In the superaromatic molecules, the bonding intrapolyhedral electron system ensures the stability of the cluster skeleton and the surface system ensures the electron delocalisation. The manifestation of superaromaticity in real cluster complexes, like the manifestation of the usual aromaticity in cyclic organic molecules, requires the fulfilment of specific geometrical conditions, which apparently follow from the requirement for the overlap of orbitals in the intrapolyhedral electron system. An increase in the size of the inner cavity, the appearance of open faces, or the introduction of atoms of post-transition elements into the polyhedral skeleton lead to a gradual loss of the property of superaromaticity and a transition to structures of clusters which do not obey the $2n + 2$ rule.

Comparison of structural data with theoretical predictions thus makes it possible to differentiate among the set of polynuclear compounds the region of clusters for which the model of chemical bonding in a superaromatic three-dimensional system developed at the present time is valid. However, at the present level of chemical theory, the model itself is mainly empirical in character and has not been rigorously justified mathematically. The search for such mathematical justification should apparently be prosecuted in the field of topology;

¶A dependence of the type of packing of the atoms in the metallopolyhedron on the average number of valence electrons per intrapolyhedral metal atom has been proposed recently for clusters of this type on the basis of a modified Hume–Rothery rule.[150] The total numbers of valence electrons in the clusters investigated, calculated on the basis of idealised types of packing, agree with the real numbers to within 4% (the discrepancies are in the range from 0 to 13 valence electrons).

the results of such investigations (should they be successful) might introduce a significant modification into the theoretical apparatus of the chemistry of cluster compounds.

The Electronic Structure of Transition Metal Cluster Complexes with Weak- and Strong-field Ligands

G.P.Kostikova and D.V.Korol'kov

A systematic account and a survey of the results of quantum-chemical and spectroscopic studies of the electronic structure of transition metal cluster complexes are presented. In terms of the theory of canonical molecular orbitals and the theory of weak- and strong-field ligands, the concept of the structure and stability of the clusters taking into account the influence of the ligands and transition metal atoms on the characteristics of the M-M bonds has been formulated. The characteristic features of the delocalisation of the valence electrons of the M atoms in the M_n groups, the intercluster interaction, the density of the M atoms in the clusters, and the effects of cluster formation in the optical and X-ray spectra are discussed.
The bibliography includes 137 references.

I. INTRODUCTION

In the modern chemistry and physics of clusters, one of the main taks is to create a general theoretical conept concerning the structure and stability of clusters whereby one can account for the existence of these complexes and formulate the principles governing their structure as a function of the position of the transition metal in the Periodic System, the formal valence of the M atoms, and the individual nature of the ligands; such a concept would constitute a general solution of the problem of the mutual influence of the nature of the transition metal and the ligands on the stability of cluster structures. The knowledge of the electronic structure of the clusters is undoubtedly a basis for the understanding of their structure, stability, and reactivity. The electronic structure of transition metal cluster complexes has been the subject of numerous theoretical studies in the last twenty years. The present review is devoted to the discussion of the results of these investigations and also the results of experimental studies of the spectroscopic properties of cluster compounds which supplement and refine the quantum-chemical calculations of the electronic structure.

II. THE ELECTRONIC STRUCTURE OF CHLORIDE AND CARBONYL CLUSTERS

Non-empirical and semi-empirical methods of the theory of delocalised molecular orbitals,[1-6] the electron gas method,[7] topological methods,[8,9] and the ligand field theory[10] are used in the quantum chemical calculations of the electronic structures of isolated cluster complexes. The references quoted above refer to review papers which have been published during the last decade. The results of spectroscopic and theoretical studies of the nature of the M-M bonds in transition metal cluster complexes (with the exception of dinuclear complexes) with strong M-M interactions are described in a recent review.[11]

The cluster chlorides and carbonyls of transition metals have been investigated most fully both experimentally and theoretically at the present time; attention is in fact concentrated on these substances in the present review. Weak π-donors (Cl atoms) and strong π-acceptors (CO molecules) occupy positions at the opposite ends of the general series of ligands and the study of clusters incorporating precisely these ligands is therefore most fruitful for the solution of the problems mentioned above in the most general form.

Table 1. Electronic structure parameters of clusters.

Cluster	Symmetry	R_{M-M}, Å	B_{M-M}	Bonding "M-M" MO	N_{M-M}	n_{M-M}	P_{M-M}	Refs.
$Mo_2Cl_8^{4-}$	D_{4h}	2.14	1	$a_{1g}eb_{2g}$	8	8	$4(\sigma+2\pi+\delta)$	[1,6,14]
$W_2Cl_9^{3-}$	D_{3h}	2.41	1	$a_1'e'$	6	6	$3(\sigma+2\pi)$	[2-4]
$Re_3Cl_{12}^{3-}$	D_{3h}	2.47	3	$a_1'a_2''e'e''$	12	4	$2(\sigma+\pi)$	[2-4]
$Nb_6Cl_{18}^{6-}$	C_{2h}	2.86	5	$a_ua_gb_ua_gb_g$	10	2	$1(\sigma)$	[2]
$Mo_5Cl_8^{3+}$	C_{4v}	2.58	8	$a_1a_1a_1ab_1eeb_2e$	19	2.4	$1.2(\sigma+[\pi])$	[4]

$Ir_4(CO)_{12}$	T_d	2.68	1	a_1el_2	12	2	$1(\sigma)$	[2-4,11]
$Mo_2(O_2CR)_4$	D_{4h}	2.11	1	$a_{1g}e_ub_{2g}$	8	8	$4(\sigma)$	[6,15]
$Ru_2(O_2CR)_4^+$	D_{4h}	2.28	1	$a_{1g}e_u$	6	6	$3(\sigma+2\pi)$	[4,17]
$Mo_3O_{13}^{14-}$	C_{3v}	2.52	3	a_1e	6	2	$1(\sigma)$	[4]
$Ru_3O_{12}^{12-}$	C_{3v}	2.55	2	a_1ee	8	4	$2(\sigma+\pi)$	[4]

Notation: R_{M-M} is the M-M distance, B_{M-M} the number of two-centre M-M bonds, N_{M-M} the total number of valence electrons in the M-M bonds, n_{M-M} the number of valence electrons per two-centre M-M bond, and P_{M-M} the multiplicity of the two-centre M-M bond.

The results of semi-empirical[1-6,11-15] and non-empirical[16-19] molecular-orbital calculations (some examples are presented in Table 1) revealed the most important features of the electronic structures of the chloride and carbonyl clusters and the fundamental differences between clusters containing ligands of different types.

In the chloride clusters the energy splitting of the valence *d* orbitals of the M atoms in the mononuclear fragment in the field of weak π-donor ligands (Cl atoms) is slight and much less pronounced than the corresponding splitting of these atomic orbitals (AO) following the appearance of M-M bonds, i.e. on formation of the cluster (Fig.1).

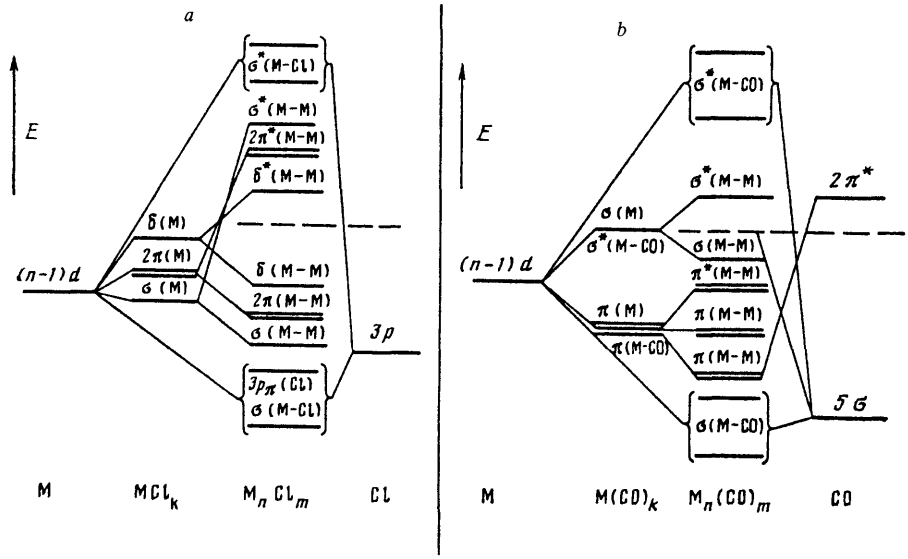

Figure 1. The molecular orbitals in the chloride and carbonyl clusters; the MO populated by electrons and the unoccupied MO are shown below and above the dashed lines respectively.[4]

The bonding and antibonding and sometimes also non-bonding molecular σ, π, and δ orbitals of the M–M bonds arise in the electronic structure of the chloride cluster under these conditions. The number and symmetry of these MO are rigorously individual for each chloride cluster, are determined by its stereochemistry, and are the most important characteristic of its electronic structure.[1,4]

A different picture is observed in the electronic structure of carbonyl clusters: the energy splitting of the valence *d* orbitals of the M atoms of the mononuclear fragment in the field of strong π-acceptor ligands (CO groups) is pronounced and greatly exceeds their energy splitting induced by the formation of the M–M bonds when the cluster is produced (Fig. 1).[4,20,21]

This, the first important difference between the electronic structures of the chloride and carbonyl clusters, is caused by the fact that in the carbonyl clusters the two-centre M–L bonds are characterised by an enhanced multiplicity (M ← CO donor–acceptor σ interactions and M → CO dative π interactions) owing to the strong π-acceptor character of the CO groups, in contrast to the chloride clusters, where the two-centre M–L interactions represent virtually single two-electron bonds predominantly of the covalent σ-type. As a result of the different types of behaviour of the valence *d* orbitals of the M atoms in the fields of different ligands, the following situation arises: in the electronic structure of the chloride cluster, the molecular orbitals which are occupied by electrons and are responsible for the M–M interactions always constitute a single (and fairly isolated as regards energy) group, which incorporates in the general case σ, π_1, π_2, and δ MO (with increase of the number of valence *d* orbitals of the M atoms involved in the bonding with the Cl atoms and with the increase of the coordination number of each M atom in the cluster, initially the δ compound and then the π_1 and π_2 components are successively eliminated from the M–M interactions and only the σ component remains). In the vast majority of the known systems only the bonding molecular orbitals associated with the σ, π_1, π_2, or δ M–M interactions are occupied by electrons, while the corresponding antibonding MO are populated by only one–two electrons and in only rare instances.[1–4] On the other hand, in the electronic structure of the carbonyl cluster the electron-occupied MO of the M–M interactions are always clearly subdivided into two groups, which are not interconvertible in terms of energy: the first includes all the bonding and antibonding π molecular orbitals, while the second includes the bonding σ molecular orbitals of the M–M interactions. The electronic energies of the MO of the first group are appreciably reduced because these MO are simultaneously solely bonding orbitals in relation to the dative M → CO π-bonds; the electronic energies of the MO of the second group are greatly increased because they are simultaneously solely antibonding orbitals in relation to the M–CO σ-bonds. Insofar as all the molecular orbitals which are bonding in relation to the dative M → CO π-bonds and hence all the bonding and antibonding MO of the M–M π-bonds are fully populated by electrons in the electronic structure of the carbonyl cluster, only the highest (in terms of energy) occupied MO of the M–M σ-bonds are responsible for the M–M interactions in the carbonyl cluster.[4,20,21]

The above characteristics features of the electronic structure of the carbonyl clusters are the reason why the bonding and antibonding contributions to the M–M π-bonding approximately cancel out, while the π-contribution to the energy of the M–M interactions is either altogether absent or is slightly antibonding, the π-electron density being concentrated in the region of the M–CO bonds and mainly only single M–M σ-bonds, characterised by comparatively large internuclear distances and a reduced strength, are formed. The solution of the variational problem for the $Re_2(CO)_{10}$ cluster[22] showed that the decrease of the overall M–M bond energy is almost wholly responsible for the increase of the total energy of the cluster with decrease of the M–M distance below the equilibrium value of 3.02 Å; the decrease of the overall M–M bond energy is caused in its turn by the π-antibonding effects, by the energy destabilisation of the carbonyl cluster owing to the M–M π-interactions.

The electronic structure of the chloride clusters presupposes the bonding character of not only the σ- but also frequently the π- and even δ-interactions of the M–M type. For this reason, the multiplicity of the two-centre M–M bonds in such clusters varies within wide limits, reaching the limiting unique value $4(\sigma + 2\pi + \delta)$ for the M–M bonds in the $Re_2Cl_8^{2-}$, $Tc_2Cl_8^{3-}$, $Mo_2Cl_8^{4-}$, and similar dinuclear clusters. In the chloride clusters the multiple two-centre M–M bonds arise whenever this is allowed by the stereochemistry of the cluster group and the effective number of electrons involved in the M–M interactions. This is why the energies of the two-centre M–M bonds and the M–M distances in the chloride clusters vary within wide limits, ranging from weak interactions and long bonds in certain hexanuclear clusters to very strong interactions and extremely short bonds in the dinuclear groups.[23,24]

Thus M–M bonds with very high multiplicities and energies and sharply reduced M–M distances are formed only in the chloride clusters: such two-centre bonds involve σ-interactions, frequently π_1- and π_2-interactions, and sometimes even δ-interactions, whose electron densities concentrated in the region of the M–M bond hardly affect the ligands. The high stability of the chloride clusters of the formally low-valence 4*d* and 5*d* elements (Nb, Ta, Mo, W, Tc, Re), determined by the high M–M bond energies, is accompanied by the instability of the corresponding mononuclear anions ($TaCl_6^{4-}$, $MoCl_6^{4-}$, WCl_6^{3-}, $ReCl_6^{3-}$), which agrees with experimental findings.[25]

The second important difference between the electronic structures of the chloride and carbonyl clusters concerns the character of the M–M bonds. In the chloride clusters the main contribution to the MO of the M–M bond and to the overall orders of these bonds comes solely from the valence $(n-1)d$ orbitals of the M atoms and the bonds between the metal atoms are formed in the interaction of virtually only the $(n-1)d$ electrons of the M atoms.[1–4,26] In the carbonyl cluster also the valence *ns* and particularly *np* orbitals of the M atoms make a significant contribution together with the $(n-1)d$ orbitals, sometimes even the dominant contribution, to the σ-bonding M–M molecular orbitals and to the overall orders of the M–M σ-bonds.[21] This difference between the electronic structures is probably caused by the fact that in the chloride clusters the M atoms supply the *ns* and *np* electrons for the formation of bonds with ligands, such electrons being most suitable for this purpose in terms of symmetry and energy, while most of the $(n-1)d$ electrons are retained for the formation of various M–M bonds. On the other hand, owing to the high π-acceptor capacity of the ligands, in the carbonyl clusters a considerable proportion of the valence $(n-1)d$ electron density, which is more suitable as regards symmetry and energy than the *ns* and *np* states of the M atoms, is involved in the dative M → CO π-bonds; as a result of the formation of direct M–M σ-bonds, the number of the remaining $(n-1)d$ electrons is clearly insufficient and the use of the valence *ns* and particularly *np* electrons of the M atoms is necessary. The increased *np* character of the molecular orbitals of the M–M σ-bonds in the carbonyl clusters also entails (together with the antibonding character of these MO in relation to the donor–acceptor M–CO σ-bonds already mentioned), an increase of the energies of these MO, which accounts for the appreciably reduced energy of the two-electron two-centre M–M bonds in the cluster carbonyls compared with the cluster chlorides.[3,21]

This second difference is significant in the chemistry of cluster compounds in yet another respect. It is actually the decisive cause of the situation where 3*d* elements form cluster carbonyls but not cluster chlorides. In particular, the formation of the M–M bond in $Mn_2(CO)_{10}$ (i.e. the formation of a cluster) is associated with the involvement in this σ-bond of the valence 4*s* and 4*p* electrons of the Mn atoms not participating in the dative π-bonding with the ligands; on the other hand the participation of all the 4*s* and 4*p* electrons of the Cl atoms in the bonds with the ligand in $Cr_2Cl_9^{3-}$ explains the absence of any kind of M–M bond in this anion (i.e. the absence of a cluster), because, owing to the spatial contraction of their charge clouds, the valence 3*d* electrons of the M atoms cannot alone ensure the formation of any kind of strong M–M bond over the long M–M distances characteristic of both $Mn_2(CO)_{10}$ and $Cr_2Cl_9^{2-}$ (2.92 and 3.21 Å).[22,27]

The third difference lies in the fact that in the chloride clusters the molecular orbitals of the M–M bonds are of the purely "metallic" character and the contribution of the valence orbitals of the ligands to them is small; on the other hand, in the carbonyl clusters this contribution is appreciable. An important feature of the electronic structure of the chloride cluster is as follows: in the unique MO system of the cluster, the molecular orbitals responsible for the M–M interactions always constitute a distinct and isolated, in terms of energy and character, group and are predominantly of the $(n-1)d$ electron type: the isolation of these molecular orbitals is independent of either the energy and steric characteristics of the valence orbitals of the M atoms (i.e. of the nature of the transition element) or of the symmetry of the cluster group, which means that the M–M and M–L electronic interactions in the chloride clusters are to a large extent isolated from one another and their mutual influence is very weak, while the properties of the M–M and M–L bonds (in the first place their energies) are additive; in the cluster carbonyls everything is completely different and the characteristics of their M–M and M–L bonds are non-additive.

The isolation of the electronic M–M and M–L interactions in the chloride clusters makes it possible to solve the problem of their stability in a generalised form. The molecular orbitals of the M_n groups, which constitute the "metallic nuclei" of all the known chloride clusters of the 4*d* and 5*d* elements, have been calculated[2,28–30] (the symmetry of the point group of the cluster is indicated in brackets): M_2 for $M_2X_8(D_{4h})$, M_2 for $M_2X_9(D_{3h})$, M_2 for $M_2X_8(C_{2v})$, M_2 for M_3X_9 or $M_3X_{12}(D_{3h})$, M_2 for $M_3X_{12}(C_{3v})$, M_4 for $M_4X_{16}(C_{2h})$, M_4 for $M_4X_{16}(T_d)$, M_6 for M_6X_8 or $M_6X_{14}(O_h)$, and M_6 for M_6X_{12} or $M_6X_{18}(O_h)$. The electronic interactions arising in typical cases within the limits of each M_n group (direct M–N bonds) are represented by a characteristic set of bonding, non-bonding, and antibonding MO. These are in fact the molecular orbitals of the M–M bonds in the unique electronic structure of the M_nX_m chloride cluster as a whole. The number and character of such MO are determined not only by the number of M atoms in the M_n group but also by the number of ligands and the symmetry of their arrangement in the corresponding cluster group, i.e. by the detailed stereochemistry of the entire M_nX_m chloride cluster.[2,4,28,29]

There exist also chloride clusters, where, among the molecular orbitals responsible for the M–M interactions, only the bonding MO are populated (as a rule completely) by electrons (not involved in the M–L bonds), while the corresponding antibonding MO are unoccupied or in rare instances are populated by 1–2 electrons.[10] The stability of the M_nX_m chloride cluster as a whole and of its M_n group separately should therefore be attributed precisely to this (optimum) electron population of the molecular orbitals of the direct M–M bonds. The characteristic number of electrons ensuring the maximum stability of the M_n group when M–M bonds arise in it as a consequence of the complete population of all its bonding MO (and only the bonding MO) by electrons can be determined for each M_n group.

Thus it is possible to outline the limits of stability of each M_nX_m cluster taking into account its characteristic number of electrons and the individuality of the *d* element (the total number of valence electrons of the M atom) and its formal valence (the number of valence electrons of the M atom in the M–L bonds). Namely, by sorting through the transition metals of various Groups in the Periodic System, i.e. by scanning the number of valence electrons in their atoms, it is possible to outline the range of 4*d* and 5*d* elements (and at the same time indicate their formal valences), which can form stable chloride clusters.[4] It is then found that the clusters can be stable only in structures of the lowest chlorides of heavy Group V, VI, and VII *d* elements, since the total number of valence electrons in their atoms is such that it enables them to ensure the stability of one or (more frequently) several forms of clusters for a low oxidation state. On the other hand, the number of valence electrons in Group III and IV *d* elements is too small and that of the electrons of the M atoms (for any realistic oxidation states of the metal), not involved in the formation of bonds with the ligands, is clearly insufficient to populate the bonding orbitals of the M–M bonds in the M_n cluster of any form and hence for the formation of a more or less stable chloride cluster. In the atoms of Group VIII 4*d* and 5*d* elements the number of valence electrons is too large, which leads to the population by the electrons not involved in the M–L bonds not only of the bonding but also of the antibonding molecular orbitals of the M–M bonds in a cluster of any form and hence to a decisive destabilisation of the structure (and the absence of any cluster); for a low formal valence of M, whereupon a large number of the valence electrons of the M atoms are involved in the M–L bonds and whereupon a seemingly optimum number of electrons remains available for the formation of the M–M bonds, the possibility of the formation of such bonds and of the M_n cluster is sharply limited (owing to the large number of bonds of each M atom with the ligands) by purely steric factors.

The results of calculations of the molecular orbitals of both the M_n groups[2,28–30] and the M_nX_m cluster groups as a whole[2,3,11] indicate, firstly, the criteria of the stability of one or several forms of chloride clusters for a given formal valence of a specific *d* element. These results show that both dinuclear and trinuclear but not hexanuclear chloride clusters should be stable for Tc and Re; the dinuclear cluster should be relatively unstable for Nb and Ta and octahedral clusters should be most characteristic; almost all the known forms of cluster groups should be stable for Mo and W in different oxidation states (2–4). The above approach possesses predictive power in relation to almost all *d* elements.

Secondly, these results explain the stability of the integral oxidation states of some *d* elements ($MoCl$–Mo_6Cl_{12}, WCl_3–W_6Cl_{18}, $ReCl_3$–Re_3Cl_9, etc.) and the non-integral oxidation states of others ($NbCl_{2.33}$–Nb_6Cl_{14}, $NbCl_{2.67}$–Nb_3Cl_8, $TaCl_{2.50}$–Ta_6Cl_{15}, etc.), i.e. the causes of the non-stoichiometry of their lowest chlorides; in the presence of six (Mo, W) or seven (Tc, Re) valence electrons in the M atom, the maximum stability of particular chloride clusters is attained for an integral electronic configuration of the M atom (d^2, d^3), i.e. for an integral formal valence of the metal M characterising the number of its valence electrons in the bonds with the ligands. When five (Nb, Ta) valence electrons are present in the M atom, the cluster groups with a non-integral (between d^2 and d^3) electronic configuration of the M atoms are mainly stable, which accounts for their fractional formal valence in the corresponding non-stoichiometric chlorides.

Thirdly, the results of calculations reveal and explain the unique ability of the heavy Group VI *d* elements to produce the greatest number of stable clusters among almost all the known forms. It was found that all the oxidation states (2, 3, and 4) potentially suitable for cluster formation are thermodynamically stable for molybdenum and tungsten, because in these oxidation states the Mo and W atoms have the electronic configurations (d^4, d^3, d^2), which are most suitable in the sense that the number of valence *d* electrons in each M atom capable of participation in the M–M bonds ensures the stability of at least one or even several different forms of clusters by populating only the bonding (but not antibonding) M–M molecular orbitals.

These results made it possible to establish a distinct relationship between the stable form of the chloride cluster (and its stability in general), the formal valence of the transition metal, and its position in the Periodic System, and, finally, to explain why chloride clusters are stable in the main only for the heavy Group V, VI, and VII transition elements (Nb, Ta, Mo, W, Tc, Re) and are as a rule unstable for the Group III, IV, and VIII elements (La, Hf, Os, Ar, Pd, and their analogues).[3,4]

The characteristics of the electronic structure of the carbonyl clusters revealed by the calculation show that each M atom supplies (regardless of the stereochemistry of the cluster and its component mononuclear fragments) exactly six valence electrons for the formation of the necessary (for the existence of the carbonyl cluster) dative M–CO π-bonds. The molecular orbitals (bonding in relation to the dative M–CO π-interactions) occupied by these electrons are at the same time both bonding and antibonding in relation to the M–M π-interactions. The valence electrons of the M atoms involved in the dative M–CO π-bonds are therefore as a whole "frozen" in the M–L bonds and do not participate in M–M bonds. This is precisely the reason why the carbonyl clusters are stable only for those transition metals in the atoms of which the number of valence electrons is greater than six (i.e. at least seven). Only then do the σ-bonding M–M molecular orbitals which have higher energies and are responsible for the formation of the M–M bonds in the carbonyl clusters, become populated with electrons. This accounts for the known fact that the cluster carbonyls are formed mainly only by Group VII (Mn, Tc, Re) and particularly VIII (Fe, Co, Ru, Rh, Os, Ir) transition metals and are unstable for the metals in the first half of the transition series.[10]

It is of interest that hitherto no clusters have been found where each M atom would supply exactly six of its valence electrons for the formation of the M–M bond. On the one hand, these can be caused by the special stability of the spin-paired d^6 electronic configuration[31–33] and, on the other hand, it follows directly from the considerations described above: six electrons are too many for the formation of an energetically stable cluster with π-donor ligands (Cl) but are too few to ensure the occupation of the σ-bonding M–M molecular orbitals in the cluster with π-acceptor ligands (CO) and hence to impart energy stability to the latter.

III. DISTRIBUTION OF CLUSTERS IN THE PERIODIC SYSTEM

The isolated nature of the M–M and M–L interactions in the chloride clusters and, in contrast, the strong mutual influence of these interactions in the carbonyl clusters permit the conclusion that the main features of the clusters with π-donor ligands should be almost independent of the individual characteristics of ligands of this type and should remain almost unchanged on passing from one π-donor ligand to another. On the other hand, clusters with π-acceptor

ligands should be extremely sensitive to the individual characteristics of ligands of this type and their structure should change significantly on replacing one π-acceptor ligand by another.[4]

The available experimental facts confirm these ideas or at least do not conflict with them.[31-42] Indeed clusters with many different π-donor ligands have properties which are similar in broad outline (the replacement of these ligands does not influence greatly the structure and stability of the cluster) although there are no sufficient grounds for a fully unified approach to these clusters. On the other hand, the replacement of π-acceptor ligands leads to significant changes in the structure and stability of the clusters; one of the causes of this is probably that the π-acceptor ligands ensure to some extent the delocalisation of the valence electrons of the M atoms on formation of the dative M–L π-bonds as a function of the individual properties. Thus, in contrast to Tc, Re, Ru, Rh, Os, and Ir, "pure" carbonyl clusters are unknown for Pd and Pt, whose atoms have the maximum number (ten) of valence electrons, but instead either the molecular dinuclear cations of the type $[Pd_2(CO)_2]^{q+}$, with a reduced (owing to the ionisation of the complex) effective number of valence electrons in the M atoms[44] or the dinuclear compounds $Pd_2(PPh_3)_4(NO)_2$ and $Pt_2(PPh_3)_4(NO)_2$, where the ligands are NO molecules with π-acceptor properties even more pronounced than those of the CO groups, are stable.[44] New features in the electronic structure of M–M bonds can be observed in cluster groups with PR_3 ligands: $Ru_2(\mu\text{-}PPh_2)_2.(NO)_2$, $Rh(PPh_3)_4(CO)_2$, $Rh_2Cl_2(PF_3)_4$, $Ir_2Cl_2(PF_3)_4$, $Rh_2(PF_3)_8$, $Ir_2(PF_3)_8$, etc. Such compounds are known hitherto only for some of the elements of the platinum group.[45-50]

Thus the main conclusion which follows from the results of the study of the electronic structure of the clusters of *d* elements can be formulated thus: the M–M interactions in the clusters are determined not only by the nature of the *d* element but also depend significantly on the nature of the ligands, because the electronic structure of different M–L bonds has by no means the same influence on the electronic structure of the M–M bonds. In clusters with ligands of the first type fundamental differences are observed in the stereochemistry, energy, and multiplicity of the M–M bonds, in the stability of the clusters as a function of the position of the transition metal in the Periodic System, etc. However, one should note that, together with the natural similarity of the properties of the isoelectronic clusters within the limits of any one variety (for example, the 40-electron $MO_6Cl_8^{4+}$ and $Nb_6Cl_{12}^{2+}$ clusters or the 8-electron MO_2 cluster from $Mo_2Cl_8^{4-}$ and the Re_2 cluster from $Re_2Cl_8^{2-}$), there is evidence[4] indicating definite signs of similarity in the properties of isoelectronic clusters belonging to different categories [for example, the 72-electron $Mo_2Cl_8^{4-}$ and $Mo_2(O_2CR)_4$ clusters, the 108-electron $Re_2Cl_{12}^{3-}$ and $Ru_3O_{12}^{2-}$ clusters, or the 18-electron W_6 cluster from W_6Cl_{18} and the Rh_6 cluster from $Rh_6(CO)_{16}$]. This must be taken into account to avoid overestimating the differences between the structures of the chloride, carbonyl oxygen, carboxylate, and other clusters of 4*d* and 5*d* elements.

The mutual influence of the metal atoms and the ligands in the clusters is manifested mainly by the fact that a specific region in which the cluster structures of the *d* elements occur in the Periodic System is characteristic of each ligand. The discussion of the influence of the ligands on the character of the M–M interactions in the transition metal clusters and hence on the structure and properties of the clusters is on the whole treated in the present review in the nature of a survey, because the Cl atoms constitute a prototype of a whole series of comparatively weak π-donor ligands, while CO molecules serve as a prototype of a series of active π-acceptor ligands; this general approach helps in securing an answer to the main question: with which transition metals and with what ligands can stable cluster structures be formed?

Ligands of the π-donor type should promote the occurrence of cluster structures in compounds of heavy (4*d*, 5*d*) transition elements only in the first halves of the series for low oxidation states of the metal, whereupon the valence electrons of the M atoms not involved in bonds with the ligands can form strong M–M σ-, π-, and even δ-bonds. The formation of cluster structures in yttrium, lanthanum, zirconium, and hafnium compounds is most difficult because of the small number of valence electrons in their atoms. Cluster structures of π-donor ligands cannot arise in formally low-valence compounds of the remaining 4*d* and 5*d* elements owing to the critically large number of valence electrons in their atoms, which leads to an excess of electrons in the M–M bonds, as a result of which the antibonding M–M orbitals are effectively populated and the bonds between the metal atoms vanish.

Ligands of the π-acceptor type should promote the appearance of cluster structures in compounds of all (3*d*, 4*d*, 5*d*) transition elements only in the second halves of the series, whose atoms have a sufficient number of valence electrons also for the formation of the dative M–L π-bonds necessary to ensure the stability of the compounds and for the formation of M–M bonds. The appearance of cluster structures is most difficult in compounds of the elements of the copper subgroup and especially zinc owing to the supersaturation of their atoms by valence electrons. Cluster structures with π-acceptor ligands cannot appear in compounds of the *d* elements at the beginning of the transition series in connection with the small number of valence electrons in their atoms, which is frequently insufficient even for the formation of strong M–L bonds in the mononuclear complexes. Thus the limits of the stability of the transition metal cluster compounds in the Periodic System can be represented schematically as follows:

Sc	Ti	V	Cr	Mn	Fe	Co	Ni	Cu	Zn
Y	Zr	Nb	Mo	Tc	Ru	Rh	Pd	Ag	Cd
La	Hf	Ta	W	Re	Os	Ir	Pt	Au	Hg

π-donor ligands — π-acceptor ligands

An analogous concept concerning the formation and structure of transition metal cluster complexes has been developed within the framework of the ligand field theory.[10]

Thus despite the fact that a detailed explanation of the similarity and differences between all the characteristics of clusters with ligands of different types is so far impossible, one can already achieve a reliable and simple interpretation of the fundamental features of the cluster theory—the question of the stability of clusters as a function of the nature of ligands and also the electronic state of the transition metal atoms and the position of the transition metal in the Periodic System, i.e. the nature of the *d* element.

IV. THE INFLUENCE OF THE TYPE OF LIGANDS ON THE STRUCTURE OF CLUSTERS

The influence of the nature of ligands on the properties of cluster compounds is manifested not only by the fact that the type of ligands (more precisely the character of the M–L bonds) determines in many respects the electronic structure of the M–M bonds and that a specific region of the occurrence of clusters in the Periodic System is characteristic of each type of ligand, but also by the fact that the key properties of some (for example, chloride) clusters are associated with

their "metallic nucleus" (the M_n group), while the properties of others (carboxylate, carbonyl, and oxygen clusters) are in many respects determined by the ligand environment.

Furthermore the character of the interaction of the clusters in crystals of different transition metal compounds is likewise determined in many respects by the nature of the ligands. The clusters differ appreciably in their capacity to enter or not enter into the intercluster interaction: some of these (chloride and related systems) usually remain crystal-chemically isolated in the form of "island complexes", while others (oxygen and similar groups) are involved as a rule in strong intercluster interactions and because of this all the cluster fragments throughout the crystal are drawn together into a kind of "supercluster". This influences the properties of cluster compounds and in the first place structure-sensitive properties such as the X-ray electronic and emission spectra, the chemical shifts of the lines due to the metal in such spectra, the optical electronic and vibrational infrared and Raman spectra, the magnetic properties of the crystal, its conductivity, etc.

1. Non-bridged Dinuclear Chloride Clusters

One of the most striking manifestations of the "non-interference" of the ligand environment in the formation of the electronic structure of the M–M bond is provided by the non-bridged dinuclear M_2L_8 clusters with D_{4h} symmetry (Fig. 2). Such clusters are formed by Group VI and VII 4*d* and 5*d* elements (Mo, W, Tc, Re) with participation of ligands of the type Cl^-, Br^-, I^-, SCN^-, etc.

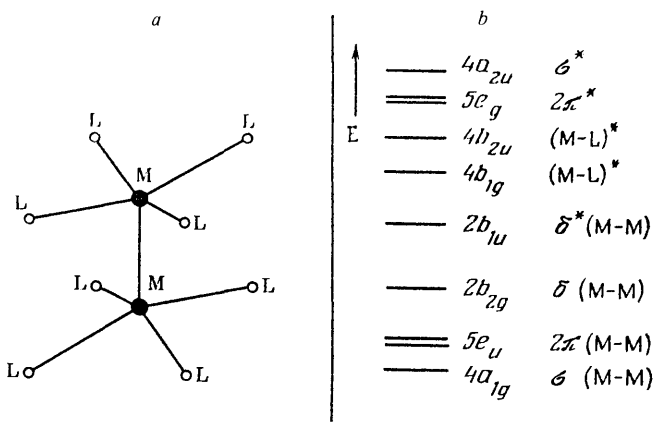

Figure 2. The molecular structure (*a*) and the one-electron energy diagram (*b*) of the highest occupied and lowest unoccupied molecular orbitals of the dinuclear M_2L_8 clusters with D_{4h} symmetry.[17]

The chloride clusters M_2Cl_8 have been most thoroughly investigated.[1,12,14,15,17,30,51–54] The unusual stereochemistry of the M_2Cl_8 clusters (the especially short M–M distance and the eclipsed orientation of the MCl_4 fragments linked to one another directly via an M–M bond without any bridging ligands), their extremely high thermodynamic stability, the specificity of the ligand substitution processes and oxidation-reduction processes, as well as many other properties—all these are factors which are undoubtedly directly related to the characteristics of the electronic structure of the multiple M–M bonds and can be accounted for at the electronic level by the formation of the quadrupole ($\sigma + 2\pi + \delta$) M–M bond.

Thus the two-centre M–M bonds with the maximum possible multiplicity (4) and the highest energy known hitherto among cluster compounds exist in the M_2Cl_8 clusters. Eight valence *d* electrons (four electrons from each M atom) are effectively involved in this strong bond and one (δ) component of this bond limits the mutual rotation of the two MCl_4 fragments about the line of the M–M bonds, i.e. about the rotational fourfold axis of the cluster, promoting thereby a significantly eclipsed (D_{4h}) but not crossed (D_{4d}) conformation of the dinuclear group. Precisely because the energy of the M–M δ-bond is sufficiently high, the M_2Cl_8 (D_{4h}) cluster is not converted into the D_{4d} form where the endo-effect of the interligand repulsion would have been sharply reduced but the M–M δ-bond would have been absent. The barrier to the internal rotation of M_2Cl_8, calculated as the difference between the total energies of the cluster for the eclipsed (D_{4h}) and crossed (D_{4d}) conformations, is close to the energy of the M–M δ-bond[12,30,54] and this result shows yet again that the unusual (D_{4h}) conformation of the M_2Cl_8 cluster arises due to the strong M–M δ-bond without which the observed D_{4h} form of the non-bridged chloride clusters would have been energetically unstable.

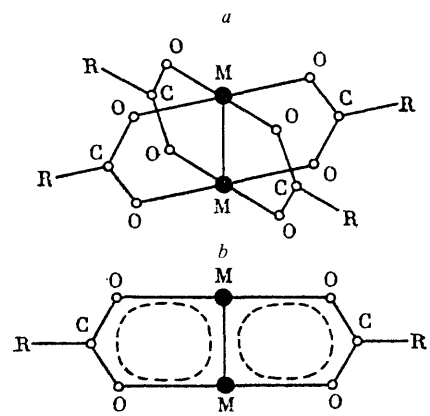

Figure 3. The molecular structure of the dinuclear $M_2(O_2CR)_4$ carboxylate clusters with D_{4h} symmetry (*a*) and the system of delocalised M–M and M–L π-bonds (*b*).[59]

2. Dinuclear Carboxylate Complexes

In contrast to the non-bridged chloride clusters M_2Cl_8, where the electronic structure of the M–M bond plays the main role, the dinuclear carboxylate clusters (clusters with O_2CR ligands) constitute an example of the active involvement of the ligand environment in the formation of the cluster complex as a whole. The $M_2(O_2Cr)_4$ cluster groups, which are characteristic mainly of heavy Group VI, VII, and VIII *d* elements,[55–58] also have the D_{4h} symmetry (Fig. 3), but, in contrast to M_2Cl_8, where the M–L bonds are predominantly of the single σ-character without an appreciable π-contribution and where the involvement of the valence electrons of the ligands in the M–M molecular orbitals is small, in the $M_2(O_2CR)_4$ carboxylate clusters the π-interaction also makes

an appreciable contribution to the M–L bond and the multiplicity of the latter is greater than unity; furthermore, the molecular orbitals of the M–M and M–L bonds do not differ in this instance quite so markedly in their one-electron energies and the contributions of the valence *d* orbitals of the metal atoms.

Compared with M_2Cl_8, the role of the ligands in the formation of M–M bonds in $M_2(O_2CR)_4$ is appreciably enhanced, particularly as regards the M–M π_1- and π_2-interactions.[15,59] In the $M_2(O_2CR)_4$ cluster the energy of the M–L π-interaction which ensures its additional stabilisation, is optimum when the cluster has the D_{4h} symmetry. Indeed, for bidentate ligands such as the O_2CR groups, the D_{4h} form does in fact ensure the most favourable conditions for the formation of a single system of delocalised π-bonds in the $M_2(O_2CR)_4$ cluster with participation of both M atoms in the ligands. Such a system of delocalised π-bonds is illustrated schematically in Fig.3 for each half fragment of the $M_2(O_2CR)_4$ cluster; this scheme can probably be extended also to the M–M and M–L π-bonds. The results of quantum-chemical calculations, on the basis of which the above conclusions have been reached, do not conflict with the X-ray electronic spectra of $M_2(O_2CR)_4$.[59–61]

Thus, for monodentate ligands (M_2Cl_8 dinuclear chloride clusters), the stabilisation of the D_{4h} form of the cluster is impossible without the formation of the M–M δ-bond. On the other hand, the stability of the D_{4h} form of the $M_2(O_2CR)_4$ carboxylate clusters must be accounted for by the bidentate character of the O_2CR ligands and the above characteristics of M–M and M–L π- and possibly σ-bonds in these dinculear clusters rather than by the presence of an M–M δ-bond.

The fact that the D_{4h} M_2Cl_8 chloride clusters exist only for M atoms with a d^4 electronic configuration, i.e. when eight valence electrons participate effectively in the M–M bond and when this two-centre bond is in fact quadruple (all the bonding σ, 2π, and δ molecular orbitals of the M–M bond are occupied by electrons, while the corresponding antibonding MO are unoccupied) with a strong δ-component constitutes convincing evidence for the above explanation. Even for a slight deviation of the electronic configuration of the M atom from the d^4 configuration to one side or another, i.e. for any change in the number of electrons involved in the M–M bond, the D_{4h} M_2Cl_8 chloride clusters are not as a rule formed. In this situation the formation of the δ-component of the M–M bond is impossible owing to the absence of valence electrons in the bonding δ molecular orbital of the M–M bond (when the total number of electrons in the two-centre M–M bond is less than eight) or owing to the appearance of electrons in the antibonding δ^* molecular orbital (when the total number of electrons is greater than eight).

On the other hand, the $M_2(O_2CR)_4$ carboxylate clusters exist in the D_{4h} form not only for the d^4 electronic configuration of the M atoms, when a quadruple M–M bond with a strong δ-component is formed, but also for large deviations from these configurations—for d^5, d^6, and even d^7 M atoms when the δ-component of the M–M bond is absent and the two-centre M–M interaction is as a whole significantly weakened. Indeed, the electronic structure of the two-centre M–M bond in the $M_2(O_2CR)_4$ clusters is quite varied: ranging from a quadruple M–M bond with a high energy in the molybdenum and rhenium clusters to the M–M bond with a reduced energy and multiplicity in the ruthenium and rhodium clusters, where the effective numbers of electrons in the M–M bonds are much greater than eight (Table 2).

The increase of the M–M distance and the paramagnetism of the complexes $Ru_2(O_2CC_3H_7)_4Cl$ and $Rh_2(O_2CCH_3)_4.2H_2O$ show that the M–M bonds in the complexes are significantly weakened; they are apparently triple ($\sigma + 2\pi$) and not quadruple ($\sigma + 2\pi + \delta$) and do not include a δ-component, because the excess (above eight) valence electrons in $Ru(O_2CC_3H_7)_4^+$ (eleven electrons) and $Rh_2(O_2CCH_3)_4$ (fourteen electrons) populate only the antibonding M–M δ^*-molecular orbital, i.e. they prevent the appearance of the δ-component in the M–M bonds; the remaining excess electrons populate the antibonding MO of the M–L bonds (Fig.2). The M–M antibonding $2\pi^*$ and σ^* MO still remain unoccupied under these conditions; this preserves the M–M triple ($\sigma + 2\pi$) bond in the cluster, which is apparently characteristic of $Ru_2(O_2CR)_4^+$ and $Rh_2(O_2CR)_4$.

Table 2. Electronic structure parameters of M–M bonds in the $M_2(O_2CR)_4$ clusters.

Parameter	Cluster			
	$Mo_2(O_2CR)_4$	$Re_2(O_2CR)_4^{2+}$	$Ru_2(O_2CR)_4^+$	$Rh_2(O_2CR)_4$
Electronic configuration of M atoms	d^4	d^4	d^5—d^6	d^7
M–M distance, Å	2.11	2.24	2.28	2.45
Multiplicity of M–M bond	$4(\sigma+2\pi+\delta)$	$4(\sigma+2\pi+\delta)$	$3(\sigma+2\pi)$	$3(\sigma+2\pi)$
No. of valence electrons in M–bond	8	8	11	14
References	[17, 59]	[17, 59]	[17, 59]	[17, 59]

A strong influence by the bidentate O_2CR ligands on the stereochemistry of the clusters is also manifested by the fact that the D_{4h} M_2Cl_8 chloride clusters are stable only for heavy (4*d*, 5*d*) elements, while the dinuclear D_{4h} $M_2(O_2CR)_4$ carboxylate groups are stable also in the case of light (3*d*) elements; an example of this is provided by the dimeric copper and chromium acetates.

3. The Conformational Transformations of Carbonyl Clusters

Transition metal chloride and carbonyl clusters have significantly different stereochemistries, particularly in the case of the heaviest (5*d*) transition elements: the differences consist in the fact that the ligands in the chloride clusters very often form bridge bonds with the M atoms, while in the carbonyl clusters all the ligands are always terminal.

One of the main stereochemical characteristics of the carbonyl clusters is their tendency towards the *trans*-disposition of the CO groups relative to the M–M bonds, i.e. approximately along the line of the two-centre M–M bonds. Owing to the absence of the π-component in the M–M bonds in the carbonyl clusters, such dispotion of the ligands is most favourable for the formation of strong dative M–CO π-bonds, i.e. for the maximum energy stabilisation of the carbonyl cluster as a whole.[21,22,62] In particular, such are the molecular and electronic structures of the $Ir_4(CO)_{12}$ tetrahedral carbonyl cluster with T_d symmetry[63,64] (Fig.4). However, steric factors prevent the ideal *trans*-disposition of the CO groups relative to the two-centre M–M bonds; these groups are "deflected" towards the centre of the Ir_4 tetrahedron and the C–Ir–Ir valence angle is 150°, i.e. much less than 180°. Such distortion of the molecular structure of the $Ir_4(CO)_{12}$ leads to some destabilisation of the dative Ir–CO π-bonds.

In the isoelectronic tetranuclear $Co_4(CO)_{12}$ carbonyl cluster the M–CO bonds are much shorter[40] and the steric limitations under discussion therefore increase so sharply that $Co_4(CO)_{12}$ with a tetrahedral structure becomes energetically unstable:

the CO groups in the tetrahedral $Co_4(CO)_{12}$ would have been too remote from the *trans*-disposition relative to the two-centre M–M bonds, for which the formation of strong dative M–CO π-bonds is possible. It is therefore likely that $Co_4(CO)_{12}$ has a conformation different from that of $Ir_4(CO)_{12}$ and in the energetically stable state assumes the C_{3v} molecular structure, where three out of the twelve ligands are of the bridging type (Fig.4).

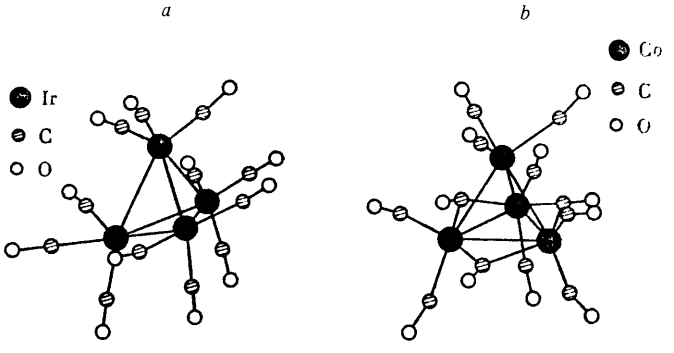

Figure 4. The molecular structure of tetranuclear carbonyl clusters: *a*) $Ir_4(CO)_{12}$ (T_d); *b*) $Co_4(CO)_{12}$ (C_{3v}).[62]

An analogous phenomenon for $Ir_4(CO)_{12}$ is hardly feasible. The appearance of bridging CO groups in the molecular structure of any carbonyl clusters requires that the M–M and M–CO bond lengths must meet severe requirements, rigorously specified by the extent and angular distribution of the virtual (unoccupied by electrons in free CO molecules) $2\pi^*$ MO of the CO groups, the only ones which can give rise to dative M–CO π-bonds necessary for the existence of the carbonyl cluster. Indeed in all the carbonyl compounds with bridging CO groups without exception, the M–C–M valence angle lies within very narrow limits (80–87°).[65] Clearly, on passing from atoms of 3*d* elements (Co) to those of 5*d* elements (Ir), which are characterised by a much greater extent of the valence orbitals, the necessity for the preservation of the angular distribution characteristic of the bridging M–C–M group would lead to such a marked deviation of the M–CO bond lengths from their normal values in the carbonyl cluster of a 5*d* element with bridging ligands that sufficiently strong M–CO bonds (primarily σ-bonds) could hardly exist at all.

However, on the whole, the bridging CO groups as a rule stabilise the carbonyl cluster and the only limitation is the "rigidity" of the valence electronic structure of the CO group. This is precisely the reason why carbonyl clusters with bridging ligands are formed mainly by 3*d* elements, while 5*d* elements produce carbonyl clusters solely with terminal ligands [$Os_3(CO)_{12}$, $Ir_2(CO)_8$, $Ir_4(CO)_{12}$, etc.[40]]. The clusters of 3*d* elements [$Fe_3(CO)_{12}$, $Co_2(CO)_8$, $Co_4(CO)_{12}$, etc.] can exist both in the form with bridging ligands (this is most characteristic of such clusters) and in the form incorporating only terminal ligands. In this sense the conformational transformations of carbonyl clusters constitute an entirely realistic physical process. The appearance of a carbonyl cluster of a 3*d* element in the form without a bridging ligand requires special conditions (high temperature, molecular solutions) ensuring the energy activation necessary for such a conformational transformation.[65]

The carbonyl clusters of 4*d* elements occupy a intermediate position in this respect: in some cases they incorporate bridging CO groups [$Rh_4(CO)_{12}$], while in others all the ligands are terminal [$Ru_3(CO)_{12}$, $Rh_2(CO)_8$].

The inability of the 5*d* elements to form carbonyl clusters with bridging CO groups has an important consequence: the 3*d* and 4*d* elements in a particular Group in the Periodic System form carbonyl clusters of a kind which are absent for the heaviest (5*d*) transition metals. As an example, we may point to the stability of $Fe_2(CO)_9$, $Co_6(CO)_{16}$, $Rh_6(CO)_{16}$ and the absence of analogous derivatives of osmium and iridium.[40,42]

The causes of the preferential existence of the chloride clusters of 5*d* elements in a form involving bridging ligands and the absence of bridging ligands from molecular structures of the carbonyl clusters of these *d* elements have been discussed in detail[66] on the basis of the results of calculations for one-electron molecular orbitals of the trinuclear $Re_3Cl_{12}^{3-}$ and $Os_3(CO)_{12}$ groups.

Thus the absence of M–M π-bonds and, what is most important, the angular distribution of the valence $2\pi^*$ MO of the CO groups forming the dative M–CO π-bonds explain the conformational transformations of the carbonyl clusters of 3*d* elements, their existence in the form of molecular structures with bridging ligands, and the absence of similar phenomena in the chemistry of the cluster carbonyls of 5*d* elements.[21,62]

4. Oxygen-containing Cluster Compounds of 4*d* and 5*d* Elements and Their Characteristic Features; Intercluster Interactions

The influence of the ligand environment on the structure of the clusters and on the electronic structure of their M–M bonds is manifested particularly strikingly in the case of the cluster oxides. Distinctive clusters with oxygen atoms as ligands have been discovered so far for a comparatively small number of transition metal oxides: $La_4Re_6O_{19}$ (Re_2 groups), $Au_2^{II}Mo_3O_8$, and $A_2^{II}W_3O_8$ (where A^{II} = Mg, Mn, Fe, Co, Ni, Zn, or Cd) (Mo_3 and W_3 groups), $Ba_3Ru_3O_9$ (Ru_3 group), and certain others.[25,40,67–81] The oxygen clusters are formed only by 4*d* and 5*d* elements (clearly identified oxygen clusters of 3*d* elements have not so far been discovered) and in addition by elements in the middle of the transition series only.

We may note that in the crystal structures of the dioxides strong M–M bonds exist only for the 4*d* and 5*d* elements precisely in Groups VI and VII of the Periodic System (MoO_2, WO_2, TcO_2, and ReO_2, where the M–M bonds are probably double). On the other hand, in the dioxides NbO_2 and TaO_2 these bonds are greatly weakened and in the platinum group metal dioxides (RuO_2, OsO_2, etc.) the M–M bonds are most probably absent; the M–M bonds are known *a priori* to be absent from ZrO_2 and HfO_2, because of the highest oxidation state of the metal. The transition to 3*d* elements is accompanied by a sharp decrease of the strength of the M–M bonds and their disappearance (VO_2, CrO_2, MnO_2, CoO_2, etc.).

In the oxygen clusters (as well as chloride clusters) the M–M bonds arise with the preferential involvement of the valence *d* electrons of the M atoms and can be both single and multiple (in particular, double). However, in contrast to the chloride clusters, in the chloride clusters the M–L bonds have a multiplicity greater than unity (with a considerable π-contribution) and the M–M and M–L interactions are not isolated; on the other hand, the inter-relation between the M–M and M–L interactions (the mixing of the molecular orbitals of these bonds with respect to energies and the

contribution of the M and L atomic orbitals) constitute a permanent element in the structure of any oxygen cluster. The M–M bonds in such clusters (particularly the π-components) are formed with participation of the bridging oxygen atom; the decisive role of the bridging oxygen atoms in the formation of a system of delocalised π-bonds between the metal atoms is apparently the cause of the absence of non-bridged oxygen clusters. In an oxygen cluster the bridging ligands promote the delocalisation of the valence electrons of the M atoms over the M–M bonds of the π-type; the mixing of the molecular orbitals of the M–M and M–O bonds takes place owing to the transfer of electron density from the bridging oxygen atoms, which behave as π-donors (this effect is characteristic of polynuclear oxygen complexes, without it, such complexes apparently could not exist).

All these distinctive features of the electronic structures of oxygen clusters can be traced quite reliably (both experimentally and theoretically), in particular in the trinuclear $Mo_3O_{13}^{14-}$ and $Ru_3O_{12}^{12-}$ groups.[67,79,80] A specific feature of the M–M and M–O π-interactions in the oxygen clusters, noted above, explains an unexpected characteristic of the electronic structure of the $Ru_3O_{12}^{12-}$ (Fig.5), namely that the M–M π-bonds in the linear Ru_3 group (with Ru–Ru double bonds) are formed not only between neighbouring metal atoms [Ru(1)–Ru(2), (Ru(2)–Ru(3)] but also directly between the terminal metal atoms [Ru(1)–Ru(3)], separated from one another by "bridging" M atoms [Ru(2)]. On the other hand, both M–M σ-bonds are to a marked extent localised in the two-centre Ru(1)–Ru(2) and Ru(2)–Ru(3) fragments.

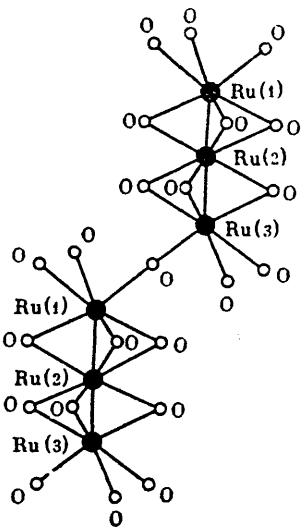

Figure 5. The $Ru_3O_{12}^{12-}$ (or $Ru_3O_6O_{6/2}^{6-}$) fragments of the crystal structure of barium ruthenite $Ba_3Ru_3O_9$.[78]

The results of the analysis of the magnetic properties of the $Ba_3Ru_3O_9$ crystal and of the characteristic features of the exchange interaction in the isolated $Ru_3O_{12}^{12-}$ cluster, carried out[79] within the framework of the Heisenberg–Dirac–Van Vleck model (which makes it possible to investigate the magnetism of cluster paramagnetic compounds), are fully consistent with the presence of two unpaired electrons in the MO of $Ru_3O_{12}^{2-}$ and with the strong electronic interaction of the terminal metal atoms in the linear Ru_3 cluster. The terminal atoms in the Ru_3 trimer are only formally geometrically isolated from one another. Apparently the M atoms in the cluster tend to equalise their states, not only by forming groups in which the M atoms are known to be equivalent (for example triangular Mo_3 clusters, as in $Mo_3O_{13}^{14-}$) but also by forming bonds between M atoms "not in contact" and which are in addition separated by the "third" M atom. In the linear Ru_3 cluster all three M atoms are probably in similar electronic states, which in no way follows *a priori* from its steterochemistry. [On the contrary, the non-equivalence of the electronic states of the middle Ru(2) atom, on the one hand, and the terminal Ru(1) and Ru(3) atoms, on the other, should seemingly follow from the geometry of the linear Ru_3 cluster.]

In cluster oxides the ligand environment not only determines in many respects the electronic structure of the M–M bonds but (and this is particularly important) is responsible for the strong intercluster interaction in the crystal structure. The bridging oxygen atoms, each linking two M atoms in different "neighbouring" clusters, ensure (also as a result of the formation of π-donor bonds with each M atom of this kind) the appearance of a single system of delocalised M–M and M–O π-bonds with the simultaneous participation of all the clusters (i.e. ensures the delocalisation of the valence π-electron density of the M atoms over all the clusters at once). Such strong intercluster interaction (Fig.5) is distinctly reflected in almost all the properties of the corresponding crystal and in the first place is manifested by a high conductivity ($Ba_3Ru_3O_9$, for example, exhibits metallic conductivity[78]). In contrast to this, in the cluster chlorides (which are dielectrics) such delocalisation of the valence electron density of the M atoms is negligible and in this sense one may speak of the absence of an appreciable intercluster interaction in their crystal structures.

V. THE EFFECTS OF CLUSTER FORMATION

The formation of cluster groups in crystalline structures of transition metal compounds naturally makes its own impression to a greater or lesser extent on all the physical characteristics of these compounds and this distinguishes them from the corresponding mononuclear complexes. Evidently the first in these series of properties should be the specific characteristics of the crystal structures of the cluster compounds which are revealed in X-ray diffraction studies, showing that groups of several (two or more) M atoms in direct contact, which are more or less isolated from one another, exist in the crystal;[31–40] the M–M internuclear distances within the limits of such groups are close to the values for the corresponding metallic crystal or even much smaller. The distances between the M atoms in different (neighbouring) clusters are as a rule much greater.

This factor by itself indicates the formation of M–M bonds in the cluster crystal together with the usual M–L bonds. The formation of M–M bonds has been confirmed by the magnetic properties of cluster compounds (or at least the latter do not conflict with their formation):[31–40] in the vast majority of cases the effective magnetic moments of cluster compounds are greatly reduced (down to the diamagnetic level) compared with the values expected on the basis of the formal valence of the M atom. Here we have in mind the following situation. In a cluster compound the M atoms always have a low formal valence (this is a permanent condition for cluster formation) and therefore several valence electrons (d^m), not involved in bonding to the ligands and responsible for the very high paramagnetism, should therefore remain in

each M atom. However, owing to the pairing of the spins of the valence electrons of the M atoms in the M–M bonds, the experimental effective magnetic moment of cluster compounds is always much less than the value expected for the d^m configuration and not only in terms of the approximation of the spin only values but also when account is taken of effects such as spin–orbital coupling, antiferromagnetism, etc.[27,34]

The formation of clusters with strong M–M bonds makes an important additional contribution, additional to that of the M–L bonds, to the total energy of the crystal structure. The energy effects of cluster formation (the M–M bond energies) in the chlorides and oxides of heavy *d* elements and in the carbonyls and certain other compounds of transition metals have been estimated from the enthalpies of formation of these compounds,[4,23,24,34,79,82–84] by semi-empirical calculation of the molecular orbitals of the corresponding isolated clusters,[2–4,12,21,23,51,79,84] and even by direct mass-spectrometric measurement of the energies of dissociation of clusters into mononuclear fragments.[85]

Both experimental and theoretical results have shown that the M–M interaction energies in the cluster chlorides and oxides with heavy *d* elements (calculated per electron involved in such interactions) are usually in the range 25–35 kcal, i.e. the structure is fairly stable despite the fact that these compounds include clusters of different *d* elements, with different formal valences of the M atoms, and with extremely different stereochemistries. This range is in fact most characteristic of the M–M interaction energies in the metallic crystals of 4*d* and 5*d* elements; the latter factor indicates that the formation of an M–M bond in clusters is one of the principal energy factors ensuring the compensation of the endothermic effect of the breakdown of the structure (i.e. the compensation of the enthalpy of atomisation) of the crystal of the transition metal on formation of its formally low-valence chlorides and oxides. At the same time, the stability indicated by the E_{M-M} values does not rule out the formation (particularly in chloride clusters—Table 3) of two-centre M–M bonds with different energies up to very high values, depending on the number of electrons in these bonds and hence on the M–M distances.

Table 3. Parameters of the two-centre M–M bonds in the chloride and carbonyl clusters.

Cluster	R_{M-M}, Å	n_{M-M}	E_{M-M}, kcal	k_{M-M}, mdyn Å^{-1}	Refs.
$Re_2Cl_8^{2-}$	2.24	8	270	4.2	[6]
$Mo_2Cl_8^{4-}$	2.14	8	297	3.4	[6, 53]
$W_2Cl_9^{3-}$	2.41	6	155	1.2	[26]
$W_6Cl_8^{4+}$	2.61	2	59	0.3	[26]
$Mo_6Cl_8^{4+}$	2.61	2	44	0.3	[26]
$Nb_6Cl_{12}^{2+}$	2.92	1.3	34	0.3	[2]
$Ta_6Cl_{12}^{3+}$	2.93	1.2	33	0.3	[2]
$Mn_2(CO)_{10}$	2.92	2	17	0.6	[22]
$Tc_2(CO)_{10}$	3.04	2	31	0.7	[22]
$Re_2(CO)_{10}$	3.02	2	38	0.8	[22]
$Os_3(CO)_{12}$	2.88	2	28	0.9	[66]
$Ir_4(CO)_{12}$	2.68	2	31	1.2	[64]

Notation: R_{M-M} is the M–M distance, n_{M-M} the number of valence electrons per two-centre M–M bond, E_{M-M} the energy of this bond, and k_{M-M} the force constant of the M–M stretching vibrations.

In the carbonyl clusters of 4*d* and 5*d* elements the M–M interaction energies (also calculated per electron) are lower by a factor of approximately 1.5–2.[4,20,85] The cause of this is that in the electronic structure of a carbonyl cluster the bonding σ MO responsible for the M–M bonds have an enhanced energy, because these MO are at the same time antibonding in relation to the M–*trans*-CO σ-interactions and in addition a large contribution to such orbitals comes not only from the $(n-1)d$ MO but also from the valence *np* orbitals, having an increased electron energy, of the M atoms. Furthermore, one should bear in mind that single (two-electron) two-centre M–M bonds of the σ-type are usually formed in carbonyl clusters (without an appreciable π-contribution), the bonds having comparatively large internuclear distances.

Thus the large contribution of the M–M bonds to the total energy of the cluster confirms the dominant role of the M–M interactions in the phenomenon of cluster formation (particularly in compounds of the formally low-valence chlorides and oxides of 4*d* and 5*d* elements) and the principal cause of the existence of clusters may be seen in the high M–M bond strength.

VI. SPECTROSCOPY OF CLUSTER COMPLEXES

The formationof clusters is manifested in EPR, NQR, Mössbauer, and magnetic circular dichroism spectra.[11,86–90] However, cluster formation is revealed most directly in optical, vibrational, X-ray emission, and X-ray electronic spectra; the last spectra yield the most direct information about the states of the valence electrons of the M atoms and ligands, about the valence of the M atoms, about the nature of the M–M bonds in the clusters, and about the electronic structure as a whole and also reveal the qualitative and quantitative characteristics of cluster compounds which are absent from mononuclear complexes; these appreciable differences between the properties of cluster and mononuclear compounds reflect the phenomenon of cluster formation.

1. Optical Electronic Spectra

The experimentally observed absorption maxima in the optical electronic spectra of cluster compounds mainly reflect the electronic transition from the occupied bonding MO of the M–M bonds to the corresponding unoccupied non-bonding or antibonding MO. These are "metal–metal" transitions, which are apparently characteristic of clusters in general, but have been most thoroughly investigated in the cluster chlorides of 4*d* and 5*d* elements.[11,26,27,51,92–103]

The generally accepted interpretation of the optical electronic spectra is based in this instance on the hypothesis that one-electron transitions involving the M–M MO, delocalised in the clusters between the M atoms and having a predominantly *d*-electron character, are mainly responsible for the absorption in the visible region of the spectra. Despite this assumption, the long-wavelength electronic transitions in the spectra of the compounds investigated reflect fairly accurately the electronic structure of the M–M bonds in the clusters: the number of bands, their positions in the spectrum, and their relative intensities agree with the number of MO of the M–M bonds, their energy sequence, their electron populations, and finally their symmetry, which makes it possible to distinguish (within the framework of the selection rules for the optical spectrum) the allowed and forbidden transitions.[26,51]

In contrast to the cluster compounds, the optical electronic absorption spectra of complexes without an M–M bond can be simply described in terms of *d*–*d* transitions significantly localised at each M atom; for this reason, the form of the spectrum constitutes an indication of the cluster or mononuclear nature of the complex.

2. Vibrational Spectra

In the study of cluster compounds by vibrational spectroscopic methods attention is naturally concentrated on the vibrations of the M–M bond, which can be regarded as characteristic for such bonds (apart from a small contribution by M–L bonds only). This characteristic nature of the vibrations consists in the fact that the optical absorption spectra of cluster compounds in the infrared range contain bands at frequencies in the range 100–400 cm^{-1}, frequencies closer to the lower limit being characteristic of clusters with comparatively weak (single) M–M bonds, while frequencies characteristic of clusters with very strong (quadruple) M–M bonds lie near the upper limit of the above range.

The results of studies on cluster transition metal chlorides, oxides, and carbonyls by infrared and Raman spectroscopic methods,[11,79,103–121] namely the ν(M–M) frequencies and k_{M-M} force constants for the two-centre M–M bonds, yield information about the strength of these bonds. The available data (presented in part in Table 3) make it possible to compare the force constants (or frequencies) of the stretching vibrations, the effective numbers of electrons, the energies, and the internuclear distances for the two-centre M–M bonds in clusters. The correlations between these characteristics are unambiguous and usually reveal a parallel variation of $k_{M-M}[\nu(M-M)]$, n_{M-M}, and E_{M-M}, in particular their increase as the M–M distances are shortened.

The situation is more complex in cluster oxides in the presence of strong intercluster interactions. Whereas in the infrared spectra of $Mg_2Mo_3O_8$ and $Zn_2Mo_3O_8$, where the internuclear interaction is comparatively weak, the stretching vibration frequencies of the Mo–Mo bonds in the trinuclear Mo_3 clusters are manifested (at approximately 200 cm^{-1}),[79] in the infrared spectra of $Ba_3Ru_3O_9$, MoO_2, WO_2 and RuO_2 with strong (double) M–M bonds, there is virtually no absorption in the frequency range 100–1700 cm^{-1}, i.e. the M–M stretching vibrations are not shown.[79] This can be accounted for by the specific features of the $Ba_3Ru_3O_9$, MoO_3, WO_2, and RuO_2 structures expressed by the fact that these compounds have, instead of an island structure, a coordination structure, which ensures their metallic conductivity[121] and precludes the manifestation in the spectrum of vibrations localised in the quasi-molecular fragments.

3. X-Ray Emission Spectra

The cluster chlorides and oxides with certain 4*d* elements, mainly Nb, Mo, and Ru,[4,79] have been most fully investigated by this method. The L_{β_2} and L_{γ_1} lines of the M atoms, which reflect the distribution of the valence 4*d* electrons of the M atoms, responsible for the formation of the M–M bonds, among the occupied MO of the clusters, have been used for the X-ray spectroscopic study of the valence electron structures of these M atoms. Fig.6 presents as an example the L_{β_2} spectrum of molybdenum in $Cs_3Mo_2Cl_8$. The X-ray spectra of cluster chlorides, which yield information about the energy sequence of the occupied MO of the cluster, the electron populations, the contributions to the MO by the valence 4*d* orbitals of the M atoms, etc., permit the following conclusions:

(1) The 4*d* orbitals of the M atoms make the main contribution to the M–M MO, which have the highest energies and lie above the MO of the M–Cl bonds, formed predominantly with the participation of the 5*p* orbitals of the M atoms, this implies that the M–M and M–L electronic interactions are in this instance truly isolated from one another to a large extent with respect to both the energies of the MO responsible for such interactions and the contributions of the valence atomic orbitals (AO).

(2) The 4*d* electrons of the M atoms participate mainly in the M–M bonds and to a much lesser extent in the M–Cl bonds; the M–M interactions, which are predominantly of the *d*-electron type, are largely localised within the limits of the M_n group of the "metallic nucleus" of the cluster.

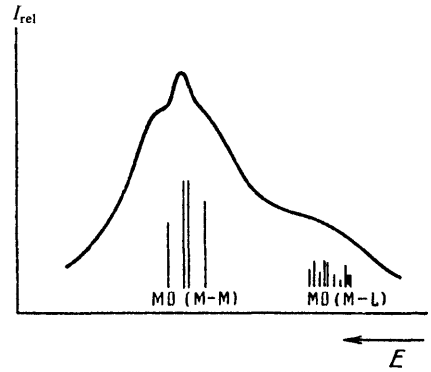

Figure 6. The X-ray emission L_{β_2} spectrum of molybdenum for $Cs_3Mo_2Cl_8$.[4]

At the same time the parameters $K_{\beta_{1,3}}$ of the line due to chlorine in the X-ray spectra of the same cluster chlorides show[4] that not all the valence 3*p* electrons of the Cl atoms are involved in the M–Cl bonds without conflicting with the idea that mainly M–Cl σ-bonds are formed with a low π-contribution to the metal–ligand interaction and that a large proportion of the $3p\pi$ electrons of the Cl atoms remain in a pseudoatomic state.

The X-ray spectra of cluster oxides have a somewhat different appearance. In the oxygen cluster the occupied MO are of a "mixed" character (they are simultaneously responsible for the M–M and M–O bonds) and the valence 4*d* orbitals of the M atoms make a considerable contribution to all these MO, including the MO of the M–L bonds. In the oxygen cluster the MO with a large contribution by the *d* AO of the metal therefore have a much greater energy range than in the chloride cluster, where the large (sometimes predominant) contribution of the *d* AO of the metal is present only in the highest-energy occupied MO, responsible almost exclusively for the M–M interactions, and not in the MO of the M–Cl bonds. The energy range including the MO of the chloride cluster with a large contribution by the valence *d* orbitals of the M atoms is much narrower.

All this ultimately explains why the X-ray spectra of the metal, reflecting the distribution of the valence *d* electrons of the M atoms among the molecular orbitals of the clusters (this applies particularly to the L_{β_2} spectrum of molybdenum), contain a wider band in the case of the cluster oxide (with a large involvement of the *d* electrons of the M atoms in the M–L bonds) than in the cluster chloride (with a small involvement of the *d* electrons of the M atoms in the M–L bonds) of the same transition metal.[79]

The study of the chemical shifts of the emission lines (*K*, *L*, etc.) of heavy *d* elements in the X-ray spectra of their various compounds yields important information. The results of

measurements of the chemical shifts of the K and L lines of Nb, Mo, and W in the X-ray emission spectra of numerous cluster and mononuclear compounds are available.[4,122-124] The chemical shifts ΔE have been measured for cluster compound–corresponding metal pair combinations. It has been found that the ΔE peaks for the metal increase linearly with increase of the formal valence of the M atoms for the chlorides in the structures of which there are no clusters and M–M bonds are known to be absent; Fig.7 presents as an example the values of ΔE(Nb) in the system of niobium chlorides. The linearity in the variation of the ΔE can be explained by the successive changes in the effective number of valence electrons of the M atoms not involved in bonding to ligands and localised in the pseudoatomic 4*d* or 5*d* states based on the M atom. The number of such electrons n is equal to the difference between the total number of valence electrons of the M atoms and their formal valence V_M, i.e. the number of their valence electrons in the M–Cl bonds. The observed linearity of the variation, implying proportionality of the changes in ΔE when the number of the unbound 4*d* or 5*d* electrons of the M atom is altered, corresponds to the overall physical nature of the effect of the chemical shifts of the X-ray lines.[125]

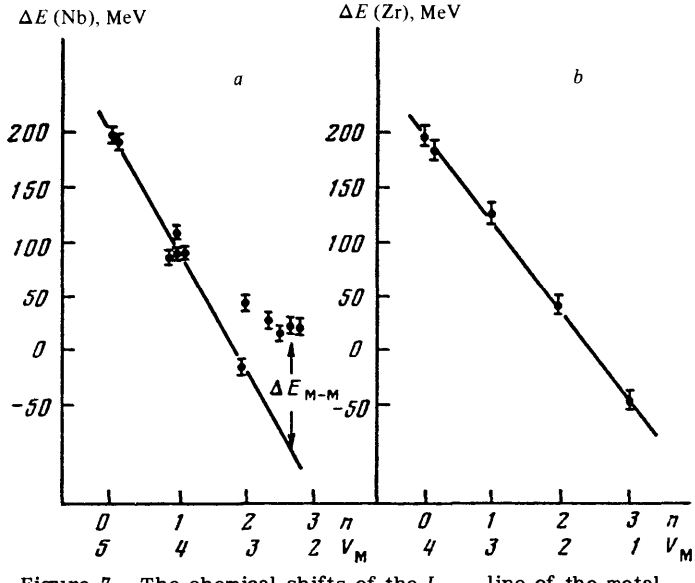

Figure 7. The chemical shifts of the $L_{\alpha_{1,2}}$ line of the metal (ΔE) in the X-ray spectra of niobium (*a*) and zirconium (*b*) chlorides as a function of the formal valence of the metal V_M and the number n of the valence electrons of the M atom not involved in the M–Cl bonds:[4,124] *a*: 1) $NbCl_5$; 2) $KNbCl_6$; 3) $NbCl_4$; 4) K_2NbCl_6; 5) Rb_2NbCl_6; 6) Cs_2NbCl_6; 7) $Cs_3Nb_2Cl_9$; 8) K_3NbCl_6; 9) Nb_3Cl_8; 10) $CsNb_4Cl_{11}$; 11) Nb_6Cl_{14}; 12) $K_4Nb_6Cl_{18}$; *b*: 1) $ZrCl_4$; 2) Na_2ZrCl_6; 3) $ZrCl_3$; 4) $ZrCl_2$; 5) ZrCl.

The chemical shifts of the lines in the X-ray spectrum of the metal for cluster compounds always deviate sharply from the linear relation characteristic of mononuclear compounds (Fig.7). These deviations reflect appreciable delocalisation of the valence 4*d* or 5*d* electrons of the M atoms not involved in bonds with the ligands, i.e. they reflect the effective electronic interactions between the metal atoms in the cluster chlorides. The "anomalous" values of ΔE thereby indicate directly the formation of M–M bonds in the chloride clusters. These deviations (ΔE_{M-M}) from the linear relations increase in proportion to the increase of the number of the valence electrons of the M atom which are not involved in the M–Cl bonds and are therefore fully available for involvement in the M–M interactions.

In the series of chlorides of the same heavy *d* element incorporating M atoms with the same formal valence, the deviations of ΔE from linearity, due to the M–M interactions in the clusters, increase in succession with increase in the number of electrons in the M–M bonds and also with decrease of the M–M distances and the accompanying decrease of the effective magnetic moments, i.e. as the M–M bonds become stronger. This can be traced particularly clearly in relation to the chlorides of the formally tervalent molybdenum (Fig.8), where the limiting M–M distance (approximately 3 Å), which is the beginning of the range of distances in the chlorides of 4*d* and 5*d* elements for which clusters with M–M bonds are virtually not formed, is very clearly shown.

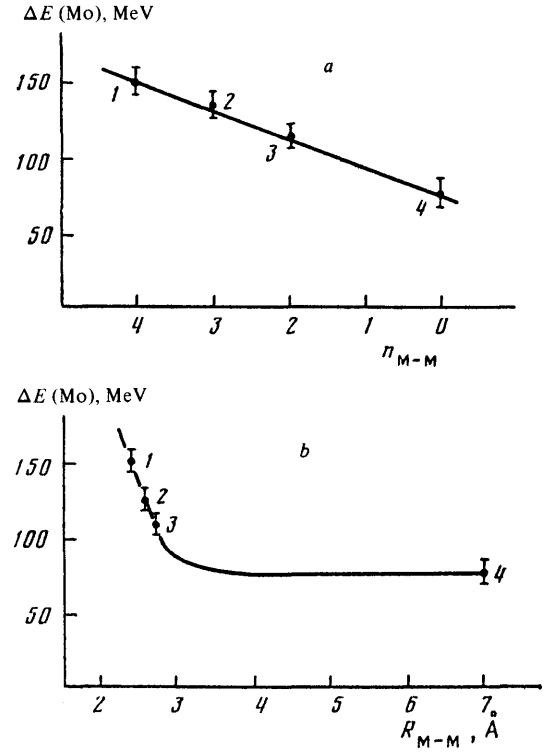

Figure 8. The chemical shifts of the $L_{\alpha_{1,2}}$ line of molybdenum ΔE in the X-ray spectra of the chlorides of the formally tervalent molybdenum as a function of the number n_{M-M} of the valence electrons of the M–M bonds (*a*) and the M–M distance R_{M-M} (*b*):[4,123] 1) $K_3Mo_2Cl_9$; 2) $Cs_3Mo_2Cl_9$; 3) $MoCl_3$; 4) K_3MoCl_6.

Study of the chemical shifts of the X-ray $L_{\alpha_{1,2}}$ line of molybdenum in the series of its formally low-valence chlorides with two-centre M–M interactions, i.e.

$$Mo_2Cl_{10}\,(MoCl_5) \underset{d^1}{} — \underset{d^2}{MoCl_4} — \underset{d^3}{MoCl_3} — \underset{d^3}{Cs_3Mo_2Cl_9} — \underset{d^3}{K_3Mo_2Cl_9} —$$
$$— \underset{d^3-d^4}{Cs_3Mo_2Cl_8} — \underset{d^4}{K_4Mo_2Cl_8}\ ,$$

has shown that, with increase of the number of 4*d* valence electrons of the Mo atom (d^m), not involved in bonds with the ligands, i.e. with decrease of the formal valence of the metal, the tendency towards M–M bond formation increases sharply: whereas in the Mo_2Cl_{10} (d^1) dimer direct M–M electronic interactions are completely absent, the Mo–Mo distances are 3.85 Å, and the chemical shift due to the involvement of the valence 4*d* electrons of the Mo atoms in the Mo–Mo bonds is zero, in the dinuclear $Mo_2Cl_8^{4-}$ (d^4) cluster there exists a quadrupole ($\sigma + 2\pi + \delta$) Mo–Mo bond, the Mo–Mo distances are 2.14 Å, and the chemical shift due to the involvement of the eight 4*d* electrons of both Mo atoms in the Mo–Mo interactions has proved to be the highest among those known.[123]

In addition, yet another important example clearly indicates the major role of the valence d^m electronic configuration of the metal atom in the formation of M–M bonds. In the series of compounds of the formally tervalent (d^3) molybdenum ($MoCl_3$, $Cs_3Mo_2Cl_9$, $K_3Mo_2Cl_9$), the ΔE differ markedly, which implies that the Mo atoms with the d^3 configuration form strong M–M bonds with increased multiplicity only under sterically favourable conditions and that the M–M distance is most likely to be the decisive factor in this instance. On the other hand, in the series of chlorides of formally bivalent (d^4) molybdenum the ΔE are almost identical despite the markedly different M–M distances and there is a sharp variation in sterochemistry from the dinuclear $Mo_2Cl_8^{4-}$ (D_{4h}) cluster to the hexanuclear $Mo_6Cl_8^{4-}$ (O_h) cluster; in this case the decisive factor is the effective number of electrons capable of forming direct M–M bonds.[4,123]

Thus the chemical shifts in the X-ray emission spectra of the cluster chlorides of heavy *d* elements reveal a delocalisation of the valence electrons of the M atoms in excess of that determined by the metal–ligand bonds, i.e. they do not correspond to the distance of M–Cl bonds alone in such compounds but can be accounted for by simultaneous M–M bond formation in the clusters. The ΔE constitute a direct conformation of the existence of effective M–M electronic interactions in the chlorides of heavy *d* elements.

4. X-Ray Electronic Spectra

The cluster chlorides, oxides, carbonyl, and carboxylates of certain heavy *d* elements have been investigated by X-ray electronic spectroscopy (ESCA),[126] which makes it possible to measure the energy distribution (orbital energies) of the valence electrons and also of the internal levels of the atoms in molecular complexes in crystals.

The X-ray electronic spectra of the valence region of the cluster compounds mentioned above[4,11,59–61,79,80,127–129] make it possible to determine the ionisation potentials (absolute energies) of the occupied MO, their electon populations, the contribution of the basis AO to the valence MO, and certain other characteristics of the electronic structure of the clusters. The parameters of these spectra refine and supplement the results of quantum-chemical calculations of the electronic structure of clusters. In particular, the photoelectron spectra (He-I–He-II) of trinuclear, tetranuclear, and hexanuclear carbonyl clusters confirm the calculated characteristics of the molecular orbitals of the M–M and M–CO bonds.[11,128] The photoelectron and X-ray electronic spectra of the dinuclear chloride and carboxylate d^4 complexes, M_2L_8, indicate directly the formation of the quadruple M–M bond.[59–61,127]

The parameters of the X-ray electronic spectra of the valence region of the chloride complexes indicate clearly the separation of the M–M MO from all the remaining MO and their position in the highest energy region: this is manifested particularly strikingly when the electronic structure of the same chloride cluster is described in terms of X-ray electronic and X-ray emission spectroscopic data.[129] In a concerted study of the electronic structure of the $Mo_2Cl_8^{4-}$ cluster[129] the energies of the internal Mo ($3d_{5/2}$) and Cl ($2p_{3/2}$) levels were measured in the X-ray electronic spectrum, while the energies of the L_{α_1}-Mo, L_{β_2}-Mo, K_{α_1}-Cl, and $K_{\beta_{1,3}}$-Cl X-ray lines were measured in the X-ray emission spectrum. Next the K_{α_1}-Cl and $K_{\beta_{1,3}}$-Cl spectra were superimposed on the valence ESCA spectrum on the same energy scale (Fig.9). It was then shown that the highest occupied MOs of the $Mo_2Cl_8^{4-}$ cluster do indeed represent the virtually pure 4*d* electronic states of the Mo atoms (multiple Mo–Mo bonds), while the energies of the MO involving the valence electrons of the ligands (Cl atoms) are much lower and reflect the existence of the M–L bonds and the $3p_\pi$ AO of the ligands.

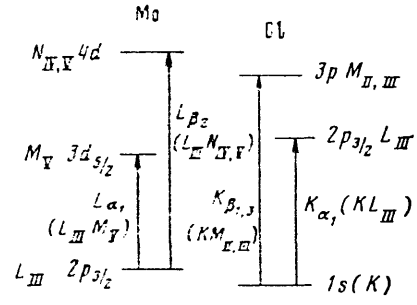

Figure 9. Schematic illustration of the method used in the superposition and the superimposed (with respect to energy) X-ray emission $K_{\beta_{1,3}}$.Cl (curve *1*), L_{β_2}.Mo (curve *3*) spectra and the X-ray electronic spectrum of the valence region of the $Mo_2Cl_8^{4-}$ cluster (curve 2).[129]

The X-ray electronic spectra of the valence region for cluster chlorides, oxides, and dimeric carboxylates with strong metal–metal bonds ($K_4Mo_2Cl_8$, $K_3Re_3Cl_{12}$, $K_3W_2Cl_9$, $Zn_2Mo_3O_8$, $Ba_3Ru_3O_9$, $Mo_2(O_2CCH_3)_4$, etc. differ appreciably from those for the corresponding mononuclear compounds of the same heavy *d* elements (K_3MoCl_6, K_2ReCl_6, K_2WCl_6, etc.). The formation of the cluster group (via the M–M bonds) in the structure of the chloride of a 4*d* or 5*d* element induces specific changes in the ESCA spectrum of such a cluster chloride (Fig.10). The formation of a cluster chloride with M–M bonds, whose electron density is concentrated in the "metallic nucleus" of the cluster, gives rise to significant changes in the interelectronic interaction in the polynuclear complex as a whole and "groups" the MO of this complex in terms of their energies in a specific manner.[4,59,60,79] It may be that the influence of the M–M bonds in the chloride cluster shortens the energy range within the limits of which the molecular orbitals of the M–L bonds, the pseudoatomic orbitals of the ligands, etc. are located compared with the greater possibilities for the energy distribution of the MO in a mononuclear complex. In this case it is understandable why the valence X-ray electronic spectra of the cluster chlorides consist of comparatively narrow bands grouped in terms of types of electronic interactions (M–M, M–L, AO–L, etc.).

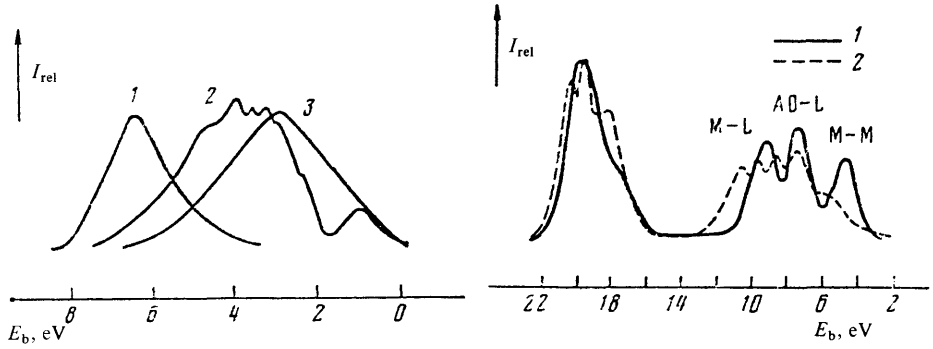

Figure 10. The X-ray electronic spectra of the valence regions in $K_3Re_3Cl_{12}$ (curve *1*) and K_2ReCl_6 (curve *2*).[6]

The experimental energies of the internal levels of the M atoms in the chlorides, dimeric carboxylates, and oxides of 4*d* elements (Mo, Ru) have led to the following finding (Fig. 11). In the series of mononuclear molybdenum chlorides these energies increase successively with increase of the formal valence of molybdenum on passing from the metal to the higher chlorides, which can be explained by the increase of the number of valence electrons of the Mo atom in the Mo–Cl bonds and the corresponding increase of the effective positive charge on the Mo atom. For the cluster molybdenum chlorides (particularly those with strong M–M bonds), the chemical shifts greatly exceed the corresponding values of ΔE(Mo) for mononuclear chlorides with the same formal valence of the metal; this effect is caused by the additional delocalisation (additional to that due to the M–Cl bonds) of the valence 4*d* electrons of the M atoms in the M–M bonds in the chloride clusters.[24] The effects of the chemical shift of the internal levels of the transition metal atoms in the X-ray electronic spectra as well as the chemical shifts in the X-ray emission spectra[122,123] indicate an increase of ΔE for the cluster chlorides compared with the mononuclear chlorides having the same formal valence of the M atoms.

The pattern of the chemical shifts of the $3d_{5/2}$ level for the M atoms is somehow more complex for mononuclear and cluster molybdenum and ruthenium oxides.[79,80] The cause lies in the special character of the metal–oxygen bonds, which apparently possess a donor–acceptor π-component (M⇇O or M⇇C⇉M), which promotes the "leakage" of the valence electronic charge to the M atoms, particularly on formation of clusters with M–M bonds, and also in the cooperative interactions in these crystals manifested by their electrical conductivity. However, here too the effects of cluster formation are fairly distinctive, although in a somewhat different form. Thus X-ray electronic studies of a series of formally heterovalent compounds of a heavy *d* element make it possible to observe the formation of clusters (particularly those with strong M–M bonds) and yield varied information about their electronic structure.

VII. THE NATURE OF THE M–M BONDS IN THE CHLORIDE CLUSTERS OF 4*d* AND 5*d* ELEMENTS

The X-ray spectroscopic chacteristics of the cluster chlorides of 4*d* and 5*d* elements provide a preliminary answer to the following question: what is the physical nature of the M–M bonds present in the chloride cluster? Do they resemble the bonds between the M atoms in the corresponding metals or do they represent a different type of interaction?

In any system of chlorides of the heavy *d* elements the appearance of valence *d* electrons of the M atoms in the M–M bonds (the formation of the cluster) and the further increase of their number immediately entail a deviation of the chemical shift of the X-ray *K* or *L* line of the metal (relative to the ΔE for the corresponding mononuclear chlorides without M–M bonds but with the same formal valence of the M atoms) in the direction of the highest chloride, where all the valence electrons of the M atoms are involved in the M–Cl bonds and where the maximum valence of the metal obtains. In other words, the formation of M–M bonds in a cluster chloride always shifts ΔE in the same direction as that which occurs with increase of the number of valence electrons of the M atom in covalent bonding to the ligands (M–Cl). The contributions to the overall chemical shifts of the *K* or *L* line of the metal in the X-ray spectrum of a cluster chloride due to the formation of M–Cl and M–M bonds always have the same sign.

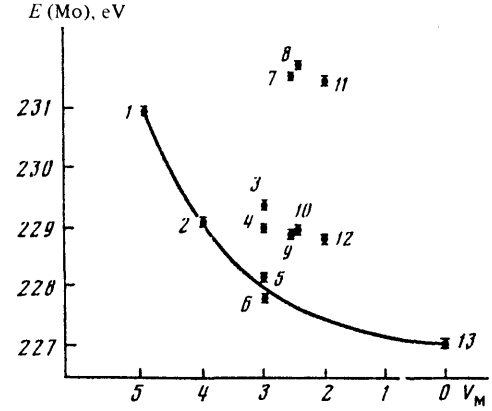

Figure 11. The energy of the $3d_{5/2}$ level in molybdenum atoms (E_b) in the X-ray electronic spectra of molybdenum chlorides as a function of the formal valence of molybdenum V_M.[4,124]

All this implies that the M–M bonds in the cluster chloride of a 4*d* or 5*d* element are formed in a manner similar to that of the M–Cl bonds. Precisely in this sense does the valence of the atoms of 4*d* or 5*d* elements in their cluster chlorides

greatly exceed (sometimes by a factor of 2–3) the formal value[3,30] determined by the involvement of a specific number of valence electrons of each M atom in the formation of M–Cl bonds alone.

Thus the M–M bonds in the cluster chlorides of heavy transition metals are close in their nature to the homoatomic covalent bonds. According to the results of molecular-orbital calculations,[4,11] the M–M bonds are localised (despite the fact that, with the exception of dinuclear clusters, they are many-centre bonds within the limits of the "island" cluster group) and different from the usual metallic bonds with their cooperative character.

If the M–M bonds in the chloride clusters resembled the usual metallic bonds in terms of the distribution of charge density of the valence electrons of the M atoms involved in them then measurement of the chemical shift relative to the lines due to the metal would have shown that the contribution to the overall chemical shift due to the formation of M–M bonds is zero. Consequently there would have been no deviations of ΔE (for cluster chlorides) from the linear relations observed for the mononuclear derivatives.

The latter is fully confirmed by the X-ray spectroscopic characteristics of zirconium chlorides.[124] The crystals of formally low-valence zirconium chlorides contain no clusters and have a chain or layer structure,[131] but the bonds between their M atoms are close to the usual metallic bonds in crystalline zirconium. Accordingly, the dependence of the chemical shift of the $L_{\alpha_{1/2}}$ line of zirconium on its formal valence and on the number of valence electrons of each zirconium atom not involved in bonds with the ligands is distinctly linear, which confirms the usual metallic nature of the M–M bonds with their cooperative character and the delocalisation of the valence electrons of the M atoms throughout the lattice of the non-cluster zirconium chlorides (ZrCl, $ZrCl_2$, or $ZrCl_3$; Fig. 7).

Thus the study of the chemical shifts of the emission *K* and *L* lines of heavy transition metals in the X-ray spectra of the mononuclear and cluster chlorides makes it possible to demonstrate the formation of M–M bonds in the clusters, to investigate the electronic structure of these bonds, and, what is most important, makes it possible to elucidate the nature of the M–M interaction in the cluster chlorides of 4*d* and 5*d* elements.

The cluster carbonyls, which frequently exist in the form of molecular crystals incorporating weakly interacting $M_n(CO)_m$ fragments, are apparently very closely related to the cluster chlorides, the main structural characteristic of which consists of the presence of a quasi-isolated "island" M_nX_n group. Cluster oxides constitute an example of crystal structures of a different nature—with a strong intercluster interaction and a high level of delocalisation of the valence electrons of the M atoms in the M–M bonds not only within the limits of the cluster but also between clusters in contact.

