more stable for the monosubstituted homologues (XLIX) and (L) under these conditions. The parameters obtained are close to those for other P(III) ⇌ P(V)[67] and P(V) ⇌ P(VI)[80] spirocyclisation processes.

The derivatives of the *gem*-disubstituted hydroxyacids (LII) and (LIII) and the phosphorane (LIV), synthesised with participation of benzohydroxamic acid, exist in the phosphorane forms over a wide temperature range (Fig.1). It is striking that the cyclic derivative of phenylethanediol (LX), whose structure is close to that of the spirophosphorane (LIV), does not pass to the spirophosphorane form under any of the conditions investigated. This has been attributed to the much lower dissociation constants K_1 of the phosphate (LX) compared with the phosphorylated derivative of benzohydroxamic acid (LIV):[67]



(LX)

The hydroxyphosphoranes (LVI)–(LVIII) containing endocyclic P–C bonds are exceptionally stable. These compounds have been isolated and exist as hydroxyphosphoranes in the crystalline state; the equilibrium with the phosphinate isomer is observed only in solutions of the tetrasubstituted hydroxyphosphorane (LVI).[69,76] The perfluoropinacone derivative (LIX) is so stable under the usual conditions that it can be easily recrystallised in the presence of moisture; the five-membered rings are not ruptured by sulphuric acid and potassium hydroxide.[79] In the latter case the poassium hydroxyphosphoranide is formed readily.

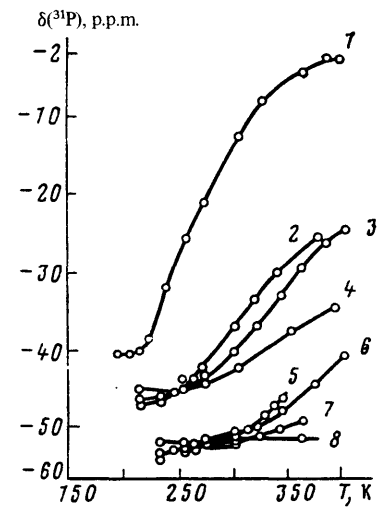


Figure 1. The influence of temperature on $\delta(^{31}P)$ for hydroxyphosphoranes:[67] 1) (XLVIII) (DMF); 2) (XLIX) (DMF); 3) (L) (DMF); 4) (LI) (DMF); 5) (LII) (CD_3CN); 6) (LII) (PhCN); 7) (LII) (DMF); 8) (LIII) (DMF); the numbering of the compounds is the same as in Table 1.

The XRD data for the triethylammonium salt of the hydroxyphosphorane (LIII)[74] and the salts of oligomeric hydroxyphosphoranes[75] confirmed that they have the TBP structure with five-membered rings in the *a* and *e* positions and the oxy-anion in the *e* position. The exocyclic P–O^- bond in these compounds is shortened, which reflects its double bond character.[73] This is caused in its turn by the influence of the oxo-group, as a result of which the phosphorus atom acquires a significant positive charge and the hydroxyphosphorane acquires fairly pronounced acid properties (Table 1).

**Approximate estimate.
***$\delta(^{31}P)$ for oligomers: −45 for the complex of the trimer with DMSO; −42.5 for the complex of the pentamer with trimethylamine.[75]

Note. Numbers in square brackets denote references (Ed. of Translation).

The fact that XRD data[63,66] for the hydroxyphosphinate (XXXVII) and the hydroxyphosphate (XLIV) confirm the favourable entropy of the hydroxyphosphorane ring closure is striking. The hydroxy-group in the 2-position in the alkylene (arylene) ether group is in direct proximity (~3 Å) to the P(IV) atom.

(La)	−4.8	−11	−1.3

* 30° C.

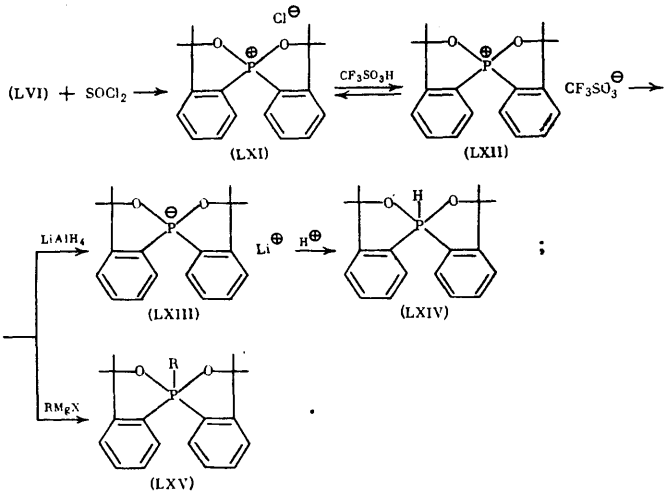
The isolation of stable hydroxyphosphoranes permitted well-founded inferences about their acid properties. This problem is of fundamental importance because hydroxyphosphoranes are partial esters of the hypothetical pentacoordinate phosphorus acid $P(OH)_5$.[81] At different stages of the investigation of hydroxyphosphoranes, their acid properties were estimated within wide limits—from pK_a = 10–11 [64,66] to claims that the strength of these acids is fairly high.[65] The latter were based on the ability of hydroxyphosphoranes to form stable hydrogen-bonded complexes with dimethylformamide (DMF) and dimethyl sulphoxide (DMSO) and ammonium salts with tertiary amines.[65,67,68]

Indeed direct determination of the pK_a (Table 1) demonstrated their fairly marked dependence on the character of the substituents. It was found that the dissociation constants of the oxo-substituted hydroxyphosphoranes (LIII) and (LV) are higher than those of the strong dichloroacetic and diphenylphosphoric acids.[73–75] As expected, in the general case the acid properties of the hydroxyphosphoranes increase sharply after the introduction of electron-accepting substituents into the five-membered rings (Table 1).

The study of the comparative reactivities of the hydroxyphosphoranes (LVI)–(LVIII) also demonstrated a significant role of the nature of the substituents in the ring. Whereas the methylated derivatives (LVI) is readily converted into the quasi-phosphonium compound (LXI) on treatment with thionyl chloride, the analogous salts are not formed from compounds (LVII) and (LVIII). In these cases the electron-accepting ring substituents apparently destabilise the positive charge on the phosphorus atom. On the other hand, the difference between the acid strengths is such that the sodium salt of the acid (LVII) can be formed on treatment with alkali, whereas compound (LVI) is deprotonated only with sodium hydride. The oxo-analogue (LVIII) is converted into a phosphorus(IV) derivative in aqueous alkaline solutions.[69]

The anion exchange between compound (LXI) and trifluoromethanesulphonic acid leads to the triflate (LXII); the latter is reduced to the phosphoranide anion (LXIII), which gives rise to the hydroxyspirophosphoranes (XLIV) on acidification. It is of interest that the first representatives of hydroxyphosphoranes have been obtained by oxidising hydrophosphoranes.[65,67] Alkylation (arylation) of the cations (LXII) with Grignard reagents affords the alkyl(aryl)spirophosphoranes (LXV).[69]

The description of the TBP structure of hydroxyphosphoranes is based on the concept of hypervalent bonds: the apical and central atoms of the TBP are linked by a three-centre four-electron delocalised bond, which consists of one unoccupied and two occupied MO made up of a single *p* orbital of each atom involved in the hypervalent bond.[69,82] Such a structure presupposes the presence of long bonds between the electronegative *a*-atoms and the central atom carrying a partial positive charge.



The stability of the TBP increases after the introduction of electron-accepting substituents at the *a*-atoms and is increased by the five-membered ring and Ingold–Thorpe effects. It is believed[69,82] that a significant difference between the electronegativities of the *a*- and *e*-atoms, which is achieved by introducing σ-donor carbon-centred or p_π-donor heteroatomic equatorial ligands, is an important factor stabilising hypervalent structures. It has also been suggested[79] that steric shielding by bulky substituents, for example trifluoromethyl substituents in the structure of compound (LVII), can also promote an increase of the stability of such systems. This is evidently likewise true of hypervalent compounds of other elements (S, Si, I).[82]

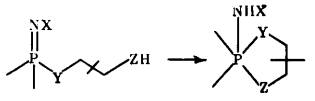
The importance of the synthesis and study of the structure and properties of hydroxyphosphoranes goes beyond the framework of the investigation of this new class of OPC alone. After the isolation and identification of hydroxyphosphoranes, the hydroxyphosphorane concept and the hypothesis of the role of phosphorus(V) intermediates in the nucleophilic substitution reactions at P(IV) received powerful experimental support. Data for the new type of phosphorus(V) acids combined with data for the strong acids of tetracoordinate phosphorus and weak acids of tricoordinate phosphorus constitute an integral picture of the complex problem of the relation between the structure and acidity of organophosphorus acids. It is extremely significant that the pathways leading to the approach to hydroxyphosphoranes presupposes the "opening" of the very strong (120–150 kcal mol^{-1} [83]) P=O bond (in essence addition to the P=O bond). Apparently energy is then gained as a result of the spirocyclisation of the reaction products.[2,69,76] This makes it necessary to look again at the character of the driving forces in many reactions of OPC: it may be that the formation of strong P=O bonds (or their analogues), as, for example, in the Arbuzov or Wittig reactions, is not the only factor which

determines the energy relations of chemical processes involving OPC and that account must be taken also of other factors, for example, the spirocyclisation and the effects accompanying it (see above).

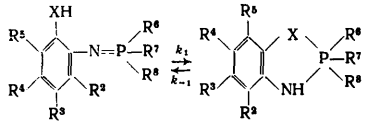
IV. AMINOPHOSPHORANES. THE PHOSPHIMIDE–PHOSPHORANE TAUTOMERISM

As stated above, the P=O double bond can participate in the addition reactions of H-containing nucleophiles with formation of hydroxyphosphoranes. In intermolecular addition reactions [Eqn.(1)] the latter are not detected—the interaction models the first stage of the nucleophilic substitution process at the tetrahedral phosphorus atom [$S_N2P(IV)$] which proceeds via an addition-elimination mechanism. Intramolecular addition to the P=O bond, particularly when it is accompanied by spirocyclisation, in some cases leads to stable hydroxyphosphoranes and this principle can evidently serve as the basis of the synthesis of stable cyclic phosphoranes.

Indeed the intramolecular addition of the γ-ZH functional group in alkoxy- or aryloxy-substituents to the P=N bond of phosphorus imides makes it possible to obtain stable aminophosphoranes (see Cherkasov et al.[2] and the literature quoted therein):



The intramolecular addition reactions involving the phosphimino-group and leading to spirocyclic aminophosphoranes are as a rule irreversible (see, however, Dahl et al.[84]), whereas in the series of monocyclic λ^5-diaza- and λ^5-oxazabenzophospholans it is possible to observe the ring–chain phosphimide–phosphorane tautomerism [Eqn.(4)] after the appropriate selection of substituents at the phosphorus and nitrogen atoms and in the benzene ring:



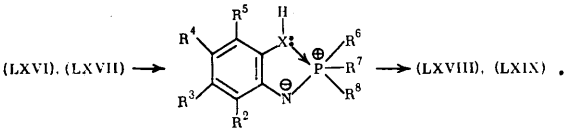
(4)

(LXVI): X = O; (LXVII): X = NR^1 (LXVIII): X = O; (LXIX); X = NR^1.

The study of the thermodynamics of equilibrium (4) in several reaction series[85–87] demonstrated the appreciable influence of temperature and of the nature of the solvent on the ratio of the tautomeric forms. Thus in nitrobenzene more than 90% of the acyclic phosphorus(IV) is present in the equilibrium mixture, whereas in tripropylamine the degree of cyclisation reaches 100%. With decrease of temperature, the equilibrium constant $K = k_1/k_{-1}$ increases [the content of the cyclanes (LXVIII) and (LXIX) increases].

The electronic influence of substituents is clearly shown when the groups in the phosphorus and imine components of the molecules are varied. Hydrogen atoms at the phosphorus atom fully displace the equilibrium towards aminophosphoranes. Electron-donating substituents in the imine fragment (R^3 = t-Bu) favour the phosphorus(V) form, while electron-accepting substituents ($R^3 = Ph_3C$) increase the content of the phosphimides (LXVI) in the tautomeric mixture.[85]

Thus the enhancement of the electron-donating properties of the atom X (O and N) to which a mobile hydrogen atom is attached and of the electron-accepting properties of the phosphorus atom promotes cyclisation. This is seen particularly clearly in the diazaphospholan series:[87] the NMR spectra of *N*-unsubstituted acyclic phosphimides (LXVII), R^1 = H, show only the phosphorus(IV) signal. These results are satisfactorily consistent with the mechanism involving the nucleophilic addition of the heteroatom X to the phosphorus atom in the cyclisation process.[85]



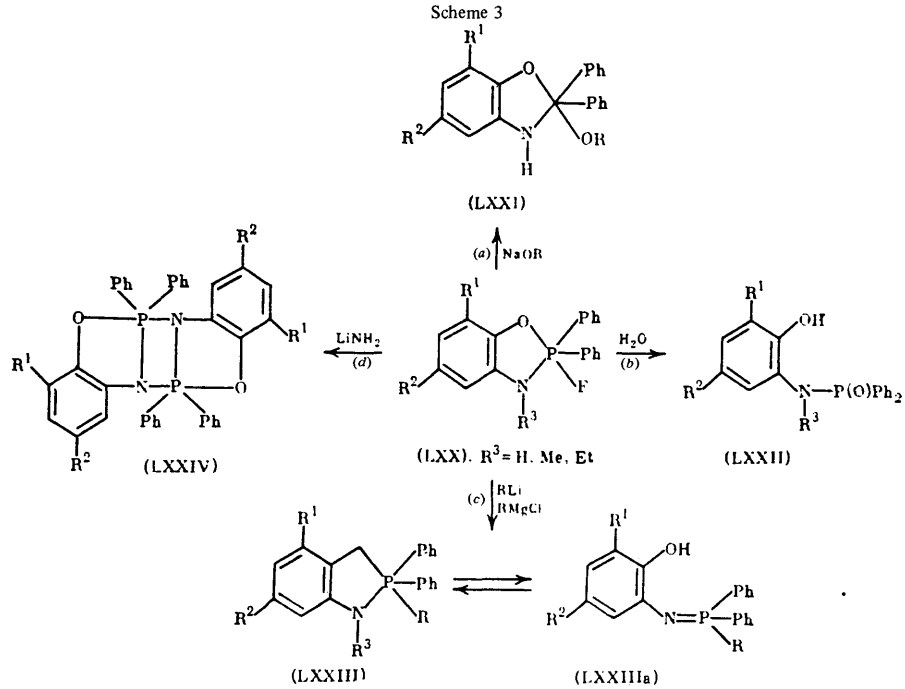
However, the steric characteristics of the substituents play a decisive role. In the series of oxaza-derivatives the equilibrium (LXVI) ⇌ (LXVIII) is displaced towards λ^5-oxazaphospholans only for R^4 = t-Bu.[85,86] Appreciable amounts of the phosphoranes (LXIX) appear in the mixture when the free rotation of the phosphimino-group in phosphimides is hindered (R^2 = t-Bu).[87]

This reaction series also illustrates the spirocyclisation effect which stabilises the phosphorus(V) form. The inclusion of phosphorus atoms in the five-membered ring, as in compound (LXVII, $R^7 = R^8$ = 2,2′-biphenylene), makes it possible to detect appreciable amounts of λ^5-diazaphospholans in the mixture even in those cases where the nitrogen atom is unsubstituted (R^1 = H).[87]

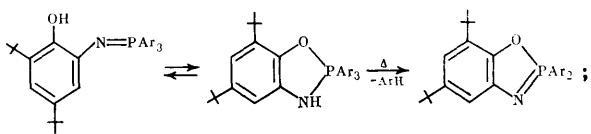
The observed features of the interconversions of phosphimides and aminophosphoranes are also manifested in the synthetic results of certain reactions of λ^5-oxazaphospholans.[88] Thus the ligand exchange of fluorine in the aminofluorophosphorane (LXX) for an alkoxy-group (Scheme 3, reaction *a*) does not alter the coordination of the phosphorus—the phosphorane (LXXI) is obtained, while hydrolysis (reaction *b*) leads to the phosphinamidate (LXXII) and not to an aminohydroxyphosphorane. The substitution of the fluorine atom by carbon-centred nucleophiles (reaction *c*) for R^3 = H induces the appearance of a mixture of products [(LXXIII, R^3 = H) ⇌ (LXXIIIa)]; when R^3 = alkyl, such tautomerism is naturally impossible and the only reaction product is the λ^5-oxazaphospholan (LXXIII, R^3 = Me or Et). The interaction of compound (LXX) with lithium amides (reaction *d*) leads to diazadiphosphetidines (LXXIV), evidently via the stage involving the formation of the phosphimine (LXXVI) with an endocyclic P=N bond:[88]†

† For information about the ease of dimerisation of cyclic phosphimides, see Dahl et al.[84] and Sheldrick et al.[89] and the literature quoted therein.

Scheme 3



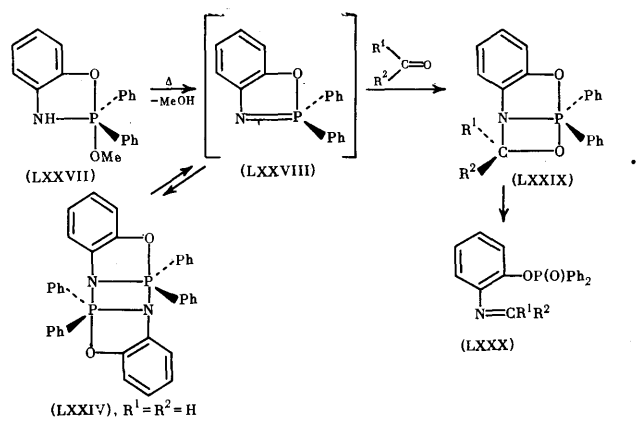
The phosphimides (LXXVI, a and b) are also formed when the phosphimides (LXXV, a and b) are heated above the melting point, which is accompanied by the evolution of the corresponding hydrocarbons:[90]



(LXXV, a and b) (LXXVI, a and b)

Ar = Ph (a), *n*-MeC_6H_4 (b)

The ability of cyclic aminophosphoranes to be converted into phosphimides has found a synthetic application in the reactions with carbonyl compounds.[91] The interaction of phosphorane (LXXVII) with aldehydes, ketones, and formamides proceeds via a stage involving the formation of the phosphimide (LXXVIII), which is converted into the phosphinates (LXXX) via a mechanism analogous to that of the Wittig reaction:

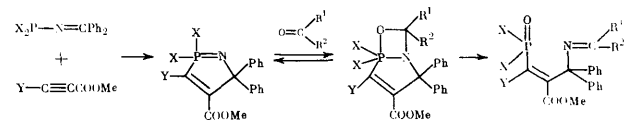


(LXXVII) (LXXVIII) (LXXIX) (LXXX)

(LXXIV), $R^1 = R^2 = H$

The formation of the phosphimide (LXXVIII) has been confirmed by the isolation of its dimer (LXXIV, R^1, R^2 = H) on thermolysis of compound (LXXVII) in solution or in the liquid state. The formation of the same final products (LXXX) as a result of the reaction of diazaodiphosphetidine (LXXIV) with carbonyl compounds indicates the reversibility of the dimerisation reaction (LXXVIII) ⇌ (LXXIV).

The transition state (LXXIX) (or the intermediate) in these reactions is modelled by the stable adducts (LXXXII, R^1 = Me or CF_3; R^2 = Me, CF_3 or Ph), obtained and isolated as a result of the consecutive [2 + 2]-cycloaddition reactions,[89,92] accompanied by a change in the coordination number of the phosphorus atom [P(III) → P(IV) in compound (LXXXI) and P(III) → P(V) in compound (LXXXII)]:



(LXXXI) (LXXXII) (LXXXIII)

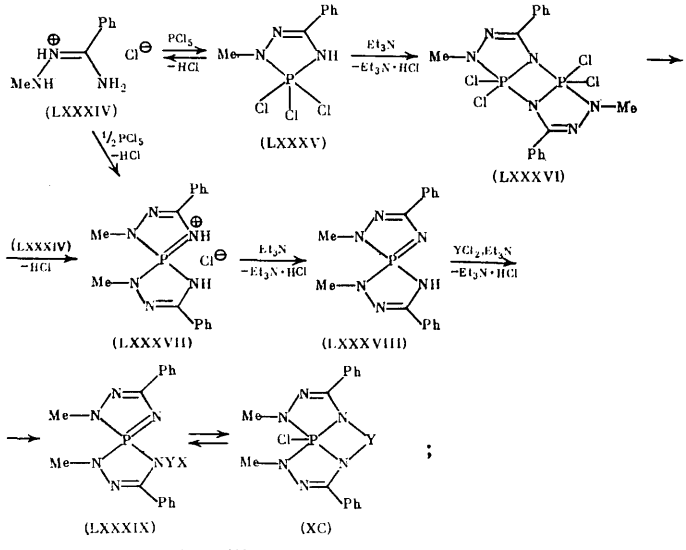
The stability of the cyclic adducts (LXXXII) with an aminophosphorane structure increases with decrease of temperature and with increase of solvent polarity. Acyclic phosphimides do not give rise to stable aminophosphoranes in their reactions with carbonyl compounds.[89]# The influence of the electron-accepting properties of the substituents in the carbonyl partner must also be optimal: the equilibrium in the reaction with acetone is wholly displaced towards the initial compounds. The adducts (LXXXII, $R^1 = CCl_3$, R^2 = H) with chloral and (LXXXII, $R^1 = C_6H_4NO_2$-*p*, R^2 = H) with *p*-nitrobenzaldehyde are converted into the aldiminophosphine oxides (LXXXIII, R = CCl_3 or $C_6H_4NO_2$-*p*, R^2 = H) with rupture of the phosphimide bond even at room temperature.

A version of the [2 + 2]-cycloaddition of hexafluoroacetone to an unstable phosphimide with an exocyclic P=N bond has been discussed by Storzer et al.[93]

The driving force of the cycloaddition reaction is the reduction of the angular strain in the TBP of the phosphorane (LXXXII) compared with the phosphimide (LXXXI). According to XRD data,[89] the structure of the phosphorane (LXXXII) deviates only slightly from the ideal TBP, whereas the initial compound (LXXXI), in which the endocyclic CPN angle differs greatly from the tetrahedral value, is destabilised by an appreciable steric strain.[92]

Interesting P(IV) ⇌ P(V) interconversions have been observed in the series of spirocyclic tetraaminophosphoranes.[94] The thermal condensation of equimolecular amounts of *N*-methylbenzamidrazone hydrochloride (LXXXIV) with phosphorus pentachloride leads to diaminotrichlorophosphorane (LXXXV), which is converted into the diazadiphosphetidine (LXXXVI) on treatment with bases. The same reaction with a twofold excess of compound (LXXXIV) is completed by the formation of the immonium chloride (LXXXVII); the latter is dehydrochlorinated by a tertiary amine to the spirocyclic phosphazene (LXXXVIII). The same compound can be arrived at by treating the dimer (LXXXVI) with the initial compound (LXXXIV) (Scheme 4):[94,95]

Scheme 4



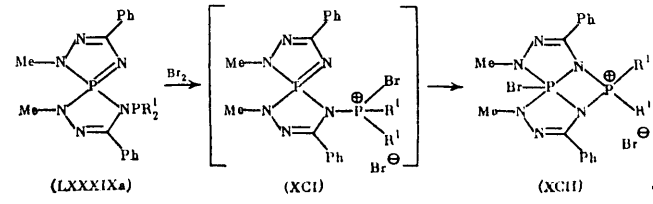
On passing from compounds (LXXXV) and (LXXXVI) to the spirocyclanes (LXXXVII) and (LXXXVIII), the phosphorus atom becomes a weaker electron acceptor (replacement of two chlorine atoms by amino-groups), so that the triaminophosphazene (LXXXVII) has an ionic structure, in contrast to the diamine analogue (LXXXV), and its dehydrochlorination product is monomeric [cf. the transition (LXXXV) → (LXXXVI)].

Phosphorylation of the phosphazene (LXXXVIII) by dichlorophosphines and dichlorophosphine oxides enabled Schmidpeter et al.[94] to observe a new type of reversible P(VI) ⇌ P(V) transitions—the phosphazene–diazadiphosphetidine rearrangement, involving the migration of chlorine (and not of a proton as in the previous examples) between the P(III) and P(IV) atoms in compound (LXXXIX) and an increase of the coordination number of one of the phosphorus atoms in compound (XC). This is accompanied by a pronounced shift of the $\delta(^{31}P)$ signal from ~50 p.p.m. for the P(IV) atoms in compound (LXXXIX) to −10 to −40 p.p.m. for the phosphorane phosphorus in compound (XC), the P(V) chemical shift depending significantly on the structure of the fragment Y.

The position of the tautomeric equilibrium is also determined by the nature of the P substituent in the fragment Y: the stronger the electron-accepting properties of the P(III) in the tricyclic tautomer (XC), the greater the shift of the equilibrium towards this tautomer. For the group Y = PPh, the tautomer (XC) is not detected and the introduction of the dimethylamino-group at P(III) lowers appreciably the content of the phosphorane: at room temperature in chloroform the ratio (LXXXIX) : (XC) is 73 : 27 for Y = $PNMe_2$.

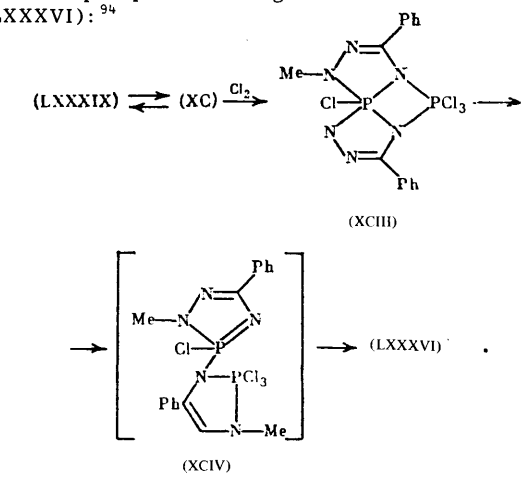
Each of the tautomeric forms (LXXXIX) and (XC) is chiral and can exist as two diastereoisomers and therefore in the general case four isomers may be present in the equilibrium mixture.[94] Thus, when crystalline compound (XC, Y = PCl) (one stereoisomer) is dissolved in chloroform, only a mixture of the diastereoisomers of compound (XC) in proportions of 92 : 8 is initially observed but after a week a mixture of three isomers is detected in the solution—one isomer of compound (LXXXIX) and two isomers of compound (XC) (32 : 63 : 5). The equilibrium mixture of the four isomers of compounds (LXXXIX) and (XC) with Y = POPh in benzene (17 : 30 : 27 : 26) is converted into a single crystalline isomer (XC, Y = POPh) after the removal of the solvent.[94]

It is of interest that the isomerisation described above takes place not only as a rsult of the transfer of a halogen between the P(III) and P(IV) atoms but also in the phosphazene–phosphonium system:[94]

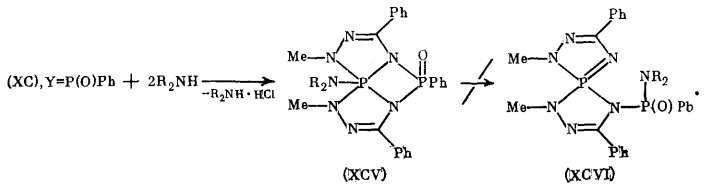


Bromination of the phosphazenes (LXXXIXa, R^1 = Ph or NMe_2) leads to tricyclic phosphorane–phosphonium isomers (XCII) and not to the expected spirophosphorane phosphazene–phosphonium isomers (XCI).

An even more complex reorganisation of the molecules takes place as a result of the bromination of the mixture of compounds (LXXXIX) and (XC, Y = PCl). The diphosphorane (XCIII), which exists only for a short time in solutions, undergoes in succession two types of isomerisation—the skeletal rearrangement to the hypothetical phosphazene (XCIV) as a result of the opening of the four-membered ring with transfer of the hydrazone group and subsequent closure of a new diazadiphosphetidine ring with formation of the dimer (LXXXVI):[94]



The amination of the halogenophosphoranes (XC) with ammonia, primary or secondary amines, and hydrazine leads to stable pentaaminophosphoranes (XCV) which are incapable of the P(V), P(IV)⇌P(IV), P(IV) tautomerism:



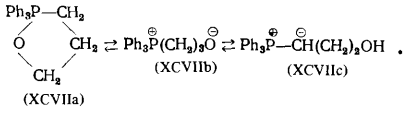
(XCV) (XCVI)

On reaction with aldehydes and ketones, the hydrazide [XCV, R_2N = N(He)NH_2] is converted into the corresponding hydrazones. It has been noted[94] that compounds of pentacoordinate phosphorus linked to five N-ligands as a rule tend to be converted into phosphorus(IV) derivatives. For example, the substitution of the halogen atoms in the dimer (LXXXVI) by amino-groups induces its conversion into the monomeric form.[95] In this sens compounds (XCV), which are not converted into the isomeric phosphonatophosphimides (XCVI), constitute a fairly rare example of stable pentaaminophosphoranes. §

V. OTHER TAUTOMERIC TRANSFORMATIONS OF PHOSPHORANES. PHOSPHOROTROPIC PROCESSES

Various types of tautomeric transformations into compounds of tricoordinate, tetracoordinate, pentacoordinate, and hexacoordinate phosphorus have been observed for compounds of pentacoordinate phosphorus. Equilibrium transitions between compounds of pentacoordinate and dicoordinate phosphorus are so far unknown. The discovery and investigation of the phosphite–phosphorane and phosphimide–phosphorane tautomerism indicates the relative ease of the dissociation of the P=O and P=N bonds and the stability of the phosphoranes arising in such a process. All these equilibrium processes are characteristic only of cyclic, mainly λ^5-1,3,2-diheterophospholan, systems; in this case there is no analogy with acyclic compounds.

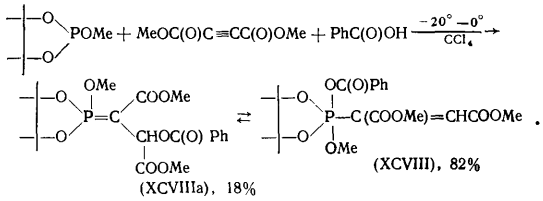
The dissociation of the P=C bond with formation of a phosphonium centre also proceeds fairly readily but the phosphorane–ylide equilibrium could not be observed for a long time, although some examples of the dual (both as a phosphorane and as an ylide) behaviour of phosphorane systems have been noted. Thus the λ^5-1,2-oxaphospholan (XCVII) has the structure of a compound with a pentacoordinate phosphorus atom (XCVIIa), but in some reactions it behaves as the betaine (XCVIIb), while in reactions with aldehydes and ketones it also reacts as a phosphonium ylide (XCVIIc):[97,98]



(XCVIIa) (XCVIIb) (XCVIIc)

The equilibrium between an ylide and a phosphorane has been reported but it is associated with the addition-elimination of the methanol molecule:[99]

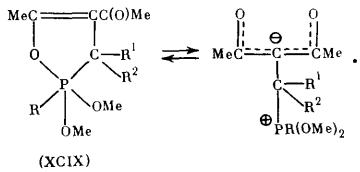
The first piece of evidence for the existence of the ylide–phosphorane equilibrium has been obtained[100] in a study of the interaction of cyclic phosphites with acetylenedicarboxylate ester in the presence of benzoic acid:



(XCVIIIa), 18% (XCVIII), 82%

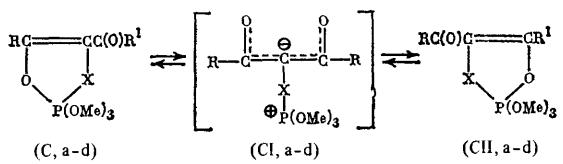
In methylene chloride the fraction of compound (XCVIIIa) increases to 37%, but, after the removal of this solvent and dissolution in CCl_4, the previous ratio is restored.

The phosphorane–phosphonium betaine tautomerism has been postulated for the monocyclic λ^5-1,2-oxaphospholens (XCIX) on the basis of the exchange of the methyl groups of the acetylacetonate system observed from ^{1}H NMR spectra.[3,4,10,101] An analogous phenomenon was believed[102,103] to be characteristic also of spirophosphorane systems:



(XCIX) (5)

The existence of the two tautomeric forms (Ca) and (CIIa), observed in solutions at room temperature [the ratio (Ca) : (CIIa) = 1 : 2 and is independent of the nature of the solvent], is apparently associated with the appearance of an intermediate dipolar ion (CI), which, however, is not detected in the spectra owing to its short life span:[104–106]



(C, a-d) (CI, a-d) (CII, a-d) (6)

(a) R=Ph; R^1 = Me; X = CHPh, $CHC_6H_4NMe_2$-*p*, $CHC_6H_4NO_2$-*p*;
(b) R = Me; R^1 = Me; X = CHMe, CHPh, $CHC_6H_4NMe_2$-*p*, $CHC_6H_4NO_2$-*p*;
(c) R = R^1 = Ph; X = O; (d) R = R^1 = Ph; X = NPh

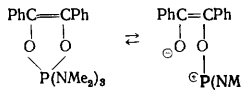
Detailed studies of the ^{1}H, ^{13}C, and ^{31}P NMR spectra of the (C, a–d)–(CII, a–d) systems as a function of temperature showed than an intramolecular transfer of the phosphorus-containing group takes place in such systems between two oxygen atoms;[107,108] the tautomeric process is degenerate for the phosphoranes (C, b–d)–(CII, b–d).

The chemical shifts of the phosphorus nuclei in all the solvents[107,108] remain unchanged over a wide temperature range (from −35° to +125 °C) and are observed in the regions characteristic of the resonance of the nuclei of pentacoordinate phosphorus(−27 to −51 p.p.m.). Thus the phosphonium structure is not an equilibrium component of these systems—the equilibrium is between two phosphorane forms

§ The synthesis of other aminophosphoranes containing two phosphorus atoms with different types of coordination has been described.[96]

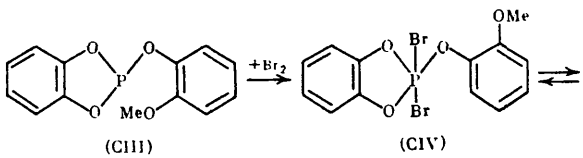
Eqn.(6) and the phosphorane–phosphonium tautomerism [Eqn.(5)] is not observed for compounds of this kind. The temperature-induced changes in the NMR spectra of phosphoranes described in other investigations[3,4,101–103] should apparently be interpreted analogously.

For exactly the same region, it is impossible to give an unambiguous answer concerning the possibility of the phosphorane–phosphonium equilibrium in aminophosphoranes:[101,109,110]

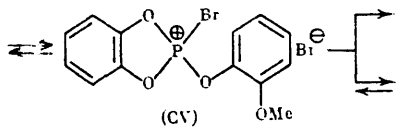


Detailed study of these systems by ^{1}H, ^{13}C, and ^{31}P NMR over a wide temperature range in solvents of different polarity led the authors[111,112] to the conclusion that the observed spectral changes are associated with the different polarities of the P–O bond, which depend on the dielectric constant of the medium.

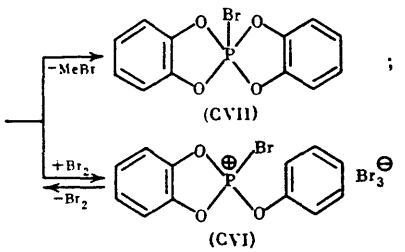
The existence of the equilibrium between the phosphorane and phosphonium structures has been demonstrated by low-temperature ^{13}C NMR in a study of the halogenation of the cyclic phosphite (CIII):[113]



(CIII) (CIV)



(CV)

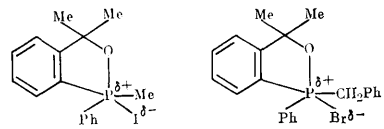


(CVII) (CVI)

At low temperatures (−100 °C) the dibromophosphorane (CIV) [$\delta(^{31}P)$ = 110 p.p.m.] and the phosphonium tribromide (CVI) (35 p.p.m.) were detected. The intermediate bromide (CV) ultimately symmetrises to form bromospirodiphenylenetetroxyphosphorane (CVII) (−28 p.p.m.); in essence this is an unusual version of the Arbuzov reaction, the second stage involving the dealkylation of the alkoxy-group separated from the phosphorus atom by the phenoxy-bridge. The driving force of this version of the Arbuzov reaction is spirocyclisation to compound (CVII) (see Section III) and not the formation of the thermodynamically favourable P=O bond as in the classical Arbuzov reaction.

The phosphorane–phosphonium equilibrium is characteristic also of acyclic phosphoranes. In acyclic systems this equilibrium is as a rule displaced towards the phosphonium form, while in cyclic systems it is displaced towards the phosphorane form, owing to the pronounced ring strain arising in cyclic, specially spirocyclic, phosphonium cations. Thus only the product with pentacoordinate phosphorus has been detected on chlorination of ethylene phosphorochloridite.[114]

The structure of the monocyclic phosphoranes (CVIII) and (CIX) is intermediate between the halogenophosphorane and phosphonium halide structures:[115,116]

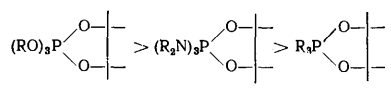


(CVIII) (CIX)

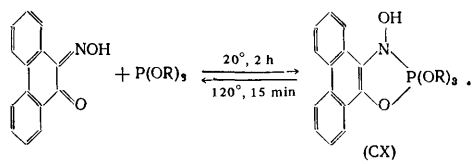
The appreciably ionic character of the phosphorus–halogen bond shifts the $\delta(^{31}P)$ signals of these compounds to the region characteristic of phosphonium structures, while the *ortho*-protons of the aromatic ring and the diastereotopic benzyl protons in compound (CIX) are manifested in the "phosphorane" region. By varying the substituents at the phosphorus atom, it is possible to alter the polarity of the phosphorus–halogen bond, whereupon the ^{1}H NMR spectra of such structures become characteristic in many cases of ionic compounds. This behaviour is very close to that observed for the NMR spectra of the adducts of α-dicarbonyl compounds with tris(amino)phosphines.[111,112]

VI. THERMOLYSIS OF PHOSPHORANES

It has already been stated that the stability of λ^5-1,3,2-diheterophosphacyclanes increases in the sequence acyclic < monocyclic < spirocyclic. This is valid also for their thermal stabilities. The series based on the influence of exocyclic groups at the phosphorus(V) atom on the thermal stabilities of monocyclic phosphoranes has been established:[117]



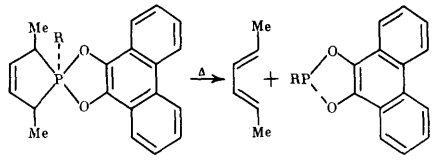
Many cyclic phosphoranes have such high thermal stabilities that they can be vacuum distilled, but some phosphoranes, obtained from phosphites or their analogues and α-dicarbonyl or αβ-unsaturated carbonyl compounds, decompose on heating intot the initial reactants, which indicates the reversibility of their formation reactions.[118–121] The phosphoranes formed after prolonged heating (50–60 °C) of trimethyl phosphite with dibenzylideneacetone, benzylideneacetophenone, and benzylidene-α-tetralone dissociate into the starting materials at a higher temperature (>90 °C).[122,123] The thermolysis of λ^5-1,3,2-oxaphospholans (CX) also leads to the ready elimination of trialkyl phosphites and the regeneration of the initial *o*-quinone monoxime:[124]



(CX)

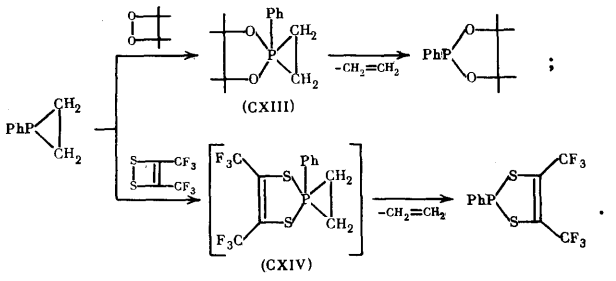
The rate of decomposition of λ^5-1,3,2-diheterophospholans is determined to some extent by the stereochemistry of the cyclic molecular skeleton.[125–128] Thus the study of the thermal decomposition of the stereoisomeric spirophosphoranes (CXI) established that steric factors exert a decisive influence on the rate of stereospecific fragmentation with formation of a diene and phosphonite (CXII): for the *cis*-disposition of the substituents R and Me in the phospholen ring, the decomposition proceeds much more readily; the bulky phenyl group at the phosphorus atom also accelerates the

fragmentation. The influence of electronic factors on this process is insignificant:[128]



(CXI) (CXII)

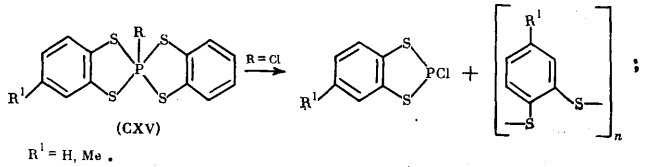
The thermal stability of λ^5-1,3,2-diheterophosphacyclanes varies within very wide limits depending on the structure of the rings and the nature of the substituents at the phosphorus atom (see Arbuzov and Polezhaeva[10] and the references quoted therein). As an example of extremely low stability, one may quote the spirophosphorane formed on interaction of phenylphosphiran with dioxetan.[129] The λ^5-dioxaphospholan (CXIII), containing a three-membered ring, is stable only at −80 °C; at room temperature it decomposes with elimination of ethylene. An analogous behaviour evidently obtains also in the case of the dithiaphospholen (CXIV):[130]



(CXIII) (CXIV)

These reactions involve a kind of "transcyclisation" of the phosphorus(III) derivatives.

Phosphoranes containing sulphur atoms linked directly to the phosphorus atom have been investigated much less than their oxygen analogues. The stability of the spiro-phosphoranes with four sulphur atoms (CXV) depends greatly on the exocyclic substituent R and decreases in the sequence Me > Ph ≫ Cl:

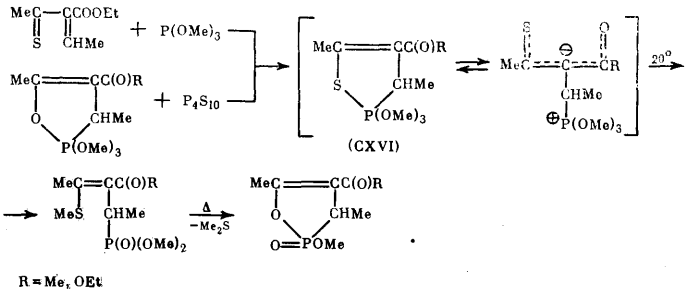


(CXV)

R^1 = H, Me.

Although in the latter case (R = Cl) the compound does form, it decomposes immediately with formation of oligomeric sulphides. The authors explain this instability by the unfavourable position of the chlorine atom in the e-position in the TBP or in the apical position of a square pyramid.[131]

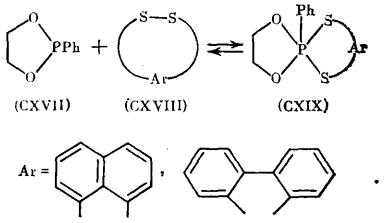
The monocyclic phosphoranes (CXVI) containing the 1,2-thiaphospholen ring cannot be isolated. They readily isomerise already in the course of their synthesis with migration of the methyl group to the nucleophilic sulphur atom:[132,133]



(CXVI)

R = Me, OEt

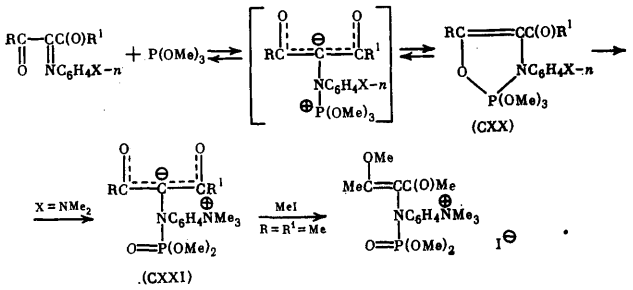
The first instance of reversible insertion in the disulphide linkage has been described.[134] The mode of the reaction of the cyclic phosphonite (CXVII) with the cyclic aromatic disulphides (CXVIII) depends on the nature of the solvent employed:



(CXVII) (CXVIII) (CXIX)

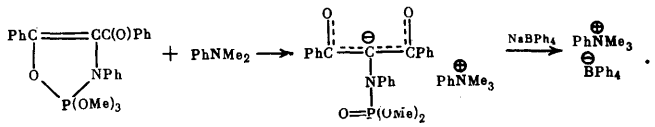
In acetonitrile the spirophosphoranes (CXIX) are formed readily and can be obtained in a crystalline state. In other media (CH_2Cl_2, $CHCl_3$) the reverse reaction predominates. Both processes proceed quantitatively without the formation of side products and are specific to the (CXVII) + (CXVIII) pair only.

The influence of the nature of the solvent on the stability of phosphoranes has been noted fairly frequently. The reversible formation reaction of the phosphoranes (CXX) has been observed for the interaction of 2-monoanils of 1,2,3-tricarbonyl compounds with trialkyl phosphites.[135–137] For X = H, the phosphorane (CXX) was isolated in a crystalline form. For X = NMe_2, the formation of phosphoranes in solution has been detected by ^{31}P NMR at room temperature. The attempts to isolate them in a crystalline state were unsuccessful: either the initial compounds are recovered (in ether) or the betaines (CXXI) are formed (in methylene chloride or in an excess of the phosphite). The betaines (CXXI), which are ammonium inner salts, are formed as a result of the O → N migration of the methyl group. The rearrangement of the phosphoranes into the stable betaine system, observed for the first time in Refs.135–137, shows that phosphoranes have the capacity to alkylate tertiary amines.

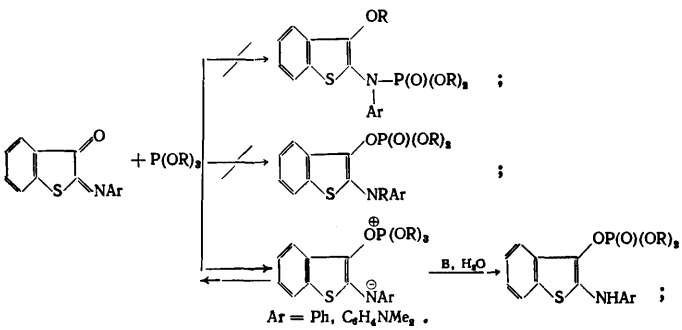


(CXXI)

This was also confirmed by the model reaction[138]

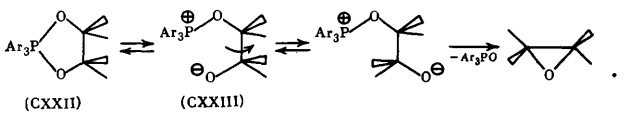


The monoanil of benzothiophen-2,3-dione does not react with trialkyl phosphites in a dry solvent; in the presence of moisture, the reaction proceeds via a protonation, but not alkylation, mechanism:[139]



Ar = Ph, $C_6H_4NMe_2$.

The thermolysis of λ^5-1,3,2-dioxaphospholans (CXXII) leads to the formation of epoxides with inversion of the configuration at the carbon atom[140-143] (see Arbuzov and Polezhaeva[10] and the references quoted therein). The mechanism of this reaction involves the heterolytic dissociation of the P–O bond, rotation about the C–C bond, and irreversible intramolecular substitution of the sp^3-carbon atom with formation of an epoxide:

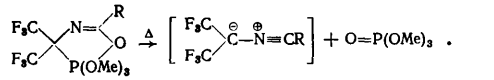


(CXXII) (CXXIII)

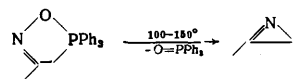
The study of the kinetics of these reactions by NMR [145] showed that they are of first order with respect to the phosphorane and that the thermolysis rate constants vary linearly with the σ constants of the substituents in the exocyclic aromatic groups (ρ = −3.5). The negative sign of ρ indicates the acceleration of the decomposition process with enhancement of the electron-donating properties of the varied groups, which facilitate the dissociation of the P–O bond and evidently stabilise the phosphonium centre in the intermediate (CXXIII).

At the same time the introduction of electron-donating groups should hinder the nucleophilic substitution reaction at the irreversible epoxide elimination stage, so that, when account is taken of effects which compensate one another, a fairly large absolute value of ρ is somehwat unexpected. The activation energy for the decomposition process (~20 kcal mol^{-1}) is close to that for the reactions of phosphoranes involving the rupture of the endocyclic P–O bond,[144] and the heterolytic dissociation reaction (CXXII) → (CXXIII) is therefore most important.[145]

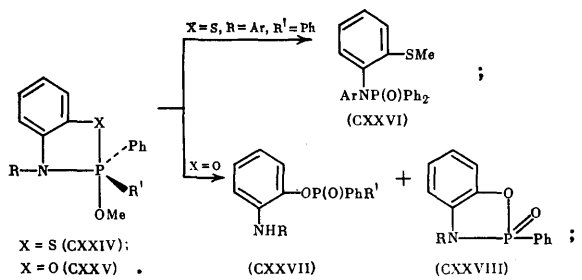
The thermal and photolytic decomposition of λ^5-1,4,2-oxazaphospholens leads to the formation of nitrile ylides[146] (see Arbuzov and Polezhaeva[10] and the literature quoted therein). Their formation was detected with the aid of dipolarophiles. The reaction with these substances leads to products of [3 + 2]- and [3 + 1]-cycloaddition:[147,148]



The pyrolysis of λ^5-1,5,2-oxazaphospholens is accompanied by the formation of azirines in high yields.[149] Bearing in mind the ready availability of such initial phosphoranes, which are obtained from α-bromoketones or ketoylides and triphenylphosphine, and also the possibility of carrying out all the stages without isolating the intermediates, the above method of synthesis of azirines can be regarded as fairly general and suitable for preparative purposes:



The formation of phosphoryl compounds on thermal decomposition of cyclic oxaphosphoranes has been frequently observed. The formation of compounds of tetracoordinate phosphorus as a result of thermal rearrangements of phosphoranes is rarer. Thus, on heating, the 1,3,2-thiazaphospholane (CXXIV) is converted into the phosphinamidate (CXXVI). On the other hand, the corresponding λ^5,1,3,2-oxazaphospholans (CXXV) are thermally very stable.[152] Their thermolysis in the gas phase[153] leads to the formation of products with retention [compound CXXVII)] or cleavage [compound (CXXVII)] of the oxazaphospholan ring depending on the character of the exocyclic substituents at the phosphorus atom: for R^1 = OMe, the main product is compound (CXXVIII), which has a cyclic structure:



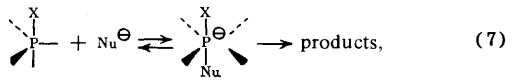
X = S (CXXIV); X = O (CXXV).

VII. NUCLEOPHILIC SUBSTITUTION AT A PENTACOORDINATE PHOSPHORUS ATOM

The mechanism of nucleophilic substitution reactions at a pentacoordinate phosphorus atom [S_N2P(V)] has not been studied in quite such detail as the mechanism of substitution reactions at a phosphorus(IV) atom. To some extent this is associated with the fact that the chemistry of phosphoranes has developed mainly during the last two decades. However, the main difficulty consists in the exceptionally high rates of hydrolysis (solvolysis) of phosphorus(V) compounds.

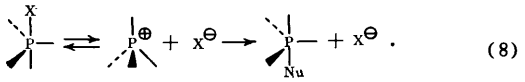
The kinetic study of these processes is complicated by the presence of a large number of stages—the reaction rarely stops after the rupture of one of the two bonds between phosphorus(V) and the heteroatom and usually develops further.

Two probable mechanisms of the $S_N2P(V)$ reactions have been discussed:[154–156] an associative mechanism involving hexacoordinate transition states and (or) intermediates:



(7)

and a dissociative mechanism with intermediate formation of phosphonium ions:



(8)

The study of the kinetics of the hydrolysis of pentaaryloxyphosphoranes demonstrated the exceptional sensitivity of the rate of reaction to the electronic and especially steric effects of the substituents at the benzene ring in neutral and alkaline media (Table 3).[154] The rate of reaction increases with enhancement of the electron-accepting properties of the substituent and is sharply retarded after the introduction of *ortho*-groups. This influence of the substituent X, the magnitude of the kinetic isotope effects (KIE) ($k_{H_2O}/k_{D_2O} = 3$ in hydrolysis by water and approximately unity in acid hydrolysis), and the absence of a salt effect are not characteristic of a dissociative process [Eqn.(8)] but agree well with the rate-determining attack by the water molecule or the hydroxide anion on the pentacoordinate phosphorus atom in pentaaryloxyphosphoranes:[154]

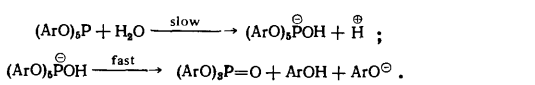


Table 3. Kinetics of the hydrolysis of pentaaryloxyphosphoranes $(XC_6H_4O)_5P$ at 25 °C in 25% dimethoxyethane.[154]

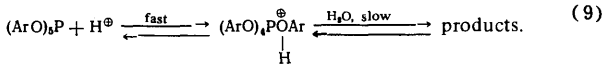
Reaction rate constant	X				
	H	*o*-Me	*p*-Me	*o*-Cl	*p*-Cl
k_{H_2O}, s^{-1}	0.202	$1.1\cdot10^{-5}$	0.0197	0.106	390
k_{H^+}, mol litre^{-1}s^{-1}	16.4	1.3	79	—	—
k_{OH^-}, mol litre^{-1}s^{-1}	11.4	$7.5\cdot10^{-4}$	3.4	—	—

Notation: k_{H_2O} is the rate constant for neutral hydrolysis ("plateau" on curve *2* in Fig.2), k_{H^+} the rate constant for acid hydrolysis (left-hand branch of curve *2*), and k_{OH^-} the rate constant for base hydrolysis (the right-hand branch of curve *2*).

An increase of the steric hindrance by the ligands destabilises the octahedral intermediate (or the transition state). By imparting a positive charge to the phosphorus atom, electron-accepting substituents accelerate the slow stage of the reaction, namely the attack by the nucleophile on the phosphorus(V) atom.

The acid-catalysed reaction proceeds with protonation of the phosphoranes and the subsequent rate-determining substitution of the phenol by water:



(9)

The acid hydrolysis reaction is less sensitive to the influence of substituents but in this case too the steric effect of the group X is manifested distinctly by a decrease of k_{H^+} (Table 3). The rate of reaction varies linearly with the concentrations of H^+ and OH^- in the strongly acid and strongly alkaline media respectively (Fig.2).

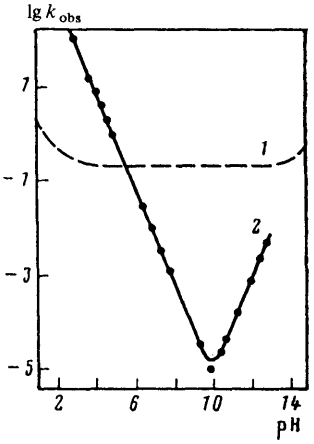


Figure 2. Dependence of the rate of hydrolysis of phosphorane (k_{obs}) on the pH of the medium: 1) penta-aryloxyphosphoranes; 2) spirophosphoranes (CXXIX).[154,155]

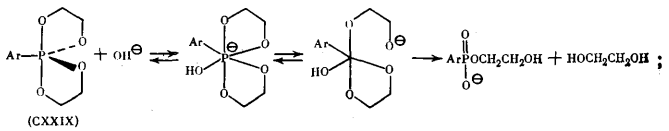
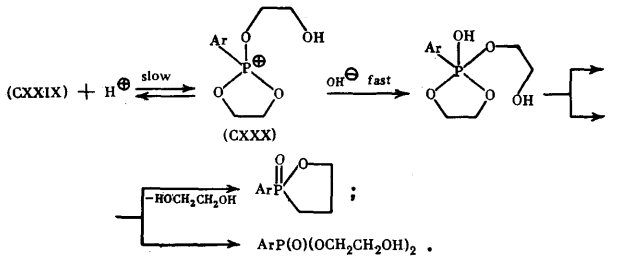
Another type of influence of the pH on the rate was established in a study of the kinetics of the hydrolysis of spirocyclic phosphoranes.[155] The alkaline reaction (in the pH range pH > 10, Fig.2) of the phosphoranes (CXXIX) is also described satisfactorily within the framework of the associative mechanism. In these reactions, involving the opening of the rings in λ^5-1,3,2-dioxaphospholans, and also in exocyclic substitution reactions involving alkoxy(aryloxy)-spiro-phosphoranes,[156] an increase of the reactivity of the organophosphorus substrates is observed after the introduction of electron-accepting substituents into the ligands.

However, in the range pH < 9 the hydrolysis of compound (CXXIX) resembles very closely the analogous reactions of dioxolan orthoesters, for which a dissociative carbonium mechanism has been established. It has been suggested[155] that the experimental results agree best with the acid-catalysed rate-determining dissociation reaction (CXXIX) ⇌ (CXXX) and the rapid cleavage of one or both rings:



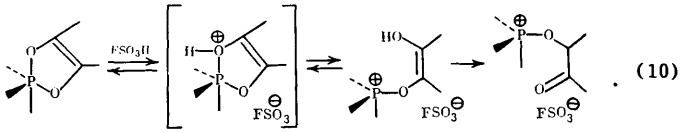
(CXXIX)

Ar = C_6H_4Me-*p*, Ph, C_6H_4Cl-*p*.



The pre-equilibrium protonation of the neutral oxaphosphorane (CXXIX) takes place with the simultaneous rupture of the P–O bond, so that the existence of the protonated phosphorane [Eqn.(9)] as an intermediate in cyclic systems is not obligatory.[155] This may be associated with the considerable ring strain in the protonated cyclic phosphorane. In this sense the acid hydrolysis of the phosphoranes (CXXIX) resembles the nucleophilic substitution reactions of five-membered cyclic phosphates.[2,157] It is believed[156] that in the general case the contribution of the dissociative mechanism should increase with enhancement of the electron-accepting properties of the ligands in the phosphorane.

Little is known about the existence of protonated phosphoranes. The formation of the protonated structure of a spirobicyclic phosphorane in the reversible acid catalysed hydroxyphosphorane–phosphate reaction (XLIII) ⇌ (XLIV) has been reported.[64] The study of the temperature variation of the ^1H, ^{13}C, and ^{31}P NMR spectra of certain monocyclic phosphoranes in the presence of small amounts of HSO_3F showed[158,159] that the protonated hydroxyphosphoranes are real intermediates in the reversible transition between dihydroxyphospholens and the isomeric enolphosphonium ions:



(10)

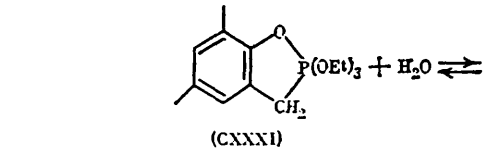
Table 4. Activation parameters for the phosphorane–dipolar ion equilibrium [Eqn.(10)].

Phosphorane	$\Delta H^{\neq}$, kcal mol^{-1}	$\Delta S^{\neq}$, e.u.	$\Delta G^{\neq}$, kcal mol^{-1}	Refs.
	2.8	−37	12.0	[159]
	3.0	−40	13.0	[160]
	2.6	−44	13.5	[160]

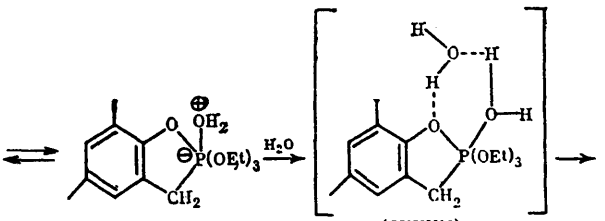
The rate of this process, which can be regarded as a model of intramolecular phosphorylation, is limited by structural factors and is entropy-controlled (Table 4). The equilibrium [Eqn.(10)] involves the bimolecular proton transfer between the protonated and neutral λ^5-1,3,2-dioxaphospholens. Equilibration is rapid when the ring contains a double bond and slow for saturated rings. It follows from the activation parameters for the phosphorane–phosphonium ion equilibrium[160,161] that the rigidity of the five-membered ring facilitates the ring closure to form the bicyclic phospholan structure, while in the case of a six-membered ring the process is less effective (Table 4).

The equilibria described here [Eqn.(10)] play an important role in the mechanism of the intramolecular phosphorylation of the 2-OH group in RNA, which is facilitated by the ribose ring.[160] It has also been noted that phosphorane–betaine interconversions of this kind are responsible for the ligand reorganisation processes involving spirocyclic arylphosphoranes, which are promoted by methyltrifluoromethanesulphonate.[162]

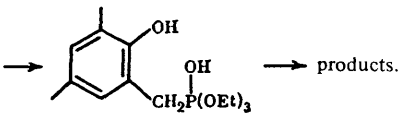
The associative mechanism has been demonstrated for the hydrolysis of the monocyclic phosphoranes (CXXXI) and (CXXXIII) in aqueous organic media.[163,164] The high values of the KIE (greater than 3), the large negative activation entropies, data concerning the influence of solvent polarity on the reaction rates, and the second (or higher) order of the reaction with respect to water suggest the formation of octahedral intermediates with phosphorus(VI). The subsequent involvement of a second water molecule in the process leads to ring opening products. The phosphorane (CXXXI) can form under these conditions the trimolecular complex (CXXXII):[163]



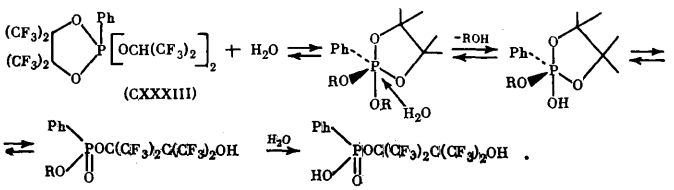
(CXXXI)



(CXXXII)



The hydrolysis of compound (CXXXIII) includes two pre-equilibrium stages—the formation of a hexacoordinate intermediate and exothermic opening of the λ^5-dioxaphospholan ring:[164]



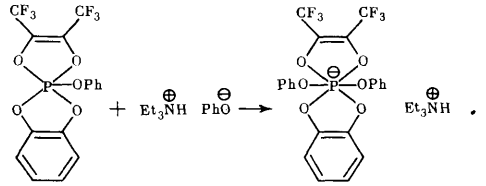
(CXXXIII)

The formation of intermediate hexacoordinate phosphorate anions in the base hydrolysis of phosphoranes is especially probable in the series of λ^5,1,3,2-diheterophospholans. This

has been confirmed by numerous examples of the isolation or identification in solutions of phosphorus(VI) anions[166–169] (see Sarma et al.[165] and the literature quoted therein).

It has also been suggested that hexacoordinate intermediates can arise in the hydrolysis of ethylene methyl phosphate in highly alkaline media.[170,171] However, recent NMR studies of this process failed to confirm such a possibility.[172]

The stereochemical relations in the process involving an increase of the coordination number [P(V) → P(VI)] are clearly demonstrated by the comparison of the molecular structures of the phosphorane (CXXXIV) and the phosphate anion (CXXXV) (Fig.3), formed as a result of the addition of the phenoxide ion to the phosphorus atom in compound (CXXXIV).[165] It is usually suggested that the attack by the nucleophile on the central atom takes place in the equatorial plane of the TBP:[167,173]



(CXXXIV) (CXXXV)

The approach of the phenoxide anion to the O(3) atom from the rear (Fig.3*a*) should lead to a "phosphorate" with the *trans*-disposition of the PhO groups; the *cis*-configuration is a result of the addition of PhO^- to O(2) and O(4) from the rear. It has been established[165] that the most favourable steric disposition of the ligands in the "phosphorate" (CXXXV) (Fig.3*b*) is obtained following the attack on O(4) from the rear in the last sbustituted region of the phosphorane (CXXXIV). The alternative attack on O(3) from the rear gives rise to the sterically less favourable "phosphorate".

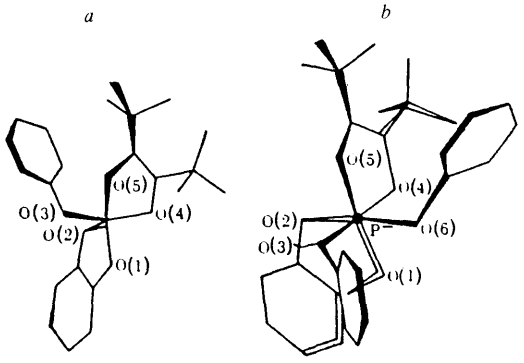


Figure 3. Molecular structures: *a*) phosphorane (CXXXIV); *b*) "phosphorate" (CXXXV).[165]

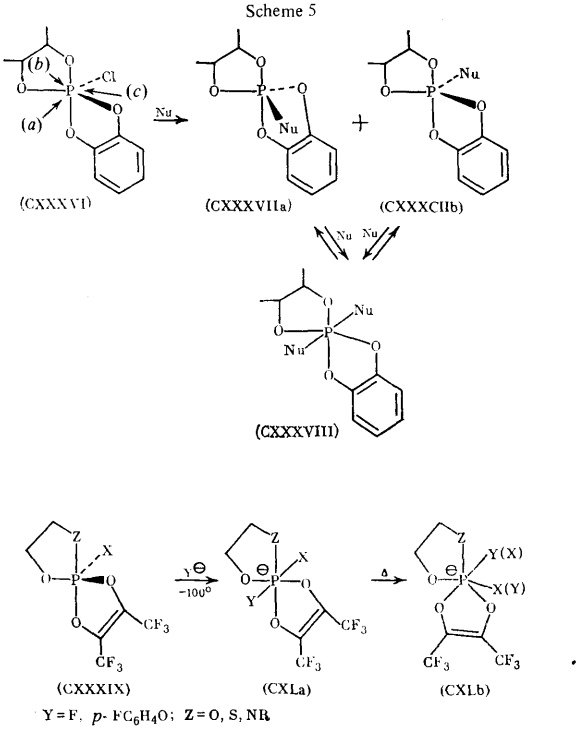
The stereochemical result of the $S_N2P(V)$ reactions depends to some extent on the nature of the nucleophile added to phosphorus(V) and on the leaving group.[173] The attack by the nucleophile on the phosphorus atom in exocyclic substitution reactions involving the phosphorane (CXXXVI) can proceed in principle via one of three pathways in the equatorial plane of the TBP (pathways *a*–*c*, Scheme 5). The *trans*-substitution via pathway *a* leads to the inversion of the configuration of the phosphorus atom, while *syn*-attack (pathways *b* and *c*) affords a product with retention of the configuration. Determination of the ratio of the stereoisomers (CXXXVIIa) and (CXXXVIIb) (7 : 1) by low-temperature ^{31}P NMR showed that the reactions of compound (CXXXVI) with dimethylamine and lithium dimethylamide proceed with the preferential inversion of configuration: $k_a = 7(k_b + k_c)$.

On substitution of PhO^- at −78 °C, the stereoisomeric composition corresponds to (CXXXVIIa) : (CXXXVIIb) = 1 : 1, while at room temperature the composition changes in favour of the isomer (CXXXVIIb) (0.64 : 1). Methyllithium gives rise to a mixture of equal amounts of the isomeric phosphoranes. The equilibration of the stereoisomers can be achieved via the hexacoordinate intermediate (CXXXVIII).

These results might have been interpreted on the assumption that the nucleophilic substitution at P(V) does not require the attack by the nucleophile of the leaving group.[173] However, it was later established for the interaction of phosphoranes of type (CXXXIX) with ionic nucleophiles at low temperatures (between −60° and −100 °C) that only the less stable *trans*-anions (CXLa), which isomerise to the "*cis*-phosphorates" (CXLb) on heating, are formed initially:

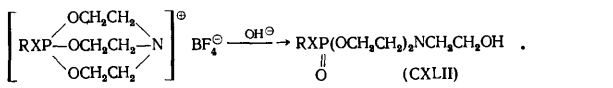
Scheme 5



The ease of the *trans*-attack, which is a kinetically controlled process, is due to the stereoelectronic effect of the LEP of the heteroatoms adjoining the P–Nu bond.[2,173] The *trans*-attack on spirocyclic phosphoranes of the type (CXXXIV) and (CXXXIX) is facilitated by the appropriate orientation of the LEP orbitals of the four heteroatoms, while the *cis*-attack is facilitated by only two of these orbitals.[174] The formation of the more stable *cis*-isomers (CXXXV) and (CXLb) is a thermodynamically controlled process, determined by the steric situation at the phosphorus(VI) atom [see the above remarks concerning the "phosphorate" (CXXXV)]. It has been noted[173] that the dissociative mechanism of the exocyclic nucleophilic substitution in spirocyclic phosphoranes is apparently impossible due

to the pronounced angular strain in the intermediate spirocyclic phosphonium cation. An analogous *cis–trans* isomerisation has been established also in a study of the interaction of the fluoride anion and the *p*-fluorophenoxide anion with λ^5-oxathia- and λ^5-oxaza-phospholens.[175]

As a consequence of the highly electrophilic properties of the phosphorus(V) atom, the attack by the nucleophile in the S_N 2P(V) processes is almost always directed at the phosphorus centre, in contrast to the nucleophilic substitution reactions at P(IV), where both the tetracoordinate phosphorus atom and the endo- or exo-cyclic carbon atoms can serve as centres for the nucleophilic interaction.[2] However, an instance of the selective pseudoequatorial attack by nucleophiles on the carbon atom in the TBP structure of the tricyclic phosphatranes (CXLI) has been observed recently:[176]



(CXLII)

The transannular N → P bond in these compounds ensures quinary coordination of the phosphorus atom. In all cases (X = O or S) the products of the alkaline hydrolysis are the phosphates (CXLII) and nucleophilic attack is directed selectively to the pseudoequatorial carbon atom. It is believed[176] that such interaction is a consequence of the internal properties of the electronic configuration of the TBP: as a consequence of the dative transfer of electron density from the pseudoequatorial oxygen atom to the phosphorus atom, in the initial structure there is already some predisposition towards the formation of the P=O π-bond, which arises as a result of the reaction. A deficiency of electron density is therefore produced at the pseudoequatorial carbon atom, which renders this centre most sensitive to nucleophilic attack.

---o0o---

The data presented in this review demonstrate the multiplicity of the chemical properties of λ^5-1,3,2-diheterophosphacyclanes. The discovery of the role of cyclic phosphoranes and related structures with a phosphorus atom in the heterocycle (phosphonium cations, phosphoranide and hydroxyphosphoranide anions, "phosphorate" anions, and phosphorane–base complexes) as intermediates in many reactions of OPC, including those which have become classical, is of fundamental importance in this connection. This permits well-founded conclusions about the mechanisms of the reactions of OPC and indicates the usefulness of their investigation, particularly in relation to cyclic OPC. Various tautomeric processes and the relative ease with which the coordination number of the phosphorus atom can change in chemical reactions of OPC [P(III)–P(IV)–P(V)–P(VI)], which are particularly clearly manifested in the chemistry of cyclic phosphoranes, to a large extent predetermine the unity and wide variety in the phosphorus chemistry.

At the same time numerous questions concerning the reactivity of λ^5-1,3,2-diheterophosphacyclanes, such as the influence of the size of the heterocycle, of endocyclic heteroatoms, and of exocyclic functional groups and the quantitative estimation of the electronic and steric characteristics of phosphorus(V)-containing groups still await a more far reaching elucidation.

The Electronic Structure and Reactivity of Palladium Compounds

O.V.Gritsenko, A.A.Bagatur'yants, I.I.Moiseev, and V.B.Kazanskii

The state of the quantum-chemical theory of the electronic structure of palladium compounds has been examined. The results of quantum-chemical calculations for palladium(II) and palladium(0) compounds and palladium clusters, and also of calculations for model reactions of palladium compounds, have been discussed. Methods for analysing the relationship between the electronic structure and reactivity of palladium complexes have been examined.
The bibliography contains 121 references.

I. INTRODUCTION

The high catalytic activity of metallic palladium in heterogeneous catalysis, for example the hydrogenation of unsatuarated compounds,[1] the catalytic reforming of petroleum,[2] and the conversion of carbon monoxide into methane or methanol,[3] is well known. Interest in the chemistry of palladium has been increasing since the late nineteen-fifties, when it was found that Pd^{II} complexes can oxidise alkenes selectively at low temperatures to give carbonyl compounds,[4,5] vinyl esters, acetals, and ketals.[6] These reactions not only provided a basis for industrial methods for obtaining acetaldehyde and vinyl acetate but also initiated the development of a new field in homogeneous metal-complex catalysis, based on the thermodynamic analysis of possible catalyst–substrate reactions and its use to construct a catalytic cycle.[7]

In the earliest papers by Syrkin and co-workers[5,6] it was suggested that the key compounds in the oxidation of alkenes by palladium complexes are organic derivatives of palladium with a metal–carbon σ-bond, produced by reactions of the initially formed alkene π-complexes of Pd^{II}. This suggestion, which at first appeared unusual and was not immediately accepted by organometallic chemists of the classical school, was subsequently proved by direct synthetic methods[7-9] and confirmed by kinetic studies.[9,10]

The chemistry of organic derivatives of palladium is now among the most well developed fields of the organic chemistry of transition metals.[11,12] It has become clear that the coordination possibilities of Pd compounds, their electronic structure, and their reactivity, which changes with change in the nature of the solvent and the ligands not taking direct part in the reaction, are most important factors which must be taken into account both in the analysis of the mechanism of the action of catalysts and in the prediction of their catalytic effect.

In the present review, the results of the quantum-chemical study of the electronic structure of palladium compounds are discussed. The main aims of the review are to compare the results obtained by different workers and by different

methods, to compare data on the electronic structure and properties of compounds of palladium and other elements of the platinum group, and to find methods for the quantum-chemical analysis of the relationship between the electronic structure of transition metal complexes and their reactivity.

II. GENERAL CONCEPTS

In the nature of the filling of its electron levels, the palladium atom occupies a unique position in the periodic system. Thus it is only for this atom in the ground state ^1S that the valence d-level is completely filled (electron configuration $4d^{10}$) while the outer 5s and 5p atomic orbitals (AO) are unoccupied. It should be noted for comparison that for the other elements of the platinum triad with ten valence electrons, the outer s-level is partly or completely filled: thus for platinum the ground state is the atomic state ^3D (configuration $5d^96s^1$), and for nickel ^3F (configuration $3d^84s^2$). As a result, the ionisation potential of the palladium atom $I_{Pd} = 8.33$ eV[13] corresponds to the ionisation of a 4d AO, whereas in the case of platinum the first ionisation potential $I_{Pt} = 9.0$ eV corresponds to the removal of an electron from the 6s AO. This characteristic feature of the electronic structure is related to the fact that in the Pd atom, the outer 5s and 5p AO have relatively high energies. Table 1 shows that the energies of electron promotion $d^{10} \rightarrow d^9s^1$ and $d^{10} \rightarrow d^9p^1$ increase considerably in the order Ni < Pt < Pd. At the same time, for palladium the outer 5s and 5p AO are much more extended in space (that is more diffuse) than its 4d AO. Thus the average radius of the Hartree–Fock 5s AO of palladium, equal to 0.194 nm for the state $d^9s^1(^3D)$, is more than twice the corresponding radius of the 4d AO (Ref.17, see Table 1), and much greater than the covalent radius of palladium (~0.13 nm).

Table 1. Ionisation potentials I, promotion energies E, and average radii R_d of the Hartree–Fock d AO of nickel, palladium, and platinum.

Atom	I, eV ($d^{10} \rightarrow d^9$)	E, eV		R_d, nm
		($d^{10} \rightarrow d^9s^1$)	($d^{10} \rightarrow d^9p^1$)	
Ni	5.81 [14]	−1.79 [15]	1.72 [16]	0.055 [17]
Pd	8.33 [14]	0.95 [15]	4.23 [13]	0.076 [17]
Pt	8.20 [14]	−0.76 [16]	3.28 [13]	—

Note. Numbers in square brackets denote references (Ed. of Translation).

Thus quantum-chemical calculations for palladium systems, in particular Pd^0 compounds, are of considerable interest, since the results reveal in purest form the role of the outer s and p orbitals of the transition metal in coordinate bond formation. Thus for example the ability of the Pd atom with its filled d level to undergo Pd ← L donor–acceptor interaction should be determined by the contribution of the unoccupied 5s and 5p AO to bond formation.

In the Ni–Pd–Pt series, the relative energetic and geometric characteristics of the valence d AO of palladium are characteristic of an element of the second transition series. With reference to energy, these orbitals are even more stable than the d AO of elements of the third transition series, whereas with respect to size they are still fairly highly localised.

Most published quantum-chemical studies have been devoted to calculations of the electronic structure of compounds of palladium in its typical formal oxidation states Pd^0 and Pd^{II}. The problem of determining the oxidation state in complexes of metals in low oxidation states is not simple. The formal oxidation state of a metal in a complex compound is defined as the charge produced on the given atom after the removal of the ligands. It is assumed that in the leaving carbon-containing ligands and acido-ligands (for example H^-, Cl^-, OH^-), the electron pair of the M–L bond remains associated with the ligand (that is the ligand is removed as an anion), and that molecular ligands are removed as uncharged species. In view of the variety of electronic characteristics of ligands, the classification of complexes according to the formal oxidation state of the metal is to a large extent arbitrary. The position becomes even more complicated when the ligands (for example the carbon atom in the system PdC examined in Refs.18 and 19) do not exist as free anions in solution.

One way of determining the oxidation state is by analysing the electron densities of the transition metal atom in a complex. Sometimes, the formal oxidation state is related to the effective charges of the atoms in the molecules, calculated by quantum-chemical methods. The charge of a transition metal atom, however, depends to a significant extent on the population of the outer s and p orbitals, and in the case of palladium an appreciable proportion of the electron density of these orbitals is localised outside the sphere of the covalent radius.[20] It seems more justified to relate the oxidation state not to the total charge of the palladium atom but to the total population of its valence d AO, which are localised mainly within the sphere of the covalent radius. If it is assumed that an increase in the oxidation state by one unit corresponds to an increase in the vacancy in the d level by 1 e, then the valence electron configuration of palladium is d^{10} for Pd^0, and d^8 for Pd^{II}.

To conclude this section, the quantum-chemical methods used in the calculations for the specific systems which will subsequently be examined can be considered. The different approaches were analysed in detail in Ref.21. For transition metal compounds, a reliable calculation of the bond strengths and the potential surfaces of reactions requires a non-empirical calculation using a large number of basis AO with subsequent allowance for the effects of electron correlation. A qualitatively reliable picture of the electron density distribution, and the relative energies of coordination for the simplest systems, can also be obtained, however, by non-empirical calculations by the SCF MO LCAO method using small basis sets requiring a much smaller volume of calculations. The volume of non-empirical calculations is often further reduced by using the valence approximation, in which the influence of the core electrons is effectively taken into account using atom pseudo-potentials.[22]

Since for most palladium systems the non-empirical level of calculation remains unattainable, simplified semi-empirical methods involving the complete neglect of differential overlap (CNDO)[23] and incomplete neglect of differential overlap (INDO),[24] and also the extended Hückel method (EHM),[25] are most frequently used. The approximations introduced in these methods lower the reliability of the quantitative results of the calculations. To decrease the error of the approximate methods, their parameters are calibrated using available experimental and theoretical data. The results of the calculations are analysed using different indices of

electronic structure, such as the Wiberg indices W_{AB}, the bond orders, and the two-centre components of the total energies E_{AB}.[26] Comparison of these indices makes it possible to study the regular features of the change in the electronic structure and reactivity in a series of related systems.

The SCF Xα scattered wave (SCF-Xα-SW) method[27] has also been used to study the electronic structure of Pd compounds. This method makes it possible to calculate satisfactorily the electronic spectra of transition metal compounds. At the same time, the approximations introduced in the SCF-Xα-SW method do not make it possible to calculate reliably the coordination energies and potential energy surfaces, and the specific form of representation of the wavefunction creates certain difficulties in the interpretation of the results of the calculations, in particular in the determination of the different indices of the electronic structure.

III. QUANTUM-CHEMICAL CALCULATIONS OF THE ELECTRONIC STRUCTURE OF PALLADIUM COMPOUNDS

1. The Electronic Structure of Pd^{II} Compounds

Typical palladium(II) compounds are square-planar complexes, for example K_2PdCl_4, and also the mixed complexes PdX_nY_{4-n} (where X represents an acido-ligand, Y a neutral donor ligand, and $n = 2$).[13] Calculations for the anionic complex $PdCl_4^{2-}$ have been carried out by the non-empirical SCF MO LCAO method,[28,29] the SCF-Xα-SW method,[30] and the semi-empirical INDO[31,32] and CNDO[33,34] methods.

The results of the calculations at first sight are inconsistent with the view that in the $PdCl_4^{2-}$ anion the oxidation state of palladium is +2. Thus according to the results of a non-empirical pseudo-potential calculation in the valence approximation in a minimum basis set[28] and INDO calculations,[31,32] the charge of the Pd atom is only 0.5e. If the total population of the 4*d* AO is considered, however, the electron distribution within the sphere of the covalent radius of the Pd atom is close to that expected for a Pd^{II} complex. The value obtained for the vacancy in the *d* level (~1.5e) is only 0.5e lower than that formally assigned to Pd^{II} (see section I).

As noted above, the low effective charge of Pd is due to the appreciable population of the diffuse outer 5*s* and 5*p* AO (their total population is close to 1e[31,32]). Their diffuse character is responsible for the appreciable contribution of these partly filled Pd orbitals to the Pd–Cl covalent bonding as a result of their extensive overlap with the orbitals of the Cl atom. Thus the overlap integrals of the 5*s* and $5p_x$ AO of palladium with the $3p_x$ AO of chlorine are $S(5s3p_x) = 0.23$ and $S(5p_x3p_x) = 0.32$, whereas $S(4d_{x^2-y^2}3p_x) = 0.10$.[32] Thus the outer 5*s* and 5*p* AO of palladium, together with the valence 4*d* AO, play an important part in the Pd^{II}–L bonding interaction.

Although expansion of the basis set in a non-empirical calculation for $PdCl_4^{2-}$ [28] has a marked influence on the effective charges of the atoms obtained by a Mulliken population analysis, the picture of the electron density distribution changes little, and the reported change in the effective charges is related to the arbitrary nature of the Mulliken procedure. Thus the negative charge of Pd, obtained in the non-empirical calculation in a two-exponent basis set,[28] is due to the assignment to the Pd atom of electron density associated with the polarisation *p* functions, which are much more diffuse than the 5*s* and 5*p* AO of palladium, corresponding to the bound atomic states. In fact, however, an appreciable proportion of this electron density should have been assigned to the ligands.

Thus to determine whether the charges obtained by semi-empirical methods are reasonable, they must be compared with the charges obtained by the non-empirical SCF MO LCAO method in a comparable minimum basis set. In this case the INDO parametrisation schemes[31,32] apparently give a reasonable electron distribution picture, whereas the CNDO parametrisation scheme[33] gives an unrealistic electron distribution.

Different methods give different relative distributions of the energies of the MO of the $PdCl_4^{2-}$ ion. Thus for the energies of the *d* levels (more accurately the energies of the MO consisting chiefly of the *d* AO of Pd), the following relationships have been obtained: $d_{x^2-y^2} > d_{xy} > d_{xz} \cong d_{yz} > d_{z^2}$,[30] $d_{x^2-y^2} > d_{xz} \cong d_{yz} > d_{xy} > d_{z^2}$,[32] and $d_{x^2-y^2} > d_{z^2} > d_{xz} \cong d_{yz} > d_{xy}$.[28,31]

The comparison of the results of calculations by the MO LCAO and Xα methods is somewhat arbitrary, since the energies of the MO have a different physical significance in these methods. The highest occupied MO were found to be those consisting chiefly of the *d* AO of the Pd atom in Ref.30, or the AO of the Cl atom in Refs.28, 31, and 32. The energies of the electron transitions were estimated in Refs.29 and 32 by independent SCF calculations for the ground and excited states; in Ref.34 by the SCF method with allowance for electron correlation within the framework of configuration interaction; and in Ref.30 by the transition state method.[27] The calculated energies of the lowest *d*–*d* transition and the lowest allowed charge-transfer transition L → Pd agree with the experimental data[35] in the case of the CNDO method.[34] This agreement may be accidental, however, since the energies of the subsequent *d*–*d* transitions show less satisfactory agreement with the experimental data.

The dependence of the electronic structure of square Pd^{II} complexes on the type of ligand has been studied.[33,36,37] CNDO calculations for the complexes PdX_4^{2-},[33] $PdX_3(C_2H_4)^-$ [36] (X = F, Cl, Br), and $Pd(PH_3)_2XY$ (X, Y = H, Cl, $OCOCH_3$, OH)[37] showed that in all cases the electron density on the Pd atom increases with decrease in the electronegativity of the ligands. For example, the effective charge of Pd calculated for the complexes *trans*-$XYPd(PH_3)_2$ increases from 0.51e for X, Y = H to 0.67e for X, Y = OR.[37] As in the case of $PdCl_4^{2-}$ examined above, the magnitude of the vacancy in the 4*d* level of Pd correlates with the formal oxidation state of palladium, that is in all cases it is close to 2e. An important role in the bonding interaction is played by the outer 5*s* and 5*p* AO of the Pd atom, which, in accordance with the calculated[37] covalent components of the Pd–L bond energy (E_{PdL}^{cov}), makes a significant contribution to the Pd–L covalent bonding. The observed increase in the charge of Pd with increase in the electronegativity of the ligands agrees with published data on the X-ray electron spectra[38–40] of Pd^{II} complexes.

A comparative estimation of the strength of the Pd–X bond in the complexes PdX_4^{2-} and the Pd^{IV} complexes PdX_6^{2-} showed[33] that the strength of the Pd–X bond increases with increase in the electronegativity of X and the coordination number of Pd. The regular features observed agree with conclusions[41] based on the experimental determination of the vibrational wavenumbers and force constants for the complexes $M_2[PdX_4]$ and $M_2[PdX_6]$.

The static *trans*-influence (and also *cis*-influence), revealed by the dependence of the strength of a palladium–ligand bond on the nature of the ligand in the *trans* (or *cis*) position, has been studied.[37,42,43] The stronger the *trans*

(or *cis*) influence of a ligand, the weaker the bond formed by its *trans* (or *cis*) partner in the square complex. Calculations have been carried out for the complexes $[PdCl_3L]^q$,[42] *trans*-$X_2Pd(NH_3)_2$ and *cis*-$X_2Pd(NH_3)_2$,[43] and *trans*-$XYPd(PH_3)_2$.[37] Series giving the order of the static influence of ligands have been constructed by analysing the two-centre components of the total energy E_{AB} and the Wiberg indices W_{AB}, which correlate with the strengths of the corresponding bonds.

The calculations for the complexes $[PdCl_3L]^q$ by the CNDO method[42] showed that the *trans*-influence of the ligand L decreases (and the strength of the Pd–Cl bond correspondingly increases) in the order $CN^- > CH_3^- > NO_2^- > H^- > Cl^- > SCH_3^- > NH_3 \cong CO \cong C_2H_4 > (CH_3)_2S > (CH_3)_2SO > H_2O$. Exactly the same series was obtained for the corresponding platinum complexes. From these and published data it was concluded that the position of a ligand in the order of the static *trans*-influence in palladium and platinum complexes is determined by its donor–acceptor properties; with increase in the donor power of the ligand, its *trans*-influence generally increases.

The calculations by the INDO method for the complexes *cis*-$PdX_2(NH_3)_2$[43] gave the following order of the *trans*-influence: $H^- > SCN^- > NCS^- > Cl^- > NH_3 > H_2O$. The *cis*-influence in the complexes *trans*-$PdX_2(NH_3)_2$ increases in the same order as the *trans*-influence in the corresponding *cis*-complexes, but the range of change in the values of E_{PdN}^{cov} with change in the nature of the *cis*-ligands is smaller by a factor of approximately 3.

The calculations for the complexes *trans*-$PdXY(PH_3)_2$ by the CNDO method[37] showed that for all ligands Y the *trans*-influence of X decreases in the order $X = H^- > Cl^- > OCOCH_3^- > OH^-$. The decrease in the *trans*-influence of the ligands in this series correlates with the increase in the negative charge on the ligand (more accurately on the atom of the ligand closest to palladium). This agrees with the published conclusion[42] that the *trans*-influence of a ligand increases with increase in its donor power. The hydride ligand, which shows the strongest *trans*-influence in the series studied, also forms the most covalent bond with palladium (judging from the values of the effective charges on X or from the Wiberg indices W_{PdX}). The highly covalent nature of the Pd–H bond is due to the lower electronegativity of H compared with other anionic ligands, and to the better ability of the 1*s* AO of the H atom to overlap with the diffuse 5*s* and 5*p* AO of the Pd atom.

The published quantum-chemical data on the *trans*-influence of the ligands in square Pd^{II} complexes[37,42,43] agree with one another. The *trans*-influence is revealed thermodynamically by the dependence of the instability constants k_{Cl} for the reaction

$$trans\text{-}[LMCl_3]^- + H_2O \rightleftharpoons [L(H_2O)MCl_2] + Cl^-$$

on the nature of L.

The order of the change in k_{Cl} agrees with the theoretical order of the *trans*-influence,[42] although the quantum-chemical calculation did not take account of the influence of solvation on this reaction. The conclusion that H has a strong *trans*-influence in Pd^{II} complexes is confirmed by the results of an X-ray diffraction study of the complex *trans*-$ClPd(H)(PPh_3)_2$, for which the bond length $R(Pd–Cl) = 0.247$ nm is much greater than the average value for Pd^{II} complexes, $R(Pd–Cl) = 0.223$ nm.[45] Thus the available experimental data confirm the regular features of the change in the *trans*-influence obtained theoretically.

A comparative study of the electronic structure of related complexes of Pd^{II}, Ni^{II}, and Pt^{II} has been carried out.[34,46–48] The complexes MCl_4^{2-}, $M_2Cl_6^{2-}$, $[MCl_3(C_2H_4)]^-$, and ML_2 with σ-donor ligands show an increase in the covalent character of the M–X bonds in the order Ni < Pd < Pt, revealed by a decrease in the effective charge of the central atom. A comparative non-empirical pseudo-potential calculation for the anion of Zeise's salt $[PtCl_3(C_2H_4)]^-$ and its palladium analogue[46] showed that on going from Pd to Pt the strength of the M–C_2H_4 bond increases: thus the calculated energy of the dissociation $[Cl_3M(C_2H_4)]^- \rightarrow [Cl_3M]^- + C_2H_4$ is 25 kcal mole^{-1} for Pt, and only 12 kcal mole^{-1} for Pd. In both cases the structures of $[Cl_3M(C_2H_4)]^-$ with ethylene arranged at right angles to the plane of the complex are energetically more favourable than those with the equatorial arrangement of the alkene molecule. The barrier to the rotation of ethylene about the M–C_2H_4 bond is low, and is to a large extent due to the increase in the C–Cl repulsion interaction on going to the planar structure. An estimate of the strength of the bonds in the complexes ML_2 by the CNDO method[48] also indicates that the strength of the M–L bond increases with increase in its covalent character in the order Ni < Pd < Pt. These results agree with the experimental estimation of the strengths of the M–C_2H_4 and M–L bonds in the complexes $[Cl_3M(C_2H_4)]^-$ and ML_2.[49]

The results are determined by the general regular features, noted above, in the change in the electronic structure of the transition elements, namely the increase in the diffuse character and simultaneous stabilisation of the valence *d* orbitals on going from the elements of the first transition series to the elements of the second and third series. The energy of interaction of orbitals *i* and *j* can be estimated in second-order perturbation theory using the expression[50]

$$E_{ij} = -\frac{H_{ij}}{\varepsilon_i - \varepsilon_j} \qquad (1)$$

where H_{ij} is the integral of the resonance interaction of the orbitals, which increases with increase in the degree of overlap of the orbitals, and ε_i and ε_j are the orbital energies. The more diffuse character of the 4*d* AO of the Pd atom and the 5*d* AO of the Pt atom compared with the 3*d* AO of the Ni atom is responsible for their greater overlap with the ligand orbitals, and hence for the higher value of E_{ij}. Moreover, for Pd and Pt, the lower-lying 4*d* and 5*d* AO are closer in energy to the ligand orbitals involved in the M–L bonds, compared with the 3*d* AO of the Ni atom. This also leads to an increase in E_{ij} as a consequence of the decrease in the difference $\varepsilon_i - \varepsilon_j$. Thus the electronic characteristics of the *nd* AO are responsible for the increase in the covalent bonding M–L in the order Ni < Pd < Pt.

The decrease in the polarity of the M–Cl bonds is also responsible for the observed[30,34] closer relative positions of the non-bonding levels of the M and Cl atoms for $PdCl_4^{2-}$ and $Pd_2Cl_6^{2-}$, compared with the corresponding Pt complexes. The highest occupied MO of the $PtCl_4^{2-}$ and $Pt_2Cl_6^{2-}$ ions consist chiefly of the *d* AO of the Pt atom, and lie appreciably higher than the other occupied MO. In the case of the Pd complexes, the relatively high effective charges of Pd and Cl stabilise the non-bonding MO consisting chiefly of the *d* AO of palladium, and destabilise the non-bonding MO localised on Cl (ϕ_{Cl}). This leads to the observed[30,34] approach of the energies of ϕ_{Cl} and the highest occupied molecular orbitals (HOMO) of the $PdCl_4^{2-}$ and $Pd_2Cl_6^{2-}$ ions.

This review of the results of quantum-chemical calculations for Pd^{II} complexes reveals the following regular features of their electronic structure: 1) the electronic characteristic correlating with the formal oxidation state of palladium in

Pd^{II} complexes is the magnitude of the vacancy in the valence 4*d* level of the Pd atom, which is close to 2e for the complexes for which calculations have been carried out; an important role in the Pd–L bonding interaction is played not only by the valence 4*d* AO but also by the outer 5*s* and 5*p* AO of palladium; 2) the electron density at the palladium atom decreases with increase in the electronegativity of the ligands; 3) the static *trans*-influence of the ligand generally increases with increase in its donor power; and 4) in a series of related compounds of Ni^{II}, Pd^{II}, and Pt^{II}, the strength of the M–L bonds increases with increase in their covalent character in the order Ni < Pd < Pt.

2. The Electronic Structure of Pd^0 and Pd^I Compounds

Compounds of zero-valent palladium (formal oxidation state 0) have been the subject of more non-empirical calculations than other palladium systems. The only Pd^I compound for which quantum-chemical studies have been carried out is apparently PdH.[17,18,51] The reason is probably that Pd^I compounds began to attract the attention of chemists only comparatively recently.[52–54] Calculations have been carried out[55] for the hydride complex of Pd^I $Pd_2(PH_3)_2H_2$. The study of the electronic structure of this complex, however, was not the aim of this work,[55] and its results will be discussed below (section V) in relation to the problem of the dissociative reaction of molecular hydrogen with palladium systems.

Following the principle formulated above, the oxidation state of palladium will be related to the magnitude of the vacancy in its valence *d* level. The data given in Table 2 show that, in agreement with the above conclusion, the magnitude of the *d* vacancy correlates with the formal oxidation state. Thus for the Pd^0 complexes $Pd(H_2)$, Pd(CO), and $Pd(C_2H_4)$, the electron configuration of the *d* AO is close to d^{10} (the values of the populations were not given for $Pd(C_2H_4)$, but the electron configuration of Pd is close to d^{10} [58,59]). On the other hand, for Pd^I hydride, the configuration of the *d* AO is close to d^9. It is also shown below that the magnitude of the *d* vacancy is one of the important electronic factors determining the relative strength of Pd–L bonds.

Comparison of the results of calculations for the PdCO, PdH, and PdC systems,[18] carried out in the same pseudopotential scheme, also makes it possible to estimate the oxidation state of Pd in palladium carbide. Table 2 shows that the magnitude of the *d* vacancy for palladium in PdC (~0.5e) is approximately equal to the average of the values for zero-valent palladium in PdCO and univalent palladium in PdH. Thus if the above criterion is applicable, the oxidation state of palladium in PdC is intermediate between 0 and +1. Unfortunately, there are no published data on the electron distribution in alkylpalladium systems, in particular for the important model system $PdCH_3$. It would also be of interest to estimate the change in the actual oxidation state of palladium in complexes with increase in its coordination number. In Refs.59 and 60–62, however, which give the results of non-empirical calculations for $Pd(C_2H_4)_n$ and $Pd(CO)_4$, no data are given on the population of the *d* AO of the Pd atom.

The formation of a *d* vacancy when the palladium atom is introduced into a complex may take place both as a result of Pd → L transfer of electron density and as a result of the promotion of electrons from the 4*d* to the 5*s* and 5*p* AO of palladium. In all the systems given in Table 2 except $Pd(H_2)$, the effective charge of Pd is positive as a result of Pd → L charge transfer. In the case of $Pd(H_2)$, the coordination of molecular hydrogen is determined chiefly by the donor–acceptor interaction of the filled σ-orbital (bonding orbital) of H_2 with the 5*s* and 5*p* AO of the Pd atom,[41] and the calculation in a minimum basis set gives a negative charge on the Pd atom. The positive charge of Pd, obtained in Ref.56 using two-exponent basis functions for H, is due to the population of the diffuse components of the 1*s* AO of the H atom. The assignment of a corresponding proportion of electron density to hydrogen is not completely justified, since the diffuse components of the 1*s* AO of the H atom overlap considerably the diffuse orbitals of the Pd atom, and their overlap density cannot be separated unambiguously.

Table 2. Results of non-empirical calculations for various simple model complexes of Pd^0 and Pd^I.

Compound	Z_{Pd}, e	Q_s, e	Q_p, e	Q_d, e	E_d, kJ mole^{-1}	Refs.
Pd (H_2)*	−0.08	0.24	0.12	9.72	23	[56]
Pd (H_2)	0.07	0.11	0.09	9.73	27	[56]
Pd (CO)	0.06	0.28	0.22	9.56	192	[57]
Pd (CO)	0.01	0.19	0.08	9.72	75	[18]
Pd (C_2H_4)	0.10	—	—	—	50	[58]
Pd (C_2H_4)	0.19	—	—	—	272	[59]
PdH	0.11	0.44	0.08	9.37	108	[18]
PdH	0.32	0.35	0.11	9.22	135	[17]
PdH	0.15	0.58	0.09	9.18	193	[54]
PdC	0.20	0.10	0.11	9.59	130	[18]
PdC	0.28	0.09	0.11	9.52	121	[19]

Notes: E_d is the dissociation energy, Z_{Pd} the effective charge on the Pd atom, and Q_s, Q_p, and Q_d the total populations of the valence 4*d*, 5*s*, and 5*p* AO of the Pd atom.

*For $Pd(H_2)$ the first row gives the results of the calculation in a minimum basis set, and the second row the results for an expanded basis set.

On going along the series of compounds PdL from L = H_2 to CO and C_2H_4 [56,57,59] there is a considerable increase in the dative transfer of electron density to the ligand, corresponding (in the Dewar–Chatt–Duncanson model) to the π-component of the Pd–L interaction. This is related to the fact that the unoccupied π*-orbitals of CO and C_2H_4, taking part in the dative interaction, have much lower energies than the antibonding orbital of H_2. Comparison of the results of non-empirical calculations for $Pd(H_2)$ [56] and PdCO,[57] carried out with allowance for all the electrons, shows that the increase in the dative interaction on going from $Pd(H_2)$ to PdCO is also accompanied by an increase in the donor–acceptor component, that is a synergic effect is observed. This leads to an appreciable increase in the strength of the bond, which for L = CO or C_2H_4 shows clearly defined covalent character. The observed increase in the strength of the Pd–L bond corresponds to the decrease in the total population of the 4*d* AO and the increase in the populations of the 5*s* and 5*p* AO of the Pd atom.

Overall, however, the total population of the 5*s* and 5*p* AO of palladium in Pd^0 and Pd^I compounds is much lower than 1e, that is the corresponding value for typical Pd^{II} complexes. This is due primarily to the fact that the ligands in the Pd^0 and Pd^I compounds are capable of donor–acceptor

interaction with the 5*s* and 5*p* AO to a much smaller extent than in the case of the anionic ligands of Pd^{II} complexes. In the Pd^0 and Pd^I compounds, the increase in the covalent contribution to the Pd–L bonding, accompanying the change to the electron configurations d^9s^1 or d^9p^1, does not compensate the expenditure of energy in the electron promotion $4d \rightarrow 5s$ or $4d \rightarrow 5p$. As a result, for a coordinate bond in these compounds, the optimum electron configuration of Pd is one in which the 5*s* and 5*p* AO have a low population.

Calculated data on the strength of the Pd–L bond Pd^0 and Pd^I compounds are contradictory, as can be seen, for example, by comparing the values given in Table 2 for the Pd–L (L = CO, C_2H_4) coordination energies obtained in different studies. It is of interest to compare the energies of different Pd–L bonds for which non-empirical calculations have been carried out in comparable and sufficiently large basis sets and in the same pseudo-potential scheme for PdCO, PdH, and PdC.[18] The increase in the *d* vacancy (chiefly in the $4d_\sigma$ AO oriented in the bond direction) on going from the zero-valent palladium compound PdCO to the univalent palladium compound PdH decreases the Fermi repulsion interaction between the electron of the $4d_\sigma$ AO of the Pd atom and the σ-orbitals of the ligands. This electronic factor is responsible for the greater strength of the Pd–H bond, compared with the Pd–CO bond.

The Pd–C bond in palladium carbide is even stronger than the Pd–H bond, although the magnitude of the *d* vacancy is smaller in the first case.[18,19] This is explained by the specific features of the electronic structure of the C atom acting as ligand. In the case of PdC, the σ-orbital of the carbide atom is unoccupied, and the only repulsion interaction of the Fermi type is the interaction of the electrons of the filled levels $d_\pi - \phi_\pi(C)$, which is much weaker than the corresponding interaction of the σ-orbitals. The resulting Pd–C bond is a single σ-bond. This bond, although stronger than the Pd–CO and Pd–H bonds, according to Ref.19 should be weaker than M–C multiple bonds, where M represents metals of neighbouring groups of the periodic system.

The $Pd...C_2H_4$ bond energy has been estimated[58,59] by a non-empirical calculation in the valence approximation using different pseudo-potential schemes. The value E_d = 50 kJ mole^{-1} was obtained for the dissociation energy of the $Pd...C_2H_4$ bond;[58] this shows qualitative agreement with infrared and ultraviolet spectroscopic data for this compound isolated in an inert matrix, which indicate the formation of a weak $Pd...C_2H_4$ bond.[63]

The high value obtained in Ref.59 for E_d for $Pd...C_2H_4$ (see Table 2) is apparently due to the overestimation (in the pseudo-potential scheme used[59]) of the contribution of the dative interaction of the 4*d* AO of palladium with the antibonding σ*-orbital of ethylene. The data in Ref.58, where a different scheme was used to construct the pseudo-potential, and also the results of a calculation for PdC_2H_4 by the SCF-Xα-SW method,[64] in agreement with qualitative perturbation theory, indicate that there is practically no interaction of the 4*d* AO of palladium with the high-lying σ*-orbital of C_2H_4.

A comparative study of the electronic structure of Pd^0 and Pd^I compounds in a series of related compounds of metals of the platinum group has been carried out.[17,47,64–66,51] In all the M^0 compounds for which calculations were carried out, as in the M^{II} complexes examined above, the effective charge of M decreases (the covalent character of the M–L bonds increases) in the order Ni, Pd, Pt. This is due to the fact that, as noted above, the d AO of the heavy metals (palladium and platinum) form more covalent bonds with the ligand orbitals, compared with the 3*d* AO of nickel.

This conclusion is confirmed by an analysis of the dative component of the M–L interaction in the π-complexes $M(C_2H_4)$[64] and $M(O_2)(PH_3)_2$.[66] In the complexes of both types, the bonding interaction of the filled d_π orbitals of the M atoms with χ_π ligand orbitals of appropriate symmetry increases in the order Ni < Pd < Pt. This conclusion was reached in Ref.64 from an analysis of the correlation diagrams of the one-electron levels, obtained by the SCF-Xα-SW method, and in Ref.66 by comparing the contributions of the dative interaction to the covalent component E_{M-O_2}, obtained by the CNDO method. In the last case it was shown that, in spite of the decrease in the transfer of electron density and going from Ni to Pt, the energy contribution of the dative interaction increases because of the increase in the overlap of the d_π and χ_π orbitals and the corresponding increase in the contribution of the covalent bonding M–L.

The large contribution of the dative interaction is responsible for the greater strength of the coordinate bond in the $Pd(C_2H_4)$ system compared with the isoelectronic system $[Ag(C_2H_4)]^+$.[59] In the case of $Pd(C_2H_4)$, the main contribution to the bond is made by the dative interaction of the $4d_\pi$ AO of palladium with the π*-orbital of ethylene, whereas in the case of $[Ag(C_2H_4)]^+$ it is made by the donor–acceptor interaction of the 5*s* and 5*p* AO of silver with the σ-orbital of ethylene, and the bond energy in the first case is 2.3 times that in the second.

In all the compounds studied, the estimated strength of the Pd–L bonds is lower than that of the corresponding Pt–L bonds, but in the case of $M(O_2)(PH_3)_2$, and also the hydrides MH,[17] the $Pd...O_2$ and Pd...H bonds are less stable than the $Ni...O_2$ and Ni...H bonds. Experimental data obtained for complexes with molecular nitrogen (in matrices)[67] and phosphine complexes[68,69] of zero-valent metals of the platinum group show that in these complexes Pd^0 again forms the weakest bonds.

Thus analysis of the quantum-chemical data indicates that the electronic factor preventing the formation of strong bonds in Pd^0 compounds is the relatively small magnitude of the *d* vacancy, which is related to the fact that the energy of electron promotion $nd \rightarrow (n+1)s$ or $nd \rightarrow (n+1)p$ has the highest value among the elements of the platinum group. With increase in the oxidation number, the magnitude of the *d* vacancy increases, but in the case of the hydride PdH it is again lower than the corresponding values for NiH and PtH, and the population of the 5*s* AO of palladium is lower that that of the 4*s* AO of nickel and the 6*s* AO of platinum. The Fermi repulsion interaction of the electrons of the filled $4d_\sigma$ AO of palladium and the σ-orbitals of the ligands decreases the strength of the Pd–L bond.

Calculations for Pd^0 complexes with a coordination number $n > 1$ were carried out not only in Ref.66 but also in Refs.62, 59, and 70. An interesting characteristic feature of Pd^0 and Pt^0 complexes is that, in addition to 18-electron complexes ML_4, low-coordinate 16-electron trigonal planar complexes ML_3 are also known. Examples of these complexes are provided by the complexes of palladium with tertiary phosphine ligands $Pd(PR_3)_3$ and the mixed phosphine complexes $PdX(PR_3)_2$ (X = alkene, O_2).[71,72] 14-electron complexes $Pd(PR_3)_2$ have also been obtained.[16] Experimental data indicate that the strength of the coordinate bond in Pd^0 complexes and the reactivity of these complexes depend on the coordination number of palladium.[16,73] The aim of the theoretical study is to determine the electronic factors which, in addition to steric factors, determine the optimum coordination number for Pd^0 complexes.

Comparative calculations for PdL_n complexes with different coordination numbers n[59,70] show (in agreement with experimental data) that the strength of the Pd–L coordinate bond decreases with increase in n. Thus a non-empirical pseudo-potential calculation for the complexes $Pd(C_2H_4)_n$ with $n = 1$, 3, and 4[59] showed that the coordination energy E_c corresponding to one ethylene molecule decreases on going from $n = 1$ to $n = 3$ and $n = 4$ by factors of 1.2 and 1.4 respectively. The marked decrease in the calculated values of E_c on going from $n = 1$ to $n = 4$ explains the fact that the coordination number of palladium in the compounds $Pd(C_2H_4)_n$ synthesised in inert matrices does not exceed 3.[63]

The electronic factors responsible for the decrease in the strength of Pd–L coordinate bonds when L is an electron σ-donor were established[70] by CNDO calculations for the model phosphine complexes $Pd(PH_3)_n$ ($n = 1$–4) and the hypothetical complexes $Pd(H_2)(PH_3)_n$ ($n = 1$–3). In this case a criterion of coordinative unsaturation of the complexes is provided by the relative energy of the lowest unoccupied MO (LUMO), localised on the transition metal atoms.[74] For phosphine complexes of Pd^0, these orbitals consist chiefly of the 5*s* and 5*p* AO of the Pd atom. Analysis of the results of the calculations[70] showed that the $L_nPd...H_2$ coordination energy and the strength of the individual Pd–L bonds decrease considerably with decrease in the valence angle L–Pd–L, or, which is the same thing, with change in the formal hybridisation of the 5*s* and 5*p* AO of palladium. The energy of the LUMO of the complexes PdL_n increases with increase in n, that is, as expected, the coordinative unsaturation of the complexes decreases with increase in the number of phosphine ligands.

The electronic factor responsible for the relative stability of the coordinatively unsaturated complexes PdL_n is the fact that the transfer of electron density to the 5*p* AO of the Pd atom becomes energetically unfavourable with increase in n.

Thus in the unsaturated 16-electron complexes PdL_3 and even in the 14-electron complexes PdL_2, the population of the high-lying 5*p* AO of palladium involved in bonding may reach a value such that its increase on the coordination of new ligands is energetically unfavourable. The optimum coordination number of the complexes of the platinum group metals is therefore determined not only by steric factors but also by electronic factors, in particular the relative arrangement of the *s*, *p*, and *d* levels of the M atom. This conclusion makes it possible to explain the observed difference in the coordination numbers of complexes of Ni^0, Pd^0, and Pt^0 with the same phosphine ligands, and also the difference in the coordination numbers for complexes ML_n with ligands having similar steric characteristics but different electronic characteristics.[16,73]

Analysis of the results of these quantum-chemical calculations of the electronic structure of Pd^0 and Pd^I compounds leads to some general conclusions. For Pd^0 and Pd^I compounds, as in the case of Pd^{II} compounds, the magnitude of the vacancy in the valence *d* level correlates with the formal oxidation state of palladium. The population of the outer 5*s* and 5*p* AO generally increases with increase in the *d* vacancy. The relatively small magnitude of the *d* vacancy is the electronic factor decreasing the strength of the Pd–L bonds in the Pd^0 compounds. The strength of the M–L bonds in compounds of a metal in a low oxidation state generally increases in the order Ni < Pd < Pt, if the main contribution to the bond is made by the dative component of the M–L interaction. When the donor–acceptor component of the M–L interaction is decisive, the strength of the Pd–L bond may be the lowest among the platinum group metals. The electronic factor responsible for the possible existence of coordinatively unsaturated Pd^0 complexes PdL_n (where L is an electron σ-donor and $n = 2$ or 3) is the fact that, with increase in n, the filling of the high-lying 5*p* AO of palladium, involved in the formation of the Pd–L bonds, becomes energetically unfavourable.

3. The Electronic Structure of Palladium Clusters

In the present section, the results of the quantum-chemical study of atomic clusters Pd_n ($n = 2$–79)[51,75–85] and the few calculations for polynuclear complexes Pd_mL_n[34,86,87] are discussed. The experimental and theoretical study of clusters is an important independent field.[88] At the same time, quantum-chemical calculations for clusters, in particular palladium clusters, are also of interest for the theory of catalysis, particularly heterogeneous catalysts, in relation to the problem of studying the electronic structure and properties of catalytic systems. The cluster model makes it possible to obtain valuable information on the electronic nature of the Pd–Pd bond, and also on the dependence of the properties of the system on the number of Pd atoms.

A key cluster system is the simplest cluster Pd_2, for which experimental spectroscopic data are available.[89,90] The main aim of the quantum-chemical studies carried out in Refs.51 and 75 was the estimation of the strength of the bonds formed by two palladium atoms with filled *d* levels. The calculations for Pd_2 were carried out by the non-empirical SCF MO LCAO method[75] and also by the two-configuration SCF method,[51] in the valence approximation. A pseudo-potential non-empirical calculation has also been carried out for the cluster Pd_3.[75] A number of calculations for the clusters Pd_5, Pd_6, and Pd_{13}, and also a study of the adsorption of atomic oxygen and CO on Pd_5 clusters and of atomic hydrogen on Pd_6 clusters, have been carried out by the SCF-Xα-SW method.[76–78] The other cluster calculations[79–87] were carried out in the CNDO approximation, and also by the EHM.

The results of the calculations for Pd_2 carried out by different methods are contradictory. Thus the calculation by the two-configuration SCF method[51] gives the dissociation energy value $E_d = 72.3$ kJ mole^{-1}, in satisfactory agreement with the spectroscopic estimate of 63 ± 19 kJ mole^{-1}.[90] On the other hand, a non-empirical SCF MO LCAO calculation[75] in a minimum basis set with the addition of polarisation *d* functions gave a bond energy value close to zero. A calculation in a basis set selected according to the "counterbalance" scheme,[91] that is using a complete molecular basis set in the calculation for individual palladium atoms, gave a potential curve of the repulsion type. In Ref.75, a calculation for the cluster Pd_3 was carried out using the same basis set as for Pd_2, and, as in the case of Pd_2, it was concluded that no bond is formed. The standard choice of basis set and the use of the "counterbalance" scheme give the same value of E_d for Pd_3. The most stable Pd_3 structure examined was the linear structure.[75]

A possible reason for the lack of agreement in the results in Refs.51 and 75 may be that in Ref.75 the effects of Coulombic correlation, which are particularly important for transition metal clusters,[92] were not taken into account.

According to the results of non-empirical calculations[51,75] and CNDO and EHM calculations,[79–81] the bond between palladium atoms with a filled 4*d* level is due chiefly to the participation of the unoccupied 5*s* AO of the Pd atoms in the bonding interaction. According to Refs.75 and 79, palladium in Pd_2 has a valence electron configuration close to d^{10}. On the other hand, the electron configuration

calculated in Refs.51 and 81 is close to d^9s^1. This difference is undoubtedly due to the characteristic features of the calculation methods used.

A comparison[82] of the results of calculations for the clusters Pd_{13} and Pd_{19} by the standard EHM and the version self-consistent with respect to charges and configurations showed that the first method gives an insufficiently reliable picture of the electron density distribution. In the standard version, in particular, the total population of the 4*d* AO of palladium is lowered considerably, and this may be the reason for the electron configuration d^9s^1 obtained for Pd_2 in Ref.81. In the case of the non-empirical calculation,[51] the use of the atom pseudo-potential to take effective account of the interaction of the valence and core electrons gives an incorrect (compared with the experimental estimate[15]) difference in the energies of the configurations d^{10} and d^9s^1, and this may influence the calculated values of the population of the 5*s* AO. To obtain more reliable information on the electron configuration of Pd in Pd_2 it is apparently necessary to carry out a more rigorous non-empirical calculation with allowance for all the electrons, and also with allowance for the effects of Coulombic correlation.

Thus even for the simplest palladium cluster, the data on the nature of the Pd–Pd bond are still unreliable. With allowance for this, the analysis of the results of calculations for more complex clusters can be carried out primarily on the basis of qualitative conclusions about the regular features of the change in the electron characteristics in a series of related systems. Calculations for clusters larger than Pd_2 have been carried out by the EHM,[82–85] and Pd_{13} has also been studied by the SCF-Xα-SW method.[76]

In Ref.76 it was found that an appreciable charge accumulates on the central Pd atom in Pd_{13}. The orbitals localised on the outer atoms are mainly the HOMO, many of which are non-bonding. In turn, a low-lying bonding MO with an appreciable contribution from the 5*s* AO of palladium is localised chiefly on the central Pd atom. These results show qualitative agreement with the results of a calculation for the cluster Pd_{19}, self-consistent with respect to charges and configurations, carried out by the EHM.[83]

The adsorption of atomic hydrogen on Pd clusters was studied in Refs.77, 79, and 85, and the adsorption of atomic oxygen and CO on Pd_5 was studied in Ref.78 (the calculations for the reaction of H_2 with Pd_2 and Pd_9 clusters, carried out in Ref.85, will be discussed in section IV). For all the clusters, an appreciable contribution to the Pd–L bond is made by the 5*s* and 5*p* AO of palladium. Thus in the octahedral cluster Pd_6H, according to the results of a calculation by the SCF-Xα-SW method,[77] the contribution of the 5*s* and 5*p* AO of palladium to the MO corresponding to the Pd–H bond is 76% of the contribution of the *d* AO.

In Ref.78, the same method was used to carry out a calculation for two structures of $Pd_5(O)$ modelling two possible versions of the coordination of O on a metallic palladium surface. In the first structure, the O atom is coordinated to the central Pd atom of a Pd_5 cluster (all the Pd atoms lie in the same plane). In the second structure, four Pd atoms lie in same plane, and the O atom and the fifth Pd atom lie on the principal axis of Pd_4, on different sides of this plane. The calculated spectra and the experimental infrared spectra for the adsorption of atomic oxygen on metallic palladium were compared. It was concluded that the single-point adsorption of O corresponds to the experimentally observed form of adsorption with a weak O–M bond, and that the many-point adsorption corresponds to the form of adsorption with a relatively strong O–M bond.

The electronic structure of dinuclear palladium complexes has been studied.[34,86,87] In Ref.87, calculations were carried out for the linear systems formed by the Pd^0 phosphine complexes $Pd_2(PH_3)_2$ and $Pd_2(PPhH_2)_2$, and also for a number of structures $Pd_2(PPhH_2)_2$, modelling the intramolecular coordination Pd...P in the dinuclear complexes $Pd_2(PPh_3)_2$.[93,94] The results of the population analysis indicate that a weak Pd–Pd bond is formed. This bond, in agreement with the results obtained for the dinuclear clusters Pd_2, can be described as a σ-bond produced mainly by the interaction of the $4d_{z^2}$ AO of one Pd atom and the 5*s* AO of the other Pd atom.

As noted in Ref.87, the formation of a Pd–Pd multiple bond might have been expected for the linear structures. Thus in terms of the concept of isolobality developed by Hoffmann,[95] if the difference in the filling of the orbitals are ignored, the fragment PdL, which has boundary sp_z, p_x, and p_y orbitals, can be compared with a CH group. As shown by the analysis in Ref.87, however, Pd–Pd multiple bonds involving *spd* hybrid orbitals are not formed, since electron promotion for the 4*d* to the high-lying 5*p* AO is energetically unfavourable.

The unoccupied 5*p* AO of palladium in Pd_2L_2 can take part in additional interactions. Thus the bonding donor–acceptor interaction of the 5*p* AO of a Pd atom with a phenylphosphine ligand of a neighbouring Pd atom (more accurately with the filled π-orbital of the aromatic ring) leads to additional stabilisation of the complex Pd_2L_2 and is possibly the reason for the observed stability of the coordinatively unsaturated complexes $Pd_2(PPh_3)_2$.[87]

In dinuclear and polynuclear Pd^{II} compounds, the distance between the palladium atoms is usually appreciably greater than the sum of their covalent radii. The electronic structure of the complex of palladium with dithioacetic acid $Pd_2(CH_3CSS)_4$, which has a short Pd–Pd bond and in which all four dithioacetate ligands occupy bridging positions, has been studied.[86] It is of interest to compare the results obtained with the results of a calculation[34] for the complex $Pd_2Cl_6^{2-}$ with two bridging ligands, where it is known that there is no direct Pd–Pd interaction. According to Refs.34 and 86, the absolute magnitude of the effective charge of the bridging ligands Cl and CH_3CSS ($Z_{Cl} = -0.41e$, $Z_{CH_3CSS} = -0.50e$) is smaller than that of the corresponding values $Z_{Cl} = -0.60e$ and $Z_{CH_3CSS} = -0.53e$ for the terminal Cl atoms in $Pd_2Cl_6^{2-}$ and the ligands CH_3CSS in the mononuclear complex $Pd(CH_3CSS)_2$. The Pd–Pd bond in $Pd_2(CH_3CSS)_4$ is a weak σ-bond. In Ref.34 it was noted that it is important to take account of configuration interaction in the calculation of the electronic spectra of $Pd_2Cl_6^{2-}$. Allowance for this factor leads to a marked displacement of the bands in the calculated spectra of $Pd_2Cl_6^{2-}$ to longer wavelengths compared with $PdCl_4^{2-}$, and to better agreement with the experimental data.[96–98]

IV. THE QUANTUM-CHEMICAL STUDY OF REACTIONS INVOLVING PALLADIUM COMPOUNDS

The results of the quantum-chemical study of the key elementary stages of processes catalysed by palladium complexes, or reactions responsible for the production of the catalyst, will be examined. The quantum-chemical mechanisms of the most important reactions of palladium compounds, namely the reaction of Pd^{II} and Pd^0 complexes with molecular hydrogen, the hydroxopalladation of alkenes, and various other reactions, have been studied.[55,56,79,85,99–105] The first non-empirical calculations in this field were carried

out in studies of the reaction of molecular hydrogen[56] and methane[99] with a palladium atom, and also the calculation for the model reaction of the insertion of CO into the Pd–H bond in the $[HPdCO]^+$ system.[100] The other calculations were carried out by the CNDO method using the parametrisation schemes proposed in Refs.36 and 37, and also by the EHM.

1. The Study of the Reaction of Molecular Hydrogen with Palladium Compounds

An important preparatory stage in catalytic processes involving the reactions of molecular hydrogen is the coordination of H_2 to a transition metal atom. In all published quantum-chemical studies of the activation of H_2 by the reaction with palladium compounds,[55,56,79,85,101,102] the initial systems examined contained H_2 coordinated in the molecular form to a Pd atom or (in polynuclear systems) at a Pd–Pd bond.

The calculations show that molecular hydrogen can be coordinated as an isolated ligand. The results of a complete non-empirical calculation for the simplest system $Pd(H_2)$,[56] partly discussed above are of particular interest. According to Ref.56, the Pd...H_2 interaction gives a complex containing bound (albeit weakly) molecular hydrogen. Thus the calculation in the largest of the basis sets used in Ref.56 for a fixed H–H bond length (R(H–H) = 0.074 nm) gives for the optimum T-shaped structure with R(Pd–H) = 0.2 nm a bond energy of E_d = 27 kJ mole^{-1}. As noted above, the coordination of H_2 involves chiefly a donor–acceptor interaction with the outer 5*s* and 5*p* AO of the Pd atom. The results of Ref.56 led to the general suggestion that transition metals can form stable complexes with molecular hydrogen as an isolated ligand. The theory of this type of coordinate bond was developed in Ref.106. A recent report[107] of the direct structural identification of tungsten and molybdenum complexes with molecular hydrogen confirmed this suggestion.

The activation of molecular hydrogen in a catalytic process involving transition metals leads finally to the rupture of the H–H bond. Both homolytic and heterolytic rupture of the H–H bond can be expected, depending on the nature of the transition metal, its oxidation state, and the nature of the coordinated ligands. The role of the electronic factors determining the mechanism of the activation of H_2 in its reaction with palladium compounds has been studied.[55,79,85,101,102] In Ref.101, a CNDO calculation was carried out for the heterolytic rupture of the H–H bond by a dissociative replacement mechanism in the reaction of H_2 with Pd^{II} complexes. In the other works cited, the homolytic rupture of the H–H bond in the reaction of H_2 with Pd^0 compounds was modelled.

The heterolytic rupture of the H–H bond is regarded as the initial stage in the selective catalytic hydrogenation of unsaturated compounds.[93,108–110] The starting materials in this reaction are mixed Pd^{II} complexes PdX_2L, where L is phosphine ligand. An interesting feature of this reaction is that the complexes PdX_2L_2 with oxygen-containing ligands X show a much higher activity towards H_2 than the corresponding complexes with halide ligands. From an analysis of experimental data, a four-centre mechanism was proposed for this reaction,[109,110] according to which the central atom captures a hydride ion, while the coordinated anionic ligand facilitates the capture by accepting the proton liberated:

$$PdX_2L_2 + H_2 \rightarrow (H)XPdL_2 + HX$$

The process is controlled by the interaction of the orbitals which are involved to the greatest extent in the bonds which are being formed or being broken in the dissociative replacement. These orbitals are the 1*s* AO of the H atoms, the localised hybrid orbitals of the Pd and X atoms, taking part in the Pd–X bonds, and the orbital of the unshared pair of the ligand X. In the state in which the H_2 molecule occupies a vacant coordination position in the original complex, the highest occupied MO are the MO of the unshared pair of X and the MO which corresponds to the antibonding combination of the bonding orbitals of the H–H and Pd–X bonds. The lowest unoccupied MO is the bonding combination of the antibonding orbitals of the H–H and Pd–X bonds. In the final state, the highest occupied MO will be the orbital of the unshared pair of X, formed as a result of the rupture of the Pd–X bond, and the MO which corresponds to the antibonding combination of the bonding orbitals of the Pd–H and H–X bond. The lowest unoccupied MO will be the bonding combination of the antibonding orbitals of the Pd–H and H–X bonds.

The intermediate cyclic state of the system can be examined by analogy with a five-orbital system of the polyene type,[111] if it is assumed that the ends of the chain are the orbitals of the anionic ligand X, not interacting with one another. The correlation diagram for this process differs from the familiar diagram[112] for the symmetry-forbidden redistribution of the bonds in the four-centre four-electron system

$$X{-}X' + Y{-}Y' \rightarrow XY + X'Y'$$

only in the presence of the unshared pair of the anionic ligand X. This difference, however, may lead to significant differences in the energies of these two processes. The non-bonding orbital of the unshared electron pair of the ligand X correlates with the practically non-bonding HOMO of the intermediate state, so that the dissociative replacement, generally speaking, is not symmetry-forbidden.

The initial stage of this process was modelled in Ref.101. The calculation was carried out after selecting structures describing the coordination of H_2 in the unoccupied coordination position of square complexes $PdX_2(PH_3)_2$, where X = Cl, OH, $OCOCH_3$, and also structures in which the coordinated H_2 molecule was displaced towards the anionic acido-ligand.

The calculations show that one of the electronic factors responsible for the heterolysis of H_2 is the donor–acceptor interaction of the filled σ-orbital of H_2 (the bonding combination of the 1*s* AO of hydrogen) with the unoccupied 5*sp* hybrid orbital. The rehybridisation of this orbital when H_2 is displaced towards the acido-ligand X ensures a bonding Pd...H_2 interaction when H_2 approaches X in all the structures examined. This bonding interaction facilitates the heterolysis. The donor–acceptor transfer of electron density $\sigma(H_2) \rightarrow 5sp$(Pd) to the H atoms produces a positive charge, which is responsible for the direct reaction of the coordinated H_2 molecule with the anionic acido-ligand X. This interaction leads finally to the heterolytic rupture of the H–H bond.

The rupture of the H–H bond corresponds to the filling of the σ^*-orbital of H_2 (antibonding combination of the 1*s* AO of hydrogen). In the case of dissociative replacement by a four-centre mechanism being considered, the metal-complex system does not have a high symmetry, and the filling of $\sigma^*(H_2)$ involves the mixing of the LUMO of the original structure, which contains a contribution from $\sigma^*(H_2)$, with the orbital of the unshared pair of the ligand X and the occupied MO containing a contribution from the bonding σ-orbital of H_2. The resulting HOMO of the

transition state has a node at the H atom closest to the anionic ligand, and describes the polarisation of the coordinated H_2 molecule.

The electronic factors stabilising the HOMO of the intermediate state should also stabilise the intermediate state as a whole, that is it should lower the activation barrier of the reaction. In the case being considered, where the HOMO has an electron density deficit at the H atom closest to X, this electronic factor is the Coulombic attraction $H^{\delta+}...X^{\delta-}$. The calculation in Ref.101 indicates that there is appreciable direct interaction between the coordinated H_2 molecule and the oxygen-containing anionic ligands OH and $OCOCH_3$, to which the main contribution is made by the Coulombic attraction $H^{\delta+}...OR^{\delta-}$.

Analysis of the two-centre components E_{HX} and the relative energies of the structures modelling the displacement of H_2 towards X shows[101] that the heterolytic rupture of the H–H bond should be easier for complexes with oxygen-containing ligands than for chloride complexes. This is because the ligand OR has a greater affinity for the H atom carrying the positive charge. Greater basic strength in X should also facilitate the stabilisation of the final state, making the formation of HX energetically more favourable. The results of the calculations in Ref.101 make it possible to explain the available experimental data and confirm the four-centre mechanism, proposed[109,110] on the basis of these data, for the heterolytic rupture of the H–H bond in the reaction with Pd^{II} complexes.

In the reaction of molecular hydrogen with Pd^0 compounds, the activation of H_2 takes place by a different mechanism, namely the oxidative addition of H_2 with the homolytic rupture of the H–H bond:

$$M_n + H_2 \rightarrow \begin{matrix} H \\ \diagdown \\ \diagup \\ H \end{matrix} M_n$$

For example, the dissociative chemisorption of H_2 on metallic palladium takes place by the oxidative addition mechanism.[113] This mechanism was studied by quantum-chemical methods in Refs.79, 85, and 102. In Ref.102, the complete non-empirical SCF MO LCAO method in a minimum basis set was used to carry out a calculation for the dissociation of H_2 in the coordination sphere of a Pd atom. In Ref.79, the CNDO method was used to study the reaction of H_2 with a Pd_2 cluster, and in Ref.85 a calculation was carried out for the Pd_9H system by the EHM. In addition, in Ref.55, the CNDO method and the parametrisation scheme used in Ref.79 were used to carry out a comparative calculation for the reaction of H_2 with mononuclear phosphine complexes of Pd^0 and Pt^0 of the type ML_2, and also with a dinuclear complex Pd_2L_2.

In Ref.102, the dissociation of H_2 in the $Pd(H_2)$ system was modelled by increasing the H–Pd–H angle (α) for a fixed bond length R(Pd–H) = 0.17 nm, since the optimum Pd–H bond length was found to be close to 0.17 nm both for the original complex with molecular hydrogen (α = 25°) and for the final linear dihydride structure.

With increase in the angle α, the population of the 5*s* and 5*p* AO of the Pd atom increases sharply, and in the case of angular structures with $\alpha \cong 90–148°$ the valence electron configuration of the Pd atom becomes close to d^9s^1. With further increase in α, the symmetry of the Pd orbitals involved in the H–Pd–H interaction changes. This leads to inversion of the populations of the boundary orbitals; the highest occupied MO is then the orbital corresponding to the interaction of the $5p_z$ AO of the Pd atom with the σ^*-orbital of H_2, and the valence electron configuration of Pd becomes close to d^9p^1.[102]

It was found that the formation of the dihydride is energetically unfavourable. This is due to the fact that the covalent bonding of the 1*s* AO of hydrogen with the hybrid *sp* (for $\alpha < 148°$) and *pd* (for $\alpha > 148°$) orbitals of Pd does not compensate the expenditure of energy in the electron promotion from the 4*d* AO to the high-lying 5*s* and 5*p* AO of the Pd atom. As a result, the molecular complex (α = 25°) is most stable. The angular structure undergoes an activationless transformation into the molecular complex The linear structure has a higher energy than the angular structure, but there is an energy barrier between them, associated with the rearrangement of the electron configuration $d^9s^1–d^9p^1$. It follows from the results in Ref.102 that for a metal such as palladium, the dissociation of hydrogen on a single centre is impossible, since it involves the promotion of an appreciable electronic charge to the high-lying 5*s* and 5*p* AO of palladium.

In Ref.79, where a CNDO calculation was carried out for the Pd_2H_2 system, it was again concluded that the dissociation of H_2 to give terminal hydride bonds Pd–H is energetically unfavourable. The molecular complex in which the H_2 molecule, coordinated in a bridging position, is arranged symmetrically and perpendicular to the Pd–Pd axis, is most stable. The structures Pd–Pd–H_2 with single-point coordination of H_2 are less stable, but all the structures with H_2 in the molecular form are more stable than the linear and rectangular dihydride structures.[79]

The conclusion[56,79,101] regarding the relative stability of the molecular coordination of H_2 in its single-point and two-point interaction with Pd atoms agrees qualitatively with the results of an experimental study of the chemisorption of H_2 on the surface of palladium black.[113] In this study[113] pulse volatilisation under super-high vacuum conditions ($\sim 5 \times 10^{-9}$ mmHg) detected four different states of chemisorbed H_2 on the palladium surface. The study of the physical characteristics of these states indicated that the state which is formed at a temperature below 100 K and which is desorbed at 250 K with an activation energy of 54–58 kJ $mole^{-1}$ probably corresponds to the molecular state of chemisorbed hydrogen. According to Ref.113, this molecular state may play the role of intermediate in the absorption of molecular hydrogen by metallic palladium.

The EHM has been used[85] to study the dissociative chemisorption of H_2 in the model cluster system $Pd_9–H_2$. In this case the dissociation of H_2 is energetically favourable.