---o0o---

Quantum-chemical and spectroscopic studies of chloride, oxide, carboxylate, and carbonyl clusters of 4*d* and 5*d* elements have revealed the fundamental principles of their electronic structure and showed, in particular, that direct (without a decisive influence of the bridging ligands) and effective (with a high energy) M–M bonds exist in the clusters. The corresponding MO indicate a high degree of delocalisation of the valence electrons of the M atoms in the M–M bonds, in excess of that which can be account for by M–L bonds, and the valence of the M atoms in the clusters is therefore always much higher than its formal value.

One of the main distinctive features of the electronic structure of the clusters is the spatial distribution of the electron density of the M–M bonds. Experimental and theoretical results[3,132] have shown that the electron density of the M–M bonds is localised mainly at the "metallic nucleus" of the cluster (at its M_n group), although in the oxygen (especially), carboxylate, and partly carbonyl clusters the nature of the M–M bond is much more complex owing to the inter-relation of the M–M and M–L interactions and also the intercluster interaction and the "spreading" of the valence electrons of the M–M bonds throughout the crystal. The characteristics of the distribution of the valence electrons of the M–M bonds in clusters (particularly in the chloride clusters but also apparently in many respects also in clusters with other ligands) impart to them properties significantly different from those of mononuclear complexes and probably playing a primary role in the catalytic activity of many cluster compounds.[133–137] The high catalytic activity of cluster complexes (particularly of their stereochemically open forms) in the catalysis of the redox reactions of small molecules, including photochemical reactions with participation of clusters in electronically excited states,[136,137] has been recently explained using the LCAO–MO and vibronic theories.[137]

Estimation of the Stability of Clusters with the Aid of the Theory of the Electron Density Functional

Yu.A.Borisov

The likely usefulness of the application of simple versions of the theory of the electron density functional to the study of the energy characteristics of cluster compounds is discussed. Three types of cluster compounds are considered: clusters of elements as an intermediate form between a molecule and a solid, organometallic clusters, and organoelemental compounds of the *nido*-cluster type. The question of the variation of the bond energy in homoatomic clusters as a function of their size and steric structure is analysed.
The bibliography includes 104 references.

I. INTRODUCTION

The concept of the "cluster" has been widely used in recent years in various branches of chemistry. The constituent elements (atoms) of a chemical cluster are separated from one another by distances of the order of the chemical bond length and as a rule they form between one another the maximum possible number of bonds. The structural unit of the cluster is a regular or distorted polyhedron in which there are no classical two-centre chemical bonds characteristic of the usual molecules: the bonds in clusters have a many-centre character.

Since the beginning of 1970 metal clusters have been vigorously investigated by theoretical chemical methods (see the relevant reviews[1,2]). Qunatum-chemical study of these compounds within the framework of different versions of the non-empirical SCF LCAO-MO method presents significant difficulties, because the clusters contain a large number of electrons and non-empirical calculations for such systems are far beyond the scope of modern computer techniques. Semi-empirical methods (of the type of CNDO, INDO, MINDO, etc.), which have proved quite useful in organic chemistry, have proved fairly frequently to be inapplicable to transition metal clusters, because they lead to contradictory results.[3]

Quantum-statistical methods for calculations relating to complex compounds have been developing vigorously in recent years. The statistical method was initiated in the studies of Thomas, Fermi, and Dirac.[4] The Thoms-Fermi-Dirac (TFD) model has been widely used in a wide variety of fields such as nuclear, atomic, and solid state theories, astrophysics, etc.[5] The significant progress in the many-particle statistical theory has been associated with studies on the self-consistent theory of a non-uniform electron gas [the method of the electron density functional (MDF)]. The theorem that the determination of the energy of the ground state in the many-particle Schrödinger equation is equivalent to the determination of the minimum in the energy functional for a varying electron density has been proved.[6] By virtue of the theorems of the *V*- and *N*-representability of the electron density,[6-8] the method of the electron density functional has been theoretically justified.

The quantum-statistical many-particle theory has laid the foundations for a series of methods for the calculation of the electronic structure of molecules. These are in the first place different versions of the Slater-Johnson X_α method, in which a statistical exchange potential is introduced.[9] Furthermore, one should include here the discrete variation method,[10-12] which is a variety of the X_α method in terms of a basis set of atomic functions, and the local spin density (LSP) method.[13,14] The latter is a generalisation of the Hohenberg-Kohn-Sham theory[15] and differs from the Hartree-Fock scheme by taking into account all the many-particle effects at the level of the density functional. Apparently the above methods can be expected to be most successful in the solution of various problems of the theoretical chemistry of organometallic compounds, including cluster compounds. Fundamental advances which have already been made in the theory of complex and organometallic compounds are associated with the introduction of these methods in one or other variety.[9,10,16] Since exchange-correlation effects are taken into account in the LSP method, it is not surprising that the method makes it possible to calculate fairly accurately the atomisation energies of molecules[16,17] and solids.[18]

The aim of the present review is to attempt to demonstrate, in terms of simple versions of the method of the density functional, the scope of these approximations in relation to the study of the energy characteristics of cluster compounds.

In the theoretical investigation of atomic clusters, the elucidation of a number of fundamental problems is of interest. One of these is as follows: how big must the cluster be for its electronic structure to be sufficiently close to that of the corresponding crystal? For metals, this problem has been studied within the framework of various approximate quantum-chemical methods. However, it has been found that different methods yield different results. Thus in the X_α method in terms of the scattered wave approximation (X_αSW) the similarity of a cluster to a bulky metallic specimen has been observed already when the cluster contained between 10 and 20 atoms. On the other hand, calculations based on the LCAO-MO method in terms of various approximations (EHM, CNDO, etc.) lead to the conclusion that for such small clusters the details of the electronic structure have nothing in common with metals. Thus there is as yet no unambiguous answer to the first question and the solution of the relevant problem requires both more accurate calculations, for example, within the framework of the LSP method, and experimental studies of the electronic structures of small clusters.

The second fairly important question is to what extent the bond energy in clusters varies with their size and steric structure. This question is closely related to the thermodynamic stability of clusters and their "phase" transformations for different degrees of dispersion. The knowledge of such

relations will make it possible to regulate the degree of dispersion of the given substances as a function of external conditions, which is important in various branches of chemistry. Within the framework of the one-electron method it is not possible to obtain an answer to this question because calculations of the bond energies require allowance for the correlation energy; this is extremely difficult because of the need to employ complex many-determinant wave functions, requiring an extremely long computer time for their evaluation. However, within the framework of the theory of the density functional, it is possible to answer the second question, which is discussed below in relation to carbon, sulphur, phosphorus, arsenic, and alkali metal clusters.

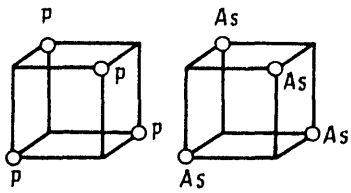

Figure 1. Tetrahedral phosphorus and arsenic clusters.

Atomic clusters can be obtained in molecular beams and also in the form of aggregates in inert matrices.[19] Fig. 1 presents phosphorus and arsenic clusters which can be detected in the gas phase at low temperatures. They have a regular tetrahedral structure. Among non-transition metals, the most unique in the sense of its capacity to produce cluster compounds is boron. Together with polyhedral clusters consisting of boron and hydrogen atoms, there exist boron clusters with beryllium, arsenic, antimony, and transition metals.

Metal clusters are obtained either in molecular beams (before the ionisation chamber of the mass spectrometer) or by condensation from the gas phase on inert supports. The latter method is most promising for the study of the properties of clusters, including their reactivity.

Metal clusters, stabilised on oxide supports, have been vigorously investigated by workers in the field of the surfaces of solids, topochemistry, and catalysis.

Atomic clusters can exist not only in the form of stable formations on the surface of a carrier but they can also be stabilised by various ligands. The simplest of these are solvates, where metallic clusters are stabilised by a ligand environment made up of solvent molecules.

The second large class of cluster compounds consists of organometallic polynuclear complexes having a central metallic nucleus with a distinct cluster structure. A modern review of the problem of the metallic bond in cluster compoounds of this kind has been published recently by Cotton and Chisholm.[20] Fig. 2 presents some examples of characteristic polynuclear cluster compounds of transition metals. According to Cotton and Chisholm,[20] transition metals can be arranged in the following sequence in terms of their ability to form metal–metal bonds in cluster compounds: Mo > Rh > Cr, Re > Tc, Ru, W, Ta, Nb > Fe, Co, Ni, Pd, Os, Ir, Pt.

One of the ways of classifying transition metal cluster compounds is on the basis of the formal oxidation state of the metal. The metal in halides and sulphides is in a high oxidation state, for example, the oxidation state of the metal is +3 in $Re_3Cl_{12}^{3-}$ and $Fe_6S_8(PR_3)_6^{2+}$, +2 in $Mo_6Cl_{14}^{2-}$, etc. There exist various cluster compounds in which the oxidation state of the metal is +1: $(\eta^5\text{-}C_5H_5)_6Ni_6\{HRh[P(OCH_3)_3]_2\}_3$, $[CH_3Rh\text{-}(cyclo\text{-}octa\text{-}1,5\text{-}diene)]_2$, and $H_6Cu_6(PR_3)_6$. A formal oxidation state of zero is observed in a large class of polynuclear metal carbonyls. Simple qualitative theories of the bond in polyhedral boranes[21] are used in calculations for certain classes of polynuclear transition metal clusters.[22] However, these theories are useful only for a formal systematic treatment of clusters and cannot be used to predict any other properties. Such studies can be regarded as a stimulus

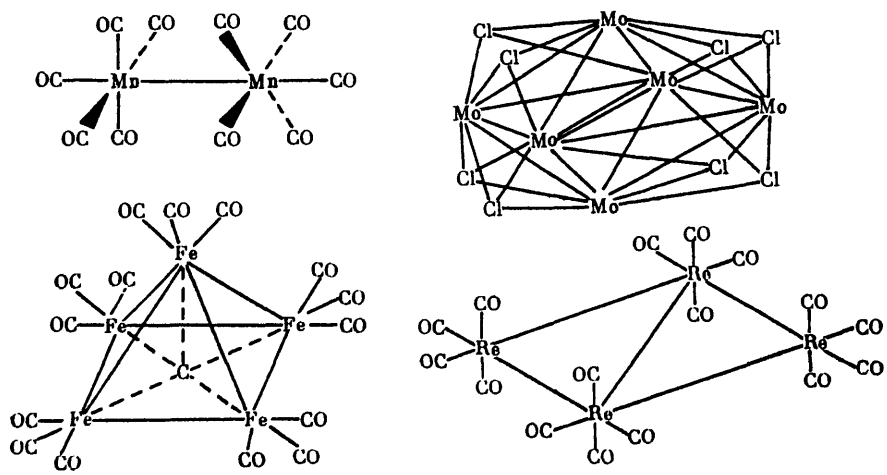

Figure 2. The most characteristic polynuclear cluster compounds.[29]

towards a more vigorous theoretical and experimental investigation of transition metal clusters in order to create a theory of this complex and interesting class of chemical compounds.

Among the simple rules obeyed by organometallic compounds, we may mention the 18-electron rule, i.e. the rule that clusters with a completely filled outer electron shell have the maximum stability.[23]

Although there are quite a few exceptions to this rule, it is useful in explaining the geometrical structural characteristics of complex organometallic compounds. This applies particularly to transition metal clusters, where simple considerations concerning hybridisation[24] or electron pair repulsion[25] are almost useless.

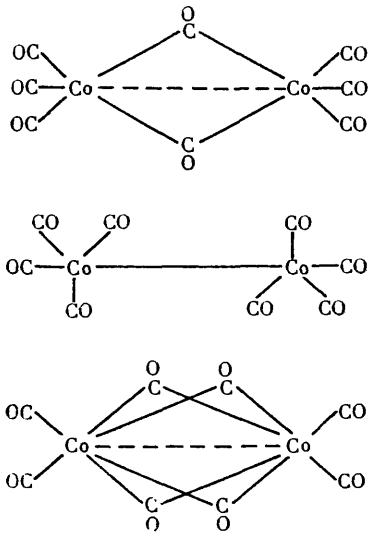

Figure 3. The structures of the dinuclear cobalt carbonyl.[26]

Many unusual structural features of metal carbonyls can be accounted for by a tendency towards the formation of an 18-electron shell. The structure of the polynuclear cobalt carbonyl $Co_2(CO)_8$ (Fig. 3*a*) can be explained from the standpoint of the formation of an 18-electron outer shell configuration. The bridging carbonyl groups form many-centre bonds and formal treatment shows that they each give up one electron to the electron shell of each cobalt atom. The diamagnetism of $Co_2(CO)_8$ indicates the formation of a Co–Co bond. Indeed the Co–Co distance is only 2.5 Å according to X-ray diffraction data.[26] It is of interest to note that in solution a second structure of the above compound (Fig. 3*b*), in which there are no bridging CO groups, coexists with that examined above;[26] this structure also satisfies the 18-electron rule. The hypothetical structure of $Co_2(CO)_8$ illustrated in Fig. 3*c* does not satisfy the 18-electron rule and, as will be shown below, is extremely unstable according to calculations by the method of the electron density functional.

Together with the 18-electron rule, analogies between the structures of cluster organometallic compounds and organopolyhedral molecules have been used in recent years. Hoffmann's principle of isolobality and the skeletal electron counting rules follow from these analogies. Since a careful review has been devoted to these questions,[27] we shall not consider them. The third type of cluster compounds (in our terminology) comprises non-classical organoelemental compounds of the type of polyhedra and *nido*-clusters. A wide variety of non-classical structures having the form of polyhedra (prismane, cubane, congressane) have been observed together with classical structures for molecules made up of carbon and hydrogen atoms only. In 1973 Bochvar and Gal'pern showed with the aid of semiempirical quantum-chemical calculations[28] that even more complex polyhedral carbon clusters can exist: a C_{20} carbododecahedron made up of 12 pentagons and a C_{60} carbo-s-eicosahedron, whose surface is made up of pentagons and hexagons alternating in an unusual manner. In these structures the carbon atoms can be linked by double bonds. Such cluster formations should be regarded as new allotropic modifications of carbon which, in contrast to the familiar graphite, diamond, and carbyne, are monomeric. Complex polyhedra made up solely of carbon and hydrogen atoms or only carbon atoms have not so far been obtained.

Extensive prospects arose in the field of the structural chemistry of polyhedral compounds after the synthesis of carbaboranes whose skeleton is made up of carbon and boron atoms. Table 1[29,30] presents typical boron clusters. A multiplicity of organometallic transition metal complexes based on carbaborane as the ligand have been obtained.[31]

Notation: N_a is the number of atoms in the cluster and N_e the number of skeletal electrons.

Although non-empirical calculations on clusters by the SCF LCAO-MO method are being carried out at the present time,[2] this method for the theoretical study of clusters can hardly be regarded as promising, one reason being that calculations for the cluster compounds of greatest interest from the chemical standpoint are far beyond the limits of the scope of this method.

In the calculation of the stability of the clusters, one must begin with methods in which the electronic correlation energy is taken into account sufficiently completely.[32] Within the framework of the usual non-empirical quantum-chemical methods, this is extremely difficult to achieve because even the calculation for diatomic and triatomic molecules by the configuration interaction method is extremely laborious. In this sense, it appears useful to investigate clusters within the framework of the theory of the electron density functional, which has been employed successfully for the solution of

certain physical problems.[6,14,15,33-40] This theory consists of a quantum-statistical examination of an electron liquid in which atomic nuclei "float". The energy of the ground state of a system consisting of N electrons and M nuclei with the charges z_1, z_2, ..., z_M is represented by the following electron density $\rho(\mathbf{r})$ functional:[6]

$$E[\rho] = -\sum_{\alpha=1}^{M} z_\alpha \int \rho(\mathbf{r}) |\mathbf{r} - \mathbf{R}_\alpha|^{-1} d\tau + \\ + \frac{1}{2}\iint \rho(\mathbf{r}_1)\rho(\mathbf{r}_2)|\mathbf{r}_1 - \mathbf{r}_2|^{-1} d\tau_1 d\tau_2 + \sum_{\alpha<\beta}^{M}\sum^{M} z_\alpha z_\beta |\mathbf{R}_\alpha - \mathbf{R}_\beta|^{-1} + G[\rho], \quad (1)$$

where $\mathbf{r}_i$ is the vector corresponding to the position of the ith electron, $\mathbf{R}_\alpha$ are vectors corresponding to the positions of the atomic nuclei in a three-dimensional cartesian space, and $d\tau_i = dx_i dy_i dz_i$. The functional $G[\rho]$ has not as yet been obtained in an explicit form. However, formally its form is as follows:

$$G[\rho] = \langle \Psi | \hat{T} + \hat{W} | \Psi \rangle - \frac{1}{2}\iint \rho(\mathbf{r}_1)\rho(\mathbf{r}_2)|\mathbf{r}_1 - \mathbf{r}_2|^{-1} d\tau_1 d\tau_2, \quad (2)$$

where $\hat{T}$ is the kinetic energy operator, $\hat{W}$ the interelectron interaction operator, and Ψ a many-electron wave function. The functional $G[\rho]$ includes the kinetic energy $G_t[\rho]$ and the exchange-correlation energy $G_v[\rho]$:

$$G[\rho] = G_t[\rho] + G_v[\rho]. \quad (3)$$

Approximate expressions containing several terms depending on derivatives of the electron density with respect to the coordinates x, y, and z have been found for $G_t[\rho]$ and $G_v[\rho]$ and the individual contributions have been estimated in relation to examples.[38-46] Analysis shows that exchange-correlation energy contributions close to the true values can be obtained for the potential energy with the aid of these expressions. In the case of the kinetic energy, it has been shown that the energy contributions do not decrease sufficiently rapidly as a function of the number of the term of the gradient expansion series, so that the principal inaccuracy of the method of the electron density functional is associated with the approximate form of the kinetic energy.[46] For sufficiently covalent systems, a method for the determination of the kinetic energy from the virial theorem (the virial-statistic approximation) has been recommended.[47-53]

We shall consider the question: what are the advantages of the method of the electron density functional compared with the LCAO-MO method? Firstly, the existence of a direct functional relation between the energy of the system and the electron density makes it possible to construct new and simple models of the chemical bond, which has been demonstrated in a number of studies.[47-53] Secondly, in the theory of the density functional the $3N$-variable problem, where N is the number of electrons, is replaced by a three-variable problem. This is because the exchange-correlation energy is formulated in the form of the electron density functional for the system. The development of the density functional theory has become even more crucial in recent years in connection with the development of methods for the experimental determination of the electron densities of substances.[54] Studies on the calculation of various energy characteristics of crystals from the experimental electron densities or even X-ray reflections are already being carried out.[55,56] The theory of the electron density functional is widely used in the calculations.

In view of the lack of an exact expression for the dependence of the kinetic energy functional on the electron density $G_t[\rho]$, a complete set of methods of the X_α type has been developed in the density functional theory.[9,57-61] In these methods the functional $G_t[\rho]$ is formulated as its quantum-mechanical analogue, so that the kinetic energy of the system is

$$T = \frac{1}{2}\sum_i \int \nabla\varphi_i^* \nabla\varphi_i d\tau, \quad (4)$$

where φ_i are one-particle functions and the summation is carried out over all the occupied spin-orbitals. For spin-polarised systems, the total energy can be formulated in this instance as follows:

$$E[\varphi_{i\alpha}, \varphi_{i\beta}] = -\sum_{\alpha=1}^{M} z_\alpha \int \rho(\mathbf{r})|\mathbf{r} - \mathbf{R}_\alpha|^{-1} d\tau + \\ + \frac{1}{2}\iint \rho(\mathbf{r}_1)\rho(\mathbf{r}_2)|\mathbf{r}_1 - \mathbf{r}_2|^{-1} d\tau_1 d\tau_2 + \sum_{\alpha<\beta}^{M}\sum^{M} z_\alpha z_\beta |\mathbf{R}_\alpha - \\ - \mathbf{R}_\beta|^{-1} + \frac{1}{2}\sum_i^{k_\alpha} \int \nabla\varphi_{i\alpha}^* \nabla\varphi_{i\alpha} d\tau + \frac{1}{2}\sum_i^{k_\beta} \int \nabla\varphi_{i\beta}^* \nabla\varphi_{i\beta} d\tau + G_v[\rho_\alpha, \rho_\beta], \quad (5)$$

where ρ_α and ρ_β are the electron densities due to electrons with the spins α and β respectively and

$$\rho_\sigma = \sum_i^{k_\sigma} \varphi_{i\sigma}^* \varphi_{i\sigma}, \quad (6)$$

Where $\varphi_{i\sigma}$ is the spin-orbital wave function for the spin σ and k_σ the number of occupied orbitals for the spin σ. By varying the energy with respect to $\phi_{i\sigma}$, we obtain an equation of the Hartree–Fock type taking into account the exchange-correlation energy determined by the functional $G_v[\rho_\alpha, \rho_\beta]$:

$$\left[-\frac{1}{2}\Delta - \sum_\alpha z_\alpha |\mathbf{r} - \mathbf{R}_\alpha|^{-1} + \int \rho(\mathbf{r}')|\mathbf{r} - \mathbf{r}'|^{-1} d\tau' + \right. \\ \left. + \frac{\delta G[\rho_\alpha, \rho_\beta]}{\delta \rho_\sigma}\right] \varphi_{k\sigma} = \varepsilon_{k\sigma}\varphi_{k\sigma}. \quad (7)$$

The expression for the exchange-correlation potential

$$V_{ex,c}[\rho_\alpha, \rho_\beta] = \frac{\delta G[\rho_\alpha, \rho_\beta]}{\delta \rho_\sigma} \quad (8)$$

has a different form in different versions of this method. For example, the following expression is used in the X_α approximation:

$$V_{X_\alpha} = \frac{9\alpha}{2}\left[\frac{3}{4\pi}\rho(\mathbf{r})\right]^{1/3}. \quad (9)$$

The advantages and disadvantages of the potential defined by Eqn. (9) in the X_αSW method, applied to calculations on clusters, chemisorption, and catalysis, have been frequently discussed in the literature.[57-59] Although the known successes of the X_αSW method in calculations on the clusters give rise to some hope, the difficulties due to the arbitrary selection of the atomic sphere radii as well as those in the interpretation of the results engender some scepticism.[62] Other versions of methods of the X_α type, which are the discrete variation method[10-12] and the LSP method,[13,14,16] are free from the disadvantages of the X_αSW method. An appreciable advantage of these procedures is the possibility of using any system of basis functions, including atomic functions, which brings these methods closer to the SCF LCAO-MO procedure.

Certain examples of the employment of simple versions of the theory of the electron density functional for the calculation of the energy characteristics of clusters are presented below and the question of the variation of the bond energy in homoatomic clusters as a function of their size and steric structure is examined.

II. THE ELECTRONIC STRUCTURE AND ENERGY CHARACTERISTICS OF ATOMIC CLUSTERS

In their review Kuz'minskii and Bagatur'yants[2] give a good selection of theoretical studies on the calculation of the electronic structures of metal clusters (mainly the semiempirical EHM, CNDO, etc. methods). The following groups have been examined:

(a) alkali metals (Li_2, Li_3, Li_4, Li_5, Li_6, Li_7, Li_8, Li_9, Li_{10}, Li_{13}, Na_2, Na_3, Na_4, Na_8, K_2, K_3);

(b) alkaline earth metals (Be_2, Be_4, Mg_2, Ca_2, Sr_2, Ba_2);

(c) aluminium group metals (Al_2, Al_5, Al_9, Al_{13}, Al_{19}, Al_{25}, Al_{43}, Al_{59}, Ga_2, In_2, Tl_2);

(d) heavy elements (Sn_2, Pb_2, Bi_2);

(e) noble metals and Group IIB metals (Cu_2, Cu_3, Cu_4, Cu_5, Cu_6, Cu_8, Cu_9, Cu_{10}, Cu_{13}, Cu_{16}, Cu_{19}, Cu_{31}, Cu_{39}, Cu_{43}, Ag_2, Ag_6, Ag_7, Ag_8, Ag_{10}, Ag_{13}, Ag_{19}, Ag_{43}, Ag_{55}, Au_2, Au_6^{2+}, Au_9^{3+}, Au_{11}^{3+}, Zn_2, Cd_2, Cd_{28});

(f) transition metals (Ti_2, Ti_3, Ti_4, Ti_5, Ti_6, V_2, Cr_2, Cr_3, Cr_4, Cr_5, Cr_6, Mn_2, Mn_{13}, Fe_2, Fe_3, Fe_4, Fe_5, Fe_6, Fe_9, Fe_{15}, Co_2, Ni_2, Ni_3, Ni_4, Ni_5, Ni_6, Ni_9, Ni_{13}, Ni_{14}, Pd_2, Pd_{12}, Pd_{19}, W_9, Pt_{13}).

Together with the homoatomic clusters, the above review[2] also quotes the results of calculations (mainly by semiempirical methods) on bimetallic heteroatomic clusters and clusters on a support.

A simple non-empirical version of the theory of the density functional, namely the virial-statistical approximation, has been used[63] to investigate the clusters. In this approximation the kinetic energy is determined from the relation between the virial theorem for the equilibrium interatomic distances in the cluster:

$$T[\rho] = -\frac{1}{2}V[\rho]. \qquad (10)$$

The total energy is then defined by the following formula:

$$E[\rho] = \frac{1}{2}V[\rho]. \qquad (11)$$

The sum of the atomic densities

$$\rho(\mathbf{r}) = \sum_{\alpha}\rho_{\alpha}(\mathbf{r}), \qquad (12)$$

where $\rho_\alpha(\mathbf{r})$ are the Hartree–Fock electron densities of the corresponding atoms α in a free state, was selected in this instance as the approximation for electron density for homoatomic systems. In the simple statistical theory (the TFD equation), Eqn.(12) for the electron density in a homoatomic molecule is fairly rigorous, which has been noted in the studies of Firsov[64] and (later) Slater.[65] Slater notes that the practical experience gained in X_α calculations has shown that Eqn.(12) for the density of the homoatomic molecules is a fairly satisfactory approximation. Analysis of non-empirical calculations[66,67] has also shown that the formation of homoatomic molecules from atoms does not entail a significant redistribution of electron density (the H_2 molecule is an exception).

The bond energies in homonuclear diatomic molecules made up of the atoms of non-transition elements ranging from Li_2 to Bi_2, calculated in terms of the virial-statistical approximation, are compared in Fig. 4 with the experimental values.[68] The atomic electron densities for the ground state in terms of a one-exponential basis set of the Slater type were used in the calculation. In the evaluation of the bond energy no adjustable parameters were employed and account was taken of all the electron shells of the atoms, both valence and skeletal. The distances between the atoms in the diatomic molecules were assumed to be equal to the experimental values.[68] In those cases where the experimental interatomic distances are not available, they were estimated from the formula

$$R(\text{Å}) = 0.3500 + 1.6072\, r_M, \qquad (13)$$

where r_M are the atomic radii of the elements.[69,70]

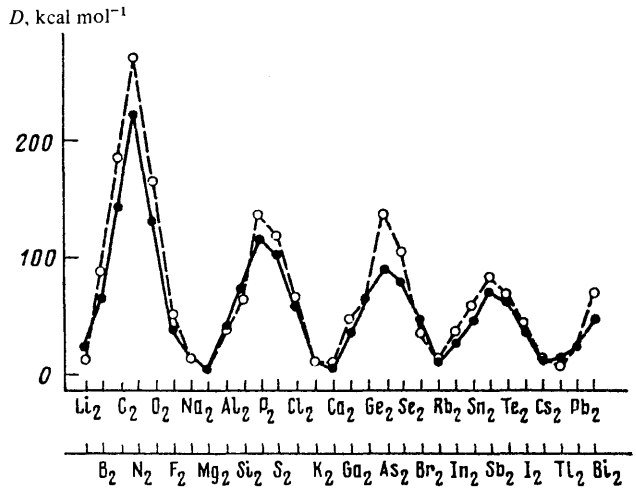

Figure 4. Comparison of the experimental (continuous line) and calculated (dashed line) bond energies in diatomic homonuclear molecules of non-transition elements.[63]

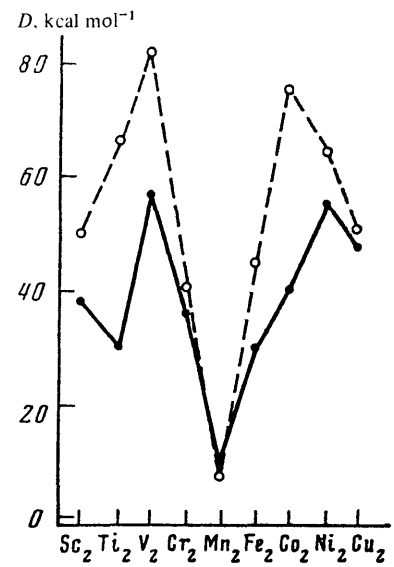

Figure 5. Comparison of the experimental (continuous line) and calculated (dashed line) bond energies in diatomic homonuclear molecules of the elements in the Fourth Period in Mendeleev's Table.[71]

A distinct qualitative agreement between the results of the calculations and the experimental data is observed. It is noteworthy that the non-empirical SCF LCAO-MO method,

which takes into account the electron correlation energy to only an insignificant extent, does not yield even a qualitatively correct picture of the changes in bond energy. In particular, for the fluorine molecule the SCF LCAO-MO calculation does not produce even a positive bond energy. The analogous relations for diatomic gas-phase molecules of the transition metals in the Fourth Period are presented in Fig. 5.[71]

The method described above has been used[63] to calculate the bond energies in the gas-phase sulphur molecules polymerised to different extents. Clusters having the compositions S_4, S_5, S_6, S_7, S_8, S_9, S_{10}, S_{11}, and S_{18} were examined. The geometrical parameters used in the calculations were taken from a theoretical calculation by the method of molecular dynamics.[72] This choice of molecular geometry is dictated by the fact that the experimental studies of S_N structures have been carried out only for a small class of compounds and their results are frequently contradictory. The calculated bond energies, evaluated per sulphur atom, for different molecules and the available experimental data are compared in Table 2. The calculations showed that the S_8 cluster in the form of a ring has the most stable configuration. It is known that orthorhombic crystalline sulphur, in which layers of cyclic S_8 molecules are stacked,[73] is thermodynamically stable. Table 2 also yields the results of calculations on diatomic molecules and tetrahedral clusters of phosphorus and arsenic (Fig. 1);[63] the calculated bond energies per atom have been compared with experimental values.[68] In agreement with the experiment, the calculation shows that the tetrahedral P_4 and As_4 clusters are more stable at low temperatures than the diatomic molecules.

Table 2. Comparison of the calculated and experimental bond energies D of sulphur, phosphorus, and arsenic molecules*.

System	D_{theor}/N, kcal mol^{-1}	D_{exp}/N, kcal mol^{-1}	System	D_{theor}/N, kcal mol^{-1}	D_{exp}/N, kcal mol^{-1}

S_9	71.8	—	As_4	73.7	63.3

*Here and henceforth D/N is the bond energy calculated per atom.

Two allotropic forms of carbon, namely graphite and diamond, for which there also exist submodifications involving a change in long-range order, were known previously. In 1978 Korshak et al.[74] discovered carbyne—the third form of carbon, consisting of filamental polymers made up of carbon atoms only. A series of quantum-chemical studies of the character of the bond in carbyne (see, for example, Stankevich and Tomilin[75]) have been carried out. It has been shown that the bonds in carbyne can alternate. Calculations have been made[63] for clusters of three allotropic forms of a carbon—graphite, diamond, and α-carbyne. Fig. 6 presents the calculated dependence of the bond energy per carbon atom on the size of the carbon cluster. The horizontal lines indicate the corresponding bond energy for crystals obtained in terms of the same approximations as those employed in the calculations on the clusters.[76] It is seen from Fig. 6 that the calculated stability series for the three allotropic forms of the carbon crystal agrees qualitatively with experiment: graphite > diamond > carbyne. When carbon clusters containing less than 20 atoms are examined, the stability series is different than for crystals: carbyne > graphite > diamond. When the number of atoms in the cluster is more than 20, a change in the above sequence takes place—curves *1* and *3* intersect (graphite > carbyne > diamond). It is seen from these calculations that, depending on the size of the clusters, the energy relations between different modifications vary. Analysis of the curves for the C_N clusters with $N \leq 50$ and data for crystals gives rise to the hypothesis that, for certain finite dimensions of the clusters, curves *2* and *3*, corresponding to diamond and carbyne, should intersect. On this basis, one may conclude that the carbyne molecule is thermodynamically stable only for a finite chain length. On further increase of its size, it should be converted into a more stable form, for example into a structure with cross-links between the polymer chains.

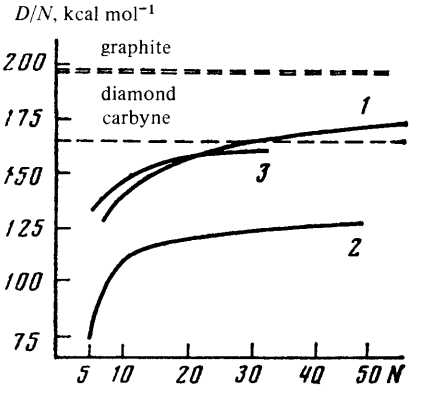

Figure 6. Dependence of the bond energies calculated per atom on the size of carbon clusters: 1) graphite; 2) diamond; 3) carbyne.[63]

Certain hypothetical carbon systems, which are formed as a result of the appearance of regular cross-links between the carbon chain macromolecules, having fourfold screw symmetry axes have been proposed.[77] In one of the hypothetical structures (I) each chain is surrounded by four chains of the same chirality ($I4_132$ symmetry group, identical lengths of all the bonds), while in another structure (II) each chain is surrounded by four chains of opposite chirality ($I\bar{4}m2$ symmetry group, the geometry is described in terms of two parameters: the bond length r_1 between neighbouring atoms in different chains and the bond length r_2 between neighbouring atoms in the same chain with $r_1 < r_2$).

Calculations have been made[78] of the bond energies for six crystalline modifications of carbon: graphite, diamond, α-carbyne, β-carbyne, and the two hypothetical systems (I) and (II). The results of these calculations are presented in Table 3. Evidently the hypothetical modification (I) is much more stable than the carbyne structures (α and β).

The different types of behaviour of the bond energy in carbon clusters as a function of their size for different allotropic forms are caused primarily by the different degrees of unsaturation of the bonds in the clusters. Diamond is a

three-dimensional crystal, graphite is close to a two-dimensional crystal, while carbyne is close to a one-dimensional crystal.

Table 3. The relative energies ΔE of various forms of carbon.[78]

Modification	ΔE, kcal mol^{-1}	Modification	ΔE, kcal mol^{-1}
Graphite	0.0	(II)	32.5
Diamond	1.5	β-Carbyne	33.0
(I)	7.4	α-Carbyne	32.8

The main conclusion which can be reached on the basis of the calculations for the carbon clusters is as follows: the energies of the "phase" transformations of the carbon clusters depend significantly on their dimensions, varying not only in absolute magnitude but also in sign. The question arises of the size of the cluster up to which one can speak of changes in its state of aggregation or a phase transition. Computer experiments performed for systems with a Lennard-Jones interaction potential have shown that phase transitions are observed for clusters consisting of ten particles.[79]

The dependence of the bond energy on the size of the cluster has been studied in greatest detail for alkali metals, particularly lithium. A scheme describing the growth of the lithium crystal has been proposed[80] on the basis of non-empirical calculations. It is noteworthy that the bond energies calculated in the above study[80] per atom for structures most favoured by energy factors increase monotonically for small dimensions of the clusters ($N \leq 5$) and then remain approximately constant at 9–12 kcal mol^{-1} (as N varies from 5 to 13).

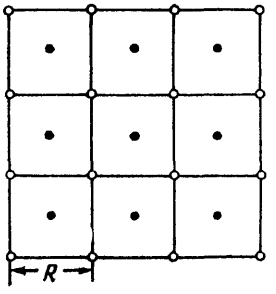

Figure 7. The geometrical structure of lithium clusters.[81]

Within the framework of the method of the gradient expansion of the energy, a study has been made[81] of the variation of the equilibrium distances and bond energies per atom for clusters of the type Li_N with N varying from 9 to 100. These are apparently the largest clusters for which theoretical calculations have been made (disregarding clusters in systems with a simple interaction potential of the Lennard-Jones type). It is noteworthy that, in contrast to the study of Fantucci and Balzarini,[80] Borisov[81] carried out a calculation for a fixed spatial symmetry of the clusters. Fig. 7 illustrates the geometrical structure of lithium clusters for the body-centred cubic lattice used in Borisov's calculations on clusters.[81] The cluster is made up of two types of layers: a layer of type L_1, designated by filled circles and containing 9 lithium atoms, and a layer of type L_2, designated by open circles and containing 16 lithium atoms. The distance between the layers is $R/2$, where R corresponds to the closest Li–Li distance within the limits of one layer. For example, the Li_{50} cluster consits of four layers: $L_1L_2L_1L_2$.

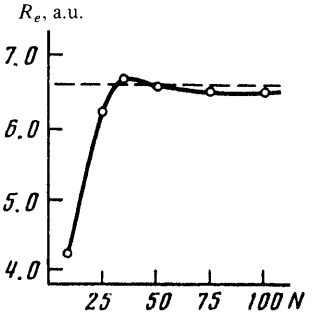

Figure 8. Dependence of the equilibrium Li–Li distance in the Li_N clusters on N.[81]

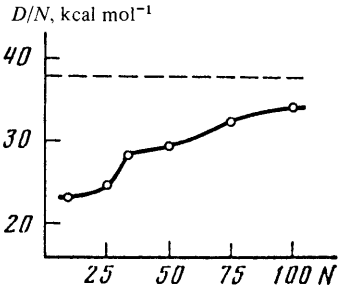

Figure 9. Dependence of the bond energy calculated per atom on the size of the lithium clusters.[81]

The energy of the Li_N clusters was optimised for each cluster with respect to the distance R. Fig. 8 illustrates the calculated dependence of the equilibrium distance R_e (in a.u.) in the Li_N clusters on N for a body-centred cubic structure. The dashed line corresponds to the experimental equilibrium distance R_e for a lithium crystal with a body-centred cubic lattice. Fig. 8 shows that, for low values of N, a marked dependence of R_e on the size of the clusters is observed. For clusters containing 34 lithium atoms, there is virtually no dependence of R_e on N. Fig. 9 presents the dependence of the bond energy per atom on the size of the Li_N clusters. The curve illustrated has a lower slope than the $R_e(N)$ curve and approaches fairly closely the corresponding experimental value for the crystal listed in Table 4.[76] The calculated bond energies have been compared with the available experimental

values.[68] Calculations for the Li_{50} clusters[81] in the body- and face-centred structures have shown that the latter structure is more favourable as regards energy, the difference between the energies amounting to 1.8 kcal mol^{-1}. For comparison, one may note that the corresponding difference for crystals is 0.3 kcal mol^{-1} (Table 4)[76] and the experimental difference is 0.49 kcal mol^{-1}.[82] Consequently the energy of the fcc → bcc "phase" transformation in the lithium clusters decreases with increase in the size of the cluster but does not change sign (in contrast to the transformations in the graphite–diamond–carbyne carbon system).

Table 4. The results of calculations for alkali metal crystals.[76]

Metal	Structure	$-E_{theor}$, a.u.	D_{theor}, kcal mol^{-1}	D_{exp}, kcal mol^{-1}
Li	hex.	7.4120	47.9	—
Li	BCC	7.4114	47.5	37.7
Li	FCC	7.4119	47.8	—
Na	BCC	158.4455	30.4	25.8
Na	FCC	158.4460	30.7	—
K	BCC	581.8500	31.3	21.5
Rb	BCC	2839.9763	22.6	19.6

Notation: E is the total energy of the crystal, hex. a hexagonal lattice, BCC a body-centred cubic lattice, and FCC a face-centred cubic lattice.

III. STABILITY OF ORGANOELEMENTAL CLUSTERS

So far few studies have been published on the calculation of the electronic properties of organometallic polynuclear clusters. Only calculations for individual cluster compounds can be encountered in the literature. The most general question for organometallic clusters is that of the character of the metal–metal bond, which has been discussed in a series of reviews (see, for example, Cotton and Chisholm.[20] The fact that the shortest distances are observed in complexes with bridging ligands has attracted attention in the analysis of the interatomic metal–metal distances in homopolymetallic π-complexes.[83] However, certain calculations have shown that the metal–metal bond is absent precisely in compounds of this type and the cluster is stabilised by interactions via bridges. Thus non-empirical calculations have been performed[84] for two cluster complexes: $Fe_3(CO)_{12}$ and $[C_5H_5Fe(CO)_2]_2$. Fig. 10 illustrates schematically the structures of these clusters. In the $Fe_3(CO)_{12}$ complex (Fig. 10a) and Fe(1) and Fe(2) atoms are joined via two bridging CO groups. Analysis of the occupied molecular orbitals (MO) has shown that there are no MO in which there is a linkage between the d orbitals of the Fe atoms. An analogous picture has been observed for the $[C_5H_5Fe(CO)_2]_2$ complex illustrated in Fig. 10b. Thus, despite the short M–M interatomic distances, there is no direct interaction between the metal atoms in the complexes indicated.

Calculations for the dinuclear nickel complex $(\eta^5\text{-}C_5H_5Ni)_2 . C_2H_2$ have confirmed the existence of a single σ-bond between the nickel atoms. Calculations for the $M_2Cl_4(PR_3)_4$ (M = Mo or W) complexes by the X_αSW method have been carried out in a recent study[86] (Fig. 11). They showed that the M–M bond in these complexes is quadruple and that the bonding molecular orbitals are of the σ, π, and δ types. The calculated[86] electronic transition energies have been fully confirmed by experiment (photoelectron spectroscopy). Thus the multiplicities of the M–M bonds in transition metal cluster compounds can vary from zero to four.

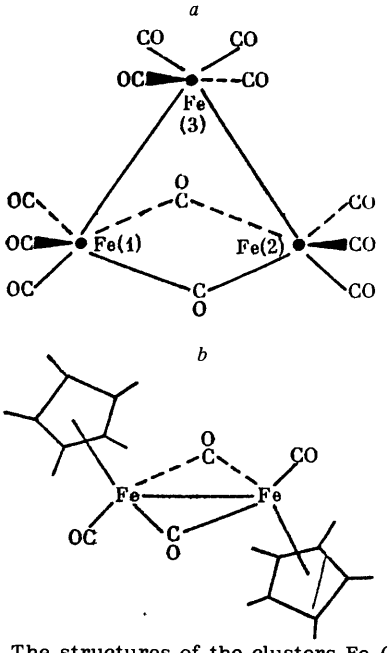

Figure 10. The structures of the clusters $Fe_3(CO)_{12}$ (*a*), $[C_5H_5Fe(CO)_2]_2$ (*b*).[84]

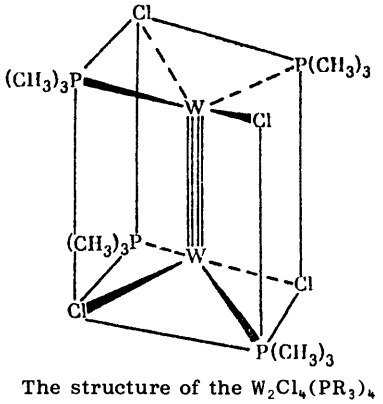

Figure 11. The structure of the $W_2Cl_4(PR_3)_4$ cluster.[86]

The study of the $Co_2(CO)_9$ cluster by various physical methods (infrared spectroscopy and X-ray diffraction)[26] showed that the compound has different structures under different conditions. According to the results of X-ray diffraction analysis,[26] the $Co_2(CO)_8$ solid phase has a structure with two C = O bridge bonds (Fig. 3*a*). In solution form (II) (Fig. 3*b*) coexists with this structure [form (I)], and the ratio of these forms can vary as a function of temperature. Whereas form (I) predominates at low temperatures, at room

temperature the concentration of form (II) is ~50%. Calculations of the atomisation energies for three structures of the dinuclear cobalt carbonyl have been carried out.[71] Structure (III), illustrated in Fig. 3*a* is hypothetical and no evidence for its existence has been obtained. Calculations have shown that stability decreases in the following sequence of structures: (I) > (II) > (III). Structure (III) proved to be least favourable on energy grounds and is hardly likely to exist. As mentioned above, the 18-electron rule also does not hold for this structure. The ease of the interconversion of structures (I) and (II) is indicated by purely chemical investigations. A study of the reaction involving the exchange of CO groups showed that all eight CO groups of the complex can be readily exchanged. Apparently equilibrium is established during the exchange reaction between forms (I) and (II) of the dinuclear cobalt carbonyl.[26]

Table 5. Certain characteristics of transition metal clusters.

Geometry	N	n_u	n_c	Cluster
Monomer	1	0	9	$Ni(CO)_4$

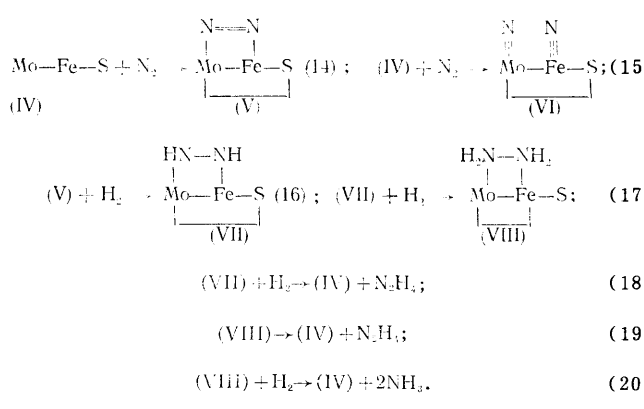
Notation: N is the number of atoms in the cluster, n_u the number of unoccupied orbitals, and n_c the number of cluster bond orbitals.

Whereas the structure of $Co_2(CO)_8$ most favoured by energy factors has bridge bonds, a direct M–M bond has been observed in the dinuclear manganese and technetium carbonyls. The energies of the M–M bond in the dinuclear $Mn_2(CO)_{10}$ and $Tc_2(CO)_{10}$ clusters have been estimated[87] within the framework of the virial-statistical approximation:[48,49] 52 and 100 kcal mol^{-1} have been obtained for $Mn_2(CO)_{10}$ and $Tc_2(CO)_{10}$ respectively, which exceeds the experimental values by a factor of approximately 2. Such unduly high calculated bond energies are apparently associated with the fact that no account had been taken of the relaxation of the bonds remaining after the rupture of the metallic bond. Thus the calculation and experiments showed that the bond strength increases on passing to heavier elements in the Periodic Table. This is a general phenomenon due to the increase of the degree of overlap of the atomic orbitals of the heavier elements and explains the increased ability of heavy transition metals to produce polynuclear carbonyl complexes.

There are as yet no quantitative theories of the dependence of the ability to form cluster compounds on the nature of the metal. However, qualitative aspects have been discussed[22] and have been justified by EHM calculations. The molecular orbitals of a cluster formed by transition metals can be divided into two classes: the unoccupied antibonding orbitals (UAO) and cluster valence orbitals (CVO). Only the CVO are suitable in terms of energy for combining with ligands and for ensuring the stability of the metallic skeleton of the cluster. Table 5[22] lists certain characteristics of transition metal clusters; it also includes examples of stable clusters corresponding to specified values of N, a specified geometry, and a specified number of valence electron n_k in the cluster valence orbitals. The n_k-electron rules are in fact extensions of the 18-electron rule to mononuclear transition metal complexes ($n_k = 18$ for $N = 1$).

It is known that metal clusters can behave as catalytic centres in various chemical reactions.[29] A simplified mechanism of the binding of nitrogen on the Mo–Fe–S model cluster, to which an important role has been attributed in the biological fixation of nitrogen, has been examined.[71] A scheme for the hydrogenation of nitrogen on the Mo–Fe–S dinuclear cluster, which is similar to that proposed by Likhtenshtein and Shilov for the catalytic hydrogenation of nitrogen in the presence of complex homogeneous catalysts, is presented below:[88]



(18)

(19)

(20)

The atomisation energies of the intermediate forms (V)–(VIII) have been calculated. The bond lengths and angles have been taken from Hardy et al.[89] and the missing interatomic distances have been determined as the sums of the covalent atomic radii.

Table 6 lists the calculated heats Q of individual stages of the reaction. Only a qualitative comparison of the heats Q is possible, because, apart from the roughness of the approximations, no account has been taken in the calculation of effects such as the influence of the protein component of the nitrogenase molecule, the pH of the medium, temperature, etc. It follows from the calculations that stage (15) is very highly endothermic. It is therefore possible to reject immediately the nitride mechanism of nitrogen fixation. In the hydrazine mechanism stage (16) is slowest and results in the formation of diimide coordinated to the catalyst. In order to estimate approximately the activation energies for the individual stages in the hydrogenation of nitrogen, we shall make use of the Brønsted–Semenov relation between the activation energy and the heat of reaction:

$$E_{act} = A_0 + 0.75\,|Q| \qquad (21)$$

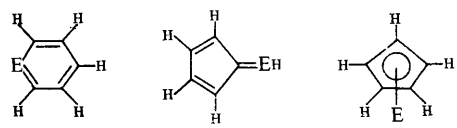
$$E_{act} = A_0 - 0.25\,|Q| \qquad (22)$$

for the endothermic and exothermic reactions respectively. Assuming that stage (14) takes place without an activation energy (this hypothesis does not alter the qualitative conclusions), we shall determine the unknown value of A_0 from Eqn.(22). Assuming further that A_0 does not change on passing from one stage to another (for radical reactions, this approximation holds[90]), the activation energies E_{act} were calculated for all the intermediate stages of the nitrogen hydrogenation reaction (Table 6). Comparison of the activation energies for the individual stages leads to the following probable pathway in the nitrogen hydrogenation reaction: (14) → (16) → (17) → (20). It was found that this pathway leads to the reduction of nitrogen to ammonia. The formation of less reduced forms is energetically unfavourable, in agreement with experiment.

Table 6. The calculated values of Q and E_{act} (kcal mol^{-1}).[71]

Stage	(14)	(15)	(16)	(17)	(18)	(19)	(20)
Q	31.5	−94.1	−50.4	18.9	0.0	−18.9	25.2
E_{act}	0.0	—	45.5	3.5	8.0	12.5	2.0

The mass spectra of π-cyclopentadienyliron carbonyl complexes π-$C_5H_5Fe(CO)_2ER_3$ containing an Fe–E bond, where E is a Group IV element (E = Si, Ge, Sn, or Pb) show intense peaks due to the $C_5H_5E^+$ ions whose intensity is sometimes a maximum.[91–96] They arise as a result of a complex rearrangement from molecular or decarbonylated ions $C_5H_5FeER_3$ (R = alkyl or halogen). This rearrangement takes place with the simultaneous involvement of at least nine bonds and has a very low activation energy. The unusually high intensity of the peaks due to the $C_5H_5E^+$ ions indicates their high stability. It is possible to put forward three possible structures of this ion, namely the elementophenyl (a), the elementofulvenyl (b), or the *nido*-cluster (c):



a *b* *c*

A calculation[97] of the atomisation energies of these structures of the $C_5H_5Ge^+$ ions showed that the structure of the *nido*-cluster has the highest stability. Similar calculations were later performed[98] for all the Group IV elements and it was shown that in all cases the cluster ions are more stable than the isomeric elementophenyl and elementofulvenyl ions and that their stability increases on passing from lead to carbon. The conclusion that the *nido*-cluster has the highest stability agrees with non-empirical calculations for $C_5H_5Si^+$ [99] and semiempirical calculations for the $C_5H_5Si^+$ and $C_5H_5C^+$ ions.[100] It is noteworthy that the predicted[97] stability of the *nido*-cluster of germanium has been confirmed by the synthesis of a compound containing this ion in the form of a *nido*-cluster.[101,102]

Calculations have been performed[103] by the SCF LCAO-MO method in the CNDO/2 approximation for the *nido*-clusters $C_5H_5E^q$, where E are the elements of the First and Second Periods (from H to Ne) and q assumes values of +1, 0, and −1. It was found that the stability of the *nido*-clusters increases with increase of the nuclear charge of the atom E, reaches a maximum, and then again falls towards the end of the Second Period. The $CpBe^-$, CpB, and CpC^+ clusters, in which the eight-electron shell is formally filled, show the highest stability under these conditions. Together with the $Me_5C_5Sn^+$ and $Me_5C_5Ge^+$ *nido*-clusters,[101,102] there exist stable molecules of the semi-sandwich type with an eight-electron shell, namely CpIn and CpTe.[104] On the basis of the results of an investigation,[103] it is possible to put forward the existence of the following *nido*-cluster: CpE^+ (E = C, Si, or Pb), CpE (E = B, Al, or Ga), and CpE^- (E = Be or Mg).

The numerous calculations for clusters of three types ("isolated" homoatomic, polynuclear organometallic, and *nido*-clusters) examined above show that the method of the electron density functional makes it possible to solve many interesting problems involving the energy relations of clusters even in its simple versions. Hitherto these simple versions have been applied to fairly covalent clusters, for which it is possible to neglect the charge transfer between the atoms (or ions). This is because the electron density of the system can be approximated by the sum of the electron densities of the free atoms (or ions).

In the future the method of the electron density functional can develop in two directions when applied to cluster theory: (1) with allowance for charge transfer between the atoms (or ions) by including the corresponding variational parameters in the electron density function, as, for example, has been done by Borisov;[46] (2) with analysis of the experimental electron densities to obtain an approximation to $\rho(\mathbf{r})$ in energy calculations, as has been done for crystals.[55,56] These improvements will naturally lead to certain complications in the calculations but the latter will nevertheless be much simpler than the calculations by the traditional quantum-chemical methods of the type of SCF LCAO-MO. Together with this, one-electron approaches based on the formal treatment of Kohn and Sham,[15] where the electron correlation is taken into account in the form of the electron density functional, show much promise for the calculation of the electronic structures of cluster compounds.

The Chemistry of the Cluster Compounds of Technetium

V.I.Spitsyn, A.F.Kuzina, A.A.Oblova, and S.V.Kryuchkov

The results of studies published up to 1983 inclusive and devoted to the synthesis and the molecular and electronic structure as well as the chemical and physicochemical properties of dinuclear and polynuclear cluster compounds of technetium are examined. It is shown that the majority of the chemical and physicochemical properties of such cluster compounds are analogous to those of the similar compounds of other *d* transition elements. However, a number of properties of the technetium cluster differ from those of other transition elements, which is explained from the standpoint of modern theoretical concepts. The bibliography includes 106 references.

I. INTRODUCTION

Technetium,[1] which is a typical representative of *d* transition elements of the second transition series, has properties most of which are similar to those of rhenium and in certain cases molybdenum. Since it is known[2-4] that the maximum capacity of transition elements for cluster formation with weak-field ligands is manifested by Group VI and VII elements, technetium is included among the most powerful cluster-forming elements. However, only the one anion $[Tc_2Cl_8]^{3-}$, in which a powerful metal–metal bond (M–M) is manifested, was known for technetium for a long time. The absence of data for this field of the chemistry of cluster compounds was due primarily to the low availability of technetium and its radioactivity.

Complexes of technetium in the lowest oxidation states are unstable and are formed as a rule with strong-field ligands, while complexes with weak-field ligands exist only in the presence of metal–metal bonds.[1] Thus the chemistry of complexes of technetium in oxidation states below 3+ with weak-field ligands can be regarded in essence as the chemistry of the cluster compounds of this element.

The studies on the chemistry of cluster compounds of technetium in the USSR were initiated at the beginning of the 1970's at the Institute of Physical Chemistry of the USSR Academy of Sciences after weighable amounts of this element had been obtained from the waste in the processing of nuclear fuel from atomic reactors.[1] This review deals with the present state of the chemistry of the cluster compounds of technetium and surveys and analyses the results of studies of the molecular and electronic structures of dinuclear and polynuclear technetium complexes with metal–metal bonds. Much attention is devoted to questions of the synthesis of cluster compounds of technetium and the investigation of their chemical and physicochemical properties.

II. SYNTHESIS AND MOLECULAR AND ELECTRONIC STRUCTURE

It is possible to differentiate two methods of synthesis of cluster compounds of technetium with weak-field ligands. The first[5] consists in the reduction of pertechnetate ions in concentrated hydrochloric acid by metallic zinc. The other method of synthesis, which has been used by the authors of this review,[6-8] is based on the reduction of pertechnetate ions by molecular hydrogen under pressure in an autoclave. This method has the advantage that the crystals produced are well formed and contain no extraneous impurities. The autoclave method had been developed initially for the synthesis of dinuclear technetium clusters with the $[Tc_2Cl_8]^{3-}$ anions and inorganic and organic cations.[6-8] Subsequently the autoclave method for the synthesis of clusters proved convenient also for the synthesis of more complex technetium clusters, including polynuclear clusters.[9-13] All the technetium clusters known at present can be divided arbitrarily into groups characterised by similar molecular and electronic structures.

1. Dinuclear Cluster Compounds of Technetium with the d^4–d^5 Electronic Configuration of the Central Atoms

These compounds constitute the most numerous groups of technetium clusters which have been investigated (Table 1, compounds 8–22). In our view this is due to the greater stability of the d^4–d^5 clusters compared with the d^4–d^4 clusters and also the fact that compounds with the $[Tc_2Cl_8]^{3-}$ anions had been obtained initially for technetium[5-8,14-16] and were subsequently employed to synthesise new technetium clusters.[9-13,17,18]

(a) *The Octachloroditechnetates* $M_3[Tc_2Cl_8].nH_2O$

Compounds of this type were first obtained by the reduction of pertechnetate ions by metallic zinc in concentrated hydrochloric acid at approximately 100 °C.[5] Later this method was used with some modifications in other studies also for the preparation of salts of octachloroditechnetate ions.[17-22] The reduction of pertechnetate ions under the given conditions is as a rule accompanied by the formation of brown solutions, which are rapidly oxidised in air to greenish-blue solutions with $\lambda_{max} \cong 615$ nm,[5] which corresponds to the absorption of light by the $[Tc_2Cl_8]^{3-}$ ions. When salts with the cations $M^+ = K^+$, NH_4^+, $^1/_3Y^{3+}$, or

Notation: $\varepsilon(X)$ is the energy of the electrons in the Cl_{2s} or $Br_{2p_{3/2}}$ skeleton, θ the Weiss constant, m the formal oxidation state of technetium, n the formal multiplicity of the Tc–Tc bonds, D a diamagnetic compound, and sp.gr. the space group.

*In these compounds there is a possibility that OH^- or H_3O^+ ions are present instead of H_2O molecules (or conversely).

**The results of a study by the authors of the review together with M.S.Grigor'ev and P.A.Koz'min.

$(C_4H_9)_4N^+$ are added to these solutions, crystals of complexes with the overall general formula $M_3[Tc_2Cl_8].nH_2O$ are formed[17–22] (Table 1).

Another method of synthesis of the octachloroditechnetate consists in the reduction of complexes of technetium(IV)–technetium(VII) in concentrated hydrochloric acid with molecular hydrogen under pressure in an autoclave at 120–180 °C.[6–8,11–13] As in the reduction with metallic zinc, the autoclave reduction is accompanied by the formation of brown solutions (λ_{max} = 465 nm), which are rapidly oxidised in air to greenish-blue solutions (λ_{max} = 645 nm). The reduction in autoclave proceeds at an initial hydrogen pressure of ~3 MPa. When technetium(IV) complexes are used as the initial compounds in the synthesis, the working temperature of the autoclave must be higher by 20–40 °C than in the case of pertechnetates, since the hexahalogenotechnetates(IV) are as a rule less soluble than the corresponding pertechnetates. Compounds having the composition $M_3[Tc_2Cl_8].nH_2O$, where $M^+ = K^+$, Cs^+, NH_4^+, PyH^+, or $QuinH^+$ are formed when salts with the cations $M^+ = K^+$, NH_4^+, $^1/_3Y^+$, or $(CuHg)_4N^+$ are added to these solutions[17–22] (Table 1).

All the octachloroditechnetates are substances which crystallise in the form of dark hexahedral needles, which give rise to a pale-grey powder on being ground. The complexes dissolve in hydrochloric acid with formation of turquoise solutions, which rapidly oxidise in air or disproportionate in its absence at low concentrations of the $[Tc_2Cl_8]^{3-}$ ions (~10^{-4} M) and are comparatively stable at high concentrations of such ions (~10^{-1} M). These compounds are sparingly soluble in polar organic solvents (clusters with organic cations are dissolved more effectively). In non-polar solvents the octachloroditechnetates do not dissolve, while in water and alkalies they rapidly hydrolyse with formation of brown colloidal solutions of the hydrated oxide $Tc_4O_5.nH_2O$.[23,24]

The autoclave method of synthesis of clusters with the $[Tc_2Cl_8]^{3-}$ anions[6-8] made it possible to observe an interesting phenomenon, which had not been noted by other workers[5,14-16,19-21] and which involves a non-stoichiometric variable content of certain singly-charged cations (M^+ = K^+, NH_4^+, or Cs^+) in octachloroditechnetate salts having the general formula $M_3[Tc_2Cl_8].nH_2O$. It was found that the composition of these clusters depends greatly on the hydrochloric acid concentration in the mother liquor from which they crystallise. For example, at an HCl concentration of 4–5 M, the K : Tc : Cl ratios in the potassium octachloroditechnetate formed are ~3 : 2 : 8, while in concentrated HCl solutions the ratios approach 2 : 2 : 8. A decrease of the content of K^+ ions in the complexes is accompanied by a decrease of the content of their water of crystallisation.

We may also note that the composition of these compounds depends on other factors as well, in particular on the rate of crystallisation. However, analysis of the diffractometer traces for the potassium octachloroditechnetate powders, obtained under different conditions, showed that the complex undergoes no appreciable crystal-chemical changes: the positions of all the lines on the diffractometer traces remain unchanged and correspond to the dimensions of the trigonal unit cell (a = 12.80 ± 0.05 Å; c = 8.30 ± 0.04 Å[25]), while the slight alteration of the intensities of the individual lines is mainly associated with the presence of a texture in the specimens.

One can assume *a priori* that the cause of the variable composition of the octachloroditechnetates may be either a variable oxidation state of technetium or the substitution of some of the cations by the H_3O^+ ions. The first version was proposed initially,[6] since the accuracy (±0.017 Å) of the X-ray diffraction study by a photomethod[25] precluded the determination of fine differences between the Tc–Tc distances in the $[Tc_2Cl_8]^{3-}$ and $[Tc_2Cl_8]^{2-}$ anions, which amount to ~0.03 Å according to the latest X-ray diffraction data[16,26,27] (Table 1). After revised X-ray diffraction data had been obtained,[16,21,26,27] an attempt was made to determine the H_3O^+ ions in potassium octachloroditechnetate, which led to their detection from the weak characteristic absorption lines in the infrared spectra [ν(OH) = 2965, 2930, and 2865 cm^{-1}; $\delta(OH)_2$ = 1610 cm^{-1} [28,29]]. The results did not conflict with the revised X-ray diffraction data,[26] according to which the K^+ ions in the unit cell of potassium octachloroditechnetate (+2.5) are present in two non-equivalent positions: sixfold (K′) and threefold (K″) (Fig.1); under these conditions, the sixfold positions were fully occupied by K^+ ions, while the threefold positions were half-occupied.

Summarising all that has been said above concerning the structure of the octachloroditechnetates(+2.5), one may conclude that their true composition is described by a formula with variable coefficients, namely $M'_6M''_{3-x}(H_3O)_x.[Tc_2Cl_8]_3.nH_2O$, where x and n vary from 0 to 3. The

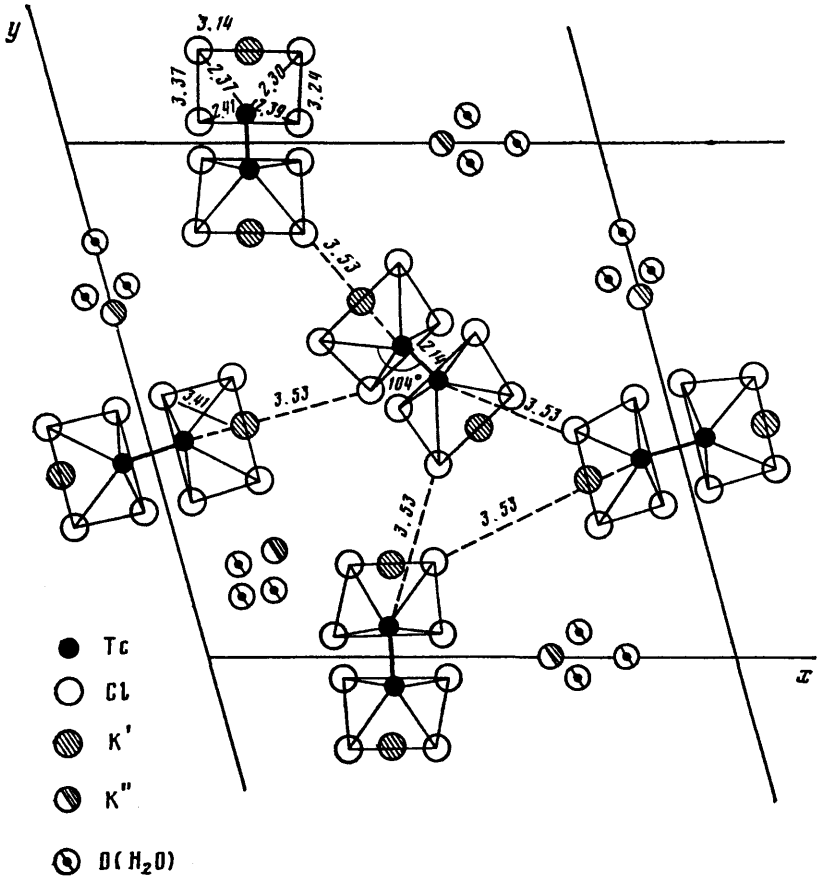

Figure 1. Projection of the unit cell of $K_6(H_3O)[Tc_2Cl_8]_3.3H_2O$ onto the xy plane.[25,26]

substitution of some of the M^+ ions by H_3O^+ ions is possible by virtue of the similarity of the properties of the hydronium cation and the alkali metal cations both in solutions and in the crystalline state.[30,31] The knowledge of such fine differences between the compositions of the octachlorodi-technetates(+2.5) is useful mainly for the study of certain solid-phase reactions, since the dissolution of these compounds leads to their dissociation into the M^+, H_3O^+, and $[Tc_2Cl_8]^{3-}$ ions and the properties of the solutions are then determined by the concentration of the octachloroditechnetate ions. The simplified formula of these complexes $M^3[Tc_2Cl_8].nH_2O$ was therefore used in subsequent studies.[7-13]

The structure of the ammonium,[14,15] potassium,[16,25,26] and yttrium[21] salts of the anion $[Tc_2Cl_8]^{3-}$ (Figs.1 and 2; Table 1) has been investigated by X-ray diffraction. The characteristic features of the molecular structure of this anion are its eclipsed conformation (D_{4h} symmetry) and a short Tc–Tc distance, much shorter than the analogous distance in metallic technetium (~2.70 Å[1]). It is striking that the change of the cation leads to an alteration of the Tc–Tc distance by ~0.04 Å (Table 1). We may note that the influence of the nature of the cation on the metal–metal distance in the rhenium and molybdenum complexes of the type $[M_2X_8]^{n-}$ (where M = Re or Mo and X = Cl or Br) with a quadruple M–M bond is weaker (the distance changes by ~0.02 Å[4,32-34]). In the case of technetium the true change in the M–M bond length on replacing the cations in the octachloroditechnetates is apparently somewhat smaller than the unduly high experimental value owing to the low accuracy of the X-ray diffraction study.[25,26]

(b) The Octabromoditechnetates $M_3[Tc_2Br_8].nH_2O$

When the potassium and ammonium halide complexes of technetium(VII)–technetium(IV) are reduced with molecular hydrogen under pressure (~3 MPa) in an autoclave in concentrated hydrobromic acid at 120–140 °C, the corresponding octabromoditechnetates(+2.5) of the type $M_3[Tc_2Br_8].2H_2O$ (where M = NH_4 or K), which are isostructural with the analogous cluster technetium chlorides,[12,13] are formed. Since the $[Tc_2Br_8]^{3-}$ ions are much less stable than $[Tc_2Cl_8]^{3-}$,[10-13,24] the formation of the octabromoditechnetates is observed only in a mixture with technetium(II) and technetium(IV) bromide complexes. This mixture can be conveniently resolved under the microscope using the distinctive characteristics of the octabromoditechnetates(+2.5) (large hexahedral needles or conglomerates of the latter, whose comminution yields a pale-brown powder). The octabromoditechnetates(+2.5) are sparingly soluble in polar and non-polar organic solvents, hydrolyse rapidly in water and alkalies, and dissolve in concentrated hydrogen halide acid solutions with formation of the $[Tc_2Br_8]^{3-}$ ions, which rapidly oxidise to $[TcBr_6]^{2-}$ or, in the absence of oxidants, disproportionate to $[Tc_2Br_6]^{2-}$ and $[TcBr_6]^{2-}$.[13,24]

(c) Dinuclear Cluster Compounds with a Structure of the "Lantern" Type

$Tc_2(o\text{-}C_5H_4ON)_4Cl$. Green crystals of $[Tc_2(o\text{-}C_5H_4ON)_4]Cl$, with sublime *in vacuo* (~10^{-9} Pa) at 350 °C without decomposition, have been obtained by the reaction of ammonium octachloroditechnetate with *o*-hydroxypyridine in nitrogen at 150 °C.[18] The compound is sparingly soluble in organic and inorganic solvents. Fig.3 illustrates the molecular structure of this cluster, which has the D_{2h} symmetry.

In contrast to $[Tc_2Cl_8]^{3-}$, the Tc–Tc bond in the oxopyridine cluster is additionally strengthened by four $o\text{-}C_5H_4ON$ bridging ligands, which have a contracting effect and lead to structures of the "lantern" type. The shortening of the Tc–Tc bond in the oxopyridine dinuclear cluster relative to the octachloroditechnetates(+2.5) amounts to ~0.015 and is close to the analogous value for dinuclear rhenium(III) clusters.[35]

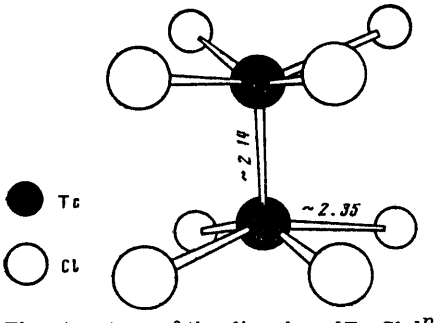

Figure 2. The structure of the dinuclear $[Tc_2Cl_8]^{n-}$ (n = 2 or 3) ions (according to a number of investigations[14,15,21,25-27]).

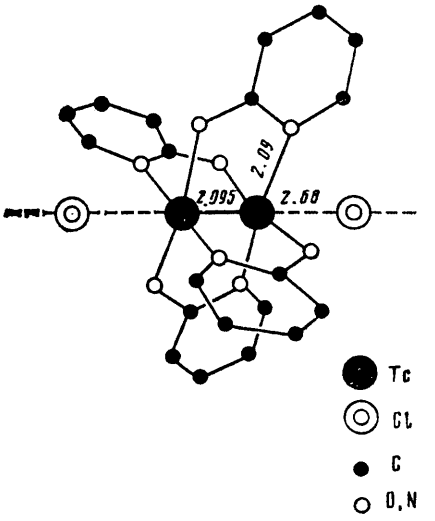

Figure 3. Fragment of the $[Tc_2(o\text{-}C_5H_4NO)_4Cl]$ structure.[18]

Acetate complexes. When $K_3[Tc_2X_8].2H_2O$ or $K_2[Tc_2X_6].2H_2O$ (where X = Cl or Br) interacts with glacial acetic acid in an autoclave at 120–200 °C in an argon or molecular hydrogen atmosphere (3–5 MPa), green crystals of the acetate dinuclear complexes having a structure of the "lantern" type are formed: $K[Tc_2(CH_3COO)_4]Cl_2$ and $[Tc_2(CH_3COO)_4]X$ (where X = Cl or Br)[9-11] (Table 1, Figs.4–6). The compounds are readily soluble in polar organic solvents and water and give rise to pale-green solutions, which gradually darken in air. On dissolution in concentrated hydrogen halide acid solutions, the corresponding octahalogenoditechnetates(+2.5) are formed.

Technetium acetate complexes without inorganic cations are volatile at ~400 °C like the oxopyridine complex which has a similar structure.

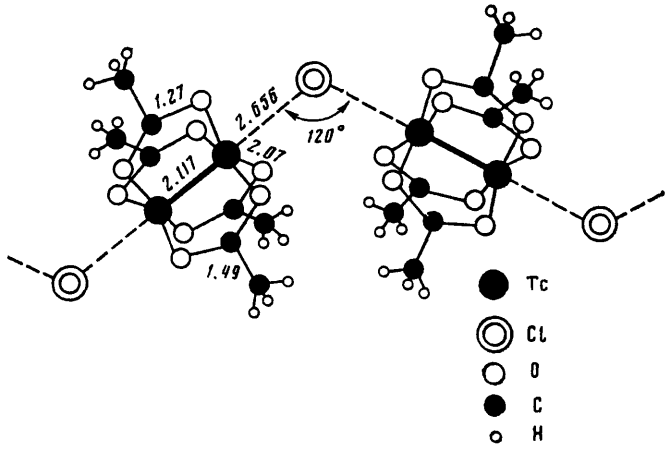

Figure 4. Fragment of the $[Tc_2(CH_3COO)_4Cl]$ structure.[36]

(d) Compounds Which Have Not Been Investigated by X-ray Diffraction

$Tc_4O_5.nH_2O$. A black powder, whose composition can be expressed by the overall formula $Tc_4O_5.14H_2O$, has been obtained by the hydrolysis of $K_3[Tc_2Cl_8].2H_2O$ in argon.[13] The freshly prepared hydrated oxide dissolves in concentrated hydrochloric acid with formation of $[Tc_2Cl_8]^{3-}$ ions. This demonstrates the retention of M–M bonds of high multiplicity in the hydrated oxide. The structure of $Tc_4O_5.14H_2O$ or its thermal degradation are accompanied, according to ESCA, infrared spectroscopic, and X-ray diffraction data[13] by irreversible structural changes. The final dehydration product is the black oxide Tc_4O_5.

The X-ray electronic and infrared spectra of Tc_4O_5 indicate the non-equivalence of technetium atoms as well as the oxygen atoms in its structure but this is not associated with the formation of a metallic technetium phase, TcO_2, or other known technetium oxides on dehydration of $Tc_4O_5.14H_2O$. According to magnetic measurements (Table 1), on the hydrated and anhydrous oxides, there is approximately one unpaired electron for each two technetium atoms, as in all the dinuclear d^4–d^5 clusters. The exact structure of the two compounds is unknown, but the set of chemical and physicochemical properties suggests the presence of Tc–Tc bonds with a high multiplicity in their structure.

$[Tc_2(C_5H_5N)_2Cl_5]$. The thermal decomposition of pyridinium octachloroditechnetate(+2.5) in argon at 250–280 °C yielded the compound $[Tc_2(C_5H_5N)_2Cl_5]$, the chemical analysis of which as well as optical and X-ray electronic spectra (Table 1) made it possible to ascribe to it a dinuclear structure with a Tc–Tc bond having a high multiplicity and with pyridine and chloride ligands.[39] The molecular structure of the compound is so far unknown. It has been isolated in the form of a dark-brown powder soluble in pyridine and unstable on dissolution in inorganic acids and alkalies. Treatment with nitric acid or a peroxide–alkali mixture as well as prolonged storage in air lead to its oxidation to technetium(IV) in the form of the stable compound $[Tc(C_5H_5N)_2Cl_4]$. In water the complex $[Tc_2(C_5H_5N)_2Cl_5]$ rapidly hydrolyses, while in alkalies it dissolves with decomposition.

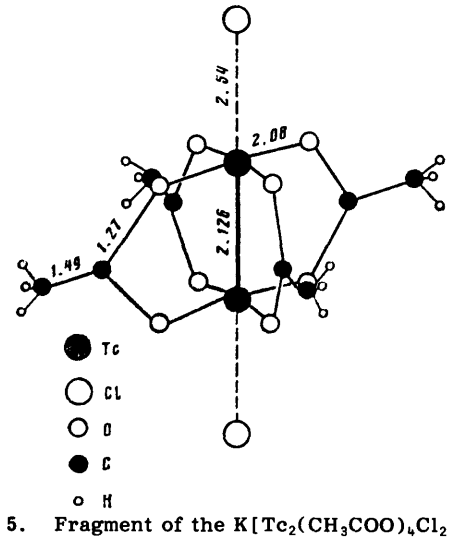

Figure 5. Fragment of the $K[Tc_2(CH_3COO)_4Cl_2]$ structure.[38]

(e) The Electronic Structure of Dinuclear d^4–d^5 Clusters

The d^4–d^5 clusters are of considerable experimental and theoretical interest, because they constitute so far the only representatives of dinuclear clusters of *d* transition elements with multiple M–M bonds having this electronic structure†. Attempts have been frequently made to examine the electronic structure of these compounds. According to the MO scheme for the quadruple M–M bond in dinuclear clusters with D_{4h} symmetry (Fig.7), the "superfluous" ninth electron in $[Tc_2Cl_8]^{3-}$ in isoelectronic clusters can be in one of the following MO: $b_{1u}(\delta^*_{M-M})$;[19,20,40,41] $a_{2u}(\sigma'_{n,\,M-M})$;[14,15,42,43] $a_{1g}(\sigma''_{M-M})$.[44] There exist indirect data confirming each of these versions but none of the confirmations constitute direct and well founded experimental results.

The claim by Cotton and co-workers[19,20,40] that the unpaired electron in the $[Tc_2Cl_8]^{3-}$ anion is in the $b_{1u}(\delta^*_{M-M})$ orbital has received somewhat more justification than others. This conclusion was reached on the basis of quantum-chemical calculations,[40] optical spectroscopic experiments,[1] and EPR of frozen solutions.[20] However, the accuracy of the quantum-mechanical calculations of the highest MO is not high and more reliable results, which are in no way directly dependent on these calculations, are provided in this instance by the EPR method. However, the EPR spectra

---

†The synthesis and electronic structure of the dinuclear d^4–d^5 rhenium cluster $\{Re_2Cl_4[P(n\text{-}C_3H_7)_3]_4\}PF_6$ have been described,[45,46] but its molecular structure has not so far been confirmed by X-ray diffraction.

(and hence also their interpretation) quoted by Cotton and Pedersen[20] arouse certain doubts. Indeed, Cotton and Pedersen[20] recorded the EPR spectra of frozen solutions of $Y[Tc_2Cl_8].9H_2O$ in a mixture of 10 vol.% of concentrated hydrochloric acid and 90 vol.% of ethanol and later it became known[13,23] that the $[Tc_2Cl_8]^{3-}$ ions undergo solvolytic reactions in such a mixture. This affects the charge of the dinuclear anions and their optical spectra, so that the EPR spectra obtained under these conditions refer to a mixture of species of the type $[Tc_2Cl_{8-n}.(Solv)_n]^{(3-n)-}$. As a result of this, the resolution of the $[Tc_2Cl_8]^{3-}$ spectrum is low, particularly that of parallel orientation lines, which might have been the cause of the inaccuracy in the determination of the parameters of the EPR spectra.

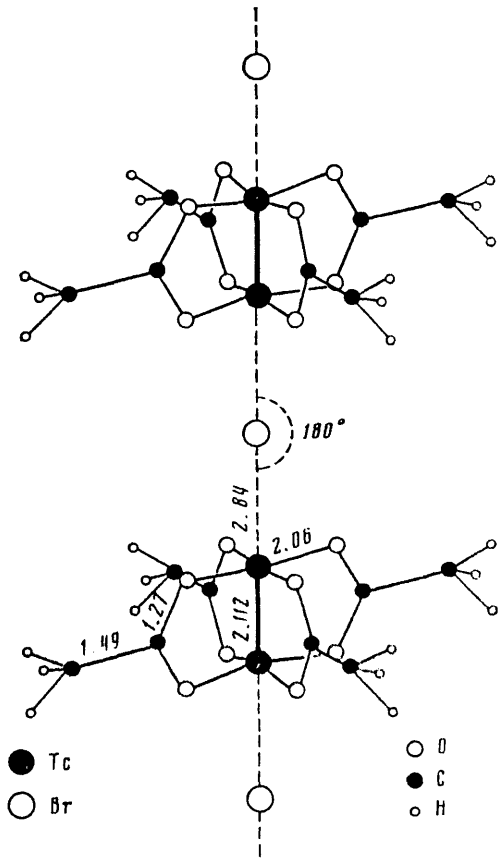

Figure 6. Fragment of the $[Tc_2(CH_3COO)_4Br]$ structure.[37]

A combined magnetochemical study of a whole series of paramagnetic dinuclear technetium clusters with a d^4–d^5 configuration of the central atoms has been carried out recently.[13,47,48] It was shown that a single broad signal with an effective g-factor of 2.09 ± 0.02 is observed in the EPR spectra of polycrystalline clusters. Their effective magnetic moment μ_{eff} does not vary with temperature and corresponds to a spin-only value for a single unpaired electron per molecule (~1.74 μ_B).

The differences between μ_{eff} and the spin-only value observed previously in other studies and their temperature dependence (Table 1) have been attributed either to the inaccuracy of the magnetochemical experiments for low amounts of the technetium compounds or to the presence of an admixture of high-spin technetium(IV) complexes.

The EPR spectra[13,47,48] of frozen vitreous specimens of the Tc_2^{5+} complexes are similar in form and give rise to a well-resolved hyperfine structure due to the two equivalent ^{99}Tc nuclei with a nuclear spin of 9/2. It has also been established that the parameters of the EPR spectra of all the technetium clusters investigated (Table 1, compounds 8, 10, 15, 16, 18, 19, and 21) agree to within experimental error and have the following values: $g_\parallel = 1.85 \pm 0.03$; $g_\perp = 2.13 \pm 0.03$; $A_\parallel = -(188 \pm 5) \times 10^{-4}$ cm^{-1}; $A_\perp = -(78 \pm 5) \times 10^{-4}$ cm^{-1}; $P = (5 \pm 1) \times 10^{-4}$ cm^{-1}. The absence of a dependence of the magnetochemical parameters of the solutions and polycrystalline substances on temperature and the nature of the ligands surrounding the Tc_2^{5+} fragment as well as the observation that $g_\parallel < 2$, $g_\perp > 2$, and $g_{av} > 2$ can be accounted for by the fact that the unpaired electron in this dinuclear fragment is in the $b_{1u}(\delta^*_{M-M})$ MO formed in the main from the $4d_{xy}$ atomic orbitals (AO) of the two equivalent technetium atoms (Table 2). In other words, the formal multiplicity of the M–M bond in the d^4–d^5 complexes is 3.5. Thus the experimental results confirm the main conclusions reached earlier from calculations of the electronic structure of $[Tc_2Cl_8]^{3-}$ by the X_α method.[40]

Table 2. The possible ground electronic states and the ratios of the g-factors in the Tc_2^{5+} cluster compounds.[13,47,48]

Ground state	HOMO	Technetium AO forming the HOMO	n	Energy of interacting MO	g_{theor}		
					$g_\parallel$	$g_\perp$	g_{av}

2. Dinuclear Cluster Compounds of Technetium with the d^4–d^4 Electronic Configuration of the Central Atoms

Compounds 4–7 (Table 1) belong to this group. The physicochemical properties of the given dinuclear clusters are close to those of the analogous rhenium and molybdenum compounds with the quadruple M–M bonds and are as a rule isostructural with them.[4,32–34]

(a) Dinuclear Cluster Compounds with a Structure of the "Lantern" Type

$\{Tc_2[(CH_3)_3CCOO]_4\}Cl_2$. The first dinuclear d^4–d^4 technetium complex was obtained by Cotton and Gage[17] and an attempt was made to substitute the chloride ions in the coordination sphere of $[Tc_2Cl_8]^{3-}$ by trimethylacetate ions. The substitution reaction was carried out by heating (t = 150 °C) a suspension of $(NH_4)_3[Tc_2Cl_8].2H_2O$ in pivalic acid under argon for 36 h. After the reaction mixture had been

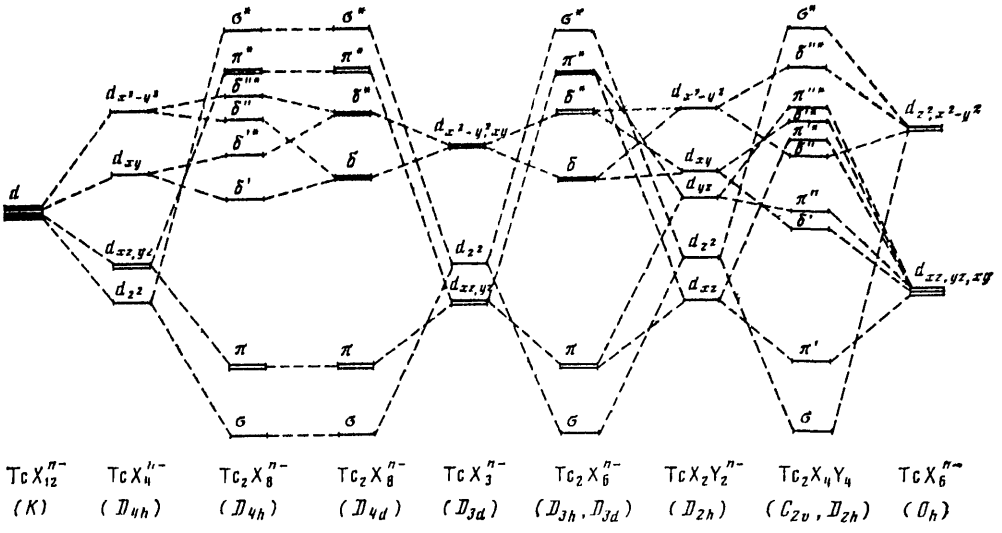

Figure 7. A simplified schematic illustration of the formation of one-electron metallic MO in dinuclear clusters of different symmetry.

cooled, fine red crystals of $\{Tc_2[(CH_3)_3CCOO]_4\}Cl_2$ precipitated; one of them was subjected to X-ray diffraction (Fig.8, Table 1), which demonstrated the similarity of the crystalline and molecular structures with dinuclear technetium and rhenium pivalate complexes.

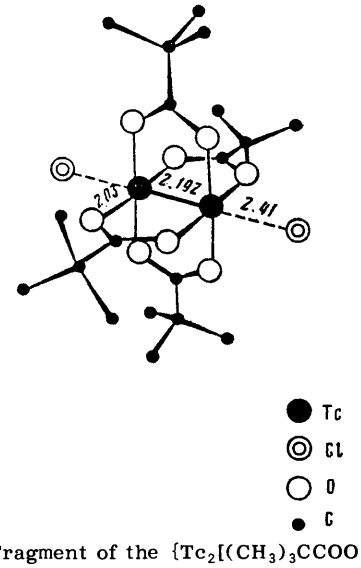

Figure 8. Fragment of the $\{Tc_2[(CH_3)_3CCOO]_4\}Cl_2$ structure.[17]

$[Tc_2(CH_3COO)_4]Cl_2$. The reduction of $[TcO_4]^-$ in a mixture of acetic and hydrochloric acids by molecular hydrogen under pressure yielded red crystals of $[Tc_2(CH_3COO)_4]Cl_2$.[49] The structure of the compound was not investigated by X-ray diffraction, but, in view of the fact that the technetium and rhenium[50] acetate complexes are isostructural, presumably it too has a structure of the "lantern" type with four bridging acetate ions in the equitorial planes and two axial chlorine atoms on either side of the quadruple Tc–Tc bond, i.e. their structure is similar to that of $\{Tc_2[(CH_3)_3CCOO]_4\}Cl_2$ (Fig.8). This structure of the acetate complex has also been confirmed by its diamagnetism and infrared spectroscopic data.

(b) The Octahalogenoditechnetates $M_2[Tc_2X_8]$

$[(C_4H_9)_4N]_2(Tc_2Cl_8)$. In contrast to $[Mo_2Cl_8]^{4-}$ and $[Re_2Cl_8]^{2-}$, the octachloroditechnetate ions have been obtained and characterised by means of chemical,[51] spectroscopic,[22] and X-ray diffraction[27] analytical methods comparatively recently. This is due to the lower stability of the $[Tc_2Cl_8]^{2-}$ ion compared with $[Tc_2Cl_8]^{3-}$ in hydrochloric acid solutions in which dinuclear cluster chlorides are as a rule formed on reduction of technetium(VII)–technetium(IV) by various reductants. However, subsequent investigations showed that the $[Tc_2Cl_8]^{2-}$ ions are much more stable in organic solvents than $[Tc_2Cl_8]^{3-}$.

This property of the octachloroditechnetate ions has been used to develop an optimum method for the synthesis of compounds with the $[Tc_2Cl_8]^{2-}$ anion.[13] For this purpose, the oxo-, oxochloro-, or chloro-complexes of technetium(VII)–technetium(IV) were reduced in concentrated hydrochloric acid (H_3PO_2, metallic zinc, or molecular hydrogen under a pressure of 3–5 MPa in an autoclave at ~140 °C can be used as reductants). An excess of a hydrochloric acid solution of tetrabutylammonium chloride is added to the resulting solution of the mixture of $[Tc_2Cl_8]^{2-}$, $[Tc_2Cl_8]^{3-}$, and $[Tc_2Cl_6]^{2-}$ ions and the solution is then extracted with a mixture of chloroform, carbon tetrachloride, and methylene chloride a characteristic feature of which is a satisfactory separation of the organic and aqueous phases. In order to

increase the solubility of technetium ions in the organic phase, acetone may also be added to the extraction mixture. When the solution is coloured an intense brown or turquoise, which corresponds to the presence of a high content of $[Tc_2Cl_6]^{2-}$ or $[Tc_2Cl_8]^{3-}$ ions respectively in the mixture, it is necessary to pass air through the extraction mixture until it becomes fully coloured bright green, but a yellow colour, indicating the formation of the $[TcCl_6]^{2-}$ ions, is not obtained. After this, the organic phase is separated and allowed to stand in air in order to evaporate the solvent slowly. Crystallisation yields bright green $[(C_4H_9)_4N]_2[Tc_2Cl_8]$ dendrites, which are less soluble than $[(C_4H_9)_4N]_2[TcCl_6]$. After two recrystallisations from acetone or methylene chloride, a pure preparation of tetrabutylammonium octachloroditechnetate is produced. Following the repeated employment of the evaporated mother liquors, formed in all the stages of the experiment, as the starting materials for the reduction of technetium chloride complexes to technetium(III), the overall yield of tetrabuytylammonium octachloroditechnetate can be increased almost to ~100%.

The preparation of crystals of tetrabutylammonium octachloroditechnetate has been described by Cotton et al;[27] they were studied by X-ray diffraction, which showed that the structure of the $[Tc_2Cl_8]^{2-}$ ions is analogous to that of the isoelectronic cluster rhenium and molybdenum chlorides and bromides with a quadruple M–M bond[4,32–36] (Fig.2 and Table 1).