The picture of the dissociative interaction of H_2 with one and with two Pd atoms obtained in Refs.79 and 102 shows complete agreement with the results of the comparative calculation[55] by the CNDO method for the interaction of H_2 with mononuclear phosphine complexes of Pd^0 and Pt^0 of the type $M(PH_3)_n$ and the dinuclear complex $Pd_2(PH_3)_2$. The latter models the complex $Pd_2(PPh_3)_2$ formed by the reduction of the compound $[(Ph_3P)Pd(OAc)_2]$ by molecular hydrogen.[93,94] $Pd_2(PPh_3)_2$ reacts with H_2 and palladium (II) complexes to form the polynuclear complexes $[(PhP)_2Pd_5]_n$ responsible for the catalysis.

Comparative calculations for mononuclear complexes of Pd^0 and Pt^0 and also dinuclear Pd^0 complexes, are of interest, since these complexes show different reactivities towards H_2. Thus mononuclear phosphine complexes PdL_n, where L is a phosphine ligand, do not react with molecular hydrogen,[71,73] the dinuclear complex $Pd_2(PPh_3)_2$ adds on H_2 easily and reversibly,[93,94] and the Pt^0 complexes PtL_2 undergo dissociative addition of hydrogen under mild conditions to give dihydride complexes of Pt^{II}.[73]

The change from mononuclear Pd complexes to the dinuclear complex corresponds to an increase in both the stability of the molecular complexes $L_nPd_m(H_2)$ with respect to

dissociation to L_nPd_m and H_2 and the relative stability of the dihydride structure HPd_mL_nH compared with the corresponding molecular complex $L_nPd_m(H_2)$. The explanation is that the formation of multicentre bonds Pd...H_2...Pd in the molecular complex and of multicentre hydride bonds Pd–H–Pd with the same strength as the corresponding bonds in the mononuclear complexes requires a smaller total transfer of electronic charge from the 4*d* to the 5*s* and 5*p* AO of palladium. In all the hydride structures, the population of the 5*s* and 5*p* AO is much greater than in the corresponding complexes with the H_2 molecule, and the hydride H atoms carry a negative charge.[55]

The dissociative addition of H_2 to the dinuclear complex Pd_2L_2 is energetically unfavourable, although to a smaller extent than the dissociative addition of H_2 to the mononuclear complexes PdL_n. The highest stability corresponds to the dinuclear structure in which the hydrogen molecule is arranged symmetrically and at right angles to the Pd–Pd bond. In the case of dinuclear structures in which H_2 is coordinated to one palladium atom, the $H_2...Pd_m$ coordination energy is lower and almost the same as for the mononuclear complexes. For reaction with two Pd atoms, the coordination energy of H_2 increases additively, and this is responsible for the additive character of the outer slightly filled 5*s* and 5*p* AO of the Pd atom with the σ-orbital of H_2.[55]

The platinum complexes have a greater ability to undergo the dissociative addition of H_2, compared with the palladium complexes.[55] This difference is due to the fact that the transitions $d \rightarrow s$ and $d \rightarrow p$ take place more readily in the case of platinum.

The above results[55] make it possible to explain experimental data on the difference in the reactivities of mononuclear and dinuclear Pd^0 complexes, and also Pt^0 complexes, with respect to molecular hydrogen. A comparison of calculated and experimental data[55] indicated that the compound formed by the reaction of $Pd_2(PPh_3)_2$ with H_2 is apparently the first example of a complex with H_2 in the molecular form. As noted above, similar complexes were recently identified for tungsten and molybdenum.[107]

These calculation results show the role of the outer *s* and *p* orbitals of the transition metal in oxidative addition. In the case of Pd^0 compounds, the oxidative addition of H_2 to one or two palladium atoms is energetically unfavourable because the formation of "normal" covalent bonds Pd–H involves considerable expenditure of energy to give the Pd atom a valence electron configuration close to d^9s^1. It may be assumed that with increase in the number of palladium atoms reacting directly with H_2, the strength of the $Pd_m...H_2$ bond will increase (both for structures with molecular H_2 and for dihydride structures), just as it increases, according to calculations,[55] on going from mononuclear to dinuclear systems.

Thus the dissociative chemisorption of molecular hydrogen on a metal is due to the multicentre interactions of the H atoms of the dissociating molecule with several metal atoms on the surface. According to Refs.55 and 114, a possible mechanism for the dissociative chemisorption of H_2 in its reaction with polynuclear palladium systems involves the initial adsorption of the H_2 molecule on a Pd atom or a Pd–Pd bond, after which the H atoms move apart into neighbouring interstices. The stabilisation of the resulting hydride structures takes place as a result of the increase in the number of metal atoms with which the hydrogen atoms interact.

The principal results of quantum-chemical studies of the reaction of molecular hydrogen with Pd^0 and Pd^{II} compounds can be summarised. The initial stage of the reaction of molecular hydrogen with Pd^{II} and Pd^0 compounds is the formation of a bound molecular complex in which H_2, acting as an isolated ligand, occupies a vacant position in the coordination sphere of Pd. The electronic factors facilitating the heterolytic rupture of the H–H bond in the reaction of H_2 with Pd^{II} complexes are the high basic strength of the anionic ligands and the involvement of the outer 5*s* and 5*p* AO of the Pd atom. The fact that the oxidative addition of H_2 to one Pd atom in Pd^0 compounds is unfavourable is related to the appreciable expenditure of energy required to give the Pd atom the configuration d^9s^1 necessary for the formation of covalent Pd–H bonds. The greater ability of phosphine complexes of Pt^0 to undergo the dissociative addition of H_2, compared with phosphine complexes of Pd^0, is due to the greater ease of $d \rightarrow s$ and $d \rightarrow p$ promotion in the case of platinum. The dissociative chemisorption of molecular hydrogen on metallic palladium is due to the multicentre interaction of the H atoms of the dissociating molecule with several metal atoms on the surface.

2. The Study of Hydroxopalladation

The practical importance of hydroxopalladation as an effective industrial method for obtaining carbonyl compounds from alkenes[7] is responsible for the interest in the mechanism of nucleophilic addition to the double bond, catalysed by palladium(II) complexes. It has been established experimentally,[7,9,10] that under the conditions of the reaction, the mononuclear π-complexes $PdCl_2(OH)(C_2H_4)^-$ and $PdCl_2(H_2O)(C_2H_4)$, and also the dinuclear derivatives $Pd_2Cl_5(OH)(C_2H_4)^{2-}$ and $Pd_2Cl_5(H_2O)(C_2H_4)^-$, are formed.

It is considered[115] that the hydroxo-complexes can be converted into σ-bonded organopalladium compounds by the inner-sphere *cis*-migration of the coordinated hydroxo-group to the coordinated alkene molecule. In solutions with high concentrations of H_3O^+ ions and (or) Cl^- ions, however, when the formation of hydroxo-complexes is hindered, according to Ref.116 *trans*-attack by the non-coordinated nucleophile on the coordinated alkene molecule takes place, that is the reaction involves an outer-sphere mechanism.

CNDO[36,104] and EHM[103] calculations have been carried out for nucleophilic *trans*-attack in model palladium π-complexes. *cis*-Attack in alkene complexes of Pd^{II} and nucleophilic addition in hydroxomercuration have also been studied.[36]

A mechanism has been proposed[115] for the stabilisation of the intermediate state in *cis*-attack by a coordinated hydroxo-group on a coordinated alkene. According to this mechanism,[115] the approaching ligands form a "quasi-π-allyl" orbital system. The electron density on the C atom closest to the nucleophile decreases, and that on the neighbouring C atom of the double bond increases. The stabilisation of the transition state in this case may be due to the donor–acceptor transfer of electron density from a non-bonding orbital of the quasi-allyl fragment to orbitals of the central atom.[117] In the case of square planar Pd^{II} complexes, this acceptor orbital is the partly filled $4d_{x^2-y^2}$ AO of palladium. As noted in Ref.115, the presence of the partly filled *d* orbital in Pd^{II} may facilitate nucleophilic *cis*-attack for the palladium systems, compared with the corresponding process for Hg^{II} complexes with the electron configuration d^{10}.

The results of a comparative calculation[36] for nucleophilic *cis*-attack on the alkene in the systems $[PdL_2(C_nH_{2n})(OH)]^-$ and $HgX(C_nH_{2n})(OH)$, where X = F, Cl, or Br, and $C_nH_{2n} = C_2H_4$, C_3H_6, or C_4H_8, confirm the proposed[115] "quasi-π-allyl" stabilisation mechanism. In accordance with the "quasi-allyl" model, it was found[36] that the alkene is appreciably polarised by the nucleophilic group. Thus for

$PdCl_2(C_2H_4)(OH)^-$, the effective charge of the C atom closest to OH^- is +0.12e, whereas the charge on the farther removed C atom is −0.32e. The contributions of the 4*d* AO of the Pd atom to the Pd–C and Pd–O bonding interactions are much greater than the corresponding contributions of the 5*d* AO of the Hg atom in the systems $Hg(C_nH_{2n})(OH)$.

A calculation[36] for intermediate structures $PdCl_2(OH)(C_3H_6)^-$ corresponding to nucleophilic attack at different atoms of propene showed that nucleophilic attack at the less extensively hydrogenated position of the alkene is facilitated by the polarisation of the alkene molecule as a result of the hyperconjugation of the methyl group. This explains why Markovnikov's rule is obeyed in this reaction.

To determine the role of the central atom in nucleophilic *trans*-attack on a coordinated alkene, a comparative calculation was carried out[103] for the addition of the hydride ion to ethylene in the model systems $H^-...C_2H_4$ and $H^-...(C_2H_4)PdCl_3^-$. The reactivity of coordinated ethylene towards the addition of H^- depends markedly on the nature of the coordination of ethylene to palladium.

The reaction of H^- with the symmetrical π-complex $(\eta^2\text{-}C_2H_4)PdCl_3^-$ is less favourable than the reaction with free ethylene. The deactivation of coordinated ethylene is due to the increase (compared with free ethylene) in the energy of the lowest unoccupied π*-MO, which makes the main contribution to the interaction of the symmetrically coordinated ethylene with H^-.

The displacement of ethylene with a change from the symmetrical coordination of the η_2-type to coordination of the η_1-type causes H^- attack to be facilitated, compared with free ethylene. This is due to the increase in the strength of the bond formed by Pd with the nearest C atom, and the corresponding localisation of the LUMO on the farther removed C atom, which is attacked by the nucleophile. There is a particularly large change in the contribution of the π-orbital of C_2H_4 to the bonding; in the original structure, the interaction of this orbital with the 1*s* AO of the H atom is a repulsion, whereas in the structure with unsymmetrical coordination of ethylene the π-orbital makes a significant contribution to the $H^-...C_2H_4$ bonding interaction.

Thus it is the possibility of unsymmetrical coordination of the alkene to the central Pd atom in the intermediate state of the nucleophilic *trans*-addition that is responsible for the activation of the alkene in this reaction. The approach of the HO^- ion to the ethylene molecule might have led to the production of the carbanion $CH_2CH_2OH^-$. The formation of this species, however, is energetically so unfavourable that ethylene (unlike acetylene, whose antibonding orbitals are slightly lower than those of ethylene) not only does not react with the hydrated OH^- ion but also does not even react with fused NaOH. The function of the palladium atom in the scheme examined[103] evidently reduces to the stabilisation of the unstable carbanion produced. A comparative calculation for the systems $H^-...(C_2H_4)ML_n$, where ML_n = $PdCl_3^-$, $PtCl_3^-$, $(C_5H_5)_2WH^+$, $Fe(CO)_5^{2+}$, $Fe(CO)_4$, $(C_5H_5)Fe(CO)_2^+$, and $Ni(PH_3)_2$, showed that palladium and platinum have the greatest ability to activate alkenes towards nucleophilic addition.

Calculations[36] for the nucleophilic *trans*-attack by the hydroxide anion in model complexes of Pd^{II} and Hg^{II} indicate that the reactivity of the fragment ML_n towards *trans*-attack by OH^- increases with increase in its acceptor power, which can be estimated from the extent of the transfer of electronic charge from X in the complexes $X[ML_n]^q$. Calculations for the complex $PdX_3(C_2H_4)^-$ and the hypothetical π-complexes $[Hg(C_2H_4)]^{2+}$ and $[HgX(C_2H_4)]^+$, where X = F, Cl, Br, showed[36] that the electron density on the C atom decreases on going from free ethylene to ethylene coordinated to Pd^{II}, and decreases further on going to ethylene coordinated to Hg^{II}. The strength of the C...O bond formed in the nucleophilic addition of OH^- increases in the same order. The quantum-chemical data obtained agree with the difference in the kinetics of the corresponding reactions; hydroxomercuration is very rapid,[118] hydroxopalladation is slow,[119] and OH^- does not add on to free ethylene in the absence of a catalyst.

An increase in the reactivity of complexes $X[ML_n]^q$ with respect to *trans*-attack by the OH^- anion with increase in the acceptor power of the fragment $X[ML_n]^q$ was also observed for π-allyl complexes.[104] Thus the replacement of the anionic ligand Cl^- (a strong electron σ-donor) by the neutral ligands PH_3 and CO (weaker σ-donors, which also have π-acceptor properties) leads to an increase in the energy of the addition of OH^- and to an increase in the two-centre component of the total energy E_{OC} in the order: $PdCl_2(\pi\text{-}C_3H_5)^- \ll PdCl(PH_3)(\pi\text{-}C_3H_5) < PdCl(CO)(\pi\text{-}C_3H_5) < Pd(PH_3)_2(\pi\text{-}C_3H_5)^+$. The quantum-chemical data obtained agree with the experimentally observed[120] increase in the rate of nucleophilic addition to $[PdCl(\pi\text{-}C_3H_5)]_2$ when triphenylphosphine is added to the reaction mixture.

The EHM has been used[105] to study the stage following the nucleophilic addition in the catalytic oxidation of ethylene to acetaldehyde, that is the decomposition of the β-hydroxyethyl σ-complex (β-palladiumethanol) formed in the preceding stage; this decomposition is accompanied by the intramolecular 1,2-transfer of hydrogen. The authors cited,[105] however, in fact carried out the calculation not for β-palladiumethanol but for the system $M(CH_2\text{–}CH_2\text{=}O)$ with a quinquevalent carbon atom, and this lowers the value of the results of this study.

The above quantum-chemical studies of the separate stages of hydroxopalladation lead to some general conclusions. The electronic factor stabilising the transition state of nucleophilic *cis*-addition to alkenes is the donor–acceptor interaction of the non-bonding orbital of the "quasi-π-allyl" system with the slightly filled orbitals of palladium. In the case of nucleophilic *trans*-attack, the activation of the alkene towards the addition of the nucleophilic group is due to the possible unsymmetrical coordination $L_nM...C_nH_{2n}$. The reactivity of the coordinated alkene increases with increase in the acceptor properties of ML_n.

3. Non-Empirical Calculations for the Model System $PdCH_4$ and the Insertion of CO into a Pd–H Bond

The results of non-empirical calculations by the SCF MO LCAO method in a minimum basis set will be examined for two model reactions: the reaction of methane with a palladium atom[99] and the insertion of CO at the Pd–H bond in the systems $[HPdCO]^+$ and H_2PdCO.[100] In Ref.99 the authors continued for the model system $Pd...CH_4$ the study of the activation of saturated compounds by reaction with a palladium atom, begun in Ref.56 with a calculation for the simplest system $Pd(H_2)$ (see above). The problem of the interaction of saturated hydrocarbons with transition metal atoms or ions is of considerable importance for the theoretical analysis of associative and dissociative chemisorption, and also for an understanding of the key reactions in catalysis by metal complexes, namely oxidative addition and reductive elimination.[121]

For the calculation,[99] three symmetrical structures were selected, in which methane is oriented with one, two, or three H atoms directed towards the Pd atom. As in the case of the $Pd...H_2$ interaction examined above, the results

of the calculation for Pd...CH_4 show that the outer 5*s* and 5*p* AO play an important role in the interaction of the Pd atom with saturated compounds. It is the participation of these orbitals in the bonding that enables the Pd atom with its filled *d* level to act as an electron acceptor in the reaction with methane. The absolute magnitude of the calculated values of the Pd...CH_4 bond energy decreases with increase in the number of H atoms directed towards the Pd atom, but the values are nevertheless close to one another. The equilibrium Pd–H distance also increases in this order.

The energy of the bond formed by molecular hydrogen with the Pd atom, calculated in the same basis set, is almost double the energy of the bond formed by methane.[56] At first sight this result appears strange, since judging from the energy of the LUMO and the experimental ionisation potentials, methane should be a better electron donor than hydrogen. In this case, however, the reaction is determined by the geometric factor, that is not by the difference in the energies of the levels but by the degree of overlap of the filled orbitals of CH_4 with the filled 4*d* and vacant 5*s* and 5*p* AO of the Pd atom.

In the structure in which only one H atom of methane can be in direct contact with the Pd atom, the overlap conditions are responsible for the weaker donor–acceptor interaction compared with H_2. In the structures in which the CH_4 molecule is oriented with two or with three H atoms directed towards the Pd atom, however, the principal role in the interaction with Pd is played by the C atom. The latter has a much larger covalent radius than the hydrogen atom, so that there is a greater Fermi repulsion interaction between the valence electron levels of Pd and CH_4. As a result, the complex of palladium with molecular hydrogen is more stable than the complex with methane.

The results[99] show that methane (and apparently alkanes in general), like hydrogen, can take part in a bonding interaction with the Pd atom in which the most important role is played by the overlap of the localised orbitals of the ligand with the diffuse outer orbitals of the transition metal.

The insertion of CO at a Pd_{surf}–H bond

$$Pd_{surf}-H + CO \rightleftarrows Pd_{surf}-CHO$$

which has been studied[100] by a non-empirical calculation for simple molecular models, is one of the stages (possibly the limiting stage) in the heterogeneous catalytic reduction of CO by hydrogen. The catalyst in this reaction is palladium deposited on an oxide support.[2] In an earlier paper[57] on the calculation of the electronic structure of the model system Pd(CO) the authors cited[100] suggested that the ability to insert CO into the M–H bond to give a formyl complex should increase with increase in the acceptor power of the transition metal. This suggestion is confirmed by experimental data which show that the active species in the reduction of CO are ionic forms of Pd stabilised by the carrier. It has also been found that the rate of the reduction of CO by hydrogen on palladium catalysts increases with increase in the electron–acceptor properties of the carrier.[2]

The dependence of the direction and the energy barrier of the migration on the magnitude of the effective charge on the Pd atom has been studied[100] by comparative calculations for the model systems $[HPdCO]^+$ and H_2PdCO. The first models the limiting case of a strongly electron-accepting environment; the second, which differs from the first in the addition of the hydride ion, which is a strong σ-donor, models the coordinative saturation of Pd in an electron-donor environment. For each system, the calculations were carried out for three structures: the original carbonyl hydride structure, an intermediate structure with a bridging Pd–H–C bond, and the final formyl structure. It was found that the addition of the hydride ion leads to a complete qualitative change in the nature of the potential curve for the migration of H to the CO group. The $[HPdCO]^+$ system can be regarded as structurally non-rigid, since there is no energy barrier to migration, and the formyl structure is even slightly more stable than the carbonyl hydride structure. On the other hand, in the case of the H_2PdCO system, the formyl structure is energetically unfavourable, and the barrier for the reverse reaction of elimination is ~15 kcal mole^{-1}. The fact that the migration of H to CO is energetically unfavourable in the last case is due to the extensive population of the 5*s* and 5*p* AO of palladium, preserved throughout the reaction.

From these results it was concluded[100] that, in agreement with experimental data, the increase in the positive charge on the Pd atom accompanying an increase in its acceptor power favours the relative stabilisation of the formyl structure. Correspondingly, an increase in the acceptor properties of the carrier may facilitate the formyl mechanism of the reduction of CO by hydrogen on palladium catalysts.

Thus the energy effect of the above model reactions and the electron density distribution accompanying them depend to a significant extent on the participation of the outer 5*s* and 5*p* AO of the Pd atom in the bonding interaction.

---o0o---

The above review of the results of quantum-chemical studies shows that the electronic structure and reactivity of palladium compounds are determined to a large extent by the characteristic features of the electronic structure of the Pd atom. These characteristic features, as noted above, are the complete filling of the 4*d* level in the ground state of the atom and the presence of diffuse outer 5*s* and 5*p* AO.

Further progress in the understanding of the mechanism of the reactions of palladium compounds will probably be associated to a large extent with the accumulation and analysis of experimental and theoretical data on the electronic character and relative strength of Pd–L bonds in series of complexes of different transition metals. In particular, the study of the electron density distribution in palladium systems in order to determine the preferred direction of attack on these complexes by different reagents is of considerable interest.

The Interconversions of Pyrylium Salts, Pyrans, Pyrones, and Their Open-chain Forms

O.V.Drygina, A.D.Garnovskii, and A.V.Kazantsev

A general scheme is proposed for the interconversions of six-membered oxygen-containing heterocylces (pyrylium salts, pyrans, and pyrones) and their open-chain forms, having selected pyrylium salts as compounds of the key type. The latest data concerning the mechanism of a number of the above transformations are examined. It is shown that ring opening is one of the most characteristic manifestations of the reactivity of six-membered oxygen-containing heterocylces.
The bibliography includes 231 references.

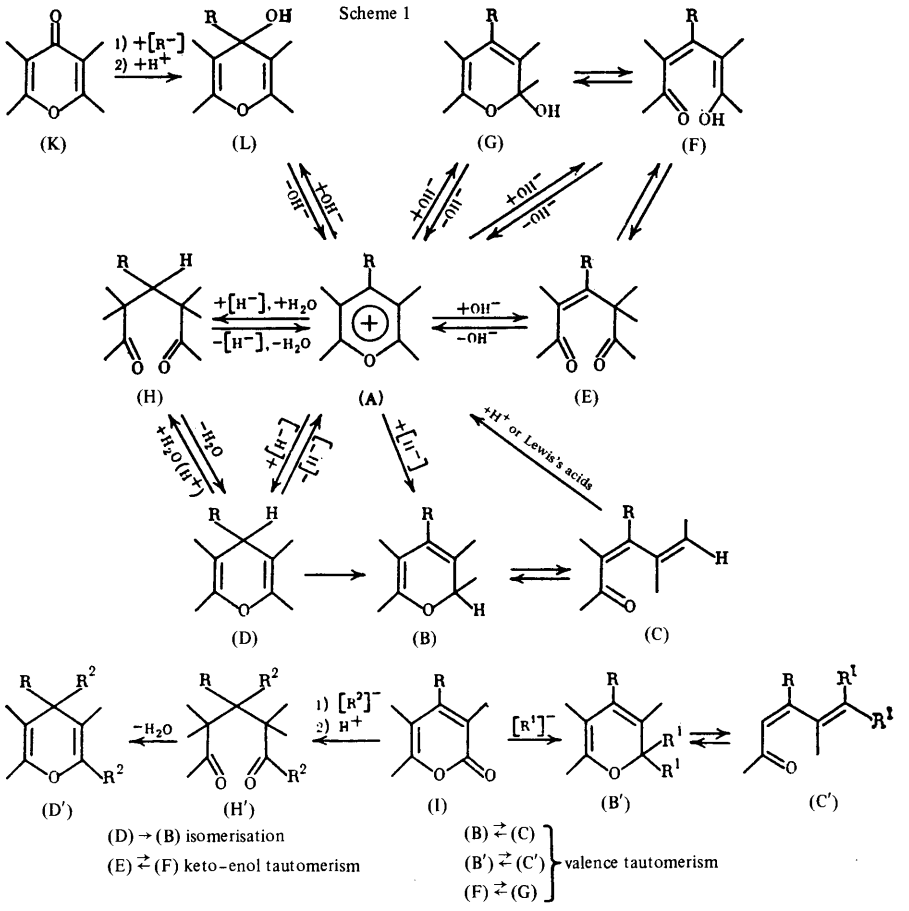
I. INTRODUCTION

Six-membered oxygen-containing aromatic and non-aromatic heterocycles (pyrylium salts, 2*H*- and 4*H*-pyrans, α- and γ-pyrones, and α- and γ-pyranols) and their open-chain forms (pentene-1,5-diones, pentadien-5-ones, pentane-1,5-diones, etc.) are readily interconverted. Individual aspects of these reactions have been the subject of studies since the beginning of this century, but investigation of the problem in terms of the complete set of its general and specific properties has become possible only recently. This has been promoted, particularly, by the application of physicochemical methods (spectroscopic and electrochemical) in practical chemical studies, by the investigation of kinetics, and also by the expansion of synthetic possibilities, for example, as a result of the vigorous application of organometallic compounds.

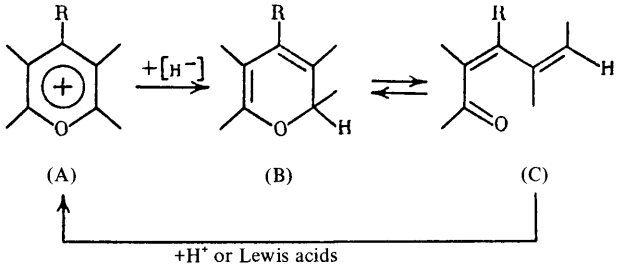
In the present review we propose a general scheme for the above reactions involving a fundamental class of heterocycles, namely pyrylium salts[1-14] (Scheme 1), as compounds of the key type. In the course of the exposition we shall deal with individual fragments of this scheme which reflect the most characteristic transitions undergone by the classes of compounds included in it†.

† In view of the complexity of the structures of the 1,5-diketones (H′) and 2*H*-pyrans (B′) formed, which are incapable of participating in the majority of the reactions considered, the transitions (I)–(H′) and (I)–(B′) are included in addition to the main scheme. We may point out, however, that diketones of type (H′) are capable of being dehydrated to 4,4′-disubstituted 4*H*-pyrans (D′) and 2*H*-pyrans (B′), which can undergo valence isomerisation to the *cis*-dienones (C′). In order to simplify Scheme 1 the addition and elimination of a hydride ion are considered in the case of the (A)–(D) transition, while the reactions of pyrilium salts with other compounds, leading to 4*H*-pyrans with a more complex structure, are dealt with in the text. Similarly the scheme indicates only the effect of the hydride ion for the (A)–(D) transitions. Other instances of the synthesis of 2*H*-pyrans on the basis of pyrylium salts are described in the text. The OH^- anion has been adopted as the effective species in the (A)–(L), (A)–(E), (A)–(F), and (A)–(G) transitions; more complex examples involving alkoxy-groups are discussed in the text.

Scheme 1



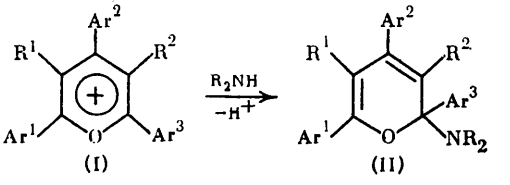
II. PYRYLIUM SALTS–2*H*-PYRANS–*cis*-DIENONES



Alkali metal tetrahydroborates ($NaBH_4$, $LiBH_4$, and KBH_4) react with pyrylium salts to form unstable 2-monosubstituted 2*H*-pyrans (B),[15–20] which rapidly isomerise to the corresponding *cis*-dienones (C). It is striking that in all cases the interaction of complex metal hydrides with pyrylium salts leads to the formation, together with the above compounds, also of 4*H*-pyrans (D) and their open-chain forms—saturated 1,5-diketones.[3]

Comparatively stable 2*H*-pyrans of type (B) and their valence tautomers, i.e. *cis*-dienones (C), are synthesised also by the reaction of pyrylium salts (A) with organometallic reagents (not included in the Scheme).[21–31]# Since the positive charge on the pyrylium cation is concentrated in the 2-, 4-, and 6-positions, as has been confirmed by quantum-chemical calculations,[12,14] 4*H*-pyrans are formed together with 2*H*-pyrans. The ratios of the products formed (2*H*-pyrans, *cis*-dienones, and 4*H*-pyrans) are determined by the structure of the pyrylium salt, the nature of the nucleophile, and the reaction conditions.

When pyrylium salts (I) are treated with dialkylamines in aprotic solvents (for example in diethyl ether), stable 2*H*-pyran derivatives (II) can be isolated in a crystalline form:[36]

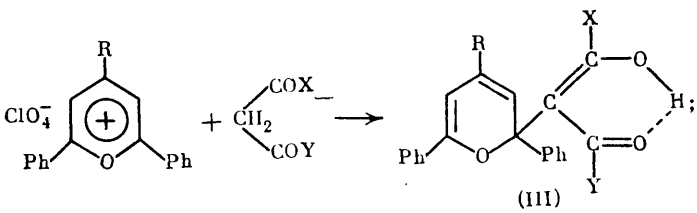


R^1 = H, Me; R^2 = Me .

#2*H*-Pyrans[32] can also be obtained by treating α-pyrones with organometallic reagents (Section IX), in the course of the isomerisation of 4*H*-pyrans (Section IV), and as a result of cyclocondensation[33–35] with participation of carbonyl compounds.

The authors[36] explained the stability of the 2*H*-pyrans (II) by the presence of substituents in the 3- or 3- and 5-positions in the pyrylium ring.

Pyrylium salts are also capable of reacting with CH acid compounds to form 2*H*-pyran derivatives. They are formed, for example, in the reaction of 2,4,6-triphenylpyrylium tetrafluoroborate with acetonedicarboxylic acid or acetylacetone.[4] The method of phase-transfer catalysis provides much greater possibilities for the synthesis of 2*H*-pyrans involving CH acid compounds.[37] 2*H*-Pyrans (III, a–g) have been obtained by this method in the reaction of 2,4,6-triphenyl and 2,6-diphenyl-4-(α-thienyl)-pyrylium perchlorates with acetoacetic ester, acetylacetone, and malonic ester:



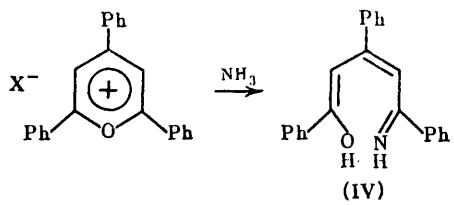
(III)

(a) R=Ph, X = Me, Y=OEt, (b) R=Ph, X=Y=Me, (c) R=Ph, X=Y=OEt; (d) *R*= , X=Y=OEt .

The isolation of the 2*H*-pyrans (III, a–g) confirms the mechanism proposed previously[5] for the reaction of pyrylium salts with active methylene groups in which the intermediate formation of 2*H*-pyrans was postulated. One of them, namely compound (Ib), has been isolated[15] in the reaction of 2,4,6-triphenylpyrylium tetrafluoroborate with acetylacetone in the presence of 1 mole of potassium t-butoxide, but its structure has not been rigorously confirmed.

The appearance of 2*H*-pyrans of type (B) is usually postulated as the first stage in the interaction of pyrylium salts (A) with various nucleophiles, leading either to recyclisation products[11–14] or to ring opening products.[8,14]§ The latter are frequently intermediates in the recyclisation of pyrylium salts; if these products are stable, the reaction terminates with their formation. The reactions of 2,4,6-trisubstituted pyrylium salts with N-containing and certain other nucleophiles, in which ring-opening products with different stabilities can be obtained, are examples of the second of the competing processes indicated.

Thus the reaction of a pyrylium salt with ammonia can lead to the isolation of the ring opening product—the relatively unstable iminoenol (IV):[38]

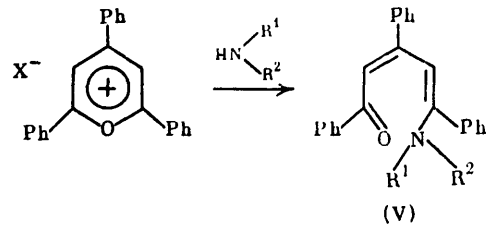


(IV)

When pyrylium salts are acted upon by amines, there is a possibility of the formation of aminopentadienones (V).[39,40]

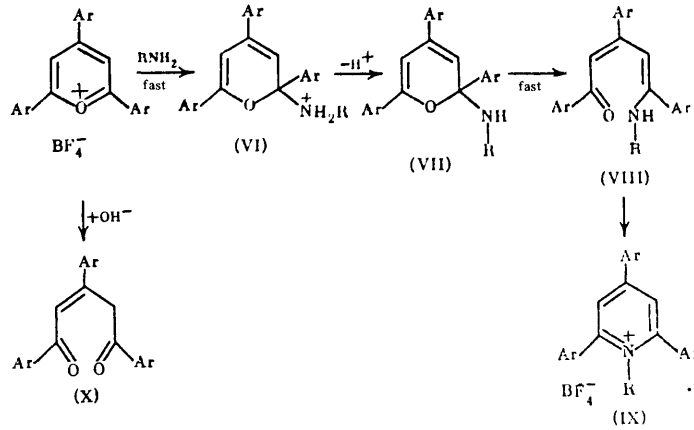
§ These products can be regarded as derivatives of the diketone forms of the pseudobases of pyrylium salts formed via the keto-groups.

In the case of primary amines the yields of compound (V) are low, while in the reaction involving secondary amines they are satisfactory:



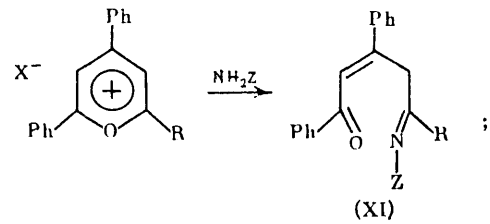
(V)

The interaction of pyrylium salts with amines has been studied in detail by Katritzky and co-workers.[41,42] The reaction pathway and the structure of the substances formed were studied, in particular, by ^{13}C NMR:



When two moles of a primary amine are introduced into the reaction, pyridinium salts (IX) are formed in quantitative yields, but, when less than two moles of the amine is used, the amount of the side product, the unsaturated diketone (X), increases. Under the reaction conditions, the latter also gives rise to a pyridinium salt, but this reaction is very slow. The authors[42] assume that the second amine molecule is necessary to abstract a proton from the intermediate (VI). The pyrylium salt which failed to react is converted by traces of water into the pentenedione (X). In particular, the reactions with n-butylamine and benzylamine take place in this way. Pyrrolidine and piperidine have been used as secondary amines. The reaction of pyrylium salts with 2 moles of a secondary amine leads to the formation of aminopentadienones of type (VIII), which do not cyclise to pyridinium salts.

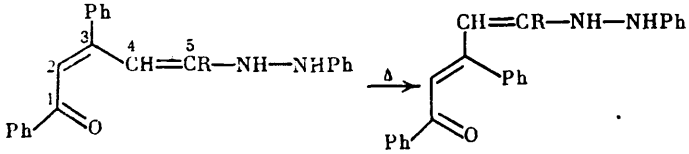
The fairly stable monoxime (XIa) and the monophenylhydrazone (XIb) are formed when a pyrylium salt interacts with hydroxylamine[43] and phenylhydrazine:[43,44]



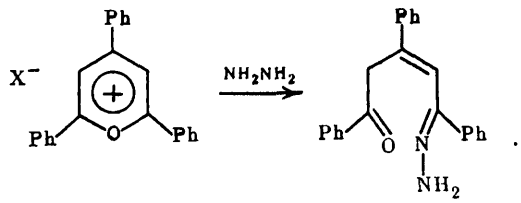
(XI)

(a) R=Ph, Z=OH; (b) R=Ph, Me; Z=NHPh .

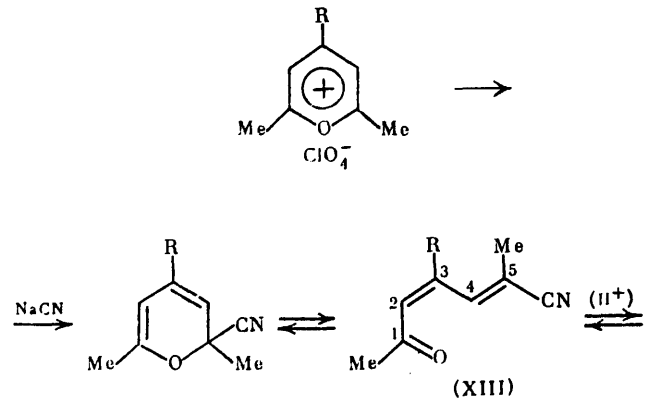
The monophenylhydrazone (XIb) is also formed as the *cis*-isomer [with a *cis*-disposition the carbonyl group and the CH=CR–NH–NHPh group relative to the C(2)=C(3) double bond], which is converted into the *trans*-isomer on refluxing in a neutral medium (ethanol):



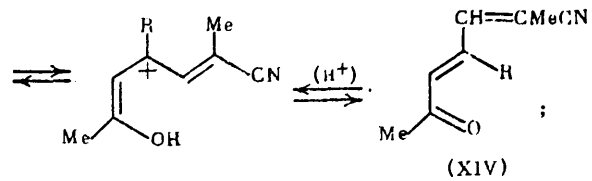
When the 2,4,6-triphenylpyrylium salt is acted upon by hydrazine hydrate, the unstable monohydrazone (XII) is formed:[45,46]



(XII)



(XIII)

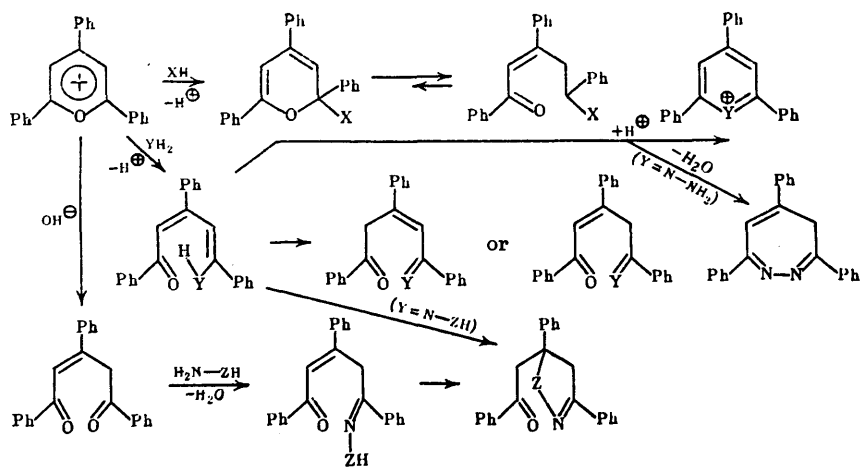


(XIV)

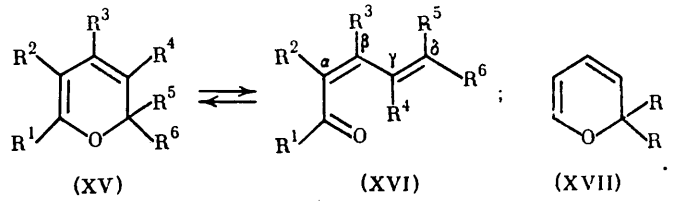
R = Me, Et.

The ring opening products in the reaction of 2,4,6-trialkylpyrylium salts with cyanides are the *cis*-cyanopentadienones (XIII). On treatment with concentrated inorganic acids, the latter react via two pathways: they are reconverted into the initial pyrylium salt, liberating hydrogen cyanide, and they isomerise to the *trans*-pentadienones (XIV). The *cis,trans*-isomeric forms are determined by the relative positions of the carbonyl group and the CHCMeCN group relative to the C(2)=C(3) double bond:[47,48]

The products of the opening of the ring in pyrylium salts, which can also be regarded as the open-chain forms of 2*H*-pyrans, are capable, as already stated above, or different types of subsequent cyclisation with formation of various heterocyclic systems. For example, compounds (IV), (V), (XIa), (XIb), and (XII) cyclise with formation of the corresponding nitrogen-containing heterocycles—pyridine, pyridinium salts, isoxazole, pyrazoles, and diazepine, as shown in the general scheme published by Balaban and Silan:[49]



The phenomenon of valence isomerism, a symmetry-allowed thermal pericyclic process[52] with a low activation energy, is characteristic of the class of 2*H*-pyrans.[50,51] It results in the establishment of a rapid and reversible equilibrium between the 2*H*-pyrans (XV) and their valence tautomers—the *cis*-dienones (XVI)¶:[53–79]



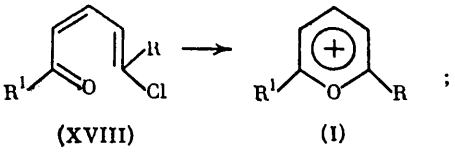
(XV) (XVI) (XVII)

For this very reason, the parent compound of the class of 2*H*-pyrans, namely unsubstituted pyran, has not so far been obtained. Quantum-chemical calculations of the stability of the valence isomers (XV) and (XVI)[80–83] give preference to the cyclic form (XV). In the course of the analysis of the pathways leading to the valence photo- and thermo-isomerisation of the 2*H*-pyran ring, taking into account the characteristic features of the electronic structure of the transition state in the reaction

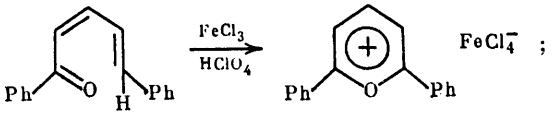
$$(XV) \underset{}{\overset{h\nu, kT}{\rightleftharpoons}} (XVI),$$

a correspondence has been observed between the energy barrier to the opening of the pyran ring and the C_{sp^3}–O bond length.[83] At the same time *ab initio* calculations have shown that open-chain forms with different geometries are more stable for both the 2*H*-pyran (XVII, R = H)[80] and its diemthyl derivative (XVII, R = Me).[82]

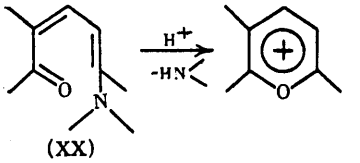
The reverse transformation of 2*H*-pyrans into pyrylium salts (A), which is characteristic of 4*H*-pyrans (D), has not been observed in the case of the 2*H*-pyran (B). However, compounds which are derivatives of dienones, for example, (XVIII)–(XXI), readily cyclise with formation of pyrylium cations:[60,84–87]



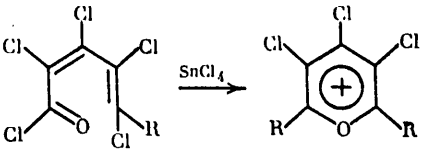
(XVIII) (I)



(XIX)

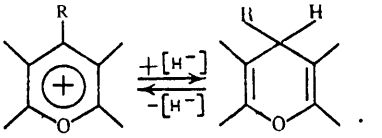


(XX)



(XXI) $SnCl_5^-$

III. PYRYLIUM SALTS–4*H*-PYRANS



(A) (D)

The transformation of pyrylium salts (A), usually with a free γ-position (R = H), into 4*H*-pyrans (D) constitutes the most thoroughly developed method of synthesis of the latter and is achieved by reduction with complex metal hydrides.[26–31,88–91] However, the methods of synthesis of 4*H*-pyrans from pyrylium salts are not restricted to this simplest case. 4-Substituted or 4,4'-disubstituted 4*H*-pyrans are also formed as a result of reaction with CH acid compounds in the presence of catalysts,[15,92–94] by reaction with organic and inorganic nucleophiles in the absence of catalysts,[95–105] with the aid of organometallic synthesis,[106–122] and by many other procedures.[123–127] The reaction of 2,4,6-trisubstituted pyrylium salts with strong nucleophiles (Grignard reagents, organolithium compounds, or complex metal hydrides) results in the formation, together with 4*H*-pyrans (D), of 2*H*-pyrans (B) and their valence isomers—*cis*-dienones (C). In an acid medium the open-chain form of the 4*H*-pyran, namely a saturated 1,5-diketone, is isolated instead of the 4*H*-pyran itself.

The reduction and dimerisation of pyrylium salts under the influence of electron donors lead to the formation of bis-4*H*-pyrans.[111,128–130]†

4*H*-Pyrans[120] are compounds of a comparatively unstable type. The unsubstituted 4*H*-pyran, which was obtained as late as 1962 from glutaric dialdehyde,[144] is a colourless liquid, which rapidly decomposes in the light at room temperature.[144,145] The introduction of substituents stabilises the pyran ring, but in this case they are frequently isolated in

¶ The dienones can exist as the *cis*- or *trans*-isomers with respect to the αβ-double bond.[44,48,75] It has been shown that only one geometrical isomer is involved in the dienone–2*H*-pyran equilibrium.[18,75] From this and also from the hypothesis that the valence isomerisation can involve only the geometrical isomer with the minimum distance between the C=O group and the C_δ atom, it has been concluded[75] that this isomer exists in the *cis*-form. Direct observation by means of ^{1}H NMR has confirmed this claim, which had been accepted previously without adequate evidence.[66,68,70,71]

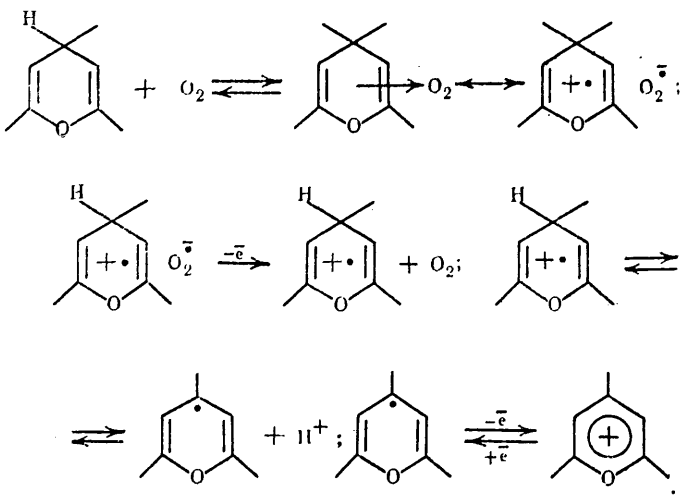
† Apart from the synthesis from pyrylium salts, 4*H*-pyrans can be obtained also by condensation involving carbonyl compounds[131–143] and by the cyclisation of 1,5-dicarbonyl compounds.[117,131,145]

the form of non-crystalline oils which are difficult to purify.[4, 16,89,107,110,111,131] On storage, many crystalline pyrans "deliquesce", but 4*H*-pyrans with carbaboranyl substituents are more stable.[113–121]

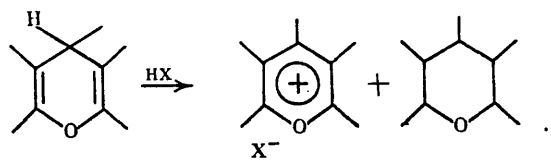
4*H*-Pyrans (D), containing a hydrogen atom in the γ-position and therefore capable of undergoing oxidative dehydrogenation, serve as convenient starting materials in the synthesis of pyrylium salts (A). 4*H*-Pyrans are dehydroaromatised with the aid of acetyl perchlorate,[108–111,115,117,119,120] triphenylmethyl perchlorate,[99,102,103,121,122,125] PCl_5,[117,125] $FeCl_3$,[4] CCl_3,[110,111,120] 2,4,6-tri-t-butylcyclohexadienone,[110,111] the tris(*p*-bromophenyl)aminium radical-cation,[110–114,116,117,120] benzenediazonium tetrafluoroborate,[110,111] tropylium tetrafluoroborate,[88] bis(2,4-dimethoxyphenyl)immonium perchlorate,[115,116,120] etc.

The transfer of a hydride ion is observed in almost all classes of organic compounds and has been the subject of controversy.[146,147]

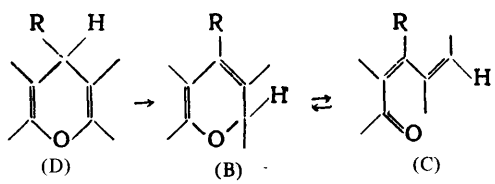
Okhlobystin and co-workers[148] investigated the dehydroaromatisation of pyrans by EPR and electrochemically; they also proposed a stepwise mechanism for this process, which is vigorously catalysed by oxygen. They suggest that the substrate undergoes one-electron oxidation in the decisive stages:



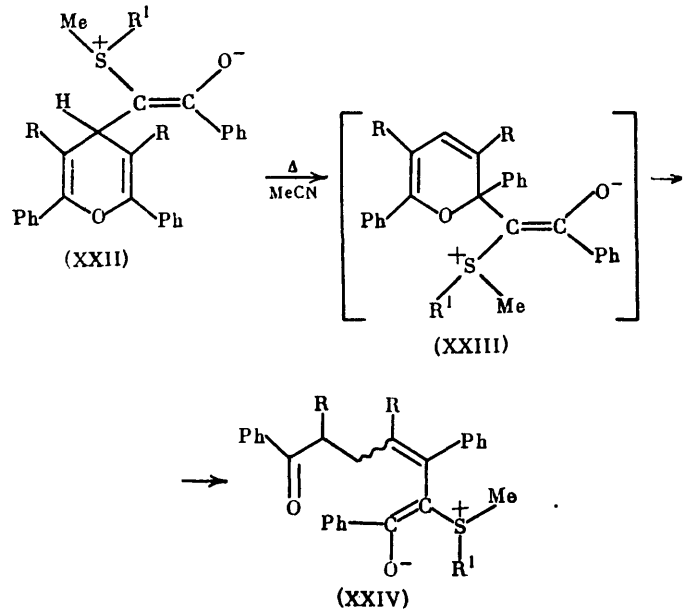
The ability to disproportionate under the influence of acids (protic and aprotic), which results in the formation of a pyrylium salt and a tetrahydropyran, is also characteristic of 4*H*-pyrans:[149,150]



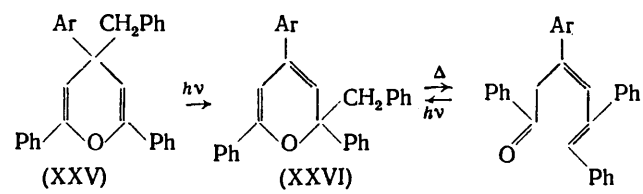
IV. 4*H*-PYRANS–2*H*-PYRANS–*cis*-DIENONES



4*H*-Pyrans (XXII)#, containing an ylide group in the 4-position, give rise to the open-chain compounds (XXIV) in the form of two geometrical isomers in the course of their thermal rearrangement.[151] There is no doubt that the first stage in the rearrangement involves the formation of 2*H*-pyrans (XXIII), which then undergo valence isomerisation to the corresponding dienones (XXIV):



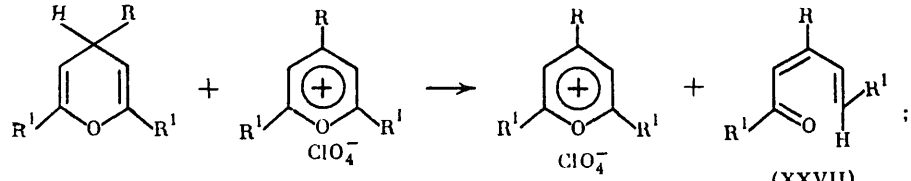
When the 4*H*-pyrans (XXV), containing the benzyl group in the γ-position, are irradiated, they readily give rise to the corresponding 2*H*-pyrans (XXVI):[152–155]



The 2*H*-pyrans (XXVI) undergo thermal isomations to non-conjugated dienones, which recyclise to the 2*H*-pyrans on irradiation. The migration of the benzyl group on photoisomerisation of 4*H*-pyrans proceeds via a singlet mechanism. The positions of the double bonds and of the substituting groups in the isomeric heterocycle are indicated by its ability to react with maleic anhydride, to form a transannular peroxide on sensitised photochemical oxidation, etc.

The hydride mobility of 4*H*-pyrans in relation to 2*H*-pyran and its open-chain isomer (a dienone) has been investigated;[90] pyrylium cations were used as hydride ion acceptors. Treatment of 2,6-triphenyl-4*H*-pyrans with the corresponding pyrylium cation leads to the formation of cinnamylideneacetophenone (XXVIIa) and 1,3,5-triphenylpenta-2,4-dienone (XXVIIb):

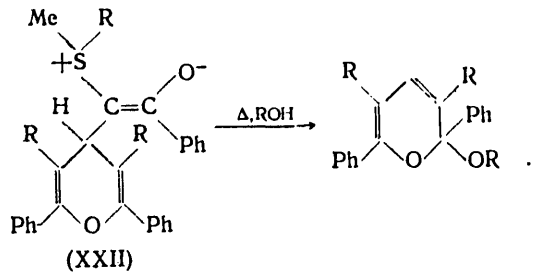
#The isomerisation of the 4*H*-pyrans (D) to 2*H*-pyrans (B) is given a conventional representation in Scheme 1, since it has been simplified by indicating hydrogen as the migrating species.



(a) R^1 = Ph, R = H; (b) R = R^1 = Ph.

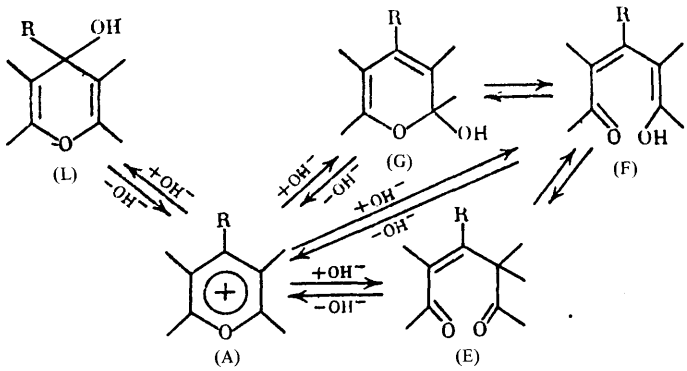
Thus it has been shown that the 2*H*-pyran is formed in the hydride transfer from the 4*H*-pyran to the 2-position in the pyrylium ring. On valence isomerisation, the 4*H*-pyran gives rise to the more stable open-chain form. In other words, 4*H*-pyrans (D) are less stable than 2*H*-pyrans (B), which are in their turn less stable than their isomeric *cis*-dienones (C).

The thermal rearrangement of the 4*H*-pyrans (XXII), containing the sulphonium ylide group in the γ-position, in methanol or ethanol results in the formation of the corresponding alkoxy-2*H*-pyrans:[151]



(XXII)

V. PYRYLIUM SALTS–PSEUDOBASES OF PYRYLIUM SALTS

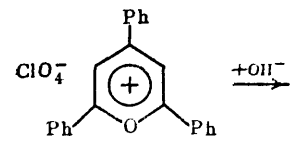


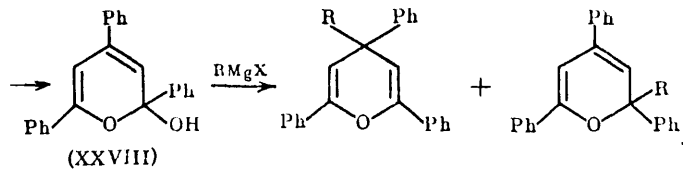
The products of the addition of *O*-nucleophiles (hydroxide and alkoxide anions) to the α- and γ-positions in pyrylium salts are referred to as the pseudobases (E)–(G) and (L).[156] Stable pseudobases have been obtained from arylpyrylium salts. Alkylpyrylium salts give rise to sensitive and unstable pseudobases, which cannot be isolated. The crystalline 4-methyl-2,6-di-t-butylpyrylium pseudobase, which can be stored for several minutes at room temperature, is an exception.[12]

The structure of the substances formed on reaction of pyrylium salts with *O*-nucleophiles is determined mainly by the structure of the initial pyrylium cations and also by the character of the reagent and has been established unambiguously only recently when spectroscopic methods (infrared, ultraviolet, and NMR spectroscopy) and X-ray diffraction methods have become available.

The first stage in the reaction of pyrylium salts with the hydroxide anion, like that in the reactions with other nucleophiles, may involve the attack on the α- or γ-position with formation of the 4-pyranol (L) or the 2-pyranol (G), which is then converted into the pentene-1,5-dione (E) (in the *cis*- or *trans*-form) or the enolic tautomer (F)§.

The hydrolysis of 2,4,6-triphenylpyrylium perchlorate in a highly alkaline medium (pH 14) yielded the corresponding α-pyranol (XXVIII)[157] in conformity with the fact that the α-positions are more reactive:[12]





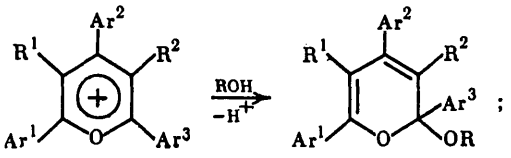
(XXVIII)

The concentration of hydroxide ions was kept constant by means of a buffered methanolic solution. On reaction with organometallic reagents, the α-pyranol produces substituted 2*H*- and 4*H*-pyrans.

The formation of 2-methoxy-2*H*-pyrans on interaction of pyrylium salts with the methoxide anion has been demonstrated by kinetic methods[158,159] and also by ^{1}H NMR [160] and ^{13}C NMR.[42] 4-Methoxy-4*H*-pyran is formed together with 2-methoxy-2*H*-pyran.[158,159] There is also a possibility of the formation of the corresponding *cis*-dienone instead of 2-methoxy-2*H*-pyran.[158,159] The ratio of the above products is determined by the structure of the initial pyrylium salt and the reaction conditions. For example, it has been shown that 2,4,6-triarylpyrylium salts having substituents in the 3- or 3- and 5-positions in the pyrylium ring give rise to stable crystalline 2-alkoxy-2*H*-pyrans on treatment with alkali metal alkoxides:[161]

---

§Because of the conventional nature of the general scheme (1), the OH^- anion has been adopted as the O-nucleophile in the fragments having a bearing on the formation of the pseudobases in order to demonstrate in a more clear-cut form the possibilities for the interconversions of compounds (A), (E), (F), (G), and (L).

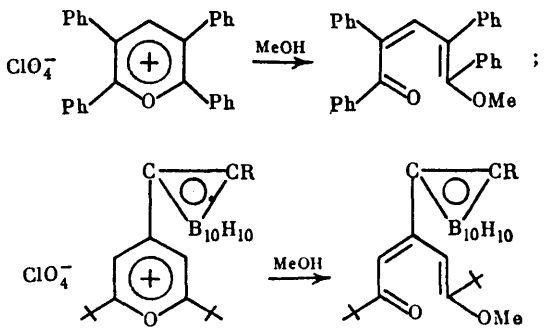


R^1 = H, Me; R^2 = Me, $PhCH_2$.

However, as a rule open-chain forms (pentene-1,5-diones or ketodienols) are formed in the course of hydrolysis or alcoholysis. The hydrolysis of, for example, 2,3,5,6-tetraphenylpyrylium[162] and 2,6-di(methoxycarbonyl)pyrylium[163] cations is carried out in an aqueous medium. However, the formation of open-chain forms of the pseudobases is usually observed in hydrolysis in the presence of inorganic and organic bases.

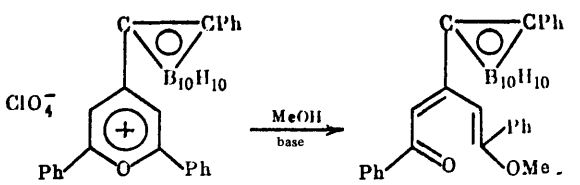
Although the formation of ketodienols is relatively uncharacteristic of pyrylium salts, nevertheless, when the latter are acted upon by alkoxides in the corresponding alcohols, the ketodienol ethers are formed readily. For example, the 2,4,6-triphenylpyrylium cation gives rise to oily methoxy- and ethoxy-derivatives as well as the crystalline isopropoxy-derivative.[49]

2,3,5,6-Tetraphenylpyrylium[162] and 2,6-di-t-butyl-4-carbaboranylpyrylium[164–166] perchlorates readily produce the corresponding stable methyl ethers of ketodienols in the course of methanolysis:



R = Me, Ph.

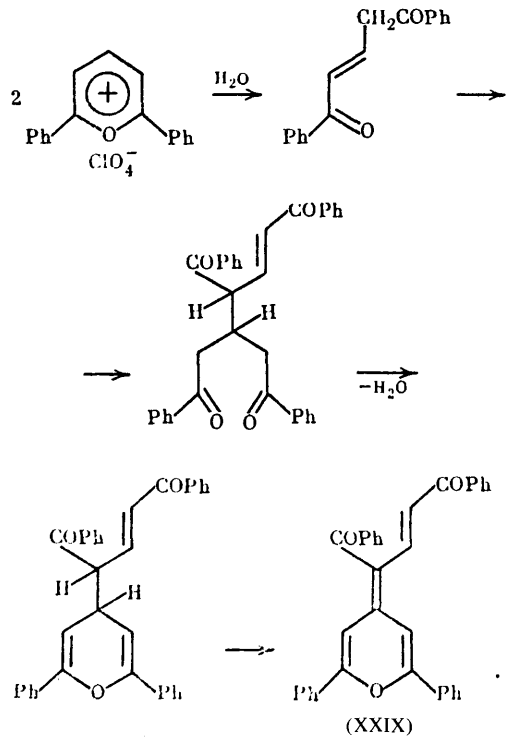
The methanolysis of 2,6-diphenyl-4-(phenyl-*o*-carbaboranyl)pyrylium perchlorate, which leads to the methyl ether of the ketodienol, takes place only in the presence of bases:



The bases used are $NaHCO_3$, MeONa, Et_3N, 5-aminotetrazole, $H_2NC_6H_4COOEt$, NH_2CONH_2, $(PhNH)_2C{=}NH$, $Me_2C{=}NOH$, and Br=NPh [?(Ed.of Translation)].

The formation of the methoxide anion, which has fairly pronounced nucleophilic properties,[167] is apparently induced by various types of acid–base interaction (autoprotolysis of the alcohol, protonation of the amine, etc.). The attack on the pyrylium ring is then undoubtedly facilitated by the electron-accepting effect of the carbaboranyl substituent; cations containing t-butyl groups in the 2- and 6-positions are especially activated.

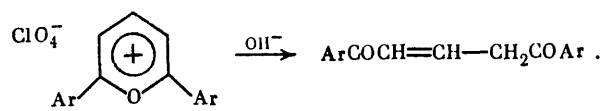
The hydrolysis and alcoholysis of 2,6-diarylpyrylium salts with a free γ-position occupies a special place. On interaction with water in the presence of bases, 2,6-diphenylpyrylium perchlorate affords 1,5-diphenyl-4-(2,6-diphenyl-4-pyranylidene)pent-2-ene-1,5-dione.[168,169] The mechanism of the formation of this compound involves the hydrolysis of the pyrylium salt to an unsaturated diketone, which undergoes Michael self-condensation; the subsequent cyclisation to the 4*H*-pyran and dehydrogenation lead to the pyranylidenediketone (XXIX):



(XXIX)

A similar reaction is common to 2,6-diarylpyrylium salts. The optimum conditions for the syntheis of pentenediones of type (XXIX) involve brief refluxing of an equimolar mixture of 2,6-diarylpyrylium perchlorate with water and pyridine in acetonitrile.

Unsaturated 1,5-diketones having the *trans*-configuration were obtained only on treating 2,6-diarylpyrylium perchlorates with an aqueous acetone solution of alkali:



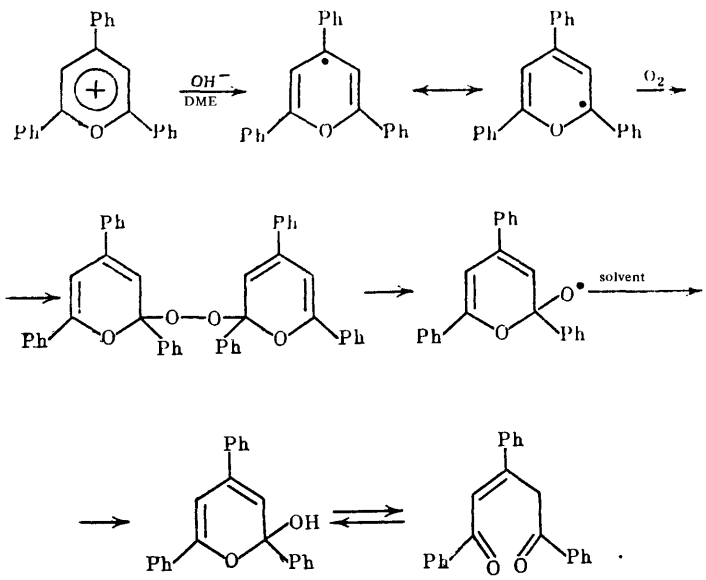
On treatment of 2,6-diarylpyrylium salts with aqueous alcoholic solutions of bases, unstable α-alkoxypyrans are formed; 3-benzoyl-6-ethoxy-6-(*p*-nitrophenyl)-2-phenylpyran was isolated in an analytically pure state. The use of sodium acetate as the base entailed the formation of a complex mixture of acetoxypyrans, whose treatment with acids produced high yields of pyrylium salts with various anions.

The elucidation of the mechanism of the hydrolysis of pyrylium salts leading to the opening of the pyrylium ring is of significant interest. Kinetic methods have been used in a number of studies.[170–172]

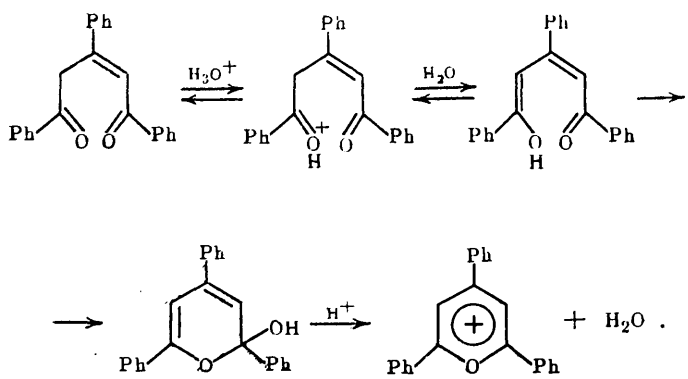
It has been found[173,174] that, on treatment with NaOH in acetone or dimethoxyethane (DME) in the absence of oxygen, 2,4,6-triphenylpyrylium perchlorate is quantitatively converted into the 2,4,6-triphenylpyranyl free radical, which was identified by EPR.

On contact of the reaction mixture with atmospheric oxygen, 1,3,5-triphenylpent-2-ene-1,5-dione is formed. The same diketone has been obtained on oxidising with atmospheric oxygen the free radical arising in the dissociation of the triphenylpyranyl radical dimer.[111]

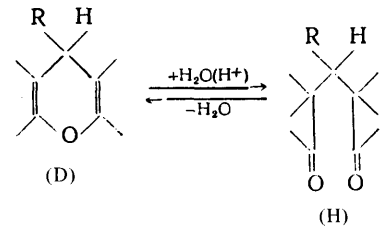
From their data, the authors[173,174] put forward the following mechanism of the formation of unsaturated 1,5-diketones from pyrylium salts:



On treatment with acids, unsaturated 1,5-diketones readily cyclise to pyrylium salts.[41] Kinetic studies of the mechanism of the reactions of the above diketones with H_3O^+ showed that the dione cyclises as a result of the rapid enolisation and subsequent ring closure of the enol to form an unstable 2-hydroxy-2*H*-pyran, which is converted into a pyrylium salt in the presence of protic acid:[175]

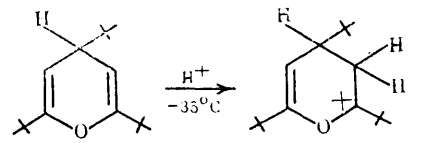


VI. 4*H*-PYRANS–SATURATED 1,5-DIKETONES



4*H*-Pyrans (D)¶ readily undergo ring opening in the course of hydration in an acid medium with formation of saturated 1,5-diketones (H).[16,93,117–120,132,133,163,176–179] Aqueous, alcoholic, or aqueous alcoholic solutions of HCl are then used as a rule and the employment of the strong perchloric acid is essential only for carbaboranyl-4*H*-pyrans.[117–120]

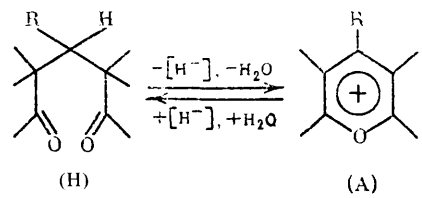
The reaction involving the opening of the pyran ring begins most probably with the protonation of the β-position of the 4*H*-pyran with subsequent addition of the hydroxide anion to the tertiary carbonium ion centre arising in the α-position. For example, it has been shown that the protonated form of 2,4,6-tri-t-butyl-4*H*-pyran, arising in a $FSO_2OH–CS_2$ mixture at −35 °C, gives rise to a well resolved ^1H NMR spectrum, indicating the non-equivalence of the methylene protons in the 3-position:[111]



The reverse reaction involving the cyclisation of the pentane-1,5-diones (H) to the corresponding 4*H*-pyran (D) has been described.[117,131,145,163,176,177,179]

Despite the fact that, on treatment with acids, δ-diketones in general tend to undergo intramolecular aldol condensation with formation of cyclohexenone derivatives, γ-pyran derivatives are formed in many instances where this is allowed by structural factors. This reaction takes place on treatment with P_2O_5,[176] concentrated H_2SO_4,[163,173] and $ZnCl_2$,[131] but saturated carbaboranyl-1,5-diketones readily cyclise even at room temperature in acetic anhydride.[119,178,179]

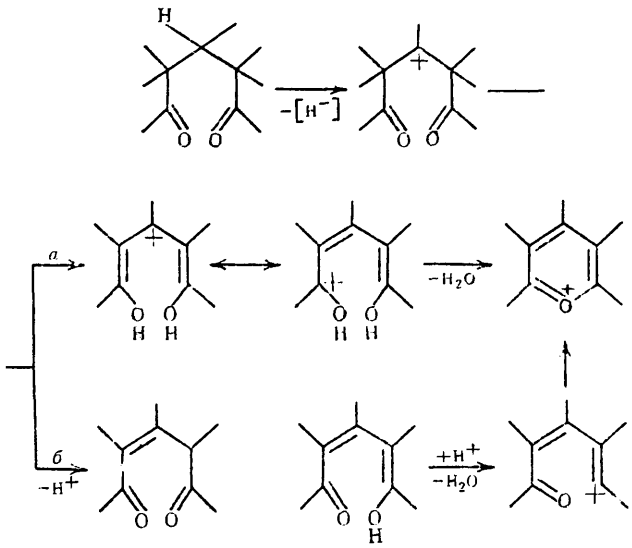
VII. SATURATED 1,5-DIKETONES–PYRYLIUM SALTS



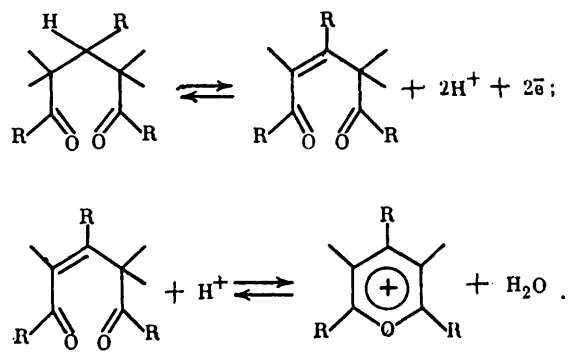
The conversion of saturated 1,5-diketones (H),[180,181] having a hydrogen atom at the C(3) atom, into pyrylium salts (A) is one of the most thoroughly investigated and most widely used methods of synthesis of pyrylium salts. An

¶ Analogous reactions are possible also for compounds (H') and (D') (Scheme 1).

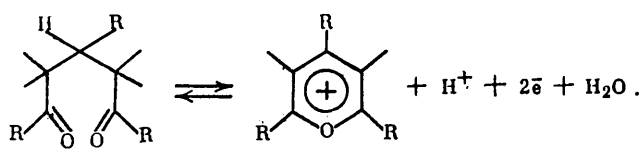
extensive compilation of the reagents used for this purpose has been published in reviews.[6,180] Since two processes take place in the course of thise reaction, namely dehydrogenation and dehydration, the question of the nature of the intermediate remained controversial for a long time. There were two hypotheses; according to the first, an unsaturated diketone is formed initially and then undergoes cyclodehydration to the pyrylium cation. It was assumed that ring closure after dehydrogenation is possible via both pathway *a* [182] and pathway *b*:[183,184]



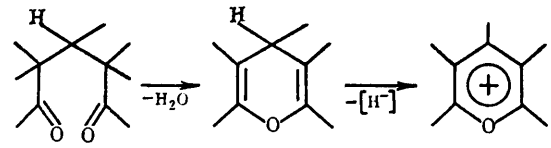
The study of the electrochemical oxidation potentials of saturated 1,5-diketones in acetonitrile using a rotating platinum electrode also led the authors[185] to the hypothesis of the initial formation of pentene-1,5-diones:



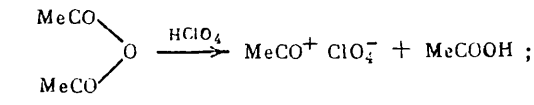
The overall process is

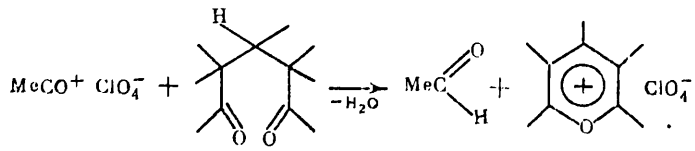


According to the second hypothesis, the initial stage in the formation of the pyrylium cation is the cyclodehydration of the 1,5-diketone with formation of a 4*H*-pyran, which is then converted into the pyrylium cation:



The abstraction of hydrogen was explained for a long time by the oxidising effect of the acid reagents. However, in the synthesis of pyrylium perchlorates in acetic anhydride, acetaldehyde was observed in the reaction mixture.[186] This finding permitted the hypothesis that organic carbonium ions, in particular that formed from acetyl perchlorate, may serve as hydride ion acceptors in salt formation†:





The supporters of the first hypothesis based their view on erroneous data showing that the cyclisation of 1,5-diketones to pyrans requires a strongly dehydrating medium[189] and also on the unsuccessful attempt to cyclise the saturated 1,5-diketone to a pyran with the aid of hydrobromic acid, which is a powerful protonating agent.[190] In the latter case one must bear in mind that the protonating medium promotes the reverse process involving the conversion of pyrans into diketones. Furthermore, there is no direct evidence for the formation of an unsaturated diketone from a saturated one and an indirect example illustrating the possibility of the dehydrogenation of an aliphatic straight chain by triphenylmethyl perchlorate is quoted in only one study,[189] the authors emphasing that it is unique.

On the other hand, it is fairly easy to split off water from a saturated 1,5-diketone with formation of 4*H*-pyrans; when carbonium ions are used, their dehydrating properties can be accounted for by the appearance of perchloric acid on interaction with acetic acid, in which most of the reactions are carried out:[191]

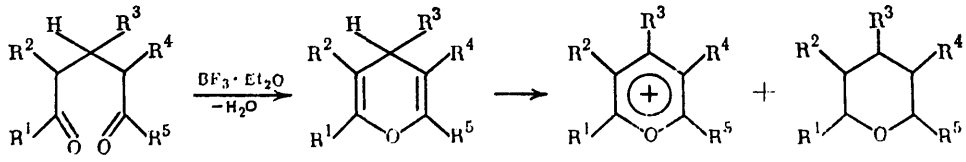
$$Ph_3CClO_4 + MeCOOH \rightarrow Ph_3COCOMe + HClO_4 .$$

Pyrylium salts have been synthesised[192] from a series of pentane-1,5-diones using trityl and acetyl cations in acetic anhydride, acetic acid, as well as their mixtures (in various proportions). It was shown that the joint action of trityl and acetyl cations is more effective than the action of each separately. On the basis of these experiments, it has been suggested that the pentanedione initially cyclises to a pyran, which is then dehydrogenated by triphenylmethyl perchlorate.

Concrete experimental evidence for the conversion of saturated 1,5-diketones into pyrylium salts via the formation of 4*H*-pyrans has been obtained recently. Thus, when penta-1,5-diones are treated with boron trifluoride etherate, 4*H*-pyrans are formed initially, their disproportionation subsequently resulting in the formation of pyrylium salts and tetrahydropyrans:[149]

---

†The study of spectroscopic and solubility data for acyl perchlorates obtained from $AgClO_4$ and acid chlorides supports a covalent structure of the acetyl perchlorate $MeC(O)OClO_3$.[188]

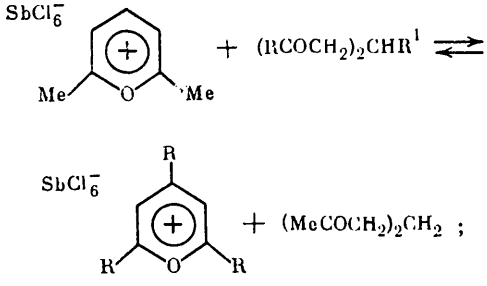


Boron trifluoride etherate apparently acts as a dehydrating agent in the first stage. This property of the trifluoride is well known.[193]

In addition, 3-carbaboranylpentane-1,5-diones are converted into 4*H*-pyrans in acetic anhydride, which acts as a dehydrating agent at room temperature.[119,178,179]

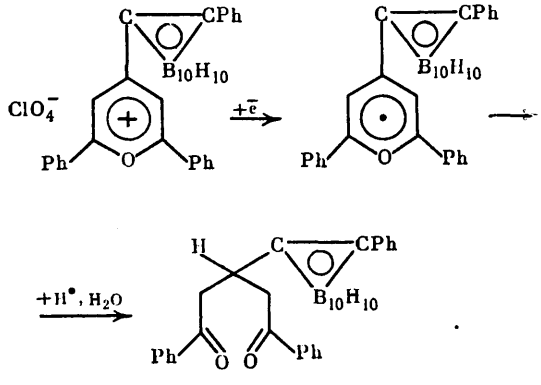
The above facts apparently make it possible to give preference to the formation of pyrylium salts from saturated 1,5-diketones via the 4*H*-pyran formation stage, as was done by a number of workers,[149,181,192,194] although it is so far difficult to give an unambiguous answer concerning the given mechanism, because the initial saturated 1,5-diketones themselves have different structures and the reaction media and the reagents employed are also varied.

Pyrylium salts can be converted in their turn into saturated 1,5-diketones. It has been shown[195] that the transfer of a hydride ion from the diketone to a less stable salt leads to the formation of a more stable salt and a new saturated 1,5-diketone:

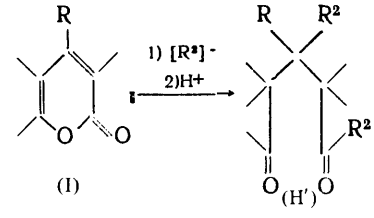


$R = R^1 = Ph$; $R = Ph$, $R^1 = H$.

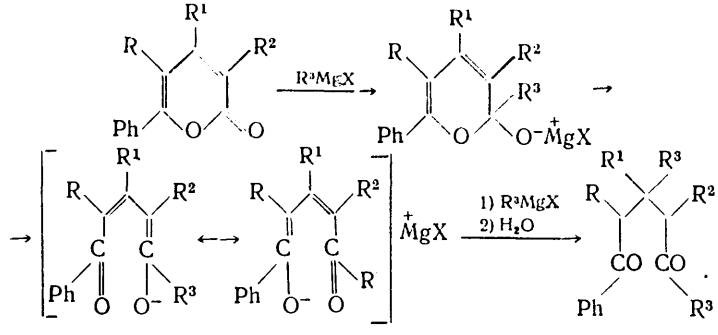
Pentene-1,5-diones are apparently formed from carbaboranylpyrylium salts via the stage in which a carbaboranylpyranyl radical is produced:[117,118]



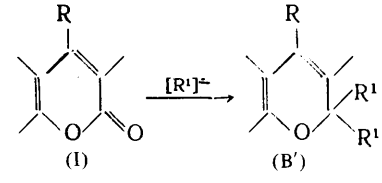
VIII. α-PYRONES–SATURATED 1,5-DIKETONES



When 2-pyrones (I)# are acted upon by Grignard reagents,[198–201] saturated 1,5-diketones (H′) may be formed. The interaction of phenylmagnesium bromide with α-pyrones containing the phenyl group in the 6-position, namely 6-phenyl-α-pyrone, 5-methyl-6-methyl-α-pyrone, and 3-methyl-6-phenyl-α-pyrone, leads exclusively to the formation of the corresponding pentane-1,5-diones in satisfactory yields.[199] In other cases saturated 1,5-diketones are formed together with keols, dienones, 2*H*-pyrans, etc. The reaction takes place via the following scheme:[199]

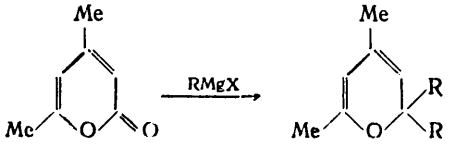


IX. α-PYRONES–2*H*-PYRANS

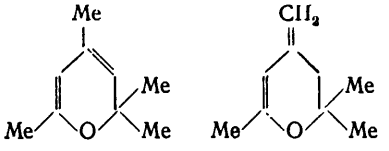


#Information about the methods of synthesis and properties of α-pyrones can be found in other reviews.[196,197]

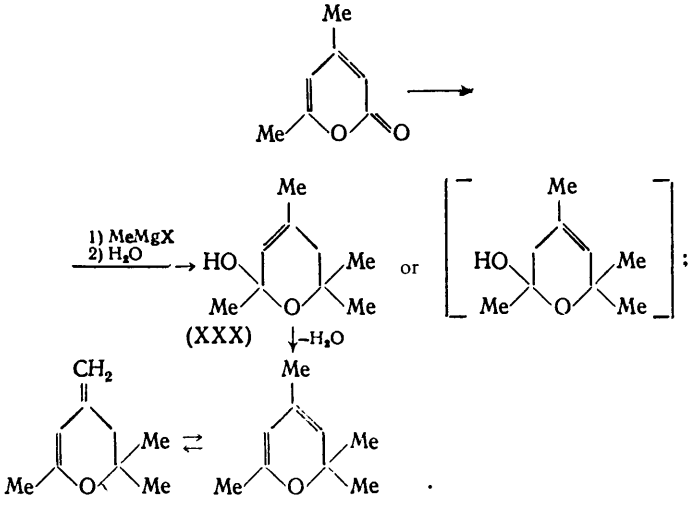
Treatment of α-pyrones with Grignard reagents is one of the main methods of synthesis of 2*H*-pyrans§.[32] The synthesis of 2*H*-pyrans by treating 2,4-dimethyl-α-pyrone with organomagnesium compounds was first reported by Gompper and Christmann:[202 203]



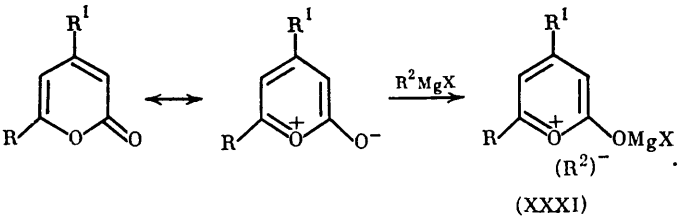
Repetition of this synthesis[204–210] showed that in the reaction involving methylmagnesium iodide, the products contained two isomers:



The isolation of the fairly unstable 6-hydroxy-2,2,4,6-tetramethyl-3,6-dihydro-2*H*-pyran (XXX) as an intermediate suggested the following mechanism of the above reaction:

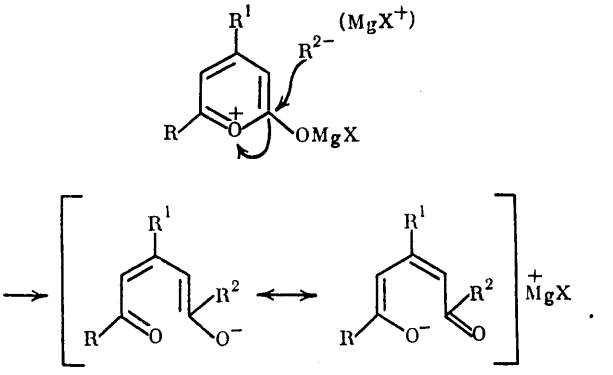


It is striking that, in the formation of 2*H*-pyrans by the reaction of α-pyrones with Grignard reagents, it is necessary to use a threefold excess [of the Grignard reagent], although it would appear that a twofold excess would have been sufficient according to the reaction stoichiometry. Experimental data showed that a complex of the pyrone with the Grignard reagent of type (XXXI) is formed initially¶:

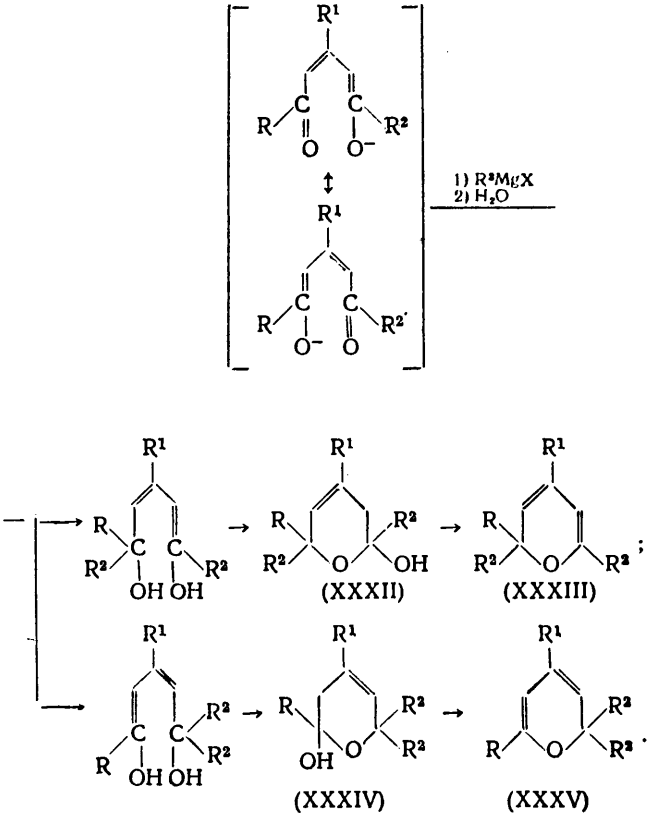


(XXXI)

On reaction with a second molecule of the alkylmagnesium halide, the ring opens with formation of the mesomeric enolate ion:



Finally, the enolate ion is attacked by a third molecule of the organomagnesium compound, which leads to two different 2*H*-pyrans—(XXXIII) and (XXXV):



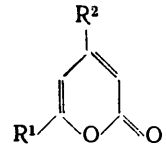
(XXXII) (XXXIII) (XXXIV) (XXXV)

§ The 2*H*-pyrans (B′) are capable of valence isomerisation to the *cis*-dienones (C′).

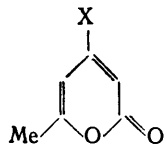
¶ The complex is a coloured compound, insoluble in ether, which decomposes during hydrolysis, occurring slowly even in an acid medium, with liberation of the initial α-pyrone.

It is striking that the dihydropyranols (XXXI) and (XXXIV) can be isolated only after hydrolysis in a neutral medium. After acid hydrolysis, the 2*H*-pyrans (XXXIII) and (XXXV) are formed.

The products of the interaction of the α-pyrones (XXXVI) and (XXXVII) with alkylmagnesium halides are 2*H*-pyrans as well as acyclic compounds: dienals, dienones, and saturated 1,5-diketones:[198]

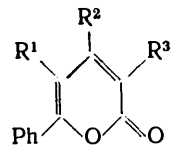


(XXXVI)
$R^1=R^2=H$; $R^1=H$, $R^2=Me$; $R^1=Me$, $R^2=Et$



(XXXVII)
X=OH, Cl, OMe .

The interaction of alkylmagnesium halides with α-pyrones (XXXVIII) containing the phenyl group in the 6-position has been investigated:[199]

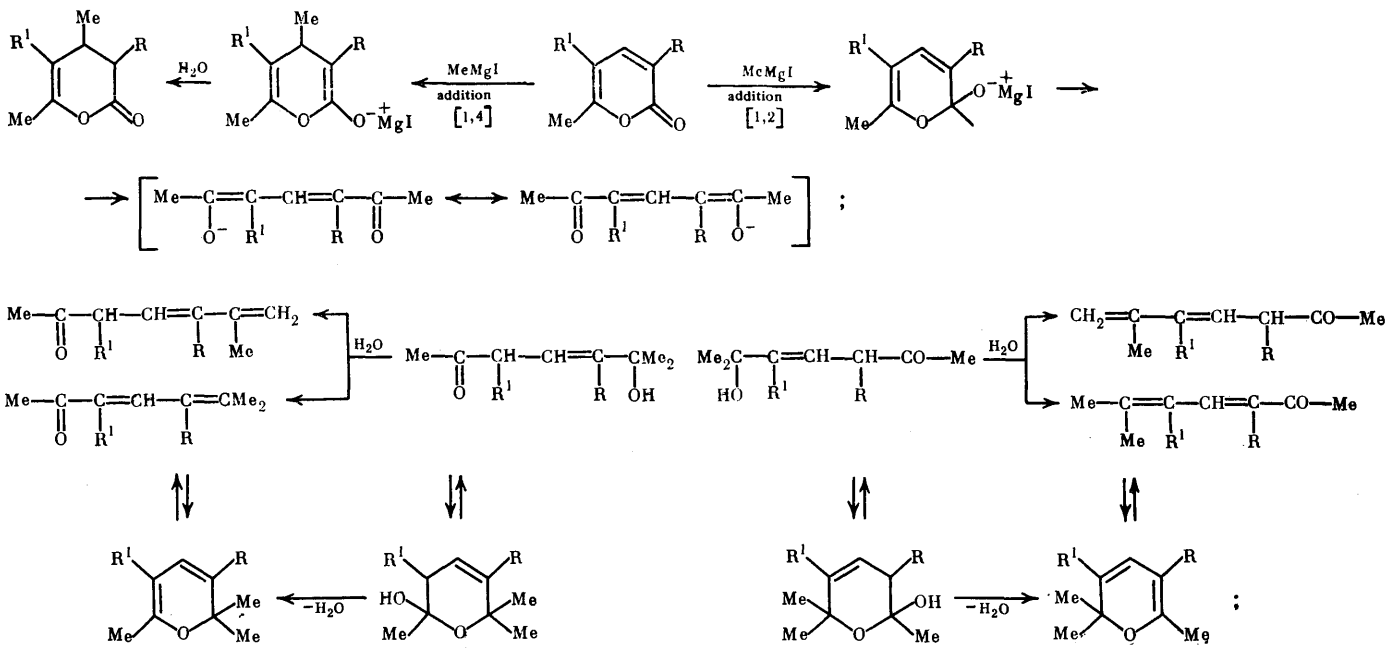


(XXXVIII)
$R^1=R^2=R^3=H$; $R^1=Me$, $R^2=R^3=H$; $R^1=R^3=H$, $R^2=Me$; $R^1=R^2=H$, $R^3=Me$; $R^1=R^3=H$, $R^2=Ph$.

Depending on the structure of the initial pyrone (XXXVIII), ketoenols, dienones, saturated 1,5-diketones, and dehydropyranols can be detected among the reaction products.

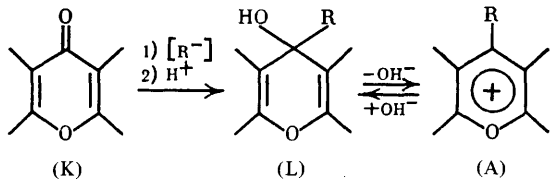
The study of the interaction of methylmagnesium iodide with α-pyrones unsubstituted in the 4-position[201,211] showed that 2*H*-pyrans can be obtained only from 3,5,6-trisubstituted derivatives. The 5,6-disubstituted α-pyrones give rise exclusively to compounds with a linear structure:

Scheme 2



R=R¹=Me; R=Ph, R¹=Me; R=H, R¹=Me; R=Me, R¹=H; R=H, R¹= *iso*-Pr; R=Ph, R¹=H; R=R¹=H

X. γ-PYRONES–γ-PYRANOLS–PYRYLIUM SALTS



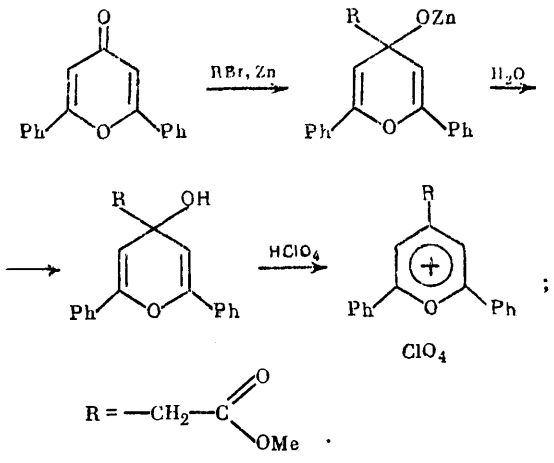
(K) (L) (A)

The γ-pyrones (K) are converted fairly readily into the γ-pyranols (L) and the latter are converted into pyrylium salts (A). The readily available 2,6-diphenyl- and 2,6-dialkyl-γ-pyrones therefore constitute a basis for the synthesis of a wide variety of pyrylium salts by interaction with organometallic compounds.

Thus the interactions of 2,6-dimethyl-γ-pyrones with methylmagnesium iodide and phenylmagnesium bromide yield respectively 2,4,6-trimethylpyrylium and 2,6-dimethyl-4-phenylpyrylium salts,[212] although Gomberg and Cone[213] and Elkaschef and Nossier[214] failed to observe a reaction between 2,6-dimethyl-γ-pyrone and phenylmagnesium bromide. There exist also other examples of the synthesis of pyrylium salts from γ-pyrones and organometallic compounds.[24,215,216]

It was assumed for a long time that the isolation of the intermediate γ-pyranols is impossible, although analogous compounds are known in the chromylium (benzopyrylium) and xanthylium series. It has been shown[109] that the alkoxides formed as a result of the interaction of γ-pyrones with organometallic compounds can be hydrolysed to γ-pyranols, which can be subsequently converted into pyrylium salts.

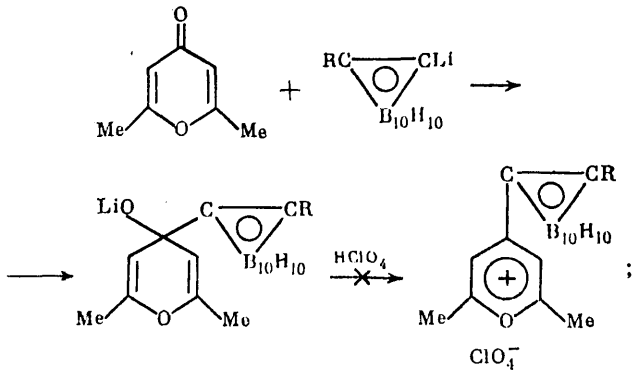
In recent years the range of organometallic compounds used in this reaction has been explained. For example, lithio-derivatives of the following heterocycles have been used: benzothiazole, pyridine, thiophen, and substituted furans.[108,109] 2,6-Diphenyl-γ-pyrone has been introduced into the Reformatskii reaction with formation of the methoxy-carbonylpyrylium cation:[217]



However, the authors were unable to extend this reaction to 2,6-dimethyl-γ-pyrone.

Indeed the reaction of γ-pyrones with organometallic compounds does not always proceed unambiguously. In particular, it has been noted[214] that the hydrolysis of the reaction mixture with dilute perchloric acid yields the pseudo-base and not the pyrylium salt.

After the interaction of 2,6-dimethyl-γ-pyrone with lithio-derivatives of *o*-carbaboranes, it was possible to isolate the intermediate lithium alkoxides derived from 2,6-dimethyl-4-R-*o*-carbaboranyl-γ-pyranols, which are precipitated during the reaction.[116,119] They are fairly stable high-melting point powders, although the alkoxides of tertiary carbaborane alcohols are usually unstable.[218] It was not possible to convert the alkoxides into the carbaboranyl-γ-pyranols on treatment with water or into pyrylium salts on treatment with perchloric acid:



R = H, Me, Ph.

---o0o---

Another specific feature of six-membered oxygen-containing heterocycles, namely the tendency towards ring opening, has been strikingly manifested against the background of the intense investigations of the recyclisation of the heterocyclic systems.[11–14] The competition between two reaction pathways—recyclisation and ring opening—actually determines the character of the reactivity of these compounds.

The experimental and theoretical data accumulated hitherto enabled us to put forward a general mechanism for the reactions of six-membered oxygen-containing heterocycles (pyrylium salts, pyrans, and pyrones) and their open-chain forms, which, in our view, may be of definite assistance to synthetic chemists in selecting the method of synthesis of compounds belonging to the above classes or in the analysis of the structure of the substances formed in the course of the reactions indicated above. The data surveyed in this review are extremely useful for the elucidation of the following important problems in the chemistry of six-membered oxygen-containing heterocycles: the mechanism of the dehydroaromatisation of 4*H*-pyrans and the valence tautomerism of 2*H*-pyrans, the mode of reaction of α- and γ-pyrones with organometallic compounds, the structure of the pseudobases of pyrylium salts and the conditions governing their formation, the pathways leading to the conversion of saturated 1,5-diketones into pyrylium salts, etc. The series of studies by Katritzky and co-workers,[219–223] who investigated the kinetics of the opening of the rings of water-soluble

pyrylium salts in hydrolysis over a wide pH range and in ammonolysis by amines and who demonstrated the structure of the products by ^{1}H and ^{13}C NMR, is instructive in connection with the foregoing findings.

Questions concerning the opening of the pyran, pyrone, and pyrylium rings as a result of their coordination interaction with metal salts are of considerable interest. It is known that, in the complex of the 2*H*-pyran system with tungsten carbonyl, the ligand is fixed in the open-chain diene form;[224] this is not unexpected bearing in mind the high stability of this isomer in the non-coordinated state.[42,225] At the same time the formation of π-allyl complexes and the fixation of the open-chain forms of the ligands in the complexes of pyrylium salts with palladium(II) [226-229] and copper[230] indicate the possibility of using complex formation as an effective method for the opening of the rings in six-membered heterocycles and for the stabilisation, on coordination, of the isomers which are unusual for the free heterocycles.

Finally, we emphasise that the experimental and theoretical development of questions concerning the relative stabilities of the valence tautomers of oxygen-containing heterocycles makes it possible to identify the characteristic features of the steric and electronic structures which control the photochemical reactivity of the series of heterocyclic systems examined above[81,83,231] and assists in the search for the specific synthesis of photochromic systems with a specified set of properties.

Fluorine-containing β-Ketoesters

K.I.Pashkevich and V.I.Saloutin

Data on the methods of synthesis, the keto-enol tautomerism, chemical properties, and applications of fluorine-containing β-ketoesters are surveyed. The characteristic features of these compounds due to the presence of fluorine atoms are specified. The bibliography includes 157 references.

I. INTRODUCTION

β-Ketoesters without fluorine (β-KE) have found applications in organic synthesis and industry. They are known as biologically active preparations and as extractants for many metals and they serve as the starting materials for the synthesis of a large number of compounds (metal chelates, ketones, and N- and S-containing heterocycles), which are also used in the national economy and in medicine. Effective and selective catalysts of polymerisation and polycondensation, pesticidal, antibacterial, antimalarial, and antiradiation preparations, and substances generating laser radiation have been found among β-KE derivatives. At the same time β-KE are of undoubted theoretical interest for the study of reactivity in relation to nucleophiles and electrophiles, tautomerism, and geometrical isomerism.

The introduction of fluorine atoms into β-KE alters their physicochemical properties, reactivity, biological activity, and other properties of practical and theoretical importance.

In many instances the presence of fluorine atoms in β-KE and their derivatives is responsible for the increase of their biological and catalytic activity and their resistance to corrosive media or leads to the appearance of new aspects of their applications. However, there have been no reviews of the literature data in this field of the chemistry of organofluorine compounds. Reviews have been published recently on fluorine-containing α-diketones and α-ketoesters [1] and β-diketones.[2] Some information about fluorine-containing β-KE (β-FKE) is available in monographs.[3-5]

The aim of the present review is to survey the literature data on the synthesis, properties, and applications of β-FKE and to compare them with those of their hydrocarbon analogues, which makes it possible to discover the features due to the presence of fluorine atoms in β-KE. The review covers the literature up to 1983 inclusive.

II. METHODS OF SYNTHESIS

The first fluorine-containing β-KE, namely trifluoroacetoacetic ester (TFAAE) was obtained by Swarts[6] by the Claisen condensation in 1926.[6] In 1929 difluoroacetoacetic ester was obtained by the same method.[7]

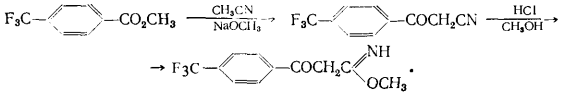
It has been shown[8] that the condensation of the methyl esters of difluoro- or trifluoroacetic acid with ethyl acetate in ether using equimolar proportions of the reactants in the presence of sodioethylene leads to the corresponding β-FKE in moderate yields (35 and 54% respectively). A method for the purification of β-FKE via copper chelates is described in the same communication. A β-KE with the heptafluoropropyl group has been obtained analogously:[9]

$$R_FCO_2C_2H_5 + CH_3CO_2C_2H_5 \xrightarrow[\text{ether}]{C_2H_5ONa} R_FCOCH_2CO_2C_2H_5;$$
$$R_F = HCF_2\ (35\%),\ CF_3\ (54\%)\ [8];\ C_3F_7\ (90\%)\ [9].$$

Acetoacetic ester (AAE) is formed by this method from ethyl acetate in 75% yield.[10] The condensation of ethyl monofluoroacetate with formic acid ester makes it possible to obtain the α-fluoro-substituted β-aldoester:[11]

$$CH_2FCO_2C_2H_5 \xrightarrow[C_2H_5ONa]{HCO_2C_2H_5} HCOCHFCO_2C_2H_5.$$

The self-condensation of monofluoroacetic ester in the presence of sodium alkoxides affords α,γ-difluoroacetoacetic ester in 23% yield.[12,13] Treatment of monofluoroacetic ester under these conditions with acetyl chloride leads to α-fluoroacetoacetic ester in 10% yield.[14] The ester of trifluoromethylbenzoic acid reacts with acetonitrile to form a β-ketonitrile whose alcoholysis makes it possible to obtain a β-ketoiminoester:[15]



The use of sodium alkoxides as condensing agents for the synthesis of β-FKE is not always effective. Thus the self-condensation of difluoroacetic ester and its reaction with trifluoroacetic ester do not lead to β-FKE on treatment with sodium alkoxides in ether,[8] although the use of sodium hydride makes it possible to obtain β-FKE containing one or two fluorine atoms in the α-position in 20–86% yields.[16,17] β-FKE with the pentafluoroethyl residue has also been synthesised by this method:[14,18]

$$C_2F_5CO_2C_2H_5 + XCH_2CO_2C_2H_5 \xrightarrow[\text{ether}]{NaH} C_2F_5COCHXCO_2C_2H_5;$$
$$X = H\ (87\%),\ F\ (70\%)\ [14].$$

t-Butyl 4,4,4-trifluoro-3-oxobutanoate and ethyl 4,4,4-trifluoro-2-methyl-3-oxobutanoate have been obtained in the same way in 56 and 50% yields.[18] 2,2,2-Trifluoroethyl formylphenylacetate is formed under analogous conditions from trifluoroethyl phenylacetate and trifluoroethyl formate:[19]

$$C_6H_5CH_2CO_2CH_2CF_3 \xrightarrow[NaH]{HCO_2CH_2CF_3} \underset{\displaystyle C_6H_5\ 46\%}{\overset{\displaystyle |}{HCOCHCO_2CH_2CF_3}}.$$

Monofluoroacetic ester reacts with t-butyl methyl ketone in the presence of sodium hydride in ether to form α,γ-difluoroacetoacetic ester.[20] Acetyl chloride and benzoyl chloride

condense with monofluoroacetic ester on treatment with sodium hydride.[14] Both the α-fluoro-derivative of AAE and a diketoester, which is a product of the acylation of the α,γ-difluoro-derivative, are formed in the first case:

$$CH_2FCO_2C_2H_5 \xrightarrow[NaH,\ ether]{C_6H_5COCl} C_6H_5COCHFCO_2C_2H_5;\ 30\%$$

$$CH_2FCO_2C_2H_5 \xrightarrow[NaH,\ ether]{CH_3COCl} CH_3COCHFCO_2C_2H_5 + CH_2FCOC(COCH_3)CO_2C_2H_5.$$

When metallic sodium is used as the condensing agent, TFAAE is formed in 77% yield;[21] trifluoroacetic ester and diethyl succinate give rise to an α-ethoxycarbonyl-substituted β-FKE in the presence of sodium:[22]

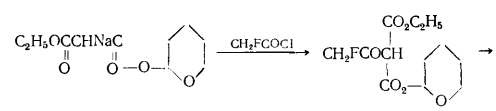
$$CF_3CO_2C_2H_5 \xrightarrow[Na,\ 80°]{(CH_2CO_2C_2H_5)_2} CF_3COCH(CH_2CO_2C_2H_5)CO_2C_2H_5.$$

It is of interest that treatment of trifluoroacetic ester with sodium in liquid nitrogen does not produce pentafluoroacetic ester but gives rise to TFAAE and sodium fluoride.[23] The abstraction of fluorine atoms has been confirmed in the preparation of TFAAE on treating pentafluoroacetoacetic ester with sodium in ether:[23]

$$CF_3CO_2C_2H_5 \xrightarrow[-NaF]{Na} [CF_2{=}C(ONa)OC_2H_5] \xrightarrow{CF_3CO_2C_2H_5} \{CF_3COCF_2CO_2C_2H_5\} \xrightarrow[-NaF]{Na} CF_3COCH_2CO_2C_2H_5 \xleftarrow[-NaF]{Na} CF_3COCF_2CO_2C_2H_5.$$

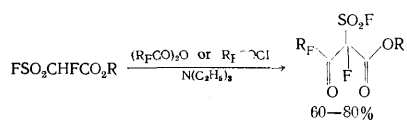
Hydrogen is probably abstracted from the solvent by the intermediate carbonium ion.

Triphenylmethylsodium was used in the condensation of trifluoroacetic ester with isobutyric ester.[17] γ-Fluoroacetoacetic ester has been obtained by acylating the sodium derivative of ethyl tetrahydropyranyl malonate with thermal decomposition of the product:[24]



$$\xrightarrow[-CO_2]{\Delta} CH_2FCOCH_2CO_2C_2H_5.$$

A convenient method of synthesis of the β-FKE with the fluorosulphonyl group in the α-position has been developed recently. It consists in the acylation of esters of fluorosulphonylfluoroacetic acid by the anhydrides or chlorides of carboxylic fluoroacids in the presence of triethylamine:[25]



60—80%

R = CH_3, iso-C_3H_7; R_F=CF_3, CF_2CF_2H, C_3F_7, C_4F_9, C_6F_{13}.

The synthesis of monofluoro- and difluoro-derivatives of β-KE by the condensation of halogen-containing esters in the presence of magnesium and mercury chloride in ether (in yields of 19—52%) has been described:[14]

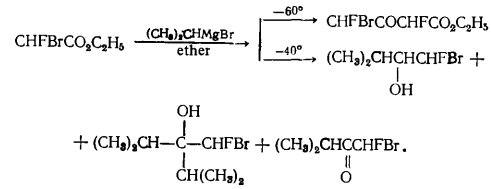
$$R^1CO_2C_2H_5 \xrightarrow[Mg,\ HgCl_2]{R^2CHXCO_2C_2H_5} R^1COCHR^2CO_2C_2H_5;$$

$R^1 = CH_2F$, X = Br, R^2=H(20%); R^1=CH_2F, X=Cl, R^2=H;
R^1=CH_2F, X=Br, R^2=CH_3 (19%); R^1=CH_3, X=Cl, R^2=F (20%);
R^1=CHFCl, X=Cl, R^2=F (52%).

Sterically hindered esters of bromine-containing carboxylic acids can also be involved in this reaction in the presence of zinc in benzene:[26]

$$C_2H_5CHFCO_2C_2H_5 \xrightarrow[Zn,\ C_6H_6]{(CH_3)_2CBrCO_2C_2H_5} C_2H_5CHFCO(CH_3)_2CO_2C_2H_5.$$

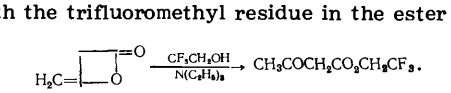
On treatment with isopropylmagnesium bromide, ethyl bromofluoroacetate gives rise to substituted β-KE at −60 °C in ether, whereas at −40 °C a mixture of alcohols and a ketone is formed:[27]



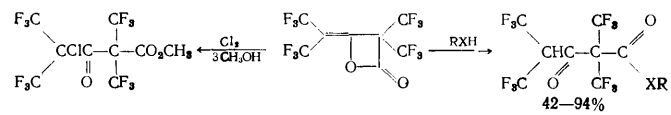
The interaction of keten and its derivatives with acid chlorides and alcohols yields β-KE which are difficult to obtain by other methods. Keten reacts with trifluoroethanol and trichloroacetyl chloride to form in a high yield β-FKE containing the trichloro- and trifluoro-methyl groups:[28]

$$CH_2{=}C{=}O + CCl_3COCl \xrightarrow[SO_2]{CF_3CH_2OH} CCl_3COCH_2CO_2CH_2CF_3.\ 79\%$$

The keten dimer reacts with trifluoroethanol to produce a β-FKE with the trifluoromethyl residue in the ester group:[29]



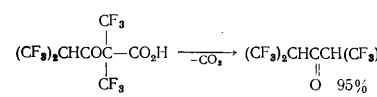
The cyclic dimer of perfluorodimethylketen forms a whole series of trifluoromethyl-substituted β-KE and their derivatives in reactions with HO-, HS-, and N-nucleophiles.[30,31] When the perfluorodimethylketen dimer is chlorinated in the presence of methanol, coupled addition takes place with formation of a γ-chloro-substituted β-FKE. In the absence of methanol, the reaction does not take place:[31]



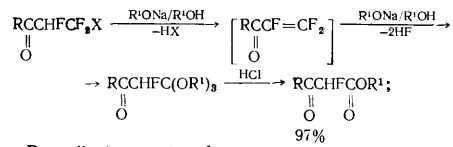
42—94%

X = O, S, or NH; R = H, alkyl, or phenyl.

The interaction of the perfluorodimethylketen dimer with water affords a β-ketoacid which is unstable at room temperature:[31]



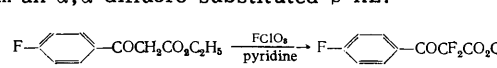
The method of synthesis of α-fluoro-substituted β-FKE involving the treatment of unsaturated fluoroketones with sodium alkoxides and subsequent acid hydrolysis of the products of the vinyl substitution of fluorine and addition to the double bond is apparently promising:[32,33]



97%

R = alkyl or aryl; R^1 = CH_3, C_2H_5; X=F, Cl.

A number of methods of synthesis of β-FKE are based on the introduction of halogen atoms into the β-KE molecule. *p*-Fluorobenzoylacetic ester reacts with perchloryl fluoride to form an α,α-difluoro-substituted β-KE:[34]



A similar reaction takes place in alcohol in the presence of sodium ethoxide.[35,36] A fluorine atom can be introduced into the isopropyl group of the β-KE when isobutyric acid ester reacts with triphenylmethylsodium and perchloryl fluoride:[37]

$$(CH_3)_2CHCO_2CH_3 \xrightarrow[(C_6H_5)_3CNa]{FClO_3} (CH_3)_2CFCOCCO_2CH_3 \quad (30\%)$$

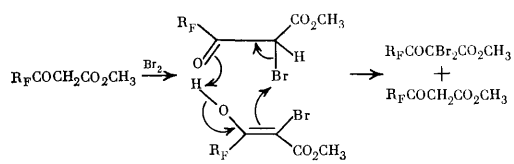
The chlorination of β-FKE or their copper chelates gives rise to α-chloro-derivatives:[38-40]

$$R_FCOCH_2CO_2R \xrightarrow[20^\circ]{Cl_2} R_FCOCHClCO_2R \xleftarrow[CHCl_3]{Cl_2} [R_FCOCHCO_2R]_2Cu;$$
$$R_F=CF_3,\ H(CF_2)_n,\ n=1,\ 2,\ 4;\ C_3F_7,\ C_4F_9;\ R=CH_3,\ C_2H_5.$$

α-Chloro-derivatives of aromatic β-FKE with fluorine-containing substituents in the aromatic ring have been synthesised also by treatment with sulphuryl chloride in chloroform (in yields of 80–90%).[41] Treatment of TFAAE with bromine in a chloroform–pyridine mixture leads to a dibromo-substituted β-KE:[40,42]

$$CF_3COCH_2CO_2C_2H_5 \xrightarrow[CHCl_3,\text{pyridine}]{Br_2} CF_3COCBr_2CO_2C_2H_5.$$

However, when an attempt was made to synthesise α-monobromo-derivatives of β-FKE by treating them with bromine, as described for α-bromotrifluoroacetoacetic ester,[39,43] it was found that they are relatively unstable.[43] At room temperature or on vacuum distillation their disproportionation to α,α-dibromo-derivatives and the initial β-FKE is observed, apparently owing to the halogenophilic attack by the enol form of the α-bromo-derivative of the β-FKE on the bromine atom of the keto-form:



$R_F = CF_3,\ H(CF_2)_n,\ C_4F_9;\ n = 1, 2, 4.$

A second halogen atom can be introduced into the α-position in the β-KE by brominating the α-fluoro-derivative:[44]

$$CF_3COCHFCO_2C_2H_5 \xrightarrow[CCl_4,\ 70^\circ]{Br_2} CF_3COCFBrCO_2C_2H_5.$$

A β-FKE containing an aromatic polyfluoro-group can be synthesised by acylating malonic ester with the chloride of pentafluorobenzoic acid with subsequent hydrolysis and decarboxylation of the acylation product or by the condensation of pentafluorobenzoic ester with ethyl acetate in the presence of diisopropylaminomagnesium bromide:[45-47]

$$C_6F_5COCl \xrightarrow[MgBr(OC_2H_5)]{CH_2(CO_2C_2H_5)_2} C_6F_5COCH(CO_2C_2H_5)_2 \xrightarrow[H_2O]{H_2SO_4}$$
$$C_6F_5CO_2C_2H_5 \xrightarrow[(iso\text{-}C_3H_7)_2NMgBr]{CH_2CO_2C_2H_5} C_6F_5COCH_2CO_2C_2H_5.$$

The same compound was formed on oxidation of the β-hydroxyester, obtained by the Reformatskii reaction, with chromium trioxide or potassium permanganate:[47]

$$C_6F_5C(=O)H \xrightarrow[Zn]{BrCH_2CO_2C_2H_5} C_6F_5CH(OH)CH_2CO_2C_2H_5 \xrightarrow{CrO_3}$$
$$\rightarrow C_6F_5COCH_2CO_2C_2H_5 + C_6F_5COCH_3 + C_6F_5CO_2H.$$
$$17\%$$

The first two methods of synthesis of pentafluorobenzoylacetic ester (PFBAE) are preferable because they lead to higher yields.

Thus one may conclude that the most universal and most convenient, as regards yields, purity of the reaction products, and the availability of the initial reagents, method of synthesis of a wide range of aliphatic β-FKE is the Claisen condensation. As for β-diketones,[2] the most convenient and most widely used method of purification of β-FKE involves the formation of copper chelates.

III. STRUCTURE AND ACIDITY

A whole series of monographs and reviews have been devoted to problems of the structure of β-dicarbonyl compounds,[48-50] but they are concerned mainly with β-KE without fluorine. Data obtained from studies of β-FKE by electronic absorption spectroscopy are virtually lacking in the literature and the available experimental absorption maxima and extinction coefficients are quoted mainly as characteristics of the given substances. The results obtained by Filler and Naqvi[51] permit the conclusion that the replacement of all three hydrogen atoms of the methyl group in AAE by fluorine atoms entails a hypsochromic shift of the absorption maximum (λ_{max} = 244 and 234 nm respectively in 2,2,4-trimethylpentane). For copper chelates of β-KE, such a shift has not been observed; on passing from AAE chelates of TFAAE chelates, there is almost no change in the position of the absorption band maxima in the ultraviolet spectra (278 and 276 nm in chloroform).[51]

*Without solvent.

Application of infrared (IR) spectroscopy to the study of the structures of halogen-containing β-KE revealed the presence of the keto- and enol forms. Table 1 shows that the reducton of halogen atoms (Cl and F) increases the absorption frequencies of the keto-groups in both the keto- and enol forms. This tendency has also been observed for the absorption by the C=C bond in the enolic forms of β-KE. In most studies it has been noted that acetoacid esters form

enols with the *U*-conformation (a *cis,cis*-enol with an intramolecular hydrogen bond):[48,50]

***Data obtained by the method involving titration with bromine.[56]

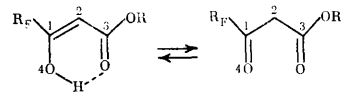
The methods for the investigation of the keto–enol equilibria involving β-KE which are most convenient and yield most information are IR and NMR spectroscopy.[19,47,50,52–55] Data for the enolisation of β-KE, obtained by titration with bromine,[56] agree satisfactorily with the results obtained by other methods (Table 2) only for β-KE without halogens. In the case of fluorine-containing β-KE they are clearly erroneous, in all probability owing to the uncertainty as to the course followed in the bromination process.[40] Table 2 shows that the introduction of halogen atoms into the α- and γ-positions in β-KE entails a sharp increase of the enol content in the equilibrium mixture, which may be attributed to a greater increase in the CH acidity than the OH acidity. The β-KE are enolised only at the carbonyl oxygen atom.[50] The lower degree of enolisation of β-KE compared with β-diketones[2,50] is in all probability associated with the greater electron density on the carbon atom of the carbonyl group owing to the presence of alkoxy-groups. The contribution of the influence of γ-substituents in the enolic forms of β-KE to the intramolecular hydrogen bond is not additive, in contrast to β-diketones.[57]

The charges on the atoms and the bond energies in the keto- and enol forms of a series of α- and γ-fluoro-substituted β-KE have been calculated[55] by Del Re's method. Correlations between the keto-enol equilibrum constants ($\lg K_e$) and the parameters of the reaction centres have been investigated. A linear relation has been observed ($r = 0.995$, $\alpha = 0.95$) between $\lg K_e$ and the charges on the β-carbon atoms in the keto and enol forms of β-KE and on the hydrogen atom of the enolic hydroxyl and also the O–H bond energy of the enol.[55]

The acidity of β-FKE has been investigated by Kurts et al.,[58] who established that the introduction of fluorine atoms into the γ-position in β-KE increases their activity, in conformity with the inductive effect of the substituents [AAE: $pK_a = 12.6$; γ-F-AAE: $pK_a = 11.2$; TFAAE: $pK_a = 7.4$ (in dimethylformamide)]; consequently the stability of the enolate ion increases under these conditions. One can also note that, on passing from β-KE to the corresponding β-diketones (replacement of OC_2H_5 by CH_3), the acidity increases [acetylacetone: $pK_a = 11.7$; trifluoroacetylacetone: $pK_a = 5.1$ (in dimethylformamide)], which also agrees with the inductive effect of the substituents.

IV. CHEMICAL PROPERTIES

Fluorine-containing β-ketoesters have four reaction centres: C(1), C(2), C(3), and O(4):



This is the reason for their varied reactivity in relation to nucleophiles and electrophiles. The introduction of fluorine atoms increases the reactivity in relation to nucleophiles and in many cases alters the reaction mechanisms compared with their hydrocarbon analogues. The presence of the ester group leads to the appearance of chemical properties uncharacteristic of fluorine-containing β-ketones.

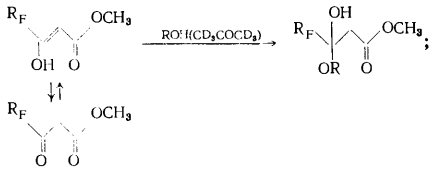
1. Interaction with Nucleophiles

HO, HS, HN, and other nucleophiles react with β-FKE, forming addition and addition-elimination products from which one can infer the characteristic features of substances of this class. In the study of reactions of the given type, the question of the direction of the primary processes, namely either via the C(1) carbon atom in the keto- or enol form or via the C(3) atom (the ester group), is significant. However, one cannot rule out the process involving the formation of a salt of the enol form. Thus the reactions of β-FKE with nucleophiles must be regarded as competing interactions with the C(1), C(2), and C(3) reaction centres. Naturally one must also take into account the influence of the medium.

(a) Reactions with Hydroxylated Nucleophiles

In the absence of a solvent, TFAAE combines with water and alcohol, forming hydrates and hemiketals, which are in equilibrium with keto- and enol forms.[59] Since the enolisation constant K_e, determined by ^{19}F NMR, increases after the addition of water to TFAAE, the authors of the above study concluded that the addition is to the keto-form and that the reaction is faster than the attainment of the keto–enol equilibrium. However, in another study by the ^{1}H and ^{19}F NMR methods, of the interaction of β-FKE with water and alcohols in deuterioacetone, it was shown that they add to the

enol form of β-FKE and that K_e diminishes with time:[60]

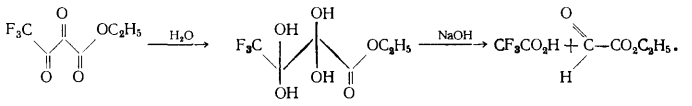


R_F=H(CF_2)$_n$, (n = 1, 2, 4), CF_3, C_3F_7, C_4F_9, R=H, CH_3, C_2H_5.

The discrepancy between the results obtained cannot be accounted for by the influence of the solvent (CD_3COCD_3), since in the case of asymmetric fluorine-containing β-diketones, hydroxylated nucleophiles also added to the enol form, the content of the keto-form hardly changing under these conditions, while the solvent (CD_3COCD_3) does not influence the reaction mechanism.[61] The results of the study of Camps et al.[59] cannot be interpreted in detail because of the inadequacy of the experimental data presented. Furthermore, the use of the analysis of the [enol]/[ketone] ratio is not quite correct, since there are no data concerning the influence of alcohols on the keto–enol equilibria of β-FKE.

An increase in the length of the fluoroalkyl group (from difluoromethyl to nonafluorobutyl) in β-FKE and also the increase of the bulk of the alkyl substituents in the hydroxylated nucleophile lead to a decrease of the fraction of the adduct, which is in all probability associated with steric hindrance.[60] It is of interest that butyl 2,2,4,4,4-pentafluoroacetoacetate reacts with butanol to form a stable adduct, which can be isolated pure, this being due to the appreciable decrease of the electron density at the C(1) centre compared with TFAAE as a result of the replacement of the methylene group by the difluoromethylene group.[16] It is clearly seen from the data of Burdett and Rogers[52] and Fomin et al.[60] that the introduction of the trifluoromethyl group in AAE instead of the methyl group entails an increase in the reactivity and stability of the products of the addition of hydroxylated nucleophiles compared with AAE, for which the formation of large amounts of adducts is not a characteristic feature. On heating PFBAE with aqueous alcohol, the ester undergoes keto cleavage to pentafluoroacetophenone, which has not been observed for benzoylacetic ester (BAE).[62]

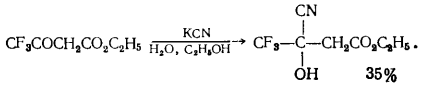
Trifluoro-α-oxoacetoacetic ester reacts with water to form a dihydrate, while in its reaction with aqueous alkali it undergoes acid cleavage:[63,64]



Thus the interaction of β-FKE containing fluoroalkyl groups in the β-position with hydroxylated nucleophiles, including the hydroxide anion, is directed to the C(1) centre. The ketone cleavage of PFBAE in a water–alcohol mixture is apparently associated with its low thermal stability.

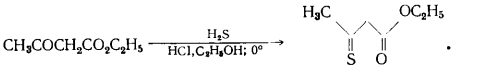
(b) Interaction with C-Nucleophiles

TFAAE reacts with potassium cyanide[65,66] to form a cyanohydrin analogously to the behaviour of carbonyl compounds without fluorine atoms:[10]

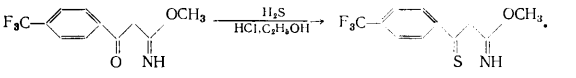


(c) Interaction with HS-Nucleophiles

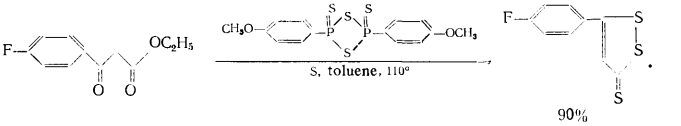
AAE reacts with hydrogen sulphide to form thioacetoacetic esters:[67]



A similar reaction of TFAAE has not so far been described. Only thio-derivatives of aromatic β-KE with the trifluoromethyl substituent in the benzene ring have been obtained:[15]



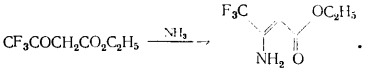
On interaction with *p*-fluorobenzoylacetic ester, the "*p*-methoxyphenylthionophosphine sulphide dimer", which is an effective thionating agent, gives rise to only a cyclic disulphide, as for AAE:[68]



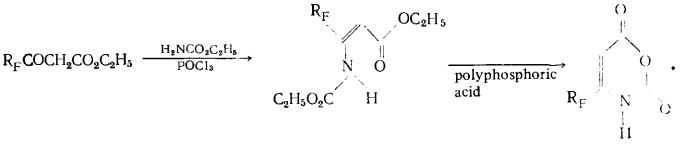
Thioesters cannot be isolated in this instance. The mechanism of the interaction of this reagent with β-KE is still obscure. This branch of the chemistry of β-FKE has remained virtually uninvestigated, while in the case of fluorine-containing β-diketones it has been adequately developed.[2]

(d) Interaction with Amines

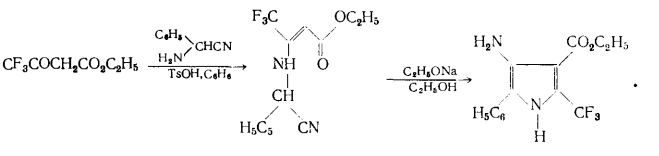
The interaction of AAE with ammonia leads to ethyl β-aminocrotonate in 90% yield.[69] TFAAE also reacts with ammonia to form β-aminotrifluorocrotonic ester:[6,70,71]



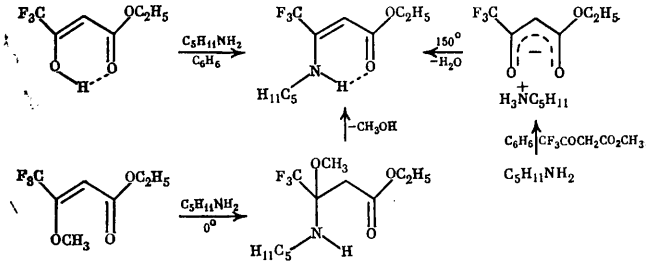
Fluoro- and trifluoro-acetoacetic esters react with urethane in the presence of phosphoryl chloride, forming esters of *N*-substituted-aminocrotonic acids, which cyclise to oxazinediones on treatment with polyphosphoric acid;[72] AAE condenses immediately to oxazinedione,[22] which can apparently be accounted for by the fact that in the case of fluorine-containing compounds the reactivity of the enamine formed is reduced in relation to electrophiles owing to the presence of electron-accepting groups (CH_2F, CF_3):



The interaction of TFAAE with α-aminophenylacetonitrile in the presence of toluene-*p*-sulphonic acid in benzene gives rise to a derivative of aminotrifluorocrotonic acid, from which a substituted pyrrole is formed on treatment with sodium ethoxide in ethanol:[73]

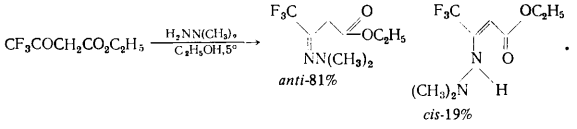


Analogous products have been obtained from AAE and *p*-fluorobenzoylacetic ester.[73] It has been shown that, depending on the order of the addition of the reactants, the interaction of TFAAE with pentylamine leads either to 4,4,4-trifluoro-3-(1-pentylamino)but-2-enoate or to the pentylammonium salt of TFAAE, which is converted into an enamine with elimination of water at 150 °C.[18] Presumably the enolic form of the β-ketoester reacts with the amine, since trifluoro-β-methoxycrotonic ester reacts with pentylamine to form initially a relatively unstable adduct which splits off methanol and is converted into 4,4,4-trifluoro-3-(1-pentylamino)but-2-enoate:[18]



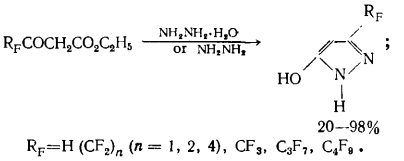
(e) Interaction with Hydrazines

TFAAE reacts with asymmetric *NN*-dimethylhydrazine to give a 62% yield of a hydrazone, which exists, according to ^{1}H NMR data, in the form of an equilibrium mixture of the *anti*-hydrazone form (81%) and the *cis*-enehydrazine form (19%):[74]



Under analogous conditions, the corresponding AAE hydrazone exists as a mixture of the hydrazone form (15% of the *syn*-isomer and 10% of the *anti*-isomer) with the enehydrazine form (72% of the *cis*-isomer and 3% of the *trans*-isomer).[74]

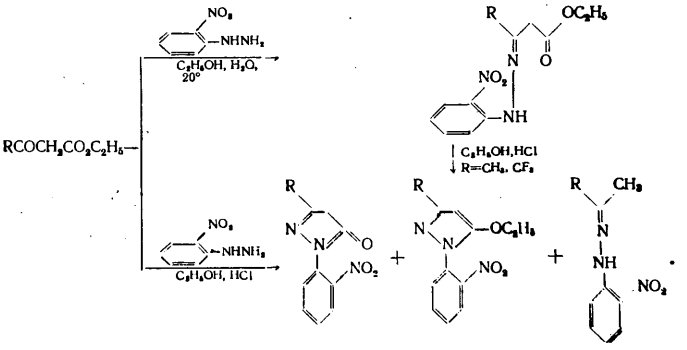
TFAAE andother β-FKE react with hydrazine hydrate or hydrazine to form 5(3)-fluoroalkyl-3(5)-hydroxypyrazoles:[75–77]



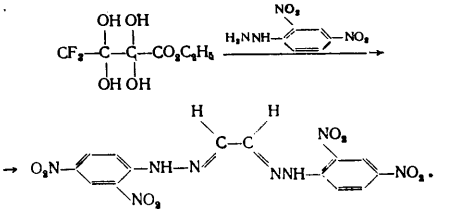
R_F=H $(CF_2)_n$ (n = 1, 2, 4), CF_3, C_3F_7, C_4F_9.

β-KE monosubstituted by fluorine in the α-position also give rise to hydroxypyrazoles.[78]

β-FKE react with phenylhydrazine and methanol at 20 °C to form *N*-phenylhydrazones, which cyclise to 5-fluoroalkyl-3-hydroxy-*N*-phenylpyrazoles on refluxing in methanol.[77] The formation of hydrazone has been noted in the reaction of γ-fluoroacetoacetic ester with 2,4-dinitrophenylhydrazine [24] and of TFAAE with 2-nitrophenylhydrazine.[79] However, as a rule oxo- or hydroxy-pyrazoles are formed in the reactions of β-FKE with hydrazines.[75–77,80,81] A more detailed study of this process in relation to the reaction of AAE or TFAAE with 2-nitrophenylhydrazine showed that the results depend to a large extent on the experimental conditions.[79] Thus the products in aqueous alcohol at 20 °C are arylhydrazones, which, on treatment with alcoholic hydrogen chloride, afford a mixture of pyrazolone, ethoxypyrazole, and the hydrazone of the corresponding methyl ketone, formed apparently on ketone cleavage of the β-KE, whereas in alcohol containing hydrogen chloride the above mixture of products is formed immediately:[79]



On treatment with 2,4-dinitrophenylhydrazine, the dihydrate of trifluoro-2-oxoacetoacetic ester decomposes with formation of glyoxal bis-2,4-dinitrophenylhydrazone:[64]

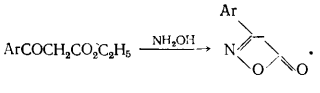


In the reactions of β-FKE with pentafluorophenyl groups in the β-position with hydrazine[62] and phenyl- and pentafluorophenylhydrazines,[82] the corresponding pyrazolones are formed. On the other hand, BAE reacts with pentafluorophenylhydrazine to form the pentafluorophenylhydrazone;[82] cyclisation to a pyrazolone is not observed in this case, apparently as a consequence of the insufficient nucleophilicity of the nitrogen in the HN groups of the hydrazone. At the same time, the pentafluorophenylhydrazone of PFBAE cyclises spontaneously to the pyrazolone, which is in all probability due to the electrophilic properties of the carbon atom in the ethoxycarbonyl group enhanced under the influence of the pentafluorophenyl residue.