Table 1 shows that the replacement of the chloride ions in $[Tc_2Cl_8]^{2-}$ by trimethylacetate ions $[(CH_3)_3CCOO]^-$ leads to an appreciable increase of the Tc–Tc distance, which is caused by the *trans*-influence of the axial chlorine atoms in $\{Tc_2[(CH_3)_3CCOO]_4\}Cl_2$ on the length of the quadruple M–M bond. The mechanism of the *trans*-influence consists in the fact that the formation of the $Tc-Cl_{ax}$ bond in the carboxylate complexes involves mainly the $4d_{z^2}$, $5s$, and $5p_z$ electrons of the technetium atoms and the $3p_z$ electrons of the chlorine atoms. Since the $4d_{z^2}$, $5s$, and $5p_z$ electrons of technetium also participate in the formation of the σ-component of the Tc–Tc bond (Fig.7), there is a mutual correlation of the $Tc-Cl_{ax}$ and Tc–Tc bond lengths. Analogous effects have been observed for the dinuclear complexes of rhenium, molybdenum, chromium, platinum metals, etc.[4,32–34,52,53]

$[(C_4H_9)_4N]_2[Tc_2Br_8]$. When several drops of hydrobromic acid are added to an acetone solution of $[(C_4H_9)_4N]_2[Tc_2Cl_8]$ and the reaction mixture is then heated briefly to boiling, a carmine-red solution is formed; this colour corresponds to the $[Tc_2Br_8]^{2-}$ ions.[22] When the solution is evaporated, carmine-red $[(C_4H_9)_4N]_2[Tc_2Br_8]$ dendrites are formed, but their exact molecular structure has not so far been established.

(c) The Electronic Structure of Dinuclear d^4–d^4 Clusters

All the dinuclear technetium complexes with the d^4–d^4 electronic configuration of the central atoms known at present are diamagnetic. According to the one-configuration approximation, the eclipsed conformation of these complexes, like that of the isoelectronic Cr, Mo, W, and Re compounds having no bridging ligands, is determined by the δ-component of the M–M bond formed mainly as a result of the overlap of the $4d_{xy}$ AO of the M atoms.[4,32–34,41,42] Fig.7 illustrates a simplified scheme for the formation of the M–M bond in dinuclear clusters with the D_{4h} symmetry, from which it follows that the highest MO in the d^4–d^4 complexes is the $b_{2g}(\delta_{M-M})$ orbital, while the M–M bond has a formal multiplicity of 4.0.

After the determination of the formal multiplicity of the Tc–Tc bonds in $[Tc_2Cl_8]^{n-}$ (n = 2, 3) and its isoelectonic technetium complexes, the question arises of the cause of the lower stability of the dinuclear d^4–d^4 clusters compared with the d^4–d^5 clusters and of the possibility of the formation of analogous dinuclear complexes by other d elements with a multiplicity of the M–M bonds of 3.5. It has been shown[13,41,48,54] that the real electronic structure of the clusters of d transition elements can be described within the framework of the MO method only when account is taken of configuration interactions (CI). Thus allowance for the CI in the d^4–d^4 complexes results in a decrease of the effective multiplicity of the M–M bond approximately to 3.0; on the other hand, allowance for the CI in the d^4–d^5 complexes hardly affects the effective multiplicity of the M–M bond, which is a direct consequence of the Brillouin theorem,[55] according to which singly excited states do not contribute to the ground electronic state of the system when account is taken of the CI by the self-consistent field methods. The quadruple bond in the d^4–d^4 complexes is therefore "diluted" as a result of the doubly excited $\sigma^2\pi^2\delta^0(\delta^*)^2$ state with an M–M double bond, whereas in the d^4–d^5 complexes the low-lying excited $\sigma^2\pi^2\delta^0(\delta^*)^1$ state makes no contribution to the overall M–M bond energy, while all the doubly excited states, occupying high positions, make a very small contribution to the ground state.

The above mechanism of the increase of the stability of the clusters with a single unpaired electron does not extend to all the dinuclear clusters of the d transition elements. It is known that the d^4–d^3 molybdenum clusters, namely $[Mo_2Cl_8]^{3-}$ and $[Mo_2(SO_4)_4]^{3-}$, are much less stable than their analogues with a quadruple M–M bond, i.e. $[Mo_2Cl_8]^{4-}$ and $[Mo_2(SO_4)_4]^{4-}$.[4,32–34] An analogous phenomenon has been observed for the dinuclear rhenium complexes $[Re_2X_8]^{3-}$, which have not so far been isolated in a pure form and whose formation has been observed only in electrochemical processes.[20,56] The complex $\{Re_2Cl_4[P(n\text{-}C_3H_7)_3]_4\}PF_6$[45,46] (where the Re–Re bond length is so far unknown) apparently constitutes an exception to this rule; the increase of its stability may be caused by the σ-donor influence of the phosphine ligands, which increases the energy of the σ-component of the Re–Re bond compared with the $[Re_2Cl_8]^{2-}$ and $[Re_2Cl_6(PR_3)_2]$ complexes.

Allowance for the CI should not therefore always increase the stability of the dinuclear clusters with a single unpaired electron. We believe than an additional cause[13] is the decrease of the effective charge Z_{eff} on the metal atoms following the formation of an M–M bond by the latter. This phenomenon had been recently observed for technetium clusters by X-ray electronic spectroscopy.[57,58] An analogous decrease of Z_{eff} is not observed in the rhenium clusters, while in the molybdenum clusters [judging from the skeletal electron energies $\varepsilon(Re_{4f_{7/2}})$ and $\varepsilon(Mo_{3d_{5/2}})$],[59–64] Z_{eff} is actually increased on the metal atoms following the formation of M–M bonds.

Estimates of the influence of the addition (or removal) of the "superfluous" electron to certain rhenium, technetium, and molybdenum clusters with the d^4–d^4 configuration have been published.[13] They showed that in the case of technetium clusters the addition of the "superfluous" electron does indeed result in the maximum gain in the repulsion energy between M atoms with like charges, the gain being greater than the loss in the δ-overlap energy. Conversely, the removal of a single electron always leads to an increase of the repulsion energy with a simultaneous decrease of the δ-overlap energy. From this it follows that the d^4–d^3 complexes should be always less stable in relation to the dissociation of the M–M bonds than the d^4–d^4 complexes with a

similar structure. We may note that the factor involving the increase of the ionic radius with decrease of the oxidation state of the metal atoms in the cluster acts in the opposite direction. Whether or not the acceptance of a superfluous electron in the d^4–d^4 system has a favourable effect depends on the ratios of all these factors. In the case of technetium the addition of the electron is energetically favourable not only for dinuclear clusters but, as will be shown below, also for the polynuclear clusters.

Cotton et al[21] recently gave another explanation of the strengthening of the M–M bonds in the d^4–d^5 technetium clusters compared with the d^4–d^4 clusters. The explanation is based on the hypothesis that, on passing from $[Tc_2Cl_8]^{2-}$ to $[Tc_2Cl_8]^{3-}$, the decrease of the energy of the δ-component of the M–M bond is accompanied by the simultaneous increase of the energy of the π- and possibly also the σ-component of this bond. If this hypothesis is valid, then, on passing from the d^4–d^4 complexes to the d^4–d^5 complexes, either an increase of the energy difference between the π_{M-M} and π^*_{M-M} MO, on the one hand, and the σ_{M-M} and σ^*_{M-M} MO, on the other, or an increase of the "metallic" character of the π_{M-M} and σ_{M-M} MO should take place.

However, the X-ray electronic spectroscopic data[13,57] have shown that none of these conditions is in reality fulfilled. For example, an increase of the splitting between the lines corresponding to the π- and δ-components of the M–M bond in the valence X-ray electronic spectrum is not observed on passing from the $[Tc_2Cl_8]^{2-}$ ion to $[Tc_2Cl_8]^{3-}$ and $Tc_2(CH_3COO)_4X$ (where X = Cl or Br) (the lines of the σ-components of the Tc–Tc bond are not shown in the spectra). An increase of the "metallic" character of the σ_{M-M} and π_{M-M} MO would have been manifested by a decrease of $\varepsilon(Tc_{3d_{5/2}})$ on passing from the d^4–d^4 complexes to the d^4–d^5 complexes, since this would have entailed an appreciable decrease of Z_{eff} on the technetium atoms. However, the real decrease of $\varepsilon(Tc_{3d_{5/2}})$ is small and corresponds to an average decrease of this quantity with decrease of the formal oxidation states of technetium by 0.5. Furthermore, with increase of the energy of the σ-component of the M–M bond in the d^4–d^4 complexes, the energy of the skeletal electrons of the axial halogen atoms would have decreased appreciably; however, the real values of $\varepsilon(Cl_{2p_{3/2}})$ and $\varepsilon(Br_{3d_{5/2}})$ (Table 1) correspond to typical values of this electron energy in the dinuclear clusters of other *d* elements.[52,53,59,60]

3. Dinuclear Clusters of Technetium Compounds with the d^5–d^5 Electronic Configuration of the Central Atoms

Six complexes with this electronic structure, having the general formula $M_2[Tc_2X_6].nH_2O$, where M = K, NH_4, or $(C_4H_9)_4N$, X = Cl or Br, and *n* = 0 or 2, have been described hitherto[10,12,13] (Table 1, compounds 23–25). These compounds are formed under the conditions of far-reaching reduction of the technetium halide complexes in concentrated solutions of the corresponding hydrogen halides. The $[Tc_2X_8]^{3-}$ ions are the direct precursors of $[Tc_2X_6]^{2-}$. Atomic hydrogen (metallic zinc or aluminium in concentrated HCl) or molecular hydrogen (under a 3–5 MPa pressure in an autoclave at 140–180 °C) can be used as the reductant. The compounds are dark-brown cryptocrystalline powders or conglomerates of acicular crystals forming flat and three-dimensional stars. The complexes are sparingly soluble in organic polar and non-polar solvents, the $[(C_4H_9)_4N]_2[Tc_2X_6]$ salts constituting an exception, since they are easily soluble in polar organic solvents and readily dissolve in hot solutions of the corresponding hydrogen halides with formation of brown solutions, which are rapidly oxidised in air to $[Tc_2X_8]^{3-}$ and further to $[TcX_6]^{2-}$. All compounds of this type are diamagnetic. The X-ray electronic spectra[13,57] (Table 1) indicate the absence of bridging halogen atoms from the molecules of these compounds.

There are at present no X-ray diffraction data for the structures of the $M_2[Tc_2X_6].nH_2O$ complexes, but the set of their chemical and physicochemical properties indicates their dinuclear structure with an M–M bond having a high multiplicity. The D_{3h} or D_{3d} symmetry of the $[Tc_2X_6]^{2-}$ ions is the most likely. Evidently, for this symmetry of the dinuclear complexes, the $4d_{xy}$ and $4d_{x^2-y^2}$ AO of technetium becomes degenerate (Fig. 7) and the Tc–Tc bond in the $[Tc_2X_6]^{2-}$ ions is quintuple—of the $\sigma^2\pi^2\delta^2_{xy}\delta^2_{x^2-y^2}$ type in contrast to the hypothetical dinuclear d^5–d^5 complexes with D_{4h} symmetry in which the multiplicity of the M–M bond would have been three: $\sigma^2 2\pi^2\delta^2_{xy}(\delta^*_{xy})^2$.

We may note that in this case the rotation of one of the (TcX_3) fragments about the Tc–Tc bond by 60° does not result in a gain of the δ-overlap energy; the hindered conformation with D_{3d} symmetry (the ethane-like structure), in which the interligand repulsions are manifested to the smallest extent, should therefore be the most preferred for the $[Tc_2X_6]^{2-}$ ions.[13]

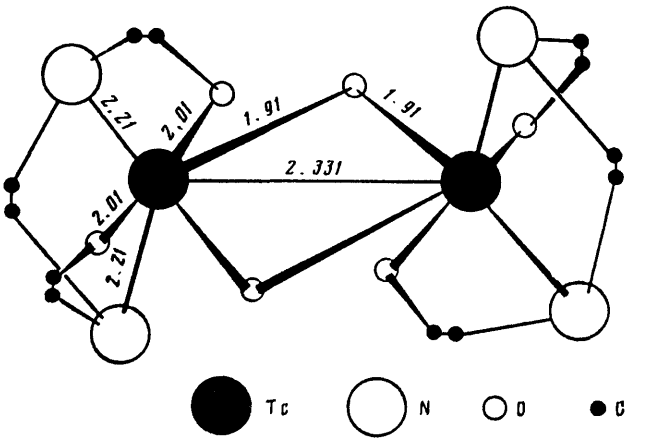

Figure 9. Schematic illustration of the immediate environment of the technetium atoms in the $[Tc_2(H_2EDTA)_2\mu\text{-}O_2].5H_2O$ structure (according to the data of Burgi et al[65]).

4. Dinuclear Clusters of Technetium Compounds with the d^3–d^3 and d^3–d^2 Electronic Configurations of the Central Atoms

$[Tc_2(\mu\text{-}O)_2(H_2EDTA)_2].5H_2O$. This compound has been obtained by reducing $[TcO_4]^-$ with an excess of $NaHSO_3$ in the presence of an excess of Na_2H_2EDTA with heating (70–80 °C) of the reaction mixture for several days.[65] After recrystallisation from 0.01 M $HClO_4$, the complex consisted of a diamagnetic cryptocrystalline red-brown powder. In constrast to all the dinuclear technetium clusters examined above, the ethylenediamine tetra-acetate complex with two bridging oxygen atoms, additionally binding the technetium

atoms, has the idealised C_{2v} symmetry. The ethylenediaminetetra-acetate ions behave as tetradentate ligands, coordinating each technetium atom to 2 nitrogen atoms and 2 oxygen atoms in the acetate group (Fig.9); the coordination polyhedra of the technetium atoms formed in this process consist of two distorted octahedra with a common edge made up of bridging oxygen atoms.

TcO_2. Technetium dioxide has a structure close to that of the ethylenediaminetetra-acetate complex described above#. According to the results of X-ray diffraction analysis of the TcO_2 powder,[66] the technetium dioxide cluster has a distorted rutile structure: six oxygen atoms are located at the vertices of a distorted octahedron in the centre of which the technetium atom is present (Fig.10). The TcO_6 octahedra are linked to one another along the edges made up of oxygen atoms forming an infinite three-dimensional network. The technetium atoms in the octahedra have been brought closer together in pairs so that one may expect the formation of Tc–Tc bonds, but their strength is much lower (and their length much greater—see Table 1) than in the ethylenediaminetetra-acetate complex. This is shown indirectly by the paramagnetism of technetium dioxide, indicating the presence of approximately one unpaired electron at each technetium atom.[13]

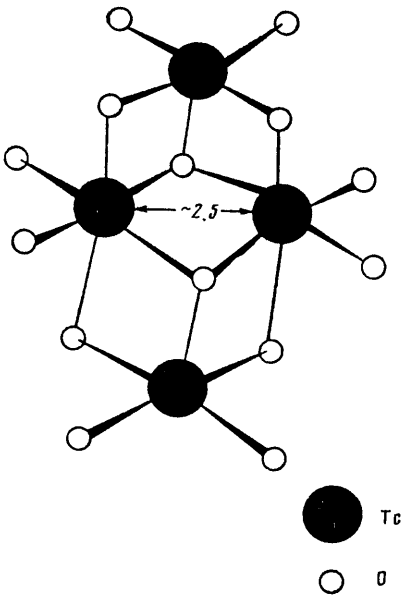

Figure 10. Fragment of the TcO_2 structure (according to the data of Magneli and Andersson[66]).

$K_3[Tc_2Cl_8O_2]$. This compound is hitherto the only representative of dinuclear technetium clusters with the d^3–d^2 electronic configuration of the central atoms. The complex has been obtained by refluxing a solution of $K_3[Tc_2Cl_8].2H_2O$ in ethyl methyl ketone in air.[11,13] This compound is a yellow–green powder sparingly soluble in ethyl methyl ketone and other organic solvents and readily soluble in inorganic acids. The complex is resistant to the action of oxidants and reductants both in the solid phase and in solutions. It can be oxidised to $[TcO_4]^-$ only after prolonged refluxing with strong oxidants such as Ce^{4+} in 0.4 M H_2SO_4. In the presence of complex-forming agents (for example, concentrated hydrochloric acid), the $[Tc_2Cl_8O_2]^{3-}$ ions decompose comparatively rapidly with formation of initially equivalent amounts of $[TcCl_6]^{2-}$ and $[TcOCl_5]^{2-}$.

Infrared spectroscopy of $K_3[Tc_2Cl_8O_2]$ indicates the presence of two types of bonds between the oxygen and technetium atoms in the structure of this complex: $\nu(Tc{=}O) = 1020\ cm^{-1}$ (strong); $\nu(Tc{-}O) = 680\ cm^{-1}$ (medium); $\delta(Tc{-}O{-}Tc) = 475\ cm^{-1}$ (medium). The X-ray electronic spectra of this compound[57] indicate the absence of bridging chlorine atoms from its structure. Thus, although there are no direct data concerning the structure of $K_3[Tc_2Cl_8O_2]$, the physicochemical properties of this complex suggest that it has a dinuclear structure with a weak metal–metal bond.

The electronic structure of the hypothetical complex $[(NH_3)_2(OH)_2Tc(\mu\text{-}O)_2Tc(OH)_2(NH_3)_2]$, with a molecular structure analogous to that of the complex $[Tc_2(\mu\text{-}O)_2(H_2EDTA)_2]$, has been calculated[65] by the extended Hückel method. The calculation led to the conclusion that a single Tc–Tc bond with the $\sigma^2\pi^2(\delta^*)^2$ electronic structure is formed in the technetium ethylenediaminetetra-acetate complex and not a triple bond ($\sigma^2\pi^2\delta^2$), which might have been suggested on the basis of the scheme in Fig.7. According to Burgi et al,[65] the reverse sequence in terms of the energy of the δ_{M-M} and δ^*_{M-M} MO responsible for the formation of the δ(Tc–Tc) bond in the given complex arises by virtue to the destabilising effect of the 2*p* orbitals of the bridging oxygen atoms. This explains the greater length of the Tc–Tc bond in the ethylenediaminetetra-acetate complex (~2.33 Å) compared with the expected length of the "truly" triple M–M bond.

However, even if this type of effect, involving the destabilisation of the δ(Tc–Tc) bond under the influence of bridging ligands, does occur, its extent is not as great as has been suggested.[65] Indeed, Table 1 shows that the expected length of the Tc–Tc triple bond should be ~2.22 Å, i.e. shorter by ~0.1 Å than in the ethylenediaminetetra-acetate complex. On the other hand, the length of the single Tc–Tc bond should be ~2.55 Å, which is greater by ~0.23 Å than the analogous length in $[Tc_2(\mu\text{-}O)_2(H_2EDTA)_2].5H_2O$. From this it follows that the difference between the energies of the δ_{M-M} and δ^*_{M-M} MO should be positive (and not negative as suggested by Burgei et al[65]) and greater in absolute magnitude than the energy of the interelectron repulsion, since otherwise the complex $[Tc_2(\mu\text{-}O)_2(H_2EDTA)_2].5H_2O$ would have been paramagnetic with two unpaired electrons (as in the case of TcO_2).

Thus it is most likely that the formal multiplicity of the Tc–Tc bond in the ethylenediaminetetra-acetate complex is 3.0 ($\sigma^2\pi^2\delta^2$). However, the δ-component of the bond is weakened, so much that its contribution to the overall energy of the M–M bond is close to zero.

The δ-level is apparently destabilised to an even greater extent in the TcO_2 and $[Tc_2Cl_8O_2]^{3-}$ complexes having a similar structure, which leads to their paramagnetism (Table 1), the value of μ corresponding to the presence of two or three unpaired electrons per molecule.

The methods of synthesis and properties of TcO_2 have been described in detail in a monograph.[1]

5. The Cluster Carbonyls

Several technetium carbonyl complexes in which metal–metal bonds are observed have been described.

$[Tc_2(CO)_{10}]$. Ditechnetium decacarbonyl was first obtained simultaneously by two groups of investigators[67,68] via the reaction

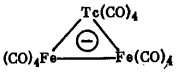
$$Tc_2O_7 + 17CO \rightarrow [Tc_2(CO)_{10}] + 7CO_2 .$$

The carbonylation was carried out in an autoclave at ~200 °C and an initial carbon monoxide pressure of ~20 MPa. It was later reported[69] that the carbonylation of TcO_2 with formation of ditechnetium decacarbonyl also takes place under milder conditions: ~2 MPa and 250 °C.

The compound $[Tc_2(CO)_{10}]$ is a colourless crystalline substance with a melting point of ~160 °C, which readily sublimes *in vacuo* (~10^{-4} Pa) at 50 °C. The compound is diamagnetic and readily dissolves in diethyl ether and other non-polar organic solvents.

In contrast to the molecules of the dinuclear complexes discussed above, the $[Tc_2(CO)_{10}]$ molecule (Fig.11 and Table 1) has the following structural features: (1) idealised D_{4d} symmetry (staggered conformation); (2) a weak M–M bond; (3) a higher strength of the bonds between the technetium atoms and axial ligands than that of the bonds involving equatorial ligands. In broad outline, the structure of the ditechnetium decacarbonyl molecule resembles those of $[Mn_2(CO)_{10}]$ and $[Re_2(CO)_{10}]$.[70] The chemical and physicochemical properties of these compounds are likewise similar. For example, the interaction of $[M_2(CO)_{10}]$ (where M = Mn, Tc, or Re) with elemental halogens in organic solvents results in the formation of compounds of the type $M(CO)_5X$ (where X = Cl, Br, or I), i.e. the oxidative addition of the X_2 molecules to the M–M bond, accompanied by dissociation, takes place.[69] The interaction of $M(CO)_5X$ with dimetal decacarbonyls in the presence of sodium amalgam results in the formation of mixed carbonyls of the type $[MnTc(CO)_{10}]$ and $[ReTc(CO)_{10}]$,[71] whose structure resembles that of ditechnetium decacarbonyl.

Irradiation of a mixture of ditechnetium decacarbonyl and iron pentacarbonyl (in molar proportions of 1 : 4) with ultraviolet light in tetrahydrofuran for 1 h yielded the mixed technetium iron carbonyl cluster $[Fe_2Tc(CO)_{12}]^-$.[72] The anion was also precipitated in the form of the tetrabutylammonium salt. A trinuclear structure of this anion has been postulated:[70]



The formation of an M–M bond is also possible in the dimeric technetium carbonyl halides having the general formula $[Tc(CO)_4X]_2$ (where X = Cl, Br, or I), which are formed when $[Tc_2(CO)_{10}]$ interacts with elemental halogens in carbon tetrachloride or chloroform on heating in a sealed tube.[69]

The interaction of cobalt carbonyl in tetrahydrofuran in the presence of an excess of the Na/K alloy in an atmosphere of CO at room temperature for 1 h yielded the anion $[Co(CO)_4]^-$, which reacted with $[Tc(CO)_5X]$ to form after 5 h a yellow-red compound having the composition $[CoTc(CO)_9]$, which is readily soluble in organic solvents. The diamagnetism of this complex suggests the presence of the heteropolar M–M bond in its structure.[73]

The formation of M–M bonds may also be expected in the structure of the polynuclear technetium tetracarbonyl hydride having the tentative structure $[HTc(CO)_4]_3$.[74]

The compound is formed as the side product in the synthesis of $[HTc(CO)_5]$ [69,75] by the interaction of ditechnetium decacarbonyl with sodium amalgam in tetrahydrofuran with subsequent acidification of the reaction mixture using concentrated orthophosphoric acid.

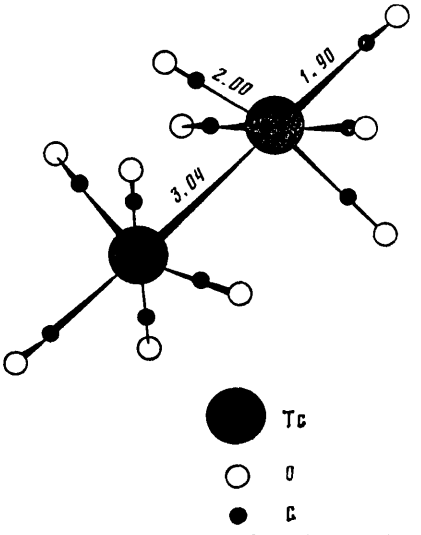


Figure 11. Molecular structure of $Tc_2(CO)_{10}$ (according to the data of Hileman et al[67]).

It is seen from the data for the chemistry of cluster technetium carbonyls presented above that in the case of strong-field ligands technetium exhibits a tendency towards the formation of clusters. In terms of this property, technetium resembles the platinum group elements.

6. Polynuclear Cluster Compounds of Technetium

Until recently, there was no information in the literature about polynuclear ($n > 4$) clusters not only of technetium but also of all the Group VIIB elements. However, such compounds are known[2,3] for Group V, VI, and VIII transition metals and the elements of the vanadium and chromium subgroup clusters with weak-field ligands have been observed, while for the platinum subgroup metals clusters with strong-field ligands have been found. Thus the possibility of the formation of polynuclear clusters by Group VIIB elements and, in particular, of technetium clusters with weak-field ligands is of undoubted interest for general chemistry.

The first communications about the synthesis[10,13] and structure[76–79] of polynuclear technetium halides appeared in 1982–83. These studies demonstrated the enhanced capacity of technetium for the formation of polynuclear clusters with metal–metal bonds. Furthermore, the compounds isolated constituted a type of cluster compounds with conjugated quadruple metal–metal bonds previously unknown for other elements. It was therefore useful to consider in greater detail the results of studies in the chemistry of polynuclear technetium clusters carried out at the present time by the authors of this review.

In the deliberate search for ways to form polynuclear technetium clusters, the authors were guided by the following postulates:[13] (1) the stability and probability of the formation of polynuclear clusters should be greater in the case of a smaller effective charge on the technetium atoms, i.e. for complexes with a lower electronegativity of the ligand; (2) it is most likely that the polynuclear technetium clusters constitute a kind of intermediate link in the reduction of dinuclear clusters with multiple Tc–Tc bonds to the metallic state; (3) other conditions being equal, the probability of the formation of polynuclear clusters should be greater at high concentrations of technetium ions in solutions; (4) in the presence of a large assortment of reductants capable of reducing dinuclear technetium clusters to polynuclear clusters, it is preferable to employ reductants which do not contaminate the final products.

It was found[10,13] that all the requirements enumerated above are satisfied by the autoclave method for the reduction of technetic acid in concentrated hydrogen halide solutions by molecular hydrogen under a pressure of 3–5 MPa at 140–220 °C. A series of experiments showed that the final product of the reduction of $H(TcO_4)$ under these conditions is a mixture of outwardly similar crystalline substances with similar physicochemical properties. The mixture composition can be described by the general overall formula $[TcX_{1.8\pm0.3}\cdot .m(H_2O, OH^-, H_3O^+)]_n$, where X = I or Br and $n > 2$§.

According to X-ray electronic data,[13,57] the technetium atoms in the compounds comprising this mixture are in an average oxidation state of 2.0–1.5 [a single narrow peak with $\varepsilon(Tc_{3d_{5/2}}) = 254.7 \pm 0.3$ eV for X = Br and $\varepsilon(Tc_{3d_{5/2}}) = 254.5 \pm 0.3$ eV for X = I is observed in the spectra], while the halogen atoms in the structures of these compounds belong to at least two types: terminal [$\varepsilon(Br_{3p_{3/2}}) = 181.1 \pm 0.3$ eV; $\varepsilon(I_{4d_{5/2}}) = 48.4 \pm 0.4$ eV] and bridging [$\varepsilon(Br_{3p_{3/2}}) = 182.8 \pm 0.3$ eV; $\varepsilon(I_{4d_{5/2}}) = 49.8 \pm 0.4$ eV]. Magnetic data indicate a weak paramagnetism of the $[TcX_2.0.5H_2O]_n$ complexes, which include ~1 unpaired electron for 4–6 technetium atoms¶.

The results of the studies of the physicochemical properties of $[TcX_2.0.5H_2O]_n$ described above suggested a polynuclear structure of the compound constituting this mixture. Subsequently this hypothesis was confirmed by the X-ray diffraction analysis of single crystals of a series of compounds forming part of a mixture of polynuclear technetium bromides.[13,76–79] Using the differences between the outer appearances and physicochemical properties of the crystals, initially investigated by methods of microcrystal chemical analysis, it was later possible to achieve an initial resolution of the mixture into its constituent parts under the microscope. Such resolution made it possible subsequently to investigate thoroughly the physicochemical properties of each phase in $[TcBr_2.0.5H_2O]_n$ and to develop the optimum methods for the synthesis of these compounds. Methods for the synthesis of hexanuclear tetramethylammonium chloride cluster compounds of technetium were developed analogously.

(a) Polynuclear Cluster Bromides

$[Tc_8Br_4\mu\text{-}Br_8]Br[H(H_2O)_2]$. This octanuclear technetium cluster is the first representative of polynuclear clusters of *d* transition elements with a complex system of M–M bonds including four conjugated quadruple Tc–Tc bonds. The compound is formed on reduction of a concentrated solution of $H[TcO_4]$ or $H_2[TcBr_6]$ by molecular hydrogen under pressure (3–5 MPa) in an autoclave at 140–160 °C in concentrated hydrobromic acid. The complex crystallises in the form of black elongated tetrahedral prisms with a metallic cluster (a black powder is obtained on grinding). The crystals are insoluble in organic acids and polar and nonpolar organic solvents.

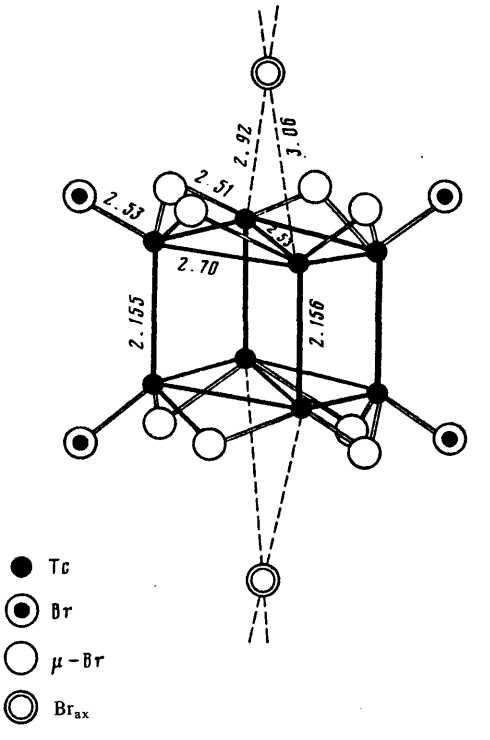

Figure 12. Fragment of the $[Tc_8Br_4\mu\text{-}Br_8]Br[H(H_2O)_2]$ structure.[78]

Fig.12 illustrates a fragment of the $[Tc_8Br_4\mu\text{-}Br_8]Br[H(H_2O)_2]$ structure. The molecule is constructed from four dinuclear Tc_2^{n+} fragments with quadruple M–M bonds located in vertical planes. Each of the eight technetium atoms is additionally bound in two "horizontal" planes by a system of M–M bonds forming two rhombs (upper and lower). Each

§ For brevity and also in view of the difficulty of the determination of the exact composition of this mixture, the above formula was used initially[10,13,57] and will be used in the present review in the form $[TcX_2.0.5H_2O]_n$.

¶ The values of μ_{eff} for $[TcX_2.0.5H_2O]$ have been determined with a low accuracy because the diamagnetic and paramagnetic contributions to the total magnetic susceptibility are comparable and the exact diamagnetic corrections for technetium compounds of this kind are unknown. For this reason, it was initially assumed[10] that the constituent compounds of this mixture are diamagnetic and only subsequent more accurate magnetic susceptibility data confirmed their weak paramagnetism,[13] the nature of which has not so been established.

technetium atom is also linked to two bridging bromine atoms which additionally span the technetium atoms in pairs in the horizontal planes. The technetium atoms located on the long diagonals of the rhombs form bonds also with the terminal bromine atoms; the remaining four technetium atoms are bound in pairs by weak electrostatic interactions in the vertical plane with two bromine atoms, each of which is analogously linked to a neighbouring polynuclear fragment.

The authors of the structural investigation[76–78] assume that the $[H(H_2O)_2]^+$ cations are present in the structure of the octanuclear complex instead of water molecules, although the location of hydrogen atoms was not established objectively. We believe[12,13] that this hypothesis requires additional investigation because the infrared spectra of this compound [namely the presence in the spectra of only the $\nu(O-H)_{H_2O} \cong 3500\ cm^{-1}$ and $\delta(H-OH)_{H_2O} \cong 1600\ cm^{-1}$ absorption bands] and its weak paramagnetism failed to confirm the presence of the $[H(H_2O)_2]^+$ cations.

$[Tc_8Br_4\mu\text{-}Br_8]Br_2[H(H_2O)_2]_2$. Under analogous conditions but at lower temperatures (130–150 °C) one of the products of the reduction of the $[TcO_4]^-$ or $[TcBr_6]^{2-}$ ions in hydrobromic acid is the complex $[Tc_8Br_4\mu\text{-}Br_8]Br_2[H(H_2O)_2]_2$. It crystallises in the form of black (without metallic lustre) elongated hexahedral prisms. On grinding, the crystals give rise to a black powder with a green tint which is soluble in hydrobromic acid and polar organic solvents with formation of a dark-green solution having a brown tint. The compound does not dissolve in non-polar organic solvents. According to preliminary data, this octanuclear complex is paramagnetic. However, a definite conclusion concerning the number of unpaired electrons is not so far possible owing to the difficulty of separating the phases and the low accuracy of the magnetochemical measurements for systems of this kind.

Preliminary X-ray diffraction data obtained for the $[Tc_8Br_4\mu\text{-}Br_8]Br_2[H(H_2O)_2]_2$ single crystal (the compound was synthesised by the authors of this review at the Institute of Physical Chemistry of the USSR Academy of Sciences and the X-ray diffraction analysis was carried out by P.A.Koz'min and co-workers at the Institute of General and Inorganic Chemistry of the USSR Academy of Sciences) have shown that its structure resembles that of $[Tc_8Br_4\mu\text{-}Br_8]Br[H(H_2O)_2]$ (Fig.12). The principal difference consists in the fact that in the case of $[Tc_8Br_4\mu\text{-}Br_8]Br_2[H(H_2O)_2]_2$ the octanuclear fragments made up of technetium atoms are not linked into infinite chains by weak electrostatic interactions with the axial bromine atoms and are separated from one another to give isolated molecules, while the axial bromine atoms are no longer bridging. The principal interatomic distances and angles in the structure of this complex are the same as in $[Tc_8Br_4\mu\text{-}Br_8]Br[H(H_2O)_2]$ (Table 1).

$[Tc_6Br_6\mu_3\text{-}(Br, OH)_6][H_3O(H_2O)_3]_2$. Following an increase of the synthesis temperature in the autoclave to ~180–200 °C and a slight decrease of the concentration of technetium ions in solution, one of the products of the reduction of $H[TcO_4]$ or $H_2[TcBr_6]$ in hydrobromic acid is a hexanuclear complex which has the tentative composition $[Tc_6Br_6\mu_3\text{-}(Br, OH)_6][H_3O(H_2O)_3]_2$ according to X-ray diffraction data for the single crystals.[79] The compound crystallises in the form of dark red-brown crystals (a red-brown powder is obtained after grinding), which are very readily soluble in polar organic solvents but less so in non-polar solvents and concentrated hydrobromic acid. The $[Tc_6Br_6\mu_3\text{-}(Br, OH)_6]^{2-}$ solutions are dark-brown and are stable in air. The hexanuclear complex is weakly paramagnetic (Table 1).[12,13]

The structure of the hexanuclear cluster technetium bromide[79] is similar to the structures of the known octahedral cluster molybdenum and tungsten halides.[2] The difference consists in the fact that in the case of technetium the positions of the bridging halogen atoms are not fully occupied (Fig.13) and some of these atoms have been substituted by bridging oxygen atoms, probably the oxygen atoms in the OH groups.

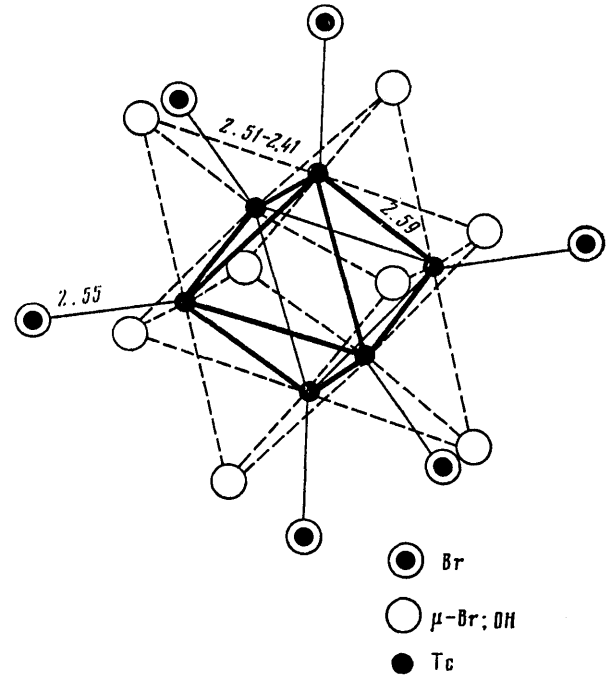

Figure 13. Fragment of the $[H_3O(H_2O)_3]_2(Tc_6Br_6\mu_3\text{-}(Br, OH)_6]$ structure (according to the data of Koz'min et al[79]).

Since X-ray diffraction analysis did not permit in this instance an unambiguous demonstration of the presence of hydrogen atoms in the structure, the above formula of the octahedral hexanuclear technetium complex cannot be regarded as finally established. Nevertheless, even the available data concerning the structure of the octahedral technetium cluster permit the important conclusion that, apart from the outer AO of the type $4d_{z^2}$, $4d_{xy,yz}$, and $4d_{x^2-y^2}$, also AO of the $4d_{xy}$ type are involved in the formation of its 15 bonding "metallic" MO.[13] We may note that a similar phenomenon has not been observed in the octahedral molybdenum and tungsten clusters, whose electronic structure is described by twelve bonding "metallic" MO formed by the AO of the metals of the d_{z^2}, $d_{xy,yz}$, and $d_{x^2-y^2}$ types.[2,80,81] Furthermore, one can state with confidence that in the technetium cluster 1–3 electrons are located in MO which are antibonding either in relation to

M–X† or M–M bonds. By virtue of the presence of these electrons, the cluster becomes paramagnetic and probably loses some of the bridging bromine atoms.

(b) Polynuclear Cluster Chlorides

The reduction of $[(CH_3)_4N]_2[TcCl_6]$ or $[(CH_3)_4N][TcO_4]$ in concentrated hydrochloric acid by molecular hydrogen under pressure (3–8 MPa) in an autoclave at 140–220 °C leads to the formation of a mixture of dark-brown almost black crystals of different geometrical shapes (tetrahedral rods, dendrides, and planar layer polyhedra). Using methods analogous to those described for $(TcBr_2.0.5H_2O)_n$, it was possible to resolve this mixture and to find the optimum conditions for the synthesis of crystals of two compounds: $[(CH_3)_4N]_3[Tc_6Cl_6\mu\text{-}Cl_6]Cl_2$ and $[(CH_3)_4N]_2[Tc_6Cl_6\mu\text{-}Cl_6]$#.

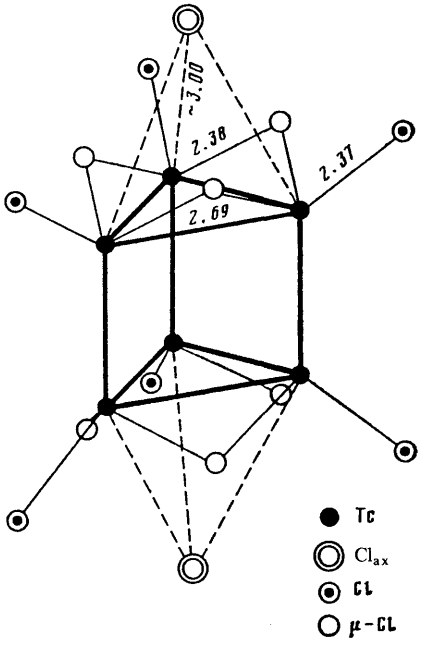

Figure 14. Fragment of the $[(CH_3)_4N]_3[Tc_6Cl_6\mu\text{-}Cl_6]Cl_2$ structure (according to the data of Koz'min et al[79]).

$[(CH_3)_4N]_3[Tc_6Cl_6\mu\text{-}Cl_6]Cl_2$ is formed with a maximum yield at 140–150 °C and an initial hydrogen pressure in the autoclave of 3–5 MPa. The compound forms elongated tetragonal rods—frequently conglomerates of such rods in the form of dendrites. After grinding, the crystals give rise to a dark-brown powder soluble in hydrochloric acid, water, alcohol, and other polar solvents, giving rise to brown solutions.[12,13]

The molecular structure of the compound is presented in Fig.14 and Table 1.[79] Evidently, in broad outline, the $\{[Tc_6Cl_6\mu\text{-}Cl_6]Cl_2\}^{3-}$ structure resembles that of the octanuclear cluster technetium bromide, but in the structure of the hexanuclear complex the Tc atoms are located at the vertices of a prism whose base consists of an equilateral triangle and not a rhomb as, for example, in the $[Tc_8Br_4\mu\text{-}Br_8].Br[H(H_2O)_2]$ structure. The vertical edges of this prism are much shorter than the horizontal edges and correspond to the quadruple Tc–Tc bonds, while the horizontal edges correspond to M–M bonds with a lower multiplicity. In addition, the technetium atoms are linked in the horizontal planes by bridging chlorine atoms. Furthermore, in the $[(CH_3)_4N]_3[Tc_6Cl_{12}]Cl_2$ molecule there are six terminal chlorine atoms and two chlorine atoms of the ionic type, which constitute a kind of axial ligands. The compound is paramagnetic (Table 1), μ_{eff} corresponding to the presence of approximately one unpaired electron per molecule.

$[(CH_3)_4N]_2[Tc_6Cl_6\mu\text{-}Cl_6]$ is formed under analogous but more severe conditions (150–180 °C) in an autoclave on reduction of $[(CH_3)_4N]_2[TcCl_6]$ or $[(CH_3)_4N][TcO_4]$ in concentrated hydrochloric acid. The crystals of this compound resemble anthracite under the microscope and have the form of orthorhombic layered plates. After grinding, a dark-brown powder with a violet tint is produced. It is soluble in hydrochloric acid, water, alcohol, and other polar solvents, giving rise to brown solutions. The complex is paramagnetic (Table 1) but it is so far impossible to specify with confidence the number of unpaired electrons in the molecule in view of the low accuracy of the magnetochemical study.

According to preliminary X-ray diffraction data, obtained by P.A.Kos'min and co-workers, the structure of the cluster is close to that of $[(CH_3)_4N]_3[Tc_6Cl_6\mu\text{-}Cl_6]Cl_2$ (Fig.14, Table 1). The differences consist in the length of the Tc–Tc bonds. For example, in the case of $[(CH_3)_4N]_2[Tc_6Cl_{12}]$ the three Tc–Tc bonds located in the vertical planes are lengthened at the expense of the shortening of the M–M bonds in two horizontal planes. Furthermore, the terminal chlorine atoms in the neighbouring polynuclear fragments play the role of axial ligands in the structure of this hexanuclear complex.

The similarity of the molecular structures of the hexanuclear technetium chlorides and the octanuclear technetium bromides suggests also the similarity of their electronic structures. For example, the vertical edges of the prism made up of the technetium atoms in the $[Tc_8Br_{12}]$, $[Tc_8Br_{12}]^+$, and $[Tc_6Cl_{12}]^-$ complexes (Figs.12 and 14 and Table 1) correspond to the quadruple M–M bonds {triple in the case of $[Tc_6Cl_{12}]^{2-}$}, formed, as in the dinuclear clusters, by the $4d_{z^2}$, $4d_{xz}$, $4d_{yz}$ AO of technetium. In addition, the $4d_{xy}$ and $4d_{x^2-y^2}$ AO of technetium also participate in the formation of this bond. However, the AO of the last two types are also involved in the formation of many-centre "metallic" MO in the horizontal planes.

Precisely because of the formation of these many-centre MO, the electron densities at the technetium atoms in the polyhedral cluster bromide are equalised, as shown by the equality of the values of $\varepsilon(Tc_{3d_{5/2}})$ for the formally heterovalent technetium atoms in these complexes (Table 1). The nature of these MO is such that they can have simultaneously both bonding (or antibonding) character in relation to

†This follows from the fact that the involvement of 5*s* AO of technetium in the formation of M–M bonds is unlikely, since they are as a rule[2–4] occupied in the formation of M–X bonds and the filling of the antibonding "metallic" MO by 7–9 electrons would have led to a considerable lengthening of the Tc–Tc bonds.

#K.E.German participated in the development of the method of synthesis of these compounds.

vertical M–M bonds and the bonding (or antibonding) character in relation to the Tc–Tc bonds in the horizontal planes. In other words, the many-centre "metallic" MO, formed mainly by the $4d_{xy}$ and $4d_{x^2-y^2}$ AO of technetium, are highly delocalised, while the remaining components of the M–M bonds remain predominantly localised at the pairs of technetium atoms.[13]

The sequence in the distribution of the many-centre MO in each specific instance can be different and depends, for example, on the ligand environment or the nuclearity of the cluster. The addition of new electrons to these MO therefore either does {as in the case of $[Tc_6Cl_{12}]^-$ and $[Tc_6Cl_{12}]^{2-}$} or does not {as in the case of $[Tc_8Br_{12}]^+$ and $[Tc_8Br_{12}]$} lead to a significant rearrangement of the system of M–M bonds in the cluster. On further addition of electrons to these MO, the role of the $4d_{xz}$, $4d_{yz}$, and even $4d_{z^2}$ AO of technetium in the formation of the many-centre M–M bonds is enhanced to an increasing extent, while their role in the formation of the Tc–Tc bonds located in the vertical planes is diminished. Ultimately, this leads to a radical rearrangement of the polynuclear cluster accompanied by the equalisation of the energies and lengths of all the M–M bonds—for example the octahedral $[Tc_6Br_6\mu_3\text{-}(Br, OH)_6]^{2-}$ cluster is formed.[13]

In conclusion of this Section, we may note that only the first steps have been taken in the chemistry of polynuclear cluster compounds of technetium: in the first place much remains obscure not only in the description of the electronic structure and mechanism of the formation of these compounds but also even in the determination of their exact composition. The unusual structure of these compounds, which have no analogues among the polynuclear clusters of other elements, the similarity of the properties and compositions of various compounds of this class to one another, and also the ease of their interconversions are all factors hindering the identification and isolation of the polynuclear technetium clusters in a pure state and hence also the investigation of their physicochemical properties. However, the data already available in this field indicate, on the one hand, the enhanced capacity of technetium for the formation of polynuclear clusters with weak-field ligands and, on the other hand, the "anomaly" in the properties of the technetium clusters compared with the typical clusters of other *d* elements. The increased capacity of technetium for the formation of paramagnetic clusters as well as clusters with a complex system of non-equivalent M–M bonds may be included among such "anomalous" properties.

III. CHEMICAL PROPERTIES IN SOLUTIONS

1. The Formation of M–M Bonds

A study[7] of the reduction of $[PyH]_2[TcCl_6]$ by molecular hydrogen under pressure in an autoclave in hydrochloric acid with a gradual increase of the working temperature showed that the $(PyH)_2.[Tc_2Cl_8]_3.2H_2O$ cluster is formed at an HCl concentration of 4–5 M. The $[TcCl_6]^{2-}$ ions, which are present prior to the formation of the clusters, are hydrolysed partially under these conditions at ~120 °C:

$$[TcCl_6]^{2-}+2H_2O\rightarrow[Tc(OH)_2Cl_4]^{2-}+2HCl. \qquad (1)$$

The hydrolysed technetium(IV) ions are readily reduced by molecular hydrogen, which is accompanied by the formation of M–M bonds:

$$[Tc(OH)_2Cl_4]^{2-} \xrightarrow{H_2} [Tc_2Cl_{8-x}(OH)_x]^{3-} \xrightarrow{HCl} [Tc_2Cl_8]^{3-}. \qquad (2)$$

The hydrolysed $[Tc_2Cl_{8-x}(OH)_x]^{3-}$ ions thus formed are rapidly converted into $[Tc_2Cl_8]^{3-}$ on interaction with concentrated hydrochloric acid. We may note that the substitution of chloride ions by H_2O molecules is also possible in reactions (1) and (2).

The above study[7] showed that the formation of $[Tc_2Cl_8]^{3-}$ ions must be preceded by a stage involving the formation of the hydrolysed clusters. The hydrolysis in an autoclave at an elevated temperature is promoted by a decrease of the concentration of hydrochloric acid as a result of its partial evaporation. We may note that the formation of hydrolysed cluster complexes is observed also in the reduction of technetium(IV) in concentrated hydrochloric acid on refluxing with metallic zinc.[5]

2. The Behaviour of the $[Tc_2X_8]^{3-}$ Ions in Solutions of Hydrogen Halides

In order to elucidate the causes of the increased stability of the hydrolysed cluster ions compared with the unhydrolysed ions, further studies were made of the behaviour of $[Tc_2X_8]^{3-}$ (where X = Cl, Br, or I) in solutions of hydrogen halides.[8,23,24,82] They were performed mainly in relation to the most stable and most readily synthesised $[Tc_2Cl_8]^{3-}$ ion (Fig.2); kinetic methods with optical recording were employed. The identity of the reaction products was in most cases confirmed by their isolation in the solid phase. The studies showed that the stability of the $[Tc_2X_8]^{3-}$ ions (where X = Cl, Br, or I) in aqueous solutions is determined by the sum of competing processes: acid hydrolysis, complex formation with subsequent disproportionation and dissociation of the M–M bonds, and oxidative addition of atmospheric oxygen to the Tc–Tc multiple bond. We shall consider these processes in greater detail.

(a) Acid Hydrolysis (Anation Reactions)

$$[Tc_2X_8]^{3-}+nH_2O\rightleftarrows[Tc_2X_{8-n}(H_2O)_n]^{(3-n)-}+nX^-. \qquad (3)$$

The acid hydrolysis (anation) reactions predominate when the concentration of hydrogen halide in solution is $\lesssim$3 M. They are not accompanied by the dissociation of the M–M bonds and the oxidation of the hydrolysis product by atmospheric oxygen. The final product of reaction (3) is the hydrated cluster technetium oxide $Tc_4O_5.14H_2O$ (Table 1). The tendency towards hydrolysis increases in the sequence of halogens Cl < Br < I.[11,13,23,24,82]

(b) Complex Formation

$$[Tc_2X_8]^{3-}+X^-\rightleftarrows[Tc_2X_9]^{4-}. \qquad (4)$$

The complex formation reactions predominate in concentrated hydrogen halide solutions. When the ligands are replaced in the sequence X = Cl, Br, and I, the equilibrium in reactions (4) shifts increasingly to the right. The $[Tc_2X_9]^{4-}$ ion formed under these conditions apparently no longer has an eclipsed conformation, its Tc–Tc bond is appreciably weakened, and it can readily undergo further reactions leading to the dissociation of the M–M bonds.[8,11,13,24,82]

(c) Disproportionation with Dissociation of the M–M Bond

$$[Tc_2X_9]^{4-}+X^- \rightleftarrows [Tc(II)]+[Tc(III)]. \quad (5)$$

The mononuclear technetium(II) and technetium(III) formed as a result of this reaction are unstable and undergo further rapid reversible reactions involving disproportionation, oxidation by atmospheric oxygen, and dimerisation:[13,24]

$$[Tc(II)]+[Tc(II)] \overset{HX}{\rightleftarrows} [Tc_2X_6]^{2-}; \quad (6)$$

$$[Tc(III)]+[Tc(III)] \overset{HX}{\rightleftarrows} [Tc_2X_8]^{2-}; \quad (7)$$

$$[Tc(III)]+[Tc(III)] \overset{HX}{\rightleftarrows} [TcX_6]^{2-}+[Tc(II)]; \quad (8)$$

$$[Tc(II)] \xrightarrow[HX]{O_2} [TcX_6]^{2-}; \quad (9)$$

$$[Tc(III)] \xrightarrow[HX]{O_2} [TcX_6]^{2-}. \quad (10)$$

In the absence of oxidants, for example atmospheric oxygen, an overall mobile equilibrium is established:[13,24]

$$4[Tc_2X_8]^{3-} \rightleftarrows 2[TcX_6]^{2-}+3[Tc_2X_6]^{2-}+2X^-. \quad (11)$$

Analysis of reactions (1)–(8) and (11) shows that there exists a narrow range of HX and technetium ion concentrations in which there is a possibility of a prolonged existence of $[Tc_2X_8]^{3-}$ and the limits of this range become very markedly narrower in the sequence of halogens Cl > Br > I. For example, at an initial concentration $[Tc_2Cl_8]^{3-} > 10^{-2}$ M and for ~3 M < [HCl] < ~6 M, the solutions of the octachloroditechnetate can exist indefinitely without visible changes in the absence of atmospheric oxygen, while the octaiododitechnetates decompose almost at the instant of their formation in hydriodic acid. The octabromoditechnetates, which can be obtained at a high (~1 M) concentration of technetium ions and a high temperature in the autoclave {when the autoclave is cooled, crystals of $M_3[Tc_2Br_8].nH_2O$ are precipitated and virtually only the $[TcBr_6]^{2-}$ and $[Tc_2Br_6]^{2-}$ ions remain in the mother liquor}, occupy an intermediate position.

Thus partial evaporation of HCl in the synthesis of $[Tc_2Cl_8]^{3-}$ by the method of Eakins et al[5] and by the autoclave method[6–8] creates favourable conditions (from the standpoint of the acidity and the concentration of technetium ions in solution) for the formation of the octachloroditechnetates(+2.5), since, on the one hand, the rate of reduction of the technetium(IV) ions increases owing to their hydrolysis,[7] and, on the other, the stability of the hydrolysed cluster ions formed increases in relation to the reactions involving disproportionation and oxidation by atmospheric oxygen.[13,23,24,82] We may note that, under the conditions of more pronounced hydrolysis, the rate of reduction of technetium(IV) increases so much that the formation of metallic technetium becomes possible.

3. Oxidation-reduction Reactions

In solutions with a high $[Tc_2Cl_8]^{3-}$ concentration the octachloroditechnetate ions can enter into reactions in which oxygen undergoes oxidative addition to the Tc–Tc multiple bond:[11,13,24,82]

$$[Tc_2Cl_8]^{3-}+O_2 \rightarrow [Tc_2Cl_8O_2]^{3-}. \quad (12)$$

The Tc–Tc bond in dinuclear $Tc^{4.5+}$ complexes formed is greatly weakened (Table 1) and the complexes readily decompose in HCl solutions to the mononuclear complexes of quinquevalent and quadrivalent technetium:

$$[Tc_2Cl_8O_2]^{3-} \xrightarrow{HCl} [TcO(OH)Cl_4]^{2-}+[TcCl_6]^{2-}. \quad (13)$$

In the absence of complex-forming agents and in aprotic solvents the $[Tc_2Cl_8O_2]^{3-}$ ions are comparatively stable and can be isolated in the form of the salt $K_3[Tc_2Cl_8O_2]$ (Table 1). We may note that the analogous reactions involving the addition of oxygen to the quadruple M–M bond in the $[Tc_2Cl_8]^{2-}$ complexes lead to the formation of mononuclear oxohalogenotechnetium(V) complexes even in aprotic solvents:[13]

$$[Tc_2Cl_8]^{2-}+O_2 \rightarrow [Tc_2Cl_8O_2]^{2-} \rightarrow 2[TcOCl_4]^-. \quad (14)$$

Oxidative addition reactions have been recently observed also for the dinuclear clusters of other *d* transition elements with multiple M–M bonds.[83] The multiplicity of the M–M bonds must decrease in these reactions. It is known from organic chemistry that similar reactions are extremely characteristic of unsaturated organic compounds. We believe that the capacity for oxidative addition reactions is a common property of homeopolar multiple bonds.

Apart from the reactions involving the oxidative addition of oxygen, the usual oxidation-reduction reactions have also been observed for dinuclear technetium clusters with multiple M–M bonds (in this case they must be accompanied by a change in the multiplicity of the Tc–Tc bonds up to their complete dissociation):[10,13,20,22,24]

$$[Tc_2Cl_8]^{2-} \xrightarrow[HCl]{O_2} [Tc_2Cl_8]^{3-}; \quad (15)$$

$$[Tc_2Cl_8]^{3-} \xrightarrow[-e^-]{O_2} [Tc_2Cl_8]^{2-}. \quad (16)$$

Reaction (15) is very rapid and takes place in hydrochloric acid solution. Reaction (16) is slower and is characteristic of aprotic solvents since the $[Tc_2Cl_8]^{2-}$ ions rapidly decompose in hydrochloric acid solutions via reactions of type (4)–(11). In the presence of an excess of the reductant, reactions (15) and (16) can also proceed in the reverse direction.

4. The Ligand Substitution Reaction

Three types of ligand substitution reactions are now known for technetium clusters.

(a) Reversible substitution of monodentate ligands by other monodentate ligands:[10,11,13,22,24]

$$[Tc_2Cl_8]^{2-}+8X^- \rightleftarrows [Tc_2X_8]^{3-}+8Cl^-; \quad (17)$$

$$[Tc_2Cl_8]^{2-}+8X^- \rightleftarrows [Tc_2X_8]^{2-}+8Cl^-; \quad (18)$$

$$[Tc_2Cl_8]^{2-}+8X \rightleftarrows [Tc_2X_8]^{2}+8Cl^-. \quad (19)$$

The equilibria in these reactions are strongly displaced to the right for X = Br or I. The formation of mixed complexes has not been observed.

(b) Reversible substitution of monodentate ligands by bidentate ligands (Figs.3–6):[9–11,13,18]

$$[Tc_2Cl_8]^{3-}+4CH_3COO^- \rightleftarrows [Tc_2(CH_3COO)_4Cl_2]^-+6Cl^-; \quad (20)$$

$$[Tc_2(CH_3COO)_4Cl_2]^- \overset{CH_3COOH}{\rightleftarrows} [Tc_2(CH_3COO)_4Cl]+Cl^-; \quad (21)$$

$$[Tc_2Cl_8]^{3-}+4o\text{-}C_6H_4(OH)N \rightleftarrows [Tc_2(C_6H_4ON)_4Cl]+7Cl^-+4H^+. \quad (22)$$

These reactions proceed in the forward direction only at high temperatures (~120 °C) and in the presence of an excess of the bidentate complex-forming agent, while the reverse reactions (20)–(22) take place also at room temperature in the presence of an excess of HCl.

(c) Oxidative substitution of monodentate ligands by bidentate ligands (Figs.4, 6, and 8):[10,13,17]

$$[Tc_2Cl_8]^{3-} \xrightarrow[-6Cl^-;\ -e^-]{(CH_3)_3CCOOH} \{Tc_2[(CH_3)_3CCOO]_4Cl_2\}; \qquad (23)$$

$$[Tc_2X_6]^{2-} \xrightarrow[-5X^-,\ -e^-]{CH_3COOH} [Tc_2(CH_3COO)_4X]. \qquad (24)$$

These reactions are irreversible; organic acid ions apparently behave in the reactions as oxidants, being converted into the corresponding alcohols and their esters.[13] Reactions (23) and (24) take place only at high temperatures (>150 °C) and in the presence of a large excess of organic acid.

Disproportionation reactions of type (11) with formation of $[Tc_2X_6]^{2-}$ and $[TcX_6]^{2-}$ take place simultaneously with the ligand substitution reactions (17), (18), and (20) involving the $[Tc_2X_8]^{3-}$ complexes. However, the analogous complexes with bidentate bridging ligands (the d^4–d^5 complexes with the "lantern" structure—see Figs.4–6) do not undergo disproportionation reactions.[9] This fact constitutes additional confirmation that the disproportionation of $[Tc_2X_8]^{3-}$ is accompanied by the dissociation of the Tc–Tc bond, while the bidentate bridging acetate ions stabilise these bonds. We may note that the dinuclear complexes with Tc–Tc bonds behave analogously also in thermal decomposition reactions.

5. Reactions of Polynuclear Cluster Compounds

On further reduction of the $[Tc_2X_6]^{2-}$ ions in an autoclave with molecular hydrogen under pressure in concentrated solutions of hydrogen halides, there is a possibility of cycloaddition reactions:[10,12,13]

$$n[Tc_2X_6]^{2-} \xrightarrow[-kX^-]{me^-} [Tc_{2n}X_{6n-k}]^{(2n+m-k)-}. \qquad (25)$$

Since reactions with an order greater than two are unlikely in solutions, one may postulate that reaction (25) takes place in stages, i.e. tetranuclear, hexanuclear, octanuclear, etc, technetium clusters should be formed in the $[Tc_2X_6]^{2-}$ reduction processes.

Hexanuclear and octanuclear technetium clusters of this type, which have not so far been synthesised for other *d* elements, have now been characterised by means of X-ray diffraction[76,79] (Figs.12 and 14 and Table 1). A characteristic feature of these clusters is the presence in their structure of several quadruple Tc–Tc bonds and of a system of many-centre M–M bonds. Several $[Tc_2X_2\mu\text{-}X_4]$ fragments, which are residues of the $[Tc_2X_6]^{2-}$ ions, can be readily differentiated in both structures. Since the appearance of the quintuple Tc–Tc bond (σ^2, $2\pi^2$, δ^2_{xy}, $\delta^2_{x^2-y^2}$) is most likely in the $[Tc_2X_6]^{2-}$ ions, reaction (25) may be regarded as a kind of cyclic polycondensation reaction involving the binding of the $[Tc_2X_6]^{2-}$ monomers to one another via the formation of many-centre M–M bonds with a simultaneous decrease of the multiplicity of the Tc–Tc bond in the monomers to 4.0. Some of the halogen ions are then split off from the monomers, while others become bridging species linking the monomers to one another.

One must note the similarity of these reactions to the analogous cycloaddition reactions of unsaturated organic compounds (for example, to the trimerisation of acetylene with formation of benzene). However, inorganic cycloaddition reactions are not accompanied by the initial formation of a system of conjugated equivalent M–M bonds of high multiplicity, although in the present instance there are grounds for such hypothesis. From our point of view,[13] the reason for this is the higher potential barrier for this kind of redistribution of electron density in the case of quadruple M–M bonds.

Special mention must be made of the role of unpaired electrons in inorganic cycloaddition reactions of type (25). For example, according to preliminary data,[13] the $[Tc_2X_6]^{2-}$ anions do not enter directly into reaction (25) and only the products of their one-electron reduction, which are probably the $[Tc_2X_6]^{3-}$ ions with unpaired electron, initiate these reactions. Thus monomers of the type of $[Tc_2X_6]^{3-}$ with a single unpaired electron behave, on the one hand, as analogues of organic radicals in polymerisation reactions and, on the other hand, the presence of the unpaired electron leads to the removal of the prohibition of cycloaddition reactions with thermal excitation (this conclusion follows from the theory of the conservation of orbital symmetry in cycloaddition reactions[85,86]).

A further increase of the temperature of the synthesis in the autoclave (in hydrobromic acid) leads to the formation of octahedral technetium clusters with equivalent M–M bonds (Fig.13 and Table 1) of the type of $[H_3O(H_2O)_3]_2[Tc_6Br_6\mu\text{-}(Br, OH)_6]$.[10,13] On the basis of general considerations, one can postulate that the compound is formed either directly in the cycloaddition reactions of the $[Tc_2X_6]^{n-}$ anions (where $n = 2$ or 3) or via a rearrangement of the hexanuclear or octanuclear clusters with quadruple M–M bonds which have already been formed. Thus, an unambiguous solution of the problem of the mechanism of the formation of the given octahedral cluster requires in the first place the elucidation of the form (polynuclear or dinuclear) in which the hexanuclear and octanuclear technetium clusters with quadruple M–M bonds exist in solution. Since the solubility of these compounds becomes appreciable only at a high temperature in the autoclave, the elucidation of the form in which these clusters exist in solutions of hydrogen halides involves considerable experimental difficulties.

Thus, the chemical properties of the technetium clusters are similar to those of the usual mononuclear complexes (hydrolytic reactions, reactions involving the substitution of monodentate ligands by other monodentate ligands, complex formation reactions, and oxidation-reduction processes) as well as typical polynuclear clusters of other *d* transition elements (reactions accompanied by a change in the multiplicity of the M–M bonds up to their complete dissociation and by the substitution of monodentate ligands by bidentate ligands with formation of complexes having a structure of the "lantern" type). However, some of the reactions of the dinuclear and polynuclear technetium clusters are characteristic also of unsaturated organic compounds with multiple homeopolar bonds: reactions involving oxidative addition to multiple bonds and reactions in which multiple bonds undergo cycloaddition with formation of closed cyclic systems.

In a number of cases "anomalies" were observed in the properties of technetium cluster compounds compared with the clusters of other *d* transition elements, for example an increased capacity for the formation of stable paramagnetic clusters or clusters with complex systems of M–M bonds, including several quadruple Tc–Tc bonds. Naturally one cannot exclude the possibility that these "anomalies" are caused solely by the lack of adequate experimental data on the clusters of other *d* transition elements and that in the future similar properties will be observed also for clusters

of other metals. However, it is likewise probable that by virtue of its "crossing" position in Mendeleev's Table, technetium should possess simultaneously the capacity for the formation of both dinuclear clusters with weak-field ligands and M–M bonds having a high multiplicity and polynuclear clusters with strong- and weak-field ligands. It may be that the "anomalous" properties of technetium clusters are due precisely to this factor and also the fact that the theory of clusters is as yet too inadequate to explain unambiguously and to predict all the wide variety of the properties of these compounds.

IV THERMOCHEMICAL BEHAVIOUR

The thermal stability of the dinuclear clusters has been studied in order to elucidate the mechanisms of the thermal decomposition and the composition of the intermediates, to establish the relation between composition and thermal stability, and to elucidate the possibility of obtaining metallic technetium and coatings based on it. Investigations have shown that the thermal decomposition of technetium cluster compounds is a multistage process, which depends on the composition and structural features of the initial compound. In many cases the thermal decomposition is accompanied by disproportionation into technetium(IV) and metallic technetium:[39,87]

$$K_3[Tc_2Cl_8]\cdot 2H_2O \xrightarrow{130-160^\circ} K_3[Tc_2Cl_8] + 2H_2O \xrightarrow{370-450^\circ} \rightarrow 5/4K_2[TcCl_6] + 1/2KCl + 3/4Tc; \quad (26)$$

$$K_2[Tc_2X_6]\cdot 2H_2O \xrightarrow{130-150^\circ} K_2[Tc_2X_6] + 2H_2O \xrightarrow{550-650^\circ} K_2[TcX_6] + Tc, \quad (27)$$

where X = Cl or Br. If the hexahalogenotechnetate(IV) formed initially is thermally stable, as, for example, $K_2[TcCl_6]$, it remains in the system up to 1100 °C; otherwise it undergoes further thermal decomposition:[88]

$$K_2[TcBr_6] \xrightarrow{700-750^\circ} 2KBr + 2Br_2 + Tc. \quad (28)$$

We may note that reactions (26)–(28) are characteristic solely of cluster complexes with inorganic cations. For organic cations, the thermal decomposition of the cluster can proceed by one of the following pathways:[39]

$$(PyH)_3[Tc_2Cl_8]\cdot 2H_2O \xrightarrow{130^\circ} (PyH)_3[Tc_2Cl_8] + 2H_2O \xrightarrow{250-280^\circ} \rightarrow (PyH)Cl + [Tc_2(Py)_2Cl_5] + 2HCl \xrightarrow{415^\circ} 2Tc + 2Py + {}^5/_2Cl_2; \quad (29)$$

$$[(C_2H_5)_4N]_2[Tc_2Cl_8] \xrightarrow{298-305^\circ} 2Tc + 5/2Cl_2 + 2(C_2H_5)_3N + HCl + C_2H_4. \quad (30)$$

The second stage of the thermolysis of $(PyH)_3[Tc_2Cl_8]\cdot 2H_2O$ (at 250–280 °C) proceeds via the mechanism of Andersen's reaction and is accompanied by the migration of pyridine to the inner coordination sphere of the dinuclear complex [the ν(Tc–N) are 234 and 258 cm^{-1}]. The disproportionation of the dinuclear complex is not observed at this stage and its Tc–Tc bond is retained.[39] This is indicated by infrared and ESCA spectroscopic data as well as measurements of the static magnetic susceptibility (Table 1). In the case of the mononuclear pyridinetechnetium(IV) chloride complex the migration of pyridine into the coordination of sphere of technetium consists of two stages:[89,90]

$$(PyH)_2[TcCl_6] \xrightarrow{250^\circ} (PyH)[TcPyCl_5] + HCl \xrightarrow{316^\circ} [TcPy_2Cl_4] + HCl. \quad (31)$$

The thermal decomposition of the tetraethylammonium cluster via reaction (30) takes place in one stage, but the metallic technetium formed in this process is frequently contaminated by the carbide TcC.[39]

The thermal decomposition of $K[Tc_2(CH_3COO)_4]Cl_2$ also takes place in one stage with absorption of much heat:

$$2K[Tc_2(CH_3COO)_4]Cl_2 \xrightarrow{400-460^\circ} 2KCl + 4Tc + 4(CH_3CO)_2O + Cl_2 + 2O_2. \quad (32)$$

In contrast to reactions (29) and (30), reaction (32) is relatively unsuitable for the preparation of pure metallic technetium in the laboratory, as in this case the final products contain large amounts of potassium chloride.

Studies of the thermal stability of dinuclear cluster carboxylates with a structure of the "lantern" type, not containing inorganic cations (Figs.4 and 6), are of considerable interest, since in this instance the decomposition of the complexes is preceded by a sublimation stage and the gaseous product formed decomposes to metallic technetium on the walls of the reaction vessel:[39]

$$2[Tc_2(CH_3COO)_4]Cl \xrightarrow{400-460^\circ} 4Tc + 4(CH_3COO)_2O + Cl_2 + 2O_2; \quad (33)$$

$$2[Tc_2(CH_3COO)_4]Br \xrightarrow{400-460^\circ} 4Tc + 4(CH_3COO)_2O + Br_2 + 2O_2. \quad (34)$$

The metallic technetium deposited on the walls of the reaction vessel is not contaminated by solid extraneous impurities. When the conditions are chosen appropriately, this method can be used to prepare technetium coatings which nowadays can be of great practical importance, in the preparation of sources of β-radiation for radiography[91] and also of anti-corrosion materials and materials resisting surface growth.[92]

Thus the data presented in the review permit the conclusion that technetium is one of the most powerful cluster forming agents: in the lowest oxidation states it is characterised by a tendency towards the formation of dinuclear and polynuclear clusters with both strong-field and weak-field ligands and M–M bonds of different multiplicity. The properties of the technetium clusters are closest to those of the analogous rhenium and molybdenum compounds.[1-4,32-34,93-106] However, there are also certain unusual properties. In the first place there is an increased tendency towards the formation of stable paramagnetic dinuclear and polynuclear clusters with a single unpaired electron in one of the antibonding "metallic" MO. The presence of this electron leads to the additional stabilisation of the technetium clusters. This phenomenon has been observed also for the clusters of other *d* elements, but in technetium it is more pronounced owing to the reduction of the effective charge on its atoms on formation of M–M bonds. Such reduction of Z_{eff} is responsible for the appearance in technetium of an increased tendency towards the formation of different types of cluster compounds with weak-field ligands which are readily interconverted. By virtue of this property, polynuclear clusters belonging to a new class with a complex system of M–M bonds, including several quadruple or triple Tc–Tc bonds, have been obtained for the first time for technetium. The polynuclear technetium clusters have an excess of electrons and are of interest for experimenters and theoreticians.

Phosphinepalladium and Phosphineplatinum Carbonyl Cluster Compounds

N.K.Eremenko, E.G.Mednikov, and S.S.Kurasov

The state of the chemistry of the cluster compounds of palladium and platinum is examined. The principal properties, structure, chemical reactions, and methods of synthesis of the phosphinepalladium and phosphineplatinum carbonyl clusters are described and the methods used to regulate the nuclearity of the clusters and their interconversions are discussed. The bibliography includes 69 references.

I. INTRODUCTION

Several classifications of the cluster compounds of metals are available at the present time,[1] but the phosphinemetal carbonyl clusters have not been differentiated into an independent group in any of them. This is justified in relation to the phosphinemetal carbonyl clusters for metals belonging to the Fe and Cl triads, which are merely modifications of the corresponding carbonyl compounds obtained by substituting some of the CO groups by tertiary phosphines. However it does not apply to phosphinemetal carbonyl clusters of metals belonging to the Ni triad, which have no corresponding neutral carbonyl precursors and which have a unique intrinsic structure.

The stability of a cluster with a specific number of metal atoms n is determined by a fairly fine balance between the number of the valence electrons belonging to the metallic framework proper, the number of electrons supplied by the ligands, and the steric characteristics of the ligands. The clusters of metals having a large number of valence electrons (Ni, Pd, Pt, Au) are able to coordinate the smallest number of ligands in the clusters of preceding transition metals, which leads, for comparable dimensions of the metallic framework, to an incomplete filling of the surface of the framework by ligands and an inadequate steric stabilisation of the cluster. Tertiary phosphines as ligands are isoelectronic with carbon monoxide and, for the same number of valence electrons introduced into the cluster molecule, ensure a more effective shielding of the surface of the metallic framework. We believe that this is the explanation of the transition from the neutral purely carbonyl clusters of the Fe and Co triads to the phosphinepalladium and phosphineplatinum carbonyl clusters and the phosphinegold clusters. In other words, just as carbonyl clusters are typical for the Fe and Co triads, the phosphinemetal carbonyl clusters are typical for platinum and palladium and characterise the capacity of these metals for cluster formation. The phosphinemetal carbonyl clusters examined in this review are not the only palladium and platinum clusters. There exist a series of clusters of these metals with a wide variety of ligands: $[Pd_4(CO)_4(OAc)_4]$,[2] $[Pd_4(phen)_4(CO)_2](OAc)_4$,[3] $[Pd_3(SO_2)_2.CNBu)_5]$,[4] $[Pd_3(\mu\text{-}Cl)(\mu\text{-}PPh_2)_2(PEt_3)_3]BF_4$,[5] $[Pt_3(CNBu_6]$,[6] $[Pt_3(\mu\text{-}SO_2)_3(PPh_3)_3]$,[7,8] $[Pt_3(Ph)(\mu\text{-}PPh_2)_2(PPh_3)_3]$,[9] $[Pt_3(\mu\text{-}Ph)(\mu\text{-}PPh_2)(\mu\text{-}SO_2)(PPh_3)_3]$,[10] $[Pt_3(cod)_3(\mu_3\text{-}SnCl_3)_2]$,[11] $[Pt_4(OAc)_8]$,[12] $[Pt_5H_8P(t\text{-}Bu_2Ph)_5]$,[13] [$Pt_7$(2,6-xylyl isocyanide)$_{12}$],[14] and $[Pd_3(\mu\text{-}CO)(dppm)_3]^{2+}$,[18] where phen = phenanthroline, cod = cyclo-octa -1,5-diene, and dppm = bis(diphenylphosphino)methane.

It is noteworthy that, apart from the series of anionic platinum carbonyls i.e. $[Pt_3(\mu\text{-}CO)_3(CO)_3]_n^{2-}$ (n = 1, 2, 3, 4, 5, 6),[15,16] $[Pt_{19}(CO)_{22}]^{4-}$, $[Pt_{26}(CO)_{32}]^{2-}$, and $[Pt_{38}.(CO)_{44}H_2]^{2-}$,[17] investigated by Chini and co-workers, the majority of the remaining compounds are represented in the literature by single examples and are not discussed in this review. The structures, physicochemical properties, and reactivities of neutral phosphinepalladium and phosphineplatinum carbonyl clusters are examined below in succession.

II. TYPES OF PHOSPHINEPALLADIUM AND PHOSPHINEPLATINUM CARBONYL CLUSTERS.

1. The Trinuclear Clusters $M_3(CO)_3L_3$

Clusters having this composition are known mainly for bulky ligands [L = P(t-Bu)$_3$, PPh(t-Bu)$_2$, and P(cyclo-C_6H_{11})$_3$ (Table 1)]. The method of their synthesis is based on the interaction of coordination-unsaturated compounds of the type of PdL_2 or PtL_2 with carbon monoxide; intermediate phosphinemetal carbonyl complexes are formed and are then converted into the $M_3(CO)_3L_3$ clusters. The reaction is rapid and the yields of the desired products are high (>90%). In certain cases hydride complexes were used as the starting compounds:[23-25]

$$3PtH_2[P(t\text{-}Bu)_3]_2 \xrightarrow{CO} \{Pt(CO)[P(t\text{-}Bu)_3]\}_3 + 3P(t\text{-}Bu)_3 + 3H_2;$$

$$3\{PtH(\mu\text{-}H)[P(t\text{-}Bu)_3]\}_2 \xrightarrow{CO} 2\{Pt(CO)[P(t\text{-}Bu)_3]\}_3 + 3H_2;$$

$$3\ trans\text{-}[PtH(NH_3)(PR_3)_2]^+ \xrightarrow[acetone]{CO} [Pt_3(CO)_3(PR_3)_3] + 3NH_4^+;$$

$$PR_3 = P(t\text{-}Bu)_3, PPh(t\text{-}Bu)_2.$$

X-Ray diffraction analysis has been carried out for the compound $Pt_3(CO)_3[P(cyclo\text{-}C_6H_{11})_3]_3$.[26] The metallic skeleton of the cluster has the form of an equilateral triangle all the sides of which are spanned by bridging CO groups (Fig.1); the phosphorus atoms are located in the plane of the triangle.

The D_{3h} symmetry of these compounds is also confirmed by ^{31}P and ^{195}Pt NMR data for the $Pt_3(CO)_3[P(cyclo\text{-}C_6H_{11})_3]_3$ cluster in solution.[21] The presence of the ^{31}P and ^{195}Pt nuclei in the cluster ensures that the NMR spectra yield much information and a virtually unambiguous interpretation of the structure of the compound in solution. Since the content of the ^{195}Pt isotope is 33.7% in natural compounds,

the ^{31}P spectrum consists of a superposition of the spectra of the three isotopomers (A), (B), and (C), while the ^{195}Pt spectrum consists of a superposition of two such isotopomers, namely (B) and (C) (Fig. 2). The content of the isotopomer with three magnetic platinum nuclei is low (3.70%) and the isotopomer is not manifested in the spectra. The observed spin–spin coupling constants are listed in Table 2.

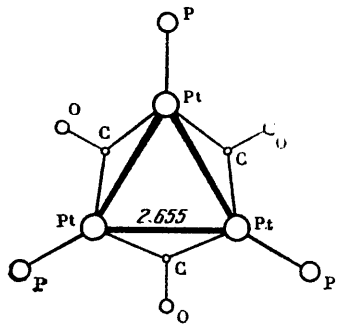

Figure 1. The structure of the $Pt_3(CO)_3[P(cyclo\text{-}C_6H_{11})_3]_3$ cluster.[26]

A more complex pattern is observed in the infrared spectra of the compounds investigated. The stretching vibrations of the CO groups in the phosphinemetal carbonyl clusters are clearly shown in the infrared spectra, which can serve as a basis for structural analysis. According to the D_{3h} symmetry, a single ν(CO) band should be observed in the spectra of these compounds. However, the data obtained (Table 3) indicate a more complex character of the spectra. In most cases two bands are observed in the ν(CO) region and for palladium compounds even three bands are found. Such increase in the complexity of the spectra of the $M_3(CO)_3L_3$ clusters is associated with the influence of a number of factors (dissociation, change in nuclearity, etc.). It is noteworthy that in the description of the infrared spectroscopic data only the solvent is usually indicated and the influence of the gas phase (inert gas, CO, air), which is insignificant in the case of trinuclear clusters, is disregarded.[27] This is probably one of the causes of the conflicting infrared spectroscopic data.

Table 1. The synthesis of phosphinemetal carbonyl clusters $M_3(CO)_3L_3$ and $M_3(CO)_3L_4$.

Cluster	Initial compound	M:P*	Conditions of synthesis	Refs.

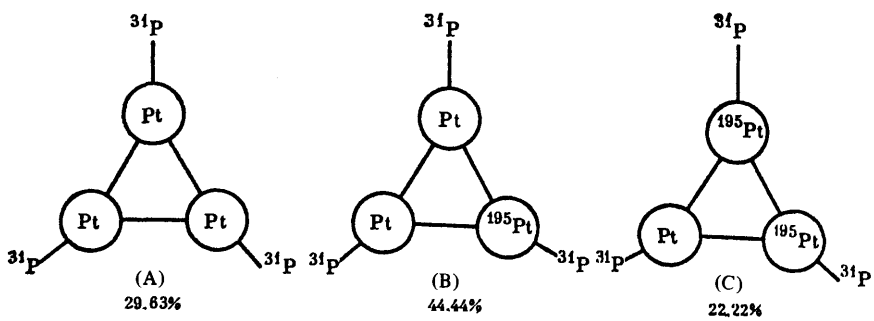

Figure 2. Principal types of the isotopomers of the $Pt_3(CO)_3L_3$ cluster.

2. Trinuclear $M_3(CO)_3L_4$ Clusters

This group of clusters is known for a fairly large number of ligands (Table 1). The trinuclear palladium clusters† are obtained by reducing $PdCl_2L_2$ with carbon monoxide (L = PPh_3) or by reducing $Pd(OAc)_2$ in the presence of NaOAc and two equivalents of a phosphine ligand [L = PPh_3, $P(C_6H_4\text{-}p\text{-}CH_3)_3$, or $P(C_6H_4\text{-}p\text{-}OCH_3)_3$]. The trinuclear platinum clusters were obtained by the following procedures:

(a) by treating the compound $Pt(cod)_2$ with phosphine and carbon monoxide. A solution of $Pt(cod)_2$ in petroleum ether is treated with carbon monoxide for approximately 0.5 h after adding the phosphine [L = PEt_3, $PMePh_2$, $PEt_2(t\text{-}Bu)$, or PPh_2Bz] and the solvent is then distilled off and the required product is extracted from the residue; the yield is 50%.[31]

(b) By reducing sodium tetrachloroplatinite. A solution of Na_2PtCl_4 is treated with the phosphine and is boiled until the complete precipitation of $PtCl_2L_2$, after which is it treated with hydrazine hydrate and saturated with carbon monoxide. A solution of KOH is then introduced, the reaction mixture is again heated, boiled, and filtered. This procedure leads to the formation of the complex $Pt^0(CO)_2L_2$, which is subsequently converted on heating into the $Pt_3(CO)_3L_4$ cluster (L = PPh_3, $PMePH_2$, or $PEtPh_2$). The yield of the required product is usually 20–40%.[22]

(c) By the interaction of platinum dicarbonyl with phosphines. A solution of Na_2PtCl_4 in acetone, alcohol, or another organic solvent is treated at room temperature with carbon monoxide for 1–2 days. After the formation of platinum dicarbonyl, concentrated ammonia is added, whereupon the solution becomes bright green and capable of reacting with phosphine. When an aromatic phosphine is added to the alcoholic solution, the precipitation of the $Pt_3(CO)_3L_4$ cluster, where L = PPh_3, $P(C_6H_4\text{-}p\text{-}CH_3)_3$, $P(C_6H_3\text{-}p\text{-}OCH_3)_3$, or PPh_2Et, begins immediately. The yield of the product after recrystallisation is approximately 50%. The reaction with straight-chain aliphatic phosphines takes place nonselectively and admixtures are formed, causing rapid decomposition of the required product.[30]

Among more specific methods of synthesis, mention may be made of the interaction of carbon monoxide with $PtH_2[P(cyclo\text{-}C_6H_{11})_3]_2$ under normal conditions[32] and with $PtMe_2(PEt_3)_2$ at 90 °C and 50 atm.[37] However, in the latter case no detailed description of the method of synthesis is available in the literature.

The structure of clusters of the type $M_3(CO)_3L_4$ has been established by X-ray diffraction for $Pd_3(CO)_3(PPh_3)_4$[33] and $Pt_3(CO)_3[P(cyclo\text{-}C_6H_{11})_3]_4$.[32] The cluster molecule is an equilateral triangle all the sides of which are spanned by μ-CO groups. Each of the two metal atoms in the base of the triangle is linked to one of the two phosphorus atoms of the phosphine ligand, while the third metal atom is linked to two other phosphorus atoms (Fig.3).

The non-equivalence of the CO groups in the cluster is reflected in the infrared spectra (Table 4). In the stretching region of the μ_2-CO groups two intense bands are usually observed at 1820–1880 cm^{-1} for the palladium compounds and at 1750–1800 cm^{-1} for the platinum compounds. We may note that the infrared spectra are to a large extent characteristic and can be used to identify the clusters.

† The methods of synthesis of the $Pd_3(CO)_3(PPh_3)_4$, Pd_4, Pd_{10} clusters, based on the interconversions of the phosphinepalladium carbonyl clusters, are examined below in Section III.

The platinum clusters have been investigated by the NMR method. The ^{31}P and ^{195}Pt NMR data agree with the results of the X-ray diffraction analysis.[32] Two types of P and Pt atoms are manifested in the spectra (Table 5) and the splitting of their signals by neighbouring atoms and the number of components of the spectrum indicate a triangular skeleton in which one platinum atom is linked to two phosphorus atoms and the two others are involved in only a single Pt–C bond.

3. Tetranuclear $M_4(CO)_5L_4$ Clusters

The conditions for the preparation of the tetranuclear palladium clusters (Table 6) are different for straight-chain aliphatic and triphenylphosphine ligands although $Pd(OAc)_2$ is used as the starting compound in both cases. The $Pd_4(CO)_5(PPh_2Me)_4$ palladium cluster[39] has been obtained by reducing $Pd(NO_2)_2(PPh_2Me)_2$ with carbon monoxide in

methylene chloride. The attempts to obtain the corresponding clusters with the PPh_3 and $PPhMe_2$ ligands by this reaction proved unsuccessful.

The tetranuclear platinum clusters have been obtained mainly by two methods (Table 6).

(a) By the disproportionation of the trinuclear clusters in carbon monoxide involving the dissolution of the compound $Pt_3(CO)_3L_4$ in acetone and its maintenance in an atmosphere of carbon monoxide for several days. Crystals of the $Pt_3(CO)_5L_4$ clusters are gradually segregated (they are usually black). The synthesis can be carried out in a different way from Na_2PtCl_4. A solution of $Pt_3(CO)_3L_4$ is obtained initially, as described above, and is then kept in an atmosphere of carbon monoxide:[22]

$$2[Pt_3(CO)_3L_4] + 3CO \xrightarrow[1\ atm]{25^\circ C} Pt_4(CO)_5L_4 + 2PtL_2(CO)_2$$
$$L=PPh_3,\ PMe_2Ph,\ PPh_2Bz$$

The yield of the product ranges from 20 to 50%.

(b) By the interaction of platinum dicarbonyl with phosphines. A solution of platinum dicarbonyl obtained by the method of Eremenko et al.[30] readily reacts with straight-chain aliphatic phosphines in equimolar proportions; the $Pt_4(CO)_5L_4$ cluster is formed in a high yield (>80%):[30]

$$[Pt_3(CO)_6]_n^{2-} + PEt_3 \rightarrow Pt_4(CO)_5(PEt_3)_4$$

Table 6. The synthesis of phosphinemetal carbonyl clusters $M_4(CO)_5L_4$

Cluster	Initial compound	M:P in synthesis	Conditions of synthesis	Refs.

$Pt_4(CO)_5(PEt_3)_4$	$[Pt_3(CO)_6]_n^{2-}$	1:1	Acetone, CO	[30]
$Pt_4(CO)_5(PPhMe_2)_4$	Na_2PtCl_4	1:2	Methanol, CO, KOH, Hydrazine	[42]
$Pt_4(CO_5)(PPh_3)_4$	$Pt_3(CO)_3(PPh_3)_4$	1:1.33	Acetone, CO	[22]
$Pt_4(CO)_2(\mu\text{-dppm})$ (dppm-O)	$[Pt_2H_2(\mu\text{-H})(\mu\text{-dppm})_2][PF_6]$	—	—	[43]

The interaction of $[Pt_3(CO)_6]_n^{2-}$ for aromatic phosphine ligands has been mentioned, but a detailed description of the experiment is not available.[22]

The formation of the tetranuclear platinum cluster in the catalytic conversion of carbon monoxide should be noted:[43]

$$[Pt_2H_2(\mu\text{-H})(\mu\text{-dppm})_2]PF_6 \xrightarrow[O_2]{P_{CO}} Pt_4(\mu\text{-CO})_2(\mu\text{-dppm})_3[dppm(:O)]$$

X-Ray diffraction studies have been carried out for four compounds: $Pd_4(CO)_5(PPh_2Me)_4$,[39] $Pd_4(CO)_5(PPh_3)_4$,[33] $Pt_4(CO)_5(PMe_2Ph)_3$,[42] and $Pt_4(CO)_2(\mu\text{-dppm})_3[dppm(:O)]$.[43] Fig. 4 illustrates the structure of the $Pt_4(CO)_5(PEt_3)_4$ cluster. Its metallic skeleton has the form of a "butterfly" or an open tetrahedron. All five M–M bonds in the cluster are spanned by μ-CO groups and each metal atom is coordinated to one phosphorus atom. The remaining compounds have analogous structures. A cluster with dppm as the bridging ligand has shorter Pt–Pt bonds owing to the chelating influence of dppm.

The structure of the tetranuclear phosphineplatinum carbonyl clusters in solution was investigated by ^{31}P and ^{195}Pt NMR. If the "butterfly" structure of the $Pt_4(CO)_5(PEt_3)_4$ is retained in solution, two types of Pt nuclei with different chemical shifts should be manifested in the NMR spectrum, making it asymmetric. Experiments showed[45] that the $^{31}P\{^1H\}$ NMR spectrum of the $Pt_4(CO)_5(PEt_3)_4$ cluster is symmetrical relative to the central intense line with δ = 36.4

p.p.m., which made it possible to postulate a tetrahedral structure of the cluster in solution. Within the framework of this model, it was possible to interpret the observed spectrum as the sum of the contributions due to clusters containing between zero and four nuclei of the ^{195}Pt magnetic isotope.[45]#

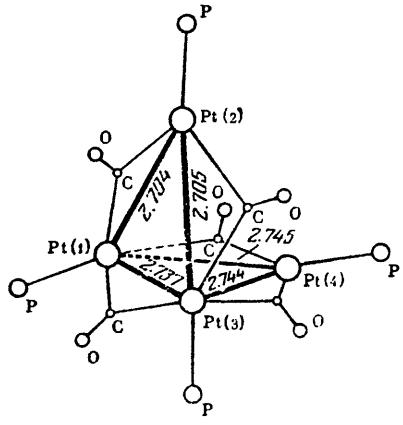

Figure 4. Structure of the $Pt_4(CO)_5(PEt_3)_4$ cluster (the X-ray diffraction analysis has been carried out by R.F.Klevtsova of the Institute of Inorganic Chemistry of the Siberian Division of the USSR Academy of Sciences).

The ^{195}Pt NMR spectrum also indicates a tetrahedral structure of the cluster (a doublet of quartets, which is a superposition of the spectra of clusters with two and three magnetic nuclei, is observed). The observed increase of the symmetry of the clusters in solution at room temperature can be explained by the stereochemical non-rigidity of the compound associated with the rapid exchange of carbonyl groups. The exchange processes remain fairly rapidly at temperatures down to -70 °C.[45]

Exchange processes have been observed for the first time also for palladium clusters whose ^{31}P NMR spectra consist of singlets—δ, p.p.m. (in benzene): -14.0 (Et) and -6.5 (Bu);[40] δ, p.p.m. (in hexane): -6.6 ($n-C_8H_{17}$) and -6.8 ($n-C_{12}H_{25}$)[45] (downfield chemical shifts relative to the H_3PO_4 signal correspond to the negative values).