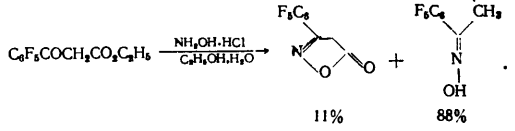
According to IR spectroscopic data, pyrazolones containing one or two pentafluorophenyl substituents consist in the solid state of a mixture of the hydroxy-form with a small amount of the keto-form, while 1,3-diphenyl-5-pyrazolone exists under these conditions as the keto-form.[82] In alcoholic solutions these pyrazolones exist in the enolic-form, while in carbon tetrachloride or in methylene chloride they are present predominantly in the keto-form.[82] It follows from the above that, in the interaction of hydrazines with β-FKE, the primary attack by the hydrazine is directed to the C(1) carbon atom, which is indicated by the formation of hydrazones in certain cases, the interaction involving the C(3) reaction centre and cyclisation to pyrazolones only under more severe conditions.[77,79]

(f) Interaction with Hydroxylamine

The *para*- and *meta*-trifluoromethyl derivatives of PAE react with hydroxylamine to form isoxazolones:[83–85]



Pentafluorobenzoylacetic ester reacts with hydroxylamine to form a salt and not an isoxazolone, which can be explained by its high acidity.[82] However, when PFBAE is heated with hydroxylamine hydrochloride in aqueous alcohol, 3-pentafluorophenyl-5-isoxazolone is obtained together with pentafluoroacetophenone oxime:[62]

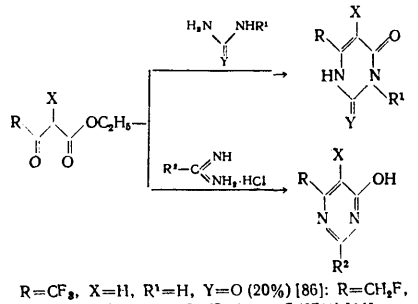


11% 88%

The formation of the oxime agrees well with the fact that, on heating in aqueous alcohol, PFBAE undergoes ketone cleavage to pentafluoroacetophenone, whose reaction with hydroxylamine affords the oxime.[62]

(g) Interaction with Ureas, Guanidine, Semicarbazides, and Amidines

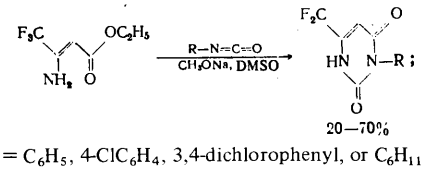
The interaction of β-FKE with ureas[14,86-88] in basic[86] or acid[14] media, with thiourea in the presence of sodium methoxide,[14] with guanidine carbonate,[14] and with carboxylic acid amidines[14-89] leads to uracils, thiouracils, isocytosines, and hydroxypyrimidines substituted in the 2-position respectively:



R=CF_3, X=H, R¹=H, Y=O (20%) [86]; R=CH_2F, X=H, R¹=H, Y=O (73%) or S (67%) [14]; R=CH_3, X=F, R¹=Ar, Y=O [87, 88];

R=CH_3, CH_2F, CF_3 or C_2F_5, X=H or F, R¹=H, Y=NH·H_2CO_3 [14]; R=CH_3, CH_2F, CF_3 or C_2F_5, X = H or F, R^2 = CH_3 or iso-C_3H_7 [14, 89].

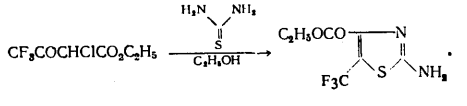
Fluorine-containing uracils are formed also from β-aminocrotonic esters and isocyanates:[71, 90]



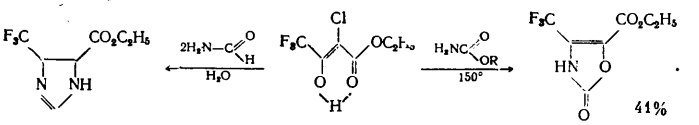
20–70%

R = C_6H_5, 4-ClC_6H_4, 3,4-dichlorophenyl, or C_6H_{11}.

If there is a chlorine atom, which is more mobile than the fluorine atom, in the α-position in β-FKE, then the reaction follows another pathway: the ethyl ester of 2-amino-4-trifluoromethylthiazolecarboxylic acid is formed on interaction with thiourea:[41,91]



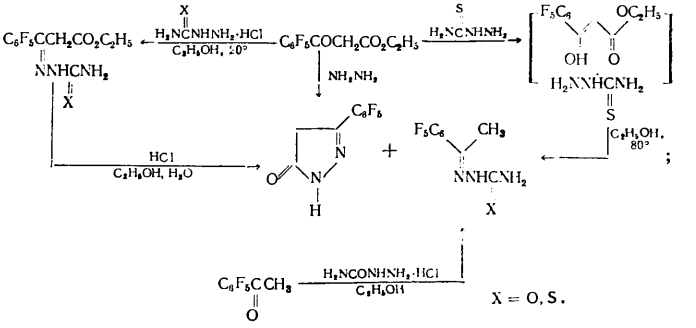
The mobility of the chlorine atom in the α-position in β-FKE is also manifested in the interaction of the chloro-substituted TFAAE with formamide or urethane:[92,93]



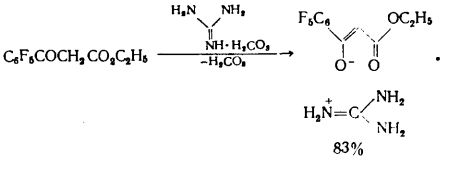
41%

The interaction of PFBAE with semicarbazide hydrochloride or thiosemicarbazide hydrochloride at 20–25 °C involves the C(1) reaction centre.[62] On heating, the PFBAE derivative undergoes the ketone cleavage and the semicarbazone residue decomposes to the hydrazone residue, so that a derivative of pentafluoroacetophenone is obtained together with pentafluorophenylpyrazolone.[62] The reaction with thiosemicarbazide gives rise not to the thiosemicarbazone but to an unstable salt, which is converted on heating into the same products as thiosemicarbazide hydrochloride.[62]

The presence of 3-pentafluorophenyl-5-pyrazolone in the products of the reaction of PFBAE with semicarbazide can be accounted for by the partial decomposition of the latter to hydrazine.[62,95] Its structure has been demonstrated by specific synthesis from a β-FKE and hydrazine:[62]



The formation of a salt with thiosemicarbazide is extremely probable, since the guanidinium salt of the enolic form of PFBAE has been isolated in the reaction with guanidine carbonate:[82]



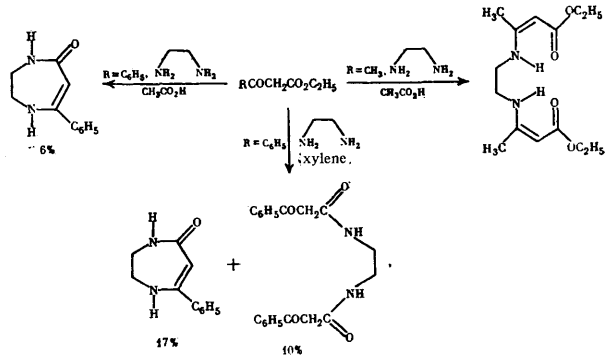
83%

In this case BAE gives rise to 4-phenylisocytosine.[94] This can be explained by the increased acidity and degree of enolisation of PFBAE compared with BAE.[47]

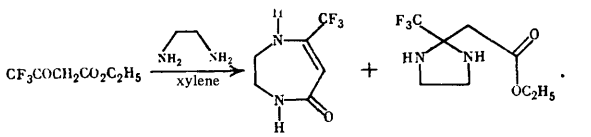
(h) Reactions with Bifunctional Nucleophiles

The interaction of AAE with ethylenediamine (EDA) in acetic acid does not give rise to an azepinone, but produces *NN'*-ethylenebis-3-amino-but-2-enoate.[96] However BAE does form 7-phenyl-1,2,3,4-tetrahydro-1,4-diazepin-5-one under

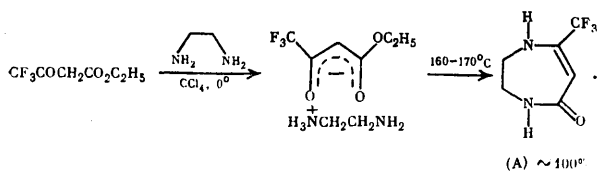
these conditions, while in xylene *NN'*-ethylenebisbenzoylacetamide is obtained in addition;[96]



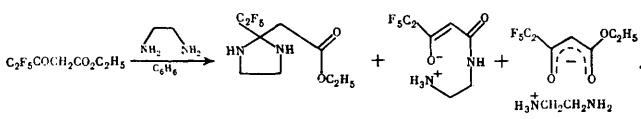
In contrast to this, the reaction of TFAAE with EDA in xylene affords a mixture of 7-trifluoromethyl-1,2,3,4-tetrahydro-1,4-diazepin-5-one (A) and 2-ethoxycarbonylmethyl-2-trifluoromethylimidazolidine (B):[97]



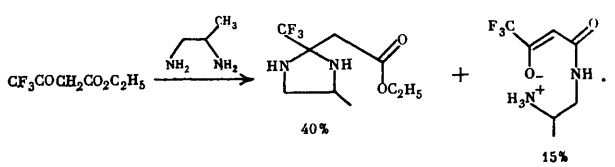
When TFAAE was added to EDA in boiling benzene, 36% of compound (B) and 10% of compound (A) were obtained while in ethanol only the product (B) was formed in 19% yield. On the other hand, after the addition of EDA in TFAAE, compound (B) was obtained in 81% yield, while the diazepine (A) was not isolated.[18] The addition of EDA to a solution of TFAAE in carbon tetrachloride results in the formation of the ethylenediammonium salt of TFAAF, which is converted quantitatively into the diazepinone (A) on heating:[18]



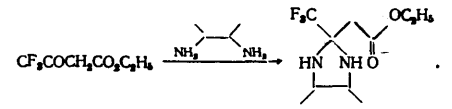
The addition of EDA to a boiling benzene solution of ethyl 4,4,5,5,5-pentafluoro-3-oxopentanoate produces 2-ethoxycarbonylmethyl-2-perfluoroethylimidazolidine, *N*-(2-aminoethyl)-3-hydroxy-4,4,5,5,5-pentafluoropent-2-enamide, and the ethylenediammonium salt of the β-FKE:[18]



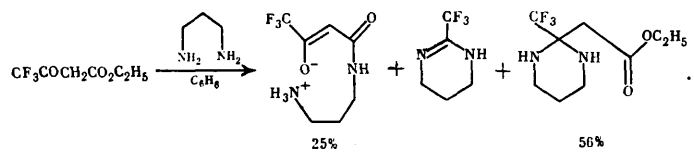
The addition of TFAAE to 1,2-diaminopropane in benzene results in a mixture of the *d*- and *l*-isomers of a substituted imidazolidine together with *N*-(2-aminepropyl)-3-hydroxy-4,4,4-trifluorobut-2-enamide, which gives rise to 2-methyl-7-trifluoromethyl-1,2,3,4-tetrahydro-1,4-diazepin-5-one on heating:[18]



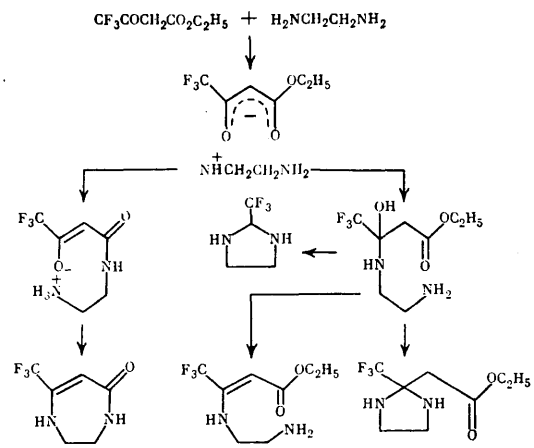
The reaction of TFAAE with 2,3-diaminobutane produces a mixture of the *d*-, *l*-, and *meso*-isomers of a substituted imidazolidine:[18]



The reaction of 1,3-diaminopropane with TFAAE leads to *N*-(3-aminopropyl)-3-hydroxy-4,4,4-trifluorobut-2-enamide, 2-trifluoromethyl-3,4,5,6-tetrahydropyrimidine, and 2-ethoxycarbonylmethyl-2-trifluoromethylhexahydropyrimidine:[18]



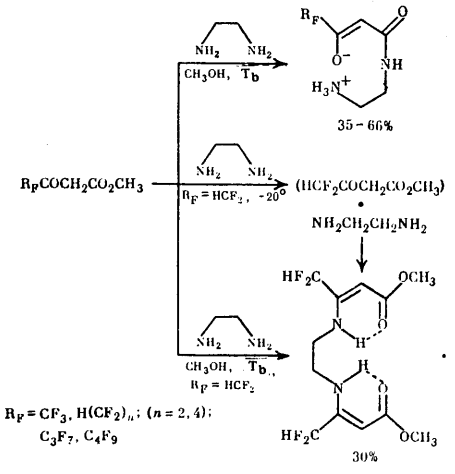
From the above data, the following mechanism of the reaction of TFAAE with EDA in aprotic solvents has been proposed:



As can be seen from the above scheme, the authors[18] suggest the presence of two competing pathways in the reaction of the TFAAE salt with EDA: the formation of an adduct via the C(1) centre with subsequent dehydration and the substitution of the ethoxy-group in the ester group of TFAAE [attack on the C(3) centre].

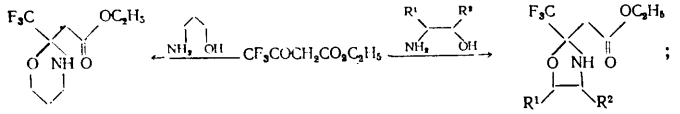
The replacement of an aprotic solvent by a proton-donating solvent (methanol) entails an appreciable simplification of the composition of the products of the reaction of β-FKE with EDA.[77] Thus, when difluoroacetoacetic ester is refluxed with EDA in methanol, 3,3'-(*NN'*-diaminoethylene)bis-1,1-difluorobut-2-enoate is formed,[77] which is also characteristic of AAE,[96] while at −20 °C it is possible to isolate a 2:1 salt of difluoroacetoacetic ester with EDA, which is converted on heating into the same dicarboxylic acid ester.[77] The replacement of the difluoromethyl group by the trifluoromethyl group or the lengthening of the fluoroalkyl residue results in the formation of an inner salt of the aminoethyleneamide of the β-ketoacid as the sole reaction

product:[77]



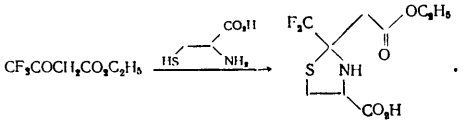
Apparently the primary process in the interaction of EDA with β-FKE in a proton-donating solvent[77] is, as in an aprotic solvent,[18] the formation of a salt of the β-FKE. However, the subsequent reaction pathway is apparently determined by the acidity of the β-FKE and, in the case where R_F = HCF_2, the reaction involving the C(1) centre (a carbonyl group) takes place, whereas under conditions where R_F has been lengthened the reaction involves the C(3) centre (the ester group).

TFAAE reacts with aminoalcohols to form 2-ethoxycarbonylmethyl-2-trifluoromethylperhydroxooxazine or the corresponding oxazolidine:[18]

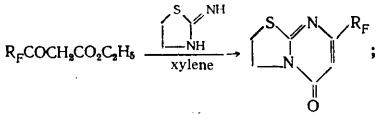


R¹=R²=H; R¹=CH₃, R²=H; R¹=H, R²=CH₃.

Cysteine reacts with TFAAE to form 4-carboxy-2-ethoxycarbonylmethyl-2-trifluoromethylthiazolidine:[18]

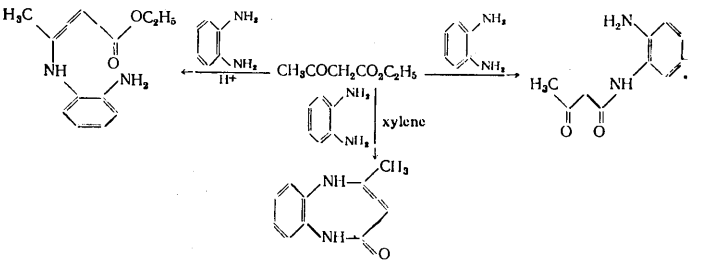


These reactions also show that the attack by the HO-, HN-, and HS-nucleophiles is directed to the C(1) centre, although in the case of the HN-nucleophiles this can be preceded by the formation of a salt with the β-FKE. 2-Iminothiazolidine reacts with β-FKE to form thiazolinopyrimidine derivatives:[98]

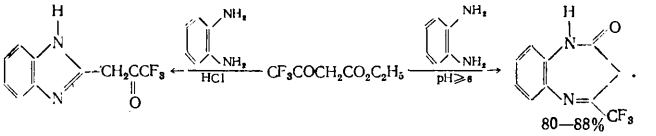


R_F = CF_3, *m*-$CF_3C_6H_4$.

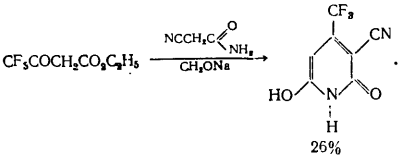
The reaction of AAE with *o*-phenylenediamine (OPDA) results in the formation of various products depending on the basicity of the medium and the character of the solvent.[99–111] In an acid medium the product of the condensation involving a keto-group is formed, in xylene containing pyridine the *o*-aminoanilide is obtained, while in a neutral medium the product is a substituted benzodiazepinone:[100]



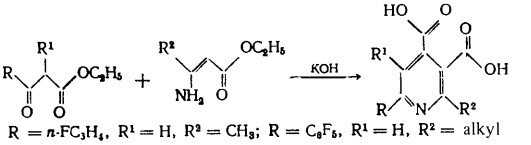
However, there exist data showing that these processes are more complex.[99,101] For example, in methanol 2-methylbenzimidazole was isolated together with a derivative of β-aminocrotonic ester.[101] The interaction of TFAAE and other β-FKE with OPDA in a neutral or weakly alkaline medium entails the formation of 4-(fluoroalkyl)-1*H*-1,5-benzodiazepin-2(3*H*)-ones,[77] while in an acid medium the product is 3-(2-benzimidazolyl)-1,1,1-trifluoro-2-propanone:[102]



Methyl-*o*-phenylenediamine reacts with TFAAE to produce a mixture of two isomers.[103] β-FKE react with bifunctional nucleophiles containing an active methylene group together with the amino-, hydroxy-, or thio-groups, which leads to different heterocyclic systems.[104–118] Thus the reaction of TFAAE with cyanoacetamide gives rise to a substituted pyridone;[104]

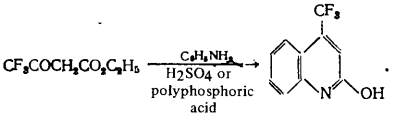


Under the influence of alkali, β-FKE react with β-aminocrotonic esters to form derivatives of dibasic acids of the pyridine series,[105] which is also characteristic of AAE:[106]



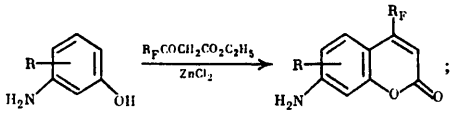
R = *n*-FC_3H_4, R^1 = H, R^2 = CH_3; R = C_6F_5, R^1 = H, R^2 = alkyl

Like AAE,[10] TFAAE reacts with aniline and its derivatives in the presence of sulphuric or polyphosphoric acid to form hydroxyquinolines and their derivatives.[107–113] The yields of the reaction products are then as a rule higher in the case of polyphosphoric acids:[108–110]



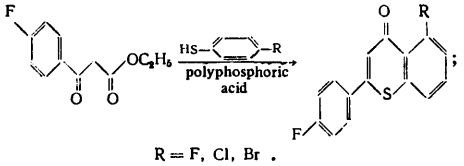
Like the fluorine-free β-KE,[10] β-FKE react with aromatic dihydric phenols and aminophenols via the hydroxy-group and the *ortho*-position in the ring, forming coumarins in

20–80% yields:[114–117]



$R_F = CF_3, C_3F_7, C_5F_{11}, C_7F_{15}$; R = OH, NH_2, $C_6H_5CH_2$— .

Thiophenols react with β-FKE via the S–H and –CH= groups:[118]



R = F, Cl, Br .

The considerable synthetic possibilities of the reactions of β-FKE with nucleophiles, which makes it possible to obtain various classes of fluorine-containing organic compounds, are evident from the foregoing data for these reactions; their characteristic features, which distinguish them from their hydrocarbon analogues, must also be emphasised.

2. Interaction with Electrophiles

The reactions with electrophiles, namely acids,[8,16,22,34,39,44,47,119] carbonyl compounds,[126–129] and alkylating and acylating agents[51,119,143,144] (see Section II about the halogenation of β-FKE) are characteristic of β-FKE, as in the case of their hydrocarbon analogues.

(a) Reactions with Acids

Fluorine-containing β-ketoesters having a fluoroalkyl substituent in the β-position and not more than one fluorine atom in the α-position undergo the ketone cleavage by sulphuric[8,16,44] or hydrobromic[39] acid with formation of fluoroalkylmethyl, fluoroalkylhalogenomethyl, or fluoroalkyldihalogenomethyl ketones in high yields (50–90%):

$$R_FCOCXYCO_2C_2H_5 \xrightarrow[-CO_2,\ -C_2H_5OH]{H^+} R_FCOCHXY;$$
R_F = fluoroalkyl; X = H, F, Cl, Br; Y = H, Br .

In the presence of two fluorine atoms in the α-position in β-FKE acid hydrolysis of the ester group, leading to β-keto acids, is observed under similar conditions and not the ketone cleavage:[16]

$$CF_2XCOCF_2CO_2C_2H_5 \xrightarrow[-C_2H_5OH]{H_2SO_4} CF_2XCOCF_2CO_2H;$$
X = H (53%), F (56%).

Ketone cleavage takes place only under more severe conditions, giving rise to 1,1,3,3-tetrafluoroacetone (62%) in the first case and 1,1,1,3,3-pentafluoroacetone (35%) in the second case.[16] Treatment of a β-KE having the $CH_2CO_2C_2H_5$ substituent in the α-position with sulphuric acid makes it possible to obtain a γ-ketoacid:[22]

$$CF_2COCHCO_2C_2H_5 \xrightarrow[-CO_2,\ -C_2H_5OH]{H_2SO_4} CF_2COCH_2CH_2CO_2H.$$
61%

Treatment of β-FKE mono- and di-substituted in the α-position with a mixture of bromine and sulphuric acid makes it possible to obtain di- and tri-halogeno-substituted methyl ketones respectively:[44]

$$CF_2COCFXCO_2C_2H_5 \xrightarrow[-CO_2,\ -C_2H_5OH]{Br_2,\ H_2SO_4} CF_2COCFXBr;$$
X = H (95%), Br (84%).

In contrast to fluoroalkyl-containing β-FKE, on treatment with concentrated sulphuric acid PFBAE hydrolyses at 20 °C to pentafluorobenzoylacetic acid, while on treatment with 20% sulphuric acid or a mixture of sulphuric and acetic acids it is cleaved to pentafluoroacetophenone:[47,82]

$$C_6F_5COCH_2CO_2H \xleftarrow{H_2SO_4\ (conc.)} C_6F_5COCH_2CO_2C_2H_5 \xrightarrow[\text{or } H_2SO_4\text{–}CH_3CO_2H]{20\%\ H_2SO_4} C_6F_5COCH_3.$$
48%

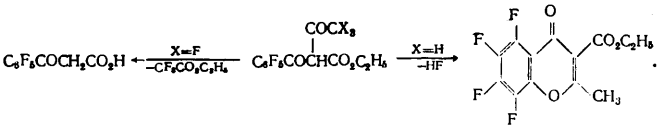
α-Ethoxycarbonylpentafluorobenzoylacetic ester reacts with 10% sulphuric acid to form PFBAE:[47]

$$C_6F_5COCHCO_2C_2H_5 \xrightarrow{10\%\ H_2SO_4} C_6F_5COCH_2CO_2C_2H_5.$$
48%

The ketone cleavage of β-FKE with benzoyl, pentafluorobenzoyl and pentafluorophenylacetyl substituents in the α-position is a convenient method of synthesising β-diketones with one or two pentafluorophenyl groups:[119]

$$C_6F_5COCHCO_2C_2H_5 \xrightarrow[-CO_2,\ -C_2H_5OH]{H_2SO_4(conc.)} C_6F_5COCH_2COR;$$
R = C_6H_5, C_6F_5 (78%), $CH_2C_6F_5$ (77%).

However, when the acetyl group is present in the α-position, a substituted flavone is formed, while in the presence of the trifluoroacyl substituent pentafluorobenzoylacetic acid is obtained.[119] The formation of the flavone can be explained by the cyclisation of the initial β-FKE owing to the intramolecular substitution of the *ortho*-fluorine atom in the pentafluorobenzene ring and the formation of pentafluorobenzoylacetic acid can be accounted for by the fact that in this case the α-ethoxycarbonyl-β-diketone undergoes acid and not keton cleavage:

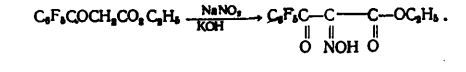


α,α-Difluoro-substituted *p*-fluorobenzoylacetic ester reacts with a mixture of hydrochloric acid and acetic acid to form the corresponding substituted benzophenone:[34]

Thus the majority of β-FKE are converted into ketones on interaction with acids. The first stage of this reaction is the acid hydrolysis of the ester group to the β-ketoacid, which is then decarboxylated to the ketone.

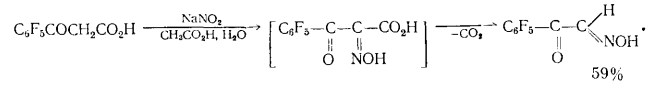
(b) Nitrosation and Diazotisation

These reactions are known only for β-FKE with the pentafluorophenyl group.[82,120] Treatment of PFBAE with sodium nitrite is accompanied by the formation of pentafluoroisonitrosobenzoylacetic ester:[82,120]



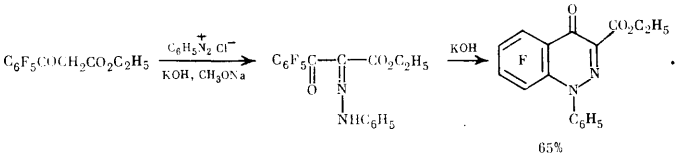
In contrast to this, pentafluorobenzoylacetic acid reacts with sodium nitrite in an acid medium to form the oxime of pentafluorophenylglyoxal, which is in all probability the

product of the decomposition of the intermediate pentafluoroisonitrosobenzoylacetic acid:[120]



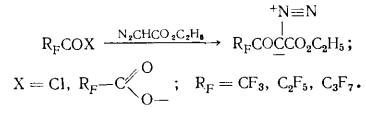
59%

The reaction of PFBAE with benzenediazonium chloride in an alkaline medium gives rise to a cinnolinone derivative:[82]

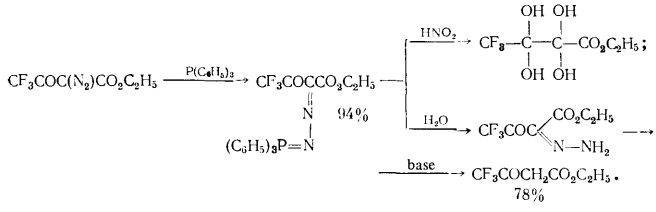


65%

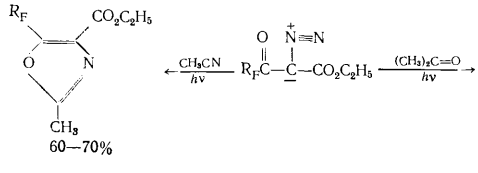
Here we should mention the α-diazo-derivatives of β-FKE, although they are not products of the reactions of β-FKE and are formed as a rule from diazoacetic ester and the chlorides or anhydrides of carboxylic fluoroacids:[64,121,122]



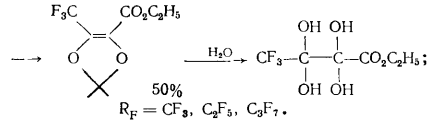
Numerous β-FKE can be obtained from these compounds.[43,64,121–125] α-Diazotrifluoroacetoacetic ester reacts with triphenylphosphine to form a product whose treatment with water gives rise to a compound with the structure of a hydrazone; the hydrolysis of the latter in a basic medium produces TFAAE.[121] However, when the product is treated with nitrous acid in tetrahydrofuran and not with water, it is possible to obtain the dihydrate of the ethyl ester of 4,4,4-trifluoro-2,3-dioxobutyric acid:[64]



As a result of the formation of trifluoroacetoxycarbonylcarbene on irradiation of α-diazotrifluoroacetoacetic ester and its homologue with ultraviolet light, it is possible to obtain from these substances heterocyclic compounds as a consequence of [2+3]-cycloaddition.[43,122–125] Thus the reaction with acetonitrile on irradiation affords oxazoles,[43,122,124,125] while the reaction with acetone produces a dioxolen.[123] The latter is hydrolysed by atmospheric moisture to the dihydrate of ethyl 4,4,4-trifluoro-2,3-dioxobutyrate:[123]



60—70%

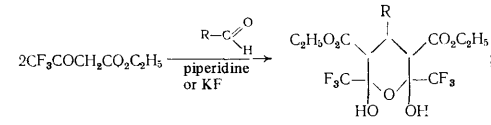


50%

$R_F = CF_3$, C_2F_5, C_3F_7.

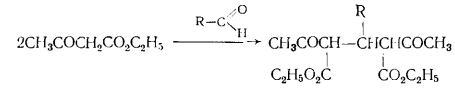
(c) Interaction with Aldehydes

TFAAE condenses with aldehydes, which involves the tetrahydropyran ring closure and the formation of 4-R-3,5-diethoxycarbonyl-2,6-dihydroxy-2,6-bis(trifluoroethyl)-tetrahydropyran:[126]

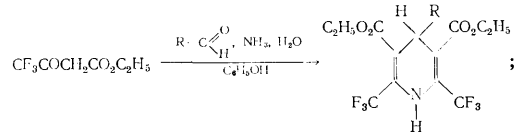


R = H (53%), CH_3 (55%), C_2H_5 (62%), C_6H_5 (19%), *p*-$CH_3C_6H_4$ (38%), *p*-FC_6H_4 (30%).

AAE reacts with aldehydes to form acyclic condensation products:[10]



In the Hantzsch reaction TFAAE apparently behaves in the same way as AAE,[10] forming 4-R-3,5-diethoxycarbonyl-2,6-bis(trifluoromethyl)-1,4-dihydropyridines:[127,128]



R = H, CH_3, C_2H_5, n-C_3H_7, C_6H_5, C_6H_4N, $O_2NC_6H_4$.

However, it has been stated that, in contrast to AAE, TFAAE involved in the Hantzsch synthesis gives rise to 2,6-dihydroxy-4-(*p*-nitrophenyl)-2,6-bis(trifluoromethyl)-piperidine-3,5-dicarboxylate, which does not split off water on treatment with sulphuric acid, acetic anhydride, titanium chloride, or dicyclohexylcarbodiimide.[129]

(d) Reactions of β-FKE Enolates

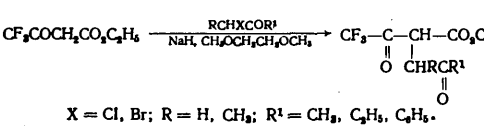
The β-KE enolate anions exhibit a dual reactivity, which depends significantly on the nature of the cation, the type of the ion pair, and the character of the solvent. These questions have been examined in detail in a review.[130] Here we shall deal only with data concerning β-FKE.

In order to account for the reactivity of the enolate anions derived from β-dicarbonyl compounds in alkylation reactions, a calculation based on the distribution of electron density in β-KE has been carried out by the LCAO-MO SCF method in the CNDO/2 approximation for the stable (*W*) and unstable (*U*) conformations of the enolate ions derived from malonic ester, AAE, TFAAE, and the chelate contact ion pair of the lithium enolate derived from AAE in the *U* conformation.[131] It has been shown that the highest negative charge is concentrated at the oxygen atom of the carbonyl group in all the enolate ions (in the *W* and *U* conformations). The introduction of the trifluoromethyl group (TFAAE) reduces the charge of the carbonyl oxygen and on the α-carbon atom of the enolate ion. A decrease of the basicity of the anion and of the alkylation rate constant corresponds to this effect.[132] It has also been established that the reactivity of the enolate ions and ion pairs derived from certain alkali metal enolates in alkylation reactions is controlled by the distribution of electron density in the highest occupied MO of the anion or its ion pair.[131] However, the negative charge on the carbonyl oxygen atom remains higher than on the α-carbon atom in all the structures; consequently the overall distribution of charges is

not the factor determining the result of the reaction, since the α-carbon atom is usually the preferred centre of attack. The distribution of electron density in the highest occupied MO of the anion or the ion pair derived from malonic and acetoacetic esters is consistent with the results of the alkylation, but the reactivity of the TFAAE anion is not controlled by the distribution of electron density in the highest occupied MO, since the alkylation reactions are in this case directed to the carbonyl oxygen atom. The presence of the trifluoromethyl group next to the carbonyl oxyen atom causes an additional increase of the negative electrostatic potential in the region of this atom compared with the region adjoining the α-carbon atom. The role of the electrostatic factor increases and the assumption that the alkylation reaction is controlled solely by electron density in the frontier MO becomes inadequate.[131]

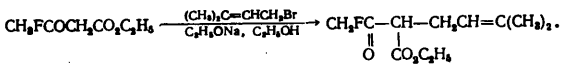
In the light of the above data, the experimental results obtained in the study of the kinetics and of the composition of the products of the alkylation of the sodium, potassium, and caesium enolates derived from AAE and its γ,γ-dimethyl and γ,γ,γ-trimethyl derivatives as well as TFAAE by ethyl tosylate in a highly aprotic solvent (hexamethylphosphoramide) become understandable.[132-134] The formation of only the *O*-isomer has been observed in the alkylation of the caesium enolate of TFAAE, while in the case of AAE and its fluorine-free derivatives, the products of both *O*- and *C*-alkylation are obtained. The effective rate constant for the ethylation of the caesium enolates decreases under these conditions in the sequence AAE > $(CH_3)_2CHCOCH_2CO_2C_2H_5$ > $(CH_3)_2CCOCH_2CO_2C_2H_5$ > TFAAE, while the acidity of β-KE diminishes in the opposite sequence. It has also been shown that, under the given conditions, the reacting species is only the enolate anion.[132,133]

The alkylation of TFAAE by α-chloro- or α-bromo-ketones in the presence of sodium hydride in dimethoxyethane gives rise to the *C*-alkylation products:[135-138]

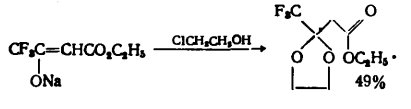


X = Cl, Br; R = H, CH_3; R^1 = CH_3, C_2H_5, C_6H_5.

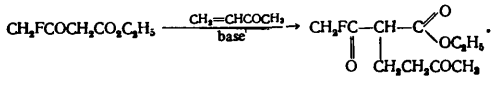
γ-Monofluoroacetoacetic ester is also alkylated at the carbon atom:[139]



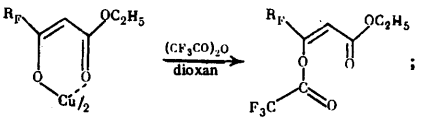
Interesting results have been obtained in the reaction of sodium enolate of TFAAE with ethylenechlorohydrin. This entails the formation of 2-ethoxycarbonylmethyl-2-trifluoromethyl-1,3-dioxolan,[140] while the sodium enolate of AAE reacts with ethylenechlorohydrin to form the *C*-alkylation product:[141]



In the Michael reaction with methyl vinyl ketone, γ-monofluoroacetoacetic and α,γ-difluoroacetoacetic esters give rise to the *C*-alkylation products:[142]

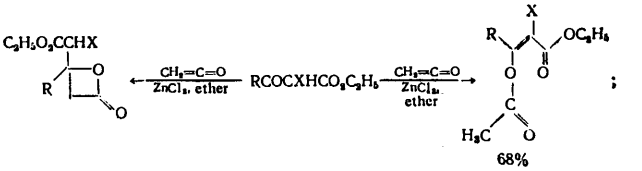


The copper chelates of β-FKE yield unstable *O*-acylation products on acylation with the anhydride of trifluoroacetic acid:[51]



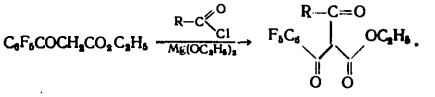
R_F = CH_2F, CHF_2, CF_3. 40-42%

It is of interest that γ-monofluoroacetoacetic ester and TFAAE react with keten to form *O*-acylation products, while α-monofluoroacetoacetic ester gives rise to the product of cycloaddition involving the keto-group under the same conditions, which the authors explain by the lower degree of enolisation of the α-fluoroester:[56]



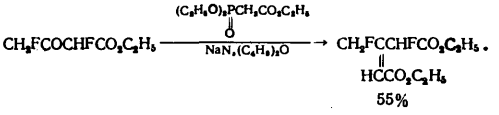
R = CH_3; X = F 68% R = CH_2F, CF_3; X = H.

The acylation of PFBAE by acid chlorides in the presence of magnesium ethoxide makes it possible to obtain *C*-acylation products, which is of interest for the synthesis of β-diketones with pentafluorophenyl groups:[119,143,144]



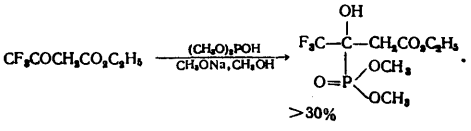
(a) Interaction with Phosphorus-containing Reagents

α,γ-Difluoroacetoacetic ester reacts with diethyl phosphonoacetate to form diethyl 4-fluoro-3-fluoromethylprop-1-ene-1,3-dicarboxylate:[17]



55%

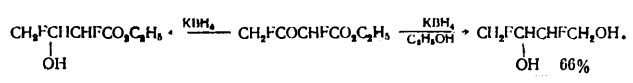
The reaction of TFAAE with dimethyl phosphite affords dimethyl 2-ethoxycarbonyl-1-hydroxy-1-trifluoromethylethylphosphonate:[56]



>30%

3. Oxidation-Reduction Reactions

The reduction of α,γ-difluoroacetoacetic ester with potassium tetrahydroborate involves only the carbonyl group or the ester and carbonyl groups depending on the reactant ratio:[13]



66%

Trifluoroacetoacetic ester reacts with sodium tetrahydroborate to give the product of the reaction of the carbonyl group while in the reaction with lithium tetrahydroaluminate both the carbonyl and ester groups are reduced:[145]

$$CF_3CHCH_2CO_2C_2H_5 \xleftarrow[\text{ether}]{NaBH_4} CF_3COCH_2CO_2C_2H_5 \xrightarrow[\text{ether}]{LiAlH_4} CF_3CHCH_2CH_2OH.$$
$$\quad OH \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad OH \quad 83\%$$

The reduction with hydrogen in the presence of Raney nickel, studied in relation to β-FKE with the heptafluoropropyl group, involves only the carbonyl group:[146–148]

$$C_3F_7COCH_2CO_2CO_3 \xrightarrow[Ni]{H_2} C_3F_7\underset{\displaystyle OH}{\underset{|}{C}}HCH_2CO_2CH_3.$$

The same reaction pathway obtains also in the biochemical reduction of β-FKE by bakers' yeast:[149]

$$R_FCOCH_2CO_2C_2H_5 \xrightarrow{\text{baker's yeast}} R_F\underset{\displaystyle OH}{\underset{|}{C}}HCH_2CO_2C_2H_5;$$
$$R_F = CF_3\,(92\%),\ C_7F_{15}\,(87\%).$$

Pentafluorobenzoylacetic ester is oxidised by selenium dioxide to ethyl pentafluorobenzoylglyoxylate:[82]

$$C_6F_5COCH_2CO_2C_2H_5 \xrightarrow[\text{toluene}]{SeO_2} C_6F_5C\overset{\displaystyle O}{\overset{\|}{-}}C\overset{\displaystyle O}{\overset{\|}{-}}C\overset{\displaystyle O}{\overset{\|}{-}}OC_2H_5.$$
$$(38\%)$$

V. APPLICATIONS

In most cases β-FKE are used as the starting materials for the synthesis of compounds with various useful properties. One of the aspects of the application of β-FKE is based on their capacity for complex formation with metal ions.[136,143,150–157] The β-FKE substituted in the α-position have been patented as extractants for the lanthanide and transuranic elements.[136,143] The chelate complexes of TFAAE with manganese, copper, cobalt, iron, and nickel have been recommended as antioxidants for various liquids and greases.[154] The copper and manganese chelates of β-FKE are effective catalysts in the formation of urethanes from isocyanates and alcohols.[155–157] β-Ketoesters with the heptafluoropropyl group are used as the starting materials for the synthesis of latexes used to impregnate fabrics in order to implant to them water-, oil-, and dirt-repelling properties and to reduce their susceptibility to inflammation.[146–148] TFAAE is used to obtain dyes suitable for the dyeing of synthetic fibres.[80]

The wide range of applications of derivatives of β-FKE such as coumarins,[114,116] pyridonaphthyridines,[112] and pyrroloquinolines [111] is based on their ability to fluoresce and to generate laser radiation.

7-Amino-4-trifluoromethylcoumarin and its salts with aminoacids and peptides are used as fluorescent markers for aminoacids and peptides in biological research.[114] Derivatives of 1,8-naphthyridine, 1,2-dihydropyrido[2,3-*b*]-1,8-naphthyridine, and 2*H*-pyrano[2,3-*b*]-1,8-naphthyridine exhibit a stable fluorescence in the range 393–482 nm in ethanol.[112] 1,6,6,7,8-Pentamethyl-2-oxo-4-trifluoromethyl-6,7-dihydro-1*H*, 2*H*, 8*H*-pyrido[3,2-*f*] indole serves as a source of blue laser radiation.[111]

Many derivatives of β-FKE exhibit physiological and pesticidal activities. α-Alkenyl derivatives of monofluoroacetoacetic ester have a hypocholesterolaemic activity.[86]

R-4-R^1-5-trifluoromethylfurans show coccidiostatic and growth accelerating activities.[135,138] Trifluoromethyltolylisoxazoles exhibit vasodilating, anticonvulsant, and muscle relaxing activities.[85] 1-Substituted 5-pyrazolones are diuretics.[81] 5-Trifluoromethylimidazoles behave as inhibitors of histamine activity.[92]

The ethyl ester of 2-acetoamido-4-trifluoromethylthiazolecarboxylic acid exhibits an antiinflammatory activity.[91] 6-(3-R-5-phenylisothiazolyl-4-formamido)penicillanic acids containing the trifluoromethyl group possess an antibacterial activity.[15]

The trifluoromethyl substituent is also present in thiazolino-5-pyrimidinones, which have been patented as analgesics.[98] Nicotinic and picolinic acids obtained from β-FKE exhibit analgesic and antipyretic activities.[105] 3,5-Diethoxycarbonyl-4-R-2,6-bis(trifluoromethyl)-1,4-dihydropyridines show cytotoxic, bacteriostatic, and hypotensive activities.[127,128] Derivatives of 3-trifluoromethylquinoline—analogues of quinine and quinidine—possess an antimalarial activity.[108–110] 5-Trifluoromethyl-2-R-quinolines are antiradiation reagents.[107] Benzothiopyrans containing fluorine exhibit an antimalarial activity.[118]

Fluorine-containing uracils possess herbicidal properties[69–71] and do not damage maize, flax, safflower, alfalfa, strawberries and gladioli.[88] 6-Trifluoromethyluracil has been used to synthesise 2-amino-6-trifluoromethylpurine, which is used as the antagonist of metabolites.[86] 4-Hydroxy-6-trifluoromethylpyrimidine is the starting material for the synthesis of insecticides.[89]

---o0o---

Thus the introduction of fluorine atoms into the molecules of β-ketoesters is responsible for the appearance of a number of their characteristic features and leads to the alteration of the physicochemical properties, reactivities, and applied properties of these compounds and their derivatives. The existing data concerning their practical application make it possible to use fluorine-containing β-ketoesters and their derivatives in the national economy. At the same time, one should note the almost complete absence of studies of the reaction mechanisms and of the optimisation of the processes described, which undoubtedly holds back the further development of this field of organic chemistry.

Halogenophilic Reactions Involving Derivatives of Four- and Five-coordinate Phosphorus

B.V.Timokhin

The general aspects of halogenophilic reactions of phosphorus compounds have been examined. Examples of the reactions of the halides of four- and five-coordinate phosphorus with readily polarisable nucleophiles, taking place with the transfer of formally positive halogen, have been reviewed.
The bibliography contains 140 references.

I. INTRODUCTION

In the light of the general problem of nucleophilic reactions at a tetrahedral phosphorus atom, the transformations of its halides are of particular interest. The reason is that, because of their accessibility and high reactivity in nucleophilic reactions, phosphorus halides are the compounds on which the organic chemistry of this element is based.

The view is now generally held that in the reaction of phosphorus halides with nucleophilic reagents, the decisive step is the attack on the central atom, and the result is the formation of the products of halogen replacement.[1,2] At the same time there is a fairly large amount of experimental material on the reactions of the halides of four- and five-coordinate phosphorus with a number of nucleophilic reagents, leading to a decrease in the coordination number of the phosphorus atom. Their results cannot be interpreted in terms of replacement reactions. It is apparently for this reason that they have hardly ever been discussed in the theoretical examination of nucleophilic reactions with P^{IV} and P^{V} halides, and have not been reviewed before. In this respect, the situation that has arisen resembles that for nucleophilic reactions in organic halides. These processes have been studied in detail, and are generally interpreted in terms of replacement reactions at a carbon atom. It is found fairly frequently, however, that in spite of a high positive charge on the carbon atom, created by the negative inductive effect of the halogen atoms, for example in polyhalogenomethanes, nucleophilic attack at this atom is hindered. Usually, in these systems, it is directed to a peripheral atom, that is an S_{N^2Hal} reaction, or halogenophilic reaction, takes place, the result of which appears as the transfer of formally positive halogen.[3,4] The prerequisites for this reaction are shielding of the carbon atom by substituents and stability of the carbanion as the leaving group.[4] The ease of nucleophilic attack on the halogen increases in the order Cl ≪ Br < I,[5-8] and its probability increases with increase in the softeness and volume of the nucleophile.[6,9,10] It has been established that these reactions on the whole are characteristic of compounds in which the halogen atom is joined to a carbon atom carrying strong electron-acceptor substituents (ester, carbonyl, nitro-, and sulpho-groups).[5-9] Halogenophilic reactions are also assumed in the reactions of nucleophilic reagents with compounds containing N–Hal,[10-13] O–Hal, and S–Hal bonds.[10]

Comparison of the values of the constants σ_I, σ_m, and σ_n for phosphorus-containing substituents and for groups facilitating the manifestation by the halogen of the properties of an electropositive atom shows that the acceptor characteristics of the phosphorus fragments are similar to or even greater than the latter (see Table). This suggests that halogenophilic reactions should also be possible for compounds having a P–Hal bond. The halides of four-coordinate phosphorus should apparently show the greatest tendency to undergo these reactions. Unfortunately, the acceptor properties have not been determined quantitatively for halogenophosphonium cations, but spectroscopic studies of intramolecular interactions in four-coordinate phosphorus chlorides containing unsaturated groups have shown that the fragment PCl_3^+, for example, has a stronger action than the $POCl_2$ and $PSCl_2$ groups.[15-17]

Values of the constants σ_I, σ_m, and σ_n for different acceptor fragments.[14]

Group	σ_I	σ_m	σ_n	Group	σ_I	σ_m	σ_n
CCl_3	0.41	0.40	0.46	$PSCl_2$	0.59	0.70	0.80
COMe	0.23	0.36	0.47	PF_4	0.45	0.63	0.80
CN	0.57	0.56	0.66	$^+PMe_2PhI^-$	—	0.71	0.83
NO_2	0.68	—	—	$^+PPh_3Cl^-$	0.76	—	—
SO_2Ph	0.57	0.59	0.70	$^+PBu_3Cl^-$	0.60	—	—
PCl_2	0.45	0.53	0.61	$^+PMe_3I^-$	—	0.74	—
$POCl_2$	0.65	0.78	0.90	$^+PMePhI^-$	—	0.71	0.83

Useful information on the electron density distribution in the P–Cl bond in compounds of four-coordinate phosphorus can be obtained by ^{31}P NMR and ^{35}Cl NQR, which make it possible to characterise the electron environment of the two partners forming the bond.[18] Analysis of the relationship between the ^{35}Cl NQR frequencies and the ^{31}P NMR chemical shifts for R_nPOCl_{3-n}, R_nPSCl_{3-n}, and $R_nPCl_{4+n}^+$ showed that with increase in the electron-acceptor properties of the substituent in the compounds of each series,

the NQR frequency increases, and the NMR signal is displaced to a higher field. This is interpreted as a decrease in the polarity of the P–Cl bond. On going from phosphoryl to thiophosphoryl compounds and then to the chlorophosphonium analogues, the NQR frequency increases, and the shielding of the phosphorus nucleus decreases. Judging from the ^{35}Cl NQR spectra, the electron density on the chlorine atom decreases. Evidence in support of this explanation is provided by the recently measured asymmetry parameters of the electric field gradient at ^{35}Cl nuclei in chlorine-containing phosphorus compounds.[19] It was shown for the case of $POCl_3$, $PSCl_3$, and $PCl_4^+.AlCl_4^-$ that the asymmetry parameters of these four-coordinate phosphorus compounds are close to zero, possibly indicating that there is practically no interaction of the unshared electron pairs of the chlorine atom with the phosphorus atom.

A decrease in the polarity of the P–Cl bond may be indicated by the decrease in its length on going from phosphoryl and thiophosphoryl chlorides[20] to the tetrachlorophosphonium cation.[21]

Thus halogenophilic reactions among P^{IV} derivatives should be expected with the highest probability for halogenophosphonium compounds. The reactions of five-coordinate phosphorus halides involving the formation of these quasiphosphonium salts may take place similarly.

In these cases, in the reaction with soft bases,[22] the appearance of the products of the reduction of phosphorus to the three-coordinate state may be accompanied by the simultaneous oxidative chlorination of the nucleophile:

These reactions may not be heterolytic. A possible alternative is one-electron transfer processes. Their examination, however, is outside the scope of the present review, the aim of which was to summarise the reactions of four- and five-coordinate phosphorus halides, taking place with the transfer of formally positive halogen, which have not previously been systematised.

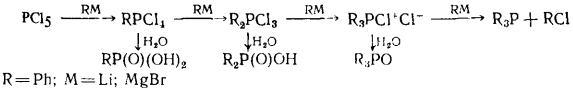
II. REACTIONS WITH ORGANOMETALLIC COMPOUNDS

A large number of reactions of phosphorus halides with organometallic compounds (OMC) are generally regarded as processes of nucleophilic substitution at the phosphorus atom.[23] At the same time, there are data indicating that a whole range of reactions of P^{IV} and P^{V} halides with OMC give products of the reduction of phosphorus to the three-coordinate state.

The first example of a reaction of this kind is the reaction of phosphorus pentachloride with phenylmagnesium bromide,[24] which gives triphenylphosphine in good yield. Reduction of PCl_5 is also observed in its reaction with *para*-trimethylsilylphenylmagnesium bromide.[25] The formation of the corresponding tertiary phosphine was detected in the reaction of phosphorus pentachloride with $PhC{\equiv}CMgBr$.[26]

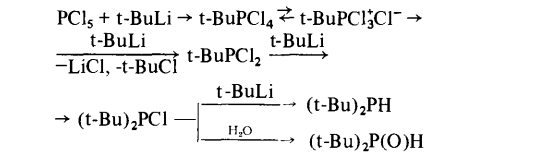
Comparatively recently, more thorough studies of these reactions were carried out, their synthetic possibilities were demonstrated, and a probable mechanism proposed. It was found that tertiary phosphines are obtained only by using an excess of OMC,[27,29,30] and that the yields of the reduction products increases with increase in the volume of the organic group in the OMC.[30] A detailed study of the products of the reaction of PCl_5 with an excess of phenyl-lithium showed that in addition to triphenylphosphine, an equivalent quantity of chlorobenzene is formed.[30] Decrease in the PCl_5 : PhLi ratio to 1 : 3 produces a fundamental change in the nature of the final product. Instead of the tertiary phosphine, its oxide is formed (after hydrolysis). Further decrease in this ratio leads to the formation of a mixture of the corresponding phosphonic and phosphinic acids.[31]

The results indicate that the reaction of five-coordinate phosphorus with phenyl derivatives of lithium and magnesium involve initially the successive replacement of halogen in the pentachloride molecule as far as the triorganodichlorophosphorane structure, whose ionised state makes possible a reduction process in subsequent reaction with the OMC:[31]



R = Ph; M = Li; MgBr

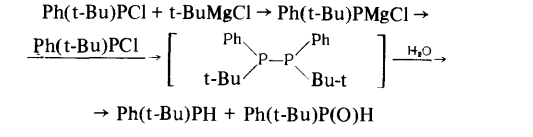
Increase in the volume of the group in the OMC molecule has a significant influence on the result of the reaction. The branching at the α-carbon atom in the isopropyl-lithium molecule leads to a marked increase in the yield of the reduction product.[29] The change to the t-butyl derivative leads to the formation of not the corresponding tertiary phosphine but a mixture of di-t-butylphosphine and di-t-butylphosphinous acid.[30] The presence of these products indicated that the reduction of five-coordinate phosphorus chloride takes place not at the triorganodichlorophosphorane stage but at an earlier stage, and is associated with the appearance of a chlorophosphonium intermediate:



The data obtained are consistent with the fact that it is impossible to replace directly all the chlorine atoms in the P^{III} compound by a t-butyl group, because of steric crowding at the phosphorus.[32,33] In this case the reaction of di-t-butylchlorophosphine, as reduction product, with an excess of the lithium alkyl gives a secondary phosphine, probably by a scheme including the transfer of a hydride ion from the lithium alkyl to the organophosphorus molecule.[32] Hydrolysis of the di-t-butylchlorophosphine remaining gives the secondary phosphine oxide (dialkylphosphonous acid).

Similar conclusions were reached in a study of the reaction of organic derivatives of phosphorus pentachloride with OMC.

The reactions of organyltetrachlorophosphoranes with an excess of an organolithium compound or Grignard reagent also give tertiary phosphines.[34–36] Increase in the volume of the group in the OMC increases the yield of reduction product.[36] The reaction of phenyltetrachlorophosphorane with t-butyl-lithium is influenced by steric and electronic factors. The expected di-t-butylphenylphosphine is not detected, and a mixture of t-butylphenylphosphine and its oxide appears.[30] The reaction probably takes place with the intermediate formation of t-butylphenylchlorophosphine, which subsequently reacts with the lithium alkyl to give the mixture of products indicated, by a scheme analogous to that proposed by Hoffmann for Grignard reagents:[33]



In this case the reduction of the five-coordinate structure at the phosphorus atom takes place at the t-butylphenyltrichlorophosphorane stage, which is different from the results

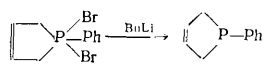
obtained in a detailed study of the reaction of phenyltetrachlorophosphorane with phenyl-lithium.[36] In the last case it was shown that the reduction and the formation of the equivalent quantity of chlorobenzene accompanying it take place at a reagent ratio of 1 : 3, that is at the stage of triphenyldichlorophosphorane formation.

In a study of the reaction of diphenyltrichlorophosphorane with phenyl-lithium in different proportions it was found that with equimolar quantities of the reagents, reduction of the phosphorane is not observed.[37] The hydrolysis of the reaction mixture gives triphenylphosphine oxide. The tertiary phosphine is formed only in a two-fold excess of the lithium aryl. The formation of chlorobenzene shows directly the halogenophilic character of the reaction. Reduction of Ph_2PCl_3 is also observed in the reaction with lithium alkyls. The yield of diphenylalkylphosphines increases with increase in the volume of the alkyl group in the organolithium compound.

The reactions of triorganotrihalogenophosphoranes with OMC have been studied in more detail. It was previously considered[38,39] that the reaction of triphenyldihalogenophosphoranes with alkylmagnesium halides gives triphenylalkylphosphonium salts. It was later established, however, that they are formed only with methylmagnesium iodide.[40] In other cases triphenylphosphine and the corresponding organic halide are obtained. Metallated derivatives of amines, pyrrole, and indole react with triphenyldihalogenophosphoranes to give aminotriphenylphosphonium salts.[41] The authors suggest that halogen transfer takes place at an intermediate stage:

$$Ph_3PHal_2 + RNHMgX \xrightarrow[-MgXHal]{} [Ph_3P + RNHHal] \rightarrow Ph_3P^+—NHR\ Hal^-$$

The reduction of cyclic dihalogenophosphoranes to the corresponding phospholenes under the influence of a lithium alkyl has been detected:[42]



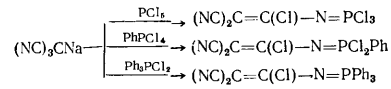
In a study of the reactions of organometallic compounds with chlorophosphoranes it was shown that the species responsible for the reduction of the phosphorus atom to the three-coordinate state are chlorophosphonium structures, either forming the basis of the chlorophosphorane structure or formed during the reaction.[27,36,37] To confirm this, the reactions were carried out between organolithium compounds and chlorophosphoranes shown by ^{31}P NMR,[43,44] ^{35}Cl NQR,[43–46] and ultraviolet spectroscopy[15–17] to be in the ionised state $R_nPCl_4^+{}_{-n}Cl^-$ in solution and in the solid state. For the reactions of $Ph_3PCl^+Cl^-$, $Ph_2EtPCl^+Cl^-$, *iso*-$Pr_3PCl^+Cl^-$, $Et_3PCl^+Cl^-$, *t*-$Bu_2PCl_2^+Cl^-$, and *iso*-$Pr_2PCl_2^+Cl^-$ it was shown that the presence of the chlorophosphonium cation in these compounds makes reduction possible under the influence of organic derivatives of lithium at the first stage of the reduction.[47] The organic halide is formed in quantities equivalent to the reaction product. The process was therefore interpreted in terms of halogenophilic attack on a chlorine atom in the phosphonium cation by the potential carbanion of the organometallic compound. Similar conclusions were reached in a study of the reactions of organolithium and organomagnesium compounds with organylchlorophosphonium hexachlorophosphates having a structurally fixed chlorophosphonium cation:[48,49]

$$R_nPCl_{4-n}^+\ PCl_6^- + R'Li \rightarrow R_nPR'_{3-n} + R'_3P + RCl + LiCl$$

R = Ph, p-ClC_6H_4, p-MeC_6H_4, p-$MeOC_6H_4$, PhCH=CH; R′ = Ph, Alk; n = 1–3

The absence of a chlorine atom in the phosphonium cation of the adduct $Ph_4P^+PCl_6^-$ makes its reduction by phenyllithium in the initial stages of the reaction impossible.[48]

Halogenophilic reactions apparently take place in the reaction of the sodium salt of tricyanomethane with phosphorus pentachloride and its organic derivatives:[50]



This is indicated by the formation of the same compounds by an independent method. Thus the expected products of the halogenophilic reaction of phosphorus pentachloride with $(NC)_3CNa$, namely PCl_3 and tricyanochloromethane, gave the same 1-trichlorophosphazo-1-chloro-2,2-dicyanoethylene.[50] An analogous reaction takes place between $(NC)_3CCl$ and triphenylphosphine.[51] Thus the first stage of the reaction of $(NC)_3CNa$ with P^V chlorides apparently involves halogen transfer:

$$R_nPCl_{5-n} + NaC(CN)_3 \rightarrow NaCl + [R_nPCl_{3-n} + ClC(CN)_3]$$

It is extremely probable that a similar process also takes place in the reaction of organyltetrachlorophosphoranes with malonodinitrile,[52] which is a strong CH acid (pK_a 11.0 [53]):

$$CH_2(CN)_2 + RPCl_4 \rightarrow HCl + [ClCH(CN)_2 + RPCl_2] \rightarrow NC—CH=C(Cl)—N=PCl_2R$$

Halogenophilic reactions can also be assumed in other cases with ionisation of CH acids:[54–56]

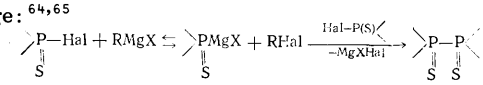
$$Ph_nPCl_{5-n} + CH_2X_2 \xrightarrow{Et_3N} Ph_nPCl_{3-n}=CX_2 + Et_3N\cdot HCl$$

X = COOEt, CN, SO_2Ph; n = 2, 3

The halogenophilic nature of the reaction is also indicated by result of the reaction of PCl_5 with a carbanion stabilised by resonance, such as phosphorus ylid:[57]

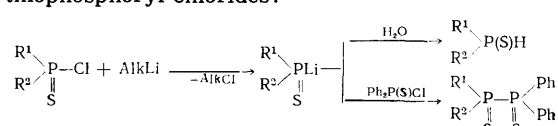
$$Ph_3P^+—\bar{C}(CH_2C_6H_4NO_2\text{-}n)COR + PCl_5 \rightarrow Ph_3P^+—C(Cl)\cdot(CH_2C_6H_4NO_2\text{-}n)COR$$

Among other reactions of OMC with P^{IV} derivatives, the transformations of the phosphoryl chlorides $R_nP(O)Cl_{3-n}$ have been most fully studied. They provide a familiar method for making a phosphorus–carbon bond, interpreted as nucleophilic replacement at the phosphorus atom.[23] The analogous reactions of thiophosphoryl chlorides have been less extensively studied. Work in this direction has established that phosphorus sulphide chlorides and arylthiophosphoryl dichlorides react with aryl-,[58] vinyl-,[59,60] and arylethynylmagnesium halides[60,61] to give tertiary phosphine sulphides. With lower alkylmagnesium halides, an "anomalous" Kabachnik reaction takes place[62,63] to give compounds with a phosphorus–phosphorus bond. The same products are formed with Grignard reagents and thiophosphoryl tribromide.[64] It has been suggested that the most probable scheme for this unusual reaction involves metal–halogen exchange:[64,65]



This scheme is confirmed by the formation of organic halides[49,65] and secondary phosphine sulphides (by hydrolysis of the exchange products).[66]

Organolithium compounds, which have an even greater tendency to undergo exchange reactions, react similarly with thiophosphoryl chlorides:[67]



R^1 = Cl, R^2 = Et, Ph, Cl; Alk = Et, Bu

This metal–halogen exchange reaction possibly takes place by a mechanism involving nucleophilic attack on the halogen. This model, for example, represents one probable scheme for the exchange reactions of organic halides.[68]

A curious feature is that increase in the concentration of the organolithium compound in the above reaction leads to the formation of tertiary phosphines.[69] This may be related to the reduction of the product of exchange by the lithium alkyl, the possibility of which was demonstrated by Trippett.[70]

Thus a soft base such as the potential carbanion of an OMC brings about reactions with various four- and five-coordinate phosphorus halides, whose results cannot be explained in terms of nucleophilic attack at phosphorus. A logical explanation of these reactions is provided by schemes including a halogenophilic reaction.

III. REACTIONS WITH COMPOUNDS OF THREE-COORDINATE PHOSPHORUS

Compounds of three-coordinate phosphorus are soft bases. It is evidently this property of P^{III} compounds that makes possible the unique reactions with polyhalogenohydrocarbons (Appel, Todd–Atherton, etc. reactions) and also with compounds containing an N–Hal or S–Hal bond. The large number of studies in this field have been summarised in several reviews,[10,71,72] where the preferred direction of these reactions, namely attack on the three-coordinate phosphorus compound at the halogen atom, is emphasised.

Similar reactions should naturally be expected for halides of four- and five-coordinate phosphorus.

Thus P^{III} compounds are fairly frequently used to reduce various halogenophosphonium derivatives.

For example, under the influence of phenyldichlorophosphine in the presence of phosphorus oxide chloride, methyldichlorophosphine is formed from the corresponding adduct of the Clay–Kinnear–Perren reaction:[73]

$$MePCl_3^+ AlCl_4^- + PhPCl_2 \xrightarrow{POCl_3} MePCl_2$$

The use of tributylphosphine instead of $PhPCl_2$ lowers slightly the yield of desired product. The reaction of $PCl_4^+SbCl_6^-$ with Bu_3P gives phosphorus trichloride and tributyldichlorophosphorane.[74] The reduction of the adducts $t\text{-}Bu_3PX^+MX_3^-$ (X = Cl, Br; M = Ge, Sn) by the action of $t\text{-}Bu_3P$ has been demonstrated;[75] the products are $t\text{-}Bu_3P.MX_2$ and $t\text{-}Bu_3PX^+X^-$. Another reaction between compounds of three-coordinate phosphorus and compounds containing a chlorophosphonium cation was discovered recently:[76]

$$Ph(R^1)PClX^+ AlCl_4^- + (R^2O)_2PR^3 \xrightarrow{H_2O} Ph(R^1)P(O)R^3$$

R^1 = Me, Et, s-Alk, CH_2OBu; R^2 = Et, Bu; R^3 = OR, OH, Cl; X = Cl, Br

It is suggested that the main stage of the reaction is halogen transfer:

$$\equiv P^+–Hal + (R^2O)_2PR^3 \rightarrow \equiv P: + HalP^+(OR^2)_2R^3$$

The reaction of the products of the Clay–Kinnear–Perren reaction with P^{III} compounds was recently studied in detail.[77] It was shown that these adducts can be reduced by triarylphosphines, triarylphosphites, and diethylaminodichlorophosphine. Chlorination of the reagent to give the corresponding chlorophosphonium salt takes place simultaneously:

$$RPCl_3^+ AlCl_4^- + R'_nPCl_{3-n} \rightarrow RPCl_2 + R'_n PCl_{4-n}^+ AlCl_4^-$$

R = Cl, iso-Pr, CCl_3; R′ = Ph, PhO, *p*-MeOPhO (n = 3), Et_2N (n = 1)

Comparison of the results with data on the reaction of chlorophosphonium cations with nitrogen bases[78] shows that on going from hard compounds, for example pyridines, to soft compounds (P^{III} compounds) there is a fundamental change in the direction of attack by the base. Thus the phosphorus atom shows acceptor properties with respect to the unidentate pyridines, giving stable complexes $PCl_4^+.2Py$, whereas with three-coordinate phosphorus compounds the reaction centre is the chlorine atom, covalently bonded to phosphorus.

Salts of diethyl hydrogen phosphite exist predominantly in the form $(EtO)_2\overset{\cdot}{P}–O^-$ with three-coordinate phosphorus, and have been used to reduce various chlorophosphonium compounds.[79] The products of this reaction also correspond to the halogenophilic reaction scheme:

$$RPCl_3^+ PCl_6^- + 2(EtO)_2P\bar{O}\,H\overset{+}{N}Et_3 \rightarrow RPCl_2 + 2(EtO)_2P(O)Cl + PCl_3 + 2Et_3N\cdot HCl$$

R = PhCH=CH, PhOCH=CH, 
$RP(O)Cl_2$ and $(EtO)_2PCl$ are formed simultaneously in low yields, and this is attributed to the ambidentate character of the diethyl phosphite anion. In this case the oxygen atom, as a hard basic centre, attacks the phosphorus in the phosphonium cation:

$$RPCl_3^+ PCl_6^- + 2(EtO)_2P–O^- \rightarrow RP(O)Cl_2 + 2(EtO)_2PCl + 2Cl^- + POCl_3$$

The appearance of diethylchlorophosphite in the reaction mixture leads to the competing reaction involving the reduction of the original chlorophosphonium compounds under the influence of this tervalent phosphorus derivative:

$$RPCl_3^+ PCl_5^- + (EtO)_2PCl \rightarrow RPCl_2 + 2EtOP(O)Cl_2 + PCl_3 + 2EtCl$$

The presence of ethyl dichlorophosphate in the reaction products confirms that this reaction takes place.

This reaction of salts of diethyl hydrogen phosphite with chlorophosphonium derivatives is directly analogous to the familiar Todd–Atherton reaction, in which the main stage is halogen transfer:

$$CCl_4 + (RO_2)P–O^- \; H\overset{+}{N}R_3 \rightarrow CCl_3^-\overset{+}{H}NR_3 + (RO)_2\overset{Cl}{\overset{|}{P}}=O$$

It has been reported[80] that PH_3 reduces the products of the phosphorylation of alkenes by phosphorus pentachloride, which have a quasiphosphonium salt structure, to the corresponding dichlorophosphines in good yield. AsH_3 reacts analogously:[81]

$$3RPCl_3^+PCl_6^- + EH_3 \rightarrow 3RPCl_2 + 3PCl_3 + 6HCl + 2ECl_3$$

R = EtOCH=CH, BuOCH=CH, PhCH(Cl)–CH_2, BuCH(Cl)–CH_2; E = P, As

Methyldichlorophosphite is used fairly successfully to reduce unsaturated chlorophosphonium derivatives:[82,83]

$$\begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!C=CHPCl_3^+ PCl_6^- \xrightarrow{CH_3OPCl_2} \begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!C=CHPCl_2 + CH_3Cl + POCl_3$$

R^1 = Me, Et; R^2 = H, Me, Cl

Compounds of three-coordinate phosphorus are widely used to reduce phosphorus pentahalides and their organic derivatives.

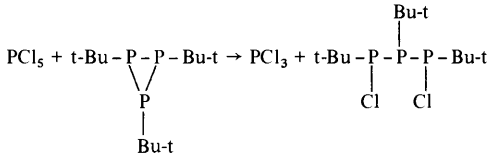
Conductometric[84] and ^{31}P NMR spectroscopic[74] studies of the reaction of phosphorus pentachloride with tertiary phosphines have shown that in the first stage of the reaction at a reagent ratio of 1 : 1, PCl_3 and the triorganyldichlorophosphorane are formed. The use of a two-fold excess of the pentachloride leads to the appearance of the triorganylchlorophosphonium hexachlorophosphate:

$$PCl_5 + R_3P \rightarrow PCl_3 + R_3PCl_2$$
$$R_3PCl_2 + PCl_5 \rightarrow R_3PCl^+ PCl_6^-$$

R = Ph, *p*-MeC_6H_4, *p*-$MeOC_6H_4$, *p*-$EtOC_6H_4$, Bu

The same result was obtained using phenyl- and diphenylchlorophosphines.[74]

Phosphorus pentachloride and pentabromide bring about the rupture of the phosphorus–phosphorus bond in tri-t-butylcyclotriphosphane:[85]

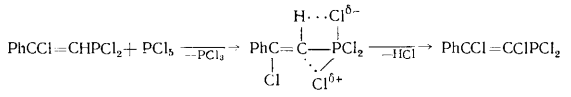


The chlorination of tri-*p*-cyclohexylphenyl phosphite to the corresponding dichlorophosphorane under the influence of phosphorus pentachloride takes place fairly readily.[86]

Unsaturated dichlorophosphines on treatment with PCl_5 give tetrachlorophosphoranes:[87,88]

$$PCl_5 + RCH{=}CHPCl_2 \rightarrow RCH{=}CHPCl_4 + PCl_3$$

The reaction of α-chlorostyryldichlorophosphine with the pentachloride, however, does not give a P^V derivative, because of the ease of the intramolecular chlorination at the vinyl carbon atom.



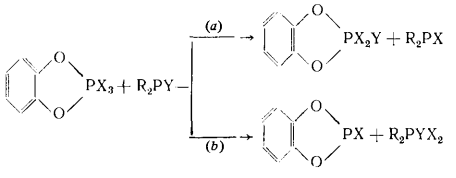
Methyl dichlorophosphite is used to reduce halogenophosphoranes:[89,90]

$$RPCl_4 + CH_3OPCl_2 \rightarrow RPCl_2 + CH_3Cl + POCl_3$$
$$R = Me,\ CCl_3,\ p\text{-}ClC_2H_4C_6H_4$$

Its use to convert distyryl- and tristyrylchlorophosphoranes into the three-coordinate state did not give satisfactory results. In this case, phosphoryl derivatives are obtained.[91]

The reduction of trihalogenophospholenes by triphenylphosphine, which is converted into the triphenyldihalogenophosphorane in the process, has been noted.[92]

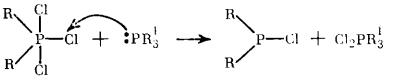
A series of studies of the reaction of P^V halides with compounds of three-coordinate phosphorus was carried out by Gloede and co-workers.[93–96] It was shown for the case of trihalogenodioxaphospholenes that cyclic halogenophosphoranes can undergo ligand exchange (*a*) and halogen transfer (*b*) with P^{III} derivatives:



R = Y = OEt, OPh; R = OPh, Y = Cl; X = Cl, Br

It is emphasised that the redox reactions (*b*) become preferred on going from the chlorides to the bromides of five-coordinate phosphorus.[94] This is consistent with the application of the principle of hard and soft acids and bases (HSAB) to halogenophilic reactions.

It has been suggested that the reduction of halides of five-coordinate phosphorus can take place not only with the participation of their halogenophosphonium form. Unionised trigonal bipyramidal halogenophosphoranes can also take part in halogenophilic reactions, and the reduction takes place as a result of attack on the halogen atom in the equatorial position by the soft base.[97] The electrophilic properties of this atom apparently arise as a result of the reaction of its unshared electron pairs with the phosphorus atom.[19] A similar intramolecular reaction has been assumed for other equatorial ligands.[98] This has been used to explain the reactions of various chlorophosphoranes with tertiary phosphines.[97] Phenyl- and diphenylchlorophosphoranes, which in weakly polar solvents have a trigonal bipyramidal structure with the organic substituents in the equatorial positions, are rapidly reduced by triphenyl- and tributylphosphines to the corresponding chlorophosphines. The reducing agent is converted into the triorganodichlorophosphorane:

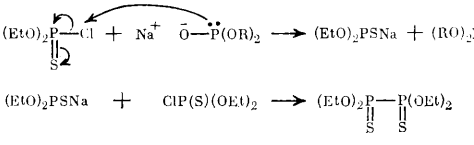


The reaction takes place analogously with CCl_3PCl_4 and $(CCl_3)_2PCl_3$, whose trichloromethyl substituents are in the apical positions.

Tertiary phosphines do not react, however, with triphenyldichlorophosphorane, which in non-polar solvents is probably present in the unionised form.[99] According to the apicophilicity rules,[100] the phosphorane in this form should have a trigonal bipyramidal structure with all the organic substituents in equatorial positions, which structurally excludes the appearance of Cl_{eq} and makes halogenophilic reactions impossible.

The successful use of white phosphorus to reduce P^{IV} and P^V halides can be explained in terms of halogenophilic reactions; the P_4 molecule can be regarded as a derivative of tervalent phosphorus. White phosphorus can reduce triorganodichloro-,[101] diorganotrichloro-,[102] and organotetrachlorophosphoranes,[103] trihalogenophospholenes,[104] and compounds containing a chlorophosphonium cation.[105–107]

Halogen transfer reactions under the influence of P^{III} derivatives are also observed in a number of thiophosphoryl halides. For example, unlike diethyl chlorophosphate, its thio-analogue reacts with sodium diethyl phosphite to give tetraethyl dithiohypophosphate:[108]



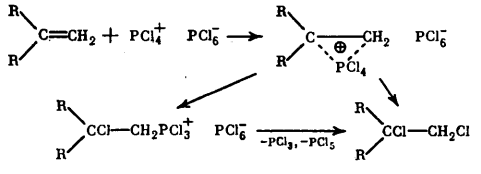
IV. REACTIONS WITH ALKENES AND ARENES

According to the HSAB principle, alkenes and arenes are regarded as soft bases, so that they can be expected to undergo reactions involving attack on a halogen atom in halogenophosphonium compounds or in derivatives of five-coordinate phosphorus.

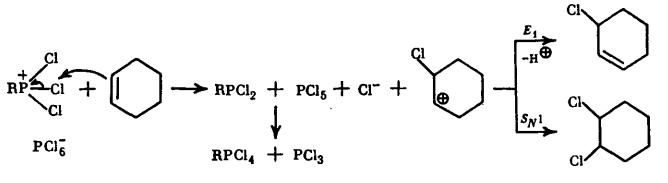
Thus phosphorus pentachloride and its organic derivatives have a chlorinating action on organic compounds of many classes, including various arenes.[109] In addition to the homolytic chlorination of alkylaromatic compounds in the side chain, a heterolytic reaction is also observed. This is indicated for example, by the chlorination of mesitylene to 2,4,6-trimethylchlorobenzene under conditions in which radical processes are inhibited.[110] An attempt was made to explain the chlorinating action of PCl_5 and its derivatives in terms of halogenophilic reactions at the chlorophosphonium cation, present in the crystalline pentachloride.[111] It was found that the model quasiphosphinium salts $PCl_4^+X^-$, where $X = AlCl_4$, BF_3Cl, $SbCl_6$, and PCl_6, and $Ph_nPCl_{4-n}^+PCl_6^-$ can, like PCl_5, chlorinate substituted benzenes in the ring. The ease of chlorination increases with increase in the electron-donor properties of the substituent in the arene. It was shown for the case of anisole that the formation of the chlorination product (*p*-chloranisole) is accompanied by the

simultaneous reduction of the phosphonium salt to three-coordinate phosphorus compounds. A necessary condition for the chlorination of the arene is the presence of chlorine in the phosphonium cation; thus the adduct $Ph_4P^+PCl_6^-$ cannot chlorinate anisole even under severe conditions.

Many authors[110,112,113] report a side reaction giving 1,2-dichloroalkanes in the phosphorylation of alkenes by phosphorus pentachloride. Moderate heating of the products of the phosphorylation of unsaturated compounds with an excess of an alkene in donor solvents (toluene, acetonitrile) also gives these dichlorides.[114] Increase in temperature and the polarity of the medium increases the chlorinating power of PCl_5 with respect to alkenes.[113] It is suggested that in polar media, phosphorus pentachloride ionises, and the resulting tetrachlorophosphonium cation reacts with the unsaturated compound.[110,113] The concerted opening of the epiphosphorane transition state leads to the production of a mixture of chlorination and phosphorylation products.



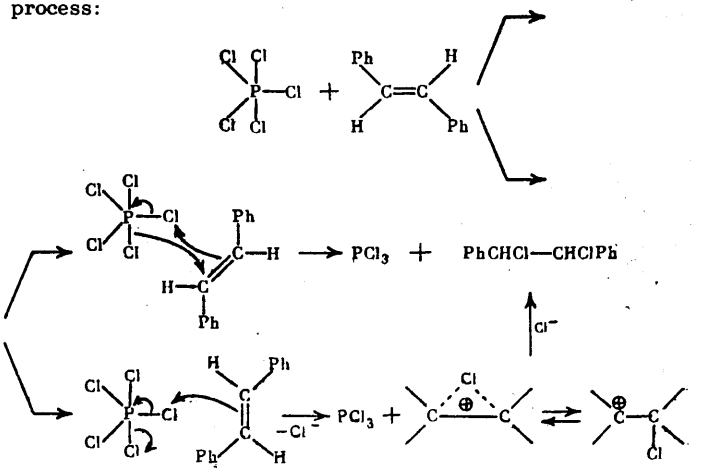
It has been shown for the case of the reactions of chlorophosphonium compounds with cyclohexene that the cation in $R_nPCl_{4-n}^+PCl_6^-$ (R = Ph, PhCH = CH; n = 1–3) is in fact responsible for the formation of alkene chlorination products.[115] Dephosphorylation of the original phosphorus-containing compound is not observed, however, and the corresponding chlorophosphoranes and phosphorus trichloride are formed. This fact, and also the presence of *trans*-dichlorocyclohexane and 3-chlorocyclohexene as alkene halogenation products provide evidence in support of a scheme involving halogenophilic attack by the alkene on the chlorine atom in the phosphonium cation:



Further evidence is provided by the increase in the difficulty of chlorinating cyclohexene with increase in the number of organic substituents in the cation, and by the fact that tetraphenylphosphonium hexachlorophosphate does not react.

It should be emphasised, however, that the formation of dichloroalkanes from alkenes and phosphorus pentachloride in weakly polar media (benzene, dichloroethane) as a result of the production of the halogenophosphonium cation in the reaction sphere does not agree with data on the state of PCl_5 in these solvents. Ultraviolet spectroscopy has shown convincingly that it is present in the unionised form.[116,117]

In a study of the chlorination of *trans*-stilbene by phosphorus pentachloride[118] it was suggested that this reaction be regarded as a halogenophilic reaction involving the unionised form of the phosphorus halide. The attack by the alkene takes place at the halogen atom in the equatorial plane of the trigonal bipyramidal PCl_5. The reaction can take place either as a concerted *anti*-addition or as a stepwise process:



V. REACTIONS WITH HALIDE ANIONS

From the above ideas about the preference of reactions with soft nucleophiles for achieving halogenophilic reactions, processes of this kind should be expected when halogenophosphonium compounds are treated with iodide and bromide anions:

$$\geq\overset{+}{P}\text{—Hal} + \text{Hal}'^- \rightleftarrows \geq P: + \text{Hal—Hal}'$$

The hard chloride anion should not be capable of bringing about these transformations.

Thus crystalline phosphorus pentachloride $PCl_4^+PCl_6^-$ is reduced to phosphorus trichloride by hydrogen iodide,[119] R_4NI,[120] and a mixture of KI and $R_4N^+Cl^-$.[121] PBr_5, which is also ionised in the solid state ($PBr_4^+Br^-$), reacts with tetraorganylammonium iodides to form PBr_3.[122] Analogous reactions take place with phosphorus pentaiodide.[123] All these transformations can be represented by the general scheme:

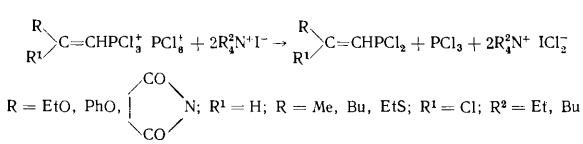
$$PX_5 + R_4N^+I^- \rightarrow PX_3 + IX + R_4N^+X^-$$
$$R_4N^+X^- + IX \rightarrow R_4N^+IX_2^-$$

In this case, tetraorganylhalogenoiodates are formed by the reaction of the interhalogen compound with the ammonium halide.

A similar scheme was observed for the reactions of phosphorus pentahalides with bromide anion donors.[120,122] As expected, the reaction of the chloride anion with chlorophosphonium compounds does not involve reduction. Derivatives of five-coordinate phosphorus are formed,[122,124] corresponding to attack by Cl^- on the phosphorus atom in the phosphonium cation.

It has been noted that the above equilibrium can be displaced towards the formation of reduction products not only by binding the interhalogen compound in a trihalide anion but also by complex formation with p-donors such as cyclic ethers and tertiary amines.[122] This makes it possible to carry out the reduction using potassium iodide.

The reduction of chlorophosphonium derivatives by tetraorganylammonium iodides has been extended to alkene phosphorylation products having a quasiphosphonium structure:[124]



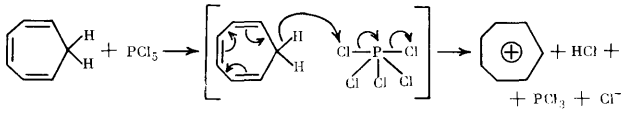
Similar donors of soft halide anions reduce the adducts obtained by the Clay–Kinnear–Perren reaction:[122]

Here, however, it should be noted that if this reaction is carried out using alkyl iodides, spontaneous reduction of the products is observed;[125] this probably involves the I^- ion formed by the ionisation of the organic halide. The formation of triphenylmethylphosphonium salts by the action of methyl iodide on triphenyldihalogenophosphoranes[126] also involves halogen transfer.

VI. REACTIONS WITH OTHER READILY POLARISABLE BASES

The hydride ion, as a soft base, should reduce phosphorus halides capable of halogenophilic reactions. This explains the reduction of triphenyldichlorophosphorane by lithium hydroaluminate[127] and of the adducts $RPCl_3^+AlCl_4^-$ by sodium and calcium hydrides.[128] The formation of tertiary phosphines in the hydrogenation of a large number of triorganodichlorophosphoranes by hydrogen in pyridine takes place for the same reason.[129]

The reaction of phosphorus pentachloride with cycloheptatriene to give tropylium chloride and phosphorus trichloride is explained by the transfer of a hydride ion to the halogen atom:[130,131]



Silicon hydrides readily reduce the products of the phosphorylation of alkenes by phosphorus pentachloride:[132,133]

The reducing power of the silanes decreases with increase in the number of chlorine atoms in the molecule of the silicon-containing reagent. An analogous conclusion was reached in a study of the chlorination of silanes by phosphorus pentachloride.[134]

Sulphur-containing bases such as diorgano sulphides, thiols, the thiocyanate ion, and the thiosulphate ion are soft bases.[22] These reagents should also undergo halogenophilic reactions with phosphorus halides. Thus triphenyl- and tributyldichlorophosphoranes can be reduced by thiophenol and alkanethiols in the presence of triethylamine:[135]

Only small quantities of thiophosphoryl derivatives were formed. This last direction becomes preferred, however, in the reaction of chlorophosphonium derivatives with ethanethiol in the absence of a tertiary amine or with potassium thiocyanate.[136]

Sodium thiosulphate reacts with crystalline phosphorus pentachloride to give $POCl_3$, $PSCl_3$, and PCl_3 in the ratio 5 : 1 : 1. The formation of the last compound involves halogenophilic attack by the $S_2O_3^{2-}$ anion.[137]

The reduction of halogenophosphonium derivatives by carbon monoxide may be noted:[138]

Carbon monoxide is also chlorinated by triphenyldichlorophosphorane.[139] These data agree with the suggestion that the soft base carbon monoxide is capable of halogenophilic reactions.

Halogen transfer is also observed in the reaction of diphenyltrichlorophosphorane with tin(II) chloride.[140]

---o0o---

The above experimental data show that halogen transfer processes are widely encountered in the chemistry of phosphorus halides. Although it is at present difficult to reach an unambiguous conclusion about the mechanism of these reactions, it can be seen that they are described fairly accurately by halogenophilic transformation schemes. In addition to the appearance of products of the reduction of the phosphorus halide, oxidative chlorination of the reagent is also generally observed. It can also be clearly seen that the decisive factor in these reactions is the softness of the base, and the application of the HSAB principle makes it possible to predict the final result fairly confidently.

The type of reaction examined above naturally should not be limited to the examples given, and the future appearance of new transformations which will extend even further the synthetic possibilities of halogen derivatives of phosphorus, an important preparative base in organophosphorus chemistry, can be expected.

Isothiocyanates of Phosphorus Acids, *N*-Phosphorylated Thionocarbamates and Thioureas

R.M.Kamalov, M.G.Zimin, and A.N.Pudovik

Current data on the synthesis, structures, the activities, and practical applications of the isothiocyanates of tri-coordinate, tetracoordinate, pentacoordinate, and hexacoordinate phosphorus acids and *N*-phosphorylated and *N*-thiophosphorylated thiocarbamates, dithiocarbamates, and thioureas are examined and surveyed.
The bibliography includes 223 references.

CONTENTS

I. Introduction 1210
II. Isothiocyanates of phosphorus acids 1210
III. *N*-Phosphorylated thiocarbamates and dithiocarbamates 1218
IV. *N*-Phosphorylated thioureas 1219

I. INTRODUCTION

Compounds in which the isothiocyanato-group is linked directly to the phosphorus atom have been attracting increasing attention by investigators, because, owing to their high reactivity, they serve as valuable starting materials and intermediates for the synthesis of a wide variety of organophosphorus compounds which are of both theoretical and practical importance.

Approximately 15 years have elapsed since the publication of the first reviews[1,2] devoted to the methods of synthesis, physicochemical properties, and applications of the isothiocyanates of phosphorus acids. During this period, the chemistry of phosphorylated isothiocyanates has developed further. It has now become necessary to survey and as far as possible arrange systematically the extensive and interesting data which have been published in recent years on this topic in the world chemical literature. Extremely unstable phosphorylated thiocyanates with the structure P–S–C≡N were synthesised and investigated for the first time during the last decade.[3-6] These compounds are intermediates in many methods of synthesis of isothiocyanates of phosphorus acids and for this reason we thought it desirable to consider them also in the present review.

According to patent data, the isothiocyanates of phosphorus acids have found applications as pesticidal[7,8] and bactericidal[9-12] preparations, as antitear and antiwear additives to lubricating oils,[13] as additives to natural and synthetic materials imparting fire resistance,[7,9,14,15] as stabilisers of polyoxymethylene,[16] as components of a cadmium-plating electrolyte which increase the corrosion resistance of the coating,[17] and as starting materials for the preparation of cation-exchange membranes.[18] In addition polymeric materials with fire-resistant properties whose molecules contain the P–N=C=S group have been synthesised.[19,20]

Among the products obtained from phosphorus-containing isothiocyanates, *N*-phosphorylated and *N*-thiophosphorylated thiocarbamates, dithiocarbamates, and thioureas occupy a special place in view of the wide variety of their practical applications. The methods of synthesis of *N*-(thio)phosphorylated thio- and dithio-carbamates, based on the reactions involving the addition of alcohols, alkoxides, mercapto-compounds, and certain acids to phosphorylated isothiocyanates, are therefore described in a special section of this review. The synthesis and properties of phosphorylated thioureas are examined in the concluding section of our review, which includes only data published after the review articles on phosphorus-containing thioureas.[1,21] In Sections III and IV we thought it essential to discuss not only the addition of various proton-donating reagents to the isothiocyanato-group but also other reactions leading to *N*-phosphorylated thio- and dithiocarbamates and thioureas. Heterocyclic derivatives in which the thiocarbamoyl group is incorporated in a ring are an exception; the chemistry of these compounds has been fairly completely described in another review[22] and is not considered in the present article.

II. ISOTHIOCYANATES OF PHOSPHORUS ACIDS

1. Methods of Synthesis

Various derivatives of tricoordinate, tetracoordinate, pentacoordinate, and hexacoordinate phosphorus containing the isothiocyanato-group linked directly to the phosphorus atom have now been obtained. Previous reviews[1,2] described the methods of their synthesis by the reactions of phosphorus acid halides with salts of thiocyanic acid or trimethylsilyl isothiocyanate, of partial esters of phosphorus(III) acids with thiocyanogen, of salts of dialkylphosphorodithioic acids with bromocyanogen, and of pyrophosphates and metaphosphonodithioates with potassium thiocyanate.

The first of the methods listed above continues to be the most convenient and most widely used because of the ready availability of the starting compounds.[3,4,7,23-40]

The interaction of phosphonochloridothioites with lead thiocyanate in ether leads to the formation of *S*-alkyl alkyl(aryl)phosphonoisothiocyanatidothioites (I):[23]

$$2R^1(R^2S)PCl + Pb(SCN)_2 \rightarrow 2R^1(R^2S)PNCS + PbCl_2. \quad (I)$$

The reactions of pentavalent phosphorus acids halides with potassium thiocyanate (or silver thiocyanate) yielded the corresponding isothiocyanates and dithiocyanates (II):[7,24-27]

$$R_nP(X)Hal_{(3-n)} + (3-n)\,KSCN \rightarrow R_nP(X)(NCS)_{3-n} + (3-n)\,KHal;$$
$$X = O, S;\ Hal = Cl, Br;\ n = 1, 2 \quad (II).$$

The reactions are usually carried out in acetone or acetonitrile between 5° and 100 °C.

Investigators have devoted much attention to the synthesis of isothiocyanates containing the phosphazene and other inorganic rings. Isothiocyanato-derivatives of phosphazenes (III) can be obtained by treating chlorophosphazenes with alkali metal or ammonium thiocyanates in organic solvents:[28]

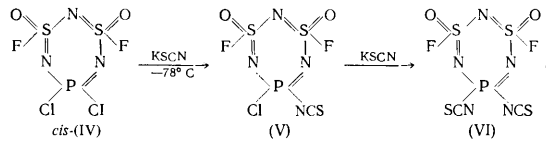
$$(NPCl_2)_n + 2n\text{KSCN} \rightarrow [NP(NCS)_2]_n + 2n\text{KCl};$$
$$n = 3, 4. \qquad \text{(III)}$$

The synthesis of fluoroisothiocyanatophosphazenes by the reaction of the corresponding monochloro- or monobromoperfluorophosphazenes with potassium or silver thiocyanate has been described.[29,30] Tetrachlorodiisothiocyanatocyclotriphosphazene has been synthesised by the reaction of $(NPCl_2)_3$ with potassium or ammonium thiocyanates.[31,32] Hexachlorodiisothiocyanato- and tetrachlorotetraisothiocyanatocyclotetraphosphazenes have been obtained analogously.[33]

It has been shown[34] that, on refluxing with KSCN in acetonitrile, 1,3,5-trichloro-1,3,5-triphenoxycyclotriphosphazene gives rise to a 96% yield of the corresponding triisothiocyanato-derivative. However, the reaction under the same conditions involving 1,3,5-tributoxy-1,3,5-trichlorocyclotriphosphazene yielded butyl thiocyanate and an oligometric product whose molecules were made up of phosphazene rings joined by P–O–P linkages and containing exocyclic butoxy- and thiocyanato-groups.

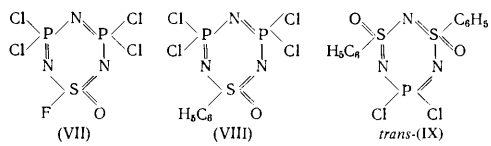
After treating compound (IV), having the *cis*-configuration, with potassium thiocyanate, the monoisothiocyanato-compounds (V) and the diisothiocyanato-compounds (VI) were isolated:[35]

Scheme 1



cis-(IV) (V) (VI)

Monoisothiocyanato-derivatives in the form of two (*cis*- and *trans*-) isomers have been obtained in proportions of 1:1 from compounds (VII) and (VIII) and compound (IX) having the *trans*-configuration:[36]



(VII) (VIII) *trans*-(IX)

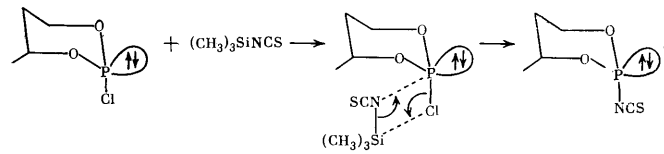
Two and four isothiocyanato-groups can be introduced into compounds (VII)–(IX) under appropriate conditions.[36]

The interaction of trimethylsilyl isothiocyanate with the chlorides of tricoordinate and tetracoordinate phosphorus acids may entail the complete exchange of halogen atoms for isothiocyanato-groups:[41,42]

$$R_{3-n}P(X)Cl_n + n(CH_3)_3SiNCS \rightarrow R_{3-n}P(X)(NCS)_n + n(CH_3)_3SiCl;$$
$$n = 1, 2, 3;\ X = \text{unshared electron pair of O and S.}$$

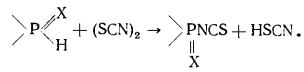
It has been demonstrated by ^1H NMR for the chloride of 1,3-butylenephosphorous acid that the reactions proceed stereospecifically with retention of the configuration at the phosphorus atom.[41] It can be shown that the reaction involves a cyclic electron transfer (Scheme 2), although one cannot rule out the possibility that the substitution takes place with the inversion and subsequent epimerisation of the reaction product at a high temperature:

Scheme 2



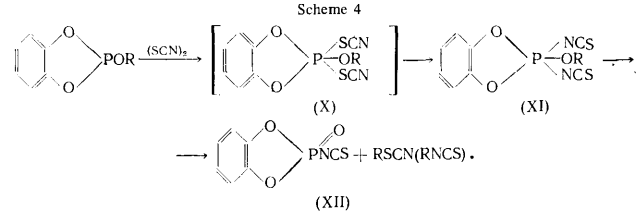
Various, including optically active, isothiocyanates of tetracoordinate phosphorus acids have been obtained in accordance with Scheme 3:[4,6,37]

Scheme 3



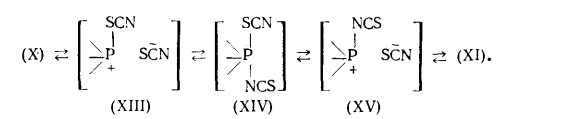
o-Phenylene phosphoroisothiocyanatidate (XII) is formed when alkyl *o*-phenylene phosphites are acted upon by thiocyanogen.[43] The diisothiocyanatophosphoranes (XI), which are stable at −40 °C and, for R = C_6H_5, also at room temperature, arise in the first stage of this reaction (Scheme 4). An increase of temperature leads to the decomposition of compounds (XI) into the phosphoroisothiocyanatidate (XII) and an alkyl thiocyanate or an alkyl isothiocyanate depending on the structure of the substituent R. When R was a primary alkyl group, an alkyl thiocyanate was formed but, when R was a secondary alkyl group, a mixture of thio- and isothio-cyanates was isolated:[44]

Scheme 4



(XII)

It has been suggested[43] that the reaction begins with the concerted addition of $(SCN)_2$ to the phosphorus atom with formation of the intermediate (X), whose conversion into the isomer (XI) is believed[43] to proceed via the equilibrium between the phosphonium structures (XIII) and (XV) and the phosphorane structure (XIV):



(XIII) (XIV) (XV)

The interaction of triphenylphosphine with thiocyanogen at −40 °C in CH_2Cl_2 leads to the phosphonium salt (XVI):[44,45]

$$(C_6H_5)_3P + (SCN)_2 \rightarrow (C_6H_5)_3\overset{+}{P}NCS\ \overline{SCN}.$$
$$\text{(XVI)}$$

When organophosphorus acids are added to the salt (XVI), phosphorylated isothiocyanates are formed in a high yield.[44] Phosphoranes and phosphonium salts of type (XI) and (XVI), containing isothiocyanato-groups, can also be obtained in a quantitative yield by the stepwise substitution of the chlorine atoms in the corresponding dichlorophosphoranes on treatment with trimethylsilyl isothiocyanates[46] or metal thiocyanates in the presence of a crown-ether.[44,46]

Phosphorus acid isothiocyanates are formed in the reactions of phosphorodithioic acids with cyanamides[47,48] and of phosphorothioic and phosphorodithioic acids with organic cyanates and thiocyanates[49–51] and also in the three-component reaction of diphenylphosphinous acid, ammonium

thiocyanate, and HCl.[52] None of these reactions are of preparative value for the synthesis of phosphorylated isothiocyanates because of the low yields and the difficulty of isolating pure products from the reaction mixture. However, a convenient method has been proposed for the synthesis of phosphoroisothiocyanatidothioates (XVII) [51,53] by the reaction of phosphorodithioic acids with an excess of alkyl thiocyanates at 80–100 °C:

$$R^1SCN + (R^2O)_2PSSH \xrightarrow{80-100^\circ C} \underset{(XVII)}{(R^2O)_2P(S)NCS} + R^1SH.$$

The reactions of bisphosphinyl disulphides (XVIII) with cyanide anion proceed via a stage involving the formation of the phosphinothioate anion (XIX) and the phosphinic thiocyanate (XX) which rearranges to the phosphinic isothiocyanate (XXI) (Scheme 5).[54] The final reaction products are the pyrophosphinomonothiomic anhydrides (XXII). When bulky substituents (for example, t-C_4H_9 or C_6H_5) are introduced at the phosphorus atom, the reactions stop at the stage involving the formation of the isothiocyanates (XXI):

Scheme 5

$$\underset{(XVIII)}{\left[R^1R^2P(O)S\right]_2} + CN^- \longrightarrow R^1R^2P(O)\!-\!S\!-\!S\!-\!P(O)R^1R^2 \longrightarrow$$
$$\longrightarrow \underset{(XIX)}{R^1R^2P(S)O^-} + \underset{(XX)}{\left[R^1R^2P(O)SCN\right]} \longrightarrow$$
$$\longrightarrow \underset{(XXI)}{R^1R^2P(O)NCS} + (XIX) \longrightarrow \underset{(XXII)}{R^1R^2P(O)OP(S)R^1R^2} + \bar{S}CN.$$

It has been shown by ^1H NMR that the fluoride of methylphosphonoisothiocyanatidic acid disproportionates with formation of the difluoride and the diisothiocyanate of methylphosphonic acid on heating (at 80 °C) for 10 weeks.[27]

In many cases phosphorylated isothiocyanates are synthesised by reactions of compounds already containing the P–NCS groups, which are accompanied by an increase of the coordination number of the phosphorus atom. Thus dialkyl phosphoroisothiocyanatidites enter into the Arbuzov reaction with alkylsulphenyl chlorides and are converted into *SO*-dialkyl phosphoroisothiocyanatidothioates (XXIV):[55]

$$\underset{(XXIII)}{(R^1O)_2PNCS} + R^2SCl \rightarrow \underset{(XXIV)}{(R^1O)(R^2S)P(O)NCS} + R^1Cl.$$

Vinyl phosphoroisothiocyanatidates and phosphorodiisothiocyanatidates can be obtained by means of the Perkow reactions from phosphoromono- and phosphorodiisothiocyanitidites, trichloroacetylphosphonate [40] and halogenopyruvate[56,57] esters, and hexachloroacetone.[57] Isothiocyanatospirophosphoranes have been synthesised by the reaction of the isothiocyanates of cyclic phosphorous acids with tetrachlorobenzoquinone [39] and dienes.[58]

A tetraisothiocyanato-derivative of hexacoordinate phosphorus (XXVI) has been synthesised from diaryloxytriisothiocyanatophosphorane (XXV) and tetraalkylammonium thiocyanate:[59]

$$\underset{(XXV)}{(C_6H_5O)_2P(NCS)_3} + Alk_4\overset{+}{N}\,N\bar{C}S \rightarrow \underset{(XXVI)}{(C_6H_5O)_2\bar{P}(NCS)_4}Alk_4\overset{+}{N}.$$

2. Phosphorothiocyanatidates and Their Rearrangement to Phosphoroisothiocyanatidates

In many of the reactions considered above one might have expected the initial formation of phosphorothiocyanatidates, which can rearrange to phosphoroisothiocyanatidates.

The first examples of phosphoroisothiocyanatidates were obtained as early as the beginning of this century, but were erroneously assumed to be the thiocyanato-derivatives.[1] The error was not corrected until the middle 1950's and in subsequent years it was established that phosphorothiocyanatidates are extremely unstable and exhibit a pronounced tendency towards isomerising to the isothiocyanatidates. The first reliable report of the synthesis of a phosphorothiocyanatidate, namely dineopentyl phosphorothiocyanatidate (XXVII), was published in 1972.[3] Compound (XXVII) was obtained by treating dineopentyl phosphorylsulphenyl chloride (XXVIII) with silver cyanide[3] or (better) with trimethylsilyl cyanide[60] in methylene chloride in the absence of atmospheric moisture and oxygen at −5 °C. At room temperature the rapid and irreversible rearrangement of the thiocyanato-derivative (XXVII) to the corresponding isothiocyanato-derivative (XXIX) is observed, the latter having being also synthesised by an independent procedure:

$$\underset{(XXVIII)}{[(CH_3)_3CCH_2O]_2P(O)SCl} + AgCN \rightarrow \underset{(XXVII)}{[(CH_3)_3CCH_2O]_2P(O)SCN}$$
$$\downarrow$$
$$[(CH_3)_3CCH_2O]_2P(O)Cl + KSCN \rightarrow \underset{(XXIX)}{[(CH_3)_3CCH_2O]_2P(O)NCS}.$$

Phosphorothiocyanatidothioates, which proved to be more stable than their oxygen analogues, have been synthesised by the same method.[4] Later new examples of the synthesis of similar compounds were published.[4–6,37,54,60–63] Stereochemical study of the rearrangement of phosphorothiocyanatidates to phosphoroisothiocyanatidates using diastereoisomeric cyclic[4,37] and optically active acyclic[5] model systems showed that it proceeds with total inversion of the configuration at the phosphorus atom. It has been noted that the isomerisation is accelerated in the presence of nucleophiles,[4,5] which was confirmed by the fact that carefully purified phosphorothiocyanatidates are stable in the absence of access by atmospheric oxygen. Their stability also increases in the presence of BF_3, which functions as a "nucleophile trapping agent".[4]

The authors suggest that the mechanism involving nucleophilic substitution at the phosphoryl centre is the most likely for the rearrangement.[4,5] Under the influence of atmospheric moisture or some other nucleophiles present in the reaction mixture at low concentrations, the thiocyanate anion is generated from the phosphorothiocyanatidates (XXX) via Scheme 6 at the beginning of the reaction. As a result of the nucleophilic attack by the nitrogen atom (a hard base) on the phosphorus atom of the thiocyanate anion (a hard acid centre) of the phosphorothiocyanatidate (XXX), the phosphoroisothiocyanatidate (XXXI) is then formed:

Scheme 6

$$Nu^- + \underset{(XXX)}{>P(X)SCN} \longrightarrow >P(X)Nu + S\bar{C}N;$$

$$S\bar{C}N + \underset{(XXX)}{X\!=\!P\!-\!SCN} \longrightarrow \left[\underset{(XXXII)}{SCN\!-\!\overset{X^-}{P}\!-\!SCN}\right]^{\neq} \longrightarrow$$

$$\longrightarrow \underset{(XXXI)}{SCN\!-\!P(X)<} + S\bar{C}N.$$

An addition–elimination mechanism with formation of a short-lived phosphorane intermediate having a trigonal-bipyramidal structure with the SCN groups in the apical positions cannot be ruled out, according to the authors,[5] for the substitution reaction considered. However, they give preference to the concerted mechanism with the transition state (XXXII) [reaction of the $S_N2(P)$ type] having the same geometry (Scheme 6).

Special investigations have shown[4,6] that many reactions leading to phosphoroisothiocyanatidates involve the formation of the corresponding thiocyanatidates as intermediates. The reactions of phosphorus acid halides with potassium thiocyanate have attracted particular attention in this connection. The available facts indicate that phosphorothiocyanatidates are not formed as intermediates in these reactions.

3. The Properties of Phosphoroisothiocyanatidates

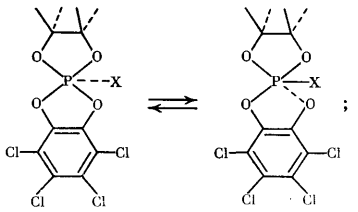
(a) Studies on Phosphoroisothiocyanatidates by Physicochemical Methods

Some data on the IR, NMR, and UV spectra of phosphorylatedisothiocyanates have been published in earlier reviews.[1,2]

In the IR spectra the ν_{as} absorption bands of the isothiocyanato-group linked to the phosphorus atom are in the range 1990–2000 cm^{-1};[29,64] in the range 730–910 cm^{-1}, intense ν(P–N) bands are present.[64] The ν(P=O) bands are located in the range 1220–1280 cm^{-1} [64] and the ν(P=S) frequencies are also close to the usual values.

It has been noted[35,36] that the introduction of the NCS group into the cyclic compounds (IV), (VII), (VIII), and (IX) induces an appreciable (up to 30 p.p.m. per NCS group) downfield shift of the signals due to the phosphorus nuclei in the ^{31}P NMR spectra.

By recording the NMR spectra over a range of temperatures, Trippett et al.[39] determined the free energy of activation ΔG^* for the pseudorotation (XXXIIIa) ⇌ (XXXb) of the isothiocyanato-group, which proved to be 17.8 kcal mol^{-1}.



(XXXIIIa) X = NCS, NCO, Cl (XXXIIIb).

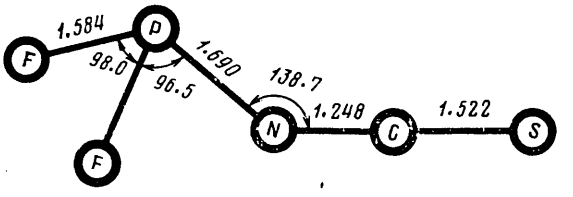
The quantity ΔG^* for the isocyanato-group is 17.5 kcal mol^{-1}. In terms of their apicophilic properties, both these groups (NCO and NCS) are close to the chlorine atom, for which ΔG^* is 17.8 kcal mol^{-1}.

The mass spectra of diethyl phosphoroisothiocyanatidate,[65] hexaisothiocyanatocyclotriphosphazene, and octaisothiocyanatocyclotetraphosphazene [66] have been investigated. The characteristic processes involving the decomposition of diethyl phosphoroisocyanatidate [65] involve the initial rupture of the P–N bond or the decomposition of ethoxy-groups, accompanied by the loss of the CH_3, C_2H_3, and C_2H_4 fragments. The mass spectra of cyclic isothiocyanates [66] indicate a greater stability of the phosphazene ring. The fragmentation of the NCS group takes place either with the elimination of the sulphur atom or with the loss of a S_2 molecule, or with the elimination of a CS_2 molecule. Data for the mass spectra of phosphoroisothiocyanatidates can also be found in other communications.[32,35,36,67]

The crystal and molecular structures of the isothiocyanates of trimeric [68] and tetrameric [69] cyclophosphazenes have been investigated by X-ray diffraction. The results have lead to the conclusion that the P–N linkage in the fragment

has a certain amount of double bond character.

A wider range of physicochemical methods have been used by investigators in the study of the molecular structure of difluoroisothiocyanatophosphine F_2PNCS (XXXIV).[70–73] The IR and Raman spectra in the gas phase, in the intermediate and far regions, have been obtained and discussed.[70,71] It has been demonstrated by photoelectron spectroscopy[72] that the lowest ionisation potentials in the molecule of compound (XXXIV) are those of the electrons of one of the π-bonds of the NCS group (10.2 eV) and the unshared electron pair of the phosphorus atom (11.9 eV). The parameters of the bond lengths and angles have been determined by electron diffraction[70] and have been refined[73] by employing a combination of electron diffaction and ^1H NMR methods in a liquid crystal solvent (see Figure). It has been shown[70] that the isothiocyanato-group is in the *trans*-position with respect to the FPF bisector.



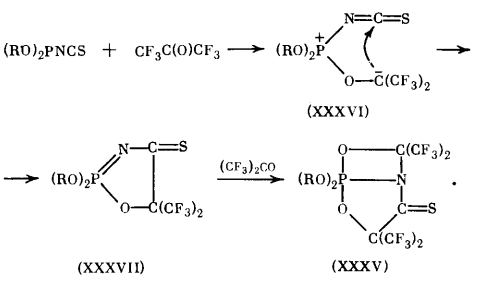
The bond lengths (Å) and valence angles (degrees) in the molecule of difluoroisothiocyanatophosphine (XXXIV).[173]

(b) Reactions of the Isothiocyanates of Phosphorus(III) Acids

Reactions involving an increase of the coordination number of the phosphorus atom and cycloaddition reactions with participation of the P̈N=C=S fragment, which plays the role of a 1,3-dipolar reagent, are most characteristic of phosphorus-(III) acid isothiocyanates.

The first example of the cycloaddition reaction has been described by Trippett and co-workers,[74] who investigated the interaction of hexafluoroacetone with dialkyl phosphoroisothiocyanatidites. A crystalline 1 : 2 adduct, the bicyclic phosphorane (XXXV), was obtained as a result:

Scheme 7



(XXXVI) (XXXVII) (XXXV)

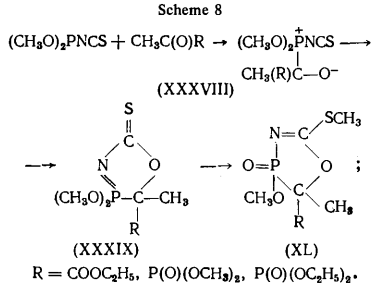
The betaine (XXXVI) (Scheme 7) is formed in the first stage and then cyclises to the imide (XXXVII), which is subjected to electrophilic attack by a second hexafluoroacetone molecule with the consequent formation of the bicyclic phosphorane

(XXXV). The strain in the trigonal bipyramid of the phosphorane becomes minimal, according to the authors,[74] when both rings occupy axial-equatorial positions and the nitrogen atom is then located in the equatorial position.

In subsequent studies a wide variety of carbonyl, imino-, and other unsaturated compounds were made to undergo the cycloaddition reaction with phosphorus(III) isothiocyanates.[40,75-78]

The interaction of dimethyl phosphoroisothiocyanatidite with acetyl phosphonates[75] and pyruvate esters[40] begins with nucleophilic attack by the phosphorus atom on the carbon atom of the carbonyl group. The dipolar ion (XXXVIII) cyclises to the intermediate (XXXIX) with a phosphimide linkage (Scheme 8). The subsequent imide–imide rearrangement with *S*-alkylation leads to substituted 3-methoxy-2-methyl-5-methylthio-3-oxo-1,4,3-oxaza-4-phospholens (XL):

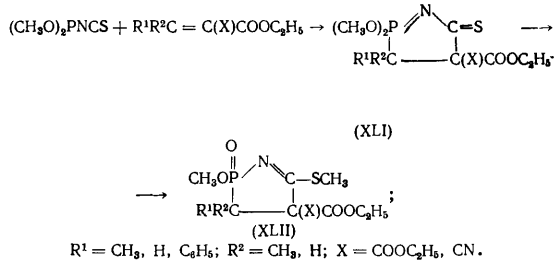
Scheme 8



(XXXVIII) (XXXIX) (XL)

R = $COOC_2H_5$, $P(O)(OCH_3)_2$, $P(O)(OC_2H_5)_2$.

In the reactions of dimethyl phosphoroisothiocyanatidite with esters of methylene- and ethylidene-malonic acids[76] and alkylidene derivatives of cyanoacetic ester,[77] the intermediates (XLI) with a P=N bond are also stabilised by the imide–imide rearrangement, being converted into *S*-alkylated products (XLII), which are formed as a mixture of the geometrical isomers:

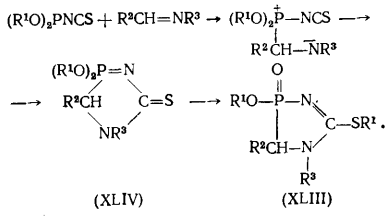


(XLI) (XLII)

$R^1 = CH_3$, H, C_6H_5; $R^2 = CH_3$, H; X = $COOC_2H_5$, CN.

It has been noted that the alkylidene derivatives of cyanoacetic ester are more reactive than the alkylidene derivatives of malonic ester as a consequence of the higher degree of polarisation of the double bond by the cyano-group.

The interaction of dialkyl phosphoroisothiocyanatidites with *N*-methylbenzylideneamine and *N*-phenyl and *N*-methyltrichloroethylideneamines results in the formation of 1,2-substituted 3-alkoxy-5-alkylthio-3-oxo-1,4,3-diaza-4-phospholens (XLIII):[78]

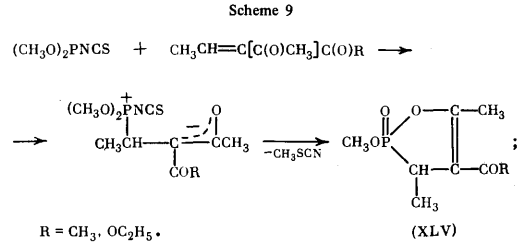


(XLIV) (XLIII)

When dimethyl phosphoroisothiocyanatidite was made to react with *N*-methyltrichloroethylideneamine, the authors isolated the products of the hydrolysis of the intermediate (XLIV) with a P=N bond—3-methoxy-1-methyl-3-oxo-2-trichloromethyl-1,4,3-diazaphospholan-5-thione.

In certain reactions of phosphoroisothiocyanatidites with unsaturated compounds the cycloaddition products involving the isothiocyanato-group are not formed and the pseudohalogen properties characteristic of this group are manifested. Thus the reactions of dimethyl phosphoroisothiocyanatidite with ethylideneacetylacetone and ethylideneacetoacetic ester lead to the formation of 4-substituted 2-methoxy-3,5-dimethyl-2-oxo-1,2-oxa-4-phospholens (XLV) and methyl thiocyanate (Scheme 9):[76]

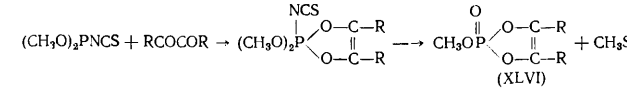
Scheme 9



R = CH_3, OC_2H_5. (XLV)

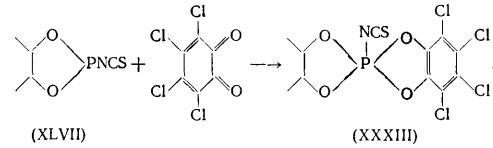
The reaction proceeds via a 1,4-cycloaddition mechanism with subsequent dealkylation in conformity with the second stage of the Arbuzov rearrangement.

The interactions of dimethyl phosphoroisothiocyanatidite with diacetyl and benzil lead similarly to the formation of 4,5-dimethyl- and 4,5-diphenyl-derivatives of 2-methoxy-2-oxo-1,3,2-dioxa-4-phospholens (XLVI):[79]



(XLVI)

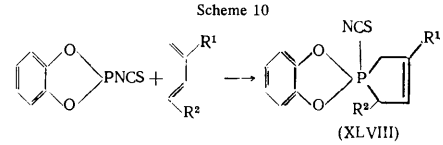
The reactions of α-dicarbonyl compounds with the isothiocyanates of cyclic phosphorous acids stop at the stage involving the formation of isothiocyanatospirophosphoranes, which is illustrated by the formation of compound (XXXIII) by the reaction of isothiocyanates of the 1,3,2-dioxaphospholan series (XLVII) with tetrachloro-*o*-benzoquinone:[39]



(XLVII) (XXXIII)

An analogous reaction in accordance with Scheme 10, which results in the formation of isothiocyanatophosphoranes (XLVII), takes place when *o*-phenylene phosphoroisothiocyanatidite reacts with 1,3-dienes, such as divinyl, isoprene, piperylene, and chloroprene:[58]

Scheme 10

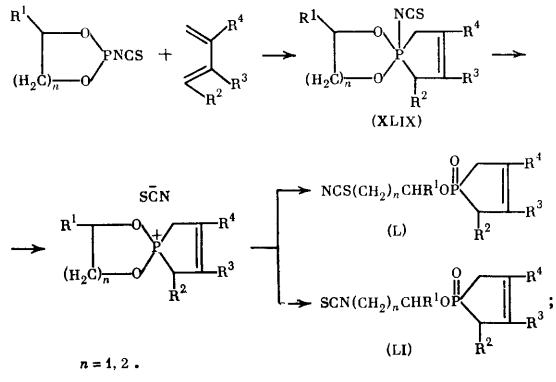


(XLVIII)

The reactivity of the dienes in condensation with phosphoroisothiocyanatidites decreases in the sequence isoprene > divinyl > piperylene > chloroprene. These data permit the conclusion that the phosphorus-containing component behaves as an electrophile. The condensation of ethylene and 1,3-butylene phosphoroisothiocyanatidites[80,81] with the same dienes does not stop at the isothiocyanatophosphorane (XLIX) stage. The phosphorane undergoes the second stage of the

Arbuzov rearrangement, giving rise to compounds of tetracoordinate phosphorus (L) and (LI):

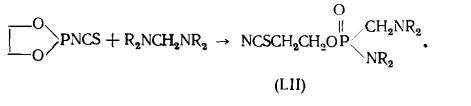
Scheme 11



The reactions with piperlyene and 2,3-dimethylbuta-1,3-diene afford only the thiocyanates (L), while in the case of divinyl, isoprene, and chloroprene two products were isolated in each case: the thiocyanate (L) and the isothiocyanate (LI).

After the thiocyanate anion has been removed from the intermediate adduct (XLIX) (Scheme 11), it can attack the most hydrogenated carbon atom of the ester group via the sulphur or nitrogen atom. Attack via the sulphur atom is preferred, because the highest negative charge is concentrated on it at the instant of the removal of the thiocyanate anion. Indeed in all cases the yield of thiocyanates predominates.

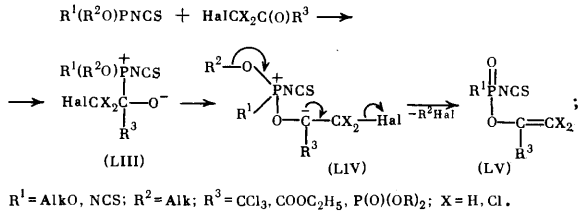
Treatment of ethylene phosphoroisothiocyanatidite with various methylenediamines including dipiperidinylmethane and di-4-morpholinylmethane yielded thiocyanatoethyl aminomethylphosphonamidates (LII).[82] These reactions apparently proceed via a mechanism similar to that described above:



(LII)

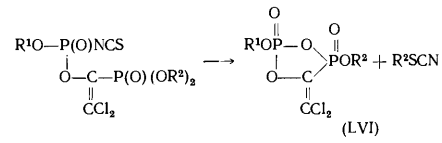
Phosphoromono- and phosphorodi-isothiocyanatidites react with α-halogenocarbonyl compounds to form the products of the Perkow reaction via Scheme 12. This has been demonstrated in relation to halogenopyruvate esters,[56,57] hexachloroacetone,[57] and trichloroacetylphosphonate esters.[40] In these reactions phosphoroisothiocyanatidites behave like trialkyl phosphites. According to Scheme 12, the reactions begin with the nucleophilic attack by the phosphorus atom on the carbon atom involved in the C=O bond with formation of the dipolar ion (LIII), which undergoes the phosphonate–phosphate rearrangement to the dipolar ion (LIV). The subsequent elimination of the alkyl halide leads to the vinyl phosphates (LV).

Scheme 12



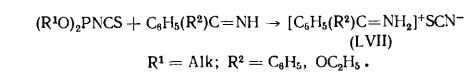
R^1 = AlkO, NCS; R^2 = Alk; R^3 = CCl_3, $COOC_2H_5$, $P(O)(OR)_2$; X = H, Cl.

The vinyl phosphates, formed in the reaction with trichloroacetyl phosphonates, are capable of cyclising to a dioxadiphospholans (LVI):[40]



(LVI)

The main product of the reaction of dialkyl phosphoroisothiocyanatidites with imines having a mobile hydrogen atom, for example, with diphenylketimine and benzimidoethyl ether, are immonium thiocyanates (LVII). The structure of the phosphorus-containing products was not established:[78]



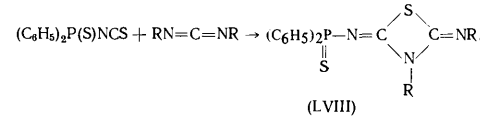
(LVII)

R^1 = Alk; R^2 = C_6H_5, OC_2H_5.

(c) Reactions of the Isothiocyanates of Tetracoordinate Phosphorus Acids

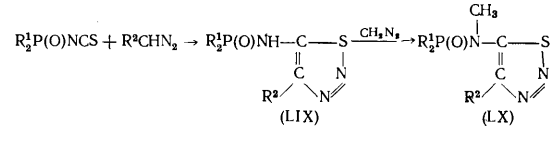
Reactions involving the addition of various nucleophiles to the NCS group are most characteristic of the isothiocyanates of tetracoordinate phosphorus acids. These reactions will be considered in the corresponding Sections devoted to the methods of synthesis of N-phosphorylated thio- and dithiocarbonates and thioureas. In the present Section we shall deal with other reactions of the isothiocyanates of tetracoordinate phosphorus acids, mainly their cycloaddition reactions.

The reactions of diphenylphosphinothioic isothiocyanate with dicyclohexyl- and diisopropyl-carbodiimides, leading to 1,3-thiazetidine derivatives (LVIII), and not 1,3-diazetidine derivatives as had been stated previously in the literature, have been described:[83]



(LVIII)

The interaction of phosphorylated isothiocyanates with diazomethane or phenyldiazomethane leads to the formation of the corresponding 5-(*N*-phosphinyl)amino-1,2,3-thiadiazoles (LIX):[84]

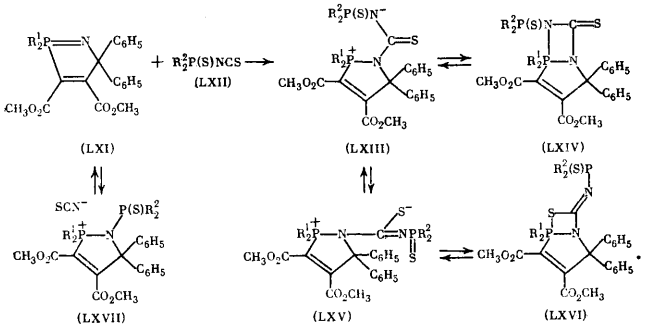


(LIX) (LX)

When the reactions are carried out with a large excess of diazomethane, 5-(*N*-methyl-N-phosphinyl)amino-1,2,3-thiadiazoles (LX, $R^2 = CH_3$) are formed. The involvement of phenylphosphonic diisothiocyanate and phosphoric triisothiocyanate in these reactions does not lead to the expected thiadiazoles, but the structure of the products formed has not been established. Dimethyl- and diphenyl-phosphinothioic isothiocyanates react with azaphospholans (LXI) to form cyclic [2 + 2]-adducts.[85] The phosphorylated isothiocyanates (LXII) (as well as isothiocyanates without phosphorus) add via the C=S bond to the phosphazine group in azaphospholes (LXI) with formation of compounds (LXVI)

containing the 1,3,2-λ^5-thiazaphosphetidine ring:

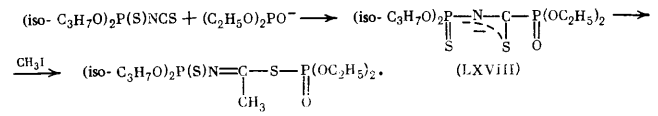
Scheme 13



When compounds (LXVI) are dissolved, the equilibrium (LXVI) ⇌ (LXV) ⇌ (LXIII) ⇌ (LXIV) is established. In the case of the dimethylphosphinyl group, it is displaced towards the form (LXIV) to a greater extent than in the case of the diphenylphosphinothioyl group. With increase of temperature to 70–90 °C, the reversible migration proceeds so rapidly that the ^{1}H NMR spectra exhibit a coalescence of the δ_{PCH_3} signals for (LXIV) and (LXV). The rearrangement proceeds intramolecularly and not via the reverse dissociation (LXVI) ⇌ (LXI) + (LXII) ⇌ (LXIV), which is demonstrated by the fact that the azaphosphole (LXI) added in excess is not involved in the coalescence. Yet another isomer-adduct (LXVII) is formed when the reaction is carried out in benzene, from which it crystallises.

It has been established by ^{31}P NMR that compound (LXVII) is converted into an equilibrium mixture of compounds (LXIV) and (LXVI) via compounds (LXIII) and (LXV) in $CHCl_3$ and more slowly in a benzene suspension.

The mesomeric anion (LXVIII) formed in the reaction of diisopropyl phosphoroisothiocyanatidothioate with sodium diethyl phosphite exhibits the 1,2-C → S mitration of the phosphoryl group in methylation:[86]



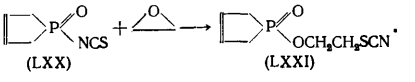
The SCN group manifests pseudohalogen properties in certain reactions of the isothiocyanates of tetracoordinate phosphorus acids. For example, phosphorylated aminoheterocycles of type (LXIX) are formed (Scheme 14) in the reactions with aminobenzazoles, benzazolone imines,[87] 2-aminothiazoles, and 2-aminothiazolines:[88]

Scheme 14

$$R^1R^2P(X)NCS + H_2NHet \rightarrow R^1R^2P(X)NHHet + HNCS;$$
(LXIX)

Het = heterocyclic group

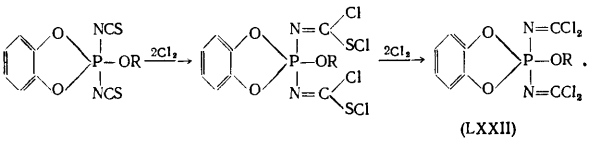
Epoxyethane is capable of being inserted in the P–N bond of the phosphorylated isothiocyanates. Isothiacyanatophosphine oxide (LXX) has been converted in this way into the 2-thiocyanatoethyl phosphinate (LXXI):[80]



The reaction with molecular chlorine, leading to phosphorylated isocyanide dichlorides (see, for example, Roessky and Janssen[30] and Derkach and Liptuga[89]), are extremely characteristic of the isothiocyanates of phosphorus acids. Many other examples of similar reactions have been quoted in a review.[1]

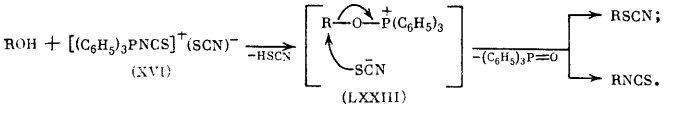
(d) Chemical Reactions of Isothiocyanates with the Phosphorane or Phosphonium Structure

Alkoxydiisothiocyanato-*o*-phenylenedioxyphosphoranes are smoothly chlorinated at −80 °C by 4 moles of chlorine to give compound (LXXII):[43]



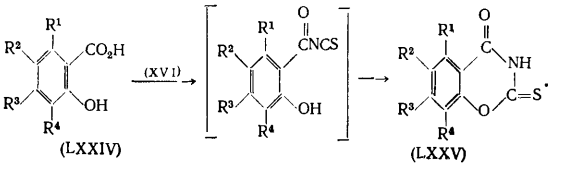
The adduct of triphenylphosphine and thiocyanogen—the phosphonium salt (XVI), described in 1977,[45] permits the synthesis of thio- and isothio-cyanates, disubstituted thioureas, amides, phosphimides, and other compounds in high yields and under mild conditions.[44,45,90–98] The adduct converts via Scheme 15 primary alcohols into thiocyanates, tertiary alcohols into isothiocyanates, and secondary alcohols into a mixture of both products[44,45] in almost quantitative yields:

Scheme 15



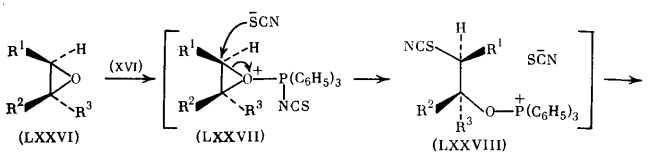
The reactions proceed via the intermediate (LXXIII), the formation of thio- or isothio-cyanates depending on the ambident character of the thiocyanate anion. Carboxylic acids give rise to acyl isothiocyanates in this reaction.[44]

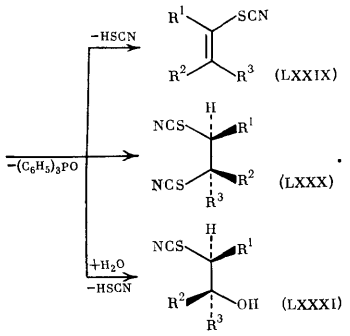
2-Thiono-3,4-dihydro-2*H*-1,3-benzoxazin-4-ones (LXXV) have been obtained in 70% yields by treating substituted salicylic acids (LXXIV) with the salt (XVI):[90]



The epoxides (LXXVI) react with the phosphonium salt (XVI) via Scheme 16 under mild conditions with the opening of the oxiran ring and the formation of mono- and di-isothiocyanato-derivatives.[94,98] The interaction of α,β-epoxyketones leads to α-thiocyanatovinyl ketones (LXXIX, R^1 = R^4CO). Regiospecific thiocyanation of monosubstituted or 1,2-disubstituted epoxides leads to the corresponding vicinal dithiocyanates (LXXX), *threo*-dithiocyanates and *erythro*-dithiocyanates being formed respectively from *trans*- and *cis*-epoxides. The reactions of 1,1-disubstituted epoxides give rise to vicinal *threo*-thiocyanatohydrins (LXXXI):

Scheme 16

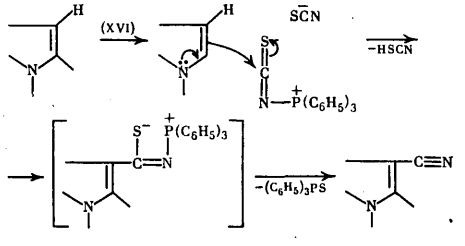




It has been suggested[98] that the electrophilic phosphorus atom of the phosphonium salt (XVI) attacks the oxygen atom of the oxiran ring with formation of the intermediate (LXXVII), which is then subjected to nucleophilic attack by the thiocyanate anion. This results in the opening of the oxiran ring and the formation of the β-thiocyanatoalkoxyphosphonium salt (LXXVIII), resembling the intermediate formed in the reactions with alcohols. In the case of α,β-epoxyketones the intermediate (LXXVIII) undergoes ready α-deprotonation by the thiocyanate anion, accompanied by the spontaneous elimination of triphenylphosphine oxide and the formation of α-thiocyanatovinyl ketones (LXXIX). The regiospecificity of the reactions can be accounted for by the stabilising effect of the neighbouring carbonyl group.

The intermediate (LXXVII), formed from monosubstituted and 1,2-disubstituted epoxides, is attacked by the thiocyanate anion at the least substituted carbon atom. A second SCN group then displaces triphenylphosphine oxide from compound (LXXVIII) via nucleophilic substitution with formation of vicinal dithiocyanates (LXXX). When the substitution by the thiocyanate anion is hindered by steric factors, as happens, for example, in the intermediate (LXXVIII) obtained from 1,1-disubstituted epoxides, hydrolysis takes place readily and leads to the formation of vicinal thiocyanatohydrins (LXXXI) and triphenylphosphine oxides.