Another cause of the transition to the tetrahedral structure of the Pt_4 cluster in solution may be associated with the addition of a sixth CO molecule from the solution. This possibility has been confirmed indirectly by the synthesis of the $Pd_4(CO)_6(PBu_3)_4$ cluster on slow crystallisation of $Pd_4(CO)_5(PBu_3)_4$ in a CO atmosphere.[46]

The infrared spectra of palladium compounds in the region of the stretching vibrations of the CO group are characterised by a single intense band; an intense band with a shoulder has also been observed for platinum clusters (Table 7).

A study has been published (A.Moor, P.S.Pregosin, L.M.Venanzi, and A.J.Welch, Inorg.Chim.Acta, 1985, 85, 103), whose NMR data agree with those of Yudanov et al.[45]

4. Pentanuclear $Pt_5(CO)_6L_4$ Clusters

The pentanuclear platinum clusters have been discovered recently. They have been synthesised by a fairly specific method (Table 8) involving the reduction of platinum(II) by metal carbonyl anions. For this purpose, a solution of $PtCl_2L_2$ in tetrahydrofuran was treated with $NaMn(CO)_5$ or $KFe(CO)_3NO$ and the reaction mixture was kept at room temperature (for 1 h for PEt_3 or 18 h for PPh_3). The reaction products were isolated chromatographically. The yield depends greatly on the nature of the carbonylate ion and the phosphine ligand; it amounts to 35% for PPh_3 and 50% for PEt_3 in the case of $NaMn(CO)_5$ and to 10% for PPh_2Me and 75% for PPh_3 in the case of $KFe(CO)_3NO$.[49]

*The Pt : P molar ratio in the synthesis is quoted.

A more effective and simple method of synthesis is based on the interaction of platinum dicarbonyl with phosphine.[36] A solution of platinum dicarbonyl, obtained as described above, is treated with phosphine in the proportions Pt : L = 5 : 4 and is allowed to stand for 10–15 h. The solvent is then distilled off and the product recrystallised from benzene–heptane, acetone–ethanol, etc. mixtures.

The reaction is fairly selective and takes place equally readily with aliphatic and aromatic phosphine. The yield of the product is usually high (80%). A method based on the increase of the nuclearity of the $Pt_3(CO)_3L_4$ clusters when they are deposited on different carriers is also of interest.

It has been suggested that the process procees on acid centres, since an analogous enlargement of the framework has been observed on treating the initial cluster with a 48% solution of HBF_4 in THF.[50]

*Solvate with three benzene molecules.

The structure of two solvates $Pt_5(CO)_6(PPh_3)_4.3Solv$ with toluene[47] and benzene[48] has been investigated. The structure of the pentanuclear cluster (Fig.5) can be regarded either as a tetrahedron with a Pt(1) metal bridge or as two orthogonal triangles with a common Pt(2) vertex;[47] the latter view is based on the presence in the molecule of the longer Pt(3)–Pt(5) and Pt(4)–Pt(5) bonds.

It is noteworthy that both X-ray diffraction data and the parameters of the infrared spectra of the pentanuclear cluster $Pt_5(CO)_6(PPh_3)_4$, obtained in two independent studies,[47,48] agree well. The infrared spectrum contains a set of bands in the ν(CO) region, characteristic of all the compounds obtained hitherto (Table 9). This agreement is not only between the number of bands but also between the ratios of their intensities. A pronounced dependence of the position and form of the low-frequency band (~1790 cm^{-1}) on the nature of the solvent (as far as the splitting of the band into two components) has also been noted.[36]

The highly characteristic nature of the infrared spectra of the pentanuclear clusters makes it possible to assume, in our view, that the compounds obtained previously,[22] to which the composition $Pt_4(CO)_5L_4$ (L = $AsPh_3$, PPh_2Bz, or PEt_3) was attributed, are apparently in reality clusters having the composition $Pt_5(CO)_6L_4$ or contain the latter in large amounts. This conclusion can be based on the analysis of the infrared spectra in the ν(CO) region. Bender and Braunstein[49] arrived at an analogous conclusion on the basis of the identity of the infrared spectra of $Pt_5(CO)_6(PEt_3)_4$ and the product to which the composition $Pt_4(CO)_5(PEt_3)_4$ had been attributed previously.[22] The compound $Pt_4(CO)_5(PPh_3)_3.1.5C_6H_6$ obtained by Ugo et al.[34] has a set of ν(CO) bands characteristic of pentanuclear clusters, but their positions differ appreciably from those of the ν(CO) bands for the compounds investigated. Thus in individual instances the form of the spectrum in the ν(CO) region is sufficiently characteristic to assign the clusters to a particular type.

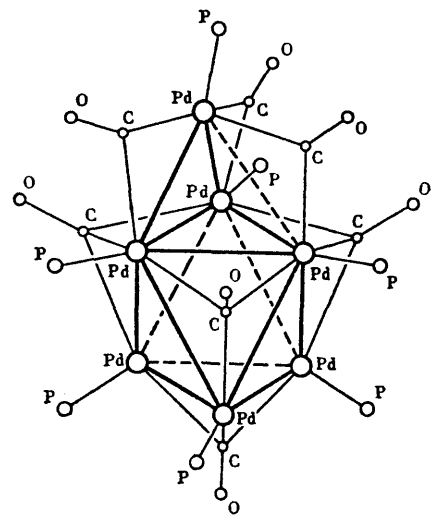

Figure 6. The structure of the $Pd_7(CO)_7(PMe_3)_3$ cluster.[51]

5. The Heptanuclear $Pd_7(\mu_3\text{-}CO)_4(\mu\text{-}CO)_3(PMe_3)_7$ Cluster

The heptanuclear cluster $Pd_7(CO)_7(PMe_3)_7$ has been obtained by reducing $Pd(\eta^1,\eta^3\text{-}C_8H_{12})(PMe_3)$ with carbon monoxide and is the only example of a cluster having the degree of nuclearity indicated.[51] Its structure has been established by X-ray diffraction (Fig.6). The cluster is a one-cap octahedron; the additional palladium atom is located asymmetrically over a face of the octahedron; one of the Pd_{cap}–Pd_{oct} distances is 3.18 Å, which greatly exceeds the lengths of the other two bonds (2.73 Å). The bond lengths within the octahedron are in the range 2.75–2.81 Å. The infrared spectrum of a specimen of the test substance

pelleted with KBr has absorption bands due to the CO groups in the low-frequency region (1825 s, 1800 v.s, 1785 sh, 1770 s, 1850 s, 1685 s).

6. The Decanuclear $Pd_{10}(CO)_{12}L_6$ and $Pd_{10}(CO)_{14}L_4$ Clusters

(a) Clusters with straight-chain aliphatic phosphines. The conditions of the synthesis of clusters of this type have been investigated in greatest detail. The compounds are formed when palladium acetate is reduced in the presence of trifluoroacetic acid. The special advantage of this method of synthesis is the possibility of obtaining individual compounds $Pd_{10}(CO)_{12}L_6$ (I) and (II) and $Pd_{10}(CO)_{14}(PBu_3)_4$ (V) within wide limits of the Pd : P ratios (Table 10).[41,52,53]

Table 10. The synthesis of the decanuclear palladium clusters by the reduction of $Pd(OAc)_2$.

Cluster		Pd:P *	Conditions of synthesis	Refs.
$Pd_{10}(CO)_{12}(PEt_3)_6$	(I)	1:3.3—1:15	Acetone, CF_3COOH	[52, 53, 46]
$Pd_{10}(CO)_{12}(PBu_3)_6$	(II)	1:4—1:10	Acetone, CF_3COOH	[52, 46]

**The $Pd_{10}(CO)_{14}(PBu_3)_4$ cluster.

The infrared and ^{31}P NMR spectra of the clusters (I), (II), and (V) have been obtained.[41,46,52–54] The absorption bands in the range 1810–1920 cm^{-1} which have been assigned to the vibrations of the bridging CO groups, and the bands at 2030–2040 cm^{-1}, assigned to the terminal CO groups, are characteristic of the infrared spectrum of cluster (V) (Table 11). The spectra of clusters (I) and (II) have a similar form and similar relative intensities of the ν(CO) bands. The spectra of clusters (II) and (V) are characterised by very similar sets of absorption bands of the bridging CO groups, but in the infrared spectrum of compound (V) these bands have undergone a hypsochromic shift of approximately 20 cm^{-1}.

The ^{31}P NMR spectrum of compound (V) (in benzene as the solvent) consists of a singlet with $\delta = -5.0$ p.p.m. The ^{31}P NMR spectra of clusters (III) and (I) are characterised by two signals with a 2 : 1 intensity ratio and $\delta = -4.0$ and +3.3 p.p.m. for compound (II) and $\delta = -11.0$ and −3.1 p.p.m. for compound (I).[52,53]

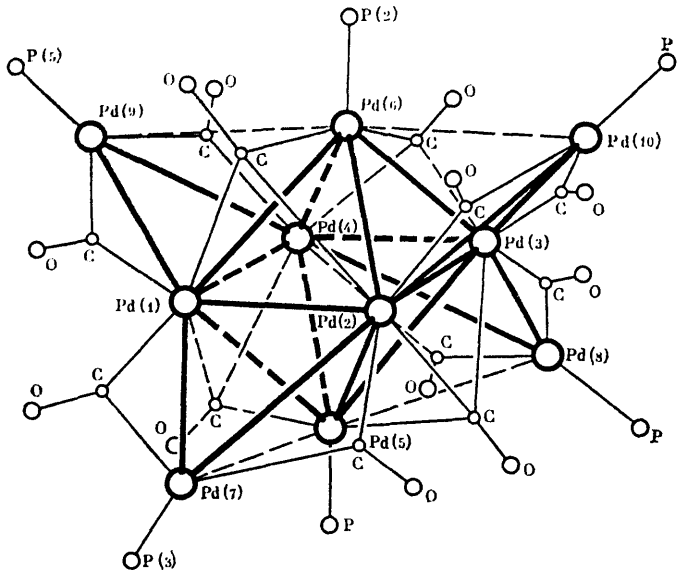

Figure 7. The structure of the $Pd_{10}(CO)_{12}(PBu_3)_6$ cluster.[53]

The spectroscopic data agree well with the structures of clusters (V) [54] and (II).[53] The structure of cluster (II) is illustrated in Fig. 7 (the n-butyl substituents are not shown).[53] Cluster (II) is an octahedron with capping palladium atoms located over its non-adjacent faces: the equatorial Pd(1)–Pd(4) atoms and the apical Pd(5) and Pd(6) atoms of the "internal" Pd_6 octahedron, as well as the Pd(7)–Pd(10) capping atoms. The Pd_{cap}–Pd_{eq} distances [2.694–2.722 (a) Å] are much smaller than the Pd_{cap}–Pd_{apic} distances [3.301–3.42 (2) Å]. The Pd–Pd distances in the internal "Pd_6" octahedral are in the range [2.791–2.851 (2) Å].[53] The eight μ_2-CO groups span the short Pd_{cap}–Pd_{eq} bonds and the four μ-CO groups are coordinated to the four free faces of the octahedron. The coordination of the CO groups to the faces is also asymmetric but, in contrast to the capping metal atoms, the carbon atoms of the μ_3-CO groups are displaced towards the apical palladium atoms, so that the Pd_{apic}–C distances [2.04–2.08 (2) Å] are shorter than the Pd_{eq}–C distances [2.23–2.35 (2) Å]. The six phosphorus

atoms of the tributyl phosphine ligands are linked to the four capping palladium atoms and the two apical palladium atoms. The ^{31}P NMR spectrum of these atoms is characterised by signals with $\delta = -4.0$ and +3.3 p.p.m.

Cluster (V) retains the same framework of metal atoms as cluster (II), but CO groups and not the PBu_3 ligand have been added to the apical palladium atoms. The $Pd_{cap}-Pd_{apic}$ distances in cluster (V) are shorter by approximately 0.015 Å than the analogous distances in cluster (II).[54] This shortening is apparently caused by the partial elimination of steric strain when the PBu_3 groups are replaced by CO groups. Another feature of the structure of cluster (V) is the presence in one molecule of three types of CO groups: four bridging μ_3-CO groups, eight bridging μ-CO groups, and two terminal groups.

(b) The influence of the acidity of the medium on the composition of the clusters. The replacement of trifluoroacetic acid by the weak acetic acid in the synthesis of the clusters $Pd_{10}(CO)_{12+x}L_{6-x}$ ($x = 0.2$) leads to a continuous variation of the composition of the product as a function of the Pd : P ratio. Under these conditions, the individual compounds (V) and (II) were obtained for stoichiometric Pd : P ratios; as the ratio decreases to 1 : 2.2, the $Pd_4(CO)_5 \cdot (PBu_3)_4$ cluster is formed. An analogous relation has been observed using PEt_3 as the ligand. It has been shown by spectroscopic methods that in the region of intermediate Pd : P ratios (from 1 : 06 to 1 : 2) a mixture of the $Pd_4(CO)_5 \cdot (PBu_3)_4$ and (II) clusters is formed.[41] In the case of triethylphosphine the mixture of compounds was resolved into the individual Pd_3 and Pd_7 clusters.[41]

Clusters having the compositions (VI) and (VII) have been obtained in a neutral medium for the stoichiometric Pd : P ratios and have been identified from infrared and ^{31}P NMR spectra. Their infrared spectra (Table 11) are analogous to those of the structurally characterised cluster (II). The ^{31}P NMR spectra of clusters (VI) and (VII) each containg two singlets with intensities in a ratio of 2 : 1, which corresponds to signals from phosphorus atoms coordinated to the four "capping" and two apical palladium atoms.[4]

It is noteworthy that in a neutral medium and in the HOAc + NaOc system with the Pd : PBu_3 = 1 : 0.4 ratio, cluster (II) with an admixture of metallic palladium is formed instead of the expected compound (V).[41] An important factor is the intermediate formation of the $Pd_4(CO)_5(PBu_3)_4$ cluster detected from the infrared spectra of the products in the initial stages of the reaction (in the HOAc + NaOAc system).[27,41]

On passing to a weakly alkaline medium (NaOAc) with the ratios Pd : PBu_3 = 1 : 1–1 : 1.4, $Pd_4(CO)_5(PBu_3)_4$ is formed in a mixture with metallic palladium, while under conditions with the ratio Pd : PBu_3 = 1 : 0.6, a mixture incorporating compound (II), $Pd_4(CO)_5(PBu_3)_4$ and metallic palladium is formed.[41]

The role of the acid consists of creating a specific equilibrium concentration of the free phosphine which is optimal for the formation of the cluster having the appropriate structure. Superstoichiometric amounts of $P(n\text{-}Alk)_3$ in the synthesis of compounds (I), (II), and (V) require the presence of a strong acid.[41,46,53] The excess ligand is bound in this case into the phosphonium salt $[HPAlk_3]^+ \cdot [CF_3COO]^-$. Otherwise in weakly acid and neutral media it is essential to reduce the concentration of $P(n\text{-}Alk)_3$ to give the stoichiometric ratios.[41]

A significant factor is that under the conditions of synthesis investigated and when the above trialkylphosphines are used, the "intermediate" $Pd_5-Pd_6-\ldots\ldots Pd_9$ structures cannot be detected either in solution or in the solid phase. Thus crystallisation during the synthesis in the $Pd(OAc)_2$–dioxan–Me_2CO–HX–PBu_3–H_2O–CO system leads only to clusters (II), (V), $Pd_4(CO)_5(PBu_3)_4$, and $Pd_4(CO)_6(PBu_3)_4$, depending on the Pd : PBu_3 ratio and the type of group X (X = CF_3COO^- or CH_3COO^-).[27,41]

(c) Clusters with aromatic phosphines. The lower basicity of aromatic phosphines precludes the regulation of their concentration by varying the acidity of the medium. The composition of the product is extremely sensitive to the Pd : P ratio during the synthesis and to the reaction time. The synthesis is therefore carried out under rigorously controlled conditions and yet despite this a reprecipitation is usually required to obtain a purer substance. Clusters (VIII)–(X) have been identified by elemental analysis and infrared spectroscopy (Table 11).[29]

7. Comparison of the Methods of Synthesis

Examination of the principal methods of synthesis of palladium and platinum clusters makes it possible to differentiate a number of common features. A low-valence complex of the metal, namely PdL_2, PtL_2, $Pt(cod)_2$, and $[Pt_3(CO)_6]_n^{2-}$, synthesised beforehand or obtained by reducing platinum(II) and palladium(II) in solution, is usually employed as the starting compound. Derivatives of the zerovalent metal are then converted into carbonyl-containing mononuclear complexes by treatment with carbon monoxide:

$$PtL_2 + 2CO \rightleftarrows Pt(CO)_2L_2;$$
$$Pd(OAc)_2 + 2CO + 3L + H_2O \rightarrow Pd(CO)L_3 + CO_2 + 2HOAc;$$
$$K_2PtCl_4 + 2L + CO \xrightarrow[N_2H_4]{KOH} Pt(CO)_2L_2.$$

As a consequence of the pronounced ability of zerovalent palladium and platinum compounds to form metal–metal bonds, in the presence of a deficiency of phosphine ligands the mononuclear phosphine metal carbonyl species are combined into clusters of different nuclearity depending on the conditions; this is shown particularly for the trinuclear compounds:

$$5Pt(CO)_2L_2 \rightleftarrows Pt_3(CO)_3L_4 + 2PtL_3 + 7CO;$$
$$3Pd(CO)L_3 \rightleftarrows Pd_3(CO)_3L_4 + 5L.$$

Another picture is observed when palladium dicarbonyl is used. X-Ray diffraction showed[15] that the $[Pt_3(CO)_6]_n^{2-}$ species have polymeric structures made up of three-membered rings linked by elongated Pt–Pt bonds. In this case mononuclear species are not produced[36] and attack by the phosphine results in the immediate splitting off of a fragment made up of three platinum atoms:

$$[Pt_3(CO)_6]_n^{-2} + 4PPh_3 \rightarrow Pt_3(CO)_3(PPh_3)_4 + [Pt_3(CO)_6]_{n-1}^{-2} + 3CO.$$

Furthermore, interconversions of clusters of different nuclearity are a common feature. Thus in an atmosphere of carbon monoxide the clusters $Pt_3(CO)_3(PPh_3)_4$ gradually disproportionates into $Pt_4(CO)_5(PPh_3)_4$ and a mononuclear complex:[22]

$$2Pt_3(CO)_3(PPh_3)_4 \xrightarrow{3CO} Pt_4(CO)_5(PPh_3)_4 + 2Pt(CO)_2(PPh_3)_2.$$

This process is particularly rapid for aliphatic phosphines, which precludes the synthesis of the trinuclear cluster with PEt_3 by reaction with platinum dicarbonyl. On the other hand, the high reactivity of the platinum clusters with aliphatic phosphines helps in effecting a wide variety of rearrangements of the clusters and leads to the selective formation of $Pt_4(CO)_5(PEt_3)_4$ and $Pt_5(CO)_6(PEt_3)_4$. The yield

and nuclearity of the clusters are in this case determined solely by the Pt : L ratio:[30]

$$[Pt_3(CO)_6]_n^{2-} + PEt_3 \rightarrow Pt_4(CO)_5(PEt_3)_4 + CO;$$
$$[Pt_3(CO)_6]_{n2}^{-} + PEt_3 \rightarrow Pt_5(CO)_6(PEt_3)_4 + CO.$$

The process involving an increase of nuclearity can be made more selective and rapid by binding the phosphines. The removal of the phosphines from the reaction media (by treatment with H^+, O_2, etc.) makes it possible to obtain clusters of high nuclearity immediately from the mononuclear species. This process has been investigated for palladium compounds.[55,56] In the case of platinum, $Pt_5(CO)_6(PEt_3)_4$ has been obtained in a high yield from the complex $Pt_4(CO)_5.(PEt_3)_4$ on treatment with CF_3COOH:

$$5Pt_4(CO)_5(PEt_3)_4 + 4CF_3COOH \rightarrow 4Pt_5(CO)_6(PEt_3)_4 + 4[HPEt_3]^+CF_3COO^- + CO.$$

In the synthesis of the pentanuclear platinum clusters by the method of Bender and co-workers[47,49] involving the reduction of $PtCl_2L_2$ by carboxylate ions, the interconversion of the clusters probably also takes place. The method yields as a rule a mixture of compounds, the most stable form $Pt_5(CO)_6L_4$ being separated in the chromatographic stage. This has been confirmed by a later study[50] where impregnation of different carriers by the $Pt_3(CO)_3L_4$ clusters leads to their conversion into pentanuclear compounds $Pt_5(CO)_6L_4$.

Much less complex transformations take place in the synthesis of the pentanuclear platinum clusters in the reaction of phosphine ligands with $[Pt_3(CO)_6]_n^{2-}$. As already mentioned, in this case the first reaction stage involves the formation of $Pt_3(CO)_3L_4$ and this stage is rapid. The compound then reacts slowly with platinum dicarbonyl to form $Pt_5(CO)_6L_4$:[36]

$$Pt_3(CO)_3L_4 + [Pt_3(CO)_6]_n^{2-} \rightarrow Pt_5(CO)_6L_4 + CO.$$

In the case of aliphatic phosphines the rates of both stages are similar and the trinuclear cluster is therefore obtained always in a mixture with compounds with a higher nuclearity. It is noteworthy that the Pt_4 cluster in solution does not undergo disproportionation and its conversion into the Pt_5 cluster requires the elimination of the phosphine ligand and its chemical binding. The disproportionation reactions take place for all the palladium cluster compounds, including the decanuclear clusters.[55,56]

III. THE INTERCONVERSION OF PHOSPHINEPALLADIUM CARBONYL CLUSTERS

It was found that in the synthesis of phosphine metal carbonyl clusters the acidity of the medium has a strong influence on the formation of compounds with a particular nuclearity; this observation has been used to synthesise one compound from another. The above possibility has been realised experimentally in two studies,[55,56] which led to the development of the method for increasing the nuclearity of phosphinepalladium carbonyl compounds. The method is based on the binding of the phosphine-containing ligand. The choice of reactant depends on the basicity of the phosphine ligand and includes acids, oxidants, organohalogen compounds, and complexes of metals in different oxidation states:[27,55,56]

$$PR_3 + H^+ \text{ (or } {}^1/_2O_2) \rightarrow HPR_3^+ \text{ (or } OPR_3); \quad (1)$$
$$PR_3 + R'X \rightarrow [R'PR_3]^+X^-; \quad (2)$$
$$nPR_3 + M(CO)_x \rightarrow M(CO)_{x-n}(PR_3)_n + nCO; \quad (3)$$
$$2PR_3 + MX_2 \rightarrow (PR_3)_2MX_2. \quad (4)$$

1. The Interconversions of Clusters in the Pd(0)–CO–P(n-Alk)$_3$ System

In a system with tri-n-alkylphosphine ligands the clusters undergo interconversions with a change in the degree of their nuclearity and the composition of the coordination shell. The $Pd_4 \rightleftharpoons Pd_{10}$ interconversion is the key factor:[55]

$$5Pd_4(CO)_5[P(n\text{-Alk})_3]_4 + 8H^+ \rightarrow 2Pd_{10}(CO)_{12}[P(n\text{-Alk})_3]_6 + 8[HP(n\text{-Alk})_3]^+ + CO;$$
$$2Pd_{10}(CO)_{12}[P(n\text{-Alk})_3]_6 + 8P(n\text{-Alk})_3 + CO \rightarrow 5Pd_4(CO)_5[P(n\text{-Alk})_3]_4.$$

The interconversion takes place with a high selectivity (>90%). The transformation $Pd_4 \rightarrow Pd_{10}$ has been carried out by treating $Pd_4(CO)_5(PEt_3)_4$ with iron pentacarbonyl (88% of compound (I) was obtained] and by treating $Pd_4(CO)_5(PBu_3)_4$ with palladium acetate or 8-bromomethylquinoline, i.e. on the basis of reactions (2)–(4). A compound from the family of phosphine palladium carbonyl clusters can also be used as an acceptor of the phosphorus-containing ligand:[55]

$$10Pd_{10}(CO)_{14}(PBu_3)_4 + 11Pd_4(CO)_5(PBu_3)_4 \rightarrow 14Pd_{10}(CO)_{12}(PBu_3)_6 + 27CO + 4Pd.$$

Cluster (II) has also been obtained from the complex PdL_4, where L = PBu_3 but with a lower yield (10%):[55]

$$10\,PdL_4 + 34\,H^+ + 12\,CO \rightarrow Pd_{10}(CO)_{12}L_6 + 34\,HL^+.$$

The reactions, which take place with a change in the composition of the coordination shell, include the following processes:[46,55]

$$Pd_{10}(CO)_{12}(PBu_3)_6 + 2H^+ + 2CO \rightarrow Pd_{10}(CO)_{14}(PBu_3)_4 + 2HPBu_3;$$
$$Pd_{10}(CO)_{14}(PBu_3)_4 + 2PBu_3 \rightarrow Pd_{10}(CO)_{12}(PBu_3)_6 + 2CO;$$
$$Pd_4(CO)_5(PBu_3)_4 + CO \rightarrow Pd_4(CO)_6(PBu_3)_4. \quad (5)$$
(XI)

In order to obtain the pure compound (V) by reaction (5), it is necessary to monitor the latter with respect to time: on treatment with an excess of H^+, metallic palladium is gradually formed.[54,55]

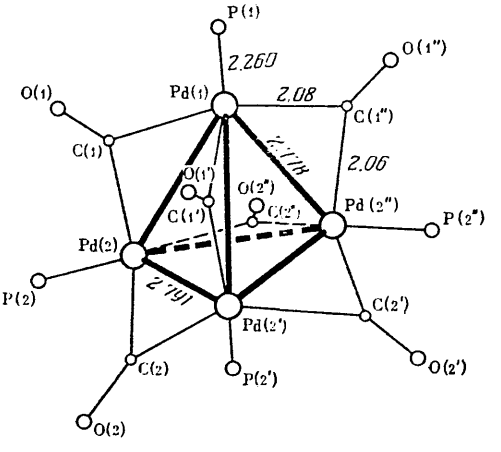

Figure 8. The structure of the $Pd_4(CO)_6(PBu_3)_4$ cluster.[46]

The structurally characterised cluster (XL) (Fig.8) has been obtained by crystallising $Pd_4(CO)_5(PBu_3)_4$ in a CO atmosphere.[46] The cluster consists of a virtually undistorted tetrahedron, all the edges of which are spanned by

the μ-CO ligands and each palladium atom is coordinated to one phosphorus atom of the phosphine ligand.

Thus the overall mechanism of the interconversion of the phosphinepalladium carbonyl clusters in the Pd(0)–CO–P(n-Alk)$_3$ system can be represented as follows:

$$PdL_4 \underset{L,N_2,\Delta}{\overset{CO}{\rightleftarrows}} Pd(CO)L_3 \underset{L}{\overset{CO,\,H^+}{\rightleftarrows}} Pd_4(CO)_5L_4 + Pd_4(CO)_6L_4 \underset{L}{\overset{CO,\,H^+}{\rightleftarrows}}$$
$$\rightleftarrows Pd_{10}(CO)_{12}L_6 \underset{L}{\overset{CO,\,H^+}{\rightleftarrows}} Pd_{10}(CO)_{14}L_4 \begin{cases} \xrightarrow{CO,\,H^+} Pd \\ \xrightarrow[L]{} PdL_4 \end{cases}.$$

This mechanism constitutes a clear illustration of one of the definitions of clusters as compounds intermediate between the classical mononuclear complexes and compact metal.

2. The Interactions of the Clusters in the Pd(0)–CO–PPh$_3$ System

The use of an acid to increase the nuclearity of clusters in this system is ineffective owing to the low basicity of the aromatic phosphine ligand. Up to $n = 4$, the binding of the triphenylphosphine ligand is not essential in view of the existence of the following equilibria in the solutions:[33,35,56–58]

$$PdL_4 + CO \rightleftarrows Pd(CO)L_3 + L;$$
$$3\,Pd(CO)L_3 \rightleftarrows Pd_3(CO)_3L_4 + 5\,L;$$
$$4\,Pd_3(CO)_3L_4 + 3\,CO \rightleftarrows 3\,Pd_4(CO)_5L_4 + 4\,L.$$

The $Pd_3(CO)_3(PPh_3)_4$ cluster is much more stable than its analogue with the PBu_3 ligand, which could not be isolated. In solution in a CO atmosphere the $Pd_3(CO)_3(PPh_3)_4$ cluster is converted into the tetranuclear $Pd_4(CO)_5(PPh_3)_4$ cluster previously characterised as $Pd_3(CO)_3L_3$.[35,58] We may note that the platinum cluster $Pt_3(CO)_3L_4$ disproportionates under similar conditions into $Pt_4(CO)_5L_4$ and $Pt(CO)_2L_2$.[22]

The composition and yield of the products of crystallisation of the compounds PdL_4, $Pd(CO)L_3$, and $Pd_3(CO)_3L_4$ in a CO atmosphere depend on the concentrations of the starting materials, the nature of the solvent, the reaction time, the temperature, and the composition of the gas phase. In some cases it is possible to obtain crystals containing two different clusters. Thus the joint crystallisation of two clusters, i.e. $Pd_3(CO)_3(PPh_3)_4Pd_4(CO)_5(PPh_3)_4.C_6H_6$, has been observed by X-ray diffraction.[33]

In solution in an atmosphere of CO the $Pd_4(CO)_6(PPh_3)_4$ cluster is also in equilibrium with the form having a higher nuclearity, namely the cluxter (VIII).[56]

The decanuclear cluster (VIII) has been obtained by oxidising PdL_4, $Pd(CO)L_3$, $Pd_3(CO)_3(PPh_3)_4$, or $Pd_4(CO)_5(PPh_3)_4$ with an oxygen–carbon monoxide mixture (in proportions of 2 : 1):[27,56]

$$10PdL_4 + 17O_2 + 12CO \rightarrow Pd_{10}(CO)_{12}L_6 + 34OL;$$
$$10Pd_4(CO)_5L_4 + 9O_2 \xrightarrow{CO} 4Pd_{10}(CO)_{12}L_6 + 16OL + 2CO_2. \qquad (6)$$

The formation of cluster (VIII) in these reactions has been demonstrated by elemental analysis, infrared spectroscopy (Table 11), and ^{31}P NMR of the solution at the end of the oxidation reaction.[27,56] The ^{31}P NMR spectrum of the solution in toluene[56] indicates the formation of $OPPh_3$ (–23.7 p.p.m.) and cluster (VIII), which gives rise to two signals, at –23.0 and –15.9 p.p.m., with an intensity ratio of approximately 2 : 1. The difference between their chemical shifts (7.1 p.p.m.) is the same as in the ^{31}P NMR spectra of clusters (I) and (II) (7–8 p.p.m.).[41,52,53] The relative signal intensities $OPPh_3 : PPh_3 = 1 : 1.6$ confirm the stoichiometry of reaction (6).

A decrease of nuclearity with formation of the individual compounds is achieved in the interaction with phosphine in the ratios (VIII) : L = 1 : 7), (VIII) : L = 1 : 11, and $Pd_4(CO)_5(PPh_3)_4$: L = 1 : 2.5 respectively:[56]

$$2Pd_{10}(CO)_{12}L_6 + 8L + CO \xrightarrow{\text{toluene}} 5Pd_4(CO)_5L_4;$$
$$3Pd_{10}(CO)_{12}L_6 + 22L \xrightarrow{\text{acetone}} 10Pd_3(CO)_3L_4 + 6CO;$$
$$3Pd_4(CO)_5L_4 + 4L \xrightarrow{\text{acetone}} 4Pd_3(CO)_3L_4 + 3CO.$$

Treatment of any of the clusters $Pd_3(CO)_3L_4$, $Pd_4(CO)_5L_4$, or (VIII) with an excess of the ligand L leads to the complex PdL_4.

The triphenylphosphinepalladium carbonyl clusters are also formed in the disproportionation reactions of clusters of different nuclearity.[56] The interaction of the stoichiometric amounts of Pd_3 and (VIII) in the presence of L in toluene leads to the Pd_4 cluster:

$$6\,Pd_3(CO)_3L_4 + Pd_{10}(CO)_{12}L_6 + 5\,CO \rightarrow 7\,Pd_4(CO)_5L_4 + 2\,L.$$

The $Pd_4(CO)_5L_4$ cluster has been obtained by the interaction of compound (VIII) and PdL_4 in toluene in the ratio (VIII) : PdL_4 = 1 : 2:

$$Pd_{10}(CO)_{12}L_6 + 2\,PdL_4 + 3\,CO \rightarrow 3\,Pd_4(CO)_5L_4 + 2\,L.$$

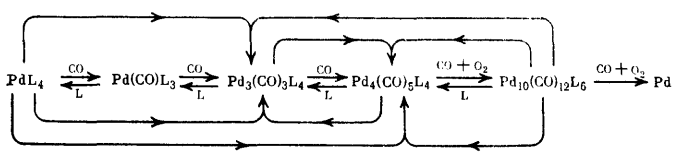
The highly labile $Pd_3(CO)_3L_4$ cluster is not formed in appreciable amounts in solution even under favourable stoichiometric conditions; the products of the reaction of compound (VIII) and PdL_4 in toluene for the ratio (VIII) : PdL_4 = 1 : 4 are $Pd_4(CO)_5(PPh_3)_4$ and $Pd(CO)L_3$:[56]

$$Pd_{10}(CO)_{12}L_6 + 4\,PdL_4 + 5\,CO \rightarrow 3\,Pd_4(CO)_5L_4 + 2\,Pd(CO)L_3 + 4\,L.$$

However, the interaction in acetone, in which all the compounds involved in the reaction are sparingly soluble, leads to the formation of $Pd_3(CO)_3L_4$ for the molar ratios (VIII) : : PdL_4 = 1 : 5 and $Pd_4(CO)_5L_4$: PdL_4 = 1 : 2:[56]

$$Pd_{10}(CO)_{12}L_6 + 5\,PdL_4 + 3\,CO \rightarrow 5\,Pd_3(CO)_3L_4 + 6\,L;$$
$$Pd_4(CO)_5L_4 + 2\,PdL_4 + CO \rightarrow 2\,Pd_3(CO)_3L_4 + 4\,L.$$

The overall mechanism of the interconversions of triphenylphosphinemetal carbonyl compounds can be formulated as follows:



An important property of the Pd(0)–CO–PR$_3$ system, where R = n-Alk and R = Ph, is the formation of isotypical Pd_4 and Pd_{10} clusters, although the PPh_3 group differs from P(n-Alk)$_3$ (for example, from PBu_3) in its steric and electronic characteristics.[59]

In contrast to the Pd(0)–CO–P(n-Bu)$_3$ system, in the system with the triphenylphosphine ligand it is not possible to isolate in a pure state the second decanuclear cluster $Pd_{10}(CO)_{14}L_4$. An increase of the duration of the treatment of solutions of the clusters $Pd_4(CO)_5(PPh_3)_4$ or (VIII) with the CO + O_2 mixture leads to the formation of a mixture of $Pd_{10}(CO)_{12}L_6$, $Pd_{10}(CO)_{14}L_4$, and metallic palladium.[56] Another difference consists of the existence of the trinuclear $Pd_3(CO)_3(PPh_3)_4$ cluster, which is stable in the solid state. As in the system with PBu_3, in that with PPh_3 it has not so far been possible to isolate compounds with an intermediate nuclearity in the range $4 < n \leq 9$.[56]

IV. CHEMICAL PROPERTIES

It is possible to differentiate two types of reactions characteristic of phosphinepalladium carbonyl clusters, namely the substitution and oxidative addition reactions. By virtue of the polynuclearity of the initial compounds, each of these reactions can lead in the general case to products of two types—with retention of the initial structure or with a change in nuclearity up to the formation of mononuclear compounds:[27]

$$Pd_n(CO)_x(PR_3)_y \begin{cases} \xrightarrow[\text{of ER}_3]{\text{substitution}} \begin{cases} \longrightarrow \text{«}Pd_n\text{»}; \\ \longrightarrow Pd(ER_3)_{3,4}; \end{cases} \\ \xrightarrow[\text{addition of RX, RHgX}]{\text{oxidative}} \begin{cases} \longrightarrow \text{«}Pd_n\text{»}; \\ \longrightarrow (PR_3)_2Pd(R)(X) + [(PR_3)Pd(RCO)X]_2 \text{ etc.}; \end{cases} \end{cases}$$

E = P, As, Sb; X = Cl, Br, I.

Cluster (V), being most depleted in the phosphine ligand, is suitable for substitution reactions. Depending on the ratio (V) : substituting ligand, compounds with different nuclearities n = 10, 4, or 1) and heterogeneous (for n = 10 or 4) or homogeneous (for n = 4 or 1) phosphorus-containing ligands are formed. Thus treatment of compound (V) with a solution PPh_3 as L in the proportions (V) : L = 1 : 2 yielded the $Pd_{10}(CO)_{12}(PBu_3)_4(PPh_3)_2$ cluster:

$$Pd_{10}(CO)_{14}(PBu_3)_4 + 2\ PPh_3 \rightarrow Pd_{10}(CO)_{12}(PBu_3)_4(PPh_3)_2 + 2\ CO,$$

while reaction involving the proportions 1 : 3.7 yielded the $Pd_{10}(CO)_{12}(PBu_3)(PPh_3)_5$ cluster.[27]

It has been shown that the triphenylphosphine ligand in the compound $Pd_{10}(CO)_{12}(PBu_3)_4(PPh_3)_2$ is coordinated not only to the apical palladium atoms but also to the capping palladium atom in the proportions $L_{cap} : L_{apic} = 1.8 : 1.0$.[27] A ^{31}P NMR study showed that the observed coordination of triphenylphosphine is caused by the simultaneous substitution of the terminal CO groups at the apical palladium atom and of the PBu_3 groups at the capping atom (with some predominance of the substitution of the CO groups). The PBu_3 liberated in this process can also substitute terminal CO groups.[27]

The decomposition of the structures of the $Pd_{10}(CO)_{14}\cdot(PBu_3)_4$ and $Pd_{10}(CO)_{12}(PBu_3)_6$ clusters with formation of $Pd_4(CO)_5(PBu_3)_{4-n}(PPh_3)_n$ clusters has been observed in the presence of a more than 4-molar excess of PPh_3. A further increase of the amount of PPh_3 (up to $Pd_{10} : PPh_3$ = 1 : 12) leads to the formation of a mixture of $Pd(CO)(PPh_3)_3$ and $Pd(PPh_3)_4$.[27] Treatment of the compound $Pd_4(CO)_5\cdot(PBu_3)_4$ with triphenylphosphine in the proportions $Pd_4 : PPh_3$ = 1 : 2 gives rise to a mixture of $Pd_4(CO)_5\cdot(PBu_3)_{4-n}(PPh_3)_n$ (where $n \cong 2$–4), $Pd(CO)(PPh_3)_3$, and $Pd(PPh_3)_4$.[27]

The interaction of the Pd_{10} clusters with an excess of L = ER_3, where E = P, As, or Sb, in the proportions $Pd_{10} : ER_3$ = 1 : 40 and less leads to the mononuclear PdL_4 complexes and can be regarded as yet another method of synthesis of these compounds:[27]

$$Pd_{10}(CO)_{12}(PAlk_3)_6 + 40\ ER_3 \rightarrow 10\ Pd(ER_3)_4 + 12\ CO + 6\ PAlk_3.$$

The complexes $Pd(PR_3)_x$ have been obtained for R—OPh (x = 4) and R = p-$CH_3C_6H_4$ or p-$CH_3OC_6H_4$ (x = 3).[27]

The advantage of the proposed method[27] of synthesis of PdL_4 and similar complexes over the familiar method[60] lies in the presence in the coordination shell of the initial cluster of carbon monoxide as the dominant ligand, which can be readily removed into the gas phase and does not therefore prevent the isolation of the pure substance.

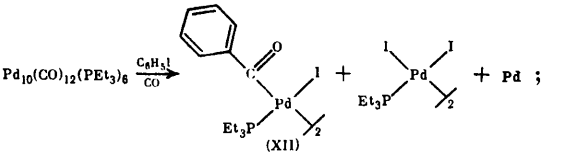
The majority of the oxidative addition reactions have been carried out with trialkylphosphinemetal carbonyl clusters Pd_4 and Pd_{10}.[61] Almost all the reactions are accompanied by the elimination of CO and the decomposition of the initial structure.

The reactions with RX and RHgX yielded products both containing the carbonyl group in the R—CO—Pd fragment and without it, as in R—Pd; carbonyl-containing compounds are then formed regardless of whether the reaction is carried out in an atmosphere of CO or in an inert gas. Furthermore, metallic palladium is produced and the compounds $[PdI_2\cdot(PEt_3)]_2$, $PdBr_2(PBu_3)_2$, etc. are formed. A wide variety of products can be accounted for, apart from the possibility of different reaction pathways, by the chemical non-equivalence of the Pd atoms in the Pd_{10} cluster. As mentioned above, three types of palladium atoms can be differentiated in the Pd_{10} structure (Fig. 7)—equatorial, capping, and apical. Among these the capping and apical atoms are most accessible to the attacking molecule, while the equatorial atoms, which lack phosphine ligands, are primarily responsible for the formation of metallic palladium. The interaction of RX, RHgX, or R_2Hg with one of the outer Pd atoms apparently causes a rapid decomposition of the $Pd_{10}(Pd_4)$ structure. The ratio of the oxidative addition products and the metal is then determined solely by the relative rates of reaction of the decomposing Pd_{10} (or Pd_4) fragments with RX, RHgX, or R_2Hg and their agglomeration to the metal.[61]

In the reaction with an excess of C_3H_5Cl the metal is not produced as a consequence of the formation of the compound $[(\eta^3\text{-}C_3H_5)Pd]_2$, which does not require additional phosphine ligands:[27]

$$Pd_{10}(CO)_{12}(PBu_3)_6 + 10\ C_3H_5Cl \rightarrow 2[(\eta^3\text{-}C_3H_5)PdCl]_2 + 6(\eta^3\text{-}C_3H_5)PdCl(PBu_3) + 12\ CO.$$

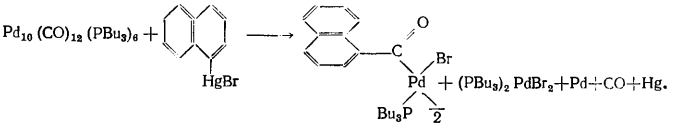
The reaction of iodobenzene with compound (I) in an atmosphere of CO and the reaction of bromobenzene with $Pd_4(CO)_5\cdot(PEt_3)_4$ in an atmosphere of N_2 lead to di-μ-iodobis[benzoyl(triethylphosphine)palladium] (XII), phenylbis(triethylphosphine)palladium bromide (XIII), and benzoylbis(triethylphosphine)palladium bromide (XIV):[27]



$$Pd_4(CO)_5(PEt_3)_4 + C_6H_5Br \xrightarrow{N_2} \underset{\text{(XIII)}}{(Ph)(Br)Pd(PEt_3)_2} + (PhCO)(Br)Pd(PEt_3)_2 + Br_2Pd(PEt_3)_2 + Pd + CO.$$

(XIV)

The interaction of α-naphthylmercury bromide with cluster (II) takes place with liberation of mercury in accordance with the general mechanism of redox demercuration[62] and is accompanied by the insertion of the CO group and the formation of di-μ-bromobis[α-naphthoyltributylphosphinepalladium]:[61]

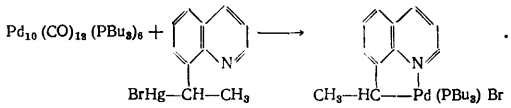


A mononuclear diarylpalladium derivative has been obtained by reaction (7) in the light in the course of seven days:[61]

$$Pd_{10}(CO)_{12}(PBu_3)_6 + (C_6F_5)_2Hg + Ph_2PC_2H_4PPh_2 \rightarrow (C_6F_5)_2Pd(Ph_2PC_2H_4PPh_2). \quad (7)$$

A chelate σ-complex of palladium(II) has been obtained as

one of the products of the reaction with 8-(α-bromomercuriethyl)quinoline:[61]



A second product of the same reaction proved to be a cluster whose infrared spectrum contains two bands due to the bridging CO groups at 1900 and 1860 cm^{-1} and which could not be isolated. However, its triethylphosphine analogue has been obtained by the reaction of the cluster $Pd_4(CO)_5(PEt_3)_4$ with 8-(α-bromomercuriethyl)quinoline.

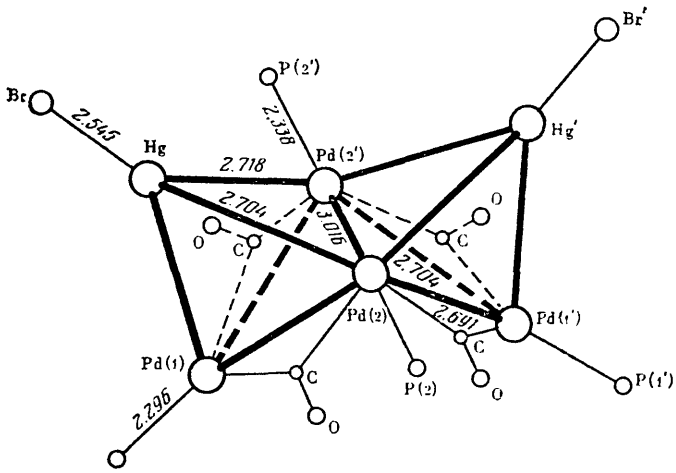


Figure 9. The structure of the $Pd_4Hg_2(CO)_4(PEt_3)_4Br_2$ cluster.[63]

The elemental composition and structure of the first heteronuclear palladium-mercury cluster $Pd_4Hg_2(CO)_4(PEt_3)_4 \cdot Br_2$ has been established by X-ray diffraction (Fig.9).[63] The cluster consists of a "butterfly", both "wings" of which are centred on the Hg—Br fragments. All the Pd—Pd bonds, with the exception of the elongated "hinged" bonds, are spanned by the μ_2-CO groups, each palladium atom being coordinated to a phosphorus atom. One may assume[27] that the charges in the cluster are separated up to the attainment of the limiting state $[(Pd_4(CO)_4(PEt_3)_4]^{2-}[HgBr]_2^{2+}$, In this compound both the anion and cation should be fairly stable: the anion is isoelectronic with the stable $Pd_4(CO)_5(PEt_3)_4$ cluster, while the mercury in the cation is in its usual +2 oxidation state.

The second heteronuclear palladium-mercury cluster has been obtained by the reaction of $Pd_4(CO)_5(PEt_3)_4$ with mercury:[64]

$$2\ Pd_4(CO)_5(PEt_3)_4 + Hg \rightarrow Pd_6Hg(CO)_6(PEt_3)_6 + 4\ CO + 2\ PEt_3 + 2\ Pd.$$

The formula of the compound has been proposed on the basis of analytical data and a cryoscopic determination of the molecular weight. In the suggested structure (Fig.10) all the CO groups are bridging (the bands at 1862 and 1822 cm^{-1} in the infrared spectrum) and span all six Pd—Pd bonds. Each palladium atom is coordinated to one phosphorus atom of the phosphine ligand.

The information available about reactions involving oxidative addition to triphenylphosphinepalladium(0) carbonyl clusters is limited: only the complex [Pd(I).(PhCO)(PPh_3). .toluene] (apparently with a dinuclear structure) has been obtained by treating a solution of PhI and $Pd_3(CO)_3(PPh_3)_4$ in toluene with carbon monoxide; $Pd(PhCO)(I)(PPh_3)_2$ was obtained as an admixture.[65]

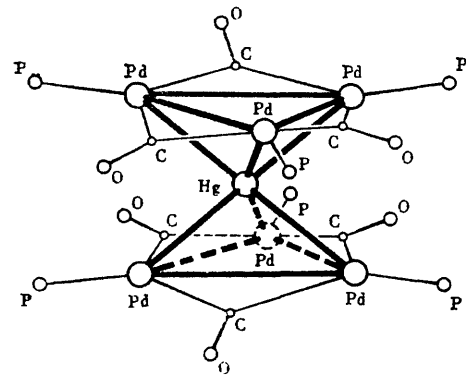

Figure 10. The suggested structure of the $Pd_6Hg(CO)_6 \cdot (PEt_3)_6$ cluster.[64]

The $Pd_3(CO)_3(PPh_3)_4$ [35] and $Pd_4(CO)_5(PPh_3)_4$ [33,35] clusters catalyse the methoxycarbonylation of aryl halides under mild conditions,[65] but the compounds themselves apparently decompose during the reaction. The following mechanism of the process has been proposed:[65-67]

$$PdL_n + PhI \rightarrow (Ph)Pd(I)L_{n-2} + 2\ L;$$
$$(Ph)Pd(I)L_{n-2} + CO \rightarrow (PhCO)Pd(I)L_{n-2};$$
$$(PhCO)Pd(I)L_{n-2} + CH_3OH \rightarrow PhCOOCH_3 + (H)Pd(I)L_{n-2};$$
$$(H)Pd(I)L_{n-2} + 2\ L + R_2NH \rightarrow PdL_n + R_2NH_2^+ + I^-.$$

where L is carbon monoxide, phosphine, or a solvent molecule. The activities of the substrates vary inversely to the C—halogen bond energy: PhI > PhBr ≫ PhCl.

The chemical properties of phosphineplatinum(0) carbonyl clusters have so far been inadequately investigated; we shall examine the main ones.

The interaction of the trinuclear clusters with carbon monoxide leads to tetranuclear platinum clusters. In contrast to the corresponding reaction of the $Pd_3(CO)_3L_4$ palladium cluster, a second platinum-containing product is formed in this reaction, namely a mononuclear complex:[22]

$$Pt_3(CO)_3L_4 + CO \rightarrow Pt_4(CO)_5L_4 + Pt(CO)_2L_2.$$

The removal of the phosphine ligands in the form of quaternary phosphonium salts or complexes with other metals is accompanied by a rearrangement of the skeleton:[48,50]

$$Pt_3(CO)_3(PPh_3)_4 \xrightarrow[\text{sorbent}]{H^+} Pt_5(CO)_6(PPh_3)_4;$$
$$Pt_4(CO)_5(PEt_3)_4 \xrightarrow[Fe(CO)_5]{H^+} Pt_5(CO)_6(PEt_3)_4.$$

Treatment with a measured amount of the phosphine ligand leads either to a cluster with a smaller number of platinum atoms in the metallic skeleton [32] or to the complete decomposition of the skeleton to mononuclear zerovalent platinum compounds: [22]

$$Pt_4(CO)_5(PEt_3)_4 + PEt_3 \xrightarrow{N_2} Pt_2(CO)_3(PEt_3)_4 + Pt(PEt_3)_x;$$
$$Pt_3(CO)_3(PPh_3)_4 + dppe \rightarrow Pt(dppe)_2 + CO + PPh_3;$$
$$dppe = Ph_2PC_2H_4PPh_2.$$

The latter reaction is used for the volumetric determination of the CO content in the cluster. [22]

The reaction of phosphineplatinum carbonyl clusters with SO_2 yielded the corresponding SO_2 containing clusters (with retention of the skeleton): [8]

$$Pt_3(CO)_3(PPh_3)_4 + 3\ SO_2 \rightarrow Pt_3(SO_2)_3(PPh_3)_3 + CO + PPh_3;$$
$$Pt_4(CO)_5(PMe_2Ph)_4 + 5\ SO_2 \rightarrow Pt_4(SO_2)_5(PMe_2Ph)_4 + 5\ CO;$$
$$Pt_3(CO)_6(PPh_3)_4 + 3\ SO_2 \rightarrow Pt_3(CO)_2(SO_2)_3(PPh_3)_4 + 4\ CO.$$

In the last case the SO_2 groups substitute all the CO groups with the exception of the terminal and one of the basal groups in the tetrahedral fragment. The reverse process, i.e. the displacement of the SO_2 groups by carbon monoxide, takes place with rearrangement of the skeleton: [8]

$$Pt_3(SO_2)_3(PPh_3)_3 \xrightarrow[CO]{60^\circ C} Pt_3(CO)_6(PPh_3)_4 + SO_2.$$

Oxidation of the trinuclear $Pt_3(CO)_3[P(t\text{-}Bu)_3]_3$ cluster with a stoichiometric amount of iodine leads to a dinuclear platinum(I) complex: [68]

$$Pt_3(CO)_3[P(t\text{-}Bu)_3]_3 + I_2 \rightarrow [PtI(CO)P(t\text{-}Bu)_3]_2.$$

The reaction with mercury takes place in a somewhat unusual manner. The trinuclear $Pt_3(CO)_3L_3$ clusters, where L = PPh(iso-Pr)$_2$, P(iso-Pr)$_3$, or PEt(t-Bu), react with mercury to form compounds in which two triangles made up of platinum atoms are linked by an Hg–Hg chain. [69] The reaction with $Pt_4(CO)_5(PEt_3)_4$ leads to the $Hg[Pt_3(CO)_3 \cdot (PEt_3)_3]_2$, which has a sandwich structure where the mercury atom links symmetrically two planar triangles made up of platinum atoms. [69]

Analysis of the literature data has shown that phosphine-metal carbonyl clusters are most typical for palladium and platinum. Whereas compounds with n = 3, 4, or 5 are known for platinum, compounds with n = 3, 4, 7, or 10 are known for palladium. Reactions involving a change in nuclearity are characteristic of palladium and platinum clusters.

The great possibilities of clusters in the formation of effective catalysts must be emphasised. The creation of effective catalytic systems based on cluster compounds will probably constitute in the immediate future the theoretically and practically most important trend in the development of catalysis.

Cluster Transition Metal Chalcogenide Halides

V.E.Fedorov, A.V.Mishchenko, and V.P.Fedin

The literature data on cluster transition metal chalcogenide halides are described systematically and discussed. The structures of these compounds are examined and compared with those of the analogous cluster metal halides and chalcogenides. The principal preparative methods of synthesis of the cluster chalcogenide halides are discussed and a systematic account is given of the first results obtained in the study of the chemical properties of this class of inorganic compounds.
The bibliography includes 102 references.

I. INTRODUCTION

The principal advances achieved in the chemistry of cluster compounds in recent years are associated primarily with the synthesis and the determination of the structures of numerous low-valence carbonyl clusters of different nuclearity, especially those characteristic of Group VIII metals.[1-4] The formation of metal carbonyl clusters is much less characteristic of the elements at the beginning of the transition series; cluster compounds with "classical" acido-ligands such as halogens and chalcogens have long been known for these metals and have been thoroughly investigated.[5-8] In contrast to the low-valence metal carbonyl clusters, in the cluster compounds with "classical" ligands the metal atom has a higher formal oxidation state and these compounds are therefore classified as high-valence clusters.[4] Although the first representative of transition metal halide clusters was obtained as early as the beginning of the century,[9] vigorous studies on the cluster niobium, tantalum, molybdenum, tungsten, and rhenium halides as well as their complexes with various ligands have been carried out in the last two decades.[5,6,8] The first structural study of cluster compounds was performed in relation to the hexanuclear molybdenum cluster.[10] The structures of the complexes of metals at the beginning of the transition series with halide ligands, in which the number of metal atoms in the cluster group varies from two to six, have now been investigated.

The chemistry of transition metal chalcogenides, in which the metal–metal pair interactions take place or clusters containing three, four, six, nine, and more metal atoms are formed is also being vigorously studied.[7] The interest in compounds of this kind has increased particularly after the discovery of superconductivity in the so called Chevrel phases which are cluster formations.[11]

A polymeric type of structure, in which bridging ligands link the cluster nuclei into infinite chains, layers, or three-dimensional formations are characteristic of cluster transition metal halides and chalcogenides. An extremely interesting feature of certain cluster halides and chalcogenides is the ability of the metallic clusters to link up with one another to produce the so-called condensed clusters.[7] For example, in the structures of binary and ternary phases of the lower transition metal halides and chalcogenides it is possible to differentiate infinite chains consisting of M_6 octahedra linked to one another via common vertices, edges, or faces.[7]

An important class of inorganic compounds consists of transition metal chalcogenide halides in which the metal atoms are coordinated simultaneously to halogens X and chalcogens Y. The chalcogenide halides have long been known,[12] but the most important results in their investigation have been obtained in the last decade.[13-15]

The main efforts of investigators have been directed to the search for reactions leading to the formation of new chalcogenide halides, the optimisation of the conditions of synthesis, and the determination of their structure, while inadequate attention has been devoted to the chemical properties of the chalcogenide halides.

Fig.1 presents the known cluster transition metal chalcogenide halides, i.e. the chalcogenide halides in which the existence of metal–metal bonds has been established on the basis of structural and other data. Evidently the formation of cluster chalcogenide halides is characteristic of metals at the beginning of the transition series, i.e. of metals for which cluster halides and chalcogenides are known.

This review discusses the structure, syntheses, and chemical properties of dinuclear, trinuclear, tetranuclear, and hexanuclear cluster transition metal chalcogenide halides.

II. THE STRUCTURE OF CLUSTER METAL CHALCOGENIDE HALIDES

1. Dinuclear Chalcogenide Halides

(a) The Chalcogenide Halides $NbYX_3$ (Y = Se or Te; X = Cl, Br, or I)

All the niobium chalcogenide halides having the general formula $NbYX_3$ are isostructural and crystallise in the monoclinic system (space group $P/2a$, $Z = 2$).[16] The unit cell parameters of the compounds $NbYX_3$ are presented in Table 1.

The structures of $NbSeBr_3$, $NbTeBr_3$, and $NbTeI_3$ have been determined.[16] The crystal-chemical formula is $[Nb_2(\mu_2\text{-}Y_2)(\mu_2\text{-}X)_2X_2(\mu_2\text{-}X)_{4/2}]_\infty$. The formal oxidation state of the metal is +4. The principal structural motif is illustrated in Fig.2*a*. It is made up of two niobium atoms with Nb = Nb distances of 2.832, 2.875, and 2.932 Å respectively for $NbSeBr_3$, $NbTeBr_3$, and $NbTeI_3$. The dichalcogenide group Y_2 is coordinated asymmetrically to two niobium atoms in relation to the metal–metal bond (rotation of the Y_2 dumbell by 4–5° from the "orthogonal" position towards the metal–metal bond). The distances in the chalcogenide group Y_2, which are 2.305 Å for Se–Se and 2.670–2.685 Å for Te–Te, are close to the length of a single bond (2.34 Å for Se_2 and 2.76 Å for Te_2).[17]

*Low-temperature modification.
**High-temperature modification.

Two bridging halogen atoms (μ_2-X) are coordinated analogously and they too are located asymmetrically in relation to the Nb–Nb bond. This asymmetry can be accounted for by the van der Waals repulsion of the halogen atoms. Each niobium atom is linked to one terminal halogen atom X; the length of the bond between niobium and the terminal halogen atom is somewhat smaller than the distance between niobium and the bridging halogen atom. The niobium–niobium fragments are linked by the bridging hydrogen atoms into an infinite chain structure.

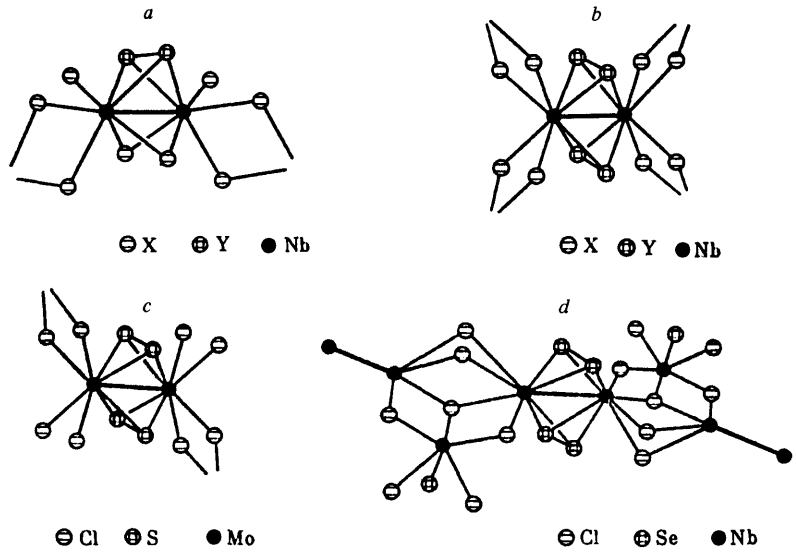

Figure 2. The structure of dinuclear niobium and molybdenum chalcogenide halides: *a*) $NbYX_3$;[16] *b*) NbY_2X_2;[18] *c*) MoS_2Cl_3;[19] *d*) $Nb_3Se_5Cl_7$.[20]

(b) The Chalcogenide Halides NbY_2X_2 (Y = S or Se; X = Cl, Br, or I)

The chalcogenide halides NbY_2X_2 crystallise in the triclinic system under normal conditions (space group $P\bar{1}$, $Z = 2$).[18] The compound NbS_2Cl_2, which has a monoclinic cell at room temperature, is an exception (Table 1). On heating, most of these phases undergo polymorphic transformations (except NbS_2I_2, which does not exhibit polymorphism); there is then a transition from a triclinic to a monoclinic unit cell (space group $C2/m$, $Z = 4$).[18] Table 1 lists the unit cell parameters for the low-temperature and high-temperature modifications of these phases.

The structure of the niobium chalcogenide halides having this composition has been established in relation to the triclinic modification of $NbSe_2Cl_2$ and the monoclinic form of NbS_2Cl_2.[18] The principal structural motif of the given dinuclear complex is presented in Fig. 2*b*. Two niobium atoms are located at the vertices of a distorted Nb_2Y_4 octahedron (D_{2h} symmetry), in which the dichalcogenide groups Y_2, coordinated to the niobium atoms as bridging ligands, make up the equatorial plane. The Nb–Nb distances in these fragments are respectively 2.871 Å in NbS_2Cl_2 and 2.873 Å in $NbSe_2Cl_2$. An interesting crystal-chemical feature of this fragment is the extremely short Y–Y distances in the Y_2 groups, amounting to 1.996 Å for S–S and 2.272 Å for Se–Se. The coplanarity of the S–S bonds in NbS_2Cl_2 indicates the absence of asymmetry in the position of Y_2, noted above in connection with the $NbYX_3$ phases. Admittedly, a slight asymmetry of the orientation of the Se–Se bonds is retained in $NbSe_2Cl_2$. The octahedral Nb_2Y_4 fragments are linked by bridging halogen atoms into layers, i.e. this structure has a layer character.

Thus the crystal-chemical formula of compounds of this type can be represented as follows:

$$[Nb_2(\mu\text{-}Y_2)_2(\mu_2\text{-}X)_{8/2}]_\infty .$$

The formal oxidation state of niobium in such compounds is +4.

(c) The Molybdenum Sulphide Chloride MoS_2Cl_3

The molybdenum sulphide chloride MoS_2Cl_3 crystallises in the monoclinic system (space group $P2_1/c$, $Z = 4$).[19] The unit cell parameters are listed in Table 1.

The MoS_2Cl_3 structure (Fig. 2*c*) can be easily obtained from the NbS_2Cl_2 structure (Fig. 2*b*) by replacing the four bridging chlorine atoms in the *trans*-positions in NbS_2Cl_2 by the terminal atoms. We shall not discuss in detail the structure of MoS_2Cl_3, which is in many respect analogous to NbS_2Cl_2; the Mo–Mo distance is 2.833 Å. In contrast to NbS_2Cl_2, the polymeric motifs in the MoS_2Cl_3 crystals are combined in space in a different manner, namely via the bridging chlorine atoms in the *trans*-positions, which leads to a three-dimensional structure. The oxidation state of molybdenum in this compound is +5.

Among the other crystal-chemical characteristic features of the MoS_2Cl_3 structure, we may mention that the distance between molybdenum and the terminal chlorine atom (2.39 to 2.45 Å) is significantly shorter than the distance between molybdenum and the bridging chlorine atom (2.51–2.56 Å). The short S–S distances (1.98 Å) in the disulphide group S_2 and the absence of asymmetry in their coordination to the two molybdenum atoms are notable.

(d) The Niobium Chalcogenide Halides $Nb_3Se_5X_7$ (X = Cl or Br)

The niobium selenide chloride $Nb_3Se_5Cl_7$ and the niobium selenide bromide $Nb_3Se_5Br_7$ crystallise in the monoclinic system (space group $P2_1/m$, $Z = 2$);[20] the unit cell parameters are presented in Table 1.

A structure of this type has been investigated in relation to $Nb_3Se_5Cl_7$. It can be regarded as derived from the MoS_2Cl_3 structure as a result of the replacement in the latter of each pair of terminal chlorine atoms in the *trans*-positions by the two unusual ligands $NbSeCl_3$ (Fig. 2*d*). The $NbSeCl_3$ ligand

is coordinated to two niobium atoms belonging to neighbouring dinuclear fragments. We may note the short distances between the niobium atom in the $NbSeCl_5$ ligand and the niobium atoms in the neighbouring dinuclear fragments (3.15 Å). Two chlorine atoms in the $NbSeCl_5$ ligand are of the μ_2-bridging type [the Nb–(μ_2-Cl) distances are 2.582 and 2.553 Å], while the third chlorine atom is of the μ_3-bridging type (the distances from μ_3-Cl to the three nearest niobium atoms are 2.629, 2.629, and 2.727 Å). This type of binding of the dinuclear fragment leads to the formation of a chain structure.

The shortest Nb–Nb distance in $Nb_3Se_5Cl_7$ is 2.944 Å. The diselenide groups Se_2 in the central Nb_2Se_4 motif exhibit an appreciable asymmetry in relation to the Nb–Nb bond.

(e) The Nature of the Metal–Metal Chemical Bond in the Dinuclear Chalcogenide Halides

In conclusion of the discussion of the structures of the dinuclear niobium and molybdenum chalcogenide halides, we may mention yet again the common crystal-chemical features of these phases:

1. The dichalcogenide ligands Y_2 (Y = S, Se, or Te), coordinated to both metal atoms, are located in the central dinuclear fragment in all the compounds. The cross-linking of the fragments into chains (for $NbYX_3$ and $Nb_3Se_5Cl_7$) and planar or three-dimensional networks (for NbY_2X_2 and MoS_2Cl_3) is achieved via the bridging halogen atoms.
2. The short metal–metal bonds (2.8–2.9 Å) within the dinuclear fragment alternate with relatively long metal–metal distances (3.9–4.3 Å) between these fragments.

As a result of the efforts of a number of teams of Soviet and foreign specialists, considerable progress has now been achieved in understanding the nature of the metal–metal bond in the dinuclear and polynuclear molecular cluster compounds.[6,21–26] Many properties of the molecular dinuclear compounds can be reasonably explained on the basis of simple theoretical models widely employed at the present time.[5,6,26,27] On the other hand, in the case of polymeric cluster transition metal chalcogenide halides, in the interpretation of the properties of which it is essential to take into account a weaker extended interaction, theoretical models developed in detail are not so far available.

The formation of metal–metal bonds in dinuclear niobium and molybdenum chalcogenide halides can be described qualitatively in approximate terms on the assumption that the metal–ligand bonds are ionic. This approach is widely used in discussing M–M bonds in dinuclear complexes of acido-ligands and has made it possible to account for many properties of these compounds (in particular, magnetic properties). Indeed, bearing in mind the oxidation states of molybdenum and niobium (Mo^{5+} and Nb^{4+}) which obtain in the dinuclear chalcogenide halides as well as the diamagnetism of these compounds, one may conclude that metal–metal bonds are formed. Here one can assume that the valence electrons of the niobium and molybdenum atoms used to form the M–M bonds populate the highest molecular orbital of the σ-type which is largely made up of the *d* orbitals of the metal atoms. This result is in qualitative agreement with the calculation of the molecular orbital diagram for the $[Nb_2(Se_2)_2]^{4+}$ cluster fragment,[28] according to which the highest occupied molecular orbital is of the σ-type, consisting to the extent of 90% of the *d* orbitals of the niobium atom.

The evaluation of the number of valence electrons of the metal atoms in accordance with Sidgwick's rule, the applicability of which to dinuclear molecular complexes has been discussed,[29] may serve as an additional basis for the assumption that the metal–metal bond does or does not exist. According to this rule, the M–M bond is absent if the number of valence electrons in the two metal atoms is 36. The evaluation of the number of valence electrons for the known dinuclear chalcogenide halides with metal–metal bonds shows that the number corresponding to the two metal atoms in the central fragment is less than 36.

The character of the M–M bond can change significantly after the appearance of intracluster bridging ligands of different types (halide and chalcogenide) and also on formation of polymer chains or two-dimensional networks from the dinuclear fragments as a result of their cross-linking by bridging intercluster halide ligands. In the former case the character of the metal–metal bond (in particular, its length) is determined to a large extent by the electronic and geometrical characteristics of the intracluster bridging ligands, while in the second there is a possibility of additional delocalisation of electron density between metal atoms belonging to different dinuclear fragments. In the general case the estimation of each factor separately is a complex experimental and theoretical problem whose solution is simplified when a series of related compounds are considered.[30]

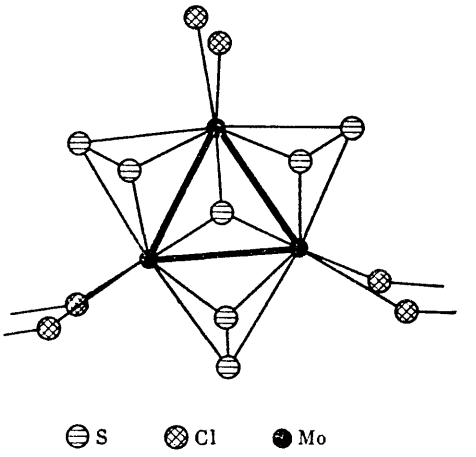

Figure 3. The structure of the trinuclear molybdenum sulphide chloride $Mo_3S_7Cl_4$.[19]

2. The Trinuclear Molybdenum Chalcogenide Halides $Mo_3Y_7X_4$ (Y = S or Se; X = Cl, Br, or I)

Of the six representatives of the trinuclear molybdenum chalcogenide halides $Mo_3Y_7X_4$, a structural study has been carried out for only one phase—the sulphide chloride $Mo_3S_7Cl_4$ (Fig. 3). The compound crystallises in the monoclinic system (space group $P2_1/c$, $Z = 4$;[19] its unit cell parameters are listed in Table 1). The three molybdenum atoms form a virtually equilateral triangle (the Mo–Mo distances are 2.748, 2.741, and 2.747 Å). One sulphur atom (μ_3-S) is located above the centre of the triangle and is linked to the three molybdenum atoms of the cluster. Two chlorine atoms in the molecule are terminal and belong to one molybdenum atom. Two pairs of chlorine atoms at the other two molybdenum atoms function as bridges linking the clusters into an

infinite zig-zag chain. The crystal-chemical formula of the trinuclear molybdenum sulphide chloride can be written thus:

The formal oxidation state of the metal in the trinuclear clusters $Mo_3Y_7X_4$ is +4.

The molybdenum chalcogenide halides $Mo_3S_7Br_4$, $Mo_3Se_7Cl_4$, $Mo_3Se_7Br_4$, $Mo_3S_7I_4$, and $Mo_3Se_7I_4$ were obtained by the same methods as $Mo_3S_7Cl_4$.[89-92] The identical compositions, the common methods of synthesis, and the consistent variation of the thermal properties and infrared spectra in the series of these compounds suggest that their structures are similar.

Within the framework of the ion-covalent model, it is assumed that the three molybdenum atoms in the cluster chalcogenide halide $Mo_3S(S_2)_3.Cl_2Cl_{4/2}$ provide 12 electrons for the formation of bonds with the ligands. Six electrons then remain for the binding of the metal atoms in the triangular Mo_3 cluster and the formal order of the Mo–Mo bond is 1.

On the other hand, evaluation of the number of valence electrons on the assumption of the formation of single Mo–Mo bonds shows that each molybdenum atom then achieves the electronic configuration of the nearest inert gas. This simplest treatment is in good agreement with experimental data: the Mo–Mo distances in the Mo_3 triangle are close to the metal–metal distance in metallic molybdenum.[17]

Speaking of the M–M distances in cluster systems of this kind, one should note in the first place the significant role of the geometrical and electronic properties of the intracluster bridging ligands.[31] To illustrate this, Table 2 presents the Mo–Mo distances in a series of trinuclear molybdenum clusters (structural type—triangle with a single cap). Table 2 shows that in compounds with a μ_3-bridging sulphur atom the Mo–Mo distances are much greater in compounds where oxygen is the μ_3-bridging atom.

Table 2. The metal–metal distances in the trinuclear cluster molybdenum compounds.

Compound	R (Mo–Mo), Å	N_0^*	Refs.

$[Mo_3OCl_3(Oac)_3(H_2O)_3]^{2+}$	2.55	8	[39]

*The number of skeletal electrons per Mo_3 cluster.

The most typical intracluster bridging ligands in the dinuclear and polynuclear chalcogenide halides are the dichalcogenide groups $(Y_2)^{2-}$ which in many respects determine the structure of the central motifs. Such groups can be readily identified by spectroscopic methods. For example, the stretching vibrations of the Y–Y bond are manifested in the Raman spectra by a highly intense band.[40,41] Analysis of the kinematic factors established that, for a fairly large difference between the masses of the metal and sulphur atoms, the hypsochromic shift of the $\nu_{(S-S)}$ frequency, due to the kinematic interaction of the S–S and M–S vibrations, is insignificant (~1 cm^{-1}).

The Raman spectra of numerous compounds containing the disulphide fragment S_2 have been investigated and the linear relations between the $\nu_{(S-S)}$ vibration frequency and the S–S bond length has been noted.[40,41] This made it possible to estimate the S–S bond length in the compounds $Mo_3S_7Br_4$ and $Mo_3S_7I_4$. Table 3 lists the S–S bond lengths in the S_2 dichalcogenide fragment obtained from X-ray diffraction data and calculated from Raman spectra.

Table 3. Dependence of the vibration frequency in the Raman spectra on the S–S bond length in the disulphide fragment.[40,100]

3. The Tetranuclear Chalcogenide Halides $M_4Y_4X_4$ (M = Nb or Mo; Y = S or Se; X = Cl, Br, or I)

The tetranuclear cluster chalcogenide halides $M_4Y_4X_4$ have been obtained for niobium and molybdenum.[45-47] All the compounds crystallise in the cubic system (space group $F\bar{4}3/m$; the unit cell parameters are listed in Table 1).

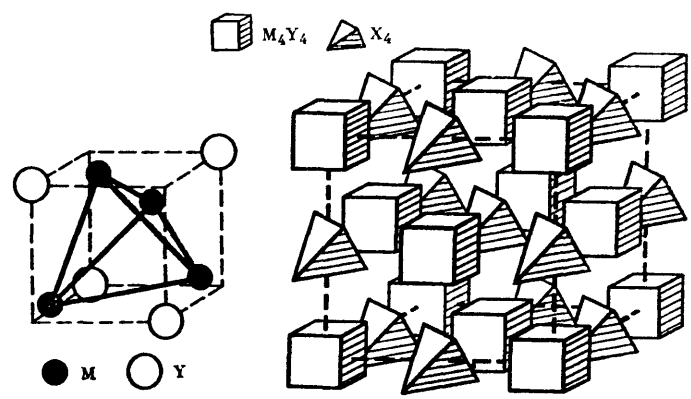

Figure 4. The structure of the tetranuclear niobium and molybdenum chalcogenide halides: *a*) the M_4Y_4 cluster group; *b*) three-dimensional representation of $M_4Y_4X_4$ made up of the M_4Y_4 cluster groups and the X_4 tetrahedra (M = Nb or Mo; Y = S or Se).[45-47]

Their structures have been investigated in relation to niobium selenide iodide $Nb_4Se_4I_4$ and molybdenum sulphide bromide $Mo_4S_4Br_4$. The structure of $Nb_4Se_4I_4$ was determined by the powder method[45] and that of $Mo_4S_4Br_4$ by X-ray diffraction of single crystals.[46,47]

(a) The Structure of $Nb_4Se_4I_4$

Niobium selenide iodide is a tetranuclear cluster containing the Nb_4Se_4 cluster group formed by interpenetrating Nb_4 and Se_4 tetrahedra (Fig. 4*a*).[45] The Nb_4Se_4 groups and the I_4 tetrahedra alternate in the $Nb_4Se_4I_4$ cubic lattice like the sodium and chlorine atoms in the NaCl crystal lattice (Fig. 4*b*). The Nb–Nb distance is 2.96 Å, which appreciably exceeds the Nb–Nb distance in metallic niobium (2.86 Å).[48] Each niobium atom is surrounded by three halogen atoms (the Nb–I distance is 3.02 Å), by three chalcogen atoms (the Nb–Se distance is 2.57 Å), and by three niobium atoms.

(b) The Structure of $Mo_4S_4Br_4$

The compound $Mo_4S_4Br_4$ has the same structure as $Nb_4Se_4I_4$.[46,47] The molybdenum and sulphur atoms occupy the vertices of the Mo_4S_4 pseudocube, the molybdenum atoms being somewhat displaced from its vertices to its centre, so that an Mo_4 tetrahedral cluster is produced. The Mo–Mo distance in the cluster (2.80 Å) is comparable to the metal–metal distance in metallic molybdenum (2.79 Å).[48] The Mo–Br (2.73 Å) and Mo–S (2.34 Å) distances in the octahedral environment of molybdenum are close to those observed in molybdenum bromides and sulphides.[55]

Another approach to the description of the structures of the niobium and molybdenum compounds $M_4Y_4X_4$ is also possible. The structure of these compounds can be represented as of the quasi-spinel type in which the anionic sublattice is made up of X and Y atoms (Fig. 4*b*). The metal atoms occupy half of the octahedral cavities usual for the chalcogenide spinels, are displaced towards the centre of the M_4Y_4 cube, and form the M_4 cluster.

A structure of the quasi-spinel type is known for ternary chalcogenides, for example, $GaMo_4S_8$, $AlMo_4S_8$,[49] and $MMo_2Re_2S_8$.[50] The framework in all these compounds consists of the M_4Y_4 tetrahedral cluster.

In the binary transition metal halides and chalcogenides tetrahedral clusters have not been so far observed, while the "butterfly" and "planar butterfly" structures obtain respectively in the anionic tetranuclear halides $[Mo_4I_{11}]^{2-}$ [51] and $[Nb_4Cl_{11}]^{2-}$.[52]

The niobium and molybdenum chalcogenide halides $M_4Y_4X_4$ are diamagnetic. Assuming an ionic model, one can postulate that the metal atoms give up 12 electrons for the formation of bonds with the ligands Y and X. In the molybdenum compounds the remaining 12 electrons in the Mo_4 cluster are used to form Mo–Mo bonds (two electrons for each edge of the tetrahedron). The formal order of the metal–metal bond in the Mo_4 tetrahedron is 1. In the niobium compound only eight electrons remain for the formation of metal–metal bonds and four electron pairs can participate in the formation of three-centre bonds along the edges of the Nb_4 tetrahedron.

4. The Hexanuclear Cluster Chalcogenide Halides

Ternary compounds of molybdenum and rhenium of the following composition belong to the hexanuclear chalcogenide halides: $Mo_6Y_{8-x}X_x$ (Y = Se, Te; X = Br, I); $Mo_6S_6X_2$ (X = Br, I); Mo_6YX_{10} (Y = S, Se, Te; X = Cl, Br, I); $Mo_6S_3Br_6$; $Re_6Se_8Cl_2$; $Re_6Y_4X_{10}$ (Y = Se, Te; X = Cl, Br). In the hexanuclear chalcogenide halides the metallic clusters constitute as a rule M_6 octahedra distorted to some extent.

For a deeper understanding of the crystal-chemical features and the somewhat unusual stoichiometry of the hexanuclear metal chalcogenide halides, it is useful to compare these phases with, on the one hand, the halide complexes and, on the other, the chalcogenide systems in which similar cluster fragments are produced.

We shall consider briefly the structures of the octahedral clusters of the above three types.

(a) Octahedral Clusters in Halide Systems

In the crystal chemistry of the lower molybdenum and tungsten halides (binary and ternary phases), the cluster group $[M_6X_8]$, which consists of six metal atoms forming the M_6 octahedron and eight halogen atoms located at the vertices of the X_8 cube (Fig. 5*a*), is well known. The M_6 octahedron is inscribed into the X_8 cube in such a way that the X atoms are located above the triangular faces of the octahedron, i.e. behave as μ_3-ligands.

In the halide systems of refractory metals the cluster groups carry a positive charge, namely $[M_6X_8]^{n+}$.[5] Each metal atom in such a group is capable of coordinating one additional ligand with formation of fragments of the type $[M_6X_8]L_6$, where L can be the same atom as X or a ligand of another kind (Fig. 5*b*). Such fragments are the main structural motif in virtually all compounds containing the $[M_6X_8]$ cluster group. Numerous binary and complex molybdenum(II) and tungsten(II) halides as well as the lower niobium iodide Nb_6I_{11} and its derivatives belong to this class of compounds.[5,53–55]

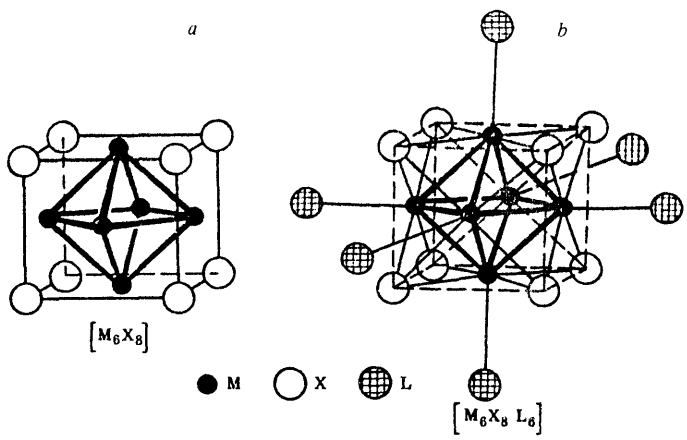

Figure 5. The cluster structure of the octahedral halide complexes: *a*) the $[M_6X_8]$ cluster group; *b*) the $[M_6X_8]L_6$ octahedral complex.

The complexes $[M_6X_8]L_6$ can be formed not only from the given molecules "own" atoms, which is observed in complexes of the type $M'_n[M_6X_8]L_6$, but also in compounds where the total number of ligands per M_6 cluster is less than 14. In these cases the coordination takes place via ligands belonging to other fragments, i.e. the ligands L become μ_2-bridging and belong simultaneously to two neighbouring cluster groups (intercluster bridges). Structures with two bridges, i.e. $[M_6X_8]L_4L_{2/2}$, four bridges, i.e. $[M_6X_8]L_2L_{4/2}$, or six bridges, i.e. $[M_6X_8]L_{6/2}$, are known. For example, certain lower niobium and molybdenum halides can be represented by the following crystal-chemical formulae: $[Nb_6I_8]I_{6/2}$;[56]

$[Mo_6Cl_8]Cl_2Cl_{4/2}$;[57] $[Mo_6Br_8]Br_4.2H_2O$.[58] The formula $[Nb_6I_8]I_{6/2}$ means that all the cluster groups $[Nb_6I_8]$ in the compound Nb_6I_{11} are linked to one another by six intercluster bridging iodine atoms in three different directions; the $[Mo_6Cl_8]$ fragments in molybdenum dichloride are joined by four intercluster bridging chlorine atoms in two directions, so that layers of interlinked cluster groups with two terminal chlorine atoms are formed; finally, a structure with isolated molecular fragments, where, in contrast to the first two examples, all the ligands L are terminal, obtains in molybdenum dibromide dihydrate, so that there are no bridge bonds at all between the cluster groups $[Mo_6Br_8]$ in the $[Mo_6Br_8]Br_4.2H_2O$ crystal.

Instances of more complex bridges linking cluster groups are also encountered. Thus the $[W_6Br_8]Br_6$ cluster complexes in crystals of the tungsten bromide W_6Br_{16} are linked into chains by additional Br_2 bridging groups,[59] while in W_6Br_{18} such complexes are linked by Br_2 bridging groups in two directions, which leads to the formation of layers[60] (Fig.6).

Table 4. Coordination of the ligands L to the metal atoms of the $[M_6X_8]$ cluster group.[5]

Compound	$[M_4X_4]L_4$	Total number of ligands in molecules	Number of intercluster bridging μ_2-ligands
$Mo_6Br_{12}.2H_2O$	$[Mo_6Br_8]Br_4(H_2O)_2$	14	0
$Cs_2Mo_6Br_{14}$	$[Mo_6Br_8]Br_6$	14	0
$CsMo_6Br_{13}$	$[Mo_6Br_8]Br_4Br_{2/2}$	13	2
Mo_6Br_{12}	$[Mo_6Br_8]Br_2Br_{4/2}$	12	4
Nb_6I_{11}	$[Nb_6I_8]I_{6/2}$	11	6

Depending on the type of ligand, their number, charge, and the character of the bonding (terminal or bridging), the complexes $[M_6X_8]L_6$ can be either negatively charged species (behaving as anions in compounds of involved composition) or uncharged.

The change to structures with bridging ligands following a decrease in the number of ligands per M_6 cluster is illustrated in Table 4. The limiting composition of a cluster compound with six simple μ_2-bridging intercluster L ligands is described by the formula $[M_6X_8]L_{6/2}$. The lower niobium iodide Nb_6I_{11}, for example, has this composition.

(b) Octahedral Clusters in Chalcogenide Systems

Octahedral cluster groups are characteristic also of binary and ternary molybdenum chalcogenides.[61,62] For example, in the lower molybdenum selenide and telluride having the analytical formula Mo_3Y_4 the main structural fragment is the $[Mo_6Y_8]$ cluster group. In the Mo_3Se_4 structure the $[Mo_6Se_8]$ cluster fragments are arranged in such a way that the molybdenum atoms of one cluster group interact with the selenium atoms of the neighbouring groups (Fig.7*a*).[63] If this case is then treated in terms of the idea that complexes of the type $[M_6Y_8]L_6$ are formed, then the Mo_6Se_8 binary phase can be described by the crystal-chemical formula $[Mo_6Se_2Se_{6/2}]Se_{6/2}$, which implies that six Y ligands in the $[M_6Y_8]$ cluster fragments function at the same time as the ligands L for other neighbouring cluster groups, i.e. behave simultaneously as intercluster bridges. This example demonstrates significant differences between the hexanuclear halide and chalcogenide clusters.

In the crystals of compounds belonging to the Mo_6Se_8 structural type the interaction of the Mo_6 metallic clusters with one another via direct metal–metal bonds is also observed (Fig.6*a*). Such interaction leads to the metallic character of the conductivity of these compounds and even to superconducting properties (MO_6Se_8 is a superconductor with T_c = 6.25 K).[11]

Another important feature of the Mo_6Se_8 structure is the existence of free channels between the cluster groups. When these channels are filled by atoms of various metals, it is possible to obtain a whole series of ternary chalcogenides having the general formula $M_xMo_6Y_8$ (Y = S or Se).[61] Such ternary chalcogenides, which have extremely interesting superconducting properties, have come to be called the Chevrel phases after one of the first investigators of substances of this class who still continues to work vigorously in the field of the chemistry of cluster compounds.[62]

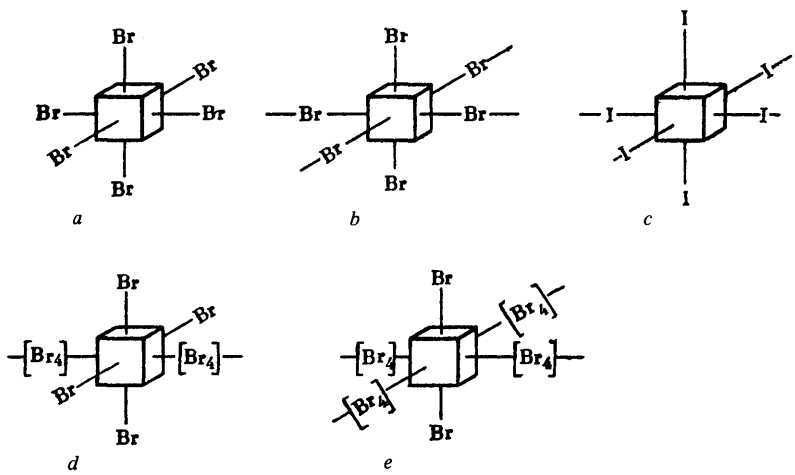

Figure 6. The intercluster bridging ligands in the octahedral transition metal halide complexes:[5] *a*) W_6Br_{14}; *b*) W_6Br_{12}; *c*) Nb_6I_{11}; *d*) W_6Br_{16}; *e*) W_6Br_{18}.

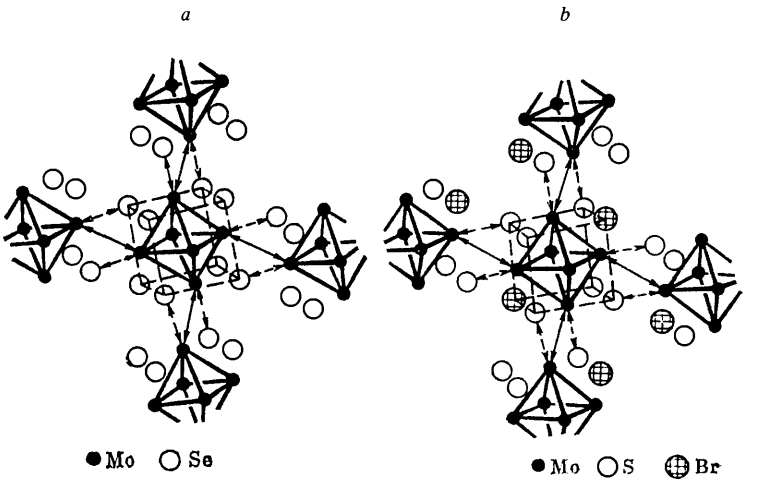

Figure 7. The structure of octahedral clusters: *a*) Mo_6Se_3;[63] *b*) $Mo_6S_6Br_2$.[78]

The chalcogenide cluster groups $[Mo_6Y_8]$, which are so characteristic of molybdenum compounds, have been unknown for other transition metals for a long time. Thus no mention whatever is made of octahedral clusters in a recently published review[64] devoted to the crystal chemistry of rhenium compounds with metal–metal bonds.

However, the most recent studies have shown that rhenium is also capable of forming octahedral cluster systems. Compounds having the composition $Mo_{6-x}Re_xY_8$ (Y = S or Se) and $Mo_4Re_2Te_8$, belonging to the Mo_6Se_8 structural type in which $Mo_{1.5}Re_{4.5}$ and Mo_4Re_2 heterometallic octahedral clusters are produced, were obtained in 1978.[65,66] Solid solutions having the composition $Mo_2Re_4S_{8-x}Se_x$ ($0 \leq x \leq 8$) and $Mo_2Re_4Se_{8-x}Te_x$ ($0 \leq x \leq 1.2$) have also been synthesised.[65]

On the other hand, octahedral rhenium clusters have been observed in the ternary sulphides $Cs_4Re_6S_{13}$,[67] $K_4Re_6S_{12}$, $Na_4Re_6S_{12}$,[68,69] $Li_4Re_6S_{11}$,[70] and finally $Sr_2Re_6S_{11}$ and $Ba_2Re_6S_{11}$.[71] The structure of ternary rhenium sulphides in which the $[Re_6S_8]$ cluster groups are linked to one another by μ_2-S and μ_2-S_2 bridging ligands (Figs.8*a* and 8*b*) are described by the following crystal-chemical formulae: $[Re_6S_8SS_{2/2}(S_2)_{3/2}]^{4-}$ (in $Cs_4Re_6S_{13}$), $[Re_6S_8S_{4/4}(S_2)_{2/2}]^{4-}$ (in $K_4Re_6S_{12}$ and $Na_4Re_6S_{12}$), and $[Re_6S_8S_{6/2}]^{4-}$ (in $Li_4Re_6S_{11}$).