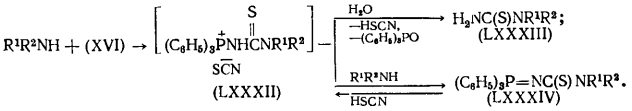
The use of the phosphonium salt (XVI) makes it possible to achieve the cyanation of pyrroles, indoles, and enamines under mild conditions and in satisfactory yields.[45,97]



The cyanation of pyrroles takes place selectively in the 2-position when the latter is unsubstituted. Otherwise, the cyano-group is introduced into the less reactive 3-position. The reactions of the salt (XVI) with indoles also proceed selectively with formation of products in which the cyano-group is in the 3-position. If an alcoholic group is present in the indole or pyrrole molecule, then its thiocyanation takes place in competition with the cyanation of the heterocycle. However, the introduction of an acyl protecting group makes it possible to avoid the first reaction.

Yet another application of the phosphonium salt (XVI) involves its use in the synthesis of substituted thioureas and amides.[91-93,95] In the first stage of the reactions with the amines, the phosphonium salts (LXXXII) are formed (Scheme 17), being converted into the corresponding 1,1-disubstituted thioureas (LXXXIII) in a high yield on treatment with aqueous acetonitrile:[91,95]

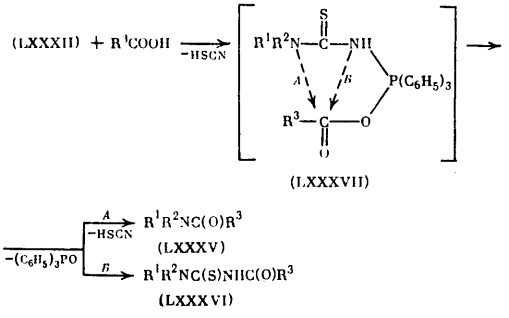
Scheme 17



The intermediate formation of compound (LXXXII) has been confirmed by chemical reactions. When the phosphonium salt (XVI) is treated with an excess of the amine, the phosphine imine (LXXXIV) is formed and is smoothly converted into the corresponding thiourea and triphenylphosphine oxide when it is treated with an aqueous solution of thiocyanic acid.

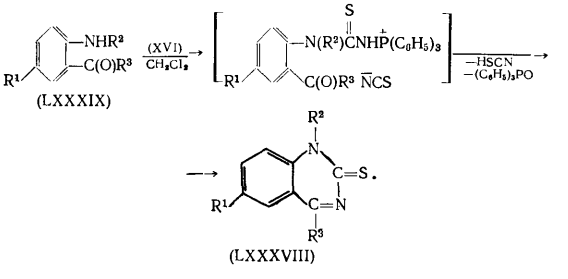
If carboxylic acids are introduced into the reaction instead of the aqueous acetonitrile, the corresponding amides (LXXXV) and/or acylthioureas (LXXXVI) are formed, depending on the structure of the initial amine and carboxylic acid:

Scheme 18



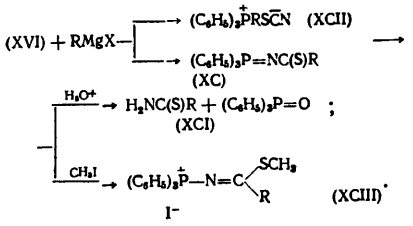
The reactions apparently begin with the attack by the carboxylate anion on the phosphorus atom in the salt (LXXXII) and lead to the intermediate (LXXXVII). The latter split off triphenylphosphine oxide and are converted either into the amide (LXXXV) via a six-membered cyclic transition state (pathway *A*) or into the acylthiourea (LXXXVI) via a four-centre transition state (pathway *B*). With the increase of the size of the substituents in the amine and the carboxylic acid, the yield of the amides (LXXXVI) diminishes, while that of the thioureas (LXXXVI) increases, which can be accounted for by the smaller dependence of the reaction via pathway *B* on the steric factor, because in this case the substituents can be located in the *trans*-position.

The adduct of triphenylphosphine with thiocyanogen (XVI) has been used also in the synthesis of 2-thiono-1,2-dihydroquinazolines (LXXXVIII) from readily available *o*-acylanilines (LXXXIX):[92,95]



The reaction of organomagnesium compounds with the adduct (XVI) proceeds with formation of phosphine imine intermediates (XC) which are converted into the thioamides

(XCI) on acid hydrolysis:[93]



In the absence of acid, it is possible to isolate compound (XC) and a small amount of the phosphonium salt (XCII). The phosphine imine (SC) is methylated by methyl iodide to the phosphonium salt (XCIII).

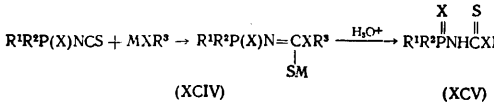
Thus the reaction of alcohols, epoxides, carboxylic acids, and organophosphorus acids and the adduct of triphenylphosphine and thiocyanogen begins with the nucleophilic attack on the phosphorus atom, which leads to the formation of phosphonium salts of the type (LXXIII) and (LXXVII). The reactions with amines, enamines, organomagnesium compounds, pyrroles, and indoles begin with the nucleophilic addition to the NCS group. Depending on the structure, the intermediates formed in these reactions on treatment with different reagents give rise to a whole range of practically important substances.[93]

III. *N*-PHOSPHORYLATED THIO- AND DITHIOCARBAMATES

It is known that the esters of tetracoordinate phosphorus acids and derivatives of thio- and dithio-carbamic acids constitute the two most numerous classes of chemical substances among the pesticidal preparations employed nowadays. The study of the biological activity of phosphorylated thio- and dithio-carbamates, in the molecule of which phosphorus-containing and thiocarbamate fragments are combined, is therefore of great interest. Substances with bactericidal,[11] antihelminthic,[99-101] insectoacaricidal,[102-105] and other pesticidal activities[106-108] have been found among *N*-phosphorylated thio- and dithiocarbamates. In addition, *N*-phosphorylated thiocarbamates can be used as antioxidants for synthetic resins and as additives to motor fuels,[104] while *N*-thiophosphoryldithiocarbamates can be employed as complex-forming agents and extractants.[109]

1. Methods of Synthesis of *N*-Phosphorylated Thio- and Dithio-Carbamates

The synthesis of organophosphorus thio- and dithiocarbamates from phosphorus-containing isothiocyanates or mixtures of tetracoordinate phosphorus acid chlorides and potassium thiocyanate on treatment with alcohols, mercaptans, or, better, with their metal derivatives has been described.[1] The *S*-metallated derivatives of *N*-(thio)phosphorylated isothio(dithio)carbamates (XCIV) formed in the latter case are converted into thio(dithio)carbamates (XCV) after acidification:

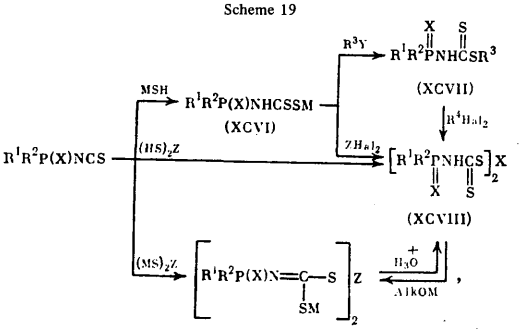


where X = O or S and M is an alkali metal. These metals have remained of key importance also in subsequent studies. Thus *S*-butyl-*N*-diphenylphosphinyl dithiocarbamate has been obtained by the reaction of diphenylphosphinyl isothiocyanate with sodium butanethiolate in the presence of triethylamine on subsequent treatment with NH_4Cl.[110]

The addition of alcohols to the NCS groups of 1,1,3,3-tetrachloro-5,5-diisothiocyanatocyclotriphosphazene,[31,32] 3,9-diisothiocyanato-2,4,8,10-tetraoxa-3,9-diphosphaspiro[5,5]undecane 3,6-dioxide, and the analogous bissulphide [104] led to the formation of the corresponding phosphorus-containing bisthionocarbamates.

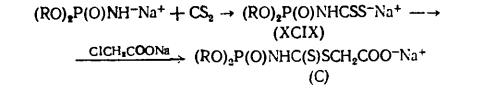
The salts of *N*-(thio)phosphorylated dithiocarbamic acids (XCVI), formed when the thioisocyanates of tetracoordinate phosphorus acids are treated with alkali metal hydrogen sulphides,[105,106,111-116] are converted into the dithiocarbamates (XCVII) on alkylation.[103,106,113] Reaction of the salts (XCVI) with alkylene or oxydimethylene dihalides leads to bisphosphoryldithiocarbamates (XCVIII):[105,117]

Scheme 19

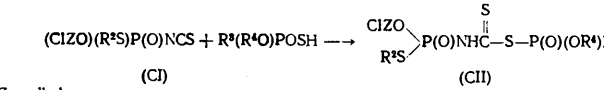


where X = O or S, M = Li, Na, K, or NH_4, Y = halogen or Ts [tosyl? (Ed.of Translation)], and Z = $(CH_2)_2O$ or a substituted or unsubstituted alkylene. In addition, compounds (XCVIII) can be obtained by treating phosphoroisothio(thio)cyanatidates with dithiols[99,117-119] or alkali metal dithiolates with subsequent acidification[101-103,105,117] and also by the reaction of dithiocarbamates (XCVII) with alkylene dihalides in the presence of bases.[117]

The possibility of obtaining *S*-sodium dialkylphosphoryldithiocarbamates (XCIX) from sodium phosphoramides and carbon disulphide has been demonstrated.[120] When compounds (XCIX) are treated with sodium chloroacetate, the paste-like sodium *S*-[*N*-(dialkylphosphoryl)thiocarbamoyl] acetates (C) are formed:

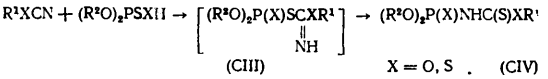


Certain acids can also be made to add to the isothiocyanato-group. In particular, the partial esters of phosphonomonothioic acids interact with phosphoroisothiocyanatidothioates (CI) to form *NS*-diphosphorylated dithiocarbamates (CII):[108]



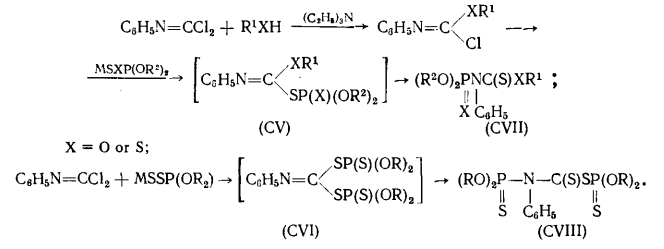
Z = alkylene.

Phosphoromonothioic and phosphorodithioic acids are capable of adding tothe C≡N bond in cyanates and thiocyanates, the adducts (CIII) rearranging readily to *N*-(thio)phosphorylated thio- or dithio-carbamates (CIV):[50,51]

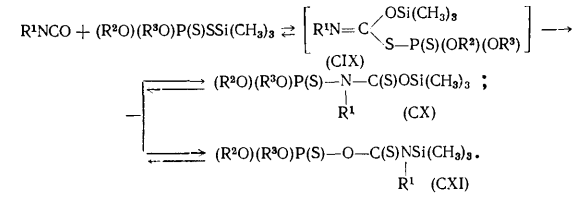


When the chlorine atoms in phenyl isocyanide dichloride are substituted via a series of stages by an alkoxy- or alkylthio-group and then by a dialkyl phosphorothioate or phosphorodithioate group (Scheme 20), *S*-(thio)phosphorylated isothio- or isodithio-carbamates (CV) are formed.[107,121] The interaction of phenyl isocyanide dichloride with salts of dialkylphosphorodithioic acids lead to analogous compounds (CVI).[107,122] However, in contrast to patent data,[123–125] it has been shown[107,121,122] that compounds (CV) and (CVI) are unstable and in the course of the process undergo an irreversible rearrangement to the phosphorylated dithiocarbamates (CVII) and (CVIII). When salts of dialkylphosphoromonothioic acids are involved in the reaction, derivatives with a P=O group are produced:[107,121]

Scheme 20

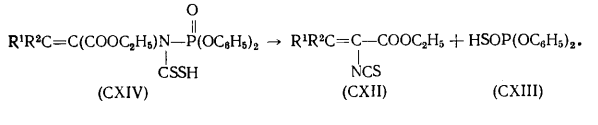


The interaction of *S*-trimethylsilyl phosphorodithioates with isocyanate leads to the adducts (CIX) which are capable of reversible isomerisation to both *N*-thiophosphorylated [compounds (CX)] and *O*-thiophosphorylated [compounds (CXI)] trimethylsilyl thionocarbamates:[126]

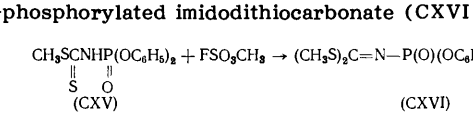


2. The Properties of *N*-Phosphorylthiocarbamates

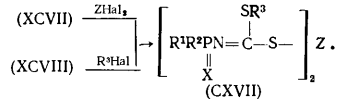
The reactions involving the addition of alcohols and mercaptans to the isothiocyanates of tetracoordinate phosphorus acids are reversible.[1] Even at room temperature *N*-(thio)phosphorylated thio- and dithio-carbamates (CIV) decompose to phosphoroisothio(thio)cyanatidates and alcohols or thiols.[50,51] An interesting decomposition into the isothiocyanate (CXII) and diphenylphosphoromonothioic acid has been observed on heating dithiocarbamates having the structure (CXIV):[127]



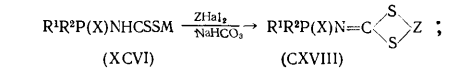
In the study of the concentration and temperature dependence of the IR spectra of solutions of *S*-alkyl *NN*-dialkylthiophosphoryldithiocarbamates, no thione–thiol tautomerism has been observed.[109] Nevertheless the alkylation of *N*-(thio)phosphorylated thio- and dithio-carbamates by different alkylating agents always leads to *S*-alkylated and not *N*-alkylated products. Thus, on treatment with methyl fluorosulphate, the dithiocarbamate (CXV) is converted into the *N*-phosphorylated imidodithiocarbonate (CXVI):[128]



Diphosphorylated bisimidodithiocarbonates (CXVII) are formed on reaction of *N*-phosphorylated dithiocarbamates (XCVII) with alkylene dihalides[103] and of diphosphorylated dithiocarbamates (CXVIII) [99,102,117,119] or their metal derivatives[103,118] with alkyl halides:

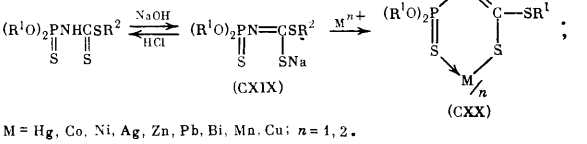


On treatment with alkylene dihalides in the presence of bases, the salts of *N*-(thio)phosphoryldithiocarbamic acids (XCVI) cyclise to *N*-(thio)phosphorylated imino-1,3-dithietans[106,111,112,115,116,129–136] or imino-1,3-dithiolans (CXVIII),[114] which have found practical application as broad spectrum pesticides:



Z = alkylene.

N-Thiophosphorylated dithiocarbamates are weak acids with $pK_a \cong 7.5$ (in aqueous alcoholic mixtures) [51,109] and are converted on treatment with alkalies into water-soluble *S*-metal derivatives (CXIX):[51]



M = Hg, Co, Ni, Ag, Zn, Pb, Bi, Mn, Cu; $n = 1, 2$.

Treatment of derivatives of compound (CXIX) by salts of thiophilic metals leads to the formation of stable complexes (CXX), which can be extracted from organic media by organic solvents, which makes it possible to employ *S*-alkyl-*NN*-dialkylthiophosphoryldithiocarbamates as extractants.[109]

IV. *N*-PHOSPHORYLATED THIOUREAS

Numerous publications devoted to the methods of synthesis and reactions of *N*-phosphorylated thioureas and also to their practical use in industry, agriculture, medicine, and veterinary science have appeared in recent years.

Numerous investigations have been devoted to the biological activity of *N*-phosphorylated thioureas. According to literature data, substances exhibiting carcinostatic and immunostimulating,[137] bactericidal,[10–12,138–142] anthelminthic,[55,143–154] arthropocidal,[55,155] nematocidal,[55,143,155,156] insectoacaricidal,[104,143,156,157] herbicidal,[140,157,158] fungicidal,[38,157,159–163] and other pesticidal[107,164,165] activities as well as preparations used to destroy ectoparasites,[166] for the prophylaxis and treatment of coccidiosis,[167] and in the therapy of radiation sickness[168] have been found among them.

In addition, the use of *N*-phosphorylated thioureas as additives to lubricating oils[169,170] and motor fuels,[104,171,172] as antioxidants for synthetic resins,[104] as additives to reduce the combustibility of organic substances,[14,15,171–174] as fire-resistant polymeric materials,[19,20] as plasticisers,[165] and as extractants[175,176] is of extremely great value.

1. Methods of Synthesis of *N*-Phosphorylated Thioureas

The method of synthesis of *N*-phosphorylated thioureas most frequently employed involves the addition of ammonia,[37,104] aliphatic amines,[5,6,30–32,51,54,60,67,104,110,143,148,155,156,164,168,169,177–179] aromatic amines,[38,47,49–51,104,110,141,146–149,151,152,154,159–162,164,169,177,178,180–186] and heterocyclic amines[38,104,137–139,141,142,159,163,164,169,186] to the NCS group in the isothiocyanates of tetracoordinate phosphorus acids. Reactions with alkylene-diamines[144,157,169] and arylenediamines[145,147,149,150,166,187,188] result in the formation of bisphosphorylated thioureas. The corresponding *N*-phosphorylated thiosemicarbazides have been isolated in the reactions with hydrazines.[38,138,139,189–191] The reactions usually proceed very readily at room temperature and lead to the formation of the required compounds in high yields.

The kinetics of the reactions of phosphoroisothiocyanatidates with aniline have been studied by IR spectroscopy:[180]

$$R_2P(O)NCS + C_6H_5NH_2 \rightarrow R_2P(O)NHC(S)NHC_6H_5\ ;$$
$$R = C_2H_5,\ C_6H_5O,\ C_2H_5,\ C_2H_5O.$$

It was found that the reactions are of second kinetic order. Phosphorylated isothiocyanates and phenyl isothiocyanates can be arranged in the following sequence in terms of their reactivities:

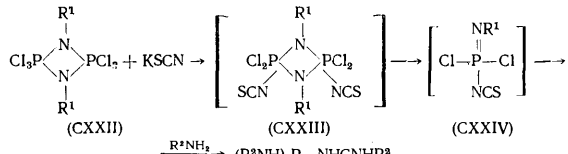
$$(C_6H_5O)_2P(O)NCS \gg (C_6H_5)_2P(O)NCS \approx (C_2H_5O)_2P(O)NCS > (C_2H_5)_2P(O)NCS > C_6H_5NCS.$$

The reactions are completed faster in acetone and dioxan than in CCl_4, which has been explained[180] by the influence of the unshared electron pairs of the oxygen atoms in the molecules of the first two solvents.

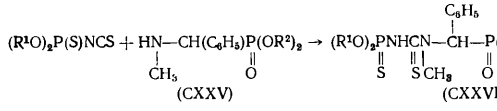
Optically active *N*-phosphorylated thioureas have been obtained by the reaction of amines with optically active phosphorylated isothiocyanates.[5,6,37,60] The reaction of the ^{32}P-labelled diphenylphosphinothioic isothiocyanate with the ε-amino-groups of the lysine side chains in proteins has been used to introduce a radioactive label into γ-globulin.[67] *N'*-hydantoinyl-*N''*-phosphorylthioureas have been obtained from the corresponding disubstituted 5-aminohydantoins and dialkyl phosphoroisothiocyanatidates and phosphoroisothiocyanatidothioates.[163]

The synthesis of thioureidophosphazoarenes (CXXI) via Scheme 21 by treatment of *NN'*-diarylhexachlorocyclophosphazans (CXXII) initially with KSCN and then with aromatic or heterocyclic amines in acetone at 0 °C has been described. It is suggested that the process proceeds via the intermediate (CXXIII) and (CXXIV):

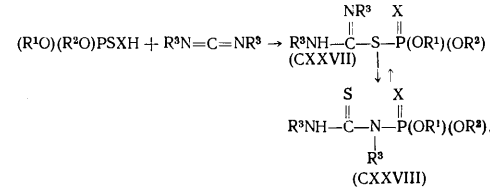
Scheme 21



Bisphosphorylated thioureas (CXXVI) are formed in the reactions of α-aminophosphonates (CXXV) with phosphoroisothiocyanatidothioates:[51]

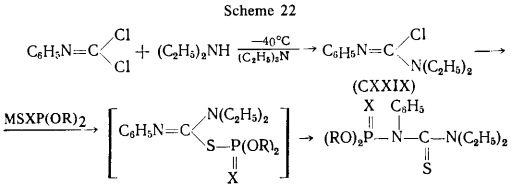


Together with the reactions of phosphorylated isothiocyanates with amines, other methods have also been used to synthesise *N*-phosphorylated thioureas, because the reactions of the amines are not free from certain limitations. In particular, thioureas in which the nitrogen atom linked to the phosphorus atom is fully substituted cannot be synthesised by these reactions. This can be achieved, for example, with the aid of the reactions of phosphorothioic and phosphorodithioic acids with carbodiimides.[140,192–199] The products of the addition of the thioacids of tetracoordinate phosphorus to the C–N bond in compounds (CXXVII), which have the isothiourea structure, can rearrange to *N*-(thio)phosphorylated thioureas (CXXVIII) in addition to undergoing other reactions. In certain cases (when R^3 = isopropyl or cyclohexyl) the rearrangement is reversible, but under the usual conditions the equilibrium is almost fully displaced towards the isomer (CXXVIII). The study of the stereochemistry of the conversion of *S*-phosphorylisothioureas into *N*-phosphorylthioureas[197,198] demonstrated the complete retention of the configuration at the phosphorus atom:



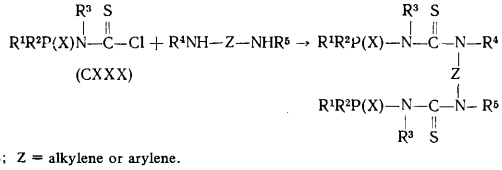
An analogous rearrangement of *S*-(thio)phosphorylated isothioureas to *N*-(thio)phosphoryl thioureas has been observed in the reaction of diethyl phosphorodithioic acid with cyanamide[48] and in exchange reactions of salts of dialkyl phosphorothioic and dialkyl phosphorodithioic acids with *NN*-diethyl-*N'*-phenylchloroformamidine (CXXIX) (Scheme 22):[107]

Scheme 22



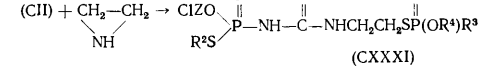
M = Na, K, NH_4; X = O or S.

Phosphoryl- and thiophosphoryl-thiocarbamoyl chlorides (CXXX) can condense with amines[155,156] and alkylene- and arylene-diamines[157] to form the corresponding mono- or bis-(thio)phosphorylthioureas:



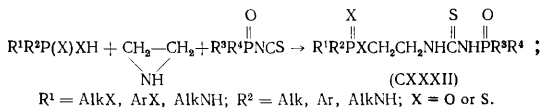
X = O or S; Z = alkylene or arylene.

Diphosphorylated thioureas (CXXXI) have been synthesised from *NS*-diphosphorylated dithiocarbamates (CI) and ethyleneimine:[200]



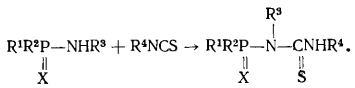
Analogous products (CXXXII) have been isolated in three-component reactions of the acid esters of phosphonic, phosphonodithioic, phosphonotrithioic, or phosphorodiamidodithioic acids with phorphoryl isothiocyanates and

ethyleneimine.[165,201,202] The corresponding *NS*-diphosphorylated thio- or dithio-carbamates of type (CII) are apparently formed in these reactions as intermediates:



$R^1 = AlkX, ArX, AlkNH;\ R^2 = Alk, Ar, AlkNH;\ X = O \text{ or } S.$

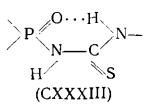
According to patent data,[155,156] phosphorylated thioureas can be obtained by adding the amides of tetracoordinate phosphorus acids to organic isothiocyanates:



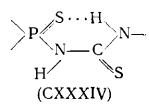
The addition of *cis*- and *trans*-2-amido-4-methyl-2-oxo-1,3,2-dioxaphosphorinanes to cyclohexyl isothiocyanate takes place in the presence of sodium hydride.[37] Diaminotetrakis(dimethylamino)cyclotriphosphazene reacts with phenyl isothiocyanate in boiling benzene to form a monosubstituted derivative of thiourea.[28]

2. The Properties of *N*-(Thio)Phosphorylated Thioureas

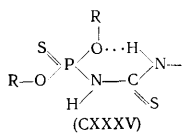
It has been established by IR spectroscopy[203] that *N*-phosphorylated and *N*-thiophosphorylated thioureas do not exhibit a tendency towards the thione–thiol tautomerism both in polar and in non-polar solvents. In a study of the concentration dependence of the IR spectra, it was found that these compounds are associated both in the crystalline state and in concentrated solutions as a result of the formation of intermolecular hydrogen bonds involving the P–NH, C=S, and P=S groups. In dilute solutions in CCl_4 an equilibrium is established between the self-associated species and their monomers. The intermolecular hydrogen bonds (CXXXIII), (CXXXIV), and (CXXXV) make a significant contribution to the stabilisation of the monomeric forms:



(CXXXIII)

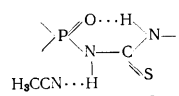


(CXXXIV)

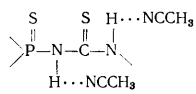


(CXXXV)

Heteroassociated 1:1 and 1:2 species arise in acetonitrile for the phosphoryl [compound (CXXXVI)] and thiophosphoryl [compound (CXXXVII)] derivatives respectively:

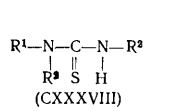


(CXXXVI)

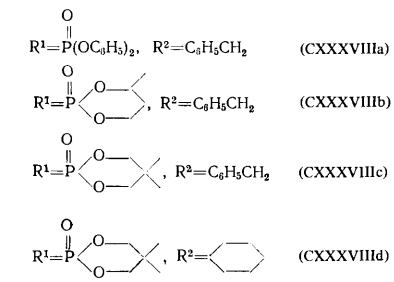


(CXXXVII)

The X-ray diffraction study of *NN'*-dibenzyl-*N*-diphenylphosphorylthiourea (CXXXVIIIa),[204] *NN'*-dibenzyl-*N*-(4-methyl-2-oxo-1,3,2-dioxaphosphorinanyl)thiourea (CXXXVIIIb),[198] *NN'*-dibenzyl-*N*-(5,5-dimethyl-2-oxo-1,3,2-dioxaphosphorinanyl)thiourea (CXXXVIIIc), and *NN'*-dicyclohexyl-*N*-(5,5-dimethyl-2-oxo-1,3,2-dioxaphosphorinanyl)thiourea (CXXXVIIId)[205] revealed significant structural and conformational differences between the dibenzyl derivatives (CXXXVIII, a–c) and the dicyclohexyl derivative (CXXXVIIId):



(CXXXVIII)



(CXXXVIIIa)

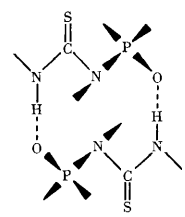
(CXXXVIIIb)

(CXXXVIIIc)

(CXXXVIIId)

In compounds (CXXXVIII, a–c) the sulphur and phosphorus atoms occupy virtually antiperiplanar positions about the SC–NP bond (torsional angle of about 160°). The thiourea fragment in the dibenzyl derivatives (CXXXVIII, a–c) is planar. A chelate six-membered ring is formed in these molecules via the intramolecular NH...O=P hydrogen bond.

The presence of the two bulky cyclohexyl substituents in the molecule of compound (CXXXVIIId) disturbs the planarity of the thiourea skeleton. The deviation of the phosphorus atom from the plane of the nitrogen and sulphur atoms in compound (CXXXVIIId) amounts to 1.435 Å while in compound (CXXXVIIIc) it is only 0.490 Å. The P–N–C–S torsional angle is 91°, so that the non-bonding S...P distance, amounting to 3.73 Å in compound (CXXXVIIId), is much shorter than in compound (CXXXVIIIc) (4.242 Å). The rotation about the PN bond in compound (CXXXVIIId) is restricted owing to the interaction of the α-protons of the cyclohexane ring with the phosphoryl oxygen; the rotation about the PN–CS bond is also hindered. The thiourea (CXXXVIIId) gives rise to the dimers (CXXXIX) in the crystalline state, which are stabilised by intermolecular hydrogen bonds:

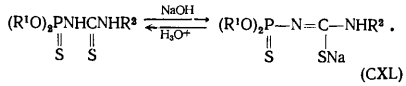


(CXXXIX)

The structural and conformational differences between the thioureas of types (CXXXVIII, a–c) and (CXXXVIIId) are also shown in the NMR spectra. The spin–spin coupling constants ^3J(P–N–C–H) for *NN'*-dicyclohexyl- and *NN'*-diisopropyl-phosphorylthioureas are unusually high (20.5 to 25.4 Hz) compared with other *N*-phosphorylated thioureas (9.5–10.0 Hz). For the thiophosphoryl derivatives, the difference between the ^3J(PH) is not quite so significant, but it does exist. On the basis of the invariance of the constants ^3J(PH) when the solvents are varied, the authors[199] concluded that the most stable conformations of the *NN'*-disubstituted phosphorylthioureas (CXXXVIII) are identical in the crystalline state and in solution.

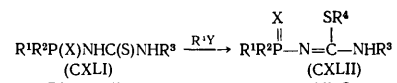
Like *N*-thiophosphoryldithiocarbamates, *N'*-substituted *N*-dialkylthiophosphorylthioureas are weak acids with $pK_a \cong 8.8$ (in an aqueous alcoholic medium) [51,176,203] and form water-soluble salts (CXL) with alkalies or alkali metal

alkoxides:[51]



(CXL)

Like *N*-(thio)phosphoryl(di)thiocarbamates, the thioureas (CXLI) are alkylated by various alkylating agents with formation of *S*-alkyl-*N*-(thio)phosphorylisothioureas (CXLII):[179,206–210]

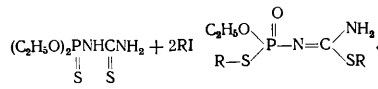


(CXLI) (CXLII)

R^4Y = AlkHal, AlkOTs, $AlkCHN_2$, Alk_2SO_4.

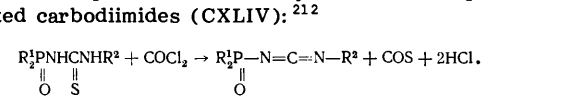
The alkylation is sometimes accompanied by the Pishchimuka rearrangement:[208]

Scheme 23



The interaction of *N*-(thio)phosphorylthiourea with Methylene Blue in 85% ethanol leads to the reduction of the dye to a substituted phenothiazine, thiourea dimerising under these conditions.[211]

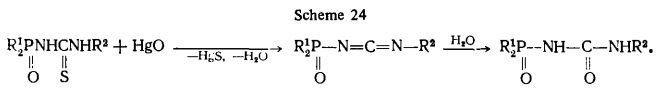
The reactions of the phosphorylthioureas (CXLIII) with phosgene in the presence of tertiary bases lead to phosphorylated carbodiimides (CXLIV):[212]



(CXLIII) (CXLIV)

The carbodiimides (CXLIV) can be obtained from compound (CXLIII) by desulphurisation with mercury(II) oxide in boiling benzene in accordance with Scheme 24. It is then essential to bind the water evolved, since otherwise the phosphorylated ureas (CXLV) are formed:[212]

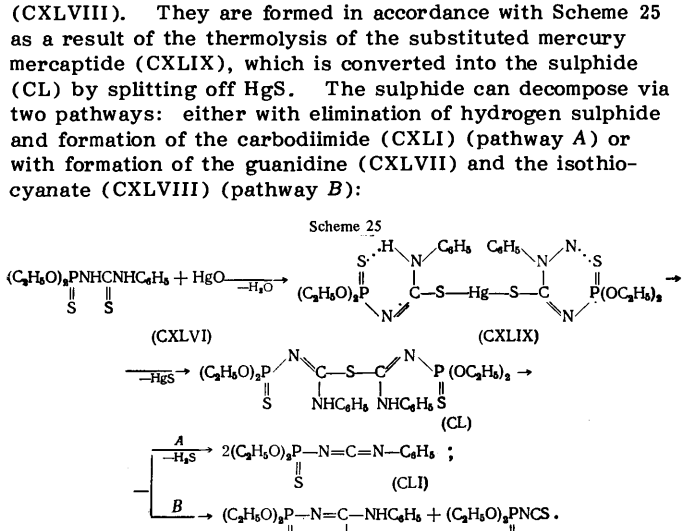
Scheme 24



(CXLIII) (CXLIV) (CXLV)

According to Grapov et al.[213], the yield of the thiophosphorylated carbodiimides is low when this method is used. The main products of the reaction of the thiourea (CXLVI) with mercury(II) oxide are compounds (CXLVII) and (CXLVIII). They are formed in accordance with Scheme 25 as a result of the thermolysis of the substituted mercury mercaptide (CXLIX), which is converted into the sulphide (CL) by splitting off HgS. The sulphide can decompose via two pathways: either with elimination of hydrogen sulphide and formation of the carbodiimide (CXLI) (pathway *A*) or with formation of the guanidine (CXLVII) and the isothiocyanate (CXLVIII) (pathway *B*):

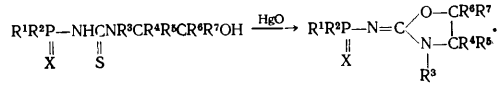
Scheme 25



(CXLVI) (CXLIX) (CL) (CLI) (CXLVII) (CXLVIII)

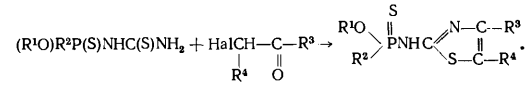
When *N*-phosphoryl- and *N*-thiophosphoryl-thiourea are heated with HgO in the presence of alcohols, mercaptans, and amines, the corresponding phosphorylated and thiophosphorylated isoureas, isothioureas, and guanidines are formed.[213,214]

The products of the addition of aminoalcohols to phosphorylated isothiocyanates (CLII) cyclise to *N*-phosphorylimino-oxazolidines (CLIII) under the influence of mercury(II) oxide with elimination of hydrogen sulphide:[215–219]



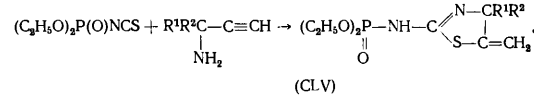
(CLII) (CLIII)

The reactions of thiophosphorylated thioureas with α-halogenoketones lead to the formation of phosphorus-containing aminothiazoles (CLIV):[220]



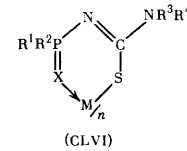
(CLIV)

Diethyl *N*-(2-thiazolinyl)phosphoramidates (CLV) are the products of the reaction of diethyl phosphoroisothiocyanatidate with substituted propargylamines:[221,222]



(CLV)

The molecules of phosphorylated thioureas contain several centres capable of forming a coordinate bond with metal ions. It has been reported in two reviews[1,21] that the formation of stable mono- or bi-ligand chelates of type (CLVI) is characteristic of these compounds. The complex formation reaction is accompanied by the displacement of one or two protons:

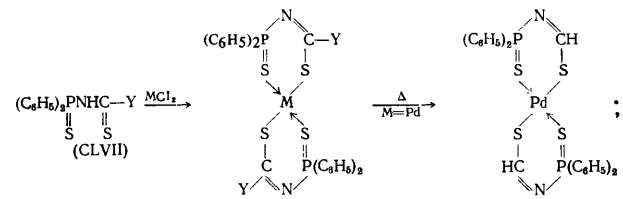


(CLVI)

X = O, S; M = Co(II), Ni(II), Cu(I); *n* = 1, 2

New data concerning the formation of complexes by *N*-(thio)-phosphorylthioureas with metal ions have been published.[51,150,152,156,175–178,186,223]

Ojima and co-workers[177,178] investigated the complex formation reactions between diphenylphosphinothioylthioureas (CLVII) and nickel(II), palladium(II), and cobalt(II) ions, which leads to the formation of 1 : 2 chelates having the structure (CLVIII):



(CLVII) (CLVIII) (CLIX)

Y = $N(CH_3)_2$, $N(C_2H_5)_2$, NHC_6H_5; M = Co(II), Ni(II), Pd(II).

In the reaction with palladium(II) ions (for R = NHC_6H_5), another chelate is isolated together with the complex (CLVIII) to which the structure (CLIX) was attributed on the basis of

IR spectroscopic, X-ray diffraction, and elemental analyses. The authors[178] believe that, when the complex (CLVIII) is heated, the ligand is partly destroyed, but the six-membered ring is retained.

The complexes with the nickel(II) and palladium(II) ions are diamagnetic at room temperature, which indicates their planar configuration. The IR and UV spectra confirm this. The cobalt(II) complexes are paramagnetic and have a tetrahedral configuration. On formation of complexes with copper(II) ions, the copper is reduced to the univalent state, but the reaction products could not be isolated in this instance.

A study of complex formation reactions of the thioureas (CLVII, R = phenylamino, *m*-tolylamino, α- and β-naphthylamino, or piperidinyl) with nickel(II) ions showed that the complexes have the 1:2 composition and in most cases have a planar structure.[186]

The formation of complexes by *N*-thiophosphorylthioureas with nickel, cobalt, mercury, and silver ions and the structures of the resulting chelates have been investigated[176,223] by spectrophotometric, potentiometric, IR spectroscopic, and ^{31}P NMR methods.

In view of the ability of *N*-thiophosphorylthioureas to form chelates which can be extracted from aqueous media by organic solvents, they can be used as extractants in analytical chemistry. Thus it has been shown[175,176] that many metal ions [Cu, Co, Ag, Cd, Au, Al, Mo, Ni, Gg, Ga, In, Bi, Pd, Pb, Zn, Mn(II), Tl, Ti] can be extracted from aqueous solutions of different acidity in the form of complexes with the aid of *NN*-diisopropyl-*N'*-phenylthiophosphorylthiourea. A procedure for the group concentration of microadmixtures of heavy metal ions in their chemical-spectroscopic analysis has been developed on the basis of the extraction properties of this compound.[175]

---o0o---

The data presented show that phosphorylated isothiocyanates as well as *N*-phosphorylated monothio- and dithiocarbamates and thioureas, which are genetically related to the isothiocyanates, possess a broad spectrum of properties useful in practice. Presumably further studies in this interesting field of organophosphorus chemistry will be directed towards a deepening of our knowledge of the structure and properties of these important and useful compounds, towards the search for new possibilities in their practical application, and also towards the development of the most technological processes for their synthesis.

The Synthesis and Properties of Silicon-, Germanium-, Tin-, and Lead-containing s-Triazines

A.S.Gordetsov and Yu.I.Dergunov

Published data on the methods of synthesis and properties of s-triazines containing group IVb elements have been summarised and systematised. The reaction mechanisms have been discussed, and various aspects of the practical application of s-triazines examined.
The bibliography contains 222 references.

I. INTRODUCTION

The first papers on the synthesis of derivatives of s-triazine appeared about the middle of last century. Thousands of compounds of this class have now been prepared and studied, and in a number of cases have found practical applications. The interest in these compounds is related to their high inertness and chemical and thermal stability, which result from the unique electronic structure of the ring, and also to the high biological activity of some derivatives. Most published data on the methods of preparation, structure, properties, and applications of organic s-triazines and their salts have been summarised in a monograph[1] and reviews,[2,3] but there has been practically no systematisation of published data on their hetero-organic analogues, which are attracting increasing interest.

The aim of the present work was to systematise published data on the synthesis, reactivity, physicochemical properties, and applications of silicon-, germanium-, tin-, and lead-containing derivatives of s-triazine in which the element-containing fragments are joined directly to the ring.

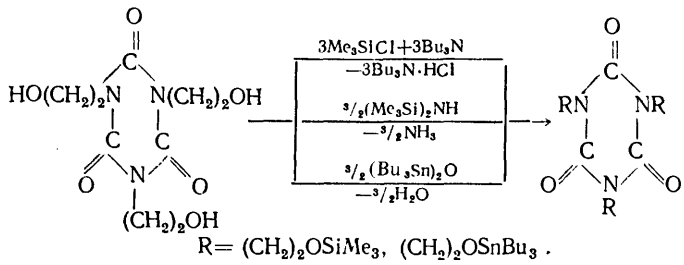
Papers dealing with carbofunctional s-triazines are not considered in detail, and are used only for comparison with data on the main group of compounds being examined, although the information on these compounds is given in full. The review includes material published in monographs, journal articles, and patents up to June 1984.

II. METHODS OF SYNTHESIS

1. The Reaction of s-Triazines with Hetero-organic Compounds

The first representative of this group of compounds, tris-(β-trimethylsiloxyethyl) isocyanurate, was synthesised in high yield by the reaction of tris(β-hydroxyethyl) isocyanurate with trimethylchlorosilane in the presence of Bu_3N [4] (scheme 1):

Scheme 1

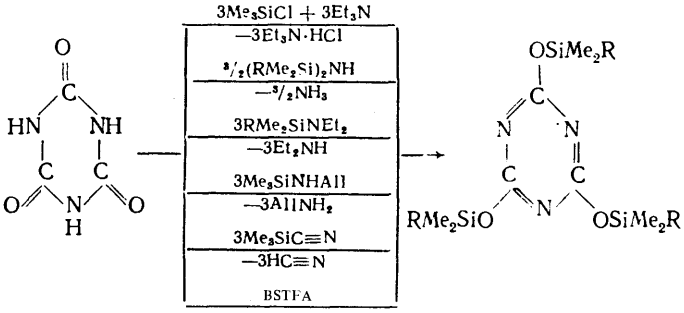


R= $(CH_2)_2OSiMe_3$, $(CH_2)_2OSnBu_3$.

The organotin analogue of the same isocyanurate was obtained in quantitative yield by the reaction with hexabutyldistannoxane,[5,6] and also by the reaction of $(Bu_3Sn)_2O$ with bis(β-iodoethyl) β-hydroxyethyl isocyanurate (yield 15%) and of tris(tributylstannyl) isocyanurate with ethylene oxide.[5]

An attempt to silylate isocyanuric acid in an autoclave at 350 °C by a shceme analogous to scheme 1 was initially unsuccessful,[7] but the use of dimethylformamide as solvent and of triethylamine (Et_3N) as HCl acceptor gave tris(trimethylsilyl) cyanurate in 74% yield[8-11] (scheme 2):

Scheme 2



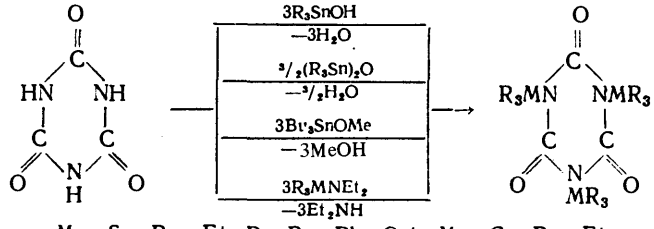
All = $-CH_2-CH=CH_2$, R = H, Me.

This cyanurate and its dimethylsilyl analogue were also obtained using the corresponding triorganosilylamines (scheme 2),[8-14] trimethylsilyl cyanide,[15] or N,O-bis(trimethylsilyl)trifluoroacetamide (BSTFA).[16]

The most promising reactions, because of their high yields and the purity of the desired products, are the reactions of isocyanuric acid with hexamethyl- or tetramethyldisilazanes (ammonium sulphate catalyst). The organosilicon cyanurates obtained can be purified by vacuum distillation, but increase in the distillation temperature or the presence of chlorine-containing impurities leads to their thermal decomposition.[12-14,17]

The first organotin s-triazines were obtained by Stamm,[18-20] again by the direct metallation of isocyanuric acid by tin-containing oxides and hydroxides (100–160 °C); with evacuation [scheme (3)]:

Scheme 3



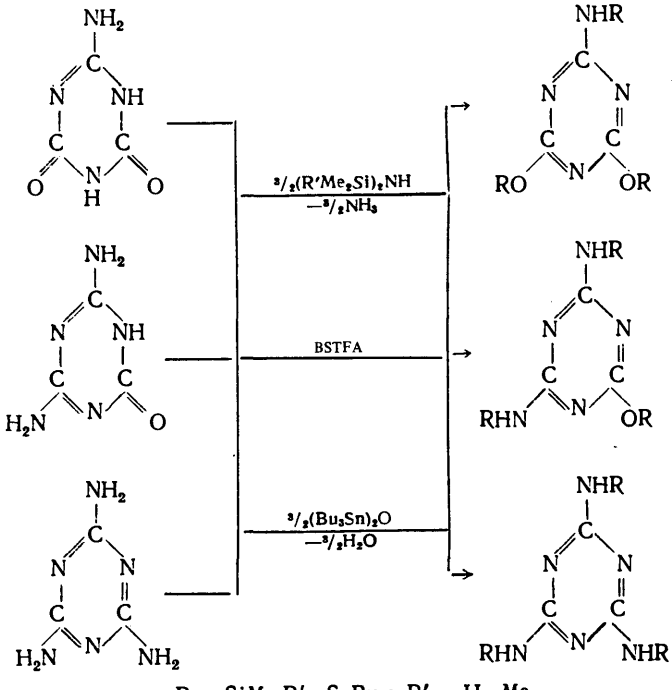
M = Sn, R = Et, Pr, Bu, Ph, Cct; M = Ge, R = Et.

The same method was later used to synthesise tris-substituted isocyanurates of triethyl- and tripropyltin.[21-23] The synthesis of these products by the reaction of cyanic acid with organotin oxides and hydroxides has been reported.[24] Under the given conditions (120–190 °C), however, the process probably involves the formation of isocyanuric acid, followed by reaction according to scheme 3.

The reaction of isocyanuric acid with methoxy- and diethylaminostannanes or diethylaminogermane gives the corresponding highly pure hetero-organic isocyanurates.[8,9,25]

Tris(organosilicon)- and tris(organotin)-derivatives of amino(hydroxy)-s-triazines were obtained similarly. Thus the reaction of the latter with hexamethyl- and tetramethyldisilazanes (HMDS and TMDS respectively) or BSTFA gave tris(trimethylsilyl)- and tris(dimethylsilyl)ammelide, -ammeline, and -melamine[9,11,16,26,27] (scheme 4):

Scheme 4



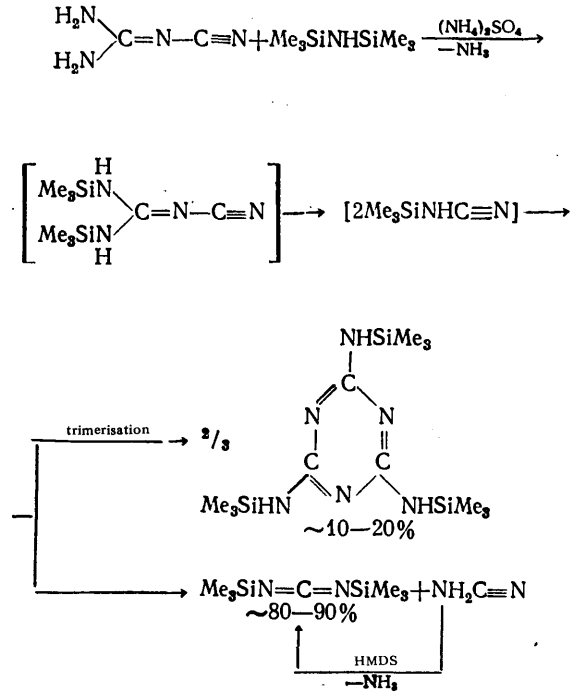
R = $SiMe_2R'$, $SnBu_3$; R' = H, Me.

The same heterocyclic compounds react with hexbutyldistannoxane to give the corresponding organotin compounds in good yield,[9,28] but they do not react with hexaethyldigermoxane.

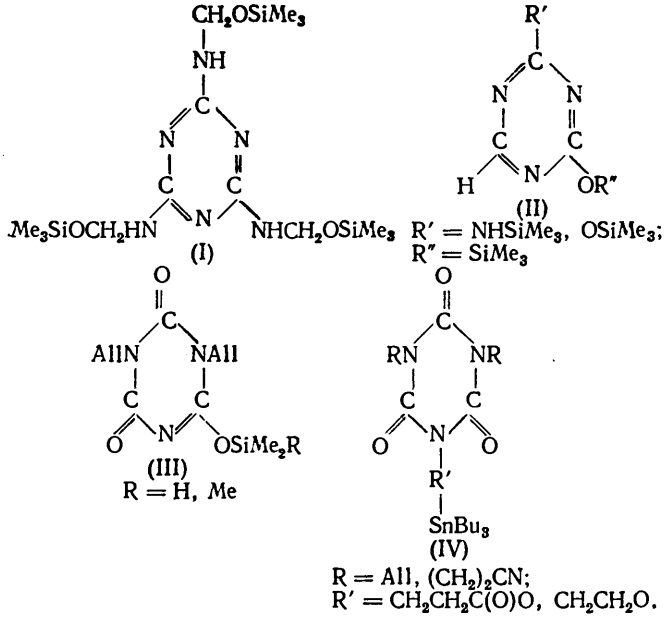
Silylation using HMDS or TMDS (ammonium sulphate catalyst) becomes increasingly difficult in the series isocyanuric acid–ammelide–ammeline–melamine, that is as the carbonyl groups are replaced by NH_2 groups. Thus the silylation of the first member of the series takes not more than 1–2 h, and a catalyst is not necessary, whereas tris-silicon-substituted melamine is obtained in 70% yield only after heating the reagents for 60 h in the presence of $(NH_4)_2SO_4$.

Other workers[29] who repeated this synthesis (H_2SO_4 catalyst, 140 °C, 6 h) were able to isolate only 2,4-bis(trimethylsilylamino)-6-amino-s-triazine in 35.5% yield, and the tris-substituted analogue was not obtained. There is no doubt that tris(trimethylsilyl)melamine exists, however, since it has been isolated in large quantities and identified as a by-product in the extended treatment of bis(trimethylsilyl)-carbodi-imide by the published methods.[30-33] A scheme for the formation of an organosilicon derivative of melamine has been proposed[33] (scheme 5):

Scheme 5

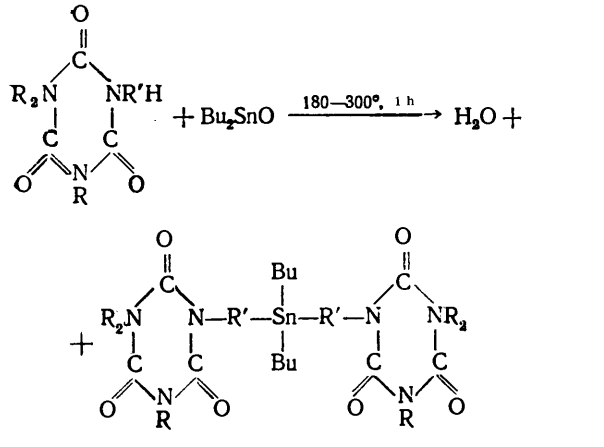


Reactions analogous to those of schemes 1–4 can also be used to obtain silylated derivatives of methylol- and organo-substituted melamines (for example compound (I),[34-37] amino-(hydroxy)-s-triazines (II),[38-42] organosilicon and organotin diallyl or dicyanoethyl isocyanurates (III), (IV),[5,6,43-45] and other compounds, frequently used as intermediates in organic synthesis:



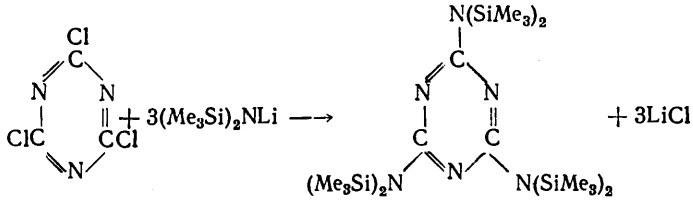
Organotin bis-triazine derivatives are formed according to a scheme which does not differ fundamentally from scheme 3 [5,6,46,47] (scheme 6):

Scheme 6



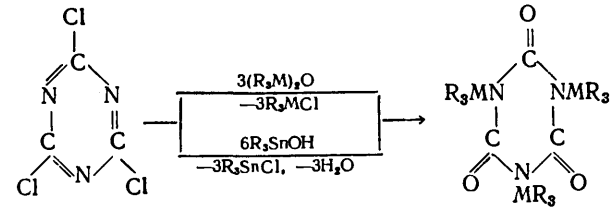
Mono-, di-, and trimethylsilyl derivatives of melamine can be synthesised using cyanuric chloride as the original s-triazine, and hexakis(trimethylsilyl)melamine has been obtained in low yield by the reaction of the latter with $(Me_3Si)_2NLi$ [29, 32,48–50] (scheme 7):

Scheme 7



Cyanuric chloride has also been used to obtain other hetero-organic s-triazines. Thus the organogermanium s-triazine tris(triethylgermyl) isocyanurate was first synthesised according to scheme 8 by heating a mixture of the reagents in dibutyl ether for a long time. The yield was 73%. [51]

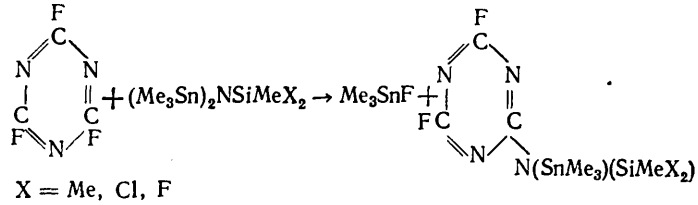
Scheme 8



M = Ge, R = Et; M = Sn, R = Et, Bu, $PhCH_2$— .

Cyanuric chloride reacts similarly with triethyltin and tribenzyltin hydroxides and hexabutyldistannoxane. [51] The use of cyanuric chloride to obtain various carbofunctional organosilicon s-triazines [48,52–57] (including trimethylsilylethynyl, [52] trimethylsilylphenyl, [53] and other derivatives) and triazine-containing polysiloxanes [58–66] has also been described. Cyanuric fluoride can be used instead of cyanuric chloride. Thus the reaction of cyanuric fluoride with mixed organosilicon–tin amines has been used to synthesise a number of corresponding mono-substituted s-triazines [67] (scheme 9):

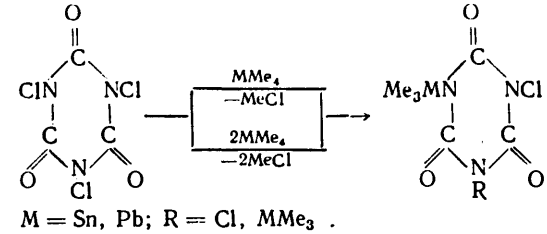
Scheme 9



X = Me, Cl, F

Trichloroisocyanuric acid has been used to synthesise hetero-organic compounds of this class. A method has been described [68] for obtaining mono- and di-substituted organotin isocyanurates and a dialkyltin bis-isocyanurate derivative using the above chlorine-containing heterocyclic compound. The same method was used to prepare the only mono- and di-substituted organolead s-triazines which have been obtained up to the present, namely dimethylplumbyl dichloroisocyanurate and bis(trimethylplumbyl) chloroisocyanurate [68] (scheme 10):

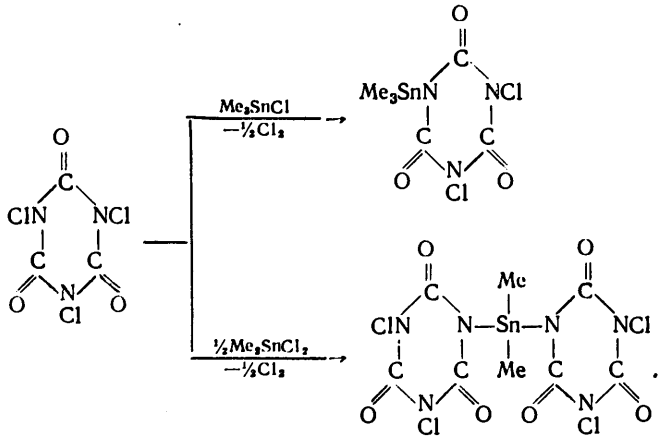
Scheme 10



M = Sn, Pb; R = Cl, MMe_3 .

If the metallating reagent contains a chlorine atom, molecular chlorine is liberated instead of methyl chloride. For example, in the case of trimethylchloro- or dimethyldichlorostannanes, the products were chlorine and trimethylstannyl dichloroisocyanurate or bis(di-chloroisocyanurato)dimethylstannane respectively (scheme 11):

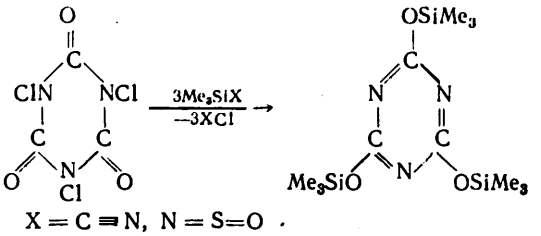
Scheme 11



The analogous organosilicon derivatives, trimethylsilyl and dimethylsilyl dichloroisocyanurates, have been described.[69]

The reaction of trichloroisocyanuric acid with trimethylsilyl cyanide and sulphinyl imide,[15] in which exchange of trimethylsilyl fragments and chlorine atoms takes place to give tris-(trimethylsilyl) cyanurate, was studied later (scheme 12):

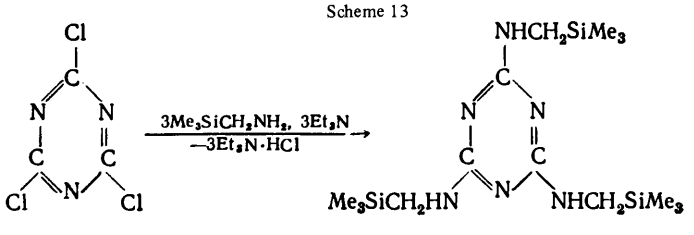
Scheme 12

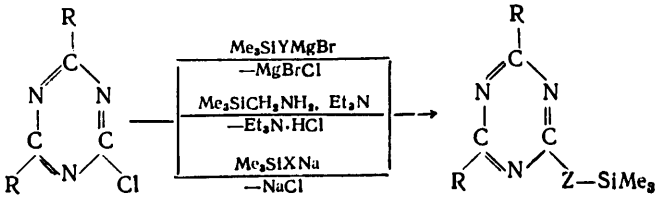


X = C≡N, N = S=O .

The routes by which cyanuric chloride and other halogenotriazines are converted into their hetero-organic analogues are extremely varied. For example, the above trimethylsilylethynyl[52] or trimethylsilylphenyl[53] heterocycles are obtained using a Grignard reagent, and a number of carbofunctional derivatives are obtained by the reaction with Me_3SiCH_2L (L = NH_2, ONa, SNa; boiling benzene, 6 h)[51] (scheme 13):

Scheme 13



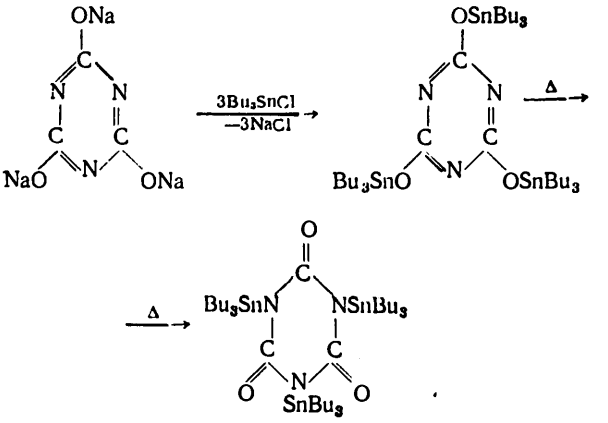


R = Cl, Y = Z = —C≡C—, —C_6H_4—; R = Ph,
X = Z = CH_2O, CH_3S; R = Ph, NH_2, Z = CH_2NH.

In contrast to this scheme, the reaction of cyanuric chloride with sodium triethylsilanolate (160–200 °C, 1 h, without solvent) gave not tris(triethylsilyl) cyanurate but its decomposition product Et_3SiNCO and NaCl.[17]

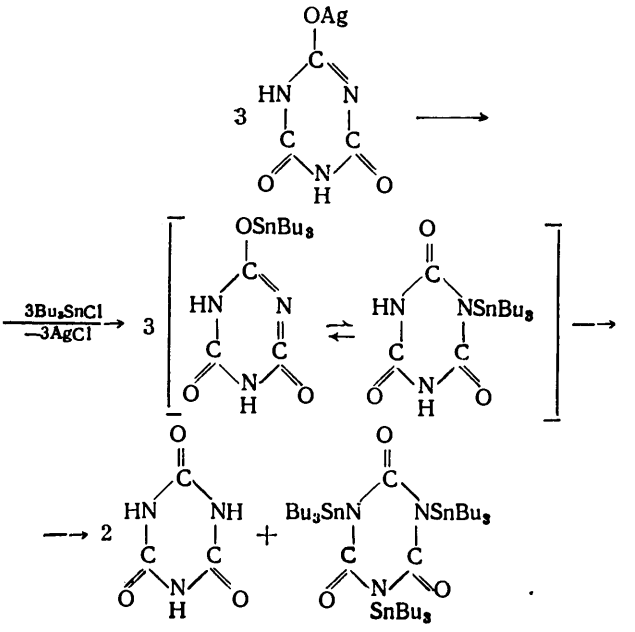
Sodium chloride is also formed in the reaction of sodium isocyanurate with tributylstannyl chloride (50 °C, 5 h), and the yield of the desired product, tris(tributylstannyl) isocyanurate, reaches only 18%.[51] The authors proposed and confirmed by infrared (IR) spectroscopy a reaction scheme involving the intermediate formation of the comparatively unstable cyanurate isomer (scheme 14):

Scheme 14



The transformations involving tributylstannyl chloride and various salts of isocyanuric acid were studied in more detail in Ref.70. The addition of moist solvents (acetonitrile, dimethylformamide) to the reaction system increases the yield of the Sn-s-triazine to 37%. In dry dimethylformamide the yield was 15%. The influence of moisture is attributed to the partial hydrolysis of the original salt to give isocyanuric acid, which is then stannylated by the hexabutyldistannoxane formed to give the tris-substituted isocyanurate according to scheme 3. The reaction of tributylstannyl chloride with thoroughly dried monosilver isocyanurate, contrary to expectations, also gave tris(tributylstannyl) isocyanurate (yield 79%) (scheme 15):

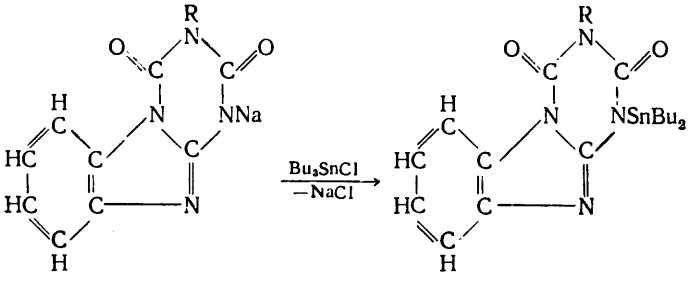
Scheme 15



Treatment of the unseparated reaction mixture with hexabutyldistannoxane gave an additional quantity of organotin isocyanurate. Similar treatment of monocalcium isocyanurate gave the same product in 70% yield.

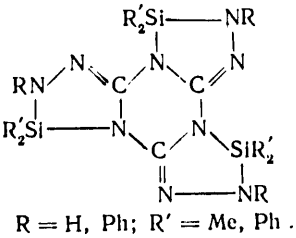
In contrast to this, the monosodium salts of triazine benzimidazoles react with tributylstannyl chloride to give the corresponding mono-substituted organotin compounds[71,72] according to scheme 16:

Scheme 16



R = $(CH_2)_5CN$, $(CH_2)_5CO_2Me$, $(CH_2)_5CO_2Et$, NMe_2, Alk, Ar etc.

A series of substituted organosilicon triazoles containing triazine rings were obtained similarly.[73]

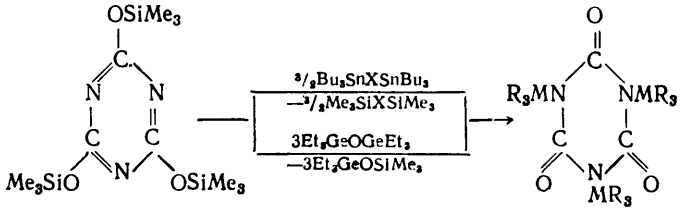


R = H, Ph; R′ = Me, Ph.

A promising method for obtaining hetero-organic s-triazines is provided by remetallation, which gives high yields and pure products. The chief condition for success is the continuous vacuum distillation of the volatile products.

This method was used to synthesise tris(triethylgermyl) and tris(tributylstannyl) isocyanurates; the substrate used was tris(trimethylsilyl) cyanurate, and hexaethyldigermoxane was remetallated to $Et_3GeOSiMe_3$ [9,33,74] (scheme 17):

Scheme 17

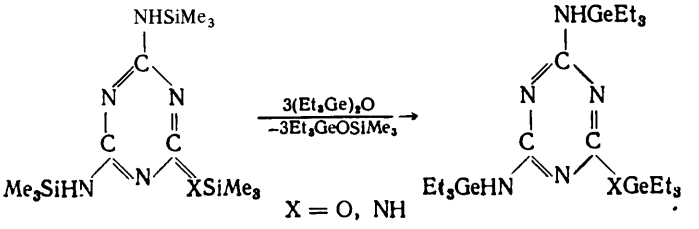


M = Ge, Sn; X = O, N=C=N.

The remetallation is reversible, and without evacuation gives a mixture of the starting materials and final products[75] (see scheme 43 in section IV).