The octahedral cluster is the principal structural fragment of the binary rhenium telluride which had been assumed to be a ditelluride for a long time. However, it has been shown convincingly[72] that the composition of this phase corresponds to the analytical formula Re_2Te_5. The crystal structure of rhenium telluride was determined by ourselves together with N.V.Podberezskaya and by Liu et al.;[73] the $[Re_6Te_8]Te_6$ cluster groups in the Re_2Te_5 structure are linked to one another by tellurium atoms (Fig.8*c*).

The first carbonyl compound containing an octahedral rhenium cluster with an incorporated carbon atom, i.e. $[Re_6(\mu_3\text{-}H)_2C(CO)_{18}]^{2-}$, has been obtained recently.[74]

Consequently the formation of hexanuclear cluster groups is characteristic of all the metals considered. However, niobium, tantalum, and tungsten compounds containing the $[M_6Y_8]$ (Y = S, Se, or Te) cluster groups are at present unknown; rhenium compounds where all the X atoms are halogens in the $[Re_6X_8]$ cluster groups have not been so far obtained either.

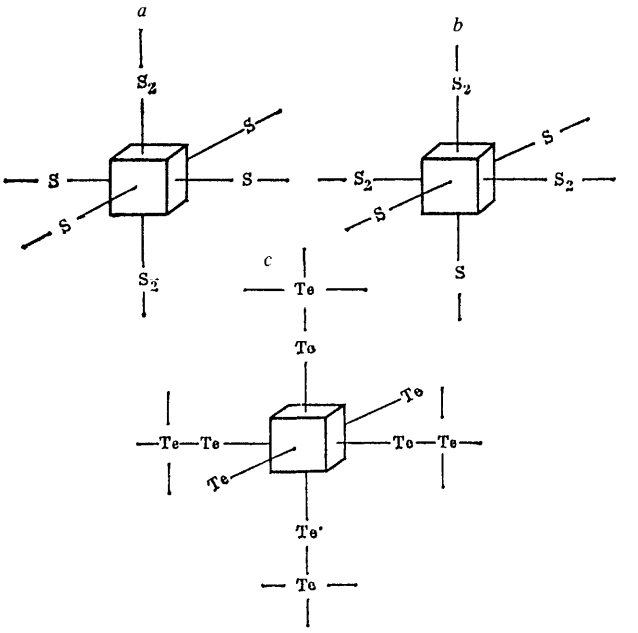

Figure 8. The intercluster bridging ligands in the octahedral rhenium chalcogenide clusters: *a*) $Na_4Re_6S_{12}$;[69] *b*) $Cs_4Re_6S_{13}$;[67] *c*) Re_6Te_{15}.[73]

Since the $[M_6X_8]$ and $[M_6Y_8]$ halide and chalcogenide cluster groups have virtually identical structures, the possibility of the formation of similar groups with mixed ligands, i.e. chalcogenide halides, is indicated; such groups in the cubane $X_{8-n}Y_n$ would contain halogen and chalcogen atoms simultaneously. The similarity of the crystal-chemical characteristics of the halogen and chalcogen atoms makes it possible to replace one ligand by another without a significant alteration in the structure of the cluster groups. Naturally, one must

bear in mind that the halogen and chalcogen atoms have different electron-accepting capacities; the electron density on the M_6 cluster therefore changes significantly following an alteration of the ligand environment of this kind, which should lead to a change of many properties of the compounds considered.

(c) Cluster Octahedral Molybdenum Chalcogenide Halides

The molybdenum chalcogenide halides Mo_6YX_{10} (Y = S, Se, or Te; X = Cl, Br, or I) belong to the Nb_6I_{11} structural type (space group P_{ccn}, orthorhombic system, $Z = 4$).[75,76] The unit cell parameters of these compounds are presented in Table 1.

The structure of the compounds has been established by the X-ray diffraction of Mo_6SeCl_{10} single crystals.[76] The crystal-chemical formula of the compounds Mo_6SeCl_{10} is $[Mo_6SeCl_7]Cl_{4/2}Cl_{2/2}$. The $[Mo_6SeCl_7]$ cluster groups are linked by four bridging chlorine atoms: two other bridging chlorine atoms link the layers to one another. The selenium atom enters into the composition of the $[Mo_6Y'_8]^+$ cluster fragment (Fig. 9*a*). The non-equivalence of the μ_3-ligands in $[Mo_6SeCl_7]$ results in the C_i symmetry of the Mo_6 cluster in Mo_6SeCl_{10}; this is the lowest symmetry among all the known octahedral clusters present in other phases with $[Mo_6Y_8]$ groups. The Mo–Mo distances in the Mo_6 cluster are in the range 2.598–2.626 Å.

As was to be expected, the Mo–Y′ distances (2.468–2.516 Å) in the $[Mo_6Y'_8]$ cluster group are somewhat greater than the average Mo–(μ_3-Cl) distance (amounting to approximately 2.46 Å) in the $[Mo_6Cl_8]$ cluster group of the corresponding chloride complexes[55] and are appreciably less than the Mo–(μ_3-Se) distances (2.52–2.58 Å) in Mo_6Se_8, which can be attributed to a different oxidation state of selenium in Mo_6SeCl_{10} than in Mo_6Se_8.

The distances between the molybdenum atoms and the six bridging chlorine atoms linking the $[Mo_6Y'_8]$ cluster groups with one another are in the range 2.494–2.534 Å, which is close to the analogous distance in molybdenum dichloride (2.49 Å).[57] Each molybdenum atom in the $[Mo_6Y'_8]$ group is at a distance of 0.09 Å from the corresponding face of the Y'_8 pseudocube (the plane passing through the four Y′ atoms); this results in the formation of a greatly flattened square pyramid.

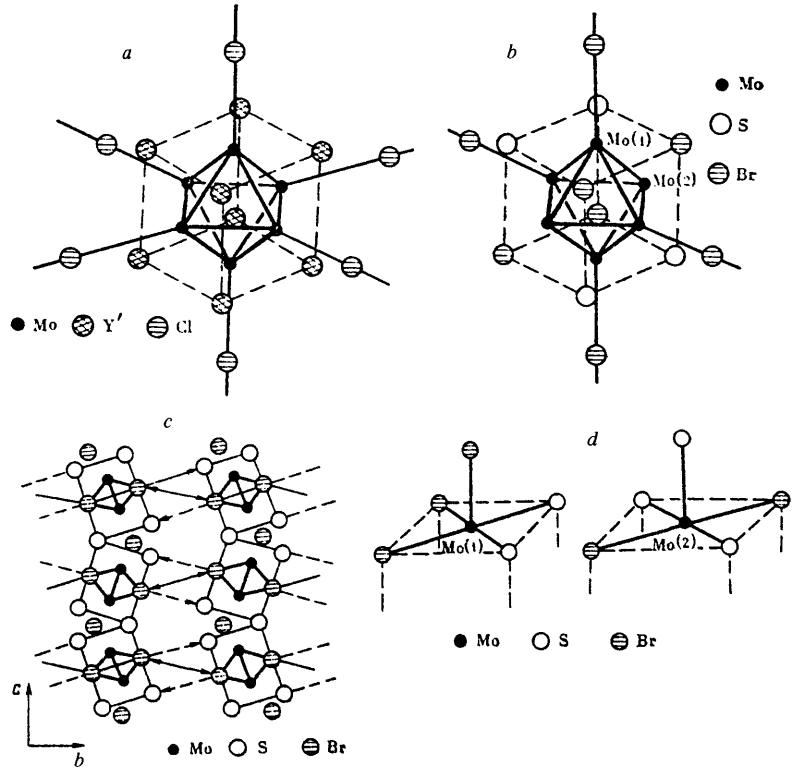

Figure 9. The structure of the hexanuclear molybdenum chalcogenide halides: *a*) a fragment of the Mo_6SeCl_{10} structure;[76] *b*) a fragment of the $Mo_6S_3Br_6$ structure;[77] *c*) three-dimensional packing of $Mo_6S_3Br_6$;[77] *d*) the difference between the coordinations of the molybdenum atoms in $Mo_6S_3Br_6$.[77]

†In this complex sevel Cl atoms and one Se atom are distributed statistically among the eight Y′ poistions of the Mo_6 coordination sphere.

The sulphide bromide $Mo_6S_3Br_6$ crystallises in the orthorhombic system (space group *Cmcm*, $Z = 4$; the unit cell parameters are presented in Table 1).[77] $Mo_6S_3Br_6$ has a layer structure, which represents a new structural type of cluster compounds containing the $[Mo_6Y'_8]$ group.

The principal structural motif of $Mo_6S_3Br_6$ is the $[Mo_6S_4Br_4]$ cluster group in which the sulphur and bromine atoms are ordered and are arranged in pairs along the diagonally opposite edges of the Y'_8 pseudocubane (Fig. 9*b*). All the bromine atoms in $[Mo_6S_4Br_4]$ belong to one cluster group and constitute μ_3-ligands usual for such structures. However, the sulphur atoms in $[Mo_6S_4Br_4]$ are non-equivalent. The two sulphur atoms located on one spatial diagonal are μ_4-ligands: they are linked to three molybdenum atoms in the given cluster group and in addition react with the molybdenum atom of the neighbouring cluster group in the direction of the *b* axis. The other two sulphur atoms are μ_6-ligands, linking two Mo_6 clusters of two neighbouring $[Mo_6S_4Br_4]$ cluster groups, which are thus linked to one another via a common sulphur atom. Consequently the principal structural motif of $Mo_6S_3Br_6$ can be described by the crystal-chemical formula $[Mo_6S_{2/2}S_{2/2}Br_4]$.

In each such group the four molybdenum atoms lying in one plane are coordinated to four bridging bromine atoms, which connect the $M_6Y'_8$] fragments in pairs. As a result, an infinite molecular chain of the $[M_6Y'_8]$ cluster groups joined by the common vertices of the pseudocubanes Y'_8 is formed in a direction parallel to the *c* axis. It can be described by the crystal-chemical formula $[Mo_6S_{2/2}S_{2/2}Br_4]Br_{4/2}S_{2/2}$.

The molecular chains extended along the *c* axis interact with one another in the direction of the *b* axis via the Mo–S bonds 2.503 Å long and Mo–Mo bonds 3.536 Å long. This results in the formation of layers parallel to the *bc* plane with a weak interaction also along the *a* axis. The Br...Br distances between the layers are in the range 3.634–3.742 Å and are close to the usual length of the van der Waals contacts between bromine atoms (Fig. 9*c*).[17]

The molybdenum atoms in $Mo_6S_3Br_6$ are crystal-chemically non-equivalent (Fig. 9*d*). The Mo(1) atoms are coordinated to three bromine atoms and two sulphur atoms via the vertices of a tetragonal pyramid, while the Mo(2) atoms are coordinated via two bromine atoms and three sulphur atoms, the sulphur atoms located at the vertex of the pyramid belonging to a neighbouring $[Mo_6S_4Br_4]$ fragment.

The Mo_6 cluster in $Mo_6S_3Br_6$ has the C_{2h} symmetry and the Mo–Mo distances are in the range 2.63–2.68 Å. These distances are intermediate between those observed in the Mo_6Se_8 and $Mo_6Br_{12}.2H_2O$ crystals.

Each molybdenum atom is located over the corresponding face of the S_4Br_4 pseudocubane, so that a flattened tetragonal pyramid with the molybdenum atom at the apex is formed. The Mo(1) atoms is at a distance of 0.10 Å from the S_2Br_2 plane, while the Mo(2) atom is virtually in the plane [the distance from the S_2Br_2 plane to Mo(2) is only 0.02 Å].

The molybdenum sulphide halides $Mo_6S_6Br_2$ and $Mo_6S_6I_2$ crystallise in the orthorhombic system (Mo_6Se_8 structural type; space group $\bar{R}3$, $Z = 1$; the unit cell parameters of these compounds are listed in Table 1).[78]

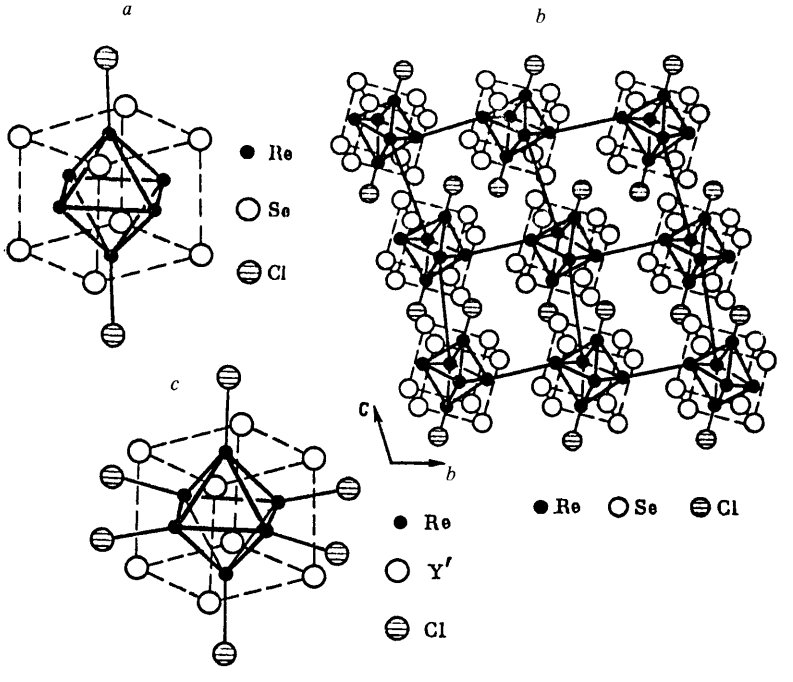

Figure 10. The structure of the hexanuclear rhenium chalcogenide halides: *a*) a fragment of the $Re_6Se_8Cl_2$ structure;[79] *b*) three-dimensional packing of $Re_6Se_8Cl_2$;[79] *c*) a fragment of the $Re_6Se_4Cl_{10}$ structure.[80]

The structure of the molybdenum sulphide bromide $Mo_6S_6Br_2$ resembles that of Mo_6Se_8.[78] An octahedron made up of molybdenum atoms is inscribed in the somewhat distorted pseudocubane S_6Br_2, the opposite two vertices of which are occupied by bromine atoms in such a way that each molybdenum atom is located above the centre of the face outside the cube at a distance of 0.18 Å. The Mo_6 octahedral cluster with D_{3h} symmetry is characterised by two independent Mo–Mo distances of 2.719 and 2.732 Å. While the Mo_6 octahedron in $Mo_6S_6Br_2$ is close to ideality, the S_6Br_2 pseudocubane in this structure is highly distorted (Fig. 7*b*).

The most important feature of the $Mo_6S_6Br_2$ structure is the fact that the halogen atoms in the cluster group are ordered and occupy two *c* positions in the direction of the threefold rhombohedral axis. This factor in fact leads to the formation of compounds with the given stoichiometry.

The interaction of the $[Mo_6Y_8]'$ motifs in the crystal takes place via the bonds between the molybdenum atoms and the sulphur atoms in other cluster groups; the length of such bonds is 2.485 Å (Fig. 7*b*). Thus the molybdenum sulphide bromide $Mo_6S_6Br_2$ has the crystal-chemical formula $[Mo_6S_{6/2}Br_2]S_{6/2}$.

Molybdenum sulphide halides have high temperatures corresponding to the transition to the superconducting state (T_c = 13.8 K for $Mo_6S_6Br_2$ and T_c = 14.0 K for $Mo_6S_6I_2$). It has been suggested that[61] the appearance of superconductivity is associated with the interaction of the molybdenum atoms belonging to neighbouring octahedral clusters and located at a distance of 3.225 Å from one another.

(d) Octahedral Cluster Rhenium Chalcogenide Halides

The rhenium selendie chloride $Re_6Se_8Cl_2$ crystallises in the triclinic system (space group $P\bar{1}$, $Z = \bar{1}$; the unit cell parameters are listed in Table 1).[79] The crystal structure of $Re_6Se_8Cl_2$ (Fig. 10) can be described as one made up of $[Re_6Se_8]Cl_2$ motifs.[79] These motifs consist of Re_6Se_8 cluster groups, which are coordinated above and below to two terminal chlorine atoms via bonds with two rehnium atoms located on the opposite faces of the Se_8 cube (the Re–Cl distance is 2.37 Å).

The $[Re_6Se_8]Cl_2$ fragments in the crystal are arranged in layers parallel to the *ab* plane. The interaction of the cluster groups in such layers takes place via the Re–Se bonds. Four rhenium atoms in each $[Re_6Se_8]$ cluster group are linked to the selenium atoms belonging to four neighbouring $[Re_6Se_8]$ fragments. The lengths of these Re–Se bonds is 2.65 Å, which differs little from that observed in $[Re_6Se_8]$, which is 2.5–2.6 Å. This arrangement is described by the crystal-chemical formula $[Re_6Se_{4}Se_{4/2}]Cl_2Se_{4/2}$. The Re...Re distances between neighbouring clusters within the layer are 3.41 and 3.44 Å (the Re–Re distances in the Re_6 cluster are in the range 2.62–2.66 Å).

The interaction of the $Re_6Se_8Cl_2$ molecular layers in the direction of the *c* axis is insignificant and takes place via the Se...Cl bonds over distances of 3.17 and 3.45 Å. This character of the interaction of the layers determines the quasi-two-dimensional properties of the crystal structure $Re_6Se_8Cl_2$.

The rhenium chalcogenide halides $Re_6Y_4X_{10}$ (Y = Se or Te; X = Cl or Br) crystallise in the triclinic system (space group $P\bar{1}$, Z = 2). The crystal structure has been determined for $Re_6Se_4Cl_{10}$ single crystals[80] (Fig. 10*c*). The rhenium selenide chloride consists of molecular crystals and the Re_6 octahedral clusters in the structure are not linked by intercluster bridging ligands, so that the crystal-chemical formula is $[Re_6Se_4Cl_4]Cl_6$. Two independent cluster fragments are located at the centres of inversion. The Re–Re distances in the octahedral Re_6 cluster are 2.601–2.618 Å. An interesting feature of this structure is the fact that the Se and Cl atoms behave as μ_3-ligands in the $[Re_6Se_4Cl_4]$ cluster group. Although an unambiguous determination of their positions is difficult, the variant where the Se_4Cl_4 pseudocubane is made up of two interpenetrating Se_4 and Cl_4 tetrahedra is the most likely. The model with the X and Y atoms at the opposite vertices of the cubane is well correlated with the spectroscopic properties of the compounds.[80]

(e) The Crystal-chemical Features of the Octahedral Cluster Molybdenum and Rhenium Chalcogenide Halides

In discussing the crystal-chemical features of the structures of the octahedral cluster chalcogenide halides, it is essential in the first place to note, as a general feature, the tendency of the $[M_6Y_8']$ cluster groups to form complexes of the type $[M_6Y_8']L_6$. If the total number of ligands (Y' + L) is 14 per M_6 cluster, then structures with isolated $[M_6Y_8']L_6$ complexes are formed as in the halide systems. This is clearly seen in relation to the rhenium chalcogenides $[Re_6Y_4X_4].X_6$ as an example, which are characterised by a molecular type of structure. With decrease of the number of ligands, the complexes $[M_6Y_8']L_6$ are formed as a result of the coordination at the L site of atoms belonging to other cluster groups. However, in contrast to the halide system discussed above, where ligands of type L constitute common intercluster bridges, in the chalcogenide halides this function is fulfilled by the Y' atoms, i.e. the atoms which form part of the $[M_6Y_8']$ cluster group. The same simple behaviour is observed in this instance too: with decrease of the number of ligands per M_6 cluster, the number of atoms common to two neighbouring cluster groups increases and the Y' begin to assume the function of intercluster bridges. This rule is well illustrated by the data in Table 5: a steady variation of the character of the coordination is seen on passing from isolated molecular chalcogenide halides of the type $[Re_6Y_4X_4]X_6$ (14 ligands per cluster) to the $[Me_6S_{6/2}Br_2]S_{6/2}$ structure (eight ligands per cluster). Depending on the atoms in the Y_8' cubane through which the cluster groups are linked to one another, structures of different size can be produced.

Table 5. Variation of the intercluster metal–metal distances as a function of the type of bridging ligands.

Compound	$[M_4Y_8']L_6$	N_L^*	$\frac{R}{(M...M)}$, Å	Character of structure	Refs.
$Re_6Se_4Cl_{10}$	$[Re_6Se_4Cl_4]Cl_6$	14	3.69	molecular	[80]
Mo_6SeCl_{10}	$[Mo_6SeCl_7]Cl_{6/2}$	11	3.687	polymeric (three-dimensional)	[76]
$Re_6Se_6Cl_2$	$[Re_6Se_4Se_{4/2}]Cl_2Se_{4/2}$	10	3.42	polymeric (layer)	[79]
$Mo_6S_3Br_6$	$[Mo_6S_{2/2}S_{2/2}Br_4]Br_{4/2}S_{2/2}$	9	3.536	polymeric (layer)	[77]
$Mo_6S_6Br_2$	$[Mo_6S_{6/2}Br_2]S_{6/2}$	8	3.225	polymeric (three-dimensional)	[78]
Mo_6S_8	$[Mo_6S_{6/2}S_2]S_{6/2}$	8	3.086	polymeric (three-dimensional)	[61]

*The number of ligands per cluster in the molecule.

It is also of interest ot note that the coordination of the ligands Y_8' changes on formation of such intercluster bridges: on formation of additional bonds, the μ_3-ligands beome μ_4-ligands and even μ_6-ligands (as has been observed in $Mo_6S_3Br_6$).

The character of the chemical bonds in octahedral cluster chalcogenide halides can apparently be described within the framework of the ionic-covalent model, where it is assumed that there is a covalent interaction between the metal atoms in the M_6 octahedron, while the bonds between the metal and the ligands are ionic. Calculations of the electronic structure of the hexanuclear metal halides and chalcogenides have convincingly confirmed the validity of this treatment.[22,61] An important feature of these systems consists in the fact that two groups of molecular orbitals are formed by the atomic *d* orbitals of the metal; 12 bonding MO (which describe 12 two-centre M–M bonds oriented along the edges of the octahedral M_6 cluster) are separated from the higher antibonding unoccupied MO.[81,82]

Consequently the formation of 12 simple two-electron M–M bonds in the M_6 cluster requires 24 valence electrons. This situation obtains in halide systems with the $[Mo_6X_8]^{4+}$ cluster group and also in the chalcogenide halides Mo_6YX_{10} and $Mo_6S_3Br_6$ (Table 6). However, in the $Mo_6S_6Y_2$ and also Mo_6S_8 chalcogenide halides the Mo_6 cluster is electron-deficient, which implies that the bonding MO, characterising the M–M interaction in the octahedral cluster, are only partly occupied. Consequently the Mo–Mo bond order should decrease in the series of compounds $Mo_6S_3Br_6 \rightarrow Mo_6S_6Br_2 \rightarrow Mo_6S_8$. A decrease of the number of valence electrons in the Mo_6 cluster entails an increase of the Mo–Mo distances (Table 6). Indeed the molybdenum sulphide Mo_6S_8, which has only 20 electrons per cluster, is thermodynamically unstable and cannot be obtained by direct synthesis from the elements. The addition of electrons to the electron-deficient cluster system stabilises the phases, which is clearly demonstrated by chalcogenide halides of the type of $Mo_6S_6Br_2$ and $Mo_6S_6I_2$ (22 electrons per cluster), and also by the $M_xMo_6S_8$ Chevrel phases, which can contain 21–24 electrons per cluster depending on the nature of the metal M. It has been shown convincingly for a large number of Chevrel phases that the interatomic Mo–Mo distances in the Mo_6 cluster depend on the number of valence electrons localised on the cluster.[61]

Table 6. Dependence of the Mo–Mo interatomic distances in the Mo_6 cluster on the number of valence electrons localised on the cluster.

Compound	R (Mo–Mo), Å	N_e^*	Refs.
$[Mo_6Cl_8]Cl_2Cl_{4/2}$	2.61	24	[59]
$Cs_2[Mo_6Cl_8]Br_6$	2.61	24	[76]
$Hg[Mo_6Cl_8]Cl_6$	2.62	24	[76]
$[Mo_6SeCl_7]Cl_{6/3}$	2.62	24	[76]
$[Mo_6Br_6]Br_4 \cdot 2H_2O$	2.64	24	[60]
$Mo_6S_3Br_6$	2.66	24	[77]
$Mo_6S_6Br_2$	2.73	22	[78]
Mo_6S_8	2.78	20	[61]

*The number of electrons per Mo_6 cluster.

Thus shorter distances between the molybdenum atoms in the Mo_6 cluster are observed in those compounds where the number of electrons per cluster approaches 24. The size of the Mo_6 octahedron can serve as a measure of the degree of occupation of the conductivity band. In the most highly contracted octahedron all the bonding states are occupied and the number of electrons per cluster is 24.

An interesting aspect of the crystal chemistry of the octahedral cluster chalcogenide halides is the variation of the shortest metal–metal distances between the clusters (Table 5). With increase of the number of bridging cross-links between the cluster groups, conditions arise for closer direct contacts between the metal atoms of neighbouring clusters. Thus the Mo–Mo distances between neighbouring clusters decrease steadily in the series of molybdenum chalcogenide halides Mo_6SeCl_{10}, $Mo_6S_3Br_6$, and $Mo_6S_6Br_2$: 3.687, 3.536, and 3.225 Å respectively.

The conducting properties of the binary and ternary chalcogenide containing the $[M_6Y_8]$ cluster groups are extemely interesting. The unique superconducting properties of the Chevrel phases are widely known.[11,62] They are determined mainly by the 4*d* electrons of molybdenum occupying the conductivity band. If the conductivity band is incompletely filled, favourable conditions arise for the appearance of superconductivity in such phases. The Mo–Mo distances between neighbouring clusters are then also significant.[61]

From this point of view, among the chalcogenide halides considered here the $Mo_6S_6Br_2$ and $Mo_6S_6I_2$ phases are of the greatest interest (22 electrons) per cluster. They are conductors and undergo a transition to the superconducting state at 13.8 and 14.0 K respectively.[78]

If the conductivity band is fully occupied, the compounds exhibit semiconducting or dielectric properties. For example, $Mo_6S_3Br_6$ and $Re_6Se_4Cl_{10}$, in which there are 24 valence electrons per cluster, can be included among such phases.

III. METHODS OF SYNTHESIS

The cluster niobium, molybdenum, and rhenium chalcogenide halides are usually obtained by the high-temperature synthesis involving prolonged heating of mixtures of different composition in evacuated sealed tubes: (a) metal + halogen + chalcogen; (b) metal chalcogenide + halogen; (c) metal halide + chalcogen; (d) metal halide + metal + chalcogen; (e) metal chalcogenide + metal halide; (f) metal + chalcogen halide. The initial substances are usually taken in proportions corresponding to the stoichiometry of the substance to be synthesised.

A general preparative method of synthesis of transition metal chalcogenide halides at high temperatures is that of gas-transport chemical reactions. A characteristic feature of these reactions, whereby it is possible to obtain high quality crystals, is mass transfer under the conditions of a temperature gradient with segregation of the solid phase in the cold zone; phases separated in space from the initial reaction mixture are then produced.[84]

(a) The Synthesis and Properties of Dinuclear Chalcogenide Halides

All the compounds having the composition $NbYX_3$ (Y = Se or Te; X = Cl, Br, or I) have been obtained by the high-temperature sealed tube synthesis from the elements. A stepwise increase of temperature with a final treatment at 800 °C for 3–4 days has been used. When a temperature difference is created at the ends of the sealed tube, mass transport and growth of acicular single crystals are observed.[16]

The chalcogenide halides $NbYX_3$ are stable in air; they form grey single crystals with metallic lustre. The thermal properties of these substances have been investigated.[16] The final product of the thermal decomposition of $NbTeI_3$ *in vacuo* is Nb_3Te_4.

Compounds having the analytical formula MYX_3 have been obtained also for other metals (M = Ta, Mo, or Re) by the interaction of the corresponding metal pentahalides with Sb_2Y_3 (Y = S or Se) in solution in CS_2.[85] However, the structure of these phases is unknown and at the present time

there are no grounds for assigning them to dinuclear compounds.

Compounds having the composition NbY_2X_2 (Y = S or Se; X = Cl, Br, or I) have been obtained by the sealed tube method in the 480–530 °C temperature gradient. The starting materials were metallic niobium, the elemental chalcogen, and niobium tetrahalides. The single crystals of niobium chalcogenide halides were grown in the cold zone of the sealed tube in the form of plates. The transport time was 3–4 weeks.[18] The compounds NbS_2Cl_2 and NbS_2Br_2 can be obtained on heating the metal in S_2Cl_2 and S_2Br_2 vapours.[86]

The compounds NbY_2X_2 are stable in air and are insoluble in the majority of solvents. On heating, they undergo polymorphic transformations (Table 1). The thermal decomposition of the compounds proceeds in different ways depending on the composition. For example, the compounds NbY_2X_2 (X = Cl or Br) decompose in accordance with the scheme

$$3NbY_2X_2\,(\text{solid}) \rightarrow NbY_2\,(\text{solid}) + X_2\,(\text{gas}) + 2NbYX_3\,(\text{gas}).$$

The chalcogenide iodides NbY_2I_2 dissociate via the reaction

$$NbY_2I_2 \rightarrow NbY_2\,(\text{solid}) + I_2\,(\text{gas}).$$

The compounds are diamagnetic and are semiconductors.[86]

Single crystals of the black sulphide chloride MoS_2Cl_3 have been obtained on heating to 450 °C a 1 : 10 mixture of $MoCl_3$ and S in S_2Cl_2.[19] A yellow-brown sulphide chloride of the same composition has been obtained on heating molybdenum pentachloride in S_2Cl_2 at 250 °C.[87] The structure of the black MoS_2Cl_3 has been established by X-ray diffraction[19] and the yellow-brown molybdenum sulphide chloride has been characterised only by infrared and Raman spectra.

Single crystals of the brown selenide chloride $Nb_3Se_5Cl_7$ have been obtained accidentally in a study of the transport of $NbSe_2Cl_2$ in the presence of $NbCl_4$ in a temperature gradient (at 535–525 °C). The transport time was 2–3 weeks.[20] The dark-blue bromide analogue $Nb_3Se_5Br_7$ has been obtained in the form of single crystals on heating a reaction mixture comprising $NbSe_2Br_2$ and $NbSeBr_3$. The authors noted a poor reproducibility of this syntheses.[20]

(b) The Synthesis and Properties of Trinuclear Chalcogenide Halides

The trinuclear chalcogenide halides $Mo_3Y_7X_4$ have been obtained in quantitative yields on heating the lower molybdenum halides MoX_2 and MoX_3 (X = Cl, Br, or I) in a sulphur or selenium melt at temperatures in the range 350–450 °C:[89–92]

$$6MoCl_3 + 24S \rightarrow 2Mo_3S_7Cl_4 + 5S_2Cl_2\ .$$

The excess chalcogen and the Y_2X_2 formed as a result of the reaction are removed by heating *in vacuo* or are washed out with CS_2.[89] Another convenient method of synthesis of the trinuclear molybdenum chalcogenide halides involves the conversion of the chalcogenide halide MoY_4X_2 (Y = S or Se; X = Br or I) on heating in sealed tubes:[93]

$$3MoS_4I_2 \rightarrow Mo_3S_7I_4 + 5S + I_2\ .$$

The cluster compounds $Mo_3Y_7X_4$ are insoluble in organic solvents and do not sublime *in vacuo*, which hinders their further purification.

$Mo_3S_4Cl_4$ single crystals have been obtained on heating molybdenum trichloride and sulphur at 450 °C in a sealed tube in the presence of S_2Cl_2.[19]

The thermal properties of the trinuclear molybdenum chalcogenide halides have been investigated. Heating of $Mo_3Y_7X_4$ *in vacuo* or in an inert atmosphere results in the formation of their corresponding dichalcogenides.[89–92]

The process has a stepwise character in an atmosphere of hydrogen; the final reduction products at model temperatures are also dichalcogenides.[89–92]

(c) The Synthesis and Properties of Tetranuclear Chalcogenide Halides

The tetranuclear chalcogenide halides $M_4Y_4X_4$ (M = Nb or Mo; Y = S or Se; X = Cl, Br, or I) have been obtained by high-temperature annealing in evacuated quartz tubes, the reaction mixture consisting of the metal, the chalcogen, and a lower metal halide.

The niobium chalcogenide halides $Nb_4Y_4X_4$ have been obtained from Nb_3X_8, metallic niobium, and the chalcogen in a two-zone furnace with a temperature gradient of 700–800 °C.[45] The molybdenum sulphide halides $Mo_4S_4X_4$ have been synthesised at 1100 °C and the reaction mixture consisted of the corresponding dihalide, molybdenum, and sulphur.[46,47]

The tetranuclear niobium and molybdenum chalcogenide halides are stable in air and are insoluble in the usual organic solvents.

(d) The Synthesis and Properties of Hexanuclear Chalcogenide Halides

Practically all chalcogenide halides of this type are obtained via solid-phase synthesis reactions using high temperatures. The only exception is $Re_6Te_4Br_{10}$, which can be obtained by the reaction of rhenium telluride with bromine even at room temperature. The reason why the reaction proceeds under such mild conditions is apparently that the initial rhenium telluride Re_6Te_{15} already contains the octahedral Re_6 cluster in its structure. The lower halides, the chalcogen, and the metal in stoichiometric amounts are used as the starting reactants for the synthesis of compounds with a high metal content.

The compounds Mo_6YX_{10} (Y = S, Se, or Te; X = Cl or Br) have been obtained by the sealed tube method, the stoichiometric amounts of $MoX_2(MoX_3)$, Mo, and Y being sintered at temperatures in the range 1000–1150 °C for 24 h with subsequent reannealing under the same conditions.[76] Single crystals suitable for X-ray diffraction studies grow during the synthesis. The colour of the single crystals of the chalcogenide halides Mo_6YX_{10} varies from red to dark-brown depending on the composition. The compounds are stable in air, are diamagnetic, and are dielectrics.

The molybdenum sulphide bromide $Mo_6S_3Br_6$ has been obtained by the sealed tube synthesis, in which stoichiometric amounts of the $3MoBr_2$ + 3Mo + 3S powders, pressed into discs, are heated at 1200 °C for 24 h. The preparation of single-phase specimens requires reannealing under the same conditions after mixing the reaction products. $Mo_6S_3Br_6$ single crystals in the form of black lustrous plates grew at 1250 °C.[77]

The chalcogenide halides $Mo_6S_6Br_2$ and $Mo_6S_6I_2$ have been obtained by the sealed tube method. Stoichiometric amounts of powdered MoX_2, molybdenum, and sulphur were pressed into discs and the reaction was carried out at 1050 °C for 24 h. After mixing the reaction products, the latter were reannelaed under the same conditions.[78] The possible admixtures in this method of synthesis of the sulphide halides $Mo_6S_6X_2$ can be the Mo_2S_3 and $Mo_4Y_4X_4$ phases. In the synthesis of $Mo_6S_6I_2$ one can also begin with a mixture of stoichiometric amounts of the elements.[94] The attempts to obtain molybdenum sulphide chlorides having the same composition were unsuccessful.

The compounds are weakly paramagnetic and exhibit metallic conductivity. On decrease of temperature, they pass to the superconducting state, the width of the transitional region amounting to 1–2 K. The critical temperatures are 13.8 K for $Mo_6S_6Br_2$ and 14.0 K for $Mo_6S_6I_2$.[78]

The interaction of $Mo_6S_6I_2$ with copper has been investigated.[94] It has been established that single-phase products having the composition $Cu_xMo_6S_6I_2$, where $0 < x < 1.2$, which are isostructural with $Mo_6S_6I_2$, can be obtained at 470 °C. With increase of the amount of copper in the $Cu_xMo_6S_6I_2$ phases, the size of the unit cell increases somewhat but the temperature of the transition to the superconducting state decreases.

The rhenium selenide chloride $Re_6Se_8Cl_2$ has been obtained by the sealed tube method at 1000 °C from a mixture of $ReCl_5$, Re, and Se.[79] The compounds $Re_6Se_4Cl_{10}$ and $Re_6Se_4Br_{10}$ are obtained by the sealed tube method in which the $ReSe_2$ + $2ReX_5$ (X = Cl or Br) reaction mixture is heated at 700–750 °C for 10–15 h (the rhenium trihalide is taken in a slight excess). The reaction products are separated by vacuum-thermal distillation.[95] The rhenium selenide bromide $Re_6Se_4Br_{10}$ is also obtained by brominating $ReSe_2$ at 650–700 °C.[96]

The compound $Re_6Te_4Br_{10}$ is obtained by brominating the rhenium telluride Re_6Te_{15} with liquid bromine. The reaction proceeds even at room temperature, but the temperature is raised to 50–60 °C to achieve a more rapid completion of the process.[96]

IV. CHEMICAL PROPERTIES

As shown in the previous sections of the review, molecular structures with a metal–metal bond are not characteristic of the chalcogenide halides—the M_n cluster nuclei are linked into infinite chains, layers, or give rise to three-dimensional structures. Such polymeric structure of the cluster chalcogenide halides is manifested in their properties: their volatility is low and they are insoluble in organic solvents, which greatly hinders the study of their chemical properties. These compounds are as a rule stable in air and their reactivity is low.

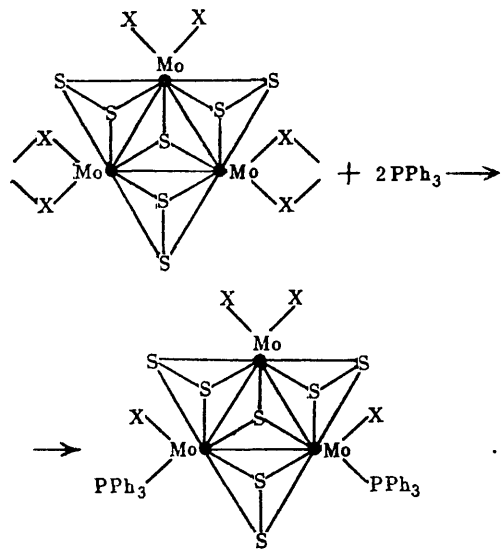
Related structural motifs arise in the cluster transition metal halides, chalcogenides, and chalcogenide halides. The chalcogenide halides occupy an intermediate position between the metal halides and chalcogenides. The cluster metal chalcogenides are frequently soluble in organic solvents, undergo complex formation reactions, and, as shown recently in relation to rhenium trihalides,[97] they enter into organometallic synthesis reactions. The cluster chalcogenides are chemically inert and decompose on treatment with strong oxidants or reductants under severe conditions.

We shall consider what synthetic approaches are possible in the study of the chemical properties of cluster chalcogenide halides. In our view, it is initially necessary to find ways of dissolving the cluster chalcogenide halides. The synthetic methods of the chemistry of complex and organometallic compounds are applicable to clusters soluble in organic solvents. In order to achieve the dissolution of the compounds, it is necessary to find reagents in the presence of which one-, two-, or three-dimensional structures are disrupted, but the main cluster fragments should persist. Monomeric structures in the cluster chalcogenide halides are usually formed with the aid of bridging halogen and chalcogen atoms or via the metal–metal intercluster interaction. The ways used to disrupt such different structures should apparently also be different.

We shall now turn to analogies from the chemistry of cluster metal halides. The reactions of hexanuclear cluster niobium, tantalum, molybdenum, and tungsten halides as well as the trinuclear rhenium halides with oxygen, sulphur-, nitrogen-, and phosphorus-containing ligands are well known. As a result of such reactions, the polymeric structures are broken up and molecular cluster complexes of metal halides with various ligands are formed, for example:[5,98]

$$Mo_6Cl_{12} + 2Et_3N \rightarrow Mo_6Cl_{12} \cdot 2Et_3N \ ;$$
$$Re_3Cl_9 + 3PPhEt_2 \rightarrow Re_3Cl_9 \cdot 3PPhEt_2 \ .$$

It has been shown recently[99] that the polymeric cluster sulphide halides $Mo_3S_7Cl_4$ and $Mo_3S_7Br_4$ interact with triphenylphosphine on heating in acetonitrile or benzonitrile, giving rise to molecular trinuclear complexes soluble in organic solvents:



The reaction of molybdenum sulphide chloride with PPh_3 in proportions of 1 : 5 produces a molecular complex having a different composition:

$$Mo_3S_7Cl_4 + 5PPh_3 \rightarrow 3S{=}PPh_3 + Mo_3S_4Cl_4 \cdot 2PPh_3 \ .$$

The formation of the triphenylphosphine sulphide can be accounted for by the elimination of sulphur atoms from the disulphide group. Reactions leading to the elimination of a chalcogen atom from the dichalcogenide group on treatment with various nucleophiles are convenient models for the understanding of many biochemical processes.[100]

Reactions involving the nucleophilic substitution of halogen atoms are of independent interest. Such reactions have been known for a long time for the cluster transition metal halides. For example, it has been shown for rhenium trihalides that the intercluster halogen atoms are the first to be involved in the substitution reaction with nucleophiles.[101] The first instance of the nucleophilic substitution of the halogen has been found for the cluster chalcogenide halides. The sulphide chloride $Mo_3S_7Cl_4$ interacts with sodium polysulphide with retention of the trinuclear cluster framework:[102]

$$Mo_3S(S_2)_3Cl_4 \xrightarrow[S_2^{2-}]{} [Mo_3S(S_2)_6]^{2-} \ .$$

Thus the first examples of the conversion of polymeric molybdenum chalcogenide halides into molecular clusters soluble in organic solvents have been found, which leads to wide possibilities for the investigation of the properties of compounds of this class.

In conclusion we may note that the study of the chemical properties of cluster transition metal chalcogenide halides may promote the solution of one of the most interesting problems in modern chemistry: Cotton has pointed out[4] the necessity for

the mutual approach of two fields of the chemistry of cluster compounds which have been largely developing independently, namely those concerned with the study of high valence clusters (the clusters with acido-ligands) and low-valence clusters (organometallic clusters). It may be that the cluster transition metal chalcogenide halides discussed in this review will prove important starting compounds for organometallic synthesis reactions, including reactions involving reactive cyclopentadienyl compounds of metals.

I. INTRODUCTION

Until the early nineteen-sixties, apparently, there were no theoretical or experimental indications of the possible existence of the NF_4^+ cation in the gas phase or in salt crystal lattices. The formula NF_4^+ appeared for the first time in Ref.1, where the dissociation energies and ionisation potentials of various fluorides were estimated, and it was concluded that salts of the NF_4^+ cation could not be obtained. Three years later, Wilson[2] devoted a special paper to the estimation of the stability of the NF_4^+ cation and its salts. He used the method of analogies, isoelectronic series, and the bond energy and ionisation potential values then available to estimate the crystal lattice energies of tetrafluoroammonium fluoride, perchlorate, sulphate, and tetrafluoroborate. The calculations showed that the first three salts should be extremely unstable relative to their possible decomposition products ($NF_3 + F_2$, $NF_3 + FClO_4$, $2NF_3 + F_2O + SO_3$ respectively) and cannot exist, and that the tetrafluoroborate may be stable at temperatures below 120 K. The possible stabilisation of the NF_4^+ cation in compounds with other polyatomic fluoro-anions was not examined,[2] although it was assumed that tetrafluoroammonium fluoroantimonate or fluoroarsenate might be more stable.[3]

Nitrogen trifluoride is extremely inert towards Lewis acids. An infrared spectroscopic study[4] of the reaction of nitrogen fluorides with Lewis acids established only weak association in the systems $NF_3 + BF_3$ (at temperatures below 148 K) and $NF_3 + BCl_3$ (below 173 K) and no association or reaction in the $NF_3 + PF_5$ system (as far as 145 K). The possible reaction $NF_3 + F_2 \rightleftharpoons NF_4^+ + F^-$ between NF_3 and fluorine in anhydrous hydrogen fluoride was noted in Ref.5. The authors of Ref.6, who studied the action of the bremsstrahlung of electrons on a number of compounds of fluorine, nitrogen, and oxygen, including a mixture of NF_3 and BF_3, were apparently close to the synthesis of NF_4^+.

In 1966, two groups of American authors[7,8] simultaneously reported the synthesis of two tetrafluoroammonium salts, the fluoroarsenate and the fluoroantimonate. In 1970, a method for preparing tetrafluoroammonium tetrafluoroborate was patented[9] in the USSR, and a paper[10] published in the same year described the properties of this compound, whose thermal stability was found to be much higher than that predicted in Ref.2. New methods for synthesising NF_4BF_4, NF_4AsF_6, and NF_4SbF_6 have since been found, and methods have been developed for preparing other tetrafluoroammonium salts. The synthesis of NF_4ClO_4 was reported[11] in 1980. The existence of this salt contradicts the predictions of Ref.2; it decomposes slowly only at 273 K.

The names "perfluoroammonium", "tetrafluoroammonium", "tetrafluoronitrogen", and "tetrafluoronitronium" have been proposed for the NF_4^+ cation. None of them can be regarded as satisfactory, but most authors prefer to call this ion the tetrafluoroammonium ion. This name will be used in the present work, but it must be borne in mind that the NF_4^+ ion cannot be obtained by replacing the hydrogen atoms in the ammonium ion, and that the formal oxidation state of nitrogen in NF_4^+ is +5, whereas that in NH_4^+ is -3. In the text, the name of the NF_4^+ ion will be abbreviated to TFA. The synthesis and properties of TFA salts were examined briefly in Refs.12 and 13.

II. SYNTHESIS OF TETRAFLUOROAMMONIUM SALTS

As shown below, the synthesis of TFA salts involves considerable experimental difficulties, and a special method of synthesis has to be developed for almost every new compound. This probably explains why TFA salts have as yet been prepared in only a few laboratories. In the present work, the experimental conditions for the synthesis of TFA salts will be examined in more detail than is usual in review papers; the "key" compounds, that is the hexafluoroarsenate, hexafluoroantimonate, and tetrafluoroborate, will be considered first, followed by the others in order of increasing atomic number of the central atom of the anion. The "key" TFA salts were synthesised first, and subsequently used to obtain various other TFA salts. The total number of TFA salts synthesised by mid-1983 was greater than 30.

$NF_4^+AsF_6^-$. This salt was first obtained[8,14] by the action of an electrical glow discharge on a mixture with the molar ratio $NF_3:AsF_5:F_2 = 1:1:2$. The method of synthesis is described in more detail in Ref.15. A mixture of NF_3, AsF_5, and F_2 was passed into a glass electrical-discharge reaction vessel, supplied from a transformer and fitted with a circulating pump, to an initial pressure of not more than 80 mmHg, after which the discharge was switched on and the reaction carried out under circulation conditions at a temperature of the walls of the reaction vessel of 195 K. The apparatus used had a low efficiency, and the synthesis of 1 g of salt took ~40 h. The same paper[15] described an unsuccessful attempt to obtain NF_4AsF_6 from NF_3, AsF_5, and an excess of F_2 by heating the reagents to 758 K at a pressure of ~168 atm in a Monel metal vessel for 12 h. Instead of the expected product, this gave $Ni(AsF_6)_2$, formed by corrosion of the walls of the autoclave.

According to Ref.3, however, when a mixture of NF_3, F_2, and AsF_5 was heated for a longer time (260 h) at 398 K, 95% pure NF_4AsF_6 was obtained. It was later established[16] that the NF_4AsF_6 specimens obtained by the high-temperature method do not have a uniform composition and contain appreciable quantities of nickel and copper salts, formed by corrosion of the walls of the Monel metal reaction vessel; salts of the $As_2F_{11}^-$ anion are not formed under these conditions.

TFA hexafluoroarsenate can be obtained photochemically.[17] Irradiation of an equimolar mixture of NF_3, F_2, and AsF_5, placed in a sapphire reaction vessel at room temperature, with a high-pressure mercury lamp (without a filter) gives NF_4AsF_6 in less than 1% yield. This low yield can be attributed to the deposition of a layer of product on the walls of the reaction vessel, leading to the absorption of ultraviolet radiation, and the low thermal stability of possible intermediate products of the photosynthesis. In an improved procedure,[18] NF_4AsF_6 was obtained by the ultraviolet irradiation of NF_3, AsF_5, and F_2 (3:3:1) in a special quartz reaction vessel which made it possible to carry out the synthesis at 77 K. The product is highly pure, and is formed at a rate of more than 1 g h^{-1}. The ultraviolet irradiation of a mixture of CF_3NF_2, AsF_5, and F_2 gives the hexafluoroarsenates of NF_4^+, $N_2F_3^+$, and N_2F^+.[18] $^{15}NF_4AsF_6$ has been obtained photochemically[18] from $^{15}NF_3$, F_2, and AsF_5; the $^{15}NF_3$ required was synthesised from $^{15}N_2$ and F_2 in an electrical glow discharge.[19]

$NF_4^+SbF_6^-$. TFA fluoroantimonate was first obtained by the reaction of NF_3 with F_2 and SbF_5 in hydrogen fluoride.[7,20] When an equimolar mixture of the starting materials was heated in a Monel metal reaction vessel at 473 K and a pressure of up to 185 atm for 2–3 d, more than 40% of the NF_3 added to the autoclave was used up. The product contained up to 25% impurities—metal salts formed by corrosion of the walls of the reaction vessel.

It was also found[7] that the TFA salt can be obtained in the absence of hydrogen fluoride.[3,20] A mixture with $NF_3:SbF_5 \approx 1:1$ with a slight excess of F_2 was placed in a heated Monel metal vessel and kept in it at 373–473 K for several days.[3] The reaction took place comparatively slowly; the degree of transformation of NF_3 after 50 h was 11% at 373 K, and 41% at 473 K. Under these conditions, the product is apparently a mixture of TFA salts containing the SbF_6^- anion and the $Sb_2F_{11}^-$ and $Sb_3F_{16}^-$ polyanions. When the TFA fluoroantimonate specimens are heated for a long time in a vacuum at 473 K, the polyanions decompose to give NF_4SbF_6.[5] Similarly, for example, $O_2^+Sb_2F_{11}^-$ is converted into $O_2^+SbF_6^-$ by heating in a vacuum to a temperature above 403 K.[21]

Further refinements[22] showed that the reaction of NF_3 with F_2 and SbF_5 at 373–397 K and a pressure of ~210 atm gives $NF_4Sb_3F_{16}$, which in a vacuum at 473 K over a period of 2–3 d gives up SbF_5 and is converted into NF_4SbF_6. It was later found[22,23] that the reaction of NF_3 with F_2 and SbF_5 at 388 K with subsequent thermal decomposition of the product in a vacuum at 473 K gives a substance with composition close to $NF_4Sb_2F_{11}$, which is converted into NF_4SbF_6 in a vacuum at a higher temperature (523–533 K). After heating for 1–1.5 h at 523–533 K in a vacuum with removal of the volatile decomposition products, the specimen is completely converted into NF_4SbF_6, and in this time interval not more than 3% of the NF_4SbF_6 obtained decomposes. Appreciable decomposition of the NF_4SbF_6 formed in this operation takes place only at 548–573 K. From these results it was concluded[23] that the reaction of NF_3 with F_2 and SbF_5 at 388–473 K and a pressure of up to 200 atm gives a product $NF_4SbF_6.nSbF_5$, where n = 2.1–3.2, depending on the reaction conditions. Thermal decomposition in a vacuum at 473 K lowers the value of n to 0.8–1.1, and thermal decomposition at 533 K gives pure NF_4SbF_6.

Thus the synthesis of NF_4SbF_6 by heating a mixture of NF_3, F_2, and SbF_5 is fairly laborious and time-consuming, but it can be used to obtain the salt in large quantities. In a simpler version[24] of the "thermal" synthesis of the salt, antimony pentafluoride is replaced by the trifluoride:

$$NF_3 + 2F_2 + SbF_3 \rightarrow NF_4SbF_6 .$$

The process is carried out at 523 K and 30–70 atm over a period of several days, and gives pure NF_4SbF_6 containing no significant quantities of polyfluoroantimonates.

The salt NF_4SbF_6 can be obtained by the reaction of NF_3 with $KrF^+SbF_6^-$ at room temperature, or by the reaction of equimolar quantities of KrF_2, NF_3, and SbF_5 in hydrogen fluoride at 295 K,[25] but this method requires krypton fluoride, which is not readily available. In addition, $NF_4SbF_6.nSbF_5$ is also formed when a mercury lamp is used to irradiate a mixture of SbF_5, NF_3, and F_2 in a quartz vessel at room temperature.[17] The reaction is slow, and the product consists of a mixture of dioxygenyl and TFA fluoroantimonates. The reaction of fluorine with quartz liberates oxygen, which is oxidised to O_2^+ in the presence of fluorine and under the influence of ultraviolet radiation:

$$5F_2 + 2SiO_2 + 4SbF_5 \rightarrow 2SiF_4 + 2O_2^+Sb_2F_{11}^- .$$

TFA fluoroantimonates can apparently also be obtained by a plasmochemical method, for example from SbF_5, NF_3, and F_2 or from SbF_5, N_2, and F_2 using an electrical glow discharge, but the reaction is difficult, because of the low volatility of SbF_5.

$NF_4^+BF_4^-$. Attempts to obtain this salt by analogy with NF_4AsF_6 and NF_4SbF_6, that is by activating the system NF_3 + F_2 + BF_3, appear quite natural, and were probably made during the search for methods for synthesising the salts of TFA with the AsF_6^- and SbF_6^- anions. Thus in 1969, an unsuccessful attempt to synthesise NF_4BF_4 in a glow discharge from NF_3, F_2, and BF_3 at a temperature of the walls of the reaction vessel of 193 K was reported.[26] Instead of the expected compound, the product obtained was $O_2^+BF_4^-$ and other salts, which were hydrolysed with the liberation of oxides of nitrogen. A later paper[27] reported that one of the authors of Ref.8 in 1967 had subjected a mixture of NF_3 with F_2 and BF_3 to an electric discharge, but obtained $N_2F^+BF_4^-$, and not NF_4BF_4. An attempt was made[7] to obtain NF_4BF_4 by the double decomposition of salts of the NF_4^+ cation and salts of the BF_4^- anion (see Ref.27). After NF_4BF_4 was synthesised in 1969[9] from NF_3, F_2, and BF_3 in an electrical glow discharge, it became clear that the authors of Refs.8 and 26 had been very close to success, and had failed because the temperature of the walls of the reaction vessel at which the experiments in the discharge were carried out was not sufficiently low.

The synthesis of NF_4BF_4 is carried out in a quartz discharge tube immersed in liquid nitrogen; a mixture of NF_3 and BF_3 in almost equimolar proportions with a slight excess of NF_3 is first condensed, after which the discharge is switched on and fluorine is slowly introduced into the reaction vessel to maintain a pressure of 30–55 mmHg in it.[9,10,28] When one of the reagents (NF_3 or BF_3) is used up, the pressure begins to increase in the apparatus in proportion to the rate of supply of fluorine; when the supply of fluorine is stopped, the pressure remains constant, indicating that the reaction is complete. The efficiency of this method of synthesis corresponds to tens of grams of product per hour in a reactor volume of 50–100 cm^3.

The photochemical method[17,18] for synthesising NF_4BF_4 has a lower efficiency than the plasmochemical method. The salt is obtained in a yield of less than 1% when a mixture of NF_3 with F_2 and BF_3 is irradiated with ultraviolet light at room temperature.[17] The low-temperature photolysis of mixtures of the same reagents is more efficient;[18] when a high-pressure mercury lamp is used as the source of ultraviolet radiation, a yield of NF_4BF_4 greater than 3 g h^{-1} is achieved. During the photolysis, it is necessary to introduce fresh portions of the reagents into the reaction vessel at intervals, to prevent the formation of a screening layer of the product on the surface of the condensed reagents. The same precautions should also be taken in the plasmochemical preparation of the salt if the process is carried out for a long time.[10,28]

TFA fluoroborate has also been synthesised by the action of bremsstrahlung on a mixture of NF_3 with F_2 and BF_3 (1:6:1) cooled to 77 K; the yield of the product in the reaction vessel with mixing of the contents was over 100 mg h^{-1} for a radiation power of 100 Mrad h^{-1}.[27]

A method for preparing NF_4BF_4 by the action of a laser on a mixture of NF_3 and BF_3 with a different gaseous source of fluorine, namely SF_6, has been patented.[29]

According to data reported in Ref. 22 (see note 3 of Ref. 22), the following method was developed for the synthesis of NF_4BF_4:

$$CsF + HF \rightarrow CsHF_2,\ NF_4SbF_6 + CsHF_2 \rightarrow CsSbF_6 + NF_4HF_2,$$
$$NF_4HF_2 + BF_3 \rightarrow NF_4BF_4 + HF$$

(all the reactions are carried out in HF). The NF_4BF_4 formed is extensively contaminated by $CsSbF_6$, which is removed by treating with bromine pentafluoride; in BrF_5, however, the reaction $NF_4BF_4 + CsSbF_6 \rightarrow CsBF_4 + NF_4SbF_6$ takes place, and the NF_4BF_4 is contaminated with NF_4SbF_6. The replacement of CsF by silver fluoride[30] in this process eliminated the stage involving treatment with bromine pentafluoride, but did not lead to an appreciable increase in the purity of the product. Further improvement[22,31] of this method gave NF_4BF_4 specimens with a purity exceeding 99%. It has been suggested that $CsBF_4$ be used instead of $CsHF_2$, and that the reaction

$$CsBF_4 + NF_4SbF_6 \rightarrow CsSbF_6 + NF_4BF_4$$

be carried out in HF at 195 K in the presence of a 10–15% excess of NF_4SbF_6, which decreases the solubility of $CsSbF_6$ in HF.

The preparation of NF_4BF_4 by the reaction of an equimolar mixture of KrF_2, NF_3, and BF_3 at 295 K in HF has been reported.[25]

Of all the methods examined for the synthesis of NF_4BF_4, the plasmochemical method appears to be the most accessible, simple, and efficient.

$NF_4^+HF_2^-.nHF$. The synthesis of this salt can be regarded as resulting from attempts to prepare TFA fluoride $NF_4^+F^-$, which, if it were stable, would be a unique compound containing 87% active fluorine. An attempt might be made to obtain $NF_4^+F^-$, for example, by a double decomposition of the type

$$NF_4^+SbF_6^- + M^+F^- \rightarrow NF_4^+F^- + MSbF_6.$$

Work by a research group (see note 4 in Ref. 11) showed that the double composition of LiF and NF_4SbF_6 in HF at room temperature gives an $LiSbF_6$ precipitate and a solution containing NF_4^+ cations, but attempts to isolate the TFA salt from the solution were unsuccessful, since the salt decomposed to NF_3, F_2, and HF.

The authors cited[11] used CsF as the ionic fluoride, but it was found that the reaction of NF_4SbF_6 with CsF in HF at 195 K does not give $NF_4^+F^-$, but leads to the formation of the unstable solid compound $NF_4^+HF_2^-.nHF$. For the synthesis of this salt, equimolar quantities of NF_4SbF_6 and CsF are placed in HF, the mixture is kept at room temperature and then cooled to 195 K, and the $CsSbF_6$ precipitate is filtered off. The excess of solvent is removed almost completely by distilling at 228 K; the residue consists of a transparent liquid, which solidifies at 195 K. The compound dissociates at 298 K:

$$NF_4HF_2 \cdot nHF \rightarrow NF_3 + F_2 + (n+1)HF$$

and the molar ratio NF_3:HF is ~10.1 at the start of the decomposition, and 1.54 at the end. It is extremely difficult to remove the solvating HF molecules completely, since the salt decomposes. Solutions of NF_4HF_2 in HF are stable at room temperature, and can be used to synthesise other TFA salts.

$NF_4^+Be_2F_5^-.BeF_2$, prepared by the thermal decomposition of $(NH_4)_2BeF_4$, reacts with a concentrated solution of NF_4HF_2 in HF. The reagents are kept for 65 h at 298 K to give $NF_4.Be_2F_5$, containing ~16% impurities.[32]

$NF_4^+AlF_4^-$. A specimen of NF_4AlF_4 containing ~17% impurities was synthesised by analogy with $NF_4Be_2F_5$, by the reaction of AlF_3 with NF_4HF_2 in HF.[32] The reaction

$$M_3AlF_6 + 3NF_4SbF_6 \rightarrow 3MSbF_6 + (NF_4)_3AlF_6$$

(M = Cs or Na) could not be carried out in BrF_5 at 298 K, or in HF at 195 K, or in molten NF_4SbF_6 at 548 K at an increased pressure of NF_3 and F_2.[32]

$(NF_4^+)_2SiF_6^{2-}$. Attempts to obtain the TFA salt with the SiF_5^- anion by low-temperature photolysis[18] were unsuccessful, as were attempts to synthesise TFA hexafluorosilicate by the double decomposition of NF_4SbF_6 and Cs_2SiF_6 in anhydrous HF.[33] Success was achieved by the reaction of SiF_4 with $NF_4HF_2.nHF$, previously freed (as far as possible) from excess HF:

$$2NF_4HF_2 \cdot nHF + SiF_4 \rightarrow (NF_4)_2SiF_6 + 2(n+1)HF.$$

This reaction gave a 95.5% pure specimen of $(NF_4)_2SiF_6$. The reaction of $(NF_4)_2SiF_6$ with an excess of SiF_4 does not give NF_4SiF_5, in contrast to $(NF_4)_2GeF_6$, which reacts with an excess of GeF_4 to give NF_4GeF_5.[33]

$NF_4^+PF_6^-$. Low-temperature photolysis[18,34] has proved suitable for the synthesis of this salt from a mixture of NF_3, PF_5, and F_2 in the ratio 3:3:1. The rate of formation of the product was only 10 mg h^{-1}. NF_4PF_6 can be obtained in larger quantities by the replacement reaction

$$NF_4BF_4 + PF_5 \rightarrow NF_4PF_6 + BF_3.$$

When a mixture of NF_4BF_4 with an excess of PF_5 is kept for 64 h at 298 K, the NF_4BF_4 is practically completely converted into NF_4PF_6.[18,35] In the reaction of NF_4BF_4 with an excess of PF_5 in HF at room temperature, the conversion of NF_4BF_4 into NF_4PF_6 is only partial (8–17%).[18] The salt can also be obtained by the reaction of NF_3 with KrF_2 and PF_5 (1:1:1) in HF at 295 K.[25]

$NF_4^+SO_3F^-$. This salt is obtained[36] by the double decomposition of NF_4SbF_6 and $CsSO_3F$ in anhydrous HF at room temperature with subsequent cooling to 195 K and filtration

at this temperature; the solvent is removed by distilling at 243 K. Solutions of NF_4SO_3F in HF are stable at 298 K for several days. TFA sulphate cannot be obtained by the analogous reaction of NF_4SbF_6 with Cs_2SO_4, since caesium sulphate reacts with HF to give $CsSO_3F$.

$NF_4^+ClO_4^-$. TFA perchlorate was synthesised[11] by the reaction of equimolar quantities of NF_4SbF_6 and $CsClO_4$ in anhydrous HF. The mixture of reagents is kept for 15 h at 195 K and for 2 h at 228 K, after which the $CsSbF_6$ precipitate is separated at 195 K, and the solvent distilled off. The purity of the product reaches 95%. Attempts to synthesise NF_4BrO_4 and NF_4IO_4 by analogous methods were unsuccessful: $NF_4.BrO_4$ is extremely unstable in HF, and decomposes explosively when isolated from solution, and IO_4^- is readily fluorinated to $IF_4O_2^-$ in HF or BrF_5.

$(NF_4^+)_2TiF_6^{2-}$ and TFA polyfluorotitanates. $(NF_4)_2TiF_6$ was obtained[37] by the reaction of saturated solutions of NF_4SbF_6 and Cs_2TiF_6 in HF (molar ratio $NF_4SbF_6:Cs_2TiF_6 = 2:1$) at room temperature, followed by filtration of the solution at 195 K and distillation of the volatile products at 323 K. Fluorotitanates containing polyanions are formed[37] by displacing BF_3 from NF_4BF_4 using titanium tetrafluoride:

$$NF_4BF_4+nTiF_4\rightarrow NF_4TiF_5\cdot(n-1)TiF_4+BF_3.$$

The reaction of NF_4BF_4 with TiF_4 in anhydrous HF at room temperature gives $NF_4Ti_2F_9$ and $NF_4Ti_3F_{13}$, and the composition of the products depends on the preliminary treatment of the TiF_4 taken for the reaction; if a specimen previously treated with fluorine at 523 K and 70 atm is used, the product is $NF_4Ti_3F_{13}$. The reaction of NF_4BF_4 with TiF_4 without a solvent at 443 K gives $NF_4Ti_2F_9$. Heating TiF_4 with an excess of NF_3 and F_2 at 453–468 K and a pressure of up to ~160 atm gives a product with a composition close to $NF_4Ti_6.F_{25}$:

$$NF_3+F_2+6TiF_4\rightarrow NF_4Ti_6F_{25}.$$

According to Ref. 25, $(NF_4)_2TiF_6$ is formed by the reaction of NF_3 with KrF_2 and TiF_4 (2:2:1) in HF at 295 K; the vibrational spectra of the product given in Ref. 25, however, differ from the spectra of $(NF_4)_2TiF_6$ given in Ref. 37.

$(NF_4^+)_2MnF_6^{2-}$. The fluorination of a mixture of $MnCl_2$ and CsF at 673 K was used to obtain Cs_2MnF_6, which then reacted with NF_4SbF_6.[38] The mixture of Cs_2MnF_6 and NF_4SbF_6 (1:2) in anhydrous HF was kept for 30 min at 298 K, after which the solution was cooled to 195 K. The solvent was then distilled off, to give 91.27% pure $(NF_4)_2MnF_6$. The salts $(NF_4)_3MF_6$ (M = Mn, Co, Cu) could not be synthesised in this way, because of the solvolysis of MF_6^{3-} in HF. The salt $(NF_4)_3CoF_6$ similarly could not be obtained by the reaction of CoF_3 with NF_4HF_2 in HF at 228 K.[38]

$(NF_4^+)_2NiF_6^{2-}$. The double decomposition of Cs_2NiF_6 and NF_4SbF_6 (1:2) in anhydrous HF at 298 K gives $(NF_4)_2.NiF_6$,[39,40] which is separated from $CsSbF_6$ by filtration at 195 K, and freed from solvent by distillation at 298 K.

$NF_4^+GeF_5^-$, $(NF_4^+)_2GeF_6^{2-}$. NF_4GeF_5 was obtained by the low-temperature photolysis[18] of a mixture of NF_3 with GeF_4 and F_2 (3:3:1). The rate of formation of the salt was only 25 mg h^{-1}, so that a different method was proposed[18] for preparing NF_4GeF_5, based on the reaction of NF_4BF_4 with a large excess of GeF_4. At room temperature without a solvent, GeF_4 displaces BF_3 from NF_4BF_4; after 64 h, the degree of conversion of NF_4BF_4 into NF_4GeF_5 was 65%, and complete conversion required repeated treatment of NF_4BF_4 with germanium tetrafluoride. The reaction of NF_4BF_4 with GeF_4 in anhydrous HF at 298 K gives 85% conversion of NF_4BF_4, but the product is a mixture of NF_4GeF_5 and $(NF_4)_2.GeF_6$. Germanium tetrafluoride is a weaker Lewis acid than AsF_5, so that it does not displace AsF_5 from NF_4AsF_6 in HF.

The salt $(NF_4)_2GeF_6$, the first TFA salt to be synthesised with a doubly-charged anion, can be obtained in quantitative yield by keeping NF_4GeF_5 in an excess of HF at 298 K. Treatment of $(NF_4)_2GeF_6$ with a large excess of GeF_4 at 298 K gives NF_4GeF_5 in quantitative yield.[18]

$NF_4^+NbF_6^-$. This compound was obtained[25] by the reaction of KrF_2 with NF_3 and NbF_5 (1:1:1) in anhydrous HF at room temperature.

$NF_4^+SnF_5^-$, $(NF_4^+)_2SnF_6^{2-}$. When mixtures of NF_3 with F_2 and SnF_4 are heated (573 K, ~150 atm), a TFA salt is not formed.[41] $(NF_4)_2SnF_6$ was synthesised from Cs_2SnF_6 and NF_4SbF_6 (1:2) in anhydrous HF at room temperature, followed by filtration of the solution at 193 K.[41] The reaction of equimolar quantities of NF_4BF_4 and SnF_4 in anhydrous HF at 298 K gives practically pure NF_4SnF_5. If however a two-fold excess of NF_4BF_4 is taken, the product is not NF_4SnF_5 but only a small quantity of $(NF_4)_2SnF_6$, even after prolonged reaction.[41]

$NF_4^+XeF_7^-$, $(NF_4^+)_2XeF_8^{2-}$. The reaction of XeF_6 with NF_4HF_2 in HF gives 98% pure NF_4XeF_7.[42,43] Prolonged exposure of a specimen to laser radiation with a wavelength of 4880 Å at room temperature leads to the decomposition of NF_4XeF_7 to give $(NF_4)_2XeF_8$ and XeF_6.

$NF_4^+WF_7^-$. A specimen of NF_4WF_7 containing 1.61% $CsSbF_6$ was synthesised[44] by the reaction of WF_6 with NF_4HF_2.

$NF_4^+WOF_5^-$, $NF_4^+W_2O_2F_9^-$. NF_4WOF_5 was synthesised by the reaction of WOF_4 with a concentrated solution of NF_4HF_2 in HF at 298 K.[45] When heated in a sapphire reaction vessel in a vacuum, NF_4WOF_5 is completely converted into $NF_4W_2O_2F_9$:

$$3NF_4WOF_5\rightarrow 2NF_3+OF_2+WF_6+NF_4W_2O_2F_9.$$

In anhydrous HF, solvolysis of NF_4WOF_5 takes place, again giving $NF_4W_2O_2F_9$.

$NF_4^+BiF_6^-.nBiF_5$. Heating equimolar quantities of NF_4BF_4 and α-BiF_5 at 448–453 K leads to the liberation of BF_3 and the formation of NF_4BiF_6.[23] The same reaction can be carried out at room temperature in anhydrous HF. As in the synthesis of TFA fluoroantimonate, the direct synthesis of TFA fluorobismuthate from NF_3, F_2, and BiF_5 gives salts of polyanions, chiefly $Bi_2F_{11}^-$. Heating a mixture of NF_3 with F_2 and BiF_5 at 448 K and a pressure of 167 atm gives a product having the formula $NF_4BiF_6.0.6BiF_5$. The thermal decomposition of $NF_4BiF_6.nBiF_5$ in a vacuum at 553 K gives $NF_4.BiF_6$.[23] A study[46] of the properties of NF_4BiF_6 as a possible replacement for NF_4SbF_6 in the preparation of TFA salts by double decomposition with alkali metal salts showed that NF_4BiF_6 has no advantages over NF_4SbF_6.

$NF_4^+UF_7^-$. A specimen of NF_4UF_7 containing small quantities of NF_4SbF_6 and $CsSbF_6$ was obtained[44] by the reaction of UF_6 with NF_4HF_2 in 88% yield relative to NF_4HF_2.

$NF_4^+UOF_5^-$. This salt was synthesised[47] from UOF_4 and NF_4HF_2 in anhydrous HF. The possible synthesis of NF_4UOF_5 by the double decomposition of NF_4SbF_6 and the corresponding alkali metal salt is inapplicable in this case, because of

the very low solubility of NF_4UOF_5 in HF. It was also impossible to synthesise the salt from UOF_4, CsF, and NF_4SbF_6 in HF.

Synthesis of other TFA salts. An unsuccessful attempt to prepare NF_4ClOF_4 and NF_4BrOF_4 by the double decomposition of NF_4SbF_6 and the corresponding caesium salts in BrF_5 at room temperature has been described.[11] The reaction of NF_4SbF_6 with $CsBrOF_4$ gives NF_3, fluorine, $BrOF_3$, and $CsSbF_6$, and $CsClOF_4$ reacts with BrF_5 to give $CsBrF_6$ and $ClOF_3$. Anhydrous HF cannot be used as solvent, since it reacts with $CsBrOF_4$. TFA nitrate cannot be obtained by double decomposition in HF, since $CsNO_3$ reacts with HF to give NO_2^+. It was also impossible to carry out F–Cl exchange between NF_4^+ and BCl_3 or between NF_2O^+ and BCl_3 to obtain salts of NCl_4^+ and NCl_2O^+ cations.[11] The double decomposition of $CsIO_2F_4$ and NF_4SbF_6 in HF does not give $NF_4IO_2F_4$, but gives *cis*- and *trans*-OIF_4OF.[11,48] The synthesis of NF_4MF_6, where M = Ru, Rh, Pt, and Au, using KrF_2 has been described[49] (without any experimental details), as has the preparation of NF_4MnF_5, formed in the HF + KrF_2 + MnO_3F + NF_3 (or N_2F_4) system.[50]

The Possible Existence of NF_5

The NF_4^+ cation can be regarded formally as an ion formed by the removal of a fluoride ion from the hypothetical higher fluoride of nitrogen NF_5. The existence of this fluoride as a sufficiently stable compound is unlikely.[12] Nevertheless, the possible existence of a compound with the empirical formula NF_5, for example as the solvated ion pair $NF_4^+F^-$ at low temperatures in an inert medium, cannot be completely excluded.

The formation of a new unstable nitrogen fluoride was noted[51] in a study of the products obtained by the radiolysis of a mixture of NF_3 with F_2 using uranium fission products. Reliable identification of the compounds was practically impossible, since the quantity of substance formed was 1–10 μmole; the authors[51] suggested, however, that they had synthesised NF_5 or F_3NNF_3. The formation of an unstable unidentified nitrogen fluoride was also observed when liquid NF_3 was irradiated at 77 K with electrons with an energy of 800 keV.[52] The formation of small quantities of a white solid substance was observed[27] as a result of the action of bremsstrahlung with a dose of 100 Mrad on a mixture of NF_3 with an excess of fluorine at 77 K. This substance decomposed at 143 K to give NF_3. The condensation of BF_3 into the mixture of the products after irradiation at 77 K, and subsequent heating of this mixture, gave a small quantity of NF_4BF_4, possibly confirming the decomposition

$$NF_4^+F^- + BF_3 \rightarrow NF_4BF_4.$$

The Mechanism of the Reactions Involved in the Synthesis of TFA Salts

A general method for preparing salts of fluorocations involves the action of a fluoride ion acceptor EF_n on a covalent fluoride RF:

$$RF + EF_n \rightarrow R^+[EF_{n+1}]^- \quad (1)$$

where E represents an atom of B, P, V, As, Sb, etc., and R a group such as ONF_2, $OClF_2$, ClF_4, etc. In a number of cases, polyatomic cations made up of non-metal atoms are formed by the action of EF_n on a mixture of two compounds

$$RF + Z + EF_n \rightarrow [RZ]^+[EF_{n+1}]^-$$

where Z = Cl_2, H_2S, etc.[12] Reaction (2), describing the formation of TFA salts, is usually referred to as the direct synthesis of TFA salts:

$$NF_3 + F_2 + EF_n \rightarrow [NF_4]^+[EF_{n+1}]^-. \quad (2)$$

A second route to NF_4^+ cation is based on the oxidation of nitrogen trifluoride, which can be carried out only using an extremely strong oxidising agent, such as a krypton salt:

$$NF_3 + [KrF]^+[EF_{n+1}]^- \rightarrow [NF_4]^+[EF_{n+1}]^- + Kr. \quad (3)$$

Since nitrogen pentafluoride as starting material does not exist, reaction (1) cannot be used to synthesise NF_4^+, and the direct synthesis of the NF_4^+ cation is achieved by the action of heat or other source of energy on the NF_3 + F_2 + EF_n system (reaction (2)). The methods for obtaining TFA salts described above show that the NF_4^+ ion can be synthesised either by heating the starting materials or by plasmochemical, photochemical, or radiation-chemical methods.

The direct synthesis of TFA salts is possible when EF_n is a fairly strong Lewis acid, monomeric, volatile, and stable under the conditions of the reaction. These requirements are completely or partly satisfied by BF_3, PF_5, GeF_4, AsF_5, SbF_5, and BiF_5. The Lewis acid taken for the direct synthesis accepts a fluoride ion and forms a stable anionic fluoro-complex.

The action of a stronger Lewis acid on a TFA salt with an anion formed by a weaker Lewis acid (for example NF_4BF_4) can displace the weaker acid (BF_3) and give a new salt with the fluoro-anion of the stronger acid. This method has been used to obtain salts of TFA and the corresponding anionic fluoro-complexes by the action of PF_5, TiF_4, GeF_4, SnF_4, and BiF_5 on NF_4BF_4. Boron trifluoride can displace HF from NF_4HF_2 to give NF_4BF_4.

The third group of reactions used for the synthesis of TFA salts involves the double decomposition of NF_4SbF_6 and caesium salts in anhydrous HF. The chief requirement of these reactions is that the starting materials should be soluble, and one of the products ($CsSbF_6$) insoluble, in HF; when this condition is satisfied, it is possible to isolate a new TFA salt, which however entrains appreciable quantities of impurity. This method has been used to prepare NF_4HF_2, NF_4SO_3F, NF_4ClO_4, $(NF_4)_2TiF_6$, $(NF_4)_2MnF_6$, $(NF_4)_2NiF_6$, and NF_4SnF_5.

A unique group of reactions for synthesising TFA salts is formed by those based on TFA hydrogen fluoride. The use of this compound is appropriate when double decomposition is impossible because the starting materials are insoluble or react with the solvent, or when the Lewis acid EF_n is polymeric and non-volatile. Salts of TFA with the corresponding anionic fluoro-complexes have been synthesised by the reactions of NF_4HF_2 with BeF_2, AlF_3, SiF_4, XeF_6, WF_6, WOF_4, UF_6, and UOF_4.

NF_4SbF_6, NF_4PF_6, $(NF_4)_2TiF_6$, NF_4NbF_6, and various other TFA salts have been obtained by oxidising nitrogen trifluoride (reaction (3)).

The mechanism of formation of the NF_4^+ cation was first represented as a set of elementary stages, without any firm experimental proof of the possibility of these stages. For the synthesis of NF_4^+ in an electrical discharge, for example, the following scheme was proposed:[8]

$$NF_3^+ + F_2 \rightarrow NF_4^+ + F,\ NF_3^+ + F \rightarrow NF_4^+,\ NF_3 + F_2^+ \rightarrow NF_4^+ + F,$$
$$NF_3 + F^+ \rightarrow NF_4^+.$$

The formation of NF_3^+, F_2^+, and F^+ ions is possible in the plasma of a glow discharge, which is a highly non-equilibrium

system, as a result of the presence of electrons with energies sufficient to ionise NF_3, F_2, or F. This ionisation cannot take place, however, on thermal or photochemical excitation of the reagents. This led[17] to an examination of the possible formation of the AsF_6 radical as an intermediate product of the direct synthesis of NF_4AsF_6. The AsF_6 radical might be formed by the reaction of F atoms with AsF_5 molecules, and, in the opinion of the authors cited,[17] should be a very strong oxidising agent, comparable with PtF_6 and capable of oxidising NF_3:

$$NF_3 + AsF_6 \rightarrow NF_3^+AsF_6^-,\ NF_3^+AsF_6^- + F_2 \rightarrow NF_4^+AsF_6^- + F.$$

This idea of the role of AsF_6 radicals might be extended to the synthesis of other TFA salts, and also dioxygenyl or xenon salts. The possibility of this mechanism for the formation of NF_4^+ was confirmed[30] when EPR recorded both stable pyramidal radical-cations NF_3^+ and unstable radicals AsF_6, SbF_6, and Sb_2E_{11}, produced by the γ-irradiation of specimens of NF_4AsF_6 and $NF_4SbF_6.0.8SbF_5$, cooled to 77 K. The formation of NF_3^+ radical-cations was also observed[53] by EPR in the low-temperature photolysis of NF_3–F_2–AsF_5 and NF_3–F_2–BF_3 mixtures. The EPR spectra of $^{14}NF_3^+$ and $^{15}NF_3^+$ radical-cations, generated by the γ-irradiation of TFA salts or by low-temperature ultraviolet photolysis, have also been studied.[54]

More detailed studies[55] of the thermal decomposition of NF_4BF_4 and NF_4AsF_6 showed, however, that the mechanism for the synthesis of salts based on radicals of the AsF_6 type is inapplicable. EPR was unable to detect any signs of the reaction of F atoms with AsF_5 to give AsF_6 radicals. Moreover, a kinetic study of the thermal decomposition of NF_4BF_4 and NF_4AsF_6 made it possible[55] to exclude from consideration a number of proposed stages in the decomposition or synthesis of these salts, and to conclude that the only scheme describing the formation and decomposition of NF_4AsF_6 and not contradicting any available experimental data must include the following reversible reactions:

$$F_2 \rightleftharpoons 2F$$
$$F + NF_3 \rightleftharpoons NF_4$$
$$NF_4 + AsF_5 \rightleftharpoons NF_3^+AsF_6^-$$
$$NF_3^+AsF_6^- + F \rightleftharpoons NF_4^+AsF_6^-.$$

In the opinion of the authors cited,[55] this scheme is applicable to other TFA salts, except those for which oxidative fluorination of the anion takes place during the decomposition. The scheme does not include reactions involving NF_5, whose existence has not been proved, but it assumes the participation of the NF_4 radical, whose existence also has not been proved experimentally. According to calculations[55] based on a Born–Haber cycle, the stage $F + NF_3 \rightarrow NF_4$ should be thermally neutral, and probably takes place without an activation energy.

The degree of dissociation of fluorine molecules under the conditions of the experiments of Ref. 55 on the synthesis of NF_4SbF_6 from NF_3, F_2, and SbF_5 is $\sim 10^{-7}$. It is difficult to decide whether the fairly low concentration of F atoms can ensure the comparatively high rate of formation of NF_4SbF_6, observed by the authors cited,[55] if account is taken of only the reaction of atomic fluorine with NF_3 and the NF_3^+ salt, without assuming the possibility of reactions involving molecular fluorine. The scheme proposed in Ref. 55 for the synthesis and decomposition of TFA salts apparently requires more detailed examination and further experimental justification.

Monofluoroammonium and Difluoroammonium Salts

Of the three possible mixed-ligand fluoroammonium cations H_nNF_{4-n} (n = 1–3), H_3NF^+ and $H_2NF_2^+$ have been obtained. $H_3NF^+X^-$ were synthesised by the action of strong proton acids HX on alkyl fluorocarbamates:[56,57]

$$NHFCO_2R + 2HX \rightarrow H_3NFX + CO_2 + RX.$$

where R = ethyl or isopropyl, and X = ClO_4^-, $CH_3SO_3^-$, or $CF_3SO_3^-$. Weaker inorganic acids such as hydrochloric acid decompose fluoro-carbamates. The reaction of the acids with $NHFCO_2R$ takes place rapidly at temperatures equal to or slightly above room temperature in a solvent (methylene chloride). The extremely hygroscopic H_3NFClO_4 and $H_3NFSO_3CH_3$ melt and decompose at 373–378 K; they attack glass, and decompose on standing. The less hygroscopic and more stable $H_3NFSO_3CF_3$, which melts with partial decomposition at 437–438 K, does not react with glass, and is soluble in ethers and nitriles.

The difluoroammonium salts $H_2NF_2^+AsF_6^-$ and $H_2NF_2^+SbF_6^-$ were obtained[58] by the usual method for synthesising fluorocations, by the action of EF_5 (E = As, Sb) on difluoroamine and HF in a medium of HF at 195 K. The salts are stable at 223 K, but at room temperature they decompose rapidly to give HF, EF_5, F_2, NF_3, and small quantities of *trans*-N_2F_2. An attempt to obtain fluoroammonium cations by the action of fluorine on the ammonium salt NH_4AsF_6 in HF was unsuccessful.[58] Similarly, adduct formation was not observed in the NF_3 + HF + SbF_5 system.[58]

III. PROPERTIES OF TETRAFLUOROAMMONIUM SALTS

The earliest studies[3,7,8,15] established that TFA compounds are ionic. The tetrahedral structure of the NF_4^+ ion is confirmed by the vibrational and ^{19}F NMR spectra. For the NF_4^+ structure with T_d symmetry, there are four forms of normal vibration: $A_1 + E + 2F_2$. All the vibrations are active in the Raman spectrum, and the A_1 line is polarised; in the infrared spectrum, only the triply degenerate vibrations are active. The laser Raman spectrum of NF_4AsF_6 [16] shows the vibrational wavenumbers of the (NF_4^+) groups at 847 cm^{-1} (ν_1, A_1), 445 cm^{-1} (ν_2, E), 1160 cm^{-1} (ν_3, F_2), and 611 cm^{-1} (ν_4, F_2). Intense absorption at 1159 cm^{-1} (ν_3, F_2) and absorption of medium intensity at 611 cm^{-1} (ν_4, F_2) are observed in the infrared spectrum of NF_4AsF_6.[59] A detailed study[19] of the vibrational spectra of $^{14}NF_4AsF_6$ and comparison with $^{15}NF_4$. .AsF_6 gave for the normal vibrations of $^{14}NF_4^+$ the values ν_1 = 848.2, ν_2 = 443.3, ν_3 = 1158.95, and ν_4 = 611.15 cm^{-1}; for $^{15}NF_4^+$, the same vibrations appear at 848.2, 443.3, 1129.7, and 609.35 cm^{-1}. The force constant of the NF stretches of the NF_4^+ ion (6.15 mdyne $Å^{-1}$) is much greater than the force constants 2.15 mdyne $Å^{-1}$ for FNO or 4.31 mdyne $Å^{-1}$ for NF_3, indicating that the strength of the NF bond in the NF_4^+ ion is unusually high for nitrogen fluorides. The estimated interatomic distance N–F in NF_4^+ is 1.24 Å (1.512 Å for FNO and 1.365 Å for NF_3).[19] The anions of the salts have practically no influence on the vibrational spectra of the NF_4^+ ion. The normal vibrations of NF_4^+, recorded in the spectra of all the salts synthesised, lie in a narrow wavenumber range of ~20 cm^{-1}, and this range is possibly determined not so much by the properties of the salts as by the quality of the experimental spectra.

The ^{19}F NMR spectra of TFA salts show that the fluorine atoms in NF_4^+ are equivalent, and that the ion has tetrahedral symmetry. The spectrum of NF_4AsF_6 (solution in HF, 298 K, 94.6 MHz) contains a triplet of very narrow bands of equal

intensity, corresponding to the NF_4^+ ion, with a chemical shift of -213.5 p.p.m. ($CFCl_3$) and a spin–spin coupling constant of 234 Hz.[59] The band width at half-height does not exceed 10 Hz, indicating that there is no N–F quadrupole coupling. Analogous ^{19}F NMR spectra were obtained for other TFA salts.

TFA tetrafluoroborate has been studied by X-ray electron spectroscopy.[28] The energy of the removal of the 1s electron of the N atom for NF_4BF_4 is 417.3 eV, which is much greater than all known values for nitrogen compounds. The energy of the removal of the 1s electron of the F atom for NF_4^+ (694.4 eV) is also greater than all known values. From these data it follows that the negative charge on the F atoms in NF_4^+ is a minimum, and that the N–F bond is less polar than the C–F or B–F bonds. From an analysis of the intensities of the ν_1 line in the Raman spectrum of NF_4BF_4,[27] it was concluded that the bonds in NF_4^+ are more covalent than those in BF_4^-.

The crystal structures of various low-temperature forms of TFA salts have been determined from the X-ray powder diffraction patterns. The salts have a tetragonal lattice with $Z = 2$. The unit cell parameters and values of the calculated density ρ are given in Table 1. The calculated[18,37,39,41] values of the parameters a and c for the lattices of $(NF_4)_2EF_6$, where E = Ge, Ti, Ni, or Sn, were corrected in Ref.38, and the corrected values are given in Table 1. The density of NF_4AsF_6, measured in a perfluorinated amine, is 2.98 g cm^{-3} at 298 K.[15]

Table 1. Crystallographic data for TFA salts.

Salt	Cell parameters, Å		ρ, g cm^{-3}	Refs.
	a	c		
NF_4BF_4	7.01	5.22	2.29	[27]
NF_4BF_4	9.944	5.229	2.27*	[18]
NF_4PF_6	7.577	5.653	2.41	[18]
NF_4AsF_6	7.70	5.73	2.72	[15]
NF_4SbF_6	7.903	5.806	2.98	[23]
NF_4BiF_6	8.006	5.821	3.68	[23]
$(NF_4)_2TiF_6$	6.99	9.28	2.51	[38]
$(NF_4)_2MnF_6$	6.90	9.23	2.64	[38]
$(NF_4)_2NiF_6$	6.828	9.270	2.71	[60]
$(NF_4)_2GeF_6$	6.92	9.25	2.75	[38]
$(NF_4)_2SnF_6$	7.05	9.41	2.93	[38]

* $Z = 4$.

Crystallographic studies[60] of powders and single crystals of 98.9% pure $(NF_4)_2NiF_6$ showed that the compound has a body-centred tetragonal cell, space group $I4/m$. The salt is made up of octahedral NiF_6^{2-} ions and tetrahedral NF_4^+ cations, and has the antifluorite structure. The calculated interatomic distance N–F in the NF_4^+ tetrahedra is 1.30–1.40 Å, and the F...F distance is ~2.2 Å.[60]

TFA salts are colourless crystalline substances, except for the bright-red compound $(NF_4)_2NiF_6$ and the yellow compounds $(NF_4)_2MnF_6$, NF_4XeF_7, NF_4UF_7, and NF_4UOF_5. The salts do not sublime, and almost all decompose without melting. The melting points are ~591 K for NF_4SbF_6 and 614 K for NF_4BiF_6; $NF_4Sb_2F_{11}$ melts at 451 K, and the melt solidifies at 434 K. The melting point of $NF_4HF_2.nHF$ increases with decrease in the number of solvating HF molecules, and approaches room temperature as $n \to 0$.

TFA salts are soluble to different extents in anhydrous HF; the solubility of $(NF_4)_2MnF_6$ is greater than 1.30 g per g HF at 297 K, the solubilities of NF_4SbF_6 and NF_4BiF_6 are 259 mg and 173 mg per g HF at 195 K, and NF_4UOF_5 is sparingly soluble. Bromine pentafluoride, in which TFA salts are less soluble than in HF, can also be used as solvent. The salts are extremely hygroscopic, and react vigorously with water, and also with common organic solvents.

1. The Thermal and Thermochemical Properties of TFA Salts

TFA salts have an unusually high thermal stability. Although the stability of the fluoroantimonate and fluoroarsenate might have been predicted by analogy with other salts of fluoro-cations, the existence of the extremely stable tetrafluoroborate was completely unexpected. The synthesis of each new TFA salt was naturally followed by a study of its thermal stability. Unfortunately, the published results are not standardised, and the data must be regarded as only approximate, particularly because of the strong catalytic influence of the walls and impurities present in the salts on the rate of decomposition. Table 2 gives the temperatures of the start of the decomposition of various TFA salts, recorded by DTA or DSC, and also manometrically or by visual observation of the behaviour of the substance when heated in a sealed capillary. Although these values are understandably inaccurate, they are useful for estimating the relative stability of the salts.

Table 2. Temperatures of the start of the decomposition of TFA salts (T, K).

Salt	T	Salt	T
NF_4BF_4	513	$(NF_4)_2SiF_6$	363
NF_4GeF_5	522*	$(NF_4)_2TiF_6$	473
NF_4SnF_5	543	$(NF_4)_2MnF_6$	373
NF_4PF_6	518*	$(NF_4)_2NiF_6$	383
NF_4AsF_6	543	$(NF_4)_2GeF_6$	511*
NF_4SbF_6	>573	$(NF_4)_2SnF_6$	513
NF_4XeF_7	348	NF_4SO_3F	283
NF_4WF_7	>398**	NF_4ClO_4	273
NF_4UF_7	>398**	NF_4WOF_5	358
		NF_4UOF_5	333

*Temperature of the start of rapid decomposition.
**In a vacuum.

The salt NF_4HF_2 is stable in HF up to room temperature, and decomposes rapidly at 328 K; $NF_4Sb_2F_{11}$ at 523–533 K in a vacuum gives up SbF_5 and is converted into NF_4SbF_6;[23] the salt NF_4BiF_6 is apparently the most stable, and melts at ~614 K.[23] Table 2 shows that the stability of the salts depends markedly on the nature of the anions. Salts with oxygen-containing anions decompose at temperatures below 373 K, whereas salts with the anionic fluoro-complex BF_4^- and anions of the type EF_{n+1}^- ($n = 4$–6) or EF_6^{2-} are much more stable, and even the salt of the weak Lewis acid SiF_4 is stable up to ~363 K. According to recent data[61] obtained by DSC, the decomposition of NF_4BF_4, NF_4PF_6, NF_4AsF_6, NF_4SbF_6, NF_4GeF_5, and $(NF_4)_2GeF_6$ begins at 435, 446, 518, 578, 374, and 440 K respectively, and the maxima of the effects are observed at 530, 533, 596, 655, 475, and 481 K. For NF_4GeF_5, the temperature of the start of the decomposition (374 K) was taken as the temperature of the transformation of the salt into $(NF_4)_2GeF_6$ according to the scheme

$$2NF_4GeF_5 \rightarrow (NF_4)_2GeF_6 + GeF_4$$

and the maximum of the effect (475 K) corresponds to the decomposition stage

$$(NF_4)_2GeF_6 \rightarrow 2NF_3 + 2F_2 + GeF_4 .$$

According to Ref.38, a specimen of $(NF_4)_2NiF_6$ after 6 h at 373 K decomposes to the extent of 9%, but in Ref.62 it is stated that the temperature of the start of the decomposition of this salt is 407 K. The decomposition of $(NF_4)_2MnF_6$ at 373 K for 20 min takes place with acceleration, after which the pressure of the gaseous decomposition products increases linearly.[38] At 373 K after 17 h, 0.17% of the $(NF_4)_2MnF_6$ taken decomposes, whereas at 403 K after the same time interval the degree of decomposition is 0.66%. In a vacuum, NF_4XeF_7 decomposes at rates of 1.6% and 28% per hour at 348 K and 373 K; NF_4WF_7 at 418 K in a vacuum after 1 h decomposes to the extent of 1.4%, and NF_4UF_7 to the extent of 25%.[44] At 358 K, NF_4WOF_5 decomposes at a rate of ~0.03% per hour, and at 428 K after 6.5 h the degree of conversion into $NF_4W_2O_2F_9$ is 90%.[45]

The decomposition of TFA salts with the anions EF_{n+1}^- (n = 3–6) and EF_6^{2-} gives NF_3, F_2, and the corresponding fluorides EF_n, for example $NF_4BF_4 \rightarrow NF_3 + F_2 + BF_3$. The decomposition of $(NF_4)_2NiF_6$ gives non-stoichiometric nickel fluoride, and is described by the equation $(NF_4)_2NiF_6 \rightarrow 2NF_3 + (3 - x/2)F_2 + NiF_{2+x}$. The decomposition of $(NF_4)_2MnF_6$ gives MnF_3 according to the scheme: $2(NF_4)_2MnF_6 \rightarrow 4NF_3 + 5F_2 + 2MnF_3$.

The decomposition of salts with oxygen-containing anions is accompanied by the reaction of fluorine with the anions to give a different set of decomposition products. The decomposition of NF_4UOF_5 is described by the equations $NF_4UOF_5 \rightarrow NF_3 + F_2 + UOF_4$, $2UOF_4 \rightarrow UF_6 + UO_2F_2$; the decomposition products contain a mixture of UOF_4 and UO_2F_2, and the decomposition of NF_4UOF_5 gives OF_2 (in small quantities). At 453 K in a vacuum, NF_4WOF_5 is converted into the more stable $NF_4W_2O_2F_9$ according to the scheme: $3\,NF_4WOF_5 \rightarrow 2NF_3 + OF_2 + WF_6 + NF_4W_2O_2F_9$. The thermal decomposition of NF_4ClO_4 and NF_4SO_3F provides a new method for synthesising the corresponding hypofluorites: $NF_4ClO_4 \rightarrow NF_3 + FOClO_3$, $NF_4SO_3F \rightarrow NF_3 + FOSO_2F$. The decomposition of NF_4ClO_4 can be used to obtain very pure $FOClO_3$, which does not decompose when handled.[63] The hypofluorite $FOIOF_4$ has been obtained[48] as a mixture of *cis*- and *trans*-isomers by the thermal decomposition of the compound $NF_4IO_2F_4$, formed as an intermediate product of the reaction of $CsIO_2F_4$ with NF_4SbF_6 in HF.

The first paper devoted to the study of the kinetics of the thermal decomposition of TFA salts[64] described the decomposition of NF_4AsF_6 specimens in a Monel metal vessel. The specimens were synthesised from NF_3, F_2, and AsF_5 in an electrical glow discharge by the method described in Ref.15. It was found that the dependence of the total pressure p of the gaseous decomposition products of NF_4AsF_6 on time t in the temperature range 448–495 K is given by the equation $p^{3/2} = At + B$, where A and B are coefficients. It was suggested that the decomposition of the salt is described by the equations $NF_4AsF_6 \rightleftharpoons NF_5 + AsF_5$, $NF_5 \rightarrow NF_3 + F_2$, but it was impossible to isolate the suggested intermediate product NF_5 in an Ne matrix to record its infrared spectrum.

The results of Ref.64 appear doubtful, since the decomposition of the salt was studied at 448–495 K, whereas DTA indicates that decomposition begins at a higher temperature, for example ~543 K;[8] this lack of agreement was noted in Ref.12. The authors cited[64] apparently used NF_4AsF_6 specimens containing considerable quantities of impurities; moreover, the walls of the Monel metal vessel react with Lewis acids in the presence of fluorine at high temperatures, so that these vessels are unsuitable for kinetic studies.

The kinetics of the thermal decomposition of NF_4BF_4 and NF_4AsF_6 have been studied[55] in a vessel of synthetic sapphire, which is stable to mixtures of F_2 with BF_3 or AsF_5. The decomposition of NF_4AsF_6 was studied at 473–511 K, and that of NF_4BF_4 at 455–488 K. The time dependence of the total pressure of the decomposition products of the salts obeyed a law analogous to that in Ref.64, but the decomposition was much slower than in Ref.64. A special experiment with a small quantity of NF_4BF_4 at 526 K showed that the decomposition is not autocatalytic, and the linear dependence of $p^{3/2}$ on t is preserved as far as a degree of decomposition of the salt of ~25%. The addition of helium to the system has practically no influence on the rate of decomposition of the salts, the addition of fluorine and NF_3 decreases the rate slightly, and the addition of BF_3 to NF_4BF_4 or of AsF_5 to NF_4AsF_6 leads to a marked decrease in the rate of decomposition.

The decomposition of the salts is characterised by fairly high activation energies: 36.6 ± 0.8 kcal mole^{-1} for NF_4BF_4, and 44.7 ± 4.2 kcal mole^{-1} for NF_4AsF_6.[55] Preliminary studies[39] of the thermal decomposition of $(NF_4)_2NiF_6$ in the range 353–401 K showed that the decomposition of this salt is not autocatalytic, and takes place with an activation energy of 35.161 kcal mole^{-1}. The decomposition of $(NF_4)_2SiF_6$ in the temperature range 361.5–372.5 K has an activation energy of 26.6 kcal mole^{-1}.[33]

Phase transformations have been detected for various TFA salts: for NF_4BF_4 at 493–503 K[10] or at 507 K[18] or at 509 K;[27] for NF_4PF_6 at 398 K;[18] for NF_4AsF_6 at 406 K;[18] and for NF_4GeF_5 at 402 K.[18] The results of a DSC study of various salts, obtained in Ref.61, are given in Table 3. In $NF_4.SbF_6$, the phase transformation almost coincides with the start of the decomposition, and cannot be recorded accurately; the estimated temperature of the start of the transformation is 598 K.[61]

Table 3. Phase transformations in TFA salts.

Salt	Temperature of the start of the effect, K	Temperature of the maximum of the effect, K	ΔH, kJ mole^{-1}	ΔS, J mole^{-1} K^{-1}
NF_4BF_4	497	510	7.58	15.27
NF_4PF_6	404	415	5.90	14.50
NF_4AsF_6	418	428	4.62	10.96

The X-ray powder diffraction pattern of the high-temperature form of NF_4AsF_6, obtained in Ref.61, shows that at 439 K the salt has a cubic lattice with parameter 9.13 Å. For one of the NF_4SbF_6 specimens, a cubic lattice with a = 5.66 Å was found at room temperature.[61]

Until recently, there were no published data on the thermodynamic characteristics of TFA salts. By 1979, the only data were for NF_4BF_4, for which the enthalpy of decomposition had been used to determine experimentally the standard enthalpy of formation, equal to −337.4 kcal mole^{-1} (unpublished data, see Refs.27, 55, and 61), from which it follows that the enthalpy of the reaction $F_2(gas) + NF_3(gas) + BF_3(gas) \rightarrow NF_4^+BF_4^-(solid)$ is −34.6 kcal mole^{-1}.[55] From the estimate in Ref.55, $\Delta H_f^0(NF_4AsF_6) \cong -372$ kcal mole^{-1}. In a DSC study of the thermal decomposition of $(NF_4)_2NiF_6$ and NF_4SbF_6, the values −247 kcal mole^{-1} and −393 kcal mole^{-1} respectively were obtained for the standard enthalpies of formation of these salts.[62] The enthalpy of formation of $(NF_4)_2NiF_6$ had previously[39] been estimated as ~−230 kcal mole^{-1}.

DSC and measurement of the heats of hydrolysis of various TFA salts by water and various aqueous solutions were used[61] to find the enthalpies of formation of the salts. The follow-

ing values of ΔH_f^0 (kJ mole^{-1}) for the solid salts were recommended:

NF_4BF_4	-1410 ± 5	NF_4SbF_6	-1669 ± 12
NF_4AsF_6	-1538 ± 11	NF_4PF_6	-1841 ± 7
NF_4GeF_5	-1473 ± 1	$(NF_4)_2GeF_6$	-1606 ± 5

The affinity of NF_3 for the F^+ ion was estimated as -845 kJ mole^{-1}, and the enthalpy of formation of NF_4^+(gas) as 784 kJ mole^{-1}.[61] From the estimate in Ref. 27, the enthalpy of formation of NF_4^+(gas) is 204 kcal mole^{-1} (853 kJ mole^{-1}). Examination of a Born–Haber cycle with the assumption that the crystal lattice energy of $NF_4^+F^-$ is -630 kJ mole^{-1} gave for the enthalpy of the reaction NF_3(gas) + F_2(gas) → $NF_4^+F^-$ (solid) the value 36 ± 40 kJ mole^{-1}.[61] From a comparison of the enthalpies of formation of TFA salts and other fluorine–nitrogen compounds, it was suggested[65] that the formation of $NF_4^+F^-$ may be exothermic.

2. The Chemical Properties of TFA Salts

TFA salts, like the salts of other fluoro-cations,[12] have an extremely high chemical activity. They react vigorously with water, alcohols, hydrocarbons, and other organic compounds, but in the absence of moisture they can be kept for a long time in Teflon, steel, or quartz containers; they are not sensitive to shock if they are not in contact with a substance capable of being oxidised.

Hydrolysis of the salts leads to the quantitative liberation of NF_3, which is extremely stable to hydrolysis and practically insoluble in water. Measurement of the quantity of NF_3 liberated has been made the basis of a method of elemental analysis which has been used repeatedly in all studies of the synthesis of TFA salts. To avoid a vigorous reaction, several millilitres of water are condensed at 77 K into a vessel containing a specimen of the salt with a mass of 0.5–1.0 g, after which the contents of the vessel are slowly heated to room temperature. The gaseous hydrolysis products are either separated by fractional condensation or analysed chromatographically.[56] The quantitative liberation of oxygen in the molar ratio $NF_3:O_2 = 2:1$ when TFA salts are hydrolysed apparently takes place only for NF_4AsF_6.[61] In the hydrolysis of, for example, NF_4SbF_6, 0.45 mole of O_2 is liberated per mole of NF_3.[23] The decrease in the quantity of oxygen liberated is due to the formation of hydrogen peroxide:

$$NF_4^+ + OH^- \rightarrow NF_3 + HOF,\ 2HOF \rightarrow 2HF + O_2,\ HOF + H_2O \rightarrow HF + H_2O_2$$

The ratio $H_2O_2:O_2$ can vary from one experiment to another, depending on the conditions. A different picture is observed in the hydrolysis of NF_4BiF_6, where 0.86 mole O_2 is liberated per mole of NF_3.[21] The BiF_6^- anion oxidises water according to the equation:

$$BiF_6^- + H_2O \rightarrow BiF_3 + HF_2^- + HF + {}^1/_2O_2$$

and this reaction may also be accompanied by the formation of H_2O_2.

The salt $(NF_4)_2NiF_6$ represents a combination of a fluoro-cation with a fluoro-anion, both of which are strong oxidising agents. The neutral compound NiF_4 corresponding to the NiF_6^{2-} anion is unstable, and decomposes to lower fluorides of nickel with the liberation of fluorine. The hydrolysis of the salt is described approximately by the equation

$$2(NF_4)_2NiF_6 + 5H_2O \rightarrow 4NF_3 + 10HF + 2O_2 + OF_2 + 2NiF_2$$

and the ratio $O_2:OF_2$ varies from one experiment to another. An interesting feature is that OF_2 is formed only when NF_4^+ and NiF_6^{2-} are present together, and is not observed in the hydrolysis of NF_4^+ or NiF_6^{2-} taken separately.[39] The appearance of OF_2 in the hydrolysis products may be due to the fluorination of the intermediate product HOF by the NiF_6^{2-} anion:

$$NF_4^+ + 2H_2O \rightarrow HOF + H_3O^+ + NF_3$$
$$HOF + NiF_6^{2-} \rightarrow OF_2 + HF + NiF_4^{2-}$$

In addition to hydrogen peroxide, ozone in quantities of several mole % is always formed as a side product in the hydrolysis of TFA salts by water, even when the hydrolysis is carried out very carefully.[61]

X-Ray electron spectroscopy has detected the formation of ONF_2^+ and NO_3^- in the reaction of NF_4BF_4 with atmospheric moisture:[28]

$$NF_4^+ + H_2O \rightarrow ONF_2^+ + 2HF$$
$$ONF_2^+ + 3H_2O \rightarrow HNO_3 + 2HF + H_3O^+$$

Up to the present, research workers have been interested chiefly in developing methods for the synthesis of TFA salts, so that a fairly large number of these compounds has been obtained. Subsequent studies will probably be directed towards the investigation of the chemical properties of the salts. TFA salts have a fairly high thermal stability, contain a large quantity of active fluorine, and decompose with the liberation of fluorine over a wide temperature range, and their reactions can be carried out at a controlled rate. These features make it possible to regard TFA salts as promising fluorinating agents in inorganic and organic synthesis. Unfortunately, reactions involving TFA salts have been little studied up to the present.

An early study[67] showed that NF_4SbF_6 in HF fluorinates chlorine to give ClF_3 at room temperature. The thermal decomposition of TFA salts with oxygen-containing cations can be used to synthesise hypofluorites.[36,48,63] The reaction of TeF_5OH with NF_4HF_2 at 250 K gives the stable hypofluorite $FOTeF_5$, whose possible existence was previously doubted.[68]

The reactions of NF_4BF_4 with various aromatic compounds have been studied.[69] The choice of NF_4BF_4 as fluorinating agent is determined, in particular, by the fact that its decomposition products NF_3 and BF_3 are inert towards organic compounds at low temperatures. The reactions of NF_4BF_4 take place by an electrophilic substitution mechanism. Benzene, toluene, and nitrobenzene react rapidly with NF_4BF_4 in anhydrous HF at 273 K to give fluoro-substituted derivatives. In the rapid stage, up to four hydrogen atoms are replaced, and the methyl group of toluene is not fluorinated. After the stage involving the rapid replacement of hydrogen atoms, a much slower stage involving the addition of fluorine atoms at the aromatic bonds begins. The reaction of NF_4BF_4 with hexafluorobenzene at 298 K in HF gives C_6F_8 (yield 94%), in which the added F atoms are in the *para*-position to one another.

3. Application of TFA Salts

TFA salts are solid sources of so-called "available fluorine", which is liberated as F_2 and NF_3 on thermal decomposition. The term "available fluorine" is preferable to the term "active fluorine", since the latter refers only to F_2, and not to fluorine in NF_3. Of the TFA compounds known at present, the following have the highest concentrations of available fluorine (%):

$(NF_4)_2XeF_8$	65.6	NF_4XeF_7	59.0
$(NF_4)_2NiF_6$	64.6	$(NF_4)_2TiF_6$	55.6
$(NF_4)_2MnF_6$	59.9	NF_4BF_4	53.7
$(NF_4)_2SiF_6$	59.0		

In the thermal decomposition of 1 cm^3 of solid $(NF_4)_2NiF_6$, the quantity of available fluorine formed is 12% greater than that from the same quantity of liquid fluorine at 86 K.[39] It is only for NF_4XeF_7 and $(NF_4)_2XeF_8$, however, that complete utilisation of the fluorine present is possible; in other cases, some of the fluorine after the decomposition of the salt remains firmly bound to the element present in the anion.

TFA salts have attracted attention as possible components of solid rocket fuels[70] and gas generators for chemical HF–DF lasers.[23,71,72] The high-density fuel mass[70] contains 25–70% TFA salt, 5–50% high-molecular-weight polytetrafluoroethylene, and 10–25% low-molecular-weight polytetrafluoroethylene. The mixture of these components is dispersed in a suitable fluorinated solvent, after which the solvent is removed and the homogenised mass is pressed or extruded.

The operation of the gas generator[23,73] is based on the liberation of F_2 and NF_3 on the combustion of granules containing a TFA salt with a small quantity of fuel, such as Teflon powder. The heat liberated by the combustion of the Teflon brings about the thermal decomposition of the TFA salt and the dissociation of NF_3 to F atoms and F_2 molecules. The decomposition of TFA salts with anionic fluoro-complexes based on volatile and completely or partly monomeric Lewis acids leads to the liberation of these acids into the gas phase, and hence to contamination of the generated mixture. The liberation of the Lewis acid into the gas phase can be prevented by introducing into the mixture a strong Lewis base such as KF, to bind the acid in a complex; the presence of KF, however, leads to a deterioration in the properties of the mixture. An alternative solution to this problem is to create self-sintering compositions. $(NF_4)_2SnF_6$, which on decomposition gives non-volatile polymeric SnF_4,[41,74] and also $N_2F_3SnF_5$,[75] have been proposed as a basis for these mixtures. TFA salts have also been proposed for increasing the detonation pressure of organic explosives.[76]

The Possibilities of the Mass-spectrometric Analysis of Involatile and Thermally Unstable Bio-organic Compounds

L.N.Gall' and M.Ya.Turkina

The possibilities of the mass-spectrometry of thermally unstable highly polar and organic and bio-organic compounds, based on the direct (without preliminary evaporation) formation of ions of the test compound, are examined.
The bibliography includes 260 references.

I. INTRODUCTION

The development of modern organoelemental and bio-organic chemistry has led to the need to determine the compositions and structures of highly polar, involatile and thermally unstable compounds, which can be studied by traditional mass-spectrometric methods.

The development of "mild" methods for the ionisation of organic compounds, namely chemical ionisation (Field and Manson,[1] 1968), field ionisation, and field desorption (Beckey,[2] 1969) began in the 1960's and techniques on a wide scale in the 1970's. The mass spectra obtained by these procedures contain intense peaks due to molecular and quasi-molecular ions, but the transfer of the test molecules to the gas phase by heat treatment was not required only in the field desorption method. The field desorption method is therefore used successfully for the analysis of involatile compounds. The advances achieved with the aid of this method have been surveyed in several reviews.[2-5]

During the last decade communications have been published on new methods for the determination of the mass spectra of involatile and thermally unstable compounds (TUC), in which the vaporisation of the test substances before ionisation has been eliminated. These ionisation procedures can be divided into two groups: the methods for the generation of ions from the solid state without heating the specimen and the methods from the selective removal of ions from a solution containing the test compound at room temperature.

The first group comprises methods based on secondary ion emission (SIE) induced by bombarding the test specimen with a beam of primary ions (secondary ion–ion emission) or a beam of neutral atoms (atom–ion emission), the method based on plasma desorption by ^{252}Cf fission fragments, and ionisation by laser radiation (LD).

The second group of methods, which began to develop somewhat later, includes the electrohydrodynamic ionisation method,[6-8] the method based on the field of evaporation of ions from solutions,[9,10] including solutions in involatile solvents deposited on the surface of field desorption emitters,[11] the "electro-scattering" method,[12-16] the "mist formation" method,[17-19] and the method based on the extraction of ions from solutions at atmospheric pressure.[20] Heat treatment of the test substances has been eliminated from all these methods and the latter make it possible to determine the mass spectra of highly polar and involatile thermally unstable compounds without their preliminary chemical modification; the high content of quasi-molecular and in most cases of intense fragment ions ensures that the molecular weights and structures of the test molecules can be determined.

The volatility and in many cases also the stability of the compound diminish with increase of its molecular weight and the scope of a method can be characterised by the upper limit to the mass of the ions obtained with its aid. Towards the middle of 1982, major advances had been achieved by investigators using the methods based on the atom–ion emission in liquid matrices (see below) and plasma desorption by ^{252}Cf fission fragments. Quasi-molecular ions of the unprotected peptide glucagon (a pancreatic hormone), the molecular weight of one of the isotopes of which is 3481.6,[21] and a biological product (bovine insulin) with a molecular weight (MW) of 5729.6 [22] were obtained by the first procedure. A record success was achieved with the aid of the method based on the plasma desorption by ^{252}Cf fission fragments, which yielded the mass-spectrum of an oligonucleotide with a molecular weight of 6278.[23] The absence of the need for enzymic and chemical treatment made it possible to reduce the size of the sample required for the analysis by the new methods and at the same time gave rise to the possibility of identifying compounds present in unpurified biological preparations. Thus the determination of the molecular weight of a peptide by the atom–ion emission method now requires 0.1 nmol of the test substance, while the determination of the aminoacid sequence in it requires 2–50 nmol.[24]

The aim of the present review is to assess the possibilities of those of the above methods which have now found extensive practical applications in the mass-spectrometric analysis of thermally unstable compounds. These include secondary emission ionisation, plasma desorption by ^{252}Cf fission fragments, and laser desorption. The review does not deal with the studies in which the mass spectra of TUC are obtained by traditional ionisation methods—electron impact or chemical ionisation but with updated types of heating or procedures for the introduction of the specimen into the ion formation region, which reduce the degree of thermal decomposition of the product.[25-28] For the analysis of biomolecules, this procedure is not likely to be useful, since an increase in

the molecular weight and in the polarity of the test molecules leads to the requirement for stronger heating and the fraction of quasi-molecular ions in the mass spectrum sharply diminishes or the ions disappear altogether.[26]

II. SECONDARY EMISSION IONISATION

1. Secondary Ion Ionic Emission

When a primary ion beam impinges against a surface, positive and negative ions derived from the adsorbed layers and the material of the support are always present among the secondary particles leaving the surface. The yield of these ions depends on many factors.[29–33] The most important characteristics, which determine quantitatively the ion formation process, are two parameters: the secondary ion emission coefficient $S^{\pm}$ (the parameter $S^{\pm}$ has been called[34,35] the absolute yield of secondary ions), i.e. the number of ions $A^{\pm}$ leaving the surface following the impact by one primary particle, and the ionisation efficiency, i.e. the ratio of the number of dislodged ions to the number of neutral particles which have left the surface.

Impact by the primary ions alters the state of the surface layer. Calculation has shown that at a current of 1×10^{-8} A cm^{-2} the number of ions incident on the surface is 6×10^{-6} ions s^{-1} $Å^{-2}$. Assuming that the energy of a single ion is transmitted to a zone with a radius of 10 Å, we find that such a surface element is exposed to impact after every 8 min. This time is longer by several orders of magnitude than that required to dissipate the energy of the nucleus. For higher current densities of the primary beam, the layers adsorbed on the support are rapidly worn away, which is manifested by a change in the intensity and composition of the ions in the secondary beam.

Benninghoven[34] introduced the concept of the "dynamic" and "static" ion formation regimes under the conditions of secondary ion–ion emission (SIIE). Bombardment of the surface by the primary beam at a current density not exceeding 1×10^{-8} A cm^{-2} has been called the static model; in this case the disruption of the surface layer is insignificant. A method employing the static regime for the preparation of the ions of an organic substance deposited in the support has been called "organic"[36] or molecular[37] SIIE. It has been shown experimentally that irradiation of a thin layer of an organic product deposited on a metallic support by a beam of Ar^+ ions at a current density of 4×10^{-9} A cm^{-2} can give rise to a steady emission of quasi-molecular ions $(M-H)^-$ for several minutes.[38] The ionisation regimes achieved at primary beam current densities exceeding 10^{-8} A cm^{-2} have been called dynamic and are used mostly for the layer-by-layer analysis of metals and semiconductors. The first secondary-emission-mass spectra of organic substances were obtained in 1971 by Tantsyrev and Nikolaev.[39]

In 1976 Benninghoven and co-workers published the secondary-emission mass spectra of four aminoacids (alanine, phenylalanine, cystine, and arginine)[38] and a year later of a further 19 aminoacids and other biologically active compounds (short peptides, vitamins, sulphamide preparations, etc.).[40–42] The spectra of pyrimidine and purine bases, nucleotides and nucleosides,[43] and folid acid[44] were published by the same workers in subsequent years. Bombardment of a specimen in the form of a thin film on a silver support was carried out in the static regime by a primary beam of Ar^+ ions with an energy of 2.25–3.00 keV and at a current density of 4×10^{-9} A cm^{-2} and above. The spectra contained fairly intense peaks due to the ions $(M+H)^+$ and $(M-H)^-$ together with characteristic fragment ions. Stable emission persisted for several minutes but came to a rapid stop if the regime ceased to be static. Subsequently direct evidence was obtained by the method of electronic spectroscopy for chemical analysis (ESCA) that irradiation by a more powerful primary beam entails the disruption of the surface layer of the organic species.[45]

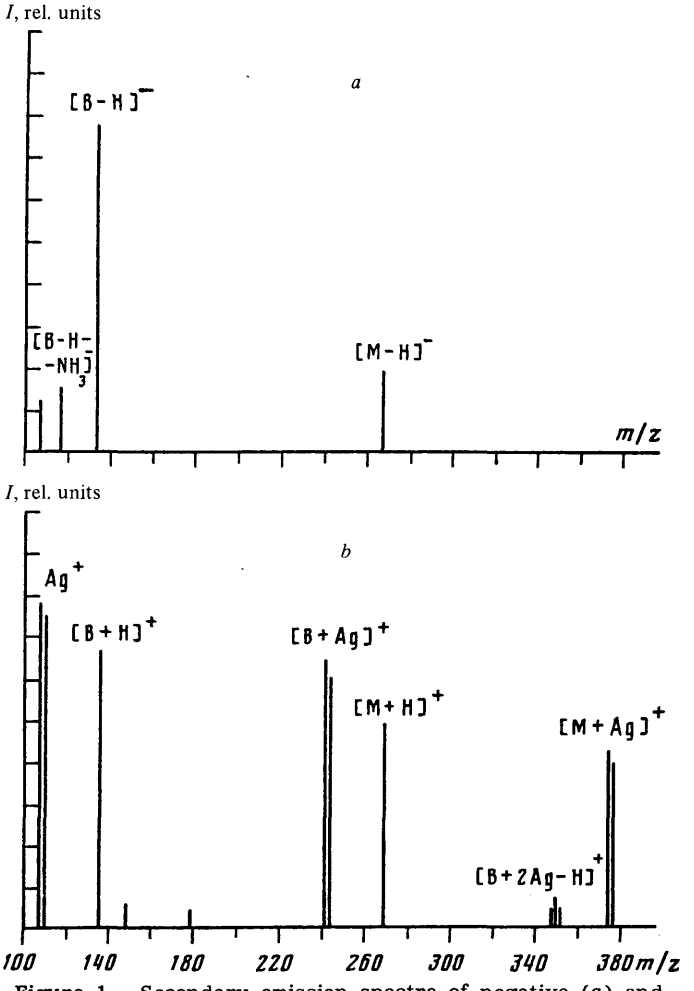

Figure 1. Secondary emission spectra of negative (*a*) and positive (*b*) adenosine ions.[43]

Apart from the protonated molecular and fragment ions of the test substance, the following can appear in secondary-emission mass spectra: (1) cationised molecular ions $(M+Ct)^+$, where Ct^+ is the cation of an alkaline metal or the metal of the support; (2) the intrinsic cations Ct^+ (or anions X^- in the spectra of the negative ions); (3) cluster ions of the type $(M_n + Ct)^+$, $(M_n + H)^+$, and $Ct.(Ct_n + X)^+$; (4) ions of the type $C_mH_n^+$ giving rise to a background spectrum in the region of low masses subsequently referred to as "chemical noise".[46] The spectra of certain compounds also contain clusters $(M - H + 2Ct)^+$ and molecular radical-ions $M^{\pm}$ and $M^{\mp}$. Clusters appear in the spectra of compounds having an

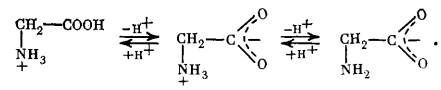
"acid" hydrogen atom,[43,47] while the source of the radical-ions has not been established. Presumably they arise at the phase interface by the interaction of neutral molecules of the test compound with the secondary electrons dislodged from the surface. Radical-ions and their fragmentation products have been observed in the spectra of atropine and nicotinamide.[41,42]

The fragmentation of the $(M + H)^+$ ions has been thoroughly investigated and takes place in accordance with the rules governing the decomposition of even-electron ions.[48,49] For example, the characteristic fragment for aminoacids is $(M - 45)^+$ [38,40-42,50] formed via the reaction

$$R{-}\underset{\overset{|}{\overset{+}{N}H_3}}{CH}{-}COOH \xrightarrow[-CO;\ -H_2O]{} R{-}\overset{+}{C}H{-}NH_2 .$$

The spectra of the purine and pyrimidine bases contain, apart from the intense peaks due to the ions $(M + H)^+$, $(M - H)^+$, or $(M + Ct)^+$, also the peaks due to the $(M + H - NH_3)^+$ and $(M + H - 43)^+$ fragments. In the spectra of the simplest nucleotides and nucleosides the peaks of the ions derived from the bases (B) and formed as a result of the decomposition of the $(M + H)^+$ ions are the most intense[43] (Fig. 1).

According to some data,[40-42] the average yield of the protonated ions from a film of an organic compound is 0.1; however, even for related compounds the values of $S^{\pm}$ differ markedly. In respect of aminoacids the yields of the ions $(M + H)^+$ from glycine and leucine differ by a factor of 150, while the ratio of the peak intensities of the fragment ions $(M - COOH)^+$ and $(M + H)^+$ varies from 10 in the alanine spectrum to 0.1 in the leucine spectrum.[42] A detailed study of the dependence of the yields of the ions $(M + H)^+$ and $(M - H)^-$ in the glycine spectrum on the experimental conditions showed that the ratio $(M + H)^+/(M - H)^-$ can be altered by a factor of 100 by changing the pH of the initial aqueous solution.[42] The yield of the ions $(M + H)^+$ increases with increasing acidity of the solution, while the addition of alkali promotes an increase of the yield of $(M - H)^-$. This is the first mention of the fact that the yield of ions under SIIE conditions can be altered and that for ionic compounds it is always higher than for neutral molecules. Using the zwitter-ionic character of the aminoacids, glycine has been converted[42] into one of the following ionic forms by the addition of acid or alkali:



Variants of this procedure for the conversion of the compound to be analysed into an ionic form was subsequently widely employed in studies by other investigators.

The possibility of changing $S^{\pm}$ makes it necessary to indicate the conditions used to prepare secondary ions in the determination of the sensitivity of the SIIE method. Benninghoven[51,52] estimated the limits within which substances of different types can be detected, assuming that not less than 10% of the number of molecules of the test substance on the target leave the surface in the form of quasi-molecular ions. If 10^{-10} of a mole of the product, i.e. 6×10^{13} molecules, have been deposited on the support, then in such a case 6×10^5–3×10^{12} ions arrive on the detector, depending on the type of mass-spectrometric analyser used (the relative aperture varies from 10^{-7} for static magnetic instruments with double focussing to 0.5 for time-of-flight instruments). Under ion counting conditions, it is possible to record reliably the signal from 1000 ions; consequently the limit for the detection of organic substances with the aid of SIIE is in the range 10^{-12}–10^{-19} of a mole. However, under real conditions, such high sensitivity cannot be achived owing to the presence of "chemical noise" and peaks due to admixtures.

Benninghoven[53] demonstrated the high sensitivity of the SIIE method in the solution of a practical clinical problem, namely the identification of medicinal drugs in urine. Narcotic drugs (morphine, codeine, meperidine, methadone) were introduced artificially into urine in an amount equivalent to 1 mg per 100 ml. A dilute (1 : 20) solution of 1 μl of urine (~0.5 g of each drug) was deposited on a support, which was placed in the focus of the primary ion beam. The $(M + H)^+$ ions from each preparation (Fig. 2) and certain fragments were observed in the mass spectra. Sodium cyclohexene-sulphonate introduced into the organism in an amount of 200 mg was not detected in the patient's urine after 12 h, but, when 18 h elapsed, its presence was demonstrated in an amount of 6.2 mg ml^{-1}.[53] The possibility of identifying 10^{-10} g of phenylalanine on a commercial double foccussing instrument

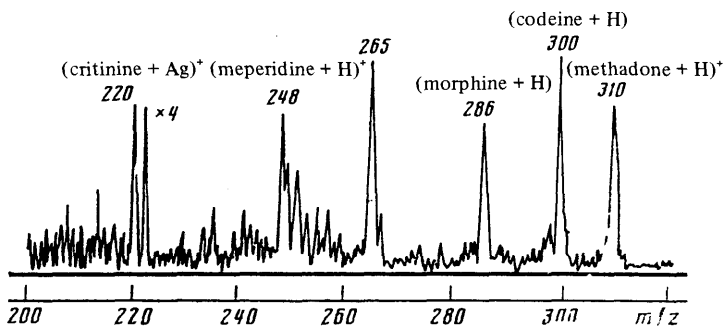


Figure 2. A fragment of the secondary emission spectrum of a mixture of narcotic substances.[53]

(Varian 311 A) has been reported.[54] The combination of the SIIE method with a time-of-flight analyser is especially promising. This application has been developed in a number of studies.[55–57]

Cooks and co-workers[58,59] were the first to initiate the development of another application of the SIIE method based on the ability of the majority of organic molecules, particularly highly polar ones, to form complexes with alkali metal cations on bombardment with the primary beam. The authors published their communication one year after the publication of the first study by Benninghoven and co-workers,[42] where the intensities of the $(M + Ct)^+$ ion peaks in the mass spectra were smaller by an order of magnitude than those of the $(M + H)^+$ peaks and their appearance was attributed to incomplete coverage of the surface of the metal support by the layer of the specimen. This hypothesis was subsequently confirmed experimentally; the composition of a flux of secondary ions from a surface coated by an aminoacid (glycine, α- and β-alanine, and serine) has been investigated with the simultaneous observation of the surface layers with aid of X-ray[60,61] and Auger spectrometers.[61] On the grounds that the cationated complexes $(M + Ct)^+$ are more stable than the protonated ions $(M + H)^+$ [56,57,62,63] [the protonated adenosine 5-monophosphate protonated ions have a lifetime ≤10 μs, while that of $(M + Na)^+$ is greater at least by an order of magnitude[63]], Cooks and co-workers developed several procedures whereby it is possible to increase the content of the cationated ions in the spectra of test substances; the specimen was deposited on the support in a mixture with metal, sulphur, carbon, silicon,[64] and alkali metal salt powders[58,64–67] and was bombarded by ions of other elements (cobalt, copper and silver).[59,61,64] Complexes with 22 elements in the Periodic System have been obtained in this way.[37]

These methods of generation of TUC ions by the SIIE procedure rapidly found applications in studies by other investigators. A detailed investigation has been made[47,68] of the dependence of the yield of the ions $(M + H)^+$, (M + cation of added salt)$^+$, and (M + cation of the metal of the support)$^+$ for different aminoacids M deposited on the support in a mixture with LiCl. By adding sodium or lithium chloride, Japanese workers obtained secondary emission mass spectra of mono-, di-, tri-, and tetra-saccharides,[69–72] adenosine, and 13 aminoglycoside antibiotics.[70,72] The authors noted that the added salts increased the intensity of the peaks of the quasi-molecular ions and decreased the extent of their fragmentation. However, the excess salt reduces the $(M + Ct)^+$ peak intensity and in addition promotes an increase of the fraction of the $(M + 2Ct + H)^+$ ions, which complicates the interpretation of the mass spectra. Analogous results have been obtained in other investigations.[47,68] Cooks and co-workers, who detected the $(M + 2Ct + H)^+$ ions in the spectrum of aminobenzoic acid,[58] proposed a simple method whereby one can avoid such complications—the use of ammonium chloride as an additive.[66,73,74] In this case the $(M + H)^+$ ions appeared in the spectrum together with the intense peak of NH_4^+ ions.

The stabilities of the $(M + Ct)^+$ complexes differ for different cations. The alkali metal cations show a greater stabilising effect. In selecting the conditions for the solution of a specific problem, one must be guided by the following rules established by Grade and Cooks:[59] (a) the $(M + Ct)^+$ cluster is more stable the more polar the molecule [for example, the peak intensity ratio $(M + Ag)^+/M^+$ in the stilbene spectrum is 500 times greater, while that in the *p*-aminobenzoic spectrum is 1000 times greater than in the anthracene spectrum]; (b) the degree of fragmentation can be regulated by producing complexes with cations of different kinds; this can be done in the spectrum obtained under electron impact conditions by altering the energy of the ionising electrons. For example, in the ionisation of *p*-aminobenzoic acid on a support made of the Ag + Pd (60 : 40) alloy the peak intensities of the ions $(M + Ag)^+$ and $[(M - COOH) + Ag]^+$ were identical, while the ratio $[Pd + (M - COOH)]^+/(Pd + M)^+$ was 7. For molecules with a high electron affinity, an attempt was made to obtain anionated complexes; however, complexes with the Cl^- and CN^- ions were not detected among the negative ions in the mass spectra of o-, *m*-, and p-aminohydroxybenzoic and mercaptobenzoic acids, 1,5-dihydronaphthalene, pentachlorophenol, nicotinamide, and 1-hydroxyanthraquinone. The spectra contained intense peaks of the ions $(M - H)^-$, $M^{\cdot-}$, and $(M - H - CO_2)^-$. The ratio $(M - H)^-/M^{\cdot-}$ increases with increasing acidity of the product. It has been noted that the spectra of negative ions contain few lines and can be readily interpreted. The interpretation is especially facilitated by comparing the spectra of positive and negative ions derived from the same product.[75]

Thus, using the ability of organic molecules to give rise to complexes with cations, it is apparently possible to obtain the mass spectra of compounds with a high molecular weight and a high polarity. These studies have only just begun. Hitherto it has been possible to obtain the quasi-molecular ions of methylated nucleosides[67] and polynucleotides[76] and it has become possible to carry out the mass-spectrometric analysis of the compositions of certain DNA and RNA after their completely enzymic hydrolysis. The mass spectra of saccharides,[69–73,77] including pentasaccharides[71,77] and octasaccharides,[72] adenosine, certain antibiotics[72,78] and oligopeptides[79,80] have been published. The aminoacid sequence in peptides can be determined from such spectra using the method of activated collisions.[80]

In estimating the sensitivity of the method employing cationated molecular ions, it is essential to take into account the differences between the capacities of the test substances for complex formation. The limit of the detection of sucrose in the mixture with LiCl proved to be 10 ng when the $(M + Ct)^+$ signal is 5 times more intense that the noise, while for adenosine the $(M + Ag)^+$ limit is 2 ng.[81] The sensitivity for glucose in a mixture of NaCl proved to be higher than 10^{-11} Cl g^{-1}.[69]

The mass spectra of organic ammonium salts and their analogues have been studied in detail under SIIE conditions.[81–87] Instead of complexes of the molecules with a proton or cation, the secondary ions are found to comprise undecomposed organic cations, some of which break down, giving rise to fragments which make it possible to infer the composition of the salt cation. Diquaternary salts do not give rise to dications in the vast majority of cases;[86] sometimes charge separation takes place, i.e. two singly-charged fragments of the dications are produced or a singly-charged cation is formed by loss of a proton.[87]

Comparison of the efficiencies of ion formation for ionic organic salts and compounds forming complexes with Ct has shown that the yield of ions derived from the quaternary ammonium salt $(C_2H_5)_4N^+I^-$ is 100 times greater than that of the ions derived from the mixture of dicyanobenzene and a copper(II) salt under identical conditions.[82] The absolute limit of the detection of the salt from the peak of the cation was 10 ng cm^{-2} (the signal exceeded the noise over 1 min).[81] A high sensitivity has been demonstrated in the identification of choline and choline esters[84] and also in the determination of muscarine and choline in thin-layer chromatographic spots.[85]

Thus the sensitivity of the method is highest for ionic compounds. Several procedures have been proposed whereby organic substances can be made to undergo a transition to a

formally ionic state; these transformations have been called a new type of "derivatisation".[87-89] For example, amphoteric compounds can be converted into an ionic form by adding inorganic acids or alkalis. As shown above, the addition of salts to basic products also increases the yield of quasi-molecular ions since metal ions are Lewis acids. By mixing amines with suitable alkyl iodides, it is possible to obtain the salts of quaternary nitrogen bases. On interaction with pyrrolidinium perchlorate, aldehydes and ketones are converted into immonium salts:

The proposed procedures extend the range of substances giving rise to intense quasi-molecular ions and characteristic fragments under SIIE conditions. Compounds not susceptible to analysis under field desorption conditions can nowadays be identified by the SIIE method. For example, after unsuccessful attempts to detect the ions of cymostatine and other thermally unstable antibiotics, the mass spectra of these molecules were obtained[78] by bombarding the specimen (in a mixture with NH_4Cl) by Xe^+ ions.

The determination of quantitative data concerning the mixture of organic products from the recorded secondary-emission mass-spectra is not always possible. In some investigations[67,76,90] the concentration of one of the components was estimated from secondary emission mass-spectrometric data using an isotopic isomer of the compound analysed as the internal standard. However, in many instances[81,91] it has been observed that formation of the ions of certain components is suppressed in the bombardment of a mixture of substances by the primary beam. For example, the spectrum of a mixture of five narcotic substances placed on a support was found to contain the $(M + H)^+$ ions derived from only three compounds.[91]

Summarising the data obtained in studied of thermally unstable compounds by the SIIE method, the following conclusions can be reached:

1. The spectra contain the intense peaks of the $(M + H)^+$, $(M - H)^-$, and $(M + Ct)^+$ ions, which make it possible to determine the molecular weight of the test substance.

2. Ionisation takes place in the solid state at room temperature or after slight heating; thermal degradation was not observed under these conditions.

3. The degree of fragmentation of the organic molecule can be regulated by altering the type of metal cation in the complex $(M + Ct)^+$ ion.

4. The method is highly sensitive, particularly for organic salts and polar compounds. Its sensitivity with respect to the three types of ion peaks decreases in the sequence organic cation > cationated molecules > protonated molecules. Under real conditions the determination of the mass spectrum under conditions where the support with an area of 0.1 cm^2 is scanned, it is necessary to deposit 10^{-10}–10^{-7} g of the test substance when the analyser employed is a commercial mass spectrometer with double focussing.[53,70]

5. The method can be used to identify products separated by thin-layer chromatography; in order to record the mass spectrum, the spot bombarded must contain at least 10 μg of the product. The first positive results using the SIIE method in a liquid chromatography–mass spectrometer system have been obtained.[46,92,93]

6. The method of preparation of the specimen for analysis is very simple and does not require a high experimental skill and lengthy preparations, as happens for example, in analysis by the FD method.

2. Secondary Atom–Ion Emission

The replacement of the primary ion beam by a beam of accelerated neutral particles has led to new possibilities for the study of involatile highly polar and thermally unstable compounds by the mass-spectrometric method. Data demonstrating that irradiation of the specimen by accelerated atoms makes it possible to ionise without decomposition heavier molecules than under SIIE conditions were surveyed towards the end of 1981.[94] For example, it has been possible to record the quasi-molecular ions of glucagon (a pancreatic hormone; MW = 3841) and the B-chain of insulin, separated from the rest of the molecule by oxidising disulphide bridges (MW = 3494).[95] The mass spectra of other biologically important products, obtained on bombardment with a beam of accelerated atoms have been published in reviews.[23,96-98] Compounds with MW > 4000 could be analysed at that time only by the plasma desorption method, with the aid of which the quasi-molecular ions of an oligonucleotide with MW = 6278 were recorded. However, by selecting the optimum balance of sensitivity and resolution, the spectra of protonated molecular ions derived from the hormone adrenocorticotropin (MW = 4538) and the undecomposed ox insulin molecule (MW = 5730) were obtained as early as 1982 on a magnetic mass spectrometer with suitable characteristics using the atom–ion emission (AIE) method[22] [FAB in Western literature (Ed.of Translation)].

The AIE method was developed and used for the first time by Tantsyrev and Kleimenov in 1973 in order to obtain the mass spectra of involatile organic molecules.[99] The object of the study consisted of thin films of polymeric substances deposited on a metallic support. The surface of the specimen was bombarded with a beam of Ar atoms having an energy of 300–3000 eV and a flux density of 10^9–10^{10} atom s^{-1} cm^{-2}. The AIE method proved to be convenient for the analysis of polymers, each of which has its characteristic spectrum suitable for its unambiguous identification; the spectra of copolymers represent a superposition of those of each polymer.[99-101]

The mutual orientation of the monomeric units in the macromolecules could be established from mass-spectrometric data[102-105] by determining the relative contents of hydrogen and deuterium when polymerisation took place with participation of a deuterium-containing monomer.[106] Apart from macromolecules, Tantsyrev and co-workers investigated the secondary-emission mass spectra of several TUC (aminoacids, secondary ammonium salts, and bases),[107] while in 1981 a systematic investigation of the mass spectra of biological substances was begun.[108-111]

In the non-Soviet literature Barber and co-workers or Surman and Vickerman (Great Britain), who published simultaneously in 1981 the secondary-electron mass spectra of several organic compounds,[112,113] are regarded as the discoverers of the AIE method as a new procedure for the ionisation of TUC. The rate of development of this new method, whereby it is possible to ionise without decomposition unstable organic molecules, is extremely high. Thus Barber and co-workers alone published in one year following the appearance of their first communication[112] not less than 17 papers devoted to the study of the mass spectra of bio-organic compounds of different classes.[22,114-129] At the present time the AIE method is widely used by many teams of investigators.[98,130-139]

The rapid spread of the new method for the ionisation of TUC is determined not only by the large amount of information derivable from the AIE spectra but also by the fact that their measurement does not require a major modification of commercial mass spectrometers.[140,141] On the basis of ion

gun designs proved a long time ago, the Kratos Company began the manufacture of AIE sources for the AEI MS902 apparatus,[117] while the Varian Mat company developed a design for a source with ionisation by an atomic beam for the MAT 731 mass spectrometer.[142]

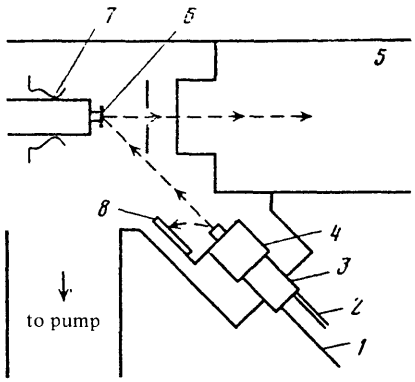

Figure 3. Schematic illustration of the ion source with the specimen bombarded by a beam of atoms[196] 1) high-voltage power supply; 2) injection of an inert gas; 3) region in which the primary ions are formed; 4) charge-transfer chamber; 5) mass analyser; 6) target with specimen; 7) vacuum lock; 8) deflecting electrode.

An apparatus has been described in which the secondary ions obtained as a result of ionic bombardment are separated by means of a static analyser with ordinary focussing;[143,144] a combination with quadrupole analysers is most frequently employed.[145] In order to obtain an accelerated atomic beam (usually a beam of Ar or Xe atoms), the ion beam initially generated is passed through a collision chamber. Fig.3 presents a systematic illustration of the AIE source. Ions undergo charge transfer on collision with the corresponding atoms in a collision chamber *4* filled with the gas from which the ions have been derived. The charge transfer cross-section is in this case large (10^{-16}–10^{-15} cm^2) [146] and approximately 50% of the ions undergo charge transfer without significant scattering of the beam in a chamber 100 mm long at a pressure of 10^{-4} mmHg.[104,146] An increase of pressure in the collision chamber by an order of magnitude decreases the degree of conversion of the ions into atoms to 10–30%.[143] The particles retaining the charge are removed from the beam by means of a special electrode *8*. The energy of the atom beam (of the order of magnitude of keV) differs somewhat from the nominal value of the applied potential difference accelerating the ions.[142] The beam of atoms bombarding the target *6* generates the maximum number of secondary ions at low angles of incidence relative to the target plane. Bombardment at an angle close to 90° leads to an increase of the fragmentation of the test molecules. The heavier the particles in the primary beam, the higher the yield of secondary, particularly quasi-molecular, ions.[94] For example, bombardment with mercury atoms increases the yield of the quasi-molecular sucrose, raffinose, and certain aminoacid ions by a factor of 10 relative to bombardment with Ar atoms.[147]

The principal distinctive feature of the preparation of secondary ions under AIE conditions involves the use of liquid targets made from volatile substances. A solution or a suspension of an organic compound in a liquid with a low vapour pressure is bombarded by accelerated atoms. This procedure has apparently led to the successful preparation of undecomposed quasi-molecular ions derived from extremely unstable and heavy biomolecules. Liquid targets were first used to obtain SE spectra by Tantsyrev, who showed that poly(propylene glycol) constitutes a convenient liquid target.[146] Glycerol is nowadays most often used as the involatile liquid, to which a small amount of an electrolyte, for example, oxalic acid, is added to ensure conductivity. The vapour pressure of glycerol at room temperature does not exceed 1×10^{-4} mmHg.[148] Apart from glycerol, epoxypropane,[139] organic and silicone oils,[95,128,149] α-monothioglycerol and its mixture with tetraethylene glycol,[95] polyglycol,[131] triglycerol, poly(ethylene glycol),[150] diethanolamine, tetraglyme, etc.[151] have been tested as solvents.

The application of liquid targets in AIE freed experimenters from many disadvantages characteristic of the SIIE method. Firstly, during bombardment by ions a positive charge is developed on the surface of the solid specimen, which must be compensated by a specially generated dark electron current. Otherwise, broad peaks, displaced towards higher mass numbers relative to integral mass peaks, appear among the recorded secondary ions peaks.[152] Charges do not accumulate on the surface of a liquid conducting target even in the presence of a small fraction of charged particles in the primary atom beam.[142] Secondly, bombardment with an atom beam makes it possible to employ lower potentials in the ion source in order to control the secondary ions; finally, under AIE conditions, the signal/noise ratio is higher by an order of magnitude than on irradiation with an ion beam.[80]

The role of the liquid phase in the mechanism of the transfer of the primary beam energy to organic molecules on the support has been investigated,[153–155] but is not as yet entirely clear. In a liquid the extent of the decomposition of the specimen molecules under the influence of high-energy primary particles apparently diminishes. On the other hand, the surface of the target is constantly renewed by undamaged portions of the specimen as a result of diffusion from internal layers. Furthermore, it has been shown[95] that certain test compounds shows an excess surface concentration, relative to the bulk-phase concentration, associated with the presence of hydrophobic groups. If these hypotheses are correct, liquid targets can be irradiated by a high-density primary beam without maintaining static bombardment conditions (for atom beams not exceeding 10^{10} atoms s^{-1} cm^{-2}), only making sure that the target does not become heated. An increase of the primary beam density entails an increase of the yield of secondary ions, i.e. ultimately leads to a diminution of the limiting concentrations of the products detected by the AIE method.

Serious experimental tests of the above postulates have not so far been published, but the advantage of liquid targets has been rapidly demonstrated and they have come to be used not only in AIE but also in the latest investigations by the SIIE method. This new procedure make it possible to obtain under SIIE conditions quasi-molecular ions derived from heavier and more unstable compounds.[77,80,156–158] It has been suggested that there are no radical differences between SIIE and AIE [89,115,139] and that the achievements by the AIE

method in the analysis of TUC are due mainly to the use of liquid targets. This has been confirmed by our study,[77] in which the use of a liquid target (diethanolamine) made it possible to obtain the quasi-molecular ions derived from an eight-membered cyclic oligosaccharide, namely γ-cyclodextrin (MW = 1679) on bombardment with Xe^+ ions. In the absence of a liquid matrix, it was possible to record only the ions of the tetrasaccharide stachyose (MW = 666).[71] Although quasi-molecular ions of heavier and more complex compounds have been obtained by the AIE method, the use of liquid targets in the SIIE method reduces the difference between the two procedures. In the future a liquid matrix will probably become an essential element of the study regardless of whether the specimen is ionised by a beam of atoms or ions. For the successful ionisation of different bio-organic substances, it is necessary in each case to select an appropriate liquid target matrix.[77,154] The elucidation of the role of the liquid phase in the ion formation mechanism has become an urgent taks in theoretical and experimental studies.

The mass spectra of organic compounds investigated under conditions involving irradiation with an atom beam do not show significant differences from the mass spectra recorded on bombardment with an ion beam.[94,147,157] A distinctive feature of the spectra obtained on a liquid target is the presence of the matrix ions. The molecules of the liquid appear in the spectrum in the form of cluster ions and fragments. For example, for glycerol (G) these are the positive ions $(G_n + H)^+$, $(G_n + Na)^+$, and to a lesser extent $(G_{n-1} + G - H + Na)Na^+$, where n reaches 15.[111] Clusters in which the molecules of the solvent and the test substance are combined sometimes appear. The spectra of negative ions contain significantly fewer clusters.[95] The presence of cluster ions has been used for the exact determination of the molecular weight of the test compound.[156] A method has been proposed for calibrating the mass scale under AIE conditions on the basis of the reference peaks of clusters comprising calcium toluenesulphonate and glycerol.[159]

Summarising the possibilities of the AIE method, we may note that the method increases the accuracy of the determination of the molecular weights of heavy molecules, since the $(M + H)^+$ and/or $(M + Ct)^+$ ions are always present in the spectra. The identification of the quasi-molecular ions among the peaks in the region of heavy masses is facilitated by comparing the mass spectra of positive and negative ions. The latter do not contain complex cluster ions and the heaviest peaks are due to the $(M - H)^-$ ions. The spectra of fragment ions make it possible to obtain information about the structure of the test compounds. The stability of the AIE spectra in time makes it possible to record the peaks of metastable ions, which are used to determine the mode of fragmentation of the test molecule.

The AIE method does not require the chemical modification of the test compounds, increases the reliability of the results, and diminishes by a factor of hundreds the amount of the test substance required for the analysis (for example, 1 μg instead of 1 mg is sufficient for the analysis of antibiotics[120]). These properties of the method altered radically the mass spectrometric procedure established previously for the determination of the aminoacid composition of peptides, in which chemical modification of the compounds was an essential stage.[3] The interpretation of the AIE mass spectrum yields nowadays information about the aminoacid sequence and about the composition of the terminal N- and C-acids.[114,115,118,119,121,130,132,161–163] The determination of the molecular weight of the peptide requires 0.1 nmol of the specimen and the determination of the aminoacid sequence requires 2–50 nmol.[24] However, one should note that sometimes not every aminoacid is represented in the spectrum by an individual peak.[132]

The high sensitivity of the AIE method is manifested in the analysis of bioproducts of different classes; data have been obtained for the molecular weights and structures of saccharides,[22,98,123,163–165] nucleotides and nucleosides,[24,117,137,166,168] lipids,[151,167,169] aminoglycoside and peptide antibiotics,[116,120,170,171] steroids,[23,134] sulphonated azo-dyes,[124–126] and a number of other compounds.[24,117,133,135,151,172] The identity of the AIE spectra of the synthesised and natural products has come to be regarded as confirmation of the structures of the natural products.[138]

Identical detection limits have been found in the mass spectra of positive and negative ions.[24] In order to increase the intensity of the quasi-molecular ions, the same procedures for the conversion of the test molecules to an ionic state are used in the AIE method as in the SIIE method.[88,95,117,124,132,173]

The quantitative aspects of the AIE method have not as yet been developed. However, the attempts to estimate the contents of the components in a mixture from the peak intensities of the quasi-molecular ions have already been made. Thus the determination of an admixture of a monomethyl-substituted quaternary amine in a mixture of dimethyl-substituted quaternary amines $(CH_2)_2N^+R^1R^2Cl^-$, entering into the composition of beef fat, has been reported.[23] The admixture concentration obtained (10%) agrees well with the result of chromatographic analysis (7.7%). At the same time it has not been possible by the AIE method to determine quantitatively nitrogen-containing cyclic compounds present in fuel shale,[131] although the qualitative identification of the individual components has been achieved successfully. The attempt to determine the content of bleomycins A_2 and B_2, differing only in the composition of the *N*-terminal aminoacids, also failed. The intensities of the formation of ions from these related compounds under AIE conditions differed appreciably.[116] A study has been made[174] of the causes of this phenomenon in order to obtain quantitative data for the dissociation constants of weak acids in solution.

The simplicity of the procedure used to prepare the specimens to carry out the analysis have led to an increasing use of the AIE technique for the measurement of the spectra. It is displacing the FD method, which has been for a long time the principal procedure for the analysis of TUC. Extensive factual data concerning the determination of the compositions and structures of biomolecules by the AIE spectroscopic method can be found in reviews.[89,98,145,151,175]

The principal difficulty, involving the preparation of ions from thermally unstable highly polar heavy molecules, has been overcome by the AIE method. Whereas several years ago the low volatility and stability of the test products constituted the main obstacle in mass-spectrometric analysis, at present the limiting factor has been the maximum capacity of mass analysers as regards the range of masses and their resolving capacity in the recording of heavy quasi-molecular ions generated under AIE conditions.[22]

3. Bombardment with High Energy Ions

A new method called desorption by high energy ions (DHEI),[176] which makes it possible to record the mass spectra of TUC by irradiating the latter with like multicharged ions speeded up in accelerators to energies ranging from several units to several tens of MeV, has been proposed recently. The general form of the mass spectra obtained is characteristic of secondary ion emission and differs little from the SIIE and AIE spectra. A distinctive feature of the

new method is the possibility of altering within wide limits the yield of the secondary ions as a function of the mass, charge, and energy of the primary beam ions (in contrast to the bombardment of the specimen by the ^{252}Cf fission fragments, whose composition is inhomogeneous and whose charge and energy vary independently of the experimental conditions).

The mass spectra of valine, obtained by bombarding a solid film of the specimen deposited on a nickel support by ^{16}O, ^{18}O, and ^{32}S ions in different charge states with energies ranging from 0.1 to 50 MeV, have been investigated.[176-180] The primary beam density was 10^3–10^4 ions s^{-1} cm^{-2} and the angle of incidence was 30° (relative to the plane of the target). The peaks of the ions $(M + H)^+$, $(M + 2Na - H)^+$, and the highly intense peak of the $(M - COOH)^+$ fragment were detected in the mass spectra. The curve for the efficiency of the generation of the $(M + H)^+$ and $(M - COOH)^+$ ions contains two maxima, corresponding to the energies of the bombarding ^{16}O and ^{32}S ions of 10 keV and 8 MeV, regardless of the energy of the particles from the primary beam.[178]

In order to explain the observed phenomenon, two mechanisms of the interaction of the primary beam with the substance of the target have been proposed. On impact by relatively slow primary particles (up to 0.1 MeV), their energy is scattered in elastic collisions of the atomic nuclei, while the energy of fast particles (tens of MeV) is consumed mainly in the electronic excitation of the molecules.[94] The irradiation of the surface valine film by ^{18}O ions with energies of 20 and 25 MeV in different charge states has shown that, with increase of the positive charge of the bombarding ions, the yield of the secondary ions also rises.[179] It has been shown[91] that the relative yield of the ions $(M + H)^+$ derived from Gly – Gly increased by a factor of 20 following the replacement of the primary beam of Cs^+ ions with an energy of 3 keV by Ge^{4+} ions with an energy of 54 MeV. The effect of raising the charge state is greater when compounds with a molecular weight in excess of 1000 are bombarded. The yield of secondary ions increases sharply with decrease of the angle of incidence of the primary beam relative to the plane of the target.[181]

The mass spectrum of a peptide with a molecular weight of 6000 has been obtained by the DHEI method;[91] following the bombardment of a thin film of ox insulin by ^{127}I ions with a 20-fold charge and an energy of 90 MeV, the mass spectra of positive and negative ions, containing peaks in the range of the molecular weights of the A- and B-chains of insulin, were recorded.[182]

The advances made have shown that, despite the complexity of the apparatus, the DHEI method can be used successfully to obtain the mass spectra of TUC, although so far only the first steps have been taken in this direction.

III. PLASMA DESORPTION BY ^{252}Cf FISSION FRAGMENTS

A new method for the analysis of involatile and relatively involatile TUC, called the method of plasma desorption by ^{252}Cf fission fragments (PlD ^{252}Cf), was developed in 1974.[183-187] The ions of the test substance are formed in the following manner: the test specimen is deposited on a thin foil behind which a ^{252}Cf source is placed. Quasi-molecular and other ions arise as a result of the penetration into the specimen of the ^{252}Cf fission products. The energy liberated under these conditions (~1000 eV $Å^{-1}$) causes the formation of a heat pulse in the specimen up to 20 000 K lasting 10^{-12} s. A cylindrical microvolume of the specimen-support with a radius of 25 Å is converted into a hot gas in which molecules of the specimen and of the support react. The ionic products of these reactions are "withdrawn" by an external electric field and are analysed in the mass spectrometer.

The spontaneous fission of the ^{252}Cf nucleus results in the formation of two fragments with unequal masses. There is a possibility of the formation of up to 40 pairs of different particles, but the formation of $^{142}Ba^{18+}$ and $^{106}Tc^{22+}$ with kinetic energies of 79 and 104 MeV respectively is most probable. The pair of fission fragments arises simultaneously (within 10^{-9} s), which leads to exceptional possibilities for the employment of the time-of-flight technieque for the recording of the mass spectra.[184,185]

The main difficulties in the employment of this method consist in the high radioactivity of the source, which usually amounts to 10–100 microcuries and in the high toxicity of ^{252}Cf. The preparation of the source is therefore a complex task.[184,187] The source is obtained by evaporating a drop of a ^{252}Cf solution deposited on a nickel or aluminium foil 1–5 μm thick; it is then covered by a polychloroacetate film, which prevents the migration of ^{252}Cf on the surface of the foil. In order to attenuate the intensity of the source, the latter can also be covered by additional layers, for example, gold.[186,187]

The specimen in the form of a thin homogeneous film ~100 mg cm^{-2} thick is usually obtained by electrosputtering.[188-190] When the film is obtained by other procedures—by depositing a drop from the solution, by cataphoresis, etc., poorly reproducible results are obtained.[188-191] The limit of sensitivity depend on the type of molecules investigated; for aminoacids, it is of the order of 10^{-9} g cm^{-2}. The recording of the spectrum for the very lowest yield of ions takes ~12 h.[185,189,191]

In virtually all cases different modifications of the time-of-flight mass spectrometer are used to obtain the mass spectrum.[191-194] Its advantages are a theoretically unlimited mass range and the convenience of combining the method for the recording of ions with a pulsed ionisation method. The modifications of the mass analyser were made largely to increase the sensivity and the resolving power. In the range of heavy masses the accuracy of the mass number determined does not as a rule exceed hundredths per cent.[193-195] The inadequate resolving power of the time-of-flight mass spectrometers is a significant obstacle in certain investigations, for example, in the determination of the aminoacid sequence in peptides.[196-198]

The mechanism of the formation of ions in the PlD ^{252}Cf method has not been fully investigated, but the majority of investigators describe it qualitatively in the following manner. At the sites of incidence of the ^{252}Cf fission fragments local plasma zones arise in a specimen where the desorbed molecules are ionised by one of two pathways: (1) via the formation of ion pairs: $2MH \rightarrow MH_2^+ + (M - H)^-$. This pathway, which is most typical for aminoacids, peptides, nucleotides, etc., involves the transfer of a proton from the acid end of one molecule to the basic end of another. (2) Via ion–molecule reactions with H^+, Na^+, K^+, or H^- ions. This results in the appearance in the spectrum of quasi-molecular ions containing an atom of the corresponding alkali metal, while the spectrum of negative ions contains protonated quasi-molecular ions.[199,200]

Aminoacids,[183,201] peptides,[184,195,201] nucleotides,[194,196-198,202,203] saccharides,[164,188,201] chlorophyll a,[204,205] antibiotics,[192,206] polytoxins,[207,208] vitamins,[188,191,193] and steroids[188,209] have been investigated by the PlD ^{252}Cf method. The results of such studies are satisfactorily reproducible from experiment to experiment and from one group of investigators to another.[204,205]

At the present time the PlD ^{252}Cf method makes it possible to obtain the heaviest ions. The ions $(2M + Na)^+$ with a mass of 12 637,[210] derived from fully protected oligonucleotides (dodecanucleotide with MW = 6278), have been recorded in the analysis of oligonucleotides.

The spectra of the test substances contain in all cases the peaks of fragment ions together with quasi-molecular peaks. The number of fragments arising in the PlD ^{252}Cf method is large even for relatively small molecules. Many fragmentation processes can be satisfactorily explained in terms of the concepts adopted in the chemistry of gas-phase ions. This enabled Field and co-workers[201] to assume, in contrast to Danigel and MacFarlane,[194] that the PlD ^{252}Cf method cannot be classified as a mild ionisation method. The method should rather be treated as one possessing dual properties: it makes it possible to obtain the intense peaks of quasi-molecular ions like the classical mild methods, and at the same time it yields an extensive fragment spectrum as in severe methods, for example, under electron impact. Such duality is not observed for other high-energy ionisation processes.

Investigators have noted that the plasma desorption method is promising and has considerable possibilities for the study of various classes of high-molecular-weight organic substances. The advantages of the method include, firstly, the possibility of the simultaneous study of the spectra of positive and negative ions, which permits a reliable determination of the molecular weight, structure, and the concomitant impurities in substances such as fully protected ribo-oligonucleotides up to heptamers inclusive.[174–176] Secondly, it became possible to establish the sequence of groups in complex organic compounds without a preliminary chemical modification in the intermediate phases of the synthesis (see, for example, Yoshihara[187]). Thirdly, with the aid of this method one can investigate unstable dissociation products of the ionised molecules and their fragmentation in the drift tube of the time-of-flight mass spectrometer.[173,184] Their presence broadens the packet of ions and impairs the resolving capacity of the spectrometer in the same way as the change in the real diameter of the ionisation spot on the target, which is related to the parameters of the ion source.[172] Finally, the method is distinguished by the simplicity of the introduction of the specimen and the lack of necessity for a special preparation of the sample, which makes it possible, in particular, to set up on the basis of this method an LC–MS (liquid chromatograph–mass spectrometer) system. In the description of the LC–MS apparatus it is stated that the fractions separated in the liquid chromatograph were deposited by electrosputtering through a capillary onto supports placed on sectors of a disc rotating at discrete time intervals (12 positions at a pressure of 10^{-3} mmHg); the sectors with the sample were inserted in succession through a vacuum lock into the chamber of the time-of-flight mass spectrometer and were exposed to the ^{252}Cf source. The LC–MS combination has been used for the quantitative analysis of biochemical compounds, in particular, of antitumour preparations: etoposide, teniposide, and alkaloids vindesine, vinblastine, and vincristine.[189]

IV. LASER DESORPTION

The first information about the generation of positive ions by means of laser radiation dates back to the beginning of the 1960's[212] and at the beginning of the 1970's laser desorption was used for the analysis of organic substances,[213,214] including thermally unstable compounds with formation of a molecular ion.[215] However, up to 1978,[216,217] laser desorption and ionisation had not yet been regarded as methods for the investigation of organic substances; mainly the use of laser in the mass spectrometry of solids was reported in literature up to 1978 and the effects of the interaction of laser pulses of different power with the test substance were investigated and classified.[218,219]

After the laser irradiation of involatile substances (salts, nucleotide–Na_2, sucrose, peptides), the cationated molecular ions and certain fragments, yielding valuable structural information, are abundant in the mass spectrum.[220] Hence it follows that at certain intensities laser radiation is capable of causing the desorption of the ionised molecules and that laser desorption (a) constitutes a mild ionisation method and (b) is promising for the analysis of thermally unstable and involatile compounds by mass-spectrometric methods. Experiments designed to investigate the mechanism of the formation of the $(M + Ct)^+$ ions have also been carried out and studies have been made of the rapid heating processes and of the role of multiphoton processes which yield a fragment spectrum.[220–222] So far the laser desorption method has been used to investigate a large series of TUC and relatively involatile compounds: oligosaccharides,[216,223–228] nucleotides and nucleosides,[224,227,229,230] glucosides,[224,225,230] aminoacids and oligopeptides,[224,226–228,230,231] vitamins and antibiotics,[232] and other bioorganic compounds.[232,233] Mass-spectrometric data obtained with laser desorption have been surveyed in two reviews.[234,235]

Parameters of the lasers used in the study of organic specimens by the laser desorption method.

Notation: λ is the wavelength, τ the duration of the pulse, W the power density, and E the energy density.

*Under continuous irradiation conditions; in the remaining cases pulse lasers were used.

Several methods, similar as regards experimental technique, have been proposed for laser desorption. The specimen is normally deposited on a copper grid from solution in ethanol or water and is irradiated by a pulse of focussed laser radiation. The laser desorption products are analysed in time-of-flight,[213–215,217,228,229,238] quadrupole,[227,236] static,[220–222,224,226] or other types of mass spectrometer.[231] A wide variety of lasers, both pulse-type and continuous emission, are used for irradiation in the range from infrared to the ultraviolet region of the spectrum (see Table).[234]

Laser desorption usually involves the formation of cluster ions of the type $(M + Ct)^+$, and H, Li, Na, K, Cs, Cu, Ag, and Pt can function as the Ct^+. In certain cases the negative $(M - H)^-$ ions are formed.[224,231,234] The mechanism of the formation of cluster and quasi-molecular ions in laser desorption is insufficiently clear and requires further theoretical and experimental studies. Cluster formation has been regarded[94,199] as the manifestation of various mild ionisation mechanisms. Numerous investigations of relatively involatile organic compounds by laser desorption methods indicate the possible occurrence of the following processes: vaporisation of molecules from the surface of the support under conditions of very rapid rise in surface temperature;[237,238] surface thermoionisation;[239] decomposition of molecules and ion–molecule reactions;[37] multiphoton ionisation processes.[223,224]

The Table presents the conditions in the formation of various groups of ions with the aid of lasers having different parameters.[224] Evidently the wavelength of the laser radiation does not have a significant influence on the character of ionisation. Quasi-molecular ions are formed when the power of the radiation is varied in the range from 10 to 10^8 W cm^{-2}, which casts doubt on the claim that multiphoton processes are essential for the formation of ions.[223,224] In the cases presented in the Table, the duration of the radiation pulses varied from 10^{-8} to 1 s, but in all cases ions were formed. Evidently, when low power pulse lasers are used, quasi-molecular ions are formed after a comparativley prolonged irradiation.[216,223] On the other hand, in the studies with powerful lasers the resolving capacity deteriorated with time and quasi-molecular ions could not be detected.[240] Analysis of the tabulated data also shows that the relation between the peak intensities of the quasi-molecular ions and the irradiation energies is determined by the material of the support.[222] If the material of the support is characterised by ready desorption (for example, in the case of quartz), then quasi-molecular ions are formed even for a low irradiation energy density; in the case of metallic supports, it is necessary to employ higher energy densities.

One may conclude that a definite minimum temperature, characteristic of the given specimen–support system and ensuring an energy balance of the system, is essential for the formation of quasi-molecular ions. The properties of the lasers (energy density, duration of pulses, the wavelength of the radiation) and those of the specimen–support system (energy absorption coefficient, thermal conductivity, heat of evaporation of the test substance, etc.) are taken into account in the balance. Lasers with a lower power density have been used in the study of the formation of quasi-molecular ions as a function of temperature.[94,200,220,245,246] The studies shows that it is possible to distinguish two temperature regimes: the lowest temperatures, at which neutral molecules are desorbed and higher temperatures at which surface ionisation and desorption of complexes with alkali metals are the most characteristic processes.[222] In all cases ion-molecule reactions in the gas phase, to which relatively involatile organic molecules are transferred without decomposition by the radiation, play a considerable role in all cases in the establishment of the final mass spectrum.

V. THE MECHANISMS OF ION FORMATION

It has been frequency noted that the mass spectra of organic and bio-organic molecules, obtained from the solid phase by different ionisation methods, are very similar. The similarity of the mass spectrum has been noted by many investigators.[51,54,66,67,94,139] Thus alanine and arginine, quaternary nitrogen-containing salts, sucrose, vitamin B_{12}, and adenosine 5-monophosphate give rise to identical mass-spectra under conditions where the specimens are bombarded by both potassium and caesium ions with energies ranging from 3.5 to 10 keV and ^{252}Cf fission fragments.[55] Under laser desorption conditions, ions can be formed with participation of thermal processes; nevertheless similar mass spectra of $(C_4H_9)_4N^+I^-$,[239] nucleotide bases,[239,240] and sucrose[239] have been obtained on irradiation of the solid products both by a low-power laser beam and by ^{252}Cf fission fragments. The spectra of sucrose recorded by the SIIE and LD methods are almost identical.[242]

The similarity of the mass spectra is determined by the following characteristics:

1. The principal ions in the spectra are even-electron particles. They include the quasi-molecular ions $(M + H)^+$ and/or $(M + Ct)^+$ and the cluster ions $(M + H)^+$, $(M + Ct)^+$, and $(M - H + 2Ct)^+$; in addition, odd-electron fragments (with odd mass numbers) appear in the spectra of compounds having the composition $C_xH_yO_z$. Tantsyrev and Saraev[248] compared the spectra of benzene obtained by the ionisation of the vapour and of a solid film (frozen on a support) by exposure to an atomic beam. The spectra had different intensities of the peaks, those due to odd mass ions proved to be significantly higher under conditions involving ionisation from the solid state.

2. The ions of organic substances leaving the surface are energetically stable. The internal energy of the secondary particles is low. The ionisation is accompanied by ion-molecule interactions. As a result, cluster ions and their fragmentation products appear in the spectra obtained by many of the methods discussed above.

3. Multistage decompositions are not characteristic of the spectra recorded. Only in the ionisation the atom-ion emission method (using a "light matrix") is it sometimes possible to record peaks of metastable ions.[249] Under the conditions of ionisation from the solid state, the recorded ions are formed during a very short time interval (several nanoseconds), which makes it convenient to combine these ionisation methods with time-of-flight analysers.

The similarity of the mass spectra discussed above permits the conclusion that the main processes involving the formation of the ions detected in the methods considered differ little from one another. Nevertheless, it was initially assumed that each ionisation method is based on an energy transfer principle characteristic only of that particular method. For example, it has been suggested that a beam of heavy multicharged ions with an energy amounting to tens of MeV transmits its momentum to the material of the support mainly as a result of electron retardation,[247] while the primary beam with an energy amounting to several keV is retarded as a result of interaction with nuclei.

We shall consider the question why the energy of the primary beam and the mass and charge state of the primary particles do not influence significantly the composition and ratios of the secondary ions in the spectrum of the given products. A common feature of all the methods involving secondary ion emission from the solid state is ultrafast transfer of momentum. When the specimen is bombarded by fast ions or atoms, the time interval during which energy is transferred amounts to 10^{-12} s, while on irradiation with a laser beam it is 10^{-8} s.[37,51] The short interaction time of the primary beam of particles or quanta with a layer of test molecules is the physical basis which justifies the combination in one group of all the ionisation methods considered. As a consequence of the ultrafast transfer of momentum, the organic molecules present on the surface at the site of impact receive, according to the majority of investigators, a small

amount of excitation energy. A rough estimate of its value under the conditions of ionisation by the $^{252}Cf^{+}$ fission fragments yield on average 1 eV.[199] This value has been confirmed by measurements in another study.[250] It becomes clear why quasi-molecular ions can be obtained in an undamaged form on exposure to a beam of ions with an energy exceeding by a factor of thousands or hundreds of thousands the bond energy in organic molecules. Theoretical calculations relating to the dynamics of the dislodgement of the ions of organic multiatomic molecules have shown that the probability of the expulsion of an undamaged molecular ion is fairly high.[251–255]

In order to account for the processes involving the formation of secondary ions on bombardment of a solid film of the test compound by a beam of fast atoms, Tantsyrev and co-workers were the first to put forward the idea of a "hot spot",[105,107,146,256,257] which reduces to the following statement: most of the energy of the primary beam is dissipated in a localised region—the "hot spot". As a result of a cascade of collisions, the set of molecules in the activated volume can be regarded as a highly heated dense gas. The size and depth of the "hot spot" depend on the character of the primary irradiation, but on the whole this mechanism explains the ion formation process in any of the methods examined, for example, that of Barber et al.[123] and Van der Peyl et al.[221] The transfer of momentum from the bombarding particles to the atoms or molecules of the target takes place isotropically, but in macromolecules with an ordered structure (polymers) the process has its characteristic features,[105,146] which will not be discussed here.

In the activated volume a fraction of the molecules are in a vibronically excited state and some are ionised. The positive and negative ions formed can leave the surface without undergoing any change. According to Benninghoven,[51] this is precisely the origin of the ions recorded in the SIE spectra. Cooks and co-workers[37,74,75,83] suggest that this mechanism is valid only for compounds with an ionic structure (for example, organic salts). When such compounds are irradiated, the "completed" ions are scattered" into a vacuum and no vibrational excitation of the ions takes place, since the process involving their formation resembles adiabatic expansion into a vacuum accompanied by cooling. Another portion of the ions formed within the hot spot are able to interact during their lifetime with the surrounding molecules on the surface. According to Tantsyrev, the cluster ions $(M_n + H)^+$ and $(M_n + Ct)^+$ arise in this way. This is not the only view in existence. Cooks and co-workers[39,73] suggest that the cluster ions appear as a result of ion–molecule interactions not on the surface but in the dense gas cloud above the spot. In one way or another, ion–molecule reactions make a significant contribution to the formation of secondary ions.

Finally a fraction of the secondary ions which have appeared are capable of undergoing unimolecular decompositions in the gas phase. The fragment ions produced make it possible to derive structure information from the SIE spectra. The three types of ions enumerated apparently determine the ionic composition of the mass spectra.

---o0o---

The development of new methods for the ionisation of thermally unstable compounds over a short period has extended the scope of mass-spectrometric studies of the composition and structure of bio-organic compounds. This required in the first place a further improvement of the analytical components of the apparatus and of the methods for the determination and treatment of mass-spectrometric data and also the solution of many theoretical problems. It became necessary to increase the range of the mass numbers with the simultaneous retention of a high resolving power and accuracy of the mass determinations. The establishment of the overall formula of the test compounds (for MW in excess of 3000), taking into account the distribution of the intensities of the isotopic peaks of the quasimolecular ions, was found to be difficult.[258] The determination of the ion formation mechanisms and also the elucidation of the role of the liquid matrix in the formation of undecomposed ions of TUC with high molcular weights is important for the correct interpretation of the results of investigations.

Studies of the characteristic features of the unimolecular decomposition reactions of heavy organic ions in activated collisions under the conditions of tandem mass spectrometry have been initiated.[259] The possibility of combining the new ionisation methods with ion-cyclotron resonance spectroscopy is being considered.[260] Further development of these trends will undoubtedly extend the applications of mass spectrometry in studies on bio-organic compounds.

Kinetics of the Oxidation of Mixtures of Organic Substances in the Liquid Phase

R.V.Kucher and I.A.Opeida

The available literature data on the kinetics of the co-oxidation of organic substances by oxygen in the liquid phase are surveyed. The methods for the determination of the rate constants for reactions involving chain propagation by peroxy-radicals in the oxidation of mixtures are analysed and the experimental kinetic parameters of the co-oxidation of binary mixtures of organic compounds of different classes are presented. The general rules governing the kinetics of oxidation reactions in mixtures are considered and the methods whereby the rates and selectivities of the oxidation reactions of individual mixture components can be regulated are demonstrated.
The bibliography includes 111 references.

V. The selectivity of the reactions of the components in co-oxidation

I. INTRODUCTION

One of the most highly developed fields in the study of oxidation reactions of organic substances is that of the theory of the homolytic oxidation of organic substances in the liquid phase. Detailed studies have now been made of the kinetics and mechanism of the oxidation of representatives of many classes of organic compounds,[1-5] but it should be noted that, because these processes yield reactive oxygen-containing products, which subsequently react, the oxidation of the individual substances takes place only in the very initial stage of the reaction. In subsequent stages the process proceeds as the coupled oxidation of the starting material and its primary oxidation products, which is normally the main cause of the low selectivity with respect to the required product at advanced stages of the reaction.

In order to regulate the oxidation process and to increase its rate and selectivity, it is necessary to known the fundamental features of the joint oxidation of various substances and in particular the parameters of the so-called "cross" reactions needed to establish the relations between the structures and the reactivities of molecules and radicals in elementary oxidation reactions.

Investigations of the oxidation of mixtures has now yielded many results important for the theory and practice of liquid-phase oxidation. These include primarily the discovery of systems where the intermediate radicals derived from one substance function as the reactants in the reaction with another substance in the course of the oxidation process, which leads to the formation of the desired product. An example of such a reaction is the joint oxidation of aldehydes and unsaturated hydrocarbons which has been studied in detail by Emanuel' and co-workers.[6-9] This reaction has been proposed[6] as an effective method for the preparation of olefin oxides.

Numerous studies have been devoted to the coupled oxidation of olefins and aldehydes (see Filippova and Blyumberg's review[10]). It has been shown that[11-13] critical phenomena are observed in the oxidation of mixtures of decane with ethylbenzene, which is due to the reactions of alkyl radicals with the hydrocarbons; the contribution of these reactions to the overall process kinetics is very considerable and controls the characteristic features of the process under the given conditions. The coupled oxidation of benzene and alcohols by molecular oxygen in aqueous solutions at 430–470 K has been investigated.[14,15] Benzene is resistant to oxidation under these conditions, while under co-oxidation conditions phenol is formed and the hydroxylating reagent is in this instance the peroxy-radical $HOO^{\cdot}$. Coupled reactions leading to the decarboxylation of organic acids both in their individual oxidation and in mixtures with other substances have been studied in detail;[4,16] the kinetic features of the process have been established. The influence of various factors on the kinetics of the coupled oxidation of benzene and cyclohexane at 460–520 K has been studied.[17,18]

The kinetics of the joint oxidation in systems containing aromatic alkyl-substituted hydrocarbons and benzaldehyde have been investigated.[19,20] Studies have been made[21-24] of the kinetics of the joint oxidation of lower olefins and the considerable influence of the mixture composition and reaction conditions on the yield of the olefin oxide and the oxidation products has been demonstrated. Aspects of the practical applications of the oxidation reactions of mixtures of hydrocarbon have been examined.[25,26]

The studies on the joint oxidation of organic substances in the liquid phase can be divided by convention into two groups. The first includes studies of the reactions occurring under the conditions of a branched chain process, which continues until advanced stages, and the process kinetics are described in this instance by a cumbersome system of non-linear differential equations whose solution is possible only by numerical methods with a computer. Theoretical analysis of the kinetics of such processes involves many difficulties and can be achieved only in isolated simplified cases. The other group of studies has been devoted to the co-oxidation processes occurring under the conditions of an unbranched chain

reaction to low degrees of conversion of the starting materials. Here the reaction scheme is much simpler and there is a possibility of determining the kinetic parameters of all the elementary steps. The results of studies of the second group are mainly discussed in the present review.

II. KINETICS OF UNBRANCHED RADICAL-CHAIN OXIDATION REACTIONS OF MIXTURES

Rigorous analysis of the kinetics of the oxidation reactions of mixtures is greatly facilitated when the reaction is carried out under conditions such that there is no chain branching. The kinetics of the oxidation of binary mixtures under the conditions of an unbranched chain reaction were investigated and analysed for the first time by Walling and McElhill,[27] who used the familiar Mayo-Walling copolymerisation equation[28] to describe the dependence of the rate of oxidation on composition. Subsequently this equation in one or other modification was used in the study of many binary mixtures of organic substances.

The general approach to the solution of the kinetic problems arising in the description of unbranched chain processes in multicomponent systems involving free radicals of different structure has been developed by Tsepalov.[29] Using this approach, it is possible to describe the kinetics of the co-oxidation reactions occurring with quadratic, linear, or mixed chain termination and also under the conditions of low oxygen pressures where one cannot neglect the reactions of alkyl radicals. The only limitation to its application is the need for fairly long chains.

In relation to the simplest case, namely the oxidation reaction of a multicomponent mixture occurring with long chains and initiated at a rate W_i at an oxygen pressure ensuring the complete conversion of alkyl radicals into peroxyradicals and with quadratic chain termination, the reaction mechanism can be formulated as follows:

$$\begin{gathered} R_iH \rightarrow R_i^{\cdot}, \\ R_i^{\cdot} + O_2 \rightarrow R_iO_2^{\cdot}, \\ R_iO_2^{\cdot} + R_jH \rightarrow R_iOOH + R_j^{\cdot}, \\ R_iO_2^{\cdot} + R_jO_2^{\cdot} \rightarrow \text{inactive products.} \end{gathered} \qquad (1)$$

The subscripts i and j vary from 1 to n, where n is the number of components. Under stationary conditions and for long reaction chains, the following equations are valid:

$$W_i = \sum_{ij} k_{tij} [R_iO_2^{\cdot}] [R_jO_2^{\cdot}], \qquad (2)$$

$$\sum_j k_{pij} [R_iO_2^{\cdot}] [R_jH] = \sum_j k_{pij} [R_jO_2^{\cdot}] [R_iH]. \qquad (3)$$

The system of equations can be formulated thus:

$$\sum_j (k_{pij} [R_jH] - b_i\delta_{ij}) [R_jO_2^{\cdot}] = 0, \qquad (4)$$

where

$$b_i = \sum_j k_{pij} [R_jH],$$

and δ_{ij} is the Kronecker delta. Solutions of this system have the following form:

$$[R_jO_2^{\cdot}] = CA_{kj}, \qquad (5)$$

where A_{kj} is the algebraic supplement to the element a_{kj} in the determinant of Eqns.(4). The constant C is determined from Eqns.(2) and (5):

$$C = \left[W_i \Big/ \left(\sum_{ij} k_{tij} A_{ki} A_{kj} \right) \right]^{1/2}. \qquad (6)$$

It can be determined analogously also for processes with linear and mixed chain termination.

The rate of consumption of each component is described by the expression[29]

$$\frac{d[R_iH]}{dt} = C \sum_j k_{pji} A_{kj} [R_iH]$$

and the overall rate of reaction is determined as the sum of the rates of consumption of all the components:

$$W = C \sum_{ij} k_{pij} A_{ki} [R_jH].$$

An important special case of a multicomponent system is a two-component system, which has been investigated in very many theoretical as well as experimental studies. The complete scheme for the initiated oxidation of the binary mixture at oxygen pressure sufficiently high to be able to neglect all the reactions of alkyl radicals apart from their interaction with oxygen can be formulated as follows:[27,28]

$$\begin{gathered} R_1H,\ R_2H \xrightarrow{W_i} R_1^{\cdot},\ R_2^{\cdot}, \\ R_1^{\cdot} + O_2 \rightarrow R_1OO^{\cdot}, \\ R_2^{\cdot} + O_2 \rightarrow R_2OO^{\cdot}, \\ R_1OO^{\cdot} + R_1H \xrightarrow{k_{p11}} R_1OOH + R_1^{\cdot}, \\ R_1OO^{\cdot} + R_2H \xrightarrow{k_{p12}} R_1OOH + R_2^{\cdot}, \\ R_2OO^{\cdot} + R_1H \xrightarrow{k_{p21}} R_2OOH + R_1^{\cdot}, \\ R_2OO^{\cdot} + R_2H \xrightarrow{k_{p22}} R_2OOH + R_2^{\cdot}, \\ \left.\begin{aligned} R_1OO^{\cdot} + R_1OO^{\cdot} &\xrightarrow{k_{t11}} \\ R_1OO^{\cdot} + R_2OO^{\cdot} &\xrightarrow{k_{t12}} \\ R_2OO^{\cdot} + R_2OO^{\cdot} &\xrightarrow{k_{t22}} \end{aligned}\right\} \text{inactive products.} \end{gathered} \qquad (7)$$

The equation for the overall rate of oxidation assumes the following form in this instance:

$$W = W_i^{1/2} \frac{r_1 [R_1H]^2 + 2[R_1H][R_2H] + r_2 [R_2H]^2}{\left(\frac{r_1^2}{a_1^2} [R_1H]^2 + 2\Phi \frac{r_1 r_2}{a_1 a_2} [R_1H][R_2H] + \frac{r_2^2}{a_2^2} [R_2H]^2 \right)^{1/2}}, \qquad (8)$$

where $r_i = k_{pii}/k_{pij}$, $a_i = k_{pii}/k_{tii}^{1/2}$, and $\Phi = k_{t12}/(k_{t11}k_{t22})^{1/}$ Analysis of this equation[30] made it possible to obtain an expression for the estimation of the effect of adding one of the components on the overall rate of oxidation and also on the rate of oxidation of each component. The form of the curve describing the dependence of the overall rate of reaction on the ratio of the concentrations of the mxiture components for variable kinetic parameters[30] and also on the absolute rate constants for chain termination in the oxidation of each component[31] has been analysed. The form of the curves describing the dependence of the overall rate of oxidation of a binary mixture and its individual components on composition has been investigated.[32-34]

The expression for the dependence of the rate of co-oxidation on composition can be simplified as follows.[34] The concentrations of the components will be expressed in terms of the volume fractions, i.e. $[R_1H] = [R_1H]_0(1 - x)$ and $[R_2H] = [R_2H]_0$, where x is the volume fraction of the second component and $[R_1H]_0$ and $[R_2H]_0$ are the molar concentrations of the components.

The boundary values of the derivatives of W with respect to x constitute a criterion which is a comparatively simple fucntion of the co-oxidation parameters and makes it possible to differentiate quantitatively various types of co-oxidation curves. Thus, for $x \rightarrow 0$, the expression for such a derivative is

$$\left(\frac{dW}{dx}\right)_{x \rightarrow 0} = W_i^{1/2} (2a_1 [R_2H]_0/r_1 - a_1 [R_1H]_0 - \Phi r_2 a_1^2 [R_2H]_0/r_1 a_2).$$

We shall consider three special cases which are possible for each of the boundary values of the derivatives, i.e. for derivatives corresponding to $x = 1$ and $x = 0$.

1. The slope of the tangent of the boundary point is zero, so that we have the straight lines AA_1 and BB_1 in Fig.1, i.e. the derivative is zero.

2. The direction of the tangent coincides with the line connecting the rates of oxidation of the individual components—a linear relation obtains.