By analogy with scheme 17, the corresponding organosilicon compounds gave for the first time tris-substituted organogermanium derivatives of ammeline and melamine[9,28] (scheme 18):

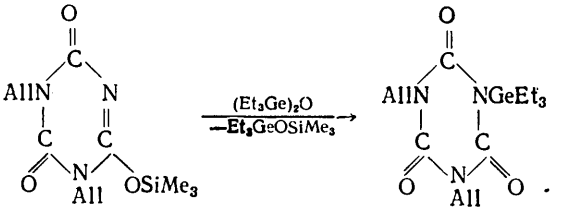
Scheme 18



X = O, NH

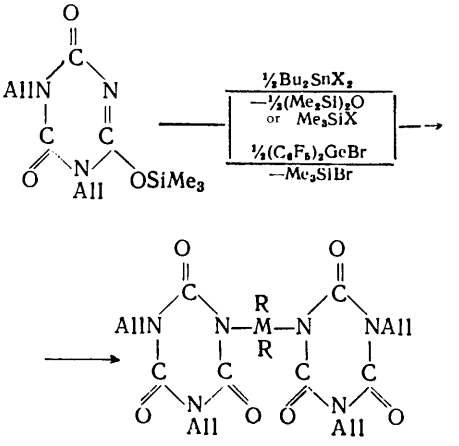
Remetallation also proved successful for the synthesis of triethylgermyl diallyl isocyanurate, since diallyl isocyanurate undergoes practically no direct reaction with hexaethyldigermoxane (200 °C, yield <5%)[43] (scheme 19):

Scheme 19



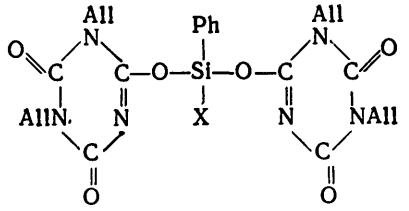
This method has been used to synthesise a number of hetero-organic derivatives of polydiallyl isocyanurates. Thus the reaction of two moles of trimethylsilyl diallyl isocyanurate with dichloro-, dibromo-, or dimethoxydibutylstannanes or dibutylstannoxane under comparatively mild conditions (100–120 °C, 0.5 h) gave bis(diallyl isocyanurato)dibutylstannane[46,76] according to scheme 20:

Scheme 20

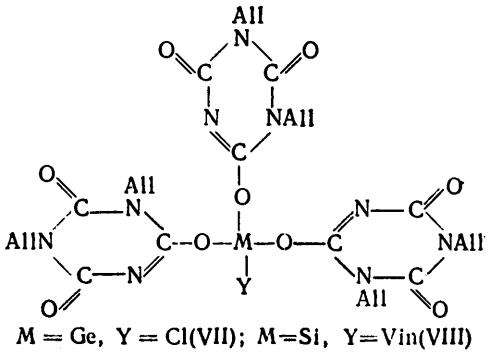


X_2 = O, $O(Me)_2$, Cl_2, Br_2; M = Ge, R = C_6F_5; M = Sn, R = Bu

The use of the corresponding hetero-organic halides and reagent ratios gave quantitative yields of bis(diallyl isocyanurato)methylphenyl- and -diphenylsilanes [compounds (V) and (VI)] and also tris(diallyl isocyanurato)chlorogermane and -vinylsilane (VII) and (VIII):[76]



X = Me(V), Ph(VI)

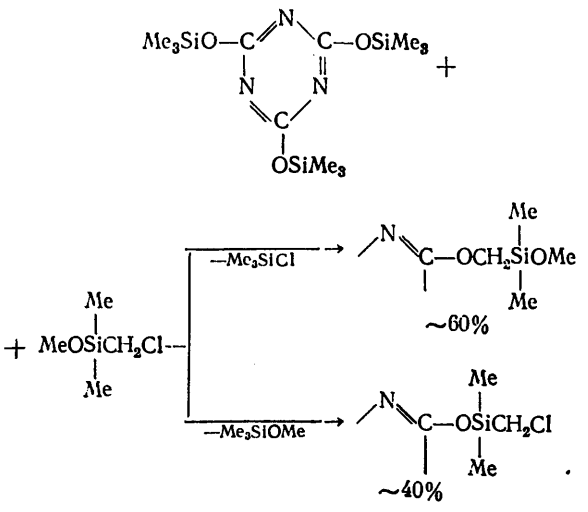


M = Ge, Y = Cl(VII); M=Si, Y=Vin(VIII)

It should be emphasised that organogermanium s-triazines are becoming accessible as a result of remetallation, since the most widely encountered starting materials, namely isocyanuric acid, ammelide, ammeline, melamine, and their many derivatives do not react with hexaethyldigermoxane under real conditions. The use of other germylating agents gives low yields of product.[9]

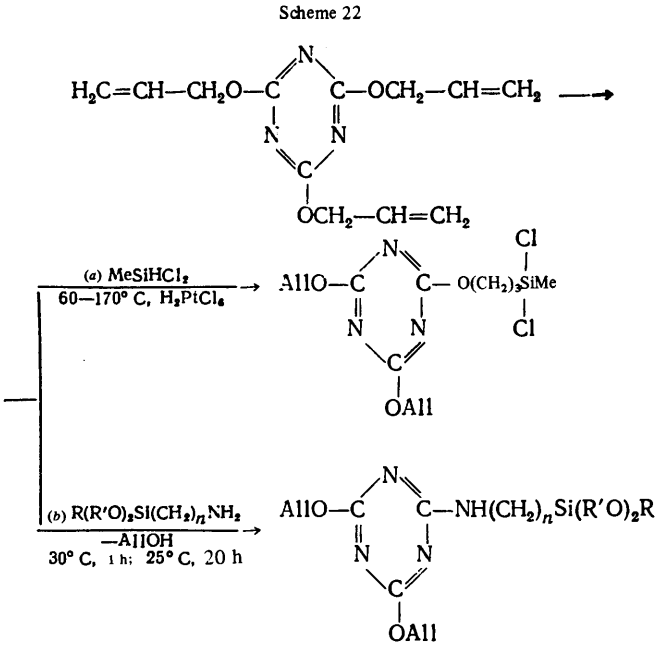
Tris(trimethylsilyl) cyanurate can react with α-chloromethylsilanes such as $(MeO)Me_2SiCH_2Cl$, $(EtO)_2MeSiCH_2Cl$, $(EtO)_3SiCH_2Cl$, etc. both in the direction of resilylation to give the alkoxytrimethylsilane and in the direction of silicoalkylation to give trimethylchlorosilane. This gives a mixture of organosilicon cyanurates containing two types of substituent in different combinations in the triazine ring[48] (scheme 21):

Scheme 21



Analogous compounds can also be obtained by the hydrosilylation of triallyl isocyanurate by chlorohydrosilanes, which, depending on the reagent ratio and the reaction conditions, gives the products of mono-, di-, and tris-addition, for example according to scheme 22a:[48]

Scheme 22



R = Me, R'O; R' = Me, Et; n = 2,4 .

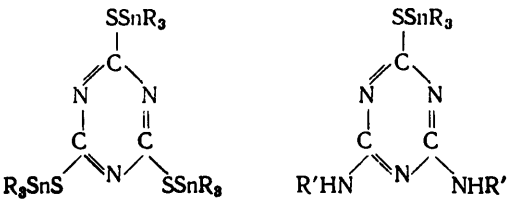
The same original s-triazine on partial ammonolysis under the influence of silylamines such as $R(R'O)_2Si(CH_2)_nNH_2$ is converted into the corresponding mono-substituted aminosilyl derivatives (scheme 22b).[77,78]

Hydrosilylation has also been used to prepare fluorosilicone-triazine polymers.[79-82]

Here it may be noted that the s-triazines synthesised according to schemes 21 and 22 [49,77,78,83] are as yet the only carbofunctional cyanurates, since other known analogues of this series exist in the oxo-form. In particular, Berger[84-87] showed by IR and NMR spectroscopy that the carbofunctional mono-, di-, and trialkyoxyorganosilicon heterocycles of this class, obtained by the reaction of triallyl isocyanurate with alkoxyhydrosilanes (100 °C, H_2PtCl_6), are isocyanurates.

A carbofunctional oxo-compound, tris[β-trimethylsilyl)-propionyl] isocyanurate, was synthesised by the reaction of tris(trimethylsilyl) cyanurate with β-(trimethylsilyl)propionyl chloride[17] (see scheme 39b, section IV).

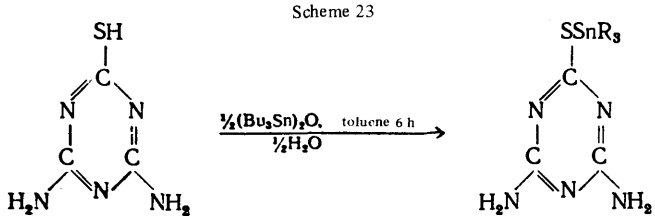
Sulphur-containing derivatives of organotin s-triazines have been obtained in good yields by the reaction of the appropriate thio-derivatives with various metallating agents according to schemes analogous to schems 1–4.[88-92] Examples of these compounds are tris[trialkyl(aryl)stannyl] trithiocyanurates and substituted trialkyl(aryl)stannylthioammelines



R = Pr, Bu, Ph, $PhCH_2$; R' = Et, Pr, iso-Pr, Bu, All, $MeO(CH_2)_2$, $MeO(CH_2)_3$ etc.

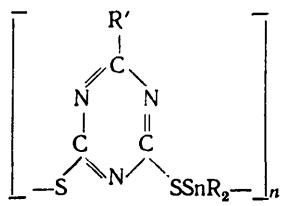
Unlike ammeline, thioammeline can undergo selective stannylation of the thiol group (scheme 23):[88]

Scheme 23



R = Pr, Bu, Ph, $PhCH_2$.

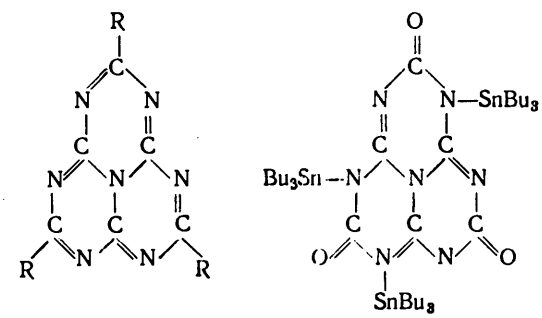
The reaction of thiotriazines or their sodium salts with dialkylstannoxanes and dichlorostannanes respectively gave oligomeric and polymeric s-triazine derivatives:[93]



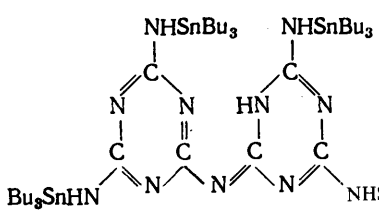
R = Me, Bu, Oct, Ph; R′ = PhO, PhNH, EtNH, Et_2N, MeO etc.; n = 5—293 .

In addition to the data on organosilicon sulphur-containing s-triazines given in scheme 13,[57] data on the preparation and uses of a number of their analogues have also been published.[94,95]

This group of methods can also be used to synthesise condensed and other complex hetero-organic systems containing s-triazine rings. Thus the reaction of hexabutyldistannoxane with cyameluric acid, melem, and melam gives tris-(tributylstannyl) cyamelurate, tris(tributylstannyl)melem, and tetra(tributylstannyl)melam respectively.[27,96,97] HMDS has been used to synthesise tris(trimethylsilyl) cyamelurate in high yield, but melem and melam do not undergo this reaction.



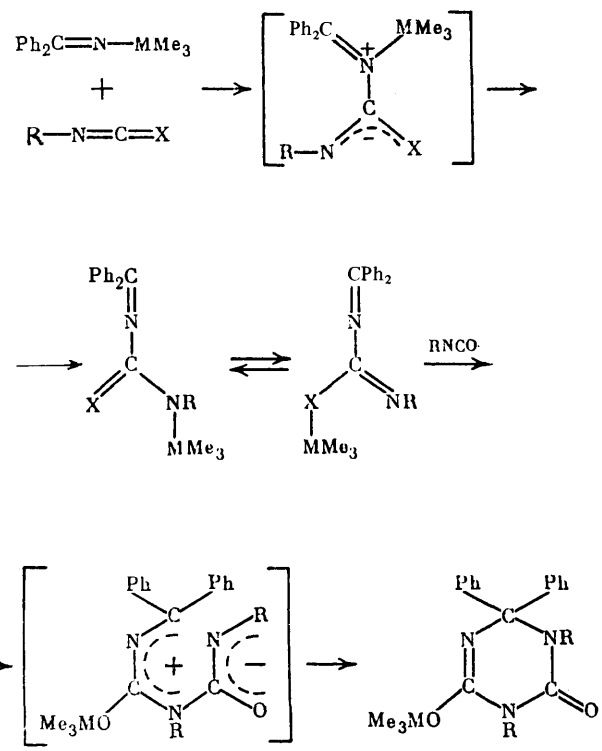
R = $OSiMe_3$, $NHSnBu_3$



2. The Cyclo-addition of Isocyanates to Substances with C=N Bonds

An extremely interesting and original method for obtaining hetero-organic s-triazines is provided by the cyclo-addition of isocyanates to the double bonds of nitrogen-containing hetero-organic compounds. In this case the s-triazine ring is formed in the reaction, and is not introduced into the system in the "prepared" form. Thus in the reaction of isocyanates with organosilicon and organotin derivatives of ketimines, a two-stage process gives the corresponding hetero-organic s-triazines (the reaction conditions are different for different M, R, and X)[98—100] (scheme 24):

Scheme 24



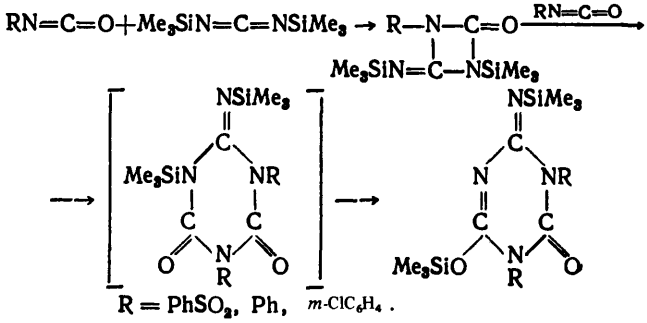
M = Si, Sn; R = Me, Ph; X = O, S .

In the first stage, the isocyanate is inserted at the element—nitrogen bond; the 1 : 1 adduct exists in two tautomeric forms (in the case of isocyanate the reaction is complete at this stage). In the second stage the next isocyanate molecule undergoes cyclo-addition with the 1 : 1 adduct.

The formation of similar s-triazines as intermediate compounds has been established in the reaction of $Ph_2C{=}N{-}S(O){-}PhSiMe_3$ with methyl isocyanate or $Cl_3CC{\equiv}N$.[101]

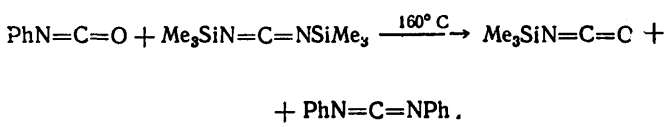
The reactions of isocyanates with organosilicon, -germanium, and -tin carbodi-imides is characteristic. The reaction of benzenesulphonyl isocyanate with bis(trimethylsilyl)carbodi-imide takes place on heating to 100—150 °C to give, depending on the conditions, four- or six-membered silicon-containing heterocycles according to scheme 25:[32,33,102]

Scheme 25



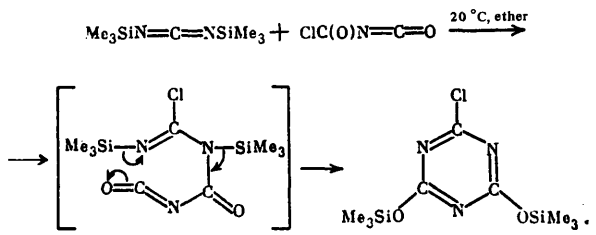
A similar scheme was proposed for the reaction of isocyanates with organic carbodi-imides.[103,104] The corresponding reactions of phenyl and *m*-chlorophenyl isocyanates take place under more severe conditions (190–250 °C, 3 h) to give as main products the corresponding organo-silicon s-triazines (yields 82–90%).[8,17,32,33,105] According to Ref. 106, the reaction of PhNCO with bis(trimethylsilyl)carbodi-imide with distillation of the volatile product (Me_3SiNCO) takes place as an exchange reaction, but no experimental proof was given (see scheme 26):

Scheme 26



In contrast to schemes 25 and 26, chloroformyl isocyanate reacts with bis(trimethylsilyl)carbodi-imide at a reagent ratio of 1:1 under mild conditions to give 2,4-bis(trimethylsiloxy)-6-chloro-1,3,5-triazine in 64% yield according to scheme 27:[32,107]

Scheme 27

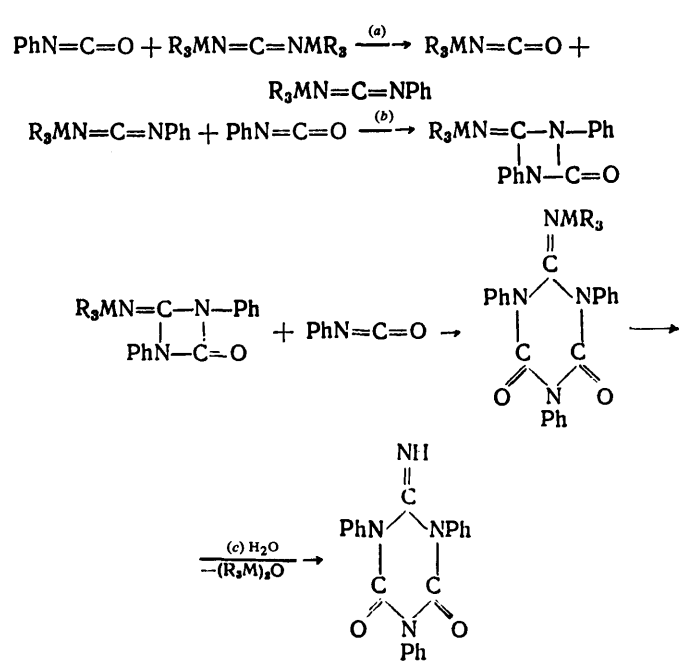


The scheme shows that the reaction begins with the electrophilic addition of isocyanate at the C=N bonds of the carbodi-imide. The product undergoes cyclisation with simultaneous migration of the Me_3Si groups from the nitrogen to the carbon atoms.

The reaction of the same isocyanate with Me_3SiNSO, instead of the expected OCN–CO–NSO and Me_3SiCl, gives tris(trimethylsilyl) cyanurate (yield 84%) and $(ClCONSO)_x$.[15]

Organogermanium and organotin s-triazines are also formed by the three-stage reaction of phenyl isocyanate with bis(tributylstannyl)carbodi-imides (scheme 28).[32,33,105,108]

Scheme 28

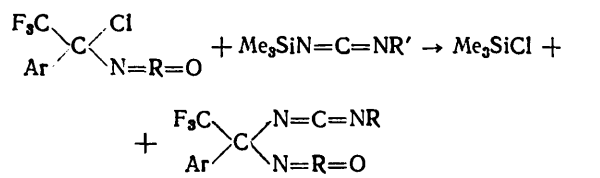


M=Ge, R=Et; M=Sn, R=Bu.

The scheme was confirmed by the IR spectra of the reaction mixtures and identification of the hydrolysis products. For example, heating phenyl isocyanate with $Bu_3SnN{=}C{=}NSnBu_3$ in the ratio 3:1 with subsequent hydrolysis of the reaction mixture gave 1,3,5-triphenyl-2-imino-4,6-dioxo-1,3,5-triazine in 61% yield. The last compound can be formed only by the hydrolytic splitting of the SnN bond of the corresponding organotin heterocycle (scheme 28c).[32,33,108]

In the case of $PhSO_2NCO$, scheme 28 is not realised, and germanium or tin s-triazines are not detected among the reaction products. The reaction involves exchange, and can be illustrated by a scheme analogous to schemes 26 and 28a. A similar result was established in a study of the reaction of unsymmetrical organosilicon carbodi-imides with α-chloroisocyanates according to scheme 29:[109–111]

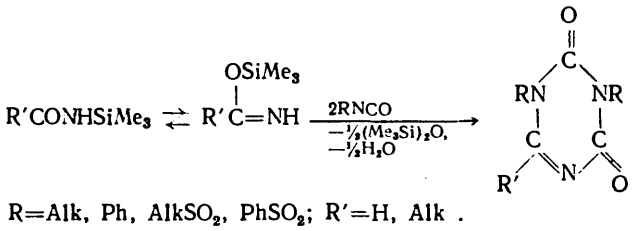
Scheme 29



R=C, S; Ar=Ph, *p*-MeC_6H_4, *p*-ClC_6H_4; R'=Ph, COOEt.

Cyclo-addition involving trimethylsilylformamides and isocyanates, leading to the intermediate formation of the corresponding organosilicon s-triazines, has been used to prepare their organic analogues, which are not readily obtainable[112] (scheme 30):

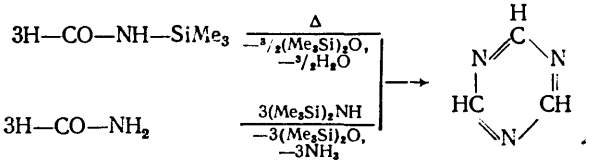
Scheme 30



R=Alk, Ph, $AlkSO_2$, $PhSO_2$; R'=H, Alk .

A similar process apparently forms the basis of the synthesis of s-triazine according to scheme 31:[113]

Scheme 31



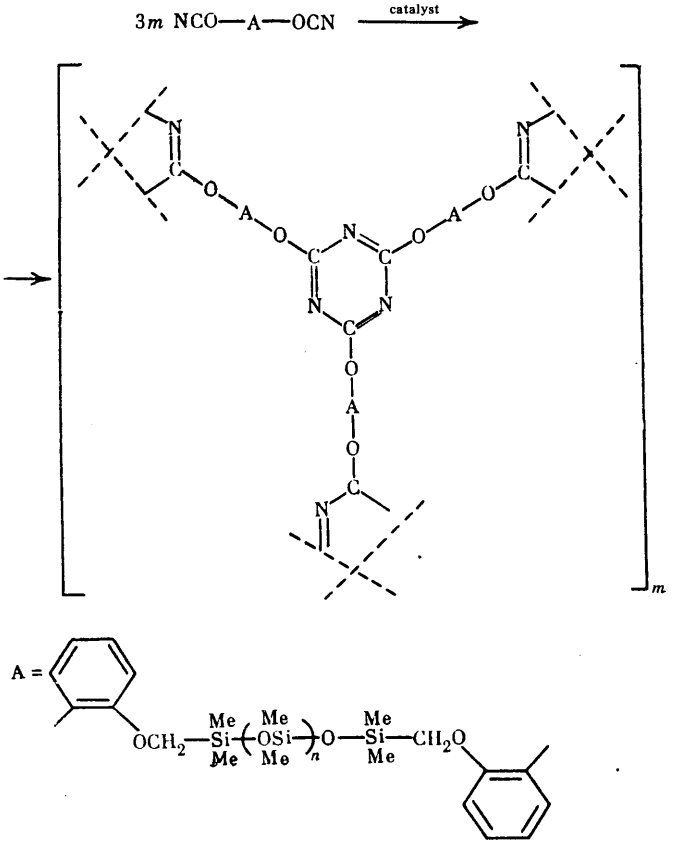
In contrast to the previous systems the analogous reactions of carbofunctional organosilicon imines give organosilicon s-triazines stable under ordinary conditions. Thus $Me_3Si(CH_2)_2C(OEt)=NH$ has been used to synthesise 2,4,6-tris-[β-(trimethylsilyl)ethyl]-1,3,5-triazine in quantitative yield.[114] The reaction of aminosilanes $R_3Si(CH_2)_3NH_2$ (R = Me, Et, Bu, EtO) with formaldehyde or paraform gave a number of other carbofunctional organosilicon analogues of the latter.[115–118] The aminosilane apparently first reacts with CH_2O by an A_N–E mechanism to give Schiff bases $R_3Si(CH_2)_3N=CH_2$, which subsequently trimerise to the corresponding s-triazines.

The addition of formaldehyde to trimethylisocyanatosilane gave as final product tris-[(trimethylsilyloxy)methyl] isocyanurate instead of its monomer $Me_3SiOCH_2N=C=O$ (CH_2O was bubbled through Me_3SiNCO at 80–83 °C.[119]

The formation of isocyanurates was also observed in the preparation of carbofunctional and organosilicon isocyanates by the reactions of KOCN with chlorine-containing siloxanes in dimethylformamide (DMF).[120–122] The improvement of the method has been protected by a series of patents devoted to the synthesis of carbofunctional s-triazines by heating mixtures of metal cyanates with various organosilyl halides in aprotic solvents (3–10 h, 90–140 °C, yield 90–95%).[123–130]

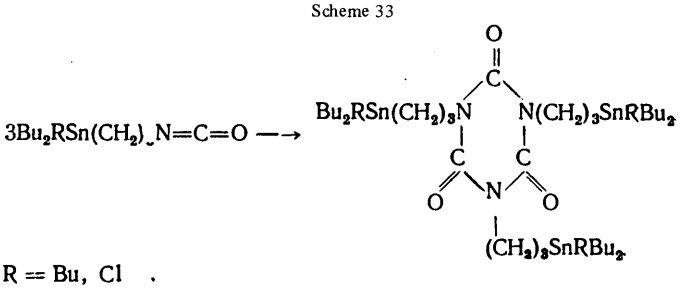
The trimerisation of isocyanates such as $Me_3SiO(CH_2)_4NCO$ by heating for a short time in DMF in the presence of $PhCO_2Na$,[131] and the preparation of polymeric cyanurate-containing siloxanes by the polycyclotrimerisation of the corresponding dicyanates according to scheme 32,[132,133] have been reported:

Scheme 32



The trimerisation of isocyanates is widely used to produce organic isocyanaurates.[134,135] In the chemistry of the heteroorganic compounds of group IVb, however, practically no use is made of this reaction, since the isocyanates R_3MNCO do not trimerise, and the corresponding data on their carbofunctional analogues are limited to the papers cited above[120–133] for the organosilicon and organotin derivatives.[136,137] In the last papers it is reported that the cyclotrimerisation of $Bu_2RSn.(CH_2)_3N=C=O$ takes place at room temperature to give high yields of the corresponding products (scheme 33):

Scheme 33



R = Bu, Cl .

Data have been published[138,139] on the analogous monosubstituted heterocycle, 2-[γ-(bromodiphenylstannyl)propoxy]-4,6-dichloro-1,3,5-triazine.

There are no published data on the synthesis and properties of germanium- and lead-containing carbofunctional s-triazines.

III. PHYSICOCHEMICAL PROPERTIES AND STRUCTURE

The hetero-organic compounds being considered are glycerol-like colourless or weakly coloured liquids, which boil at high temperatures or cannot be distilled in a vacuum, or vaseline-like or solid products. They are generally soluble in ether, dioxan, benzene, toluene, chloroform, and carbon tetrachloride, and insoluble in water; most hetero-organic s-triazines (except the carbofunctional compounds) are hydrolysed by water. The compounds can be kept practically unchanged for many months in an air-tight vessel. They are extremely stable to heat,[18-21,24] and can be vacuum-distilled with gentle heating. Some of these substances, however, decompose rapidly when heated strongly[12-14,17,49,50] or polymerise.[43,46,76] There are practically no specific published data on these processes, apart from data on the thermal decomposition of tris(trimethylsilyl) cyanurate, which at 280 °C in the pure state[12-14,17] or at 200–230 °C in the presence of chlorine-containing substances[17] decomposes to the monomer, trimethylisocyanatosilane, in quantitative yield. The reaction takes place so cleanly that it can be used to prepare $Me_3SiN{=}C{=}O$. As noted above, an attempt to obtain tris(triethylsilyl) cyanurate from cyanuric chloride and Et_3SiONa (160–200 °C, 1 h) also gave chiefly $Et_3SiN{=}C{=}O$.[17] In contrast to this, heating carbofunctional isocyanates in aprotic solvents gives the opposite result, that is the trimer is formed.[119-131]

Most workers have used IR spectroscopy to prove the structures of the hetero-organic s-triazines obtained. Some information has also been obtained from the NMR,[11,15,29,36,37,84-87,98,115,140] Raman,[15] and mass spectra[15,16,122] of these compounds. Since practically no use has been made of other instrumental methods (ultraviolet spectroscopy, X-ray diffraction), the conclusions reached from the IR and NMR spectra are extremely important. The structure of hetero-organic amino(hydroxy)-derivatives of isocyanuric acid depends chiefly on the nature of the substituent element and also on the volume of the organic groups joined to it. Thus all silicon-substituted non-carbofunctional s-triazines exist in the hydroxy-from (A) (O–Si), and the number of C=N double bonds in the ring corresponds to the number of R_3Si groups.[8-16,26,27,32,33,43,74,76,98-100,107] The explanation is probably that silicon has a higher affinity for oxygen than the other elements of group IVb; this is the reason for the high thermodynamic stability of the Si–O bond.

In contrast to this, the organogermanium, -tin, and -lead analogues for all degrees of substitution have the isocyanurate structure (B) (M–N), characterised by the presence of free carbonyl groups, whose IR bands lie in the range 1720–1620 cm^{-1}. Exceptions are the derivatives of ammeline[9,28,33] and ammelide,[99,100] since their R_3M groups (M = Ge, Sn) are joined to the ring through the oxygen atom, as in the organosilicon cyanurates. Tris(benzoyl)ammeline has a similar structure.[17] The fact that these compounds exist only in the form indicated is apparently due to steric hindrance in the formation of the corresponding nitrogen-functional isomers and hence their forced symmetrisation. The structure of the oligodiallyl isocyanurate hetero-organic compounds in Ref.76 can be explained similarly.

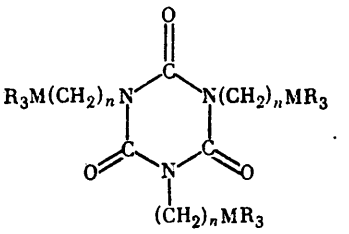
(C)



(D)

In addition to the above-mentioned bands due to carbonyl groups, the IR spectra of the organogermanium and organotin isocyanurates also contain bands due to the triazine ring with substituents on the nitrogen atom at 1480–1460 cm^{-1} and 780–760 cm^{-1}.[2,9,17,51] The marked decrease in the C=O stretching wavenumbers in the IR spectra of the organogermanium and organotin s-triazines[9,20,76] is probably due to the decrease in the strength of the C=O bonds as a result of the coordination of adjacent ring nitrogen atoms to the metal atoms, as in organotitanium isocyanurates [form (C)].[141-144] The IR spectra of s-triazines of type (A) contain bands due to the skeletal vibrations of the cyanurate ring at 1580–1515, 1460–1400, and 815–810 cm^{-1}, but do not contain carbonyl group bands.[2,8,9,11,26,28,33,43,74] The hydroxy-structure of the silicon-containing compounds is confirmed by the presence of Si–O–C group bands with a maximum at 1140–1110 cm^{-1}.[8,9,11,15,26]

The hydroxy-form of organosilicon amino(hydroxy)-s-triazines was proved convincingly in an IR and ^1H NMR spectroscopic study of their tri-substituted dimethylsilyl derivatives.[8,11] The ν(Si–H) bands in the IR spectra of these compounds are displaced to higher wavenumbers and increase in the derivative order: melamine–ammeline–ammelide–cyanuric acid. Thus in the first case ν(Si–H) lies at 2140 cm^{-1}, whereas in the last case the wavenumber is increased to 2180 cm^{-1}. This indicates that the Si–H bond in the oxygen-containing organosilicon s-triazines is stronger than that in related compounds containing $H{-}\overset{|}{\underset{|}{Si}}{-}N{=}$ fragments. One reason for this phenomenon is apparently the difference in the degree of conjugation of the Si–O and Si–N bonds. The ν(Si–H) bands of the $Me_2HSiOC{\equiv}$ (E) and $Me_2HSiNH{-}$ (F) groups of tris(dimethylsilyl)ammelide and tris(dimethylsilyl)ammeline were distinguished; they lie at 2170 cm^{-1} and 2160 cm^{-1} for (E) and at 2130 cm^{-1} and 2135 cm^{-1} for (F). The numbers of these fragments can also be estimated from the intensity ratio of the signals of the silyl protons in the ^1H NMR spectra (the chemical shifts for (E) and (F) are 4.92 p.p.m. and 4.60 p.p.m. respectively). Thus the rearrangement of the isocyanurate to the cyanurate system and vice versa may be due either to the introduction of the organosilicon substituents into the isocyanuric acid structure or to the replacement of the latter by other hetero-organic fragments containing group IVb elements[74,75] (section IV, scheme 43). The isomeric transformation of the individual hetero-organic s-triazines is generally irreversible, and in some cases it can be followed by instrumental methods. Thus scheme 14, given in Ref.51, was proved by the IR spectra of the reaction mixtures (50 °C, 5 h), which contain bands due to tris(tributylstannyl) cyanurate [form (A)] at 1560 cm^{-1} and 820 cm^{-1}. When heated to 100–150 °C, the cyanurate is converted into the isocyanurate, as shown by the appearance of bands due to the isocyanurate ring at 1480 cm^{-1} and 780 cm^{-1}, and bands due to the carbonyl groups at 1680–1620 cm^{-1} [form (B)]; the bands characteristic of form (A) disappear. In Refs.23 and 145, the tripropyl- and tributylstannyl derivatives of isocyanuric acid were erroneously assigned to hydroxy-form (A).

As noted above, carbofunctional s-triazines containing group IVb elements usually exist as the isocyanurates, as shown by IR [17,33,58,84,120,122,136,137] and ^{13}C NMR [36,37] spectroscopy. For example, according to Ref.122, $\nu_{as}(C=O)$ for organosilicon s-triazines $[RC_6H_4SiMe_2CH_2NCO]_3$ (R = Hal, p-Me_3C, p-Me_3Si, p-Me_2N) lies at 1680 cm^{-1}, and that for the organotin compounds $[Bu_2Sn(CH_2)_3NCO]_3$ (R = Bu, Cl) at 1700 cm^{-1}, [136,137] that is practically in the range of the carbonyl vibrations of ordinary organic isocyanurates. Bands due to the isocyanurate ring (1470 cm^{-1} and 775 cm^{-1}) were also detected. [136,137]

Data have been published, however, indicating that carbofunctional s-triazines may be formed when tris(allyl) cyanurate is used as the original heterocyclic compound. [4,48,77,78,83] This was confirmed by the IR spectra of the products, which show bands due to the skeletal vibrations of the ring at 820–818 cm^{-1} and the allyloxy-groups at 995–990 cm^{-1} and 950–925 cm^{-1}; the C=O group bands at about 1700 cm^{-1} are not observed. [77]

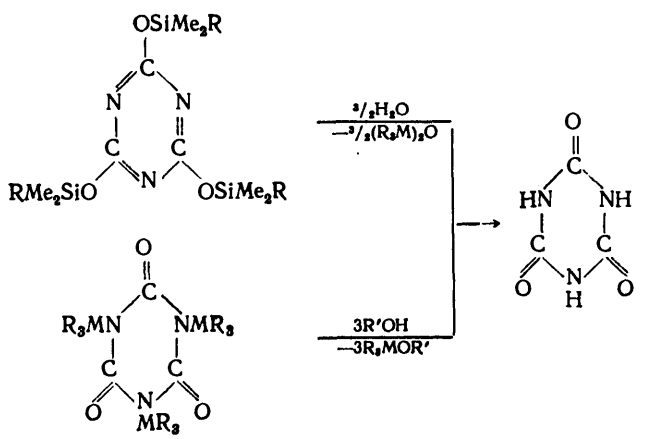
The silicon-containing derivatives of cyameluric acid, like their s-triazine analogues, exist in the O–Si form, and the tin-containing compounds exist in the N-Sn form. [96,97]

Refractometry has also been used in the synthesis and identification of hetero-organic s-triazines, and the study of a series of organosilicon, -germanium, and -tin derivatives of diallyl isocyanurate and isocyanuric acid showed that the average difference between the calculated and experimental values of the molar refraction is −1.20 cm^3 (2σ = 0.15 cm^3). This quantity can be taken as the correction for the isocyanurate ring to the refraction of compounds of this class. [146]

IV. CHEMICAL PROPERTIES

Organosilicon, -germanium, -tin, and -lead s-triazines are extremely reactive substances, but their chemical properties have been insufficiently studied. The best known reactions are those of the hetero-organic derivatives of isocyanuric acid with water and other nucleophilic reagents. Most of these substances are hydrolysed even by atmospheric moisture, so that they can be kept only in air-tight vessels or sealed ampoules. Thus tris(trimethylsilyl) cyanurate and tris(triethylgermyl) isocyanurate are hydrolysed almost instantaneously to isocyanuric acid and hexamethyldisiloxane or hexaethyldigermoxane respectively (scheme 34) [8,11,15,33,52,74] (compare with schemes 2 and 3):

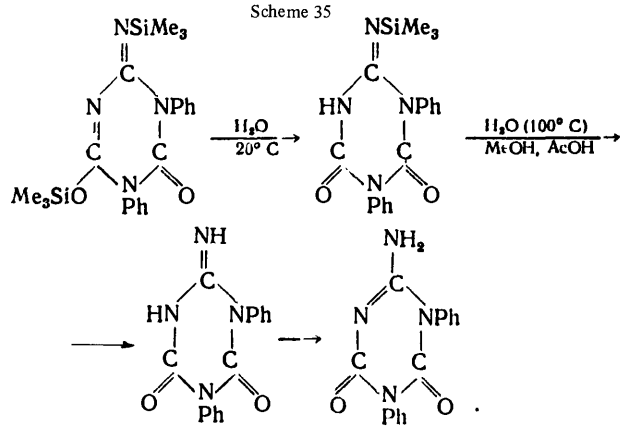
Scheme 34



M = Si, R = H, Me, R′ = H, Me, Bu, $C_{10}H_{21}$, Ph, MeCO, PhCO;
M = Ge, R = Et, R′ = H;
M = Sn, R = Bu, R′ = H, Me, Ph, o-ClC_6H_4, MeCO, PhCO.

The complete hydrolysis of tris(tributylstannyl) isocyanurate requires either a longer time or heating with water. [51] Tris(trimethylsilyl)melamine, -ammeline, and -ammelide, trimethylsilyl diallyl isocyanurate, their triethylgermyl and tributylstannyl analogues, tributylstannyl dicyanoethyl cyanurate, bis(diallyl isocyanurato)dibutylstannane, and other similar compounds are also easily hydrolysed. [9,11,26,28,33,43,105,108,147] The organosilicon imino-s-triazine obtained according to scheme 25 is hydrolysed in stages. [33,105] Its Si–O bond begins to split under the influence of moist air or ether, whereas breakdown of the Si–N bond and separation of the two trimethylsilyl groups require heating with boiling water or treatment with methanol or acetic acid. The final hydrolysis product is apparently an unstable phenyl-substituted isoammelide, which undergoes rearrangement to the corresponding ammelide [33] according to scheme 35:

Scheme 35



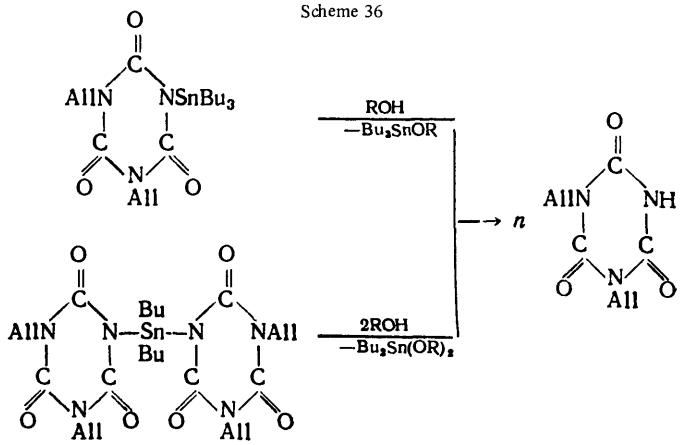
Mild hydrolysis or alcoholysis has also been used to confirm the formation of nitrogen-containing heterocycles in other cycloaddition reactions [98,99,102,108] [schemes 24, 25, and 28).

Unlike the above compounds, silatriazole trimers have an extremely high stability to hydrolysis. For example, diphenylsilyl derivatives of this group are quite stable even when boiled for 2 min with 10% HCl or NaOH. [73]

Carbofunctional s-triazines are also extremely stable to nucleophilic reagents and can even by synthesised in an aqueous-alcoholic or alcoholic medium. [115–118,123–125]

The reactions of tris(trimethylsilyl) cyanurate, [33,74] diallyl tributylstannyl isocyanurate, and bis(diallyl isocyanurato)-dibutylstannane [147] with alcohols, phenols, and carboxylic acids have also been studied (schemes 34 and 36):

Scheme 36

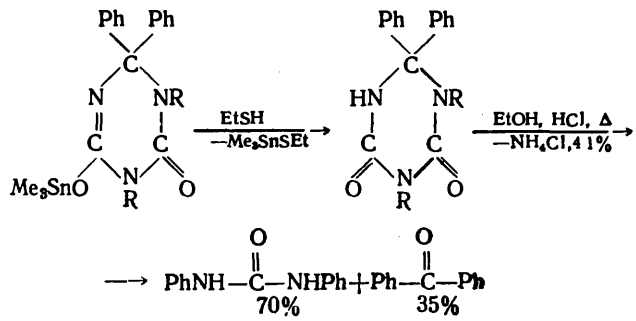


R = Et, Pr, iso-Pr, Ph, MeCO, PhCO, CCl_3CO; n = 1, 2.

The rate and extent of these reactions, and the yields of the final products, depend significantly on the nature of the central atom and the hetero-organic fragments, the reagent used, and the conditions of the process. For example, organosilicon s-triazines are much more reactive than the organotin compounds, and their reaction with hydroxyl-containing compounds is irreversible. This is because isocyanuric acid is chemically inert towards the siloxanes or alkoxy(acyloxy)silanes formed. In contrast to this, the reaction of tris(tributynylstannyl) isocyanurate with methanol is reversible.[25] The replacement of methanol by phenol, acetic acid, or benzoic acid displaced the equilibrium practically completely towards the formation of isocyanuric acid.

The reaction of 1,3,4,4-tetraphenyl-6-trimethylstannyloxy-1,3,5-triazine with ethanethiol in benzene gave the corresponding destannylated s-triazine (scheme 37):[99,100]

Scheme 37



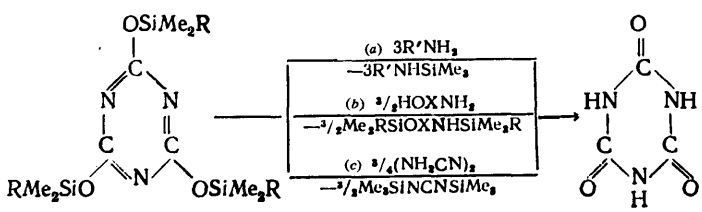
R = Me, Ph .

Subsequent hydrolysis (R = Ph; EtOH + concentrated HCl, 4 d) gave a mixture of benzophenone, N,N'-diphenylurea, and NH_4Cl.[99]

The first stage of scheme 37 has been proposed as a method for synthesising organic triazines with three different substituents on the nitrogen atoms.[99] The yields of the final heterocycles were 76–96%.

Tris(trimethylsilyl) cyanurate reacts on heating with primary amines (100–200 °C, 1–2 h)[33,74] to give isocyanuric acid and mono-substituted silylamines. An interesting feature is that the reaction is reversible. This is particularly noticeable for allylamine, which gives only 50–70% of the corresponding aminosilane (scheme 38). It is for this reason that the latter was used to prepare tris(trimethylsilyl) cyanurate[8,33] (scheme 2).

Scheme 38



R = H, Me; R' = All, Ph, n-C_7H_{15}, cyclohexyl, $Bu_3Sn(CH_2)_3$;

X = CH_2CH_2, $C_6H_4SO_2$.

Since this s-triazine is a fairly powerful silylating agent, the equilibrium for the process (scheme 38a) is determined by the comparative activity of the organosilicon reagents.

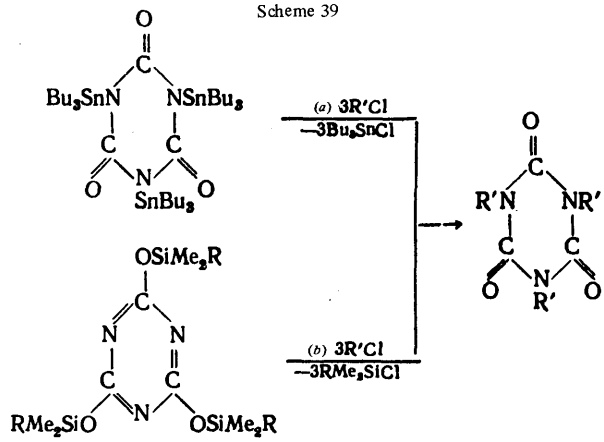
The isocyanuric acid formed when aliphatic amines are used can be removed from the reaction zone as complexes with the original amines (1:1), which decompose to their components above 240 °C.[74]

The reactions of organosilicon cyanurates with bifunctional compounds (2-aminoethanol, sulphanilic acid) do not differ fundamentally from the above reactions and take place according to the general scheme 38b.

The reaction of dicyandiamide with tris(trimethylsilyl) cyanurate gave bis(trimethylsilyl)carbodi-imide in quantitative yield (scheme 38c). The last compound can also be obtained using tris(trimethylsilyl)melamine.[31]

Organosilicon cyanurates do not react with secondary amines, and tris(tributylstannyl) isocyanurate does not react with primary amines either. It reacts readily, however, with carboxylic acid halides, forming tris(acyl) isocyanurates according to scheme 39:[17,25,33,148]

Scheme 39



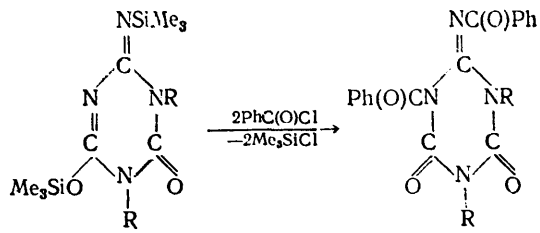
M = Sn, R' = MeCO, PrCO, PhCO, $CH_2CH(CH_3)CO$; M = Si, R = H, Me, R' = MeCO, PhCO, $Me_3Si(CH_2)_3CO$, $(CH_2)_6N{=}C{=}O$, substituted monosaccharides.

Other organotin s-triazines such as tributylstannyl and dibutylstannyl diallyl isocyanurates[147] and tris(tributylstannyl)melamine, -ammeline, and -ammelide[17] are also converted into the corresponding acylated heterocycles by the reaction with acid halides.

Scheme 39a can be used to obtain various acyl derivatives of s-triazines. It gives high yields of the products. High purity of the desired compounds is achieved by replacing the organotin s-triazines by their silicon-containing analogues.

The synthesis of various tris- and bis(acyl) isocyanurates from the corresponding organosilicon s-triazines has been described[10,17,33] (schemes 39b and 40):

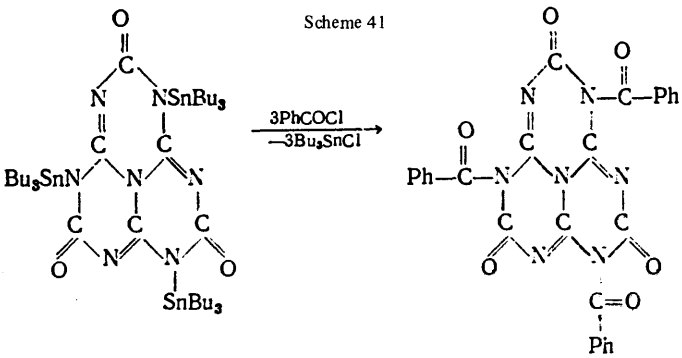
Scheme 40



R = Ph, m-ClC_6H_4 .

Tris(tributylstannyl) cyamelurate also reacts with benzoyl chloride, to give the corresponding tris(benzoyl)derivative[17] in up to 75% yield according to scheme 41:

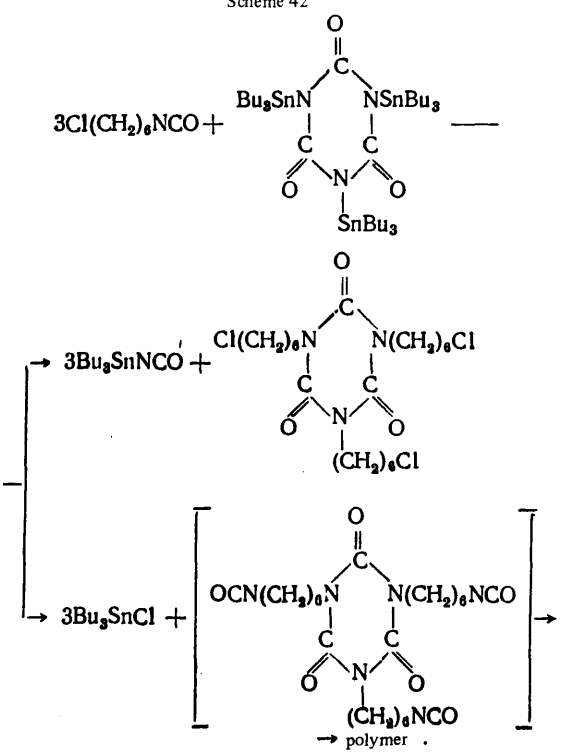
Scheme 41



Hetero-organic s-triazines do not react directly with alkyl halides or aryl halides under normal conditions or on heating,[148] but in some cases reaction takes place in polar aprotic solvents such as DMF. Thus the reaction of tris-(trimethylsilyl) cyanurate with chlorohexamethylene isocyanate gave tris(6-isocyanatohexamethylene) isocyanurate (DMF, 120–170 °C, 3–4 h, yield 96.5%).[149] An interesting feature is that heating a mixture of the same starting materials without a solvent, and heating a mixture of tris-(trimethylsilyl) cyanurate with cyanuric chloride, give exclusively trimethylsilyl isocyanate.[17] Similar splitting of the triazine ring is observed when tris(tributylstannyl) isocyanurate is heated with benzenesulphonyl chloride (120 to 160 °C). At an original reagent ratio of 1:1, tributylstannyl isocyanate is formed in high yield. Change in the ratio to 1:2 or 1:3 leads to the preferential formation of benzenesulphonyl isocyanate. The process is accompanied by considerable tar formation.[25] An attempt to carry out the reaction of tris(trimethylsilyl) cyanurate with ClC(O)NCO (reagent ratio 1:3, ether, 20 °C) gave a polymeric N-substituted tri-isocyanate, which was depolymerised at 150 °C to give 95–97% $(OCN)_2CO$.[150]

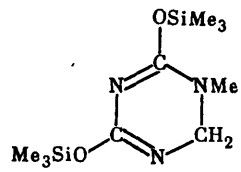
Tris(tributylstannyl) isocyanurate also reacts with $Cl(CH_2)_6NCO$ in DMF with heating to 180–210 °C for 5 h according to scheme 42:[151]

Scheme 42

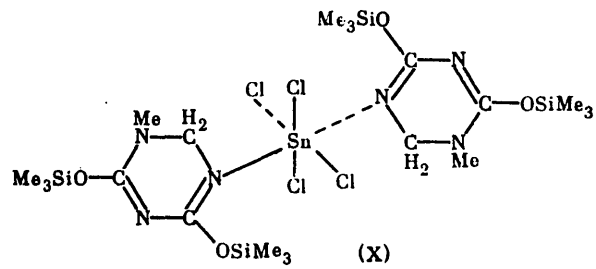


The ability of organosilicon s-triazines to react comparatively easily and quantitatively with active halogen-containing compounds has recently been widely used to synthesise nucleosides. The rate of the reaction is increased in the presence of catalytic quantities of $SnCl_4$,[140,152–158] although the reaction also takes place in its absence.[38,39] Recent investigations of the role of the catalyst[140,153] showed that it forms an intermediate compound (X), which was isolated and characterised from its ^{13}C NMR spectra. Thus the simplified scheme for the preparation of nucleosides [for example (XII)] involves the preliminary synthesis of the organosilicon s-triazine (IX), the intermediate formation of the complex (X), the reaction of the latter with the halogenosaccharide (XI) (the O-acylsaccharide), and the subsequent hydrolysis of the compound formed.[140]

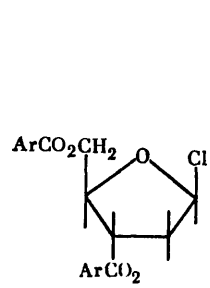
The N-glycosides obtained by these or similar operations can subsequently be methylated or deacetylated when the triazine ring contains N–H groups or the carbohydrate contains Ac–O groups respectively [for example (XIII), (XIV)].



(IX)

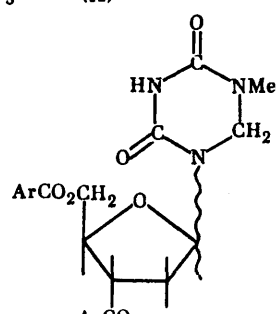


(X)

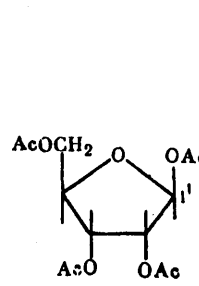


(XI)

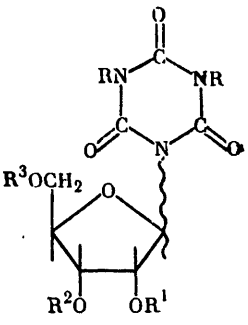
R = H, Me; R^1–R^3 = H, Ac



(XII)



(XIII)

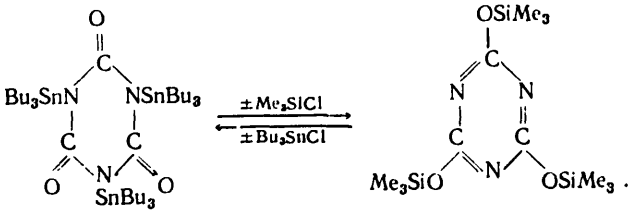


(XIV)

Instead of halogenosaccharides, their acyl derivatives,[152, 159–166] for example tetra-O-acetyl-β-D-ribofuranoside (VIII) [166] are often used. The organosilicon fragments of the s-triazines break the (1′) C–O bond of the O-glycosides and combine with the AcO groups to form compounds of the type Me_3SiOAc and the desired substituted nucleosides (XIV) (N-glycosides). The use of catalysts of the $SnCl_4$ type is necessary. New catalysts for these processes, $Me_3SiOSO_2CF_3$, $Me_3SiOSO_2C_4F_9$, and Me_3SiClO_4, have been proposed.[161] In many cases all the operations described above are carried out in a single stage by heating a mixture of all the starting materials in solvents, but here also the basis is the Gilbert–Johnson method.[161,162] In Refs.163–166, tris(trimethylsilyl) cyanurate prepared by the method of Refs.8 and 10 was used.

As noted above, tris(tributylstannyl) isocyanurate undergoes reversible remetallation with trimethylchlorosilane to give tributylstannyl chloride and a trimethylsilyl derivative of cyanuric acid, which exists in the hydroxy-form, according to scheme 43:[75]

Scheme 43

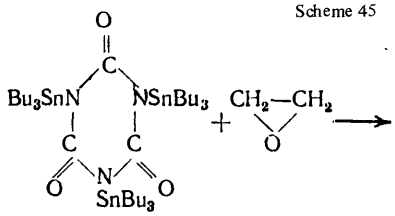


Processes similar to scheme 43 were examined in detail in section II of the present review (schemes 17–21).

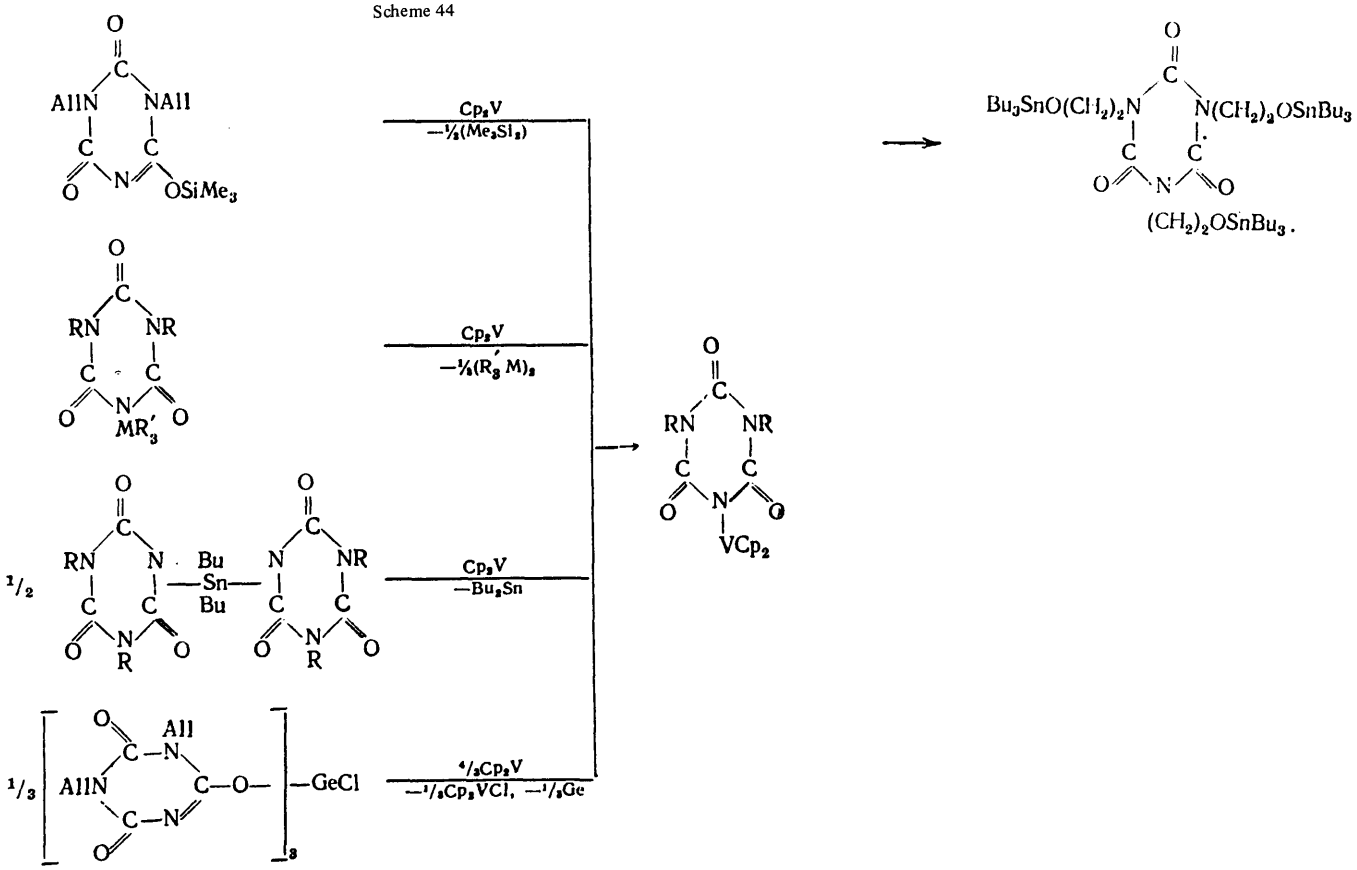
Organosilicon, -germanium, and -tin s-triazines can undergo remetallation not only with hetero-organic compounds of group IVb but also with other compounds. A group of workers including the authors of the present review published a series of papers on the reaction of Si-, Ge-, and Sn-containing derivatives of diallyl and dicyanoethyl isocyanurates with bis-(η^5-cyclopentadienyl)vanadium (Cp_2V) and of trimethylsilyl diallyl isocyanurate with vanadium tetrachloride or tris(acetyl)phosphine.[76] The use of Cp_2V as starting material led to the synthesis of the first representatives of vanadium s-triazines, which are blue–violet crystalline substances, readily oxidised by atmospheric oxygen. The reactions were therefore carried out in toluene in evacuated or argon-filled ampoules [40–50 h, 100–120 °C for the mono- and tris-triazine, and 40 h, 20 °C for the bis-triazine heterocycles (scheme 44)]. The reactivity of the compounds towards Cp_2V increases in the order Si < Ge < Sn.[147,167–170]

The insertion reaction, widely familiar for hetero-organic compounds with an element–nitrogen bond, has been little developed for s-triazines. The only example is the synthesis of tris(β-tributylstannyloxyethyl) isocyanurate using the corresponding organotin s-triazine and ethylene oxide (DMF, heating) according to scheme 45:[5]

Scheme 45



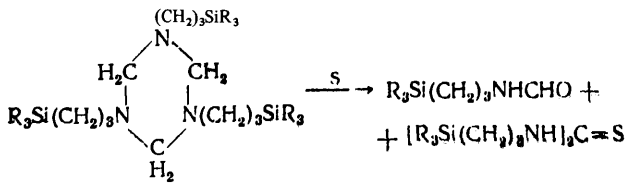
Scheme 44



M = Ge, R′ = Et; M = Sn, R′ = Bu; R = All, $(CH_2)_2Cl \equiv N$ Cp_2V = bis(cyclopentadienyl)vanadium

There are practically no published papers describing the properties of carbofunctional s-triazines. It is known only that 1,3,5-tris-(3-trialkylsilylpropyl)hexahydrotriazine, when heated with sulphur in aqueous alcohol, is converted into a 1:1.6 mixture of N-(3-trialkylsilylpropyl)formamide and N,N'-bis-(3-trialkylsilylpropyl)thiourea (scheme 46):[115-118]

Scheme 46



R = Me, Et, Bu, MeO, EtO.

Data have also been published on the reaction of 2,4-dichloro-6-[(trimethylsilyl)ethynyl]-1,3,5-triazine (scheme 13) with methanol. This reaction does not lead to the rupture of the Si—C bond of the heterocycle, but gives a good yield of the corresponding 2,4-dimethoxy-derivative, which is hydrolysed, but under more severe conditions, to 2-ethynyl-4,6-dimethoxy-1,3,5-triazine.[42]

V. PRACTICAL APPLICATIONS

s-Triazines containing group IVb elements have found extremely varied and extensive practical applications, which are continuing to expand.

The foundation for applied studies in the chemistry of compounds of this class was laid by the synthesis and successful investigation of the possible uses of carbofunctional organosilicon s-triazines and siloxane polymers based on them. They were used to improve the physical or mechanical properties of, or to give specific properties to fibrous materials (wool, viscose, cotton, nylon, glass fibre, etc.) and to prepare heat-resistant, water-resistant, and chemically resistant films and coatings for metals, wood, and various polymers.[54,55,58-66,84-87,123-131,171-182] Thus appropriate treatment of fabrics with triazine polysiloxanes gives them water-repellent properties,[60-65,123-127,182] resistance to repeated washing,[63-65] and wear-resistance.[180,181] These organosilicon products also have increased adhesive properties, so that they are often included in adhesive compositions.[84-87,171-179] The most effective adhesion promoters are isocyanurates of the type $[(RO)_{3-n}R'_nSiR''NCO]_3$, where R, R' = Alk, R'' = CH_2, and also 1,3,5-tris(trimethoxysilylpropyl) isocyanurate. These and other similar compounds are used as vulcanising additives in rubber mixtures, and also as binding and cross-linking agents in the synthesis of various polymers.[78,94,95,132,133,173-181] The synthesis of fluorosiloxanetriazine rubbers and elastomers has been patented.[79-82] These substances and their derivatives have a high thermal stability[59,128-133] and remain practically unchanged on storage.[174]

Organotin s-triazines are used as catalysts and modifying additives in the synthesis of various polymers. For example, tris(triethylstannyl) isocyanurate is used to prepare polyoxymethylene and polyethers with improved colours and transparency.[21,22] The inclusion of tris(tributylstannyl) isocyanurate, -melamine, or cyamelurate in compositions based on polyvinyl chloride gives the polymer increased stability and transparency.[27,183] The stabilising action of organotin s-triazines is increased by their ability to bind the HCl which is liberated when polyvinyl chloride is heated and which increases the rate of the thermal decomposition of this polymer. The binding of HCl by the additives is not decisive, however, since organosilicon cyanurates, which are more reactive towards HCl, are much less effective thermal stabilisers than the tin derivatives.[27] The use of the latter with familiar components (calcium and zinc stearates) gives a synergic effect.

The introduction of tris(tributylstannyl) or tris(trioctylstannyl) isocyanurates into the structures of polymers based on ε-caprolactam gives the resulting polyamide fibre bactericidal properties while preserving its strength and absence of colour.[184]

Tin-containing s-triazines have proved to be extremely effective catalysts for the reactions of isocyanates with alcohols, used in industry for the production of polyurethanes, including their film-forming organosilicon analogues.[6,47,185-193] The tributylstannyl derivatives of these heterocycles, like bis(tributylstannyl) oxide or methoxytributylstannane, have a medium catalytic activity and can be used to obtain polyurethane adhesives and coatings, an important characteristic of which is the stability of the polymer compositions.[193] In contrast to these, dibutylstannyl s-triazines, with an increased catalytic activity, can be recommended for a single-stage method for obtaining polyurethane foam, in which the process should develop vigorously from the moment when the components are mixed.[6,47]

Organotin s-triazines are active and extremely promising bactericides and pesticides with varied spheres of application. Thus they show insecticidal, acaricidal, fungicidal, and algicidal properties and are used to combat bacteria, harmful insects, mites, fungi, parasites in agricultural plants and timber, and also to prevent the fouling of fishing nets, the underwater parts of ships, etc.[19,23,71,72,88-92,138,139,145,194] According to Ref.89, thio-derivatives of tin-containing s-triazines have a low toxicity to warm-blooded animals and can therefore be used to prepare fumigants, detergents, deodorants, coatings for nylon, paper, plastics, wood, etc.

Herbicidal and fungicidal compositions based on organosilicon s-triazines have been patented.[40,195]

Hetero-organic s-triazines are often used as active intermediate compounds for preparing various analogues and derivatives, including bactericidal, pharmaceutical, and medicinal products, polymer additives,[16,34,52,196,197] fabric whiteners,[69] triazinediones,[112] bis(trimethylsilyl)carbodiimide,[49] acylated and germanium-containing analogues difficult to obtain,[9,17,25,28,74,148] and "sandwich" compounds of vanadium.[167-170]

Tris(trimethylsilyl) cyanurate, synthesised comparatively recently, has already been used to obtain trimethylisocyanatosilane,[12-14] carbonyl di-isocyanate $(OCN)_2CO$,[150] bis(trimethylsilyl) carbodi-imide, tris(triethylgermyl) and tris(tributylstannyl) isocyanurates,[74] tris(6-isocyanatohexyl) isocyanurate, which is a strating material for the synthesis of polymers,[149] triacyl isocyanurates,[10,17] and N-glycosides.[163-166]

The last group of compounds, which inlcudes other triazine-containing nucleosides,[38,39,140,152-162,198,199] is of considerable interest for the present authors. These substances are of independent interest as anti-virus, anti-bacteria, and anti-tumour products, and they can also be used in the synthesis of new macrohedral compounds of the nucleotide type.

---o0o---

While the present review was being prepared for publication, additional papers were published on the synthesis,[200-208] properties,[203,208,209] and practical applications[204-207,210-222] of organosilicon and organotin s-triazines.