3. The direction of the tangent coincides with the line describing the variation of the rate of oxidation of an individual component in an inert solvent and we have the lines AA_3 and BB_3 in Fig.1.

Having formulated and simplified the equations corresponding to each case, we obtain a set of expressions describing the relation between the co-oxidation parameters for the given boundary value of the derivative; they are written against the corresponding lines in Fig.1. Having denoted by the numerals 1–8 the sectors separated by these lines, we can divide all the co-oxidation curves into 16 types depending on the sector in which the parts of the curve corresponding to depleted mixtures are located.

Fig.2 presents certain types of such curves. A system of inequalities limiting the possible values of the co-oxidation parameters can be associated with each type of curve. The "greater than" and "less than" symbols defining the inequalities in a given sector are shown in Fig.1. For example, the following inequalities correspond to curves *1–5*:

$$r_2 < 2a_2/\Phi a_1;\ r_1 > 2a_1/a_2\Phi$$

and the inequalities

$$r_2 < 2a_2/\Phi a_1;\quad r_2 < 2a_2/\Phi a_1 - a_2^2 r_1/\Phi a_1^2;$$
$$r_2 < 2[R_1H]_0/[R_2H]_0 - \Phi a_2 r_1 [R_1H]_0/a_1 [R_2H]_0;$$
$$r_2 > 2a_2/a_1 - \Phi a_2^2 r_1/a_1^2$$

correspond to curves *2–7*.

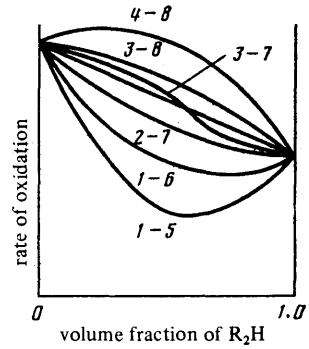

Figure 2. Types of co-oxidation curves.[34]

Using the given systems of inequalities and bearing in mind that only positive values of the parameters have a physical significance, it is possible to define rigorously the region in

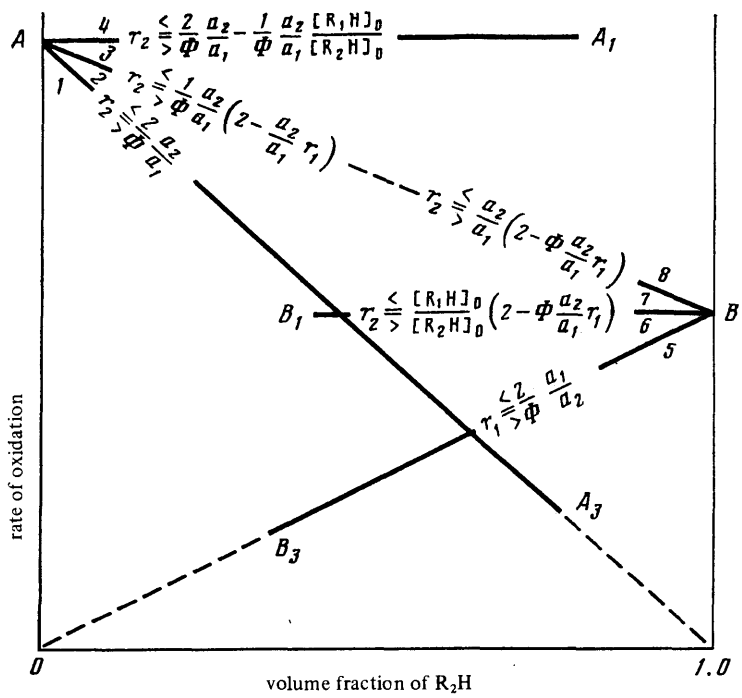

Figure 1. Equations relating the co-oxidation parameters for different boundary values of the derivative of the overall rate with respect to composition.[34]

which the co-oxidation parameters vary for each type of curve (Fig.3). As an example of the employment of the data in Fig.3, we shall analyse the problem of the type of co-oxidation parameters we should have for a system the dependence of the rate of oxidation of which on composition is described by a curve with a maximum, i.e. a curve of type *4–8*. The range of parameters *4–8* corresponds to this curve (Fig.3). Bearing in mind that all the relations presented in Fig.1 have been obtained for $a_1 > a_2$, one may conclude that an essential condition for a curve with a maximum is as follows: r_1 and r_2 should be small, not greater than 2. In practice this implies that the rate constants for the "cross" reactions k_{pij} should be comparable in magnitude or greater than the constants k_{pii}, i.e. the contribution of "cross" chain propagation reactions should predominate.

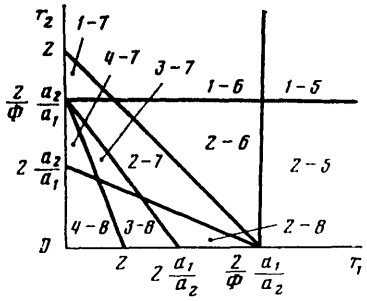

Figure 3. The ranges of the co-oxidation parameter for different types of curves.[34]

The inequalities obtained can be used also to solve the converse problem, which is of practical importance, namely the specification of the limits of the region in which the co-oxidation parameters are sought for a given type of co-oxidation curve by statistical analysis.

III. METHODS FOR THE DETERMINATION OF THE RATE CONSTANTS FOR ELEMENTARY REACTIONS IN CO-OXIDATION PROCESSES

The rate constants for the reactions of the radicals derived from one mixture component with the molecules of other components determine the specific features of the kinetics of the oxidation of the components of the mixture. In addition, they make it possible to compare the reactivities of many different molecules in reactions with the same radical and of a series of different radicals in reactions with the same molecule. At the present time there exist two methods for the determination of such constants. These are the Howard–Ingold method, based on the measurement of the rate of oxidation of one substance in the presence of the hydroperoxide of the other, and the joint oxidation method; we shall consider each of them.

1. The Howard–Ingold Method

A method has been proposed[35] for the determination of the rate constants for "cross" reactions based on the study of the kinetics of the oxidation of the hydrocarbon R_1H in the presence of the hydroperoxide R_2OOH. At high hdyroperoxide concentrations, the peroxy-radicals $R_1OO^\bullet$ and $R_2OO^\bullet$ are fully "exchanged" and the mechanism assumes the following form:

$$R_1H \rightarrow R_1^\bullet,$$
$$R_1^\bullet + O_2 \rightarrow R_1O_2^\bullet,$$
$$R_2OO^\bullet + R_1H \rightarrow R_2OOH + R_1^\bullet,$$
$$R_1OO^\bullet + R_2OOH \rightarrow R_1OOH + R_2OO^\bullet,$$
$$2R_2OO^\bullet \rightarrow \text{inactive products.}$$

The rate of reaction in this instance, subject to the condition that long chains obtain, is given by

$$W = \frac{k_{p21}}{k_{t22}^{1/2}} [R_1H] W_i^{1/2},$$

where k_{p21} and k_{t22} are the rate constants for the reactions of the peroxy-radicals formed from the hydroperoxide with the moelcules of R_1H and for quadratic chain termination respectively.

The applicability of this method has been demonstrated in relation to the oxidation of many organic substances—both hydrocarbons and their various derivatives substituted by functional groups.[36–42] However, on the basis of the results of their own study of the oxidation of tetralin in the presence of t-butyl hydroperoxide, Niki and Kamiya[43] cast doubt on the accuracy of the Howard–Ingold method. In reply to this criticism, Howard and Chenier[44] reinvestigated the same system and showed the need to ensure the complete "exchange" of the peroxy-radicals of the substance oxidised for the peroxy-radicals derived from the hydroperoxide and to make corrections for the evolution and absorption of gases in chain initiation and termination reactions.

However, the above factors are not the only ones which can significantly influence the validity of the values of the constants determined. When an attempt was made to apply this method to the determination of the rate constants for the reactions of cumenyl- and t-butyl-peroxy-radicals with polystyrene and adamantane at 348 K in solutions in chlorobenzene, results were obtained indicating a significant contribution of the chain decomposition reactions of the hydroperoxide to the given process.[45] Such decomposition, accompanied by the evolution of oxygen, leads to an unduly low measured rate of oxidation and hence introduces an error into the measured rate constant.

Thus, together with the undoubted advantages of the Howard–Ingold method, such as simplicity of the experiment and of the interpretation of the results, reliability of the results, particularly at low temperatures, and also the possibility of using it for substances with molecules having several reaction centres (the measured rate constant is then equal to the sum of the partial rate constants for the reactions of the hydroperoxy-radical with each of its centres), this method suffers from many disadvantages. The most significant of these are the rigorous requirements for the purification of the hydroperoxide and the difficulties arising from this in the determination of reproducible data, the possible complication of the process by the chain decomposition of hydroperoxides even at comparatively low temperatures (350 K), and the lack of availability of many hydroperoxides as a result of their lability.

2. The Co-oxidation Method

The method involving the joint oxidation of two substances for the determination of the co-oxidation parameters from which the rate constants for the "cross" reactions can be determined was developed much sooner than the Howard–Ingold method but the number of rate constants determined

with its aid is smaller because in many instances the accuracy of the value thus obtained is low. There exist several ways of determining the co-oxidation parameters from the results of the study of the kinetics of the co-oxidation of mixtures of two substances: (a) those based on the measurement of the consumption of the starting materials or the accumulation of each hydroperoxide; (b) those based on the measurement of the dependence of the overall rate of oxidation on the mixture composition.

The first group includes methods in which equations relating the ratio of the consumptions of the reactants (or the accumulations of the hydroperoxides) to the ratio of their concentrations in the mixture are employed:[46,47]

$$\frac{-\Delta[R_1H]}{-\Delta[R_2H]} = \frac{\Delta[R_1OOH]}{\Delta[R_2OOH]} = \frac{r_1[R_1H]/[R_2H]+1}{r_2[R_2H]/[R_1H]+1}, \qquad (9)$$

These methods have been used in a number of studies.[27,48-50] Their analysis, carried out by Niki et al.,[49] shows that small errors in the determination of concentrations lead to large errors in the determination of r_1 and r_2. Thus a 5% error in the measurement of [RH] leads to 10–30% errors in the calculated co-oxidation parameters.

The methods based on the use of Eqn.(9) are widely used for the determination of copolymerisation parameters. After the publication of the studies of Mayo and Lewis[46] and Fineman and Ross,[47] these methods were frequently modified in order to avoid their principal disadvantage, which is a marked dependence of the constants obtained on random experimental errors and also on the choice of coordinates in the linearisation of the plot of the dependence of the composition of the copolymer on the composition of the initial mixture.[51]

A significant fundamental limitation, which precludes in some cases the application of this group of methods to the determination of the co-oxidation parameters, should be noted: in order to measure the rate of consumption of a component or the rate of accumulation of the hydroperoxide with the required accuracy, one must carry out the reaction up to a significant degree of conversion: this leads to the accumulation of hydroperoxides in the system in amounts such that the contribution of their reactions

$$R_1OO^{\cdot} + R_2OOH \rightarrow R_1OOH + R_2OO^{\cdot},$$
$$R_2OO^{\cdot} + R_1OOH \rightarrow R_2OOH + R_1OO^{\cdot}$$

to the process becomes considerable. Analysis of the influence of the concentrations of the hydroperoxides formed on the accuracy of the parameters determined shows that even at concentrations of approximately 10^{-3} M the deviations can be significant.[34]

In the determination of the co-oxidation parameters from the dependence of the overall rate of oxidation on mixture composition, Eqn.(8) is employed. In the first study of this type[49,52-54] the following procedure was used: the system of non-linear equations containing three unknowns (r_1, r_2, Φ) is reduced to a system with two unknowns by eliminating one parameter on the basis of one of the equations; the resulting equations are solved in pairs by numerical or graphical methods. A disadvantage of this method is an unduly high statistical weight of one of the experiments and the consequent difficulty of a rigorous estimation of the accuracy of the parameters obtained.

Following the development of computers, it became possible to employ the methods of statistical analysis for the solution of this problem.[55,56] The accuracy of the estimates of the parameters is determined in this instance by the accuracy of the measurement of the rate of oxidation (it is usually fairly high) and also by the form of the co-oxidation curve. In particular, it has been shown[34] that, for a linear dependence of the rate of oxidation on mixture composition (and the volume fraction of the component), such a relation cannot be used to calculate the co-oxidation parameters. The latter are in this case related by equations of the type

$$r_2a_1/a_2 + \Phi r_1a_2/a_1 = 2,$$
$$r_1a_2/a_1 + \Phi r_2a_1/a_2 = 2,$$

which precludes the calculation of the unknowns r_1, r_2, and Φ, because there are only two equations. A partial solution is provided by the equation

$$\Phi = 1;\ 1/r_2 = r_1 = a_1/a_2.$$

A significant increase in the accuracy of the determination of the co-oxidation parameters can be achieved by a specific experimental design[56,57] which consists in the evaluation from preliminary estimates of the co-oxidation parameters of the ratio of the component concentrations for which the determinant of the information matrix has the maximum value; using the calculated ratio of the component concentrations, the next experiment is then performed and its results are employed in the recalculation of the co-oxidation parameters.

Table 1. Estimates of r_1, r_2, and Φ for the cumene–*o*-xylene system.[57]

No. of points	r_1	r_2	Φ
Uniform distribution of co-ordinates with respect to the composition axis			
6	1.76±0.52	0.638±0.030	1.34±0.48
12	1.27±0.22	0.658±0.017	0.99±0.26
Experimental design			
12	1.12±0.13	0.648±0.013	0.75±0.11

As an example, we present data obtained in the study of the co-oxidation of cumene and *o*-xylene[57] (Table 1). The data presented in Table 1 show that experimental design results in a considerable increase in the accuracy of the determination of all the co-oxidation parameters, particularly r_1 and Φ. The quantity r_2 for the given system (and for other systems of this type) is already determined with a satisfactory accuracy as a result of the first (non-optimal) measurements at six points distributed uniformly along the composition axis.

The literature data for the determination of the co-oxidation parameters from the dependence of the overall rate on composition show that this method, particularly when combined with statistical analysis and experimental design, ensures a satisfactory accuracy of the determination of the co-oxidation parameters. The existing experimental methods are fairly simple and permit the measurement of the quantities required for the calculation with a high accuracy. Another advantage of this method is that it makes it possible to obtain the parameters of the reactions also in cases where oxidation results in hydroperoxides which are unstable or difficult to isolate in a pure form.

Among the disadvantages of this method, one should include in the first place the dependence of the accuracy of the determination of the parameters on the form of the co-oxidation curve, which is why it cannot be applied to a whole series of systems. A significant limitation of the method can be in

many instances also the following factor. Studies of the oxidation of mixtures of substances whose molecules contain several C–H bonds with different energies have shown that the reaction kinetics are described satisfactorily by Eqn.(8). However, the kinetic parameters determined in this case are effective quantities and the expression for these include many constants for elementary reactions.[57–59]

We may also note that the effective rate constants for the chain termination reaction can be determined by the methods of non-stationary kinetics (the chemiluminescence[60] and interrupted illumination[61] methods) and in the case of a binary mixture they are described by the expression[62]

$$k_{t,\,\mathrm{eff}} = \frac{k_{t11}k_{p21}[\mathrm{R_1H}]^2 + 2k_{t12}k_{p21}k_{p12}[\mathrm{R_1H}][\mathrm{R_2H}] + k_{t22}k_{p12}^2[\mathrm{R_2H}]^2}{(k_{p21}[\mathrm{R_1H}] + k_{p12}[\mathrm{R_2H}])^2}.$$

For a multicomponent mixture, we have[63]

$$k_{t,\,\mathrm{eff}} = \frac{\sum_{ij} k_{tij}A_{ki}A_{kj}}{\left(\sum_i A_{ki}\right)^2}.$$

by the simplest kinetic scheme corresponding to the mechanism with quadratic chain termination by peroxy-radicals and the oxidation takes place with fairly long chains.[1] The mechanism of the low-temperature oxidation reaction of mixtures of aromatic alkyl-substituted hydrocarbons is described by a simple kinetic scheme and it is therefore possible to calculate the kinetic co-oxidation parameters. At a quantitative level, i.e. with determination of the co-oxidation parameters, studies have now been made on more than 60 systems (Tables 2 and 3).

IV. OXIDATION OF BINARY MIXTURES OF ORGANIC SUBSTANCES

The liquid-phase oxidation of aromatic alkyl-substituted hydrocarbons has been studied in greatest detail, which can be explained primarily by the fact that the kinetics of the oxidation reactions of such individual compounds are described

One of the most thoroughly investigated systems is the cumene–ethylbenzene system. The co-oxidation parameters for this system, measured in various investigations, agree well with one another (Table 2). The quantity Φ for the vast majority of systems is close to unity and its derivations from unity for some systems (see, for example, systems 10 and 12 in Table 2 and system 23 in Table 3) are probably

associated with the fact that in such cases Φ is an effective quantity, because the molecules of the substance undergoing co-oxidation in the presence of cumene always have several reaction centres. For systems 13 and 26 (Table 2) and 16, 18, 23, 24, 29, 30, and 34 (Table 3), the deviation of Φ from umity can be associated with the low accuracy of the determination of the co-oxidation parameters from the dependence of the overall rate of oxidation on composition, which is close to linearity for such systems.

The results of the study of the oxidation reactions of binary mixtures of aromatic alkyl-substituted hydrocarbons together with alkanes are presented in Table 4. Considerable deviations of Φ from unity are oobserved in these systems.

Studies have been made of systems comprising oxygen-containing derivatives of hydrocarbons (Table 5). One should note that, in the oxidation of ethers, the intraradical isomerisation reactions of the peroxy-radicals are significant.[4] Allowance for these reactions in the kinetics co-oxidation scheme leads to a relation between the rate of oxidation and mixture composition more complex than Eqn.(8). The co-oxidation parameters obtained using Eqn.(8) for systems containing ethers should therefore be regarded as effective quantities, i.e. as quantities incorporating the rate constants for both the intramolecular transport reaction and other elementary stages.

Eqn.(8) describes satisfactorily the dependence of the rate of oxidation of mixtures on composition for systems incorporating an aromatic alkyl-substituted hydrocarbon and an alcohol, ether, or ketone (systems 1–9 and 17–26 in Table 5), but the problem of whether or not the co-oxidation parameters are also effective quantities in this instance remains open. The point is that the determination of these parameters requires the alteration of the ratio of the hydrocarbon and the oxygen-containing derivative within very wide limits, which leads to considerable changes in the properties of the medium. The change in the properties of the medium can influence significantly the rate constants for the individual elementary stages[2] and the rate constants entering into Eqn.(8) may therefore prove not to be invariant over the entire range of concentrations of the components.

Apart from the systems presented in Table 5, studies have also been made of the kinetics of the co-oxidation of more than 50 binary mixtures of oxygen-containing compounds with polyhydric alcohols or esters in the range of compositions where the concentration of one component (R_1H) is much higher than that of the other (R_2H).[79] In this case the kinetic reaction scheme is simplified as a consequence of the low contribution of the $R_2OO^{\bullet} + R_2H$ and $R_2OO^{\bullet} + R_2OO^{\bullet}$ reactions, which makes it possible to determine experimentally the quantity α defined by the formula[79]

$$\alpha = 2\frac{k_{p12}}{k_{p11}} - \frac{1}{2}\frac{k_{t12}}{k_{t11}} \cdot \frac{k_{p12}}{k_{p21}}.$$

In many systems the second term is much smaller than the first, which enabled Degtyareva et al.[79] to estimate the quantities k_{p12}/k_{p11}, i.e. $1/r_1$. Thus $1/r_1$ for various alcohols in the n-hexadecane (R_1H)–alcohol (R_2H) systems has the following values respectively at 403 K: 2.8 for 1-decanol; 4.5 for 2-octanol; 2.2 for butane-1,3-diol; 12 for 1,1,1-tri-(hydroxymethyl)propane.

In the joint oxidation of aromatic alkyl-substituted hydrocarbons in alcohols, a sharp decrease of the rate of oxidation is observed following the addition of small amounts of an alcohol to the hdyrocarbon.[73,80] In relation to the cumene–benzyl alcohol system, it has been shown[81,82] that in this case the contribution of the reactions involving chain propagation by peroxy-radicals derived from the alcohol is negligible, which makes it possible to describe the dependence of the overall rate of oxidation W on the alcohol concentration $[R_2H]$ by the familiar[4] equation for inhibited oxidation:

$$\frac{W_0}{W} - \frac{W}{W_0} = 2\frac{k_{p12}}{(k_{t11}W_i)^{1/2}}[R_2H], \qquad (10)$$

where W_0 is the rate of oxidation of the hdyrocarbon without added alcohol. The same equation describes the kinetics of the co-oxidation of mixtures of hydrocarbons with amines.[83]

Binary systems containing aldehydes were the first systems in which co-oxidation has been investigated.[27] The parameters r_1 and r_2 for a number of systems have been determined from the kinetics of the accumulation of acids in the first hours of the co-oxidation reactions of substituted benzaldehydes (Table 6). Binary mixtures containing aldehydes and cyclohexadiene,[76] whose co-oxidation parameters have been determined using Eqn.(9), have also been investigated in detail.

A characteristic feature of the kinetics of the oxidation of mixtures incorporating aldehydes is a significant diminution of the rate of oxidation with time as a consequence of the formation in the course of the process of substances which probably possess inhibiting properties.[85,86] One of the general features of the kinetics of the oxidation of mixtures of aldehydes with organic substances of other classes is that the rate of reaction is strongly retarded not only by classical inhibitors but also virtually by all other substances with a mobile hydrogen atom or substances capable of undergoing addition reactions. Thus the oxidation of aldehydes is subjected to a powerful inhibiting effect by aromatic alkyl-substituted compounds,[76,84–86] olefins,[87–89] alcohols,[90,91] ketones,[92,93] and polycyclic hydrocarbons.[96] In some studies[86,95,96] it has been shown that the additive influences the rate of oxidation of the aldehyde via the usual mechanism of inhibited oxidation and canbe described by Eqn.(10). The kinetics of the oxidation of an aldehyde in the presence of a hydroperoxide can be described by the Howard–Ingold scheme

In the co-oxidation of two aldehydes one can observe an increase of the overall rate of oxidation of the mixture compared with the oxidation of the individual components,[77] which is associated with the increase of the rate of chain initiation in such mixtures. The maximum rate of chain initiation in the benzaldehyde–decanol mixture is attained for a 1 : 1 component ratio.

PS-diphenylmethane	0.62	1.25	1.21
PS-benzyl alcohol	0.72	20.3	2.64

Another important feature of the kinetics of the oxidation of binary mixtures containing an aldehyde is a considerable increase in the rate of oxidation of the second component, which is indicated by estimates of the rates from the co-oxidation parameters and by direct measurements.[76,79]

Data for the oxidation of mixtures of aldehydes with alkenes and also of alkenes with other substances have been examined in two studies[10,98] and are not presented in this review.

The joint oxidation of high-molecular-weight compounds in solutions and also their oxidation in mixtures with low-molecular-weight substances has so far been little studied. Only a few investigations[99,100] devoted to this problem are known. In the study of the co-oxidation reactions with participation of high-molecular-weight substances, difficulties due to the degradation of the polymers in the oxidation reaction and the influence of the co-oxidising component on the degradation arise compared with mixtures of low-molecular-weight substances (for which the principal object of study is the dependence of the rate of oxidation of the mixture and of the rates of oxidation of the individual components on composition).

It has been shown for the co-oxidation of cumene with polyethylene that the rate of degradation of the polymer diminishes linearly with increase of the concentration of cumene, although the rate of oxidation of the latter does not change in the presence of polyethylene.[99] The rate constant for the reaction of the cumenylperoxy-radical with polyethylene was determined in the same study. The rate of oxidation of cumene decreases appreciably with increase in the polystyrene content (PS) of the latter.[100] The dependence of the rate of oxidation of cumene on that of PS is described by a straight line in terms of the variables of the Eqn.(10), which enabled Guk et al.[100] to calculate the rate constant for the reaction of the cumenylperoxy-radical with PS.

For several systems, one of the components of which is polystyrene, the co-oxidation parameters have been determined (Table 7) from the overall dependence of the rate of oxidation on the composition of the binary mixture.[101] The calculation of the rate of oxidation of polystyrene in mixtures, carried out using the co-oxidation parameters obtained, showed that the addition of PS retards the oxidation of cumene and diphenylmethane but hardly influences the rate of oxidation of benzyl alcohol. Cumene and dimethylmethane in their turn accelerate the oxidation of PS, while benzyl alcohol inhibits this process. The addition of low-molecular-weight substances to a solution of polystyrene lowers the rate of its oxidative degradation.[102]

Different organic compounds have different effects on the degradation of PS in its oxidation in solution.[103] In terms of the magnitude of the inhibiting effect, they can be arranged in the sequence cumene < toluene < esters < cumenyl hydroperoxide < benzyl alcohol.

Shilov and Denisov[104] compared the relations between the rate of oxidation and composition in systems consisting of polyethylene, polypropylene, and their low-molecular-analogues—n-decane and 2,2,4-trimethylpentane respectively. In the co-oxidation of low-molecular-weight hydrocarbons a curve with a hump (of type 3–7 in Fig.2) is observed. For the polyethylene–polypropylene system, the rate of oxidation varies linearly with the composition of polymers, which has been explained[104,105] by the absence of cross-reactions in the given systems, i.e. the chain oxidation develops within each individual molecular coil.

Thus hitherto detailed studies have been made on the joint oxidation reactions of mixtures of aromatic alkyl-substituted compounds, alkanes, alkenes, alcohols, ketones, aldehydes, polyolefins, ethers, and esters. The reactions involving individual representatives of other classes have also been investigated. Thus, among chloro-derivatives, a study has been made of the joint oxidation reaction of benzyl chloride and cumene;[106] the overall rate of oxidation is found to decrease both after the addition of cumene to benzyl chloride and after the addition of benzyl chloride to cumene, i.e. the co-oxidation curve is of type *1–5*.

The kinetics of the co-oxidation of cumene in the presence of a series of amines have been investigated.[83,107] A characteristic feature of the kinetics of these processes is that small amounts of added amine diminish partly the overall rate of oxidation.

All the curves quoted in the literature for the dependence of the rate of reaction on the mixture composition are combined in Table 8 in six groups each of which includes several types (Fig.1).

The data in Table 8 show that, among the 164 systems investigated, only one is described by a curve with a maximum. Unfortunately the authors[74] do not quote the curve, stating only the co-oxidation parameters, the accuracy of the determination of which is insufficient to regard the conclusion concerning the shape of the curve as rigorously unambiguous.

Only approximately 7% of all the systems investigated exhibit small positive deviations from linearity, i.e. in these systems the rate of oxidation of the mixture is somewhat greater than the sum of the rates of oxidation of its components taken at the same concentrations in an inert solvent. Among the systems whose rate of oxidation varies with composition in accordance with a linear law, the majority are those in which the molecules of the components have similar chemical structures.

Table 8. The numbers of systems investigated described by different types of co-oxidation curves.

Composition-rate relation	Type of curve	Number of systems
Linear		35
With a maximum	*4—8*	1
With positive deviations	*3—8*	10
With negative deviations	*1—7, 2—7*	81
With a minimum	*2—6, 2—5*	35
With inflections	*1—8, 2—8, 3—5, 3—7*	2

Table 8 shows that the most characteristic feature established in the study of the kinetics of the co-oxidation of binary systems is a decrease of the overall rate of oxidation of the mixture compared with additivity, i.e. negative deviations from linearity.

The systems of inequalities which limit the values of the co-oxidation parameters are presented above in Table 1. However, they are too complex for practical analysis. In order to analyse the problem of what should be the relations between the parameters for a particular type of curve, the concept of reaction selectivity is employed.[108] We shall define the selectivities in the interaction of the reacting species in co-oxidation processes in the following manner.

1. The selectivity of the reactions of a molecule with two peroxy-radicals:

$$R_iOO^{\cdot} + R_nH \xrightarrow{k_{pin}} R_iOOH + R_n^{\cdot},$$
$$R_jOO^{\cdot} + R_nH \xrightarrow{k_{pjn}} R_jOOH + R_n^{\cdot},$$
$$S_{M_n/R_iR_j} = k_{pin}/k_{pjn};\ k_{pin} > k_{pjn}.$$

2. The selectivity of the reaction of a radical with molecules:

$$R_nO_2^{\cdot} + R_iH \xrightarrow{k_{pni}} R_nO_2H + R_i^{\cdot},$$
$$R_nO_2^{\cdot} + R_jH \xrightarrow{k_{pnj}} R_nO_2H + R_j^{\cdot},$$
$$S_{R_n/M_iM_j} = yk_{pni}/xk_{pnj};\ yk_{pni} > xk_{pnj},$$

where x and y are the numbers of equivalent atoms in the R_iH and R_jH molecules respectively.

3. The selectivity of the reaction with radicals:

$$\left.\begin{aligned} R_nO_2^{\cdot} + R_iO_2^{\cdot} &\xrightarrow{k_{tni}} \\ R_nO_2^{\cdot} + R_jO_2^{\cdot} &\xrightarrow{k_{tnj}} \end{aligned}\right\} \text{molecular products};$$
$$S_{R_n/R_iR_j} = k_{tni}/k_{tnj};\ k_{tni} > k_{tnj}.$$

For two-component mixtures, the quantities i, j, and n assume values of 1 and 2.

Using this notation, the condition for linearity can be formulated as the following equality:[34]

$$\frac{S_{R_1/R_1R_2}}{S_{M_1/R_1R_2}} + \frac{S_{M_2/R_1R_2}}{S_{R_2/R_1R_2}} = 2.$$

This equation holds in particular when the selectivities for all the species are equal, i.e. are independent of the reactivity.

The following inequality corresponds to the most general case, namely negative deviations from additivity:

$$\frac{S_{R_1/R_1R_2}}{S_{M_1/R_1R_2}} + \frac{S_{M_2/R_1R_2}}{S_{R_2/R_1R_2}} > 2. \qquad (11)$$

For many systems, the availability of experimental co-oxidation parameters and rate constants for the individual elementary reactions permits the calculation of the selectivities in formula (11). The results of such calculations make it possible to conclude that in systems containing hydrocarbons, alcohols, ethers, esters, and chloro-derivatives, the decrease of the rate of co-oxidation is caused by the higher selectivity of the reactions of peroxy-radicals compared with the reactions of molecules. In systems with aldehydes the decrease in the rate of oxidation is caused by the higher selectivity of the reactions of molecules. Analysis shows that, when the selectivity of the reactions of species depends appreciably on the reactivity (it is then unimportant whether the selectivity increases or diminishes with increasing reactivity), inequality (11) holds. The general relations governing the dependence of the selectivity on the reactivity of the reacting radicals and molecules under the conditions of a wide variation of their structures have not so far been established. It has been shown only for reactions of certain peroxy-radicals with the molecules of aromatic alkyl-substituted compounds that the selectivity of the radical changes in parallel with reactivity.[34] This is indicated by two facts.

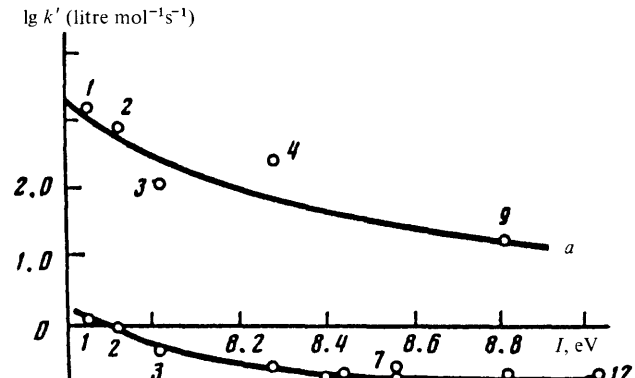

Figure 4. Dependence on the ionisation potentials of the molecules I of the partial rate constants k' for the reactions of the benzoylperoxy-radicals (a) and cumenylperoxy-radicals (b) with different substances: 1) hexamethylbenzene; 2) pentamethylbenzene; 3) durene; 4) pseudocumene; 5) mesitylene; 6) p-xylene; 7) o-xylene; 8) m-xylene; 9) toluene; 10)–12) picolines.[110]

Fig. 4 presents the variation of the partial (referred to a single reactive C–H bond) rate constants for the reactions of cumenyl peroxy- and benzoylperoxy-radicals with methyl-substituted benzene derivatives. It is seen that, with increased number of methyl groups in the ring, the partial rate constants also increase. The increase is more significant

for reactions of these molecules with the benzoylperoxy-radical, which is much more reactive than the cumenylperoxy-radical. This implies that the selectivity of the reaction of the more reactive radical, which is in this instance the benzoylperoxy-radical, is higher than the selectivity of the reaction involving the less reactive cumenylperoxy-radical.

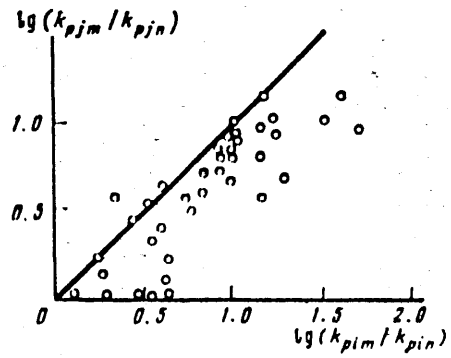

Figure 5. Relation between the selectivities of the reactions of peroxy-radicals; i is a more reactive radical than j; m is a more reactive molecule than n.[34]

The relation between the selectivities and reactivities of various peroxy-radicals can be traced also in terms of the co-oxidation parameters r_1 and r_2, which constitute the ratios of the rate constants for the reactions of two different peroxy-radicals for the same pair of molecules. We shall select from the binary systems investigated (Tables 2 and 3) those in which the oxidation of their components results in the formation of primary and tertiary, primary and secondary, or secondary and tertiary peroxy-radicals respectively. In order to determine which radical in the given pair is more reactive one can then employ the familiar reactivities in the series: primary > secondary > tertiary. The logarithm of the ratio of the rate constants for the reactions of the same pair of molecules with a less reactive radical is plotted in Fig. 5 against the logarithm of the ratio of the partial rate constants for the more reactive radical. Evidently most of the points lie below the line whose slope is unity, which demonstrates the greater selectivity of the reaction with the more reactive peroxy-radical.

V. THE SELECTIVITY OF THE REACTIONS OF THE COMPONENTS IN CO-OXIDATION

Using the approach developed by Emanuel'[109] for the estimation of the selectivities of liquid-oxidation reactions, we shall consider in greater detail the problem of the influence of the reactivity of the component on the rate and selectivity of the oxidation in mixtures.

In order to establish a relation between the co-oxidation parameters and the shape of the curve describing the dependence of the rate of oxidation of the individual components on the mixture composition, we shall make use of the limiting values of the derivative of the rate of oxidation of the component W with respect to its volume fraction in solution x for $x \to 0$ or $x \to 1$.

The systems of inequalities relating the kinetic co-oxidation parameters of various types of curves describing the rates of oxidation of the individual components are presented in Fig. 6. For example, the rate of oxidation of the second component in the region of mixtures enriched in the latter is higher than the rate of its oxidation in an inert solvent at the same concentration, provided that the following inequality holds: $r_1 < a_1/\Phi a_2$; in depleted mixtures the validity of the inequality $r_1 < a_1/a_2$ is sufficient for this purpose.

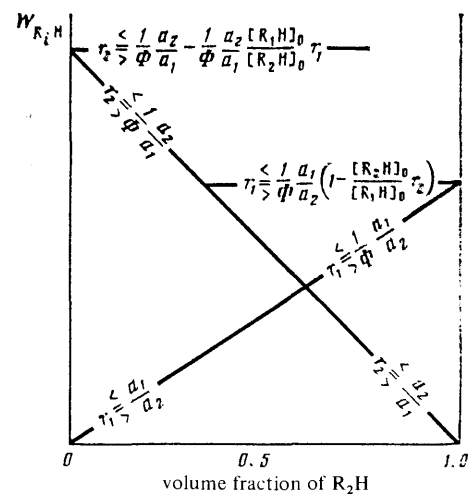

Figure 6. Equations relating the co-oxidation parameters for different derivatives of the rate of oxidation of the components with respect to composition.

The relations obtained[72] between the rate of oxidation of toluene and picoline (both these substances are relatively unreactive in liquid-phase oxidation reactions) and the composition of their mixture with cumene, whose reactivity is much higher, are presented in Fig. 7. These binary systems have been studied experimentally and their co-oxidation parameters have been obtained. Fig. 7 shows that a considerable increase of the rate of oxidation of the individual substances can be achieved in the co-oxidation reaction.

While the selectivity of the oxidation of an individual substance depends solely on the oxidation chain length and always diminishes when the substance is diluted by an inert solvent, the selectivity of the oxidation of the substance in the mixture is a complex function of the kinetic parameters and the concentrations of the components. In the simplest case of the oxidation of a mixture of two substances and subject to the condition $\Phi = 1$, the variation of the selectivity S_1 of the oxidation of the components R_1H and R_1OOH with composition is described by the expression[34]

$$\frac{1}{S_1} = 1 + \frac{(W_i k_{t11})^{1/2}}{k_{p11}[R_1H]_0 - (k_{p11}[R_1H]_0 - k_{p12}[R_2H]_0)\,x},$$

where $[R_1H]_0$ and $[R_2H]_0$ are the concentrations of the pure components and x is the volume fraction of the component R_2H. It follows from this equation that, in order to increase

the selectivity of the oxidation of a substance, it is necessary to add to it a second substance more reactive with respect to the peroxy-radicals $R_1OO^{\bullet}$.

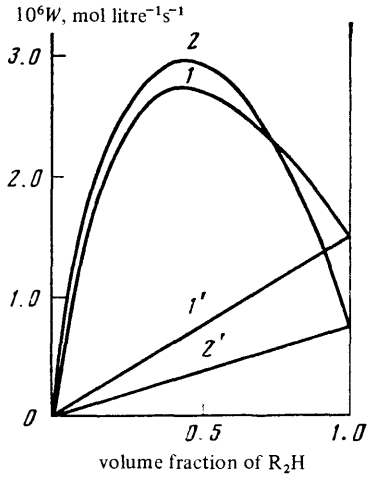

Figure 7. Dependence of the rates of oxidation of toluene (curves *1* and *1'*) and picoline (curves *2* and *2'*) on the composition of their mixtures with an inert solvent (curves *1* and *2*) and cumene (curves *1'* and *2'*) at 348 K.[72]

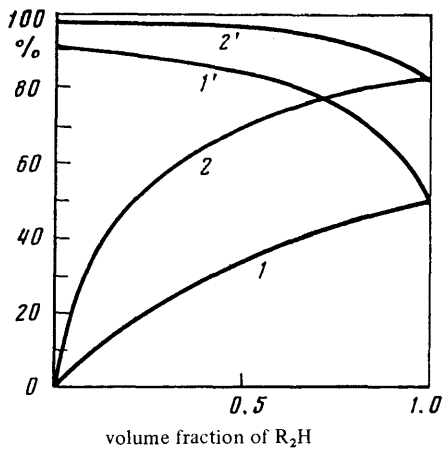

Figure 8. Dependence of the selectivity of the oxidation of the component R_2H on its content in a mixture with an inert solvent (curves *1* and *2*) and with the substance R_1H undergoing co-oxidation; $r_2 = 0.1$ (curves *1'* and *2'*) for different lengths ν of the oxidation chain: $\nu = 1$ (curves *1* and *1'*) and $\nu = 5$ (curves *2* and *2'*).

As an example, we calculated the dependence of the selectivity of the oxidation of the component R_2H in its mixture with a more reactive substance on the mixture composition for two oxidation chain lengths, namely 1 and 5; for clarity, short chains have been selected. The data presented in Fig. 8 show that, in contrast to the decrease of the selectivity on dilution of the substance R_2H by an inert solvent, the addition to R_2H of a more reactive substance entails an appreciable increase of the selectivity. For a chain length of unity, the selectivity of the oxidation of the pure substance is only 50%; on the other hand, in mixtures with a low content of this substance, the selectivity of its oxidation reaches as much as 90%. The selectivity of the oxidation of the second component also increases greatly for a chain length of 5 (from 83 to 98%).

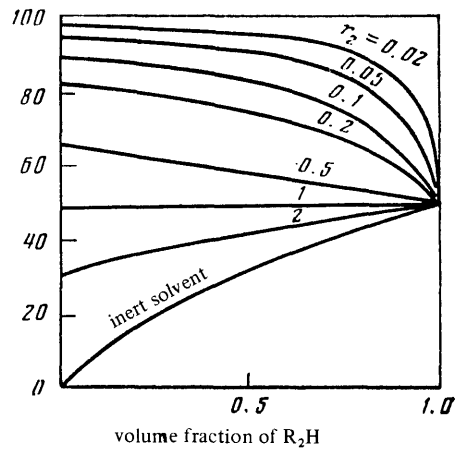

Figure 9. Dependence of the selectivity of the oxidation of the component R_2H on its content in a mixture with components R_1H having different reactivities.

In selecting the second mixture component, introduced in order to increase the selectivity of the oxidation of the required substance, its relative reactivity (relative to the given substance) is significant. The relations between the selectivity of the oxidation of the component R_1H and the mixture composition for different relative reactivities of the substance R_2H (this corresponds to different values of r_1) are presented in Fig. 9. Evidently, with increased reactivity of the second substance R_2H (a decrease of r_1 corresponds to this case), the selectivity of the oxidation of the first substance R_1H increases appreciably. Thus, in a mixture containing only 10 vol.% of a substance much more reactive than R_1H, the selectivity of the oxidation of the latter increases from 50 to 86%.[34]

The calculations and conclusions described above refer to reactions occurring under the conditions of initiated oxidation without degenerate chain branching. However, the results can be extended also to processes involving a mechanism with degenerate chain branching, provided that their main oxidation products are formed via the corresponding hydroperoxides.

Thus the oxidation of α-heptylcyclohexanone has been investigated[111] both separately and in mixtures with cumene. The results of kinetic studies showed that in co-oxidation the selectivity of the conversion of the ketone into an acid reaches 97%, while in the oxidation of the pure ketone it amounts to only 74% under the same conditions.

Thus in the oxidation of mixtures of substances with different reactivities a general feature is an increase of the selectivity of the conversion of the substance with the lowest

reactivity into hydroperoxides and products formed from the hydroperoxides in subsequent reactions.

---o0o---

The data presented above permit the conclusion that the problems of describing the kinetics of unbranched chain oxidation reactions of organic substances under various conditions have been virtually solved. The examination and comparison of the available literature data for the kinetics of the co-oxidation of binary mixtures at low temperatures and high oxygen pressures showed that the principal feature of the dependence of the rate of oxidation of mixtures on composition is negative deviations of the rate of co-oxidation from additive values. The main cause of the appreciable negative deviations (observed in the oxidation of mixtures containing substances belonging to the classes investigated, with the exception of aldehydes) is a higher selectivity of the reactions of the peroxy-radical than that of the reactions of the initial molecule with peroxy-radicals formed in the given process. This can be used to select compositions which are difficult to oxidise.

Joint oxidation can serve as an effective means of regulating both the rate and selectivity of the oxidation of substances which are difficult to oxidise and can also be used to involve in the oxidation process substances which are hardly oxidised in a pure form under the given conditions.

In theoretical terms, the development of new experimental methods for the determination of the rate constants for various elementary liquid-phase oxidation cross-reactions is of interst. The co-oxidation method can be useful in the development of a procedure for the simultaneous synthesis of several chain products, which can be more economical than the synthesis of each of them separately. A more rigorous assessment of the likely usefulness of this method will become possible after the determination of the characteristic features of the kinetics of the joint oxidation at advanced stages of the process.

The Modelling of Biological Catalysts

A.P.Purmal' and L.A.Nikolaev

A historical survey of studies on the modelling of biological catalysts is presented. Pioneering investigations, investigations which have led to new concepts, hypotheses, or principles, or those which have led to results of practical importance are examined. Attention has been concentrated on the modelling of oxidoreductases.
The bibliography includes 124 references.

CONTENTS

I. The first models of metalloenzymes 466
II. Metal complexes as models of active groups 467
III. Models of metal-free active groups of enzymes 468
IV. Metal complexes as models of catalase and nitrogenase 468
V. Models of oxidases, oxygenases, and other enzymes 470
VI. The modelling of enzymes as a pathway to new catalysts 471
VII. The role of the macromolecular component in model systems and of the protein in enzymes 472

Biological catalysts (enzymes) are specific protein catalysts present in all living cells. The study of non-protein catalysts, which accelerate the same reactions as enzymes, has been established as a field of research into the modelling of biological catalysts.

Any model reflects a particular characteristic feature of the original. If a high catalytic activity is regarded as the characteristic feature of enzymes, then colloidal solutions of metals must be regarded as the first models. Investigation of these systems dates back to the beginning of this century; the first object modelled among enzymes was catalase, which catalyses the decomposition of hydrogen peroxide under the conditions of the living cell.

I. THE FIRST MODELS OF METALLOENZYMES

Bredig and his co-workers investigated colloidal solutions of platinum and other highly dispersed noble metals and showed that these simple "models" do indeed resemble enzymes.[1,2] The study of the kinetics of catalytic processes in the presence of highly dispersed metals led to the observation of definite similarities between the kinetic characteristics of the models and the originals. Like enzymes, Bredig's models acted at very low concentrations and the dependence of the rate on the hydrogen peroxide concentration in the model systems was extremely similar to that characteristic of enzymes. This was observed not only for colloidal metals but also for metal oxide sols. The situation was the same for the influence of the pH on the catalytic activity; it was found to be similar in the model and modelled systems. An increase of the pH in both cases led to the attainment of a maximum in the rate of decomposition of the peroxide. The maintenance of solutions at elevated temperatures resulted in a decrease of the activities of both catalase and the model systems.

Comparison of the activities of specific substances (catalyst poisons) on enzymes and models is especially convincing. It was found that the models, i.e. metal sols, are inactivated by the same substances as catalase, namely by mercury compounds, cyanides, hydrogen sulphide, iodine, etc. After poisoning the platinum sol with hydrogen cyanide, the activity of the sol can be restored by the prolonged passage of air through the solution; catalase behaves in exactly the same way. Such high similarity in the dependence of various factors was to some extent due to the fact that the modelled enzyme contained a metal (iron) as part of the composition of the active group.

Metal salts have attracted the attention of many investigators,[3,4] but on the whole comparative study of the properties of sols and enzymes in fairly primitive systems has not been able to accelerate significantly progress in the modelling of biocatalysis.

It has been established[5,6] that platinum metals accelerate the decomposition of formic acid and also decompose formaldehyde (into CO and H_2). These may be seen as functions resembling the activity of oxidoreductases. The transfer of hydrogen from formaldehyde to Methylene Blue under the influence of the "Schardinger" enzyme from raw milk is modelled, according to Bredig and Sommer,[7] by the reduction of the dye with formic acid in the presence of platinum, iridium, gold, and palladium sols. For these reactions, it has been possible to demonstrate kinetic analogies with enzymes and to establish that enzyme poisons such as hydrocyanic acid and mercury salts have a poisoning effect.

In terms of activity, the sols are greatly inferior to enzymes. Thus, according to Hennichs' data,[8] a preparation of catalase from the liver is almost a thousand times more active than colloidal platinum. Admittedly, it is fairly difficult to carry out a comparison since neither their number nor the character of the distribution of the active centres on the sol particles nor the legitimacy of applying homogeneous kinetics to the microheterogeneous systems investigated are known.

There was a tendency to explain the catalysis by dispersed metals of the hydrogen peroxide decomposition reactions by the formation of intermediate peroxide compounds. Mercury peroxide compounds have been detected in the catalytic decomposition of H_2O_2 by mercury.[9]

Later studies of metal salts were concerned with the properties of tungsten,[10] colloidal silver,[11] and iron(III) hydroxide.[12]

Platinum metal salts are very unstable and their employment for preparative purposes would require an increase in their stability. This has been achieved by introducing into the colloidal metal solution the so-called protective colloids,

forming on the surface of the sol particles an adsorption layer which prevents their coagulation.[13,14] The products of the alkaline hydrolysis of egg albumin, namely the sodium salts of lysalbinic and protalbinic acids, were used as the protective colloid in 1904.[13] These acids are precipitated in an acid medium and they can be used only in neutral or weakly alkaline solutions. Using gum arabic as the protective colloid, active salts suitable for the hydrogenation of a large number of compounds over a wide pH range were obtained in 1912.[14]

Despite serious doubts about the usefulness of attempts to understand the mechanism of enzyme action by studying metal salts, careful investigation of this historical stage in the development of the science of catalysis has shown that it was by no means fruitless. If not the metals themselves then metal ions do indeed have a direct bearing on enzymes.

Progress in biological research, which had led to the discovery of the chemical nature of the active groups in metal-containing enzymes, has attracted attention to the catalytic properties of a surprising group of compounds containing a porphyrin nucleus and different metal ions coordinated to the system of pyrrole rings of the nucleus.

In 1926 the first step was taken in the study of the activities of groups characteristic of enzymes. Kuhn and Brann[15] investigated the catalytic activity of haemin—a complex of iron and a protoporphyrin ring. Compounds of this type constitute the active groups in many enzymes catalysing oxidation processes and the problem of the properties of haemin was therefore important from the standpoint of modelling. In enzymes, haemin is linked to the protein and measurement of the activity of isolated haemins threw some light on the role of the protein moieties of the molecules of biological catalysts (see Nikolaev's review[16]).

These experiments demonstrated particularly clearly that the active group, separated from its carrier, has a much lower activity and an extremely weak selectivity. The activity of haemin in the hydrogen peroxide decomposition reaction was increased by its adsorption on charcoal.[17] The adsorption activates haemin in relation to specific but by no means all the reactions in which it behaves in general as a catalyst.

Iron ions are also activated by adsorption on charcoal.[17] Such systems can be regarded as the simplest and very rough models of enzymes in which the active group and the carrier are already clearly outlined. At the same time it was shown that compounds which do not contain any metal and have a comparatively simple structure are capable of catalysing reactions characteristic of enzymes. Thus Shilov, who developed the concept of the cyclic transition complex in organic reactions,[18] studied the catalytic functions of amines and aminoacids;[19] Swain and Brown[20] showed that the catalytic effect can be determined by the simultaneous action on the substrate of two different functional groups contained in the catalyst molecule. This effect ("bifunctional catalysis") was subsequently shown to play an important role in the mechanism of enzyme action.

In the subsequent research into the modelling of enzymes, two trends were established: (1) the study of models of the active groups of enzymes in order to elucidate the characteristics of the structure and mechanism of their action as part of the composition of the enzyme; (2) the synthesis of highly active catalysts based on the existing information about the structure and specific mechanism of enzyme action.

The first of these trends outgrew in the course of its development the initial aims of the investigations and led to the formulation of a new branch of chemistry—metal complex catalysis. In our country, studies on these lines were initiated by one of the authors of this review.[21]

II. METAL COMPLEXES AS MODELS OF ACTIVE GROUPS

Nikolaev[16,22,23] carried out a series of investigations of models of the active groups of metal-containing enzymes and chose copper as the model metal. In contrast to the ions of iron, whose hydroxide $Fe(OH)_3$ has a very low solubility product, copper ions form many complexes which are stable in an aqueous medium in the presence of an excess of the ligand in solution and permit a wider variation of the nature of the ligands. Other metal ions were later also studied as catalysts of various reactions (decomposition of hydrogen peroxide, oxidation of polyphenols, oxidation of ascorbic acid, etc.) and the first relations between the catalytic activity and the nature of the ligand were formulated.

The results obtained are summarised in a monograph[16] and reviews.[22,23] The main idea, which stimulated the study of the catalytic properties of complexes, consisted in the hypothesis that the properties of the active centre in heterogeneous catalysts can be interpreted in terms of data concerning the influence of the environment of the metal ion on its activity and the complex is to some extent an analogue of the active centre "extracted" from the solid and transferred to the solution. This way of "creating bridges" between heterogeneous and homogeneous catalysis has since become promising, but progress along this pathway requires more effort than seemed to be the case at the beginning. Nevertheless, even the first steps have already shown that the variation of the activity and selectivity of catalysts of the type of metal complexes is entirely feasible and leads to extensive and interesting trends in the theory and practice of catalysis. The study of the influence of the nature of ligands, the nature of the metal ion, and the geometrical characteristics of metal complexes threw light on many aspects of the mechanism of enzyme action and clarified the problems which must be solved in theoretical enzymology.

In the first place it was found that the condition which must be fulfilled for the complex to exhibit an appreciable catalytic activity at all is the limitation imposed on the coordination number, namely the latter must not be greater than four. Complexes of the "closed" type with a coordination number of six or more are as a rule inactive.

The presence in the coordination sphere of amine nitrogen is also important for metal complex catalysts of redox processes and in particular of the decomposition of hydrogen peroxide—the introduction of oxygen into this sphere lowers the activity. American investigators[24] have shown that these conditions are to a large extent valid also in the catalysis of the hydrolytic reactions of organic substances by transition metal complexes.

The investigation of the catalytic properties of the iron complex of triethylenetetramine, which has come to be called "inorganic catalase", belongs to this series of investigations.[25,26] As in the early studies by Bredig, these investigations emphasise the similarity in the nature of the catalytic poisons of catalase and the complex investigated and also the similar isotope effects. Among all the metal complexes investigated hitherto, this system has shown the highest catalase activity (subject to the same stipulations concerning the difficulty of the correct comparison of the catalytic activities of systems in terms of their turnover number determined at different pH). It was later shown[27] that the complexes of iron ions with triethylenetetramine model an important feature of the catalase process. The mechanism of the catalysis of the decomposition of hydrogen peroxide by this complex involves a sequence of two two-electron transfers, i.e. the catalysis has a non-radical mechanism as in the case of catalase.

The properties of metal sols containing on their surfaces compounds of different composition, have been described from the standpoint of catalysis and colloid chemistry.[28] Micellar catalysis, which can be regarded as one of the aspects of the modelling of biological catalysts, should be treated as a further development of this trend.

A review of metal complexes in which the ligand is a molecule or ion of the substrate can be found in a monograph.[29]

III. MODELS OF METAL-FREE ACTIVE GROUPS OF ENZYMES

Investigations into model structures without metal ions developed in parallel with the studies devoted to the metal complex models of the active groups of enzymes. Researches into the latter led to the establishment of a new field of science—that of metal complex catalysis. Studies on the former compounds laid specific foundations for another branch of science—catalysis by organic compounds.

The possibility of creating simple organic models of enzymes was foreseen in an early stage by Ostwald[1] (p.161). The first attempts to demonstrate the similarity of the stereochemical specificities of enzymes and simple organic models were undertaken in 1908. It was shown that nicotine resolves the optical isomers of camphorcarboxylic acid at different rates[1] (p.161).

In 1927 Langenbeck investigated isatin as a model of the enzyme dehydrase and established the mechanism of its action, which has features in common with the mechanism of the enzyme action.[30] Three years later Langenbeck, Hutschenreuter, and Jütteman proposed the principle of systematic activation[1] (p.96). A number of rules were formulated whereby one could be guided whilst modifying in succession a simple organic compound, chosen as the model of the enzyme, in order to increase its catalytic activity.

A striking demonstration of the effectiveness of the principle of systematic activation is provided by the study of methylamine and its derivatives as catalysts of the decarboxylation of phenylglyoxylic acid. By successive modification of methylamine to form 3-amino-1-methyloxindole, it has been possible to increase its decarboxylase activity a thousandfold. Using this procedure, investigators approached the elucidation of the structure of the active group in decarboxylase. The results of studies by Braunstein and Shemykin[31] and by Metzler and co-workers[32-34] constituted a major advance in the employment of the modelling method in order to establish the mechanism of enzyme action. These studies were concerned with the investigation of the models of transaminases and other pyridoxal transamination, racemisation, etc. enzymes. Pyridoxal or its phosphate, i.e. a relatively simple organic compound without its protein component, served as the model system.

It is necessary to consider studies which led to the elucidation of the activating role of the macromolecular component linked to the model of the active group of the enzyme. The activation of haemin and iron ions by their adsorption on charcoal has already been mentioned above. Model systems of this kind without metal ions were described in 1932 and were called faser-catalysts.[2] Faser-catalysts are derivatives of cellulose in which the massive molecule of the cellulose carrier is linked to diethylamine, modelling the small active group of decarboxylase. The model reaction used in this study was that involving the elimination of carbon dioxide from bromocamphoric acids. Similar studies have also been carried out on the decarboxylase activities of various amines linked to lecithin present in solution in the form of an emulsion.[1]

The intrinsic contribution of the modelling method to enzymology at the beginning of the 1960s can be summarised as follows. It was shown that (1) a high activity and definite specificity of action can be reproduced also with the aid of materials of non-biological origin; (2) the activity of enzymes is associated with a small group of atoms which is extremely sensitive to any structural rearrangement (as a rule, these groups contain nitrogen forming part of a heterocycle or an aminoacid group, i.e. amino-nitrogen); (3) the coordination of atoms in the active group of the complex must leave a certain "reaction space"[16] which the substrate molecule can enter; (4) the "carrier" (in enzymes this is a protein) alters both the activity and the specificity of the action of the catalyst.

The question of the role of the macromolecular component in enzymes (the protein) remains, however, unanswered. What physicochemical factor or factors cause such influence by the protein component of the enzyme molecule on the reactivity of the active group? An answer to this question is of fundamental importance for the problem of creating synthetic highly active and selective catalysts. When the protein nature of the macromolecular component of the enzyme is in fact essential for the operation of the kinetic properties of enzymes, the prospects for creating enzyme-like catalysts of practical importance are extremely remote.

The report that the protein component of the enzyme papaine can be shortened almost by 90% by treatment with proteolytic enzymes without an appreciable loss of catalytic properties attracted much attention. Although this result did not throw light on the role of the protein in the enzyme, it undoubtedly "inspired" investigators concerned with the modelling of enzymes. Subsequent studies showed, however, that the specific activity characteristic of papaine is retained following a decrease of the number of aminoacid residues only from 187 (in papaine) to 75–80 (in the active enzyme).[35]

Tests of the results of studies on the fragmentation of papaine showed subsequently that this result was also erroneous.[36] In many of the other enzymes investigated it was likewise impossible to observe the retention of activity following a significant shortening of the protein chain. The question of the possible role of the protein component in enzymes as a factor determining their catalytic properties is discussed below.

IV. METAL COMPLEXES AS MODELS OF CATALASE AND NITROGENASE

The development of the thermodynamics of successive complex formation and the rapid accumulation of quantitative data concerning the stability constants of various metal complexes in the 1960s made it possible to carry out systematic investigations of a series of complexes of copper(II) ions, ranging from Cu^{2+} to the copper-containing protein haemocyanine, and iron(III) ions, ranging from Fe^{3+} to catalase. These investigations have been summarised[37] and have been partly described in another communication.[38] The level of development of the kinetic methods for the investigation of complex processes made it possible to operate not only with the concept of the effective catalytic activity but also with the characteristics of the process mechanism, including the rate constants for the individual stages in the most thoroughly investigated systems.[39-44]

It was shown in these studies that mononuclear complexes of copper and iron ions induce a radical-chain decomposition of hydrogen peroxide with participation of the metal complex in the initiation, propagation, and termination stages. Depending on the concentrations, the chain length varies from 3 to 50.

Thus, when more stringent requirements are imposed as regards the similarity of the properties of the enzyme and model in terms of the isotypical nature of the fundamental process mechanism, the mononuclear copper(II) and iron(III) complexes cannot be regarded as models of catalase.

Only the copper complexes whose oxidation-reduction potentials are appreciably positive, permitting the Cu(II) ↔ Cu(I) transitions in the rate-limiting chain initiation and propagation stages proved to be catalytically active. The incorporation of an oxygen-containing ligand into the coordination sphere or the formation of a copper(II) complex with four nitrogen-containing ligands lead to an unfavourable alteration of the oxidation-reduction potential and a loss of catalytic properties by the metal complexes. When the latter interact with the peroxide anion, there is hardly any generation of radicals.

The molecular mechanism of catalysis characteristic of catalase and many other metalloenzymes operates only in the case of Cu^{2+} complexes with triethanolamine[45] and Fe^{3+} complexes with ethylenediaminetetra-acetic acid[46] incorporating two metal ions in close proximity, which act as a cooperative acceptor-donor of an electron pair.

The study of catalase[47] led to the conclusion that the four ferriporphyrin groups present in catalase are also involved in the decomposition of H_2O_2 cooperatively and not autonomously. The molecular mechanism of the catalysis of the decomposition of H_2O_2 by haemocyanine is also determined by the presence in its structure of pairs of proximate copper ions,[48] jointly participating in two-electron oxidation-reduction transitions.

It is noteworthy that the first hypothesis concerning the joint action of a pair of iron ions in catalase was put forward in 1932,[49] while studies which demonstrated the transformation of the catalase activity into the peroxidase activity on dissociation of catalase into four subunits containing one iron ion each have played a significant role in reaching the conclusion that the active centre of catalase includes not less than two iron ions.[50]

In 1967–1968 Purmal'[51,52] formulated the hypothesis of a special role in oxidation-reduction catalysis of dinuclear and polynuclear complexes capable of acting in accordance with the mechanism of molecular catalysis. In these studies attention was also drawn for the first time to the polynuclear character of the majority of oxidation-reduction metalloenzymes.

In the above hypothesis it was assumed that in the case of a pair of metal ions in close proximity, each of which is a one-electron oxidation-reduction agent, there is a possibility of the simultaneous transfer of an electron pair between the substrate and the catalyst, which determines the molecular mechanism of catalysis. The two-electron oxidation-reduction corresponds to the transition from one stable valence-saturated state of the substrate to another. For the vast majority of substrates, such a process is therefore energetically more favourable than the transition of the substrate from a stable form into a reactive radical formed by a one-electron transfer. Thus the mechanism of molecular catalysis can compete successfully with the mechanism of radical reactions when the latter is not a chain mechanism with a fairly long chain length. In the case of metal ions which are characteristic two-electron agents such as thallium, for example, acting in accordance with a two-electron transfer mechanism in their interaction with organic or inorganic substrates, there is no necessity for the cooperation of two metal ions. An analogous behaviour obtains for the iron(III) complex of triethylenetetramine, already mentioned, the mechanism of the catalysis by this complex involving Fe(II) ↔ Fe(IV) transitions. The catalysis of the decomposition of H_2O_2 by nickel(II) complexes of monoethanolamine apparently takes place similarly, involving Ni(I) ↔ Ni(III) transitions.[53,54] For this complex, the radical component of the process is virtually absent and monoethanolamine is not oxidised. (This system was subsequently used in laboratory practice for the non-radical decomposition of hydrogen peroxide in the presence of organic compounds.) Cooperation in the form of the formation of binuclear or polynuclear complexes with metal ions in close proximity is essential for ions whose stable oxidation states differ by unity. The polynuclear nature of metalloenzymes determines the possibility of catalysis by the latter of oxidation-reduction reactions via mechanisms not involving the intermediate formation of free radicals.

Thus the study of an enzyme and model systems with various structural and electrochemical characteristics led to the idea that dinuclear and polynuclear complexes play a special role in the chemical and biochemical catalysis of oxidation-reduction reactions. This idea was subsequently confirmed and developed in further investigations.

One should note that studies of the catalase process constituted a major stage in the history of the development of research into the modelling of enzymes. Another process whose modelling is likely to have great practical value is that involving the fixation of molecular nitrogen. Here too, although at a higher level, the evolution of studies on the modelling of catalase, beginning with the investigation of very simple models, was repeated. For a long time, it seemed that the ability to fix inert molecular nitrogen under mild conditions is characteristic solely of the biochemical systems of microorganisms. The detailed mechanism of the enzymic nitrogen fixation has not been ultimately elucidated even today although it has long been known that transition metals (molybdenum and iron) play an important role in this enzyme system. Together with the hypothesis that the transition metal complex ions can incorporate the N_2 molecule in the coordination sphere, this fact has served as a basis for the search for systems activating molecular nitrogen.

The first study by Vol'pin and Shur,[55] who achieved the chemical fixation of N_2, was published in 1964. They showed that various transition metal (titanium, chromium, molybdenum, iron, etc.) compounds are capable of effectively binding nitrogen at room temperature in aprotic media in the presence of reductants (organolithium, organomagnesium, or organoaluminium compounds, aromatic radical-anions, and powerful inorganic reductants). In the subsequent hydrolysis of these intermediates, ammonia was formed.[56] Later this kind of fixation was achieved also under catalytic conditions.[57,58] Under the influence of reductants, compounds of transition metals in low-valence states [titanium(II), vanadium(II), and molybdenum(II)], which coordinate N_2, takes place. In the subsequent stages of the reduction of the coordinated N_2, reduction products are formed: metal complex derivatives of hydrazine and ammonia.[59] The metal-nitrogen complex was first synthesised in 1965 by Allen and Zenoff from a complex incorporating N_2H_4 as the ligand.[60] The formation of complexes containing N_2 on direct interaction between molecular nitrogen and metal complexes was first established by Shilov and co-workers.[61,62] The studies enumerated above have disproved the idea that chemical fixation of N_2 under mild conditions is impossible and, although the chemical difference between the enzyme nitrogenase and metal complex systems discovered by Vol'pin and Shilov is great, the foundations for the modelling of nitrogenase were laid.

Subsequent researches into the modelling of nitrogen fixation were prosecuted from two directions: Shilov and co-workers investigated simple inorganic and organometallic models;[63–65] Likhtenshtein and co-workers[66–69] studied the structure of the active centre of the enzyme and

developed certain general approaches to the search for and the synthesis of model systems on the basis of information obtained in the investigation of the real enzyme. The situation described above, where simple compounds, down to metal hydroxides, i.e. compounds just as simple as Bredig's first models of catalase, served as models of a complex protein compound, has been repeated. However, as in the modelling of catalase, the outward dissimilarity of titanium hydroxides and nitrogenase conceals a fundamental similarity. This similarity consists in the possibility of achieving the cooperative step in the multielectron reduction of N_2. Likhtenshtein and Shilov[70] analysed the energetics of consecutive transitions in a series of reactions:

$$N_2 \rightarrow N_2H \rightarrow N_2H_2 \rightarrow N_2H_3 \rightarrow N_2H_4 .$$

As a result of the high strength of the first bond to be dissociated in N_2, successive one-electron reduction of N_2 cannot proceed at an appreciable rate under the mild conditions of biological fixation. The energetic difficulties in the reduction of nitrogen are eliminated in the four-electron synchronous reduction of N_2 to a hydrazine derivative. The dissociation of the two bonds in the N_2 molecule is compensated by the formation of new bonds with the metal centres of the catalyst, i.e. the transition

$$M \ldots N \equiv N \ldots M \rightarrow M = N - N = M$$

implies a definite rearrangement of the electron density within the metal complex. An obligatory condition governing the possibility of such a process is the involvement in the latter of at least two metal ions.

The study of the structure of the active centre of nitrogenase led to the conclusion that it contains a pair of low-valence molybdenum ions in close proximity.[66,67] On the other hand, in the hydroxide, which is a polyhydroxo-complex according to the conditions of its preparation, there is a fairly large number of metal ions close to one another.

Thus both nitrogenase and the simple models discovered in these studies are polynuclear metal complexes despite all the differences between them. A system has been found which is capable of reducing nitrogen homogeneously in protic water–alcoholic media.[71] The conditions for the formation of this system, namely the vanadium(II) complex of catechol, and the manifestation of its activity show that a polyhydroxo-complex incorporating several vanadium ions functions in this instance. An interpretation of the mechanism of the action of nitrogenase taking into account the characteristics of its structure has been described.[66,67] Its essential features reduce to the following.

Since nitrogenase is coupled to a one-electron reductant system, in particular ferredoxin, the structure of the nitrogenase active centre constitutes a kind of device for "switching" the one-electron reduction mechanism to a four-electron mechanism. The mechanism of the enzyme action includes stages involving electron transport from the surface sections towards the iron-containing cluster in the bulk of the macromolecule, the storage by the iron-containing cluster of the electrons obtained from the one-electron reductant, and the four-electron attack on the nitrogen molecule in the nitrogenyl complex with participation of at least two metal atoms (molybdenum atoms in all probability).

The discovery of the possibility of nitrogen fixation by simple model compounds has stimulated studies on these lines. These researches underwent a rigorous and complex development in England. Studies by English researchers also developed in two directions, involving the investigation of metal complexes (their structure and the relation between structural features and reactivity in relation to nitrogen fixation) and the investigation of various aspects of nitrogenase, including gene engineering. Information about the character of the bonds involving molybdenum atoms in the active centre of nitrogenase was obtained by the modelling method. The similarity of the exafs spectra (the spectra of the fine structure of the edge of the X-ray absorption) of nitrogenase and molybdenum–sulphur complexes capable of binding and activating nitrogen confirmed the hypothesis of the presence of sulphur bridges between the molybdenum atoms in the active centre of the enzyme.[72]

The chemical investigations were directed towards the study of the reactivity of the coordinated nitrogen. The formation of complexes of N_2 with various Mn, Fe, Co, Ni, Mo, and W complexes was established. The attempt to protonate the coordinated N_2 led to the decomposition of the complexes with evolution of N_2. The subsequent reaction of the coordinated N_2 with formation of $M{=}N{-}NH_2$ was observed only for the Mo and W complexes with phosphorus-containing ligands.[73,74] The formation of two moles of NH_3 was observed on subsequent protonation.[74] It was not possible to determine the intermediates in the transition from the hydrazo-complex to NH_3,[75] i.e. an independent confirmation of the multielectron mechanism of the reduction process was obtained. These results stimulated interest in the study of the mechanism of the electrochemical reduction of nitrogen complexes with metal ions bound in one way or another to the electrode surface.[76]

Exceptionally interesting results have been obtained recently in this field. The molybdenum complexes of phospholipids, adsorbed on a mercury amalgam, proved such effective reductants for nitrogen that it was possible to follow the process at room temperature and atmospheric nitrogen pressure.[77] The above principal characteristics of the mechanism of the action of nitrogenase were reflected in this model system.

The set of studies on nitrogenase and model systems led to the formulation of ideas and principles of a general character important for the theory of selection and construction of models of polynuclear metalloenzymes with an oxidation-reduction activity. The concept of multielectron transitions involving considerable changes in the nuclear configurations was put forward.[78] Likhtenshtein suggested the principle of the "optimum movement".[79] Its essential feature is that a synchronous process, accompanied by appreciable nuclear rearrangements, is favoured by the energy factor, but, when the elementary step involves many nuclei, the rate of reaction may become vanishingly small even for significantly exothermic reactions. In other words, the number of atoms involved in the reaction should be sufficiently large to ensure favourable energy relations but sufficiently small to retain a high probability of the synchronisation of the movement of nuclei along the reaction coordinate.

Theoretical procedures for the estimation of the probability of synchronisation in processes involving many nuclei have been developed.[80]

V. MODELS OF OXIDASES, OXYGENASES, AND OTHER ENZYMES

An important set of enzymes involved in terminal oxidation processes includes oxygenases and oxidases which catalyse the reactions of molecular oxygen with various organic substrates. In 1954 Udenfriend et al.[81] proposed a hydroxylating system which leads to the same hydroxylation products as certain mono-oxygenases. Udenfriend's model system includes iron ions, ethylenediaminetetra-acetate as the ligand, and ascorbic acid or its analogues as the electron donor. The identification of the chemically reactive species leading to the reaction products in this multicomponent system was for a long time difficult. The development of kinetic research methods made it possible to demonstrate that these

species in Udenfriend's system are metal–oxygen complexes having specific reactivities.[82]

Thus, in relation to this system, it has been possible to identify the intrinsic elementary step in the catalytic action in the activation of oxygen, which can be regarded as a new stage in the modelling of enzymes—the determination of the elementary mechanism of the chemical steps in the active centre of the enzyme and their reproduction in simpler systems.

The extent to which the elementary oxidation-reduction reactions of the metal complex ions are of a general character can be seen from a comparison of the catalytic functions of copper ions in various ligand environments in the oxidation of ascorbic acid by atmospheric oxygen. It has been established[83,84] that the reactive intermediate species is the oxygen complex CuO_2^+, which interacts with the substrate via a two-electron mechanism; an analogous result has been obtained also for the oxidation of methanol.[85] This elementary step models the action of a series of so-called colourless oxidases containing a copper(I) ion in the active centre. Under certain conditions, the cooperation of two copper ions is observed in the elementary step involving the two-electron oxidation of the ascorbate anion[86] or in the elementary step involving the two-electron reduction of oxygen.[87] These reactions model the non-radical cooperative processes occurring in the case of enzymes (the so-called blue oxidases) containing in the active centre two and more copper ions in close proximity.

The results of kinetic studies on relatively simple catalytic systems for the oxidation of ascorbic acid by oxygen[88] showed that the elementary step in the model and enzyme systems is in essence of the same type.

A specific feature of the enzyme system consists apparently in a three-dimensional structure of the immediate environment of the metal ion which limits the possibility of side reactions.

A number of investigations have been devoted to models of peroxidase. We shall not consider them because only a detailed kinetic study will make it possible to distinguish the "peroxidase-like" mechanism of the formation of a complex with H_2O_2 and its subsequent reaction with the substrate from the mechanism involving $H\dot{O}_2$ and $\dot{O}H$ radicals, which is characteristic of the majority of metal complexes.

A large series of comparative studies of the spectroscopic, thermodynamic, electrochemical and catalytic properties of various metal complexes and metalloenzymes, incorporating the same metal, have been carried out by Williams,[89,91] who arrived at conclusions significant for the search for syntheses of active models and also for the understanding of the specific properties of metalloenzymes. Thus, it has been shown that zinc complexes with tetrahedral but not octahedral coordination environments exhibit a carbonic anhydrase activity. The study of model systems made it possible to propose a structure for the active centre of carbonic anhydrase, where the zinc ion is present as a complex with a deformed tetrahedral structure in which two ligands consist of the sulph-hydryl groups of the protein. Comparison of the spectroscopic and thermodynamic properties of the zinc complexes of phenanthroline and the complex formed as a result of the addition of phenanthroline to the zinc atom of the active centre of alcohol dehydrogenase made it possible to demonstrate the presence of two or three vacant sites in the coordination sphere of zinc, available for substitution by the substrate. Williams[89] was the first to put forward the hypothesis, which was subsequently confirmed, that the specificity of the reactions of any metalloenzymes with small molecules (O_2, CO_2, H_2O, H_2O_2, and N_2) is determined almost completely by the substituted coordination sphere of the complex-forming metal.

In his analysis of the spectroscopic and magnetic properties of the metal complexes and metal-containing oxygen transferring agents haemocyanine and haemerythrin, Williams[91] proposed a general mechanism of their action:

$$Cu(\bar{I}) \ldots Cu(\bar{I}) + O_2 \rightarrow Cu(II)O_2^{2-}Cu(II),$$
$$Fe(II) \ldots Fe(II) + O_2 \rightarrow Fe(III)O_2^{2-}Fe(III).$$

He emphasised a characteristic feature of the functioning of these oxygen-transferring agents which is difficult to achieve in model systems: in the absence of oxygen the reduced metal ions are located in the protein structure sufficiently far from one another not to influence their magnetic and optical properties and their reactivities. Oxygen is bound as a result of the mutual approach of a pair of metal ions, which is accompanied by a change in conformation and "strain" in the protein component of the transferring agent. He put forward similar ideas concerning the nitrogen fixation mechanism. He explained the presence of molybdenum in all the nitrogen fixing system by the fact that the following process can be formulated only for two molybdenum(III) ions:

$$Mo(III)N_2Mo(III) \rightarrow Mo(VI)(N^{3-})_2Mo(VI) \rightarrow 2NH_3.$$

The difficulty of modelling this system arises from the fact that two molybdenum(III) atoms which have approached one another must not form a strong Mo–Mo bond, retaining at the same time a vacant site in the coordination sphere for the formation of the complex with N_2.

One should note briefly that, simultaneously with the development of studies on the modelling of metalloenzymes, research into organic catalysts modelling the action of particular metal-free enzymes has developed fairly vigorously. Extensive information about these problems has been published.[92,93]

VI. THE MODELLING OF ENZYMES AS A PATHWAY TO NEW CATALYSTS

The development in the USSR of the second of the trends specified above (the synthesis of catalysts on the basis of the existing information about the structure and properties of enzymes and the principles of enzyme catalysis) was initiated successfully and logically in the USSR at the beginning of the 1960s by Khidekel'.[94–102] There is no doubt about the initial general postulate—that of the characteristics of the action of coenzymes and enzymes can be explained in principle on the basis of the fundamental postulates of organic, coordination, and polymer chemistry. However, the "unmapped regions" as regards information about systems of biological origin can pose stringent requirements on the intuition of investigators who choose this pathway.

The simplest systems, namely the complexes of copper ions with various amines, were investigated as analogues of copper-containing phenol oxidases in the initial stage of these studies.[94,95] With the aid of such catalysts, it was possible to vary widely the direction of the reactions as a result of the formation of complexes of the intermediate compounds or starting materials with the catalyst and by the variation of the composition of the catalysts. These results proved to be useful in carrying out oxidation reactions involving various phenols. It was possible to develop convenient methods for the synthesis of a number of quinonoid compounds, naphthols, and spirocyclic trimers.[96,97]

The retrospective analysis of the evolutionary pattern of the biogenesis of enzymes has been important for the selection of procedures for the synthesis of their analogues with different degrees of complexity in structure and organisation.[98,99]

Studies have been made on a series of dihydropyridine derivatives—analogues of the coenzymes nicotinamide-adenine dinucleotide and nicotinamide-adenine dinucleotide phosphate. New highly active reduction systems and catalysts for the hydrogenation of olefins, significantly superior to the existing liquid-phase hydrogenation catalysts, were obtained on the basis of these investigations.

It was possible to create new types of homogeneous and "heterogenised" complex hydrogenation catalysts—analogues of the enzyme hydrogenase. Catalysts based on the following systems were obtained: 1,4-dihydronicotinamide—a transition metal derivative, low-valence transition metal complexes with quinones and aromatic compounds, aromatic carboxylic acids, aminoacids and peptides, dyes of various types, hydroxyquinones, and aromatic hydroxyazo-compounds. Some of these catalysts proved to be suitable for a series of processes involved in fine and fundamental organic synthesis.[100] A series of studies have been devoted to the transfer of activated hydrogen by methods which are tentatively similar to the enzyme procedures.[101] Using these methods, it was possible to hydrogenate at a high rate ketones, aldehydes, and aromatic compounds and to achieve a series of selective hydrogenation processes (in particular, the reduction of the carbonyl group in the presence of the C=C double bond[102]). Systems incorporating a catalyst activating molecular hydrogen and a catalyst for the transfer of activated hydrogen have also been created.[101]

Catalytic systems of the above type make it possible to reduce at a high rate and with a high specificity a large number of organic and complex compounds.

The results concerning the catalytic hydrogenation of aromatic compounds and aromatic nitro-compounds were particularly valuable. Some of the new catalytic systems developed have been incorporated in industrial practice.[103-106]

Extensive information about systems in which homogeneous hydrogenation is effected by complexes of metals of all the Groups in the Periodic System has been published.[107] The catalysts described include those in the creation of which various natural hydrogenases served as the mobilising system.

A new interesting type of modelling of various enzymes was initiated following the development of the synthetic chemistry of polymers containing various functional groups (carboxy-, amino-, etc. groups), which are soluble in polar solvents.

The investigation of the catalytic properties of such polymers and their complexes with metal ions in the USSR was developed in the studies of Kabanov, Pshezhetskii, and Kirsh.[108-113] The activity of systems based on polyacrylic acids, polyethyleneimine, polyvinylpyridine, etc. relative to the catalase, peroxidase, ascorbic acid oxidase, catechol 1,2-oxygenase, and proteolytic functions exceeded by a factor of 10^3–10^4 the activity of the low-molecular-weight analogues, being inferior by a factor of 10^2–10^3 relative to the activities of the enzymes modelled.

VII. THE ROLE OF THE MACROMOLECULAR COMPONENT IN MODEL SYSTEMS AND OF THE PROTEIN IN ENZYMES

The study of the simplest model system has shown that their catalytic properties are "improved" when the low-molecular-weight active group is combined with a high-molecular-weight group. The stability of systems of the type of "active group–carrier" rises, while their catalytic activity as a rule also increases.

The modelling of enzymes by an independent procedure led to the conclusion that their high catalytic activity is associated with the protein, macromolecular nature of these systems. To a lesser extent, the study of model systems revealed the role of the protein as a factor determining the selectivity of the enzyme action. Nevertheless, this function of the protein component of the enzyme molecule was established initially on a speculative basis in terms of the "key–lock" model, and then also experimentally. Koshland's principle of induced correspondence gained wide recognition.[114-115] It became understood why the selectivity of enzyme action was associated with a high degree of steric correspondence between the substrate and the active centre in the enzyme structure. The factor determining this correspondence is the high structured organisation of the enzyme—up to a quaternary organisation. The absence of such organisation from model systems is sufficient to understand why the creation of a simple model with a high specificity of action in relation to polyatomic substrates is a problem unlikely to have a successful solution.

The choice of activity as the principal property of models constituted a psychologically understandable stimulus for calculations by investigators, who tried to show that the activity of their models is comparable or even superior to that of enzymes. In such calculations the activity is referred, for example, to the unit weight of the catalyst; the pH-dependent activity of the model is extrapolated to the pH range in which the enzyme functions, etc. On the other hand, when calculated data are disregarded, one may conclude that it has not been possible to create a model equal to the enzyme in its activity for their equal molar concentrations at similar pH, temperature, and substrate concentration.

The idea of the possible role of the protein as a factor determining the high activity of enzymes was put forward for the first time by Bauer in 1935,[116] who suggested that the protein can exist in equilibrium and non-equilibrium states; during the enzymic reaction, the protein passes from a non-equilibrium to an equilibrium state, while the energy of the transition is used to overcome the activation barrier to the reaction of the substrate. The energy evolved as a result of the enzymic reaction returns the protein molecule to the initial non-equilibrium state. The general principle of the possibility of employing the energy of a chemical reaction to accelerate the reaction under consideration, which appeared during the period when Semenov created the theory of branched chain reactions, was reflected in Bauer's hypothesis.

Kobozev examined from the same standpoint the problem of the relation between the catalytic activity of a low-molecular-weight compound and the properties of the high-molecular-weight substance attached to it.[117,118] His idea consisted in the hypothesis that the thermodynamically non-equilibrium mass should increase the catalytic activity of the species linked to it with respect to various reactions. He showed that in many instances a logarithmic relation is observed between the activity and the magnitude of the attached non-equilibrium mass. The specific question of the increase of catalytic activity of a species as a result of the addition of a protein to it has also been examined.[119,120] The role of the protein macromolecule is to participate in the recovery of the energy: the energy evolved in the course of the reaction is not scattered in the form of heat but is used to activate the catalytic centre.

A number of studies have been made whose aim was to specify in greater detail the problem of the possible forms of the accumulation of energy by the protein molecule.[121,122] Various approaches to the elucidation of the role of the protein in enzymes has been analysed by Blyumenfel'd.[123] His review can be supplemented only by the hypothesis of the entactic (extended, strained) state of the active centre of the enzyme put forward on the basis of the analysis of a series of model and enzyme systems.[91] According to this

hypothesis, the small activation barrier to the enzymic reaction is determined by the fact that, even before the enzyme combined with the substrate, the active centre of the enzyme contained a functional group with a high potential energy. The increased energy in the region of the active centre arises by virtue of the conformational energy of the entire protein molecule. Thus the zinc atom in carboxypeptidase or carbonic anhydrase is much more reactive than in its initial ionic form or in a complex with free low-molecular-weight ligands. When it is located in the active centre, the zinc atom is only partly bound to the protein ligands forming the strained configuration of a distorted tetrahedron. The possibility of such formations is a specific feature of the macromolecular polyligand (the protein), characterised by the presence of secondary and tertiary structures.

According to Blyumenfel'd, the conformational transformations of the protein are indissolubly linked to the elementary step in the enzymic reaction: the latter consists in a conformational change in the macromolecule (of the enzyme–substrate complex) and the rate of the substrate–product transformation is determined by the rate of this conformational change[123] (p.155). In contrast to the views presented above, in Blyumenfel'd's concept the protein molecule incorporating the active centre is in a conformationally equilibrium state before the start of the interaction with the substrate. In the region of the active centre the protein molecule passes to a conformationally non-equilibrium state only for the enzyme–substrate compound. The transition from the conformationally non-equilibrium state to the equilibrium state involves greater or smaller changes in the structural organisation of the protein—the dynamics of conformational changes. One of the most thoroughly developed dynamic models is that describing the functioning of the enzyme aspartate aminotransferase.[124]

Without considering in greater depth the current problems of modern theoretical enzymology, one can apparently speak of a relation between the high catalytic activity of enzymes and the structural-dynamic characteristics of the protein. Thus not only the selectivity of their action but also the catalytic activity of enzymes is associated with the fact that the protein consists of macromolecules with a structural organisation, the changes in the latter making the same contribution to the enzymic step as the redistribution of chemical bonds in the substrate species.

- - - o 0 o - - -

The question arises of the prospects for the creation of model catalysts with activities and selectivities similar to those of enzyme catalysts. The solution of this problem, which involves in essence the creation of synthetic analogues of enzymes rather than models, is associated with the creation and employment of polymers having a flexible structural organisation, like proteins. Naturally, this is not the only possible way of achieving a solution. It may be that the procedure involving the combination of polymers of the above kind, linked to active groups, with systems of molecular sieves of the type of zeolites will lead to success. It is also possible that an unpredictable solution will be found. This does not imply that the study of low-molecular-weight models of enzymes has lost its value. Their investigation will lead to the formulation of new hypotheses and concepts useful for the solution of practical problems.

However, one should not overestimate the role of studies on the modelling of enzymes as a method for the investigation of the latter. In this sense the modelling method is simply one of the trends in the overall research programme, including the study of the sequence of aminoacid residues in enzymes, the X-ray diffraction analysis of proteins, the determination of the nature of coenzymes, the study of the kinetics and mechanism of enzymic reactions, the identification of intermediate compounds, the investigation of the conformational states of the enzyme protein and the dynamics of the changes in these states, etc.

This field of research has already yielded promising practical results associated with the synthesis of highly active non-protein catalysts.

Thiadecalins and Condensed Thiacyclohexanes of the 2-Thiabicyclo[4.3.0]nonane Series

S.K.Klimenko and T.V.Stolbova

The latest advances in the chemistry of condensed bicyclic thiacyclohexanes of the type of thiadecalins and their analogues are examined. The results of studies on the methods of synthesis, chemical reactions, and the conformational and configurational analysis of thiadecalins, their analogues, and derivatives are surveyed.
The bibliography includes 99 references.

III. Structure and properties 481

I. INTRODUCTION

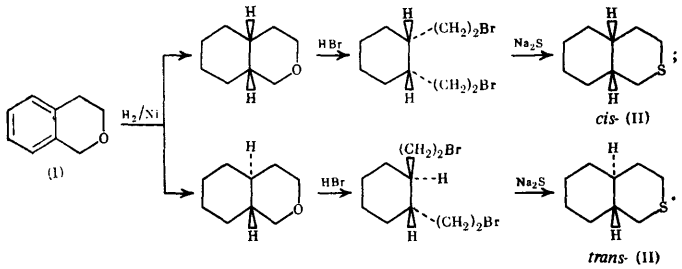
Particularly vigorous development of thiacyclohexane chemistry has occurred in the last two decades, as shown by the list of literature references quoted in this review. Major advances have been achieved in the development of synthetic methods in the synthesis of derivatives (sulphoxides, sulphones, sulphamides, sulphonium salts, and oxosulphonium salts), and in the study of the reactions and stereochemical characteristics of the structures of both the sulphides themselves and their derivatives. Whereas the original development of this field was in many respects due to the problem of the identification and utilisation of petroleum sulphides,[1,2] the shift of recent studies towards stereochemistry indicates the undoubted theoretical interest of the condensed thiacyclohexanes, primarily as thioanalogues of decalin. At the same time the search among them for substances with properties of practical value holds out much promise. It is known that certain derivatives of sulphoxides have been recommended as surfactants, flotation agents, oxidation and corrosion inhibitors, insecticides, solvents, and rare metal extractants.[3-11] The S-methylsulphonium salts play an important role in processes occurring in the living organism.[12] Among sulphonium salts, biologically active compounds[13] are being sought and thioanalogues of steroids are being synthesised.[14]

II. METHODS OF SYNTHESIS

1. *cis*- and *trans*-2-Thiadecalins derived from 1-(2-Bromoethyl)-2-Bromomethylcyclohexane

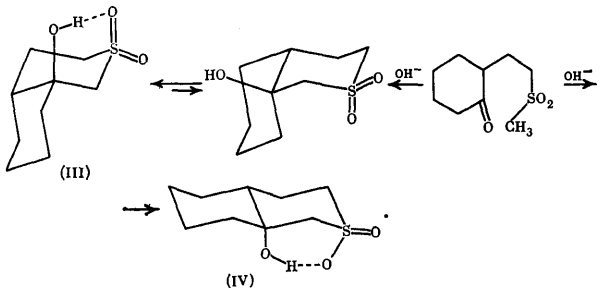
The synthesis of even the simplest condensed thiacyclohexanes is complicated by the fact that each of them can exist in two stereoisomeric forms. The synthesis of *cis*- and *trans*-2-thiadecalins (II) from isothiochroman (I) involves the preparation of 3-oxocyclo[4.4.0]decanes, the resolution of the stereoisomers, their conversion into the dibromides, and their subsequent cyclisation with sodium sulphide[15] (see the formula below).

Together with 1-thiadecalin, 2-thiadecalins (II) have been isolated from petroleum by extraction with an aqueous solution of mercury acetate.[1]

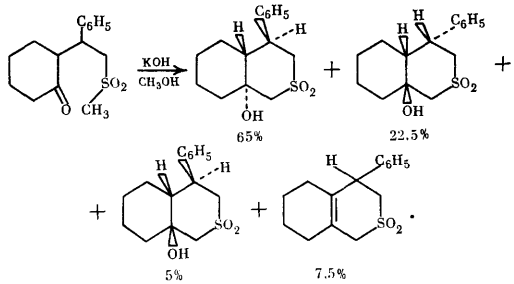


2. The Sulphones of *cis*- and *trans*-9-Hydroxy-2-Thiadecalins derived from 2-(2-Methanesulphonylethyl)cyclohexanone

The intramolecular cyclisation of 2-(2-methanesulphonylethyl)cyclohexanone under the conditions of base catalysis proceeds via the α-sulphonylcarbanion and leads to *cis*-9-hydroxy-2-thiadecalin 2,2-dioxide (III) and its *trans*-isomer (IV).[16] In the *cis*-isomer the conformation with the axial hydroxy-group is fixed by the intramolecular hydrogen bond:[16]



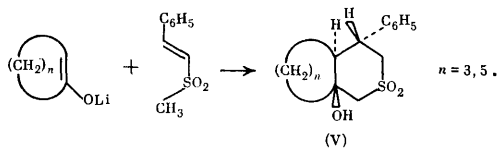
The cyclisation of 2-(α-methanesulphonylmethyl)benzylcyclohexanone under analogous conditions takes place with formation of 9α-hydroxy-4β-phenyl-*trans*-9β-hydroxy-4α-phenyl-*cis*-, and 9β-hydroxy-4β-phenyl-*cis*--2-thiadecalins 2,2-dioxides† and of the hydration product:[17]



The initial ketosulphones are obtained from 1-pyrrolidino or 1-morpholino-cyclohexene and αβ-unsaturated sulphones.[18] The cyclisation products have been separated by preparative chromatography and the configurational assignments have been made on the basis of ^{1}H NMR and infrared spectra; the *cis*-elimination reactions have also been achieved for the *O*-acetyl derivatives.[16,17]

3. Cyclisation of the Lithium Enolates of Cycloalkanes and Methyl Styryl Sulphone

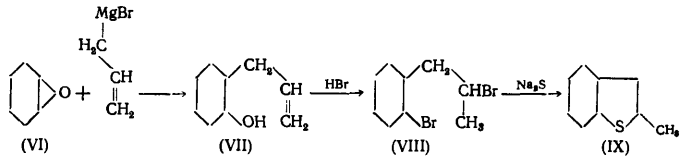
Derivatives of sulphones of 2-thiadecalin and its analogues, differing in the size of the condensed alicyclic 3-thiabicyclo-[4.3.0]nonane and 3-thiabicyclo[4.5.0]undecane# can be obtained by cyclising methyl styryl sulphone with the lithium enolates of cycloalkanes on heating in the 1:2 tetrahydrofuran (THF)–dimethylformamide (DMF) mixture. The yields of the final products (V) are 76–100%. The structural assignments have been made by means of ^{1}H NMR:[19]



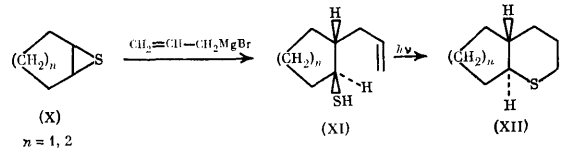
(V)

4. *trans*-1-Thiadecalins and *trans*-2-Thiabicyclo[4.3.0]-nonanes derived from Cycloalkene Sulphides and Allylmagnesium Bromides

Up to 1970 it was not possible to synthesise *trans*-1-thiadecalin. It seemed that the same method could be used for its synthesis as that for the synthesis of 2-thiadecalins but the synthesis of the corresponding dibromo-derivatives presents certain difficulties. Thus the interaction of epoxycyclohexane (VI) with allylmagnesium bromide and the subsequent reaction of 2-allylcyclohexanol (VII) with hydrogen bromide lead solely to 1-bromo-2-(2-bromopropyl)cyclohexane (VIII) whose cyclisation with sodium sulphide gives rise to a mixture of stereoisomers of 2-methyl-1-thiahydrindan (IX):[20]

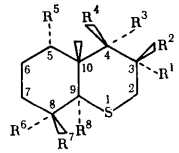


However, later the same workers[21–23] proposed the synthesis of *trans*-1-thiadecalins (XII) by the interaction of cyclo-olefin sulphides (X) with allylmagnesium bromide and subsequent intramolecular cyclisation of the allylcycloalkanethiols (XI) formed in this process:



1-Thiahydrindans or 2-thiabicyclo[3.3.0]octanes arise in the given reaction as side products.[21–23] The cyclisation of 2-allylcyclohexanethiol (XI, $n = 2$) with formation of a mixture of 1-thiadecalin (XII) and 2-methyl-1-thiahydrindan in proportions of 2:1 has been observed even after its prolonged storage; after ultraviolet irradiation, 1-thiadecalin is formed in a large amount, while on treatment with 75% sulphuric acid the product is 2-methyl-1-thiahydrindan. When crotylmagnesium bromide is used, a mixture consisting of two pairs of isomers, namely those of 4-methyl- 1-thiadecalin and 2,3-dimethyl-1-thiahydrindan, is formed in the same reaction.[22]

Despite the difficulties indicated, associated with the formation of side products, it has been possible to obtain 1-thiadecalin,[21] 4-methyl-1-thiadecalin,[22] 9-methyl-1-thiadecalin,[23] and 2-thiabicyclo[4.3.0]nonane.[24] Although the configurations of the intermediate and final products have not been investigated, the above sulphides have been described as the *trans*-isomers on the assumption that reactions involving the ring opening in the *cis*-sulphides are stereospecific and are accompanied by the formation of mercaptans with the *trans*-configuration, while no change in configuration takes place in the heterocyclisation reaction.[23] This hypothesis proved to be correct. The method proposed[21–23] has been used in another study[25] for the synthesis of 3-, 4-, 5-, 8-, and 9-monomethyl-substituted *trans*-1-thiadecalins (XII)–(XX); their configurations as well as the configurations of the initial sulphides and intermediate *trans*-2-allylcyclohexanethiols have been established by ^{13}C NMR.



(XII) all R = H; (XIII)*R^1 = 3α-CH_3; (XIV) R^3 = 3β-CH_3; (XV) R^3 = 4α-CH_3; (XVI) R^4 = 4β-CH_3; (XVII) R^5 = 5α-CH_3; (XVIII) R^6 = 8α-CH_3; (XIX) R^7 = 8β-CH_3; (XX) R^8 = 9-CH_3.

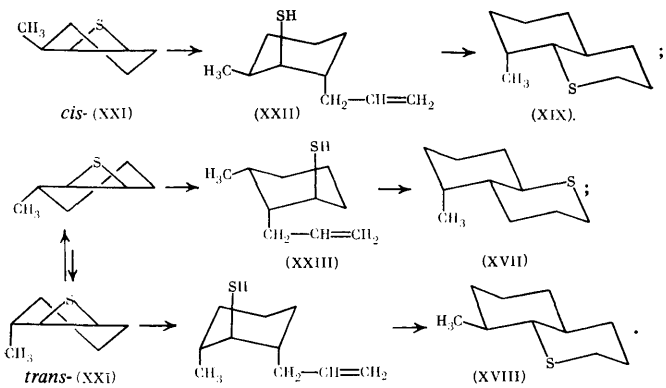
†The symbol β denotes substituents located on the same side of the ring as the hydrogen atom at C(10), while the symbol α denotes substituents on the opposite side of the ring in relation to this hydrogen atom.

#Since there is no uniformity in the literature quoted below in the names used for the same compounds, we adopted as a basis the term "thiadecalins" and, in the absence of trivial names, the term "thiabicycloalkanes".

*The substituents R not indicated here and henceforth are H atoms.

It has been shown[25] that the use of azobisisobutyronitrile (0.1 M) as the initiator of the intramolecular radical cyclisation of *trans*-2-allylcyclohexanethiols reduces to a minimum the formation of 1-thiahydrindans and thus leads to better results compared with initiation by ultraviolet irradiation.[21-24]

We shall now consider the stereochemistry of the reaction of 3-methylcyclohexene sulphide (XXI) with allylmagnesium bromide.[25] The reaction of the *cis*-isomer of compound (XXI) is accompanied by the opening of the three-membered ring with formation of compound (XXII) as an intermediate [with the *trans*-configurations at C(1) and C(2)], whose subsequent cyclisation yields only 8β-methyl-*trans*-1-thiadecalin (XIX) (in 90% yield).



cis-(XXI) (XXII) (XIX);

(XXIII) (XVII);

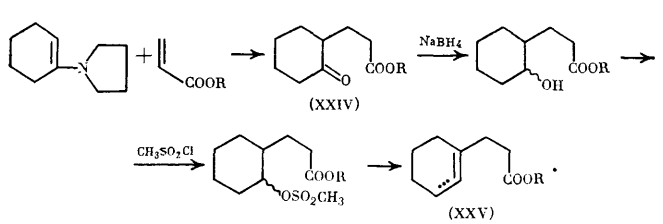
trans-(XXI) (XVIII).

If a mixture of the *cis*- and *trans*-isomers of compound (XXI) (38 and 62% respectively) is used in the reaction, then the same thiadecalin (XIX) (63%) is obtained as the main product after cyclisation despite the fact that *trans*-(XXI) predominated in the initial mixture. By virtue of its greater stability, *trans*-(XXI) reacts with allylmagnesium bromide only partially and only two products, (XVII) and (XVIII), are formed from it in comparable amounts (11 and 13%). The attack on the preferred conformer of *trans*-(XXI), leading to compound (XVII), is probably difficult for steric reasons.[25]

The *trans*-1-thiadecalins (XIII) and (XIV), arising in the cyclisation of the corresponding mercaptans, have been detected in proportions of 1:30, which can be accounted for by the addition of the thiol to the double bond in the *trans*-position in the usual manner.[25]

5. The *cis*- and *trans*-1-Thiadecalins derived from 3-(2-Oxocyclohexyl)propionates

Method (a). It is known[26] that the condensation of pyrrolidinocyclohexenes with acrylates leads to 3-(2-oxocyclohexyl)propionates (XXIV), which can be converted into the isomeric 3-cyclohex-1-enyl or 3-cyclohex-2-enyl propionates (XXV):[25,27,28]

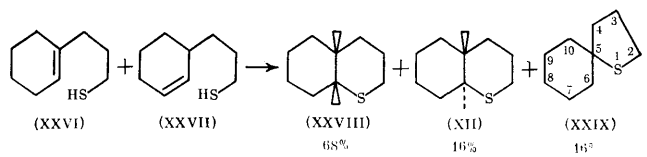


(XXIV)

(XXV)

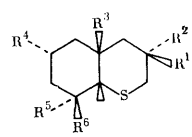
The latter are converted into 1- and 3-(3-mercaptopropyl)-cyclohexenes in accordance with the scheme[14,25]

The radical heterocyclisation of (3-mercaptopropyl)cyclohexenes (XXVI) and (XXVII) takes place preferentially with formation of *cis*-1-thiadecalins.[21] Thus, on heating with azobisisobutyronitrile in benzene, compounds (XXVI) and (XXVII) give rise to mixtures of *cis*-1-thiadecalin (XXVIII) (68%), *trans*-1-thiadecalin (XII) (16%), and 1-thia-spiro[4.5]-decane (XXIX) (16%). The predominance of the *cis*-1-thiadecalin (XXVIII) in the mixture is associated with the fact that the thioradicals add to cyclohexenes preferentially with formation of axially substituted thiacyclohexanes:[14,25,26,29]



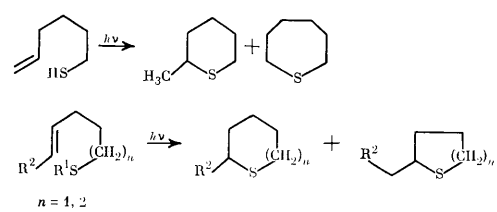
(XXVI) (XXVII) (XXVIII) 68% (XII) 16% (XXIX) 16%.

The mixtures of the products (XII), (XXVIII), and (XXIX) were separated by precipitation and recrystallisation of the complexes with $HgCl_2$ and by preparative gas–liquid chromatography (GLC). The configurations of the products were determined with the aid of ^1H and ^{13}C NMR. The 3-, 6-, 8-, and 10-monomethyl-*cis*-1-thiadecalins (XXX)–(XXXV) were isolated and characterised in this way.[25]



(XXVIII) all R = H; (XXX) $R^1 = 3\beta\text{-}CH_3$; (XXXI) $R^2 = 3\alpha\text{-}CH_3$; (XXXII) $R^3 = 10\text{-}CH_3$; (XXXIII) $R^4 = 6\alpha\text{-}CH_3$; (XXXIV) $R^5 = 8\alpha\text{-}CH_3$; (XXXV) $R^6 = 8\beta\text{-}CH_3$.

The formation of condensed thiepans can be expected in this reaction on the grounds that the photochemical cyclisation of unsaturated acyclic mercaptans or sulphides yields five-, six-, and seven-membered thiacycloalkanes:[30,31]

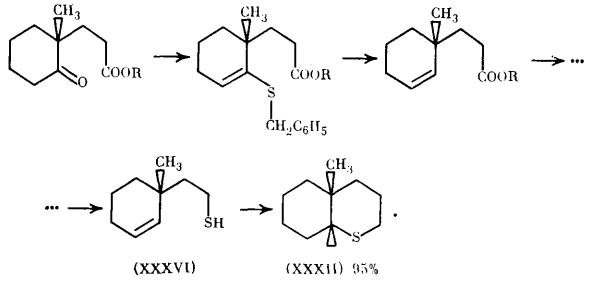


$n = 1, 2$

However, condensed thiepans were not isolated in the above reaction, which can be accounted for by the high steric requirements of the latter.[25]

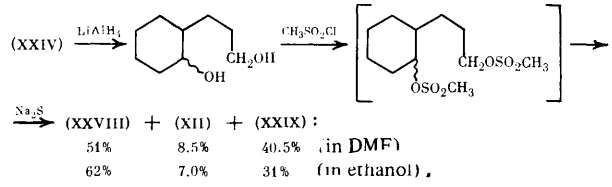
Method (b). A method described previously for 4-thia-5β-cholestanes has been used successfully in the synthesis of 10-methyl-*cis*-1-thiadecalin (XXXII).[14] 3-(1-Methyl-2-oxocyclohexyl)propionate is converted into the *S*-benzyl derivative of the thioenol by heating with benzylmercaptan in benzene. Subsequent desulphurisation of the *S*-benzyl derivative of the thioenol on activated Raney nickel leads to 3-(1-methyl-2-cyclohexenyl)propionate, which, as shown above, is subsequently converted in four stages into the

mercaptan (XXXVI) and is cyclised in the presence of azobisisobutyronitrile into 10-methyl-*cis*-1-thiadecalin (XXXII):[25]



(XXXVI) (XXXII) 95%

Method (c). The reduction of 3-(2-oxocyclohexyl)propionate (XXIV) with lithium aluminium hydride affords a mixture of the *cis*- and *trans*-diols which are treated with methanesulphonyl chloride and are converted, without isolating the bismethanesulphonates, into the *cis*- and *trans*-1-thiadecalins (XXVIII) and (XII) by heating with sodium sulphide in DMF or 50% methanol.[25] This makes it possible to reduce the number of intermediate stages:



(XXIV) → (XXVIII) + (XII) + (XXIX):

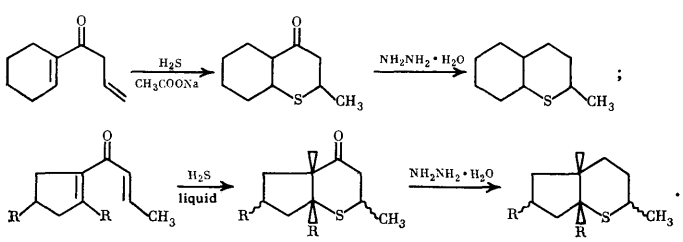
51%	8.5%	40.5%	(in DMF)
62%	7.0%	31%	(in ethanol).

1-Thiaspiro[4.5]decane (XXIX) is formed as a side product in a considerable amount. The methyl-substituted 3-(2-oxocyclohexyl)propionates behave analogously.[25]

The preferential formation of *cis*-1-thiadecalins and spirans of the type of compounds (XXVIII) and (XXIX) in the reaction considered is caused by the ready elimination of the axial methanesulphonyl group with subsequent addition of the mercapto-group to the double bond formed. The overall result of the reaction is very close to that obtained in the cyclisation of 3-(3-mercaptopropyl)cyclohexenes [see methods (a) and (b)].

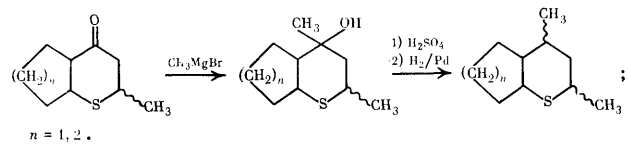
6. 2-Methyl-1-Thiadecalins derived from 2-Methyl-1-Thia-4-Decalones

The initial 2-methyl-1-thia-4-decalones can be synthesised by the familiar reaction of ketodienes with hydrogen sulphide.[32–34] A mixture of the isomers of 2-methyl-1-thia-4-decalone is formed from 1-(3-butenoyl)cyclohexene and hydrogen sulphide in the presence of sodium acetate.[35,36] The keto-group in the thiadecalones can be reduced by hydrazine hydrate with formation of 2-methyl-1-thiadecalins as a mixture of stereoisomers, which is a significant disadvantage of the method as a whole.[37–39] A mixture of the four isomeric 2-methylthiadecalins were separated chromatographically.[39]



2-Thiabicyclo[4.3.0]nonanes are obtained in accordance with an analogous scheme from the corresponding cyclopentene derivatives.[37,38] The cyclisation of ketodienes containing the planar cyclopentane ring proceeds with more difficulty and the introduction of the methyl group into the five-membered ring gives rise to additional steric hindrance. The reaction can be achieved after a considerable increase of the hydrogen sulphide concentration, which is attained by employing liquid hydrogen sulphide. The formation of derivatives of the *trans*-series in the form of five-membered derivatives is virtually ruled out.[37]

The interaction of the above ketosulphides with Grignard reagents makes it possible to synthesise 2,4-dialkyl-2-thiabicycloalkenes:[40]

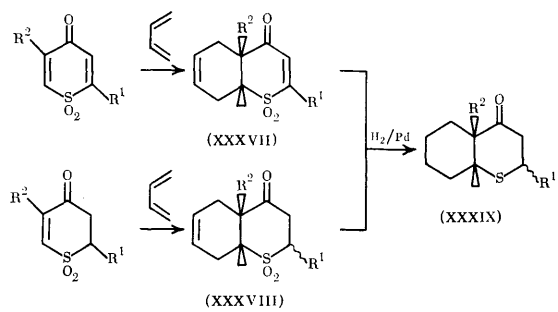


$n = 1, 2$.

Mixtures of 2-thiabicycloalkenes containing the double bond in the α-, β-, and γ-positions relative to the heteroatom are formed from cyclic carbinols on dehydration with sulphuric acid. It has been noted that the hydrogenation of these 2-thiabicycloalkenes in the presence of 5% Pd/C at 50 °C and a hydrogen pressure of 50–70 atm proceeds with difficulty and does not go to completion.[40,41]

7. The Diels–Alder Condensation of Thiopyrone and Dihydrothiopyrone Sulphones with Dienes

The Diels–Alder reaction of 4-thiopyrone and 2,3-dihydro-4-thiopyrone 1,1-dioxides with butadiene constitutes a convenient method of synthesis of the thermodynamically less stable *cis*-isomers. The condensation of 4-thiopyrone 1,1-dioxide with butadiene proceeds slowly even at room temperature, while on heating in an autoclave at 100 °C in dioxan it gives rise to 5,8,9,10-tetrahydrothiochroman-4-one 1,1-dioxide in 40% yield.[42] This method was later employed in other investigations.[36,43] Thus the corresponding oxosulphones (XXXVII) have been obtained from 2-methyl- and 2,5-dimethyl-4-thiopyrone 1,1-dioxides and butadiene. 2,5-Dimethyldihydrothiopyran-4-one 1,1-dioxide gives rise to a mixture of the stereoisomeric products (XXXVIII) differing in the position of the CH_3 group at C(2).[36] 2,3-Dihydrothiopyran-4-one 1,1-dioxide reacts with butadiene in benzene to form the condensation product in quantitative yield:[43]

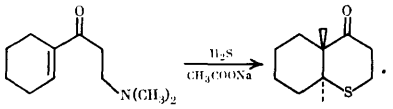


(XXXVII) (XXXVIII) (XXXIX)

The bicyclic sulphones obtained give rise to mixtures of stereoisomers (XXXIX) on reduction in the presence of palladium in dioxan or platinum in an acid medium, incomplete reduction of the keto-group to the hydroxy-group being observed in the latter case.[36] In the presence of acids, the *cis*-isomers of the oxosulphones ($R^2 = H$) isomerise to the corresponding *trans*-isomers as a result of inversion at the C(10) atom in the enolisation process.[43]

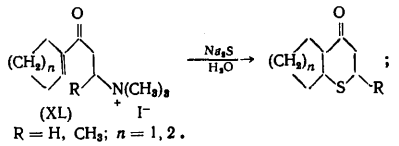
8. Thia-4-Decalones and 2-Thiabicyclo[4.3.0]-5-Nonanones Derived from 1-(3-Dimethylaminopropanoyl)cycloalkenes and Their Methiodides

On reaction with hydrogen sulphide in the presence of sodium acetate and subsequent heat treatment, 1-(3-dimethylaminopropanoyl)cyclohexene cyclises to form *trans*-1-thia-4-decalone (in 50% yield):[44]



1-(3-Dimethylaminobutanoyl)cyclohexene reacts analogously with hydrogen sulphide to form up to 78% of 2-methyl-1-thia-4-decalone.[44]

It has been shown[45] that the methiodides (XL) can be used instead of the Mannich bases. On heating to 50–60 °C in an atmosphere of nitrogen in the presence of sodium sulphide in an aqueous medium, these compounds are converted into 1-thia-4-decalones or 2-thiabicyclo[4.3.0]-5-nonanones:[45]

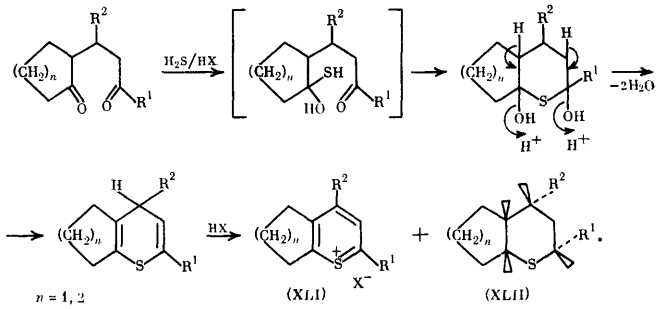


R = H, CH_3; $n = 1, 2$.

The configuration has been assigned[44,45] only for *trans*-1-thia-4-decalone.

9. Aryl-Substituted *cis*-1-Thiadecalins and 2-Thiabicyclo-[4.3.0]Nonanes

(a) *Synthesis from 1-aryl- and 1,3-diaryl-3-(2-oxocycloalkyl)-1-propanones.* The configurationally and conformationally homogeneous aryl-substituted *cis*-1-thiadecalins and 2-thiabicyclo[4.3.0]nonanes have become available as a result of the reaction of 1-aryl- and 1,3-diaryl-3-(2-oxocycloalkyl)-1-propanones with hydrogen sulphide in acid media.[46–49] On interaction with hydrogen sulphide in the presence of acids at room temperature, the 1,5-diketones ($R^1 = Ar$) undergo heterocyclisation with formation of condensed 4*H*-thiopyrans as intermediates. On treatment with protic acids (fluoroboric,[46] hydrobromic,[47,48] hydrochloric,[48] and trifluoroacetic[49]), the latter disproportionate to form the corresponding 2-aryl-5,6-polymethylenethiopyrylium salts (XLI) and 3-aryl-2-thiabicyclo[4.3.0]nonanes or 2-aryl-*cis*-1-thiadecalins (XLII, $R^1 = C_6H_5$ or $C_6H_4OCH_3$-4; $R^2 = H$; $n = 1$ or 2) in proportions of 2:1.

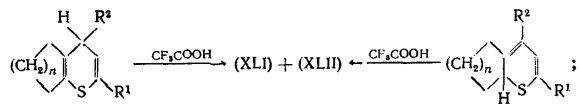


Diaryl-substituted 2-thiabicyclo[4.3.0]nonanes and *cis*-1-thiadecalins ($R^1 = C_6H_5$ or $C_6H_4OCH_3$-4; $R^2 = C_6H_5$ or $C_6H_4OCH_3$-4; $n = 1$ or 2) can be obtained from the corresponding 1,5-diketones only in trifluoroacetic acid, which functions simultaneously as the solvent and a reactant in the above reaction.[49] Complete disproportionation of the intermediate 2,4-diaryl-5,6-polymethylene-4*H*-thiopyrans is not observed in the presence of the other acids enumerated and 3,5-diaryl-2-thiabicycloalkenes, in which an angular double bond is retained, are isolated as the reaction products together with the salts.[47,48]

It has been established by ^1H and ^{13}C NMR that *cis*-1-thiadecalins having the 2α-R^1-4α-R^2-configuration are formed.[50,51] It may be that the aryl-substituted 2-thiabicyclo[4.3.0]nonanes obtained by the same method have the same configuration. Despite the fact that the yields of the required products do not exceed 30%, the presence of only one stage and stereospecificity are undoubted advantages of the method.

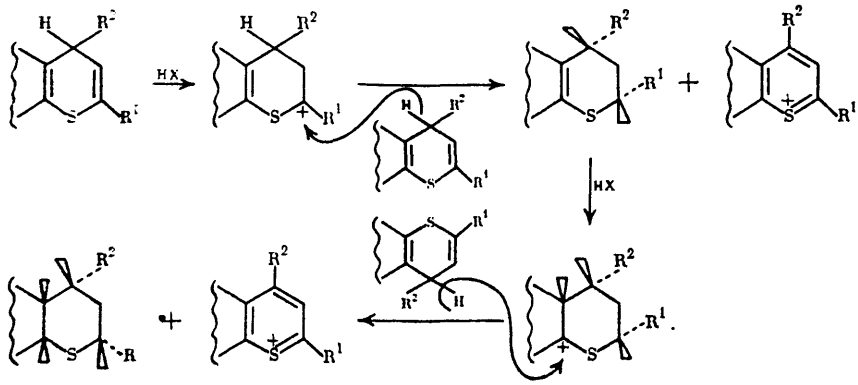
(b) *Disproportionation of 5,6-polymethylene-4H(6H)-thiopyrans and 2-thiabicycloalkenes.* The disproportionation of 5,6-polymethylene-4*H*(6*H*)-thiopyrans as a method of synthesis of condensed thiacyclohexanes can be of independent importance, since the initial compounds of the type stated can be obtained in reactions of 1,5-diketones with hydrogen sulphide in ethanol under the catalytic influence of hydrogen chloride[52] and from 5,6-polymethylenethiopyrylium salts on interaction with Grignard reagents[53] or on reduction with lithium aluminium hydride.[54,55]

2-Aryl and 2-aryl-4R-5,6-polymethylene-4*H*(6*H*)-thiopyrans disproportionate into the trifluoroacetates (XLI) and the thiacyclohexanes (XLII) in the presence of trifluoroacetic acid, which is an effective protonating and solvating agent:[51,56]



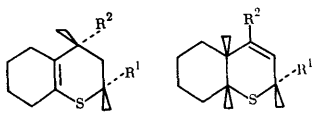
$R^1 = C_6H_5$, $C_6H_4OCH_3$-4; $R^2 = H$, C_6H_5, $C_6H_4OCH_3$-4, $C_6H_3(OCH_3)_2$-3,4, CH_3, C_2H_5, $CH_2C_6H_5$; $n = 1, 2$; $X^- = CF_3COO^-$

Thiadecalins and 2-thiabicyclo[4.3.0]nonanes arise in this reaction as a result of the ionic reduction of thiopyran with participation of a protic acid and with intermolecular transfer of a hydride ion from another thiopyran molecule to the tertiary carbonium ion generated following the protonation of the double bond of the heterocycle, as shown in the scheme below:[49,56]



The sterically less hindered double bond in the 2,3-position is reduced first in 4*H*-thiopyrans and this is followed by the reduction of the angular double bond. The same *cis*-1-thiadecalins or 2-thiabicyclo[4.4.0]nonanes are obtained from the 6*H*-isomers as from the 4*H*-isomers. The mechanism of the disproportionation of the 6*H*-isomers has been described.[56]

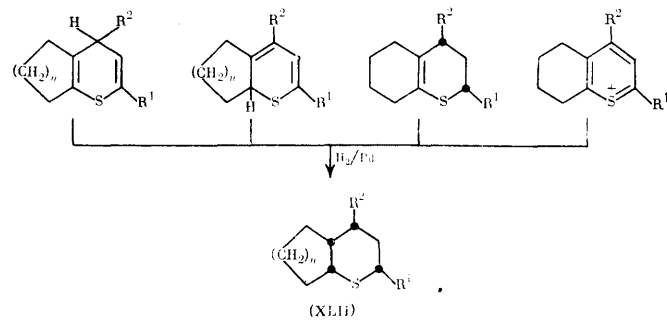
The degree of disproportionation of 5,6-polymethylene-4*H*(6*H*)-thiopyrans depends on the degree of their substitution and the nature of the protic acid. The reduction of only one double bond of the heterocycle with formation of thiabicycloalkenes is observed for the 2,4-diaryl-substituted derivatives in reactions with perchloric, hydrochloric, hydrobromic, and fluoroboric acids.[48,54]



By virtue of the hydride mobility of the α-hydrogen atoms, the condensed dihydrothiopyrans obtained in this way can also disproportionate on refluxing in trifluoroacetic acid, producing thereby thiopyrylium salts and thiacyclohexanes in proportions of 1 : 2.[57,58]

(c) *The ionic hydrogenation of 5,6-polymethylene-4H(6H)-thiopyrans and 2-thiabicyclo[4.4.0]decanes.* The reduction of the above bicyclic sulphides with trifluoroacetic acid and triethylsilane with sulphide : silane : acid ratios of 1 : 3 : 5 makes it possible to synthesise quantitatively 2α-R^1-4α-R^2-*cis*-1-thiadecalin (XLII).[51] Like disproportionation, the ionic reduction of 5,6-polymethylene-4*H*(6*H*)-thiopyrans and 2-thiabicycloalkenes gives rise to 2-thiabicycloalkanes having exclusively the *cis,cis,cis*-configuration.

(d) *The liquid-phase hydrogenation of condensed 4H(6H)-thiopyrans, dihydrothiopyrans, thiopyrylium salts, and 4H-thiopyran 1,1-dioxides.* Aryl-substituted 1-thiadecalins and 2-thiabicyclononanes of type (XLII) are formed on hydrogenation of the corresponding unsaturated heterocyclic compounds in the presence of 10% Pd/C. The *cis*-addition of hydrogen to the multiple bonds has been noted:



(XLII)

Thiopyrans and dihydrothiopyrans are hydrogenated at 100 °C at an initial hydrogen pressure of 50 atm,[48,49] while the reduction of 2,4-diphenyl-5,6-tetramethylenethiopyrylium tetrafluoroborate requires more severe conditions (a temperature of 100 °C and a hydrogen pressure of 100 atm).[60] The yields of the thiacyclohexanes (XLII) obtained from thiopyrans and dihydrothiopyrans are 75–80%, while the yields of the same compounds derived from 5,6-polymethylenethiopyrylium salts are 60%.

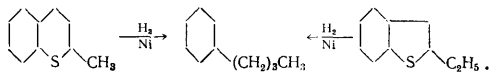
The hydrogenation of 5-oxo-2,4-diphenyl-5,6,7,8-tetrahydrothiochromene and 2,4-diphenyl-5,6-tetramethylene-4*H*-thiopyran 1,1-dioxide under the same conditions (100 °C, 50 atm) in the presence of 10% Pd/C involves the reduction of only the double bonds of the heterocycle, while the sulphonyl and carbonyl groups are unaffected.[61,62]

III. STRUCTURE AND PROPERTIES

The complexes with mercury(II) chloride, sulphoxides, sulphones, sulphimides, sulphonium salts, and ylides constitute the traditional list of derivatives of open-chain sulphides or saturated cyclic sulphides. The properties of condensed thiacyclohexanes have much in common with those

of the sulphides but any chemical reactions are very intimately related with the stereochemistry of these interesting systems. The stereochemical aspects of their study has in fact assumed a special importance in recent times.

The desulphurisation reaction in the presence of Raney nickel, which is widely used in the study of sulphides of of petroleum origin, has found hardly any applications in the chemistry of condensed thiacyclohexanes, namely as a result of the complexity of the system and the development of modern methods (^{1}H and ^{13}C NMR). The desulphurisation of condensed cyclic sulphides frequently does not even allow a conclusion concerning the size of the heterocycle[2] let alone the stereochemical features of the structure:



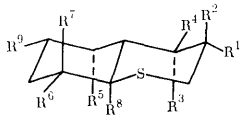
1. Complexes with Bivalent Mercury Salts

Another reaction, which has long been regarded as traditional in the study of sulphides, involves interaction with mercury salts and is used to isolate and identify thiacyclohexanes. Complexes of *cis*- and *trans*-1-thiadecalins, their alkyl derivatives, and 2-thiabicyclo[4.3.0]nonane with mercury(II) chloride, having the composition $R_2S.HgCl_2$, have been described.[21,22,24,25]

2. The Stereochemistry of *cis*- and *trans*-1-Thiadecalins

The study of the ^{13}C and ^{1}H NMR spectra of a large number of unsubstituted and methyl-substituted *cis*- and *trans*-1-thiadecalins permitted configurational and conformational assignments.[63] The signals were assigned by the method of double resonance, the parametrisation of the effects of substituents, and comparison with C- and N-analogues. The thiadecalins investigated were synthesised as described by Claus and Vierhapper.[25]

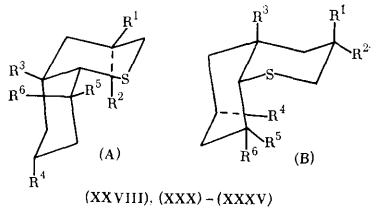
trans-1-Thiadecalins (XII)–(XX) are conformationally rigid systems for which ring inversion is ruled out. The nine expected signals have been detected in the ^{13}C NMR spectrum of *trans*-1-thiadecalin (XII). Analogous data have been obtained for methyl-substituted *trans*-1-thiadecalins. Without dwelling on the discussion of the spectra, which can be found in another communication,[63] one should note that the signals of the axial methyl groups in the spectra of the sulphides are to higher field than those of the equatorial CH_3 group. The lowest-field signals correspond to the C(9) and C(10) atoms.



(XII) – (XX)

Table 1 presents the parameters of the ^{13}C NMR spectra of unsubstituted *cis*- and *trans*-thiadecalins and some of their derivatives.[63,67,69,81,92]

At 30 °C the *cis*-1-thiadecalin (XXVIII) undergoes slow inversion, as shown by the broadening of five of the nine signals in the ^{13}C NMR spectrum. Two groups of signals are observed in the spectrum at −70 °C and can be assigned to conformers (A) and (B) (in proportions of 58:42).[63]

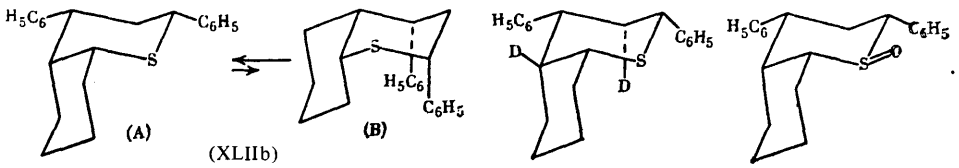


(XXVIII), (XXX) – (XXXV)

The ^{13}C NMR spectra of methyl-substituted *cis*-1-thiadecalins, namely the 3β-CH_3-derivative (XXX), the 10-CH_3-derivative (XXXII), and the 8β-CH_3-derivative (XXXV), also indicated the presence of two conformers. The conformational equilibrium has been investigated by low-temperature ^{13}C NMR.[63] Table 2 lists the ratios of the conformers, the equilibrium constants K, and the free energy differences ΔG^0.

The 3α-CH_3-derivative (XXXI), the 6α-CH_3-derivative (XXXIII), and the 8α-CH_3-derivative (XXXIV) of *cis*-1-thiadecalin are conformationally homogeneous at room temperature, the first existing in the (B) conformation and the other two in the (A) conformation, in which the *syn*-axial interactions between the substituent and the methylene groups of the ring have been reduced to a minimum. For example, the (B) conformation is ruled out for the sulphide (XXXIV) by two *syn*-axial interactions of the CH_3 group with C(2) and C(4); in contrast to this, in the (A) conformation there is only one *gauche*-interaction of the CH_3 group in the heteroatom.

The configurational and conformational assignments for 2,4-diphenyl-1-thiadecalin, obtained as described in a number of communications,[49,56,59] have been made on the basis of the ^{1}H NMR study (80 MHz) of the disulphide itself, its 3,10-dideuterio-derivative, and the 1-oxide in the presence of $Eu(dpm)_3$.[50] It has been established that the disulphide has the *cis,cis,cis*-configuration and exists in the (A) conformation owing to the destabilisation of the other conformer by the *syn*-axial interaction of the phenyl groups with one another and with C(6) and C(8).



(XLIIb)

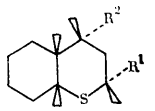
*β denotes that the substituent is located on the same side of the ring as the carbon atom at C(10) and α denotes that it is located on the opposite side of the ring relative to the hydrogen atom at C(10).
**The chemical shifts whose assignment is tentative are given in brackets.

In order to establish the configurations and preferential conformations, a study has been made of the ^{13}C NMR spectra at room temperature for 2-aryl- and 2,4-diaryl-1-thiadecalins (XLII) obtained in the disproportionation reactions and as a result of the ionic hydrogenation of condensed 2-aryl- and 2,4-diaryl-5,6-tetramethylene-4*H*(6*H*)-thiopyrans and the corresponding dihydrothiopyrans and also as a result of their hydrogenation. The signals were assigned with the

aid of spectra with incomplete decoupling from the protons and by comparing the experimental and theoretical spectra; the latter were calculated using the known parameters of the ^{13}C NMR spectra of unsubstituted *cis*- and *trans*-1-thiadecalins[63] and the increments for the equatorial phenyl group in the substituted cyclohexane.[64]



(XLII)

(a) $R^1 = C_6H_5$, $R^2 = H$; (b) $R^1 = R^2 = C_6H_5$; (c) $R^1 = C_6H_5$, $R^2 = C_6H_3OCH_3$-4; (d) $R^1 = C_6H_3OCH_3$-4, $R^2 = C_6H_5$; (e) $R^1 = C_6H_5$, $R^2 = C_6H_3(OCH_3)_2$-3,4

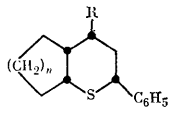
Table 2. Conformational transitions in mobile *cis*-1-thiadecalins*.[63]

Compound	(A), %	(B), %	K	ΔG^0, kcal mol^{-1}
cis-1-Thiadecalin (XXVIII)	58	42	1.4	+0.14
3β-Methyl-*cis*-1-thiadecalin (XXX)	95	5	19	+1.2
10-Methyl-*cis*-1-thiadecalin (XXXII)	33	67	0.49	−0.29
8β-Methyl-*cis*-1-thiadecalin (XXXV)	17	83	0.23	−0.65

*In $CHCl_3$ at −68 °C.

Compounds (XLII, a–e) belong to the *cis*-1-thiadecalin series. They all have the 2α-R^1-4α-R^2-configuration at C(2) and C(4) and are distinguished by a conformational rigidity, as already noted above for the sulphide (XLIIb).[50,51]

The dipole moments of certain aryl-substituted *cis*-1-thiadecalins (XLII, a, b, and e) and also 2-thiabicyclo[4.3.0]-nonanes (XLIIf, R = H) and (XLIIg, R = C_6H_5), measured by the Debye method in benzene at 20 °C, have been published.[65] The dipole moments vary from 1.51–1.96 D:



(XLII, a, b, e–g)

R	n	μ, D	n	μ, D
H	1	1.63	2	1.91
C_6H_5	1	1.51	2	1.82
$C_6H_3(OCH_3)_2$-3,4	—	—	2	1.96

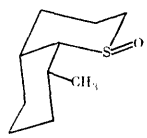
The scheme shows that the dipole moments of the corresponding 2-thiabicyclo [4.3.0]nonanes are smaller by 0.28–0.31 D than those of the *cis*-1-thiadecalins with the same substituents. On the other hand, a slight decrease (0.008 D) has been noted on passing from saturated systems to 5,6-polymethylene-4*H*-thiopyrans, which may be an indication of the equatorial position of the substituent. This is consistent with the structure of the aryl-substituted *cis*-1-thiadecalins (XLII, a–e) (with the aryl group in the equatorial position) and suggests that the aryl-substituted 2-thiabicyclo[4.3.0]nonanes have an analogous structure.

3. Sulphones and Sulphoxides

(a) *Methods of synthesis.* Certain sulphones have already been described above in the discussion of the methods of synthesis, since their formation uses sulphonyl-containing compounds as the starting materials for the synthesis of the heterocyclic system. The oxidation of condensed thiacyclohexanes, like that of thianes, results in the formation of *S*-oxides or, in the presence of an excess of the oxidant, of *SS*-dioxides. The oxidants employed are hydrogen peroxide,[21,22,24,38,66] *m*-chloroperbenzoic acid,[25,67] and t-pentyl hydroperoxide in the presence of MoCl or $Mo(CO)_6$.[68] The sulphones of 1-thiadecalin,[21,69] 4-methyl-1-thiadecalin,[22] 2-thiabicyclo[4.3.0]nonane,[24] 4-hydroxy-2-methyl-1-thiadecalin,[68] 2-methyl-1-thiadecalin,[68] 3-aryl- and 3,5-diaryl-2-thiabicyclo[4.3.0]nonanes,[59] and 2-aryl- and 2,4-diaryl-*cis*-1-thiadecalins[59] and the sulphoxides of 2-methyl-1-thiadecalins,[38,68] 6-methyl- and 8-methyl-*cis*-1-thiadecalins,[25] and 2-aryl- and 2,4-diaryl-*cis*-thiadecalins[49] have been described in the literature.

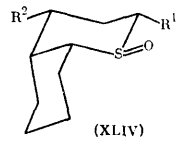
The sulphoxides with the α- and β-configurations are obtained in 55% yield by the oxidation of *trans*-1-decalin with a calculated amount of *m*-chloroperbenzoic acid.[69] A 79 : 21 mixture of the diastereoisomeric *cis*-1-thiadecalin 1-oxides with the α- and β-configurations is formed under identical conditions. The pure *cis*-1-thiadecalin 1β-oxide has been isolated by crystallising the crude product from an ether–petroleum ether mixture (yield 56%).[67]

The oxidation with *m*-chloroperbenzoic acid of the conformationally rigid 6α-methyl-*cis*-1-thiadecalin (XXXIII) and 8α-methyl-*cis*-1-thiadecalin (XXXIV), which exist in the (A) conformation,[63] leads solely to the β-sulphoxides in yields up to 90%, while the formation of the α-sulphoxides is ruled out by the powerful *syn*-axial interaction,[25,63] for example:



(XLIII) $S\alpha-CH_3$.

The formation of the sulphoxide having the β-configuration (with an equatorial S–O bond) is observed in the oxidation of the conformationally rigid 2α, 4α-diphenyl-*cis*-1-thiadecalin (XLIIb) with a calculated amount of hydrogen peroxide.[50] The sulphoxides (XLIV, a–d) have been obtained analogously and, although the configuration of the sulphur atom has not been assigned, one can state with confidence that the sulphinyl group in these compounds is equatorial:[49]

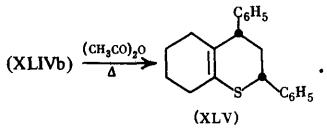


(XLIV)

(a) $R^1 = C_6H_5$, $R^2 = H$; (b) $R^1 = R^2 = C_6H_5$; (c) $R^1 = C_6H_5$, $R^2 = C_6H_4OCH_3$-4; (d) $R^1 = C_6H_4OCH_3$-4, $R^2 = C_6H_5$.

(b) *The Pummerer rearrangement.* Refluxing of 2α, 4α-diphenyl-*cis*-1-thiadecalin 1-oxide (XLIVb) in acetic anhydride under the conditions of the Pummerer reaction

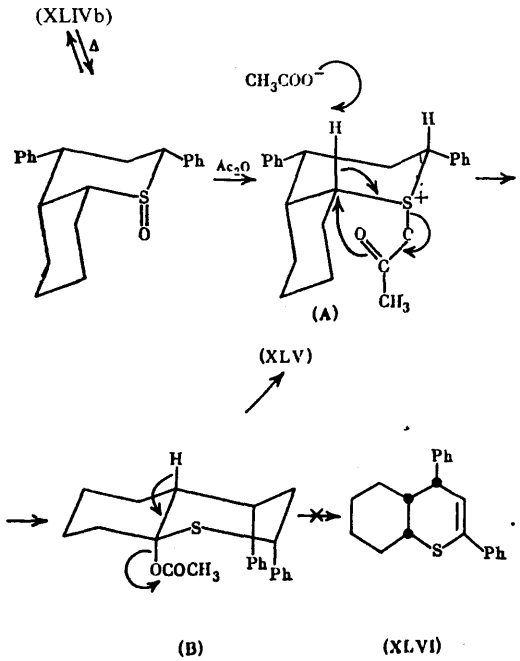
leads to the formation of *cis*-3,5-diphenyl-2-thiabicyclo[4.4.0]-$\Delta^{1,6}$-decane (XLV) as the product of the rearrangement: [70]



(XLV)

The structure of the sulphide (XLV) has been established by X-ray diffraction analysis (XDA). Both phenyl substituents occupy equatorial positions. Both rings have the distorted half-chair conformation. [70]

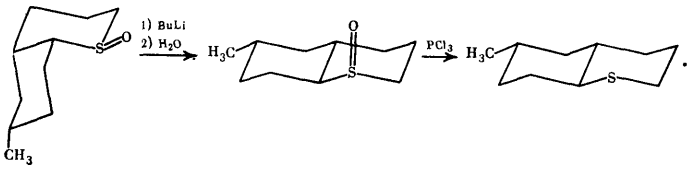
According to the generally accepted mechanism of the rearrangement of acyclic sulphoxides, the second of the two stages (*O*-acylation and deprotonation) is rate-limiting, the ylide formed being stabilised by the 3*d* orbital of the sulphur atom and being attacked by an external acetate anion. Despite the more acid character of the hydrogen atom at C(2) in the onium intermediate (A), the formation of *cis*,*cis*-3,5-diphenyl-2-thiabicyclo[4.4.0]dec-3-ene (XLVI) is not observed in the rearrangement of the sulphoxide (XLIVb):



This justifies the hypothesis that the rearrangement of the onium intermediate (A) to the 9-acetoxy-derivative (B) probably proceeds intramolecularly, as shown in the scheme, and leads to the final product (XLV) via *trans*-elimination. The absence of the isomer (XLVI) from the reaction products shows that the substituents at C(2) offers steric hindrance to the formation of the 2-acetoxy-derivative and hence of the isomer (XLVI).

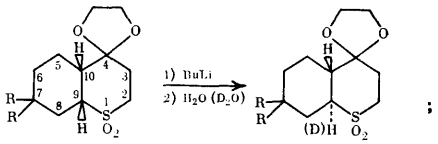
3-Methyl-2-thiabicyclo[4.4.0]dec-3-ene has been obtained under the conditions of the Pummerer rearrangement from a mixture of the four isomeric 2-methyl-1-thiadecalin 1-oxides, with 2β-methyl-*trans*-1-thiadecalins 1-oxide (89%) and 2α-methyl-*trans*-1-thiadecalin 1-oxide (7%) predominating, which should also be accounted for by the sensitivity of the reaction to steric factors. [71]

(c) *The CH-acid properties of sulphones and sulphoxides.* The *cis*,*trans*-isomerisation of sulphones and sulphoxides in the presence of BuLi and the subsequent reduction of the SO group by PCl_3 are used to obtain, for example, 6α-methyl-*trans*-1-thiadecalin, which is obtained in a low yield by other methods: [25,63]

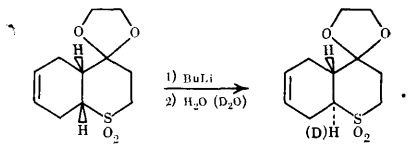


Calculations have shown that the *trans*-isomers of this sulphoxide are more stabel than the *cis*-isomers to the extent of 1.7 kcal mol^{-1}. [72] Their sulphoxide group is axial, as in thian 1-oxides. [73,74] Deuterio-derivatives, for example 9-methyl-*trans*-1-thiadecalin-2,2-d_2-1-oxide, can be obtained by the successive treatment of the sulphoxides with butyllithium and D_2O. [25]

The stereochemistry of the metallation of *cis*-sulphones (XLVIIa, R = H), (XLVIIb, $R_2 = OCH_2CH_2O$), and (XLVIII) by treatment with n-butyl-lithium in benzene at the normal temperature has been investigated. Hydrolysis of lithiosulphones leads to the *trans*-isomers (XLIX) and (L): [43,75]

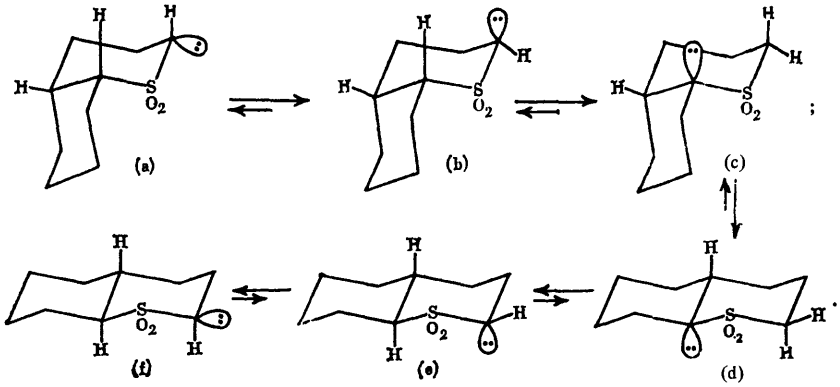


(XLVII a and b) (XLIX, a and b)



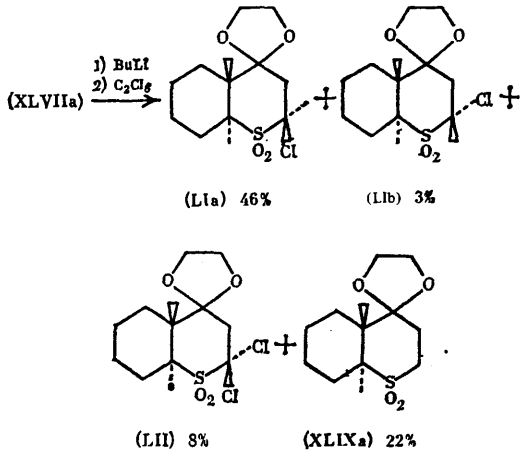
(XLVIII) (L)

The *cis*,*trans*-isomerisation, which involves the inversion of the configuration at C(9), is an intramolecular process, as shown by investigating the reaction using different reactant ratios. The structure of the final products has been confirmed by ^1H and ^{13}C NMR. It has been suggested, [43,75] that BuLi attacks the equatorial hydrogen atom at C(2), the α-sulphonyl carbanion (a) being in equilibrium with the anion (b) having the inverted configuration. Intramolecular proton transfer leads to the anion (c), which is converted into the anion (f) by proton shifts.



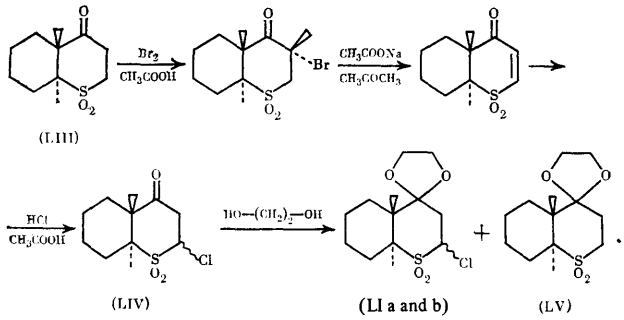
Refluxing of the sulphones (XLVII) and (XLVIII) with NaOD in a D_2O–dioxan mixture for 12 h yields trideuteriated sulphones with retention of the configuration at C(9), which can be explained by the short lifetime of the sulphonyl carbanion in a protic medium compared with the rate of inversion.[43] The mild conditions of the exchange (pH 8.5) in the experiment with the sulphone (XLVIIa) lead to the exchange of only the equatorial H(2) atom, which can be inferred from the disappearance of its signal (δ = 2.87) in the ^{1}H NMR spectrum. This is the first demonstration of a difference between the kinetic acidities of the equatorial and axial hydrogen atoms at C(2) in sulphones of type (XLVII).[43]

Chlorination of the lithiosulphonyl carbanions obtained from the *cis*-sulphone (XLVIIa) with hexachloroethane leads to a mixture of the *trans*-sulphones (LI, a and b), (LII), and (XLIXa). Products containing chlorine at C(9) were not detected:[75]



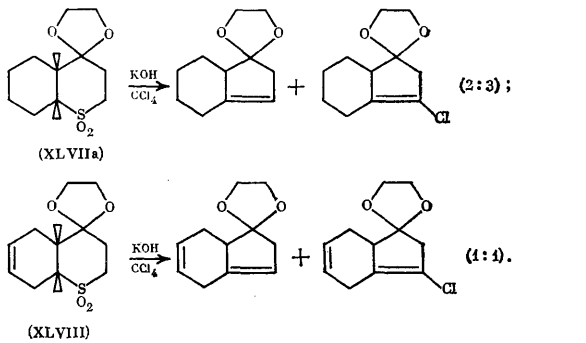
The sulphones (XLVIIb) and (XLVIII) behave analogously under the conditions indicated.

The *trans*-1-thiadecalone 1,1-dioxide (LIII) can be converted into the diastereoisomeric 2-chloro-*trans*-4-thiadecalone 1,1-dioxide (LIV) and further into the acetals (LI, a and b) in accordance with the scheme:



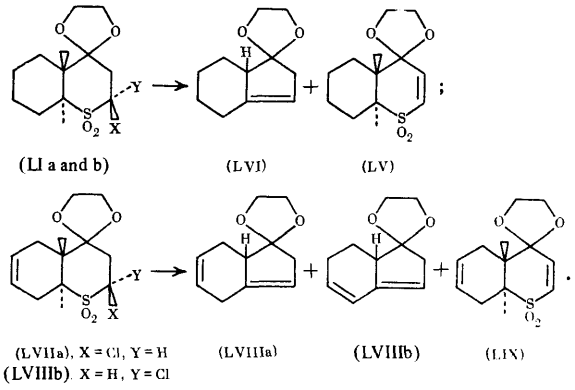
The chloro-derivatives (LI, a and b) are obtained in these reactions in low yields, which makes it preferable to halogenate the lithio-derivatives.[75] In addition, the formation of a considerable amount of the elimination products (LV) has been noted.

(d) *The Ramberg–Bäcklund reaction.* 4,4-Ethylenedioxy-*cis*-1-thiadecalin 1,1-dioxide (XLVIIa) and its unsaturated analogue (XLVIII) are converted via the Ramberg–Bäcklund reaction on treatment with KOH/CCl_4 into the acetals of hydrindenone and their chloro-derivatives:[76]



In the interaction of the α-halogenosulphones (LI, a and b) and (LVII) having the *trans*-configuration with potassium (sodium) t-butyloxide, the Ramberg–Bäcklund reaction can

compete with the 1,2-elimination of the hydrogen halide.[77] The more polar dimethyl sulphoxide (DMSO) favours the Ramberg–Bäcklund reaction while in the less polar dimethoxyethane (DME) the 1,2-elimination reaction predominates. It has been shown that the *trans*-sulphone (LVIIa) gives rise preferentially to the dienes (LVIIIa) and (LVIIIb), the latter as a result of the allyl rearrangement:[77]

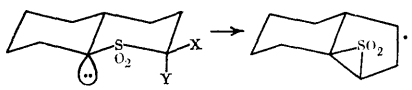


(LI a and b) (LVI) (LV)

(LVIIa), X = Cl, Y = H (LVIIIa) (LVIIIb) (LIX)
(LVIIIb), X = H, Y = Cl

The epimers of the *trans*-sulphones (LVII, a and b) behave differently in the reaction with potassium t-butoxide in DME: the isomer (LVIIa) with an equatorial halogen atom gives rise to the dienes (LVIII, a and b) while the isomer (LVIIb) with an axial halogen atom undergoes 1,2-elimination with formation of the vinyl sulphone (LIX).

It has been established[77] that the Ramberg–Bäcklund reaction, leading to an olefin, proceeds in the case of the *trans*-sulphones with the halogen in the equatorial position (X = Cl, Y = H) via the *Z*-episulphone (the sulphonyl group has the *Z*-configuration in relation to the angular hydrogen atom):

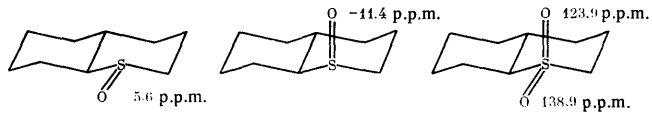


In conclusion one should note that the *cis*-configuration of the initial sulphone is more favourable for the Ramberg–Bäcklund reaction than the *trans*-configuration.[76,77]

(e) *The ^{13}C and ^{17}O NMR spectra of the sulphoxides and sulphones.* The study of the ^{13}C NMR spectrum of *cis*-1-thiadecalin 1β-oxide showed that it exists predominantly (to the extent of 65%) in the equatorial conformation.[67]

The ^{13}C NMR spectra of the 1α-oxide, 1β-oxide, and 1,1-dioxide of *trans*-1-thiadecalin have been described in a communication[69] which discusses the influence of the sulphinyl and sulphonyl groups on the chemical shifts of the carbon atoms (C_β and C_γ). The assignment of the signals to the axial and equatorial conformations of the diasteroisomeric sulphoxides has been based on the difference between the chemical shift of the C_β and C_γ atoms. Thus, of the two diastereoisomeric *trans*-1-thiadecalin 1-oxides, the isomers with the highest-field C_γ shift and the least low-field C_β shift have been assigned to the β-configuration (the S–O bond is axial) (Table 1). Compared with *trans*-1-thiadecalin, the introduction of the sulphonyl group into the molecule leads to the deshielding of the carbon atoms in the β-position [C(3) and C(9)], which can be explained by the influence of the inductive effect of the partially positively charged sulphur atom in the SO group and the β-effect of the oxygen substituent at the sulphur atom.[69]

The ^{17}O NMR spectra of the sulphoxides and the sulphone of *trans*-1-thiadecalin have been investigated. The β-isomer with the axial sulphinyl oxygen atom gives rise to a signal to a higher field than the α-isomer with an equatorial SO group ($\Delta\delta$ = 17 p.p.m.), which constitutes confirmation of the shielding by the γ-*gauche*-interaction with a CH_2 group:[78]

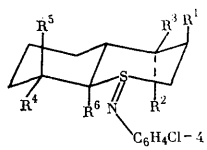


The scheme shows that the sulphonyl oxygen atoms are very highly deshielded compared with the sulphinyl oxygen atoms. The signal of the axial oxygen atom (δ = 123.9 p.p.m.) is in a higher field than the signal of the equatorial atom (δ = 138.9 p.p.m.).[78]

4. The *cis*- and *trans*-1-Thiadecalin 1-*N*-Arylimides

(a) *The synthesis of cis- and trans-1-thiadecalin 1-N-arylimides.* Sulphimides are a new class of thiadecalin derivatives. They can be regarded as isoelectronic analogues of sulphoxides. The methods of their synthesis, the mechanisms of their formation, and their structure and chemical properties have been described.[79–82] The reactions of the *cis*- and *trans*-1-thiadecalins with 4-chloroaniline and a slight excess of *N*-chlorosuccinimide (NCS) or t-butyl hypochlorite lead to the formation of the configurationally homogeneous crystalline *N*-4-chlorophenylsuphimides.[79,80] The sulphimides can be obtained also from the sulphoxides by treatment with P_2O_5 and 4-chloroaniline.[80] The configuration and the preferred conformation (in the case of mobile systems) in the series of *cis*- and *trans*-1-thiadecalin 1-*N*-4-chlorophenylimides have been determined by ^1H and ^{13}C NMR.[81]

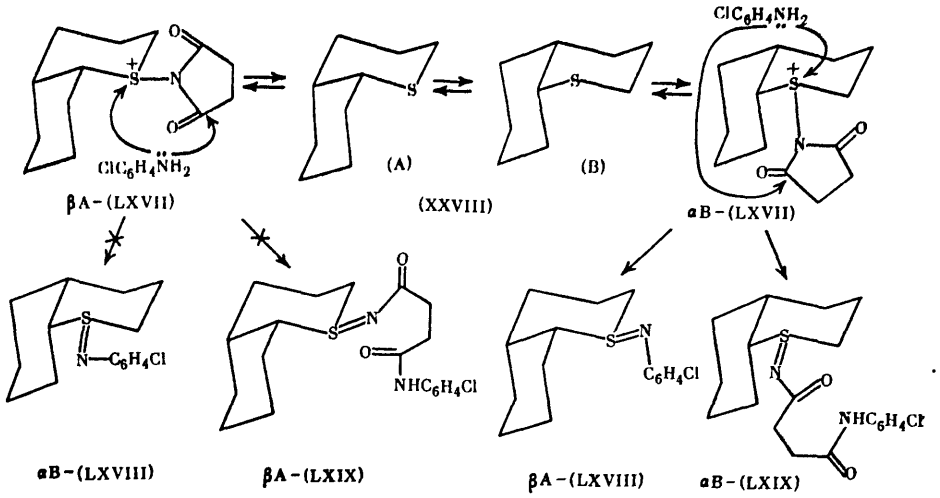
The sulphimides (LX)–(LXVI), having the α-configuration and an equatorial SN bond, have been found to form in the reactions of the *trans*-1-thiadecalins (XII), (XIV)–(XVI), and (XVIII)–(XX) with 4-chloroaniline and NCS or t-butyl hypochlorite.[79–80] The sulphimide α-(LXIV) has been obtained even from 8α-methyl-*trans*-1-thiadecalin (XVIII) despite the unfavourable mutual disposition of the equatorial methyl group and the SN bond.[80]



α-(LX) – α-(LXVI)

(LX): all R = H; (LXI): $R^1 = 3\beta\text{-}CH_3$; (LXII): $R^2 = 4\alpha\text{-}CH_3$; (LXIII): $R^3 = 4\beta\text{-}CH_3$; (LXIV): $R^4 = 8\alpha\text{-}CH_3$; (LXV): $R^5 = 8\beta\text{-}CH_3$; (LXVI): R^6 = 9-CH_3

The conformationally mobile *cis*-1-thiadecalin (XXVIII) reacts with 4-chloroaniline and NCS to form only the sulphimide β-(XLVIII), mainly in the (A) conformation, and the ring-opening product αB-(LXIX) with the α-configuration at the sulphur atom.[79,80] The proposed reaction mechanism is presented below taking into account the preferred conformations of the reaction products:

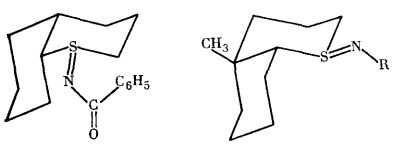


The corresponding succinimidylsulphonium chlorides are probably formed as intermediates. The substitution of the succinimidyl group in αB-(LXVII) by 4-chloroaniline takes place with inversion at the sulphur atom and leads to the sulphimide βA-(LXVIII); the product αB(LXIX) is formed from the same azasulphonium salt in a third reaction when the succinimidyl ring is opened as a result of attack on the carbonyl group, the configuration at the sulphur atom remaining unchanged.[80] The axial attack by 4-chloroaniline on the sulphur atom in the intermediate αB-(LXVII) may be facilitated by the capacity of the compound for inversion in the transition state.

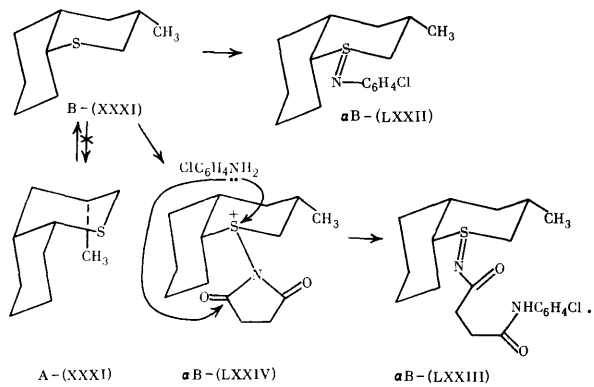
The absence of compounds αB-(LXVIII) and βA-(LXIX) from the reaction products has been explained[80] by the fact that the axial attack in the intermediate βA-(LXVII) should be hindered by the interaction with the methylene groups of the cyclohexane ring [C(5) and C(7)] and the counterion can also give rise to some hindrance. The hypothesis that azasulphonium salts may be formed in the reaction is based on the fact that the dimethyl sulphide and NCS give rise to a crystalline succinimidylsulphonium chloride.[83] Their formation is also indicated by open-chain products of the type of αB-(LXIX), which have been detected in amounts up to 30% in the analogous reactions of methyl-substituted *cis*-1-thiadecalins.

However, the results cannot be satisfactorily explained in terms of the mechanism described in all cases. Thus the reaction of *cis*-1-thiadecalin with *N*-bromobenzamide results in the formation of only benzoyl imide with the α-configuration [αB-(LXX)].

The reaction of 10-methyl-*cis*-1-thiadecalin with 4-chloroaniline/NCS or *N*-bromobenzamide yields in both cases the products (LXXI) with the β-configuration in the (A) conformation, although the initial sulphide itself exists in the (B) conformation to the extent of 67% (at −70 °C):[80]

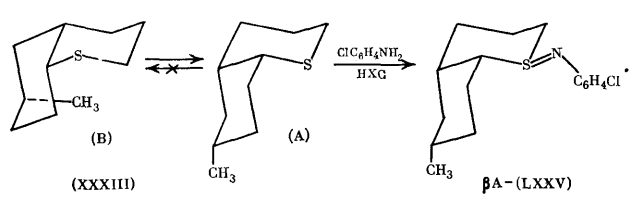


The analogous reaction of 3α-methyl-*cis*-1-thiadecalin (XXXI) led to the isolation of the imide αB-(LXXII) and the products of the ring opening in succinimide αB-(LXXIII) in high yields:[80]

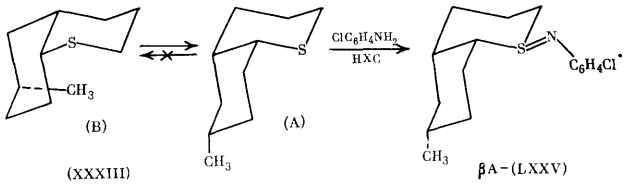


The axial attack on the intermediate αB-(LXXIV) should have led to the β-sulphimide in the (B) conformation with an axial SN bond, because ring inversion in the (A) conformation is prohibited by the *syn*-axial interaction between the CH_3 group and C(5). This attack is evidently less favourable than the competing attack on the azasulphonium salt αB-(LXXIV) at the carbonyl group, which results in the formation of the open-chain product αB-(LXXIII). The formation of the sulphimide αB-(LXXII) must be accounted for differently.

The sulphimide with the βA-(LXXV) configuration is formed in a high yield from 6α-methyl-*cis*-1-thiadecalin (XXXIII) for which ring inversion is forbidden by the *syn*-axial interaction between the methyl group and C(4):[80]



The sulphimide βA-(LXXVI) is obtained in a very low yield from 8α-methyl-*cis*-1-thiadecalins (XXXIV) for which the (A) conformation is preferred by virtue of the strong *syn*-axial interaction between the methyl group and C(2) and C(4):[80]



The facts described above do not make it possible to formulate a unique view concerning the mechanism of the formation of sulphimides in the reactions of thiadecalins with 4-chloroaniline and NCS examined above. As shown above, the reactions with alkyl-substituted *cis*-1-thiadecalin are sensitive to changes in the steric requirements and proceed differently with conformationally mobile and conformationally rigid sulphides. In the case of the conformationlly mobile compounds the reaction probably proceeds via the succinimidylsulphonium salts with the subsequent substitution of the succinimidyl component with inversion at the sulphur atom. It has been suggested that the sulphimides with conformationally rigid systems are formed with participation of *N*-chloroaniline, which rapidly reacts with the sulphides, removing them from the equilibrium mixture containing the sulphide, NCS, and the azasulphonium salt. The interaction of conformationally homogeneous *cis*-1-thiadecalins with 4-chloroaniline and t-butyl hypochlorite leads exclusively to sulphimides with an equatorial SN bond.[80] It has been suggested that the reaction in the presence of t-butyl hypochlorite also proceeds via *N*-chloroaniline. However, it is difficult to find a satisfactory explanation why the unsubstituted *cis*-1-thiadecalin (XXVIII) gives rise in this case to sulphimides having the α- and β-configurations in proportions of 1:2, while the reaction with NCS results in the formation of only the β-sulphimide [βA-(LXVIII)]. Finally, the reaction with *N*-bromobenzamide results in the formation of the α-benzoyl imide αB-(LXX).[79,80] The lack of data concerning the pyramidal inversion in *N*-arylsulphimides makes it impossible to infer whether the barrier to inversion is sufficiently low for the latter to play an appreciable role. However, according to the authors,[79,80] the isomerisation reactions accompanying the formation of the SN bond and leading to thermodynamically more stable products should be taken into account.

In contrast to the oxidation of thians to sulphoxides, where both isomers can be synthesised in an almost pure form or as a mixture depending on the oxidant and the oxidation conditions, the formation of sulphimide with an axial SN bond is difficult.[73] On the other hand the inversion of the configuration at the sulphur atom is known to occur in reactions of sulphoxides with arenesulphonylamides.[84,85]

A sulphimide with an axial SN bond has been obtained from *trans*-1-thiadecalin 1α-oxide with an equatorial SO bond on treatment with P_2O_5 and 4-chloroaniline (yield 10%).[80] The low yield of the reaction product can be explained by the fact that the axial attack by 4-chloroaniline on the sulphur atom in the intermediate formed from the sulphoxide and P_2O_5 is again difficult and the formation of a sulphide with an axial SN bond is an unfavourable process.[80]

(b) *The conformational equilibrium.* The conformational equilibrium for *N*-arylsulphimides and the sulphoxide of *cis*-1-thiadecalin has been investigated by the method of low-temperature ^{13}C NMR. The ratio of the equatorial (e) and axial conformers and the difference between their energies ΔG^0 have been determined.[67] The sulphoxide and sulphimides exist preferentially in the equatorial conformation:

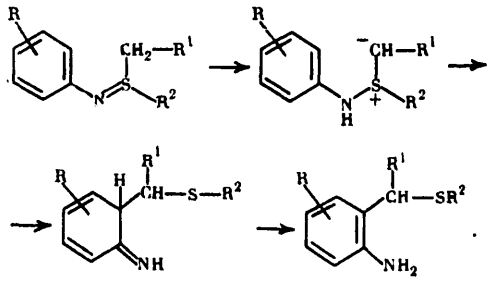
	(*e*), %	ΔG^0, kcal mol^{-1}
X = O	65	0.27
X = NC_6H_4Cl-4	>95	1.3
X = NC_6H_5	>95	1.3

A multiplicity of factors influence the observed conformational equilibrium: the *syn*-axial interactions between the axial substituent at the sulphur atom and the hydrogen atoms at C(3) and C(5), the *gauche*-interactions between the S=X group and the α-hydrogen atoms, the length of the S=X bond, the size of the heteroatom, and the polarity of the bond. At the same time, the interaction in one of the (B) conformations between the methylene groups at C(2) and C(8) is significant in *cis*-1-thiadecalin and its derivatives, which is responsible for some predominance of the (A) conformation in unsubstituted *cis*-1-thiadecalin. In contrast to thian 1-oxide, in which the SO group is preferentially axial, *cis*-1-thiadecalins 1β-oxide exists, as shown above, preferentially in the equatorial conformation, where the unfavourable interaction between C(2) and C(8) is ruled out. The above results for *cis*-1-thiadecalin 1β-oxide, *cis*-1-thiadecalin 1β-*N*-(4-chlorophenyl)imide, and the analogous 1β-*N*-phenylimide do not reveal an appreciable steric *gauche*-interaction of the substituent at the sulphur atom with the α-hydrogen atoms, and indicate at the same time the influence of the polarisation of the SX bond. In the axial conformation the SX group (X = O or N–R) is in the *gauche*-position relative to two C–C and two C–H bonds, while in the equatorial form the SX group is in the *gauche*-position relative to four C–H bonds. The dipole moments induced in these bonds by the S–X dipole should entail an increase of the fraction of the axial conformation with increase of the polarisation of the SX group by virtue of the higher polarisability of the C–C bond. Claus et al.[67] find this explanation to be the most correct.

(c) *The rearrangement of cis- and trans-1-thiadecalin 1-N-arylimides to 2-aryl-1-thiadecalins.* The configurationally and conformationally homogeneous *cis*- and *trans*-1-thiadecalin 1-*N*-(4-chlorophenyl)imides are capable of rearranging to the corresponding 2-(2-amino-5-chlorophenyl)-1-thiadecalins. The configurational assignments for the rearrangement products have been made by means of ^1H NMR.[82]

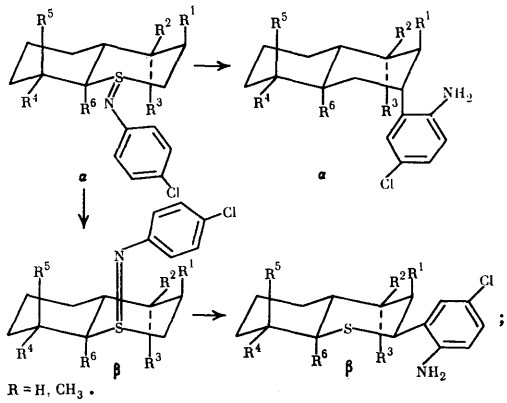
It is known[86–90] that the rearrangement of acyclic sulphimides proceeds via the azasulphonium ylide, which arises as a result of proton transfer to the nitrogen atom. This ylide is converted into cyclohexadienone imine and subsequently into the reaction product via the [2,3]-sigmatropic rearrangement. It has been shown that the rate of the

rearrangement is much higher than the rate of proton transfer:[82]



The rearrangement of 1-thiadecalin 1-*N*-arylimides proceeds with more difficulty than for the open-chain sulphimides and requires more severe conditions (heating in triethanolamine at 100–200 °C).[82] In the series of thiadecalins which are not sterically hindered the rearrangement proceeds with a high degree of stereoselectivity (>95%): sulphimides with an equatorial SN bond give rise to the rearrangement product with an axial aryl substituent, while sulphimides with an axial SN bond give rise to products with an equatorial aryl substituent. The results of the investigation confirm that the rearrangement proceeds via a cyclic transition state.

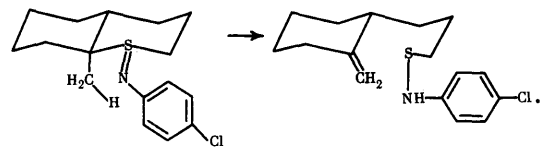
2α-Aryl-*trans*-1-thiadecalins are formed as the main products from the rigid *trans*-1-thiadecalin 1α-imides (with an equatorial bond) together with a smaller amount (<5%) of the 2β-isomers. With increase of the reaction temperature from 100° to 200 °C, the amount of the 2β-isomers increases to 25% (relative to the overall yield).



R = H, CH_3.

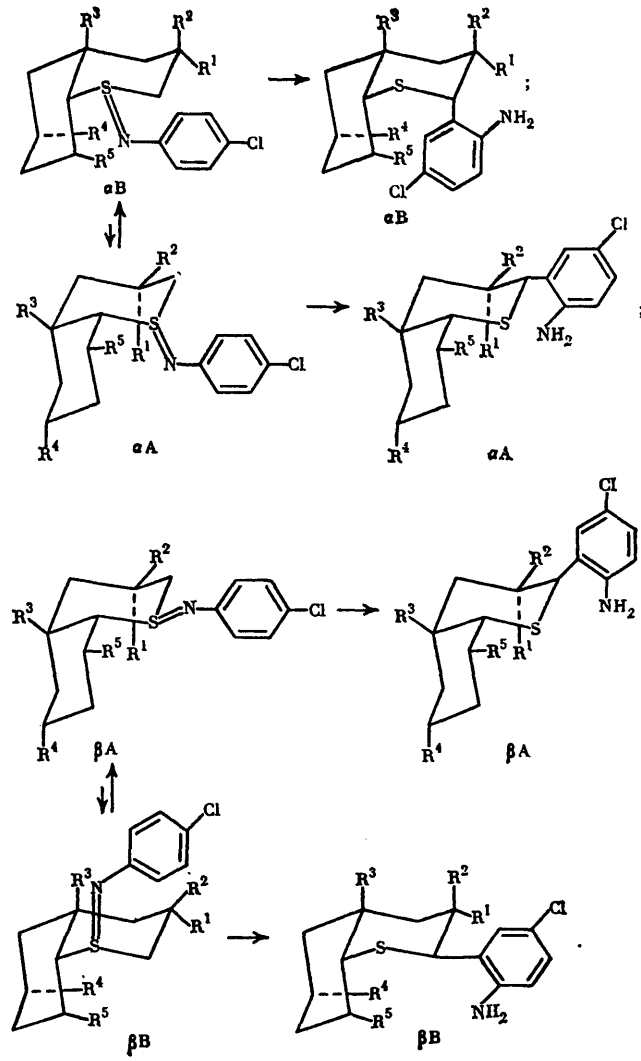
The mechanism of the rearrangement is analogous in broad outline to that of the rearrangement of acyclic sulphimides. However, the cyclic transition state in the formation of 2α-aryl-*trans*-1-thiadecalins from the 1α-imides is undoubtedly attained with more difficulty by virtue of the rigidity of the system and is more strained owing to the steric interaction between the axial hydrogen atoms at C(4) and C(9).[82] This should lead to an increase of the barrier to the rearrangement of the 1α-imide to 2α-aryl-1-thiadecalin compared with the flexible thiacyclohexane imides. In order to explain the formation of 2β-aryl-1-thiadecalines in the reactions considered one must assume the possibility of the inversion 1α-imide ⇌ 1β-imide, the inversion barrier being evidently comparable to the rearrangement barrier. It has been shown that the 1β-imide rearranges more readily to 2β-aryl-*trans*-1-thiadecalin.[82]

An unstable sulphenamide has been obtained from 9-methyl-*trans*-1-thiadecalin 1α-*N*-arylimide on heating in triethanolamine. The methyl group at C(9) in the molecule of the initial sulphenamide occupies an axial position and is close to the α-imide group, which favours the intramolecular proton transfer and the cleavage of the ring with formation of the sulphenamide:[83]



The cleavage and elimination side reactions occur also in other cases, but the indentification of the products is difficult owing to their low stability.[82]

The sulphimides of the unsubstituted and methyl-substituted *cis*-1-thiadecalins having the α- and β-configurations proceed differently under the rearrangement conditions.

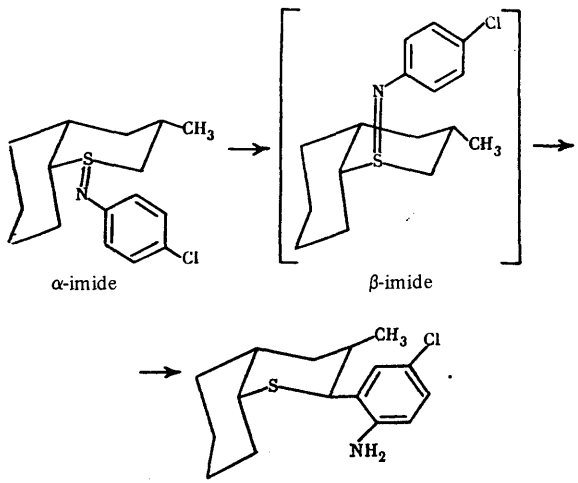


cis-1-Thiadecalin 1β-arylimide give rise to only one rearrangement product with the aryl group in the β-position, whose yield is 60%. The rearrangement of the isomeric

α-imide leads to a mixture of the α- and β-aryl-substituted products formed in proportions of 1 : 2 in an overall yield not exceeding 12%.

In the rearrangement of the α-imides, powerful *syn*-axial interactions between the aryl group and the methylene group in the 8-position must inevitably take place in the transition state, which is the cause of the formation of sulphenamides in a side reaction (the CH_2 group is in the β-position relative to the imide functional group) and of the decrease of the yield of the 2α-aryl-substituted products. The rearrangement product exists preferentially in the conformation with an equatorial aryl group at C(2).

Under the rearrangement conditions, 3α-methyl-*cis*-1-thiadecalin 1α-*N*-arylimide is converted into the 2β-aryl-substituted product, whose formation does not follow from the [2,3]-sigmatropic rearrangement of the initial sulphimide. Under the reaction conditions, the α-imide probably isomerises to the β-imide and the latter undergoes the [2,3]-sigmatropic rearrangement to the 2β-aryl-substituted product:[82]

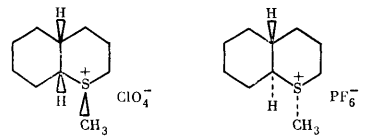


The β-sulphimides of the methyl-substituted *cis*-1-thiadecalins (the 3β-methyl-, 10-methyl-, 6α-methyl-, or 8α-methyl derivatives) give rise to 2β-aryl-substituted products on heating in triethanolamine (in 16–40% yield).

Thus the rearrangement of the *cis*- and *trans*-1-thiadecalin 1-*N*-arylimides proceeds with formation of the C(2)–aryl bond in the *cis*-position relative to the sulphimide functional group in the initial imide, i.e. suprafacially relative to the sulphimide fragment, whereupon assymetry is transferred from the sulphur atom to the C(2) carbon atom. The stereospecificity of the reaction is caused by the rigorous requirement for the retention of the orbital symmetry in the rearrangement.[82] Transfer of the aryl group to the angular position is not observed.

5. The *S*-Methylsulphonium Salts of *cis*- and *trans*-1-Thiadecalins

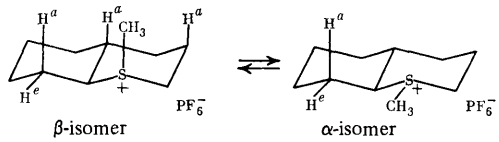
The *S*-methylsulphonium salts of *cis*- and *trans*-1-thiadecalins have been obtained by methylation with methyl iodide (with the subsequent exchange of I^- for ClO_4^-) or trimethyloxonium hexafluorophosphate.[91] 1β-Methyl-*cis*-1-thiadecalinium perchlorate constitutes a conformationally mobile system. The conformational equilibrium has been investigated by ^{13}C NMR at a low temperature in deuterioacetone (the ratio of the equatorial and axial conformers is 3 : 2).[91,92]



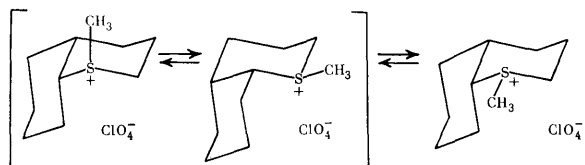
The reaction of *trans*-1-thiadecalin with trimethyloxonium hexafluorophosphate gives rise to the configurationally pure 1α-methyl isomer.[91]

The above *S*-methyl-*cis*- and *S*-methyl-*trans*-1-thiadecalinium salts undergo the pyramidal inversion at the sulphur atom on heating in deuterioacetonitrile, which makes it possible to detect diastereoisomers which are not formed on alkylation, for example, 1α-methyl-*cis*-1-thiadecalinium perchlorate or 1β-methyl-*trans*-1-thiadecalinium hexafluorophosphate.

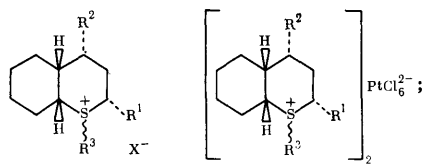
The free energy difference $-\Delta G^0_{SCH_3}$ for the two diastereoisomeric *S*-methyl derivatives of *trans*-1-thiadecalin with the equatorial and axial positions of the SCH_3 groups amounts to 0.80 ± 0.04 kcal mol^{-1}; the isomer with an axial methyl group is evidently destabilised by the *syn*-axial interaction with the hydrogen atoms at C(3), C(10), and C(8):[91,92]



The β-isomer of the *S*-methyl-*cis*-1-thiadecalinium salt exists as an equilibrium mixture of two conformers with the equatorial conformer predominating ($\Delta G^0 = -0.24$ kcal mol^{-1}). When this mixture is heated, the α-isomer is formed as a result of the inversion of the configuration at the heteroatom. The α-isomer of *S*-methyl-*cis*-1-thiadecalinium perchlorate is less favourable to the extent of 1.2 kcal mol^{-1}:[92]



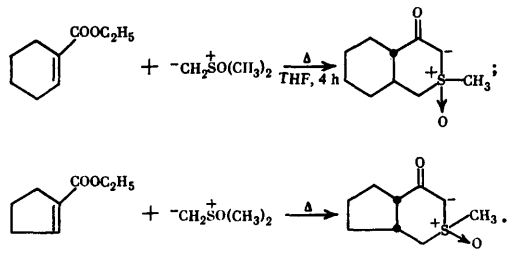
The corresponding sulphonium salts are obtained by alkylating 2α, 4α-diaryl-*cis*-1-thiadecalins with bromoacetic acid, methyl chloroacetate, acrylic acid, or methyl acrylate in the presence of hydrogen chloride.[13] The alkylation reaction usually yields a mixture of diastereoisomers with one of them predominating, but the configuration of this sulphur atom has not been determined:



$R_3 = CH_2COOH$, CH_2COOCH_3, CH_2CH_2COOH, $CH_2CH_2COOCH_3$; $X^- = Cl^-$, ClO_4^-.

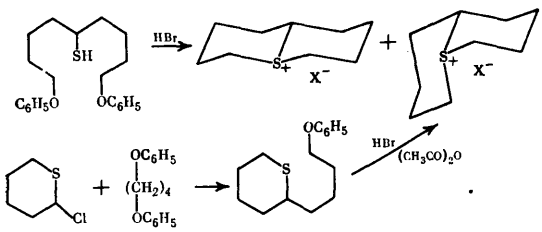
The oxosulphonium salts of condensed thiacyclohexanes are unknown. Our attempt to obtain the oxosulphonium salts by methylating 2,4-diaryl-*cis*-1-thiadecalin 1-oxides with

methyl iodide, i.e. by the method usually employed for the synthesis of acyclic oxosulphonium salts, was unsuccessful. However, oxosulphonium ylides, obtained by an indirect procedure involving the treatment of 1-ethoxycarbonylcycloalkenes with dimethylsulphoxonium methylide, have been described in the literature:[93,94]



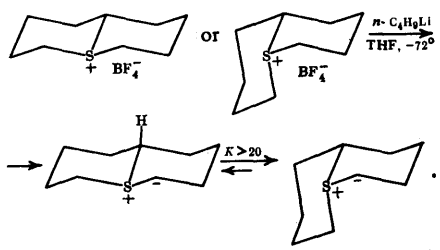
These oxosulphonium ylides are valuable intermediates in organic synthesis, for example, in the synthesis of cyclohexane derivatives with a specific configuration.[93]

The prospects for the use of sulphonium salts, and ylides based on them, as possible organic synthetic intermediates are responsible for the interest in 1-thioniabicyclo[4.4.0]-decane salts.[95-99] These are known under the name of Eastman's salts[95] and constitute a condensed heterocyclic system in the angular position of which the sulphonium centre is located. They were first obtained on heating 5-mercapto-1,9-diphenoxynonane with hydrobromic acid as a mixture of the *cis*- and *trans*-isomers in proportions of 2:3. The isomers were separated by preparative column chromatography on silica gel.[95] Eastman's salts can also be obtained from 2-chlorothiacyclohexane and phenoxybutylmagnesium chloride in the reaction involving subsequent treatment with hydrobromic acid:[96]

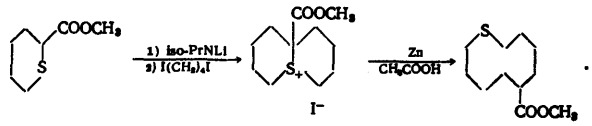


On heating to 260–270 °C in chloroform or methylene chloride, each isomer is converted into a 3:2 equilibrium mixture of the *cis*- and *trans*-isomers, formed as a result of pyramidal inversion at the sulphur atom. Heating at a lower temperature (110 °C) gives rise to a mixture in which the *trans*-isomer predominates (up to 70%).[96]

Sulphonium ylides have been obtained from *cis*- and *trans*-1-thioniabicyclo[4.4.0]decanes and their interconversion by pyramidal inversion at the sulphur atom has been investigated. It has been shown that the ylide structure in which the electron pairs of the carbanion and the heteroatom are orthogonal has the lowest energy.[97-99]



Although a more detailed consideration of these interesting compounds is not feasible within the framework of the present review, one should note that Eastman's salts and ylides based on them are important intermediates in the synthesis of macrocyclic compounds with a ring size which is not attainable by direct cyclisation, for example, of thiacyclodecane derivatives:[97]



The ylides of 1-thioniabicyclo[4.4.0]decanes are alkylated stereoselectively, which leads to the possibility of introducing new chiral centres at this stage.[97]

Chemical Reactions of β-Aminoketones

G.A.Gevorgyan, A.G.Agababyan, and O.L.Mndzhoyan

The advances in the field of the chemical reactions of β-aminoketones during the period 1970-1980 are described and arranged systematically. The question of the deamination and deaminomethylation of β-aminoketones is discussed; the possibility of alkylating various nucleophiles by β-aminoketones is demonstrated and the mechanism of the alkylation reaction is discussed. In addition, data are presented on the cyclisation, reduction, and photochemistry of β-aminoketones and the applications of the latter are described.
The bibliography includes 158 references.

I. INTRODUCTION

The literature for 1970–1980 on the synthesis of β-aminoketones were surveyed in a previous review.[1] During the period 1960–1970, another review article was devoted to the same topic.[2] Data on the aminoacid analogues of β-aminoketones were first surveyed in another communication by the present authors.[3]

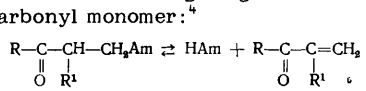
The high reactivity and also the ready availability of β-aminoketones have long attracted the attention of chemists throughout the world. Various aminoalcohols, heterocycles, αβ-unsaturated ketones, and other compounds are synthesised from them.

This paper presents a systematic account of the advances during the last decade in the field of the chemical reactions of β-aminoketones. The question of the deamination and deaminomethylation of β-aminoketones is examined. In addition, the possibility of alkylating various nucleophiles by β-aminoketones is demonstrated and the mechanism of the alkylation reaction is discussed. Data on the synthesis of secondary and tertiary γ-aminoalcohols from the corresponding β-aminoketones either by the reduction of the latter or by their interaction with organometallic compounds are surveyed. The photochemical reactions of β-aminoketones and other reactions are described.

Extensive experimental data concerning the chemical reactions of β-aminoketones have accumulated during the last decade. The β-aminoketone molecule contains two functional groups: the carbonyl and amino-groups, and the chemical reactions described below are mainly associated with these groups.

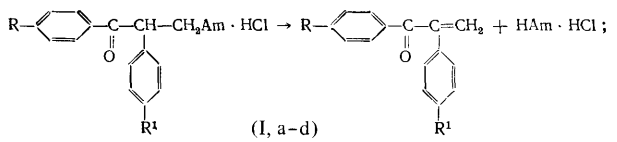
II. DEAMINATION

One of the characteristic properties of β-aminoketones is their αβ-deamination reaction, giving an amine and an unsaturated carbonyl monomer:[4]



The synthesis of carbonyl monomers from Mannich bases is based on the fact that the latter contain a mobile hydrogen atom in the α-position and tend to eliminate the amine residue. The elimination reaction has been discussed previously in a number of communications.[5-7]

The problem of the stability of β-aminoketones is particularly important for the search for new medicinal drugs. In view of this, a number of workers[8-12] investigated the kinetics of the elimination reactions of the hydrochlorides of substituted propiophenones (I, a-d) as a function of the size of the alkoxy-group, the character of the amino-group, the pH of the medium, and temperature.



(I, a-d)

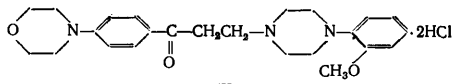
(a) Am=NC_5H_{10}, NC_4H_8, R=H, HO, CH_3O, ..., $C_7H_{15}O$, iso-C_3H_7O, iso-$C_5H_{11}O$, R^1=H;
(b) Am=NC_4H_8O, R=H, HO, CH_3O, ..., $C_5H_{11}O$, iso-$C_5H_{11}O$, R^1=H;
(c) Am=NC_4H_8, R=H, R^1=CH_3O, ..., $C_5H_{11}O$, iso-C_3H_7O, iso-C_4H_9O, iso-$C_5H_{11}O$;
(d) Am=NC_5H_{10}, NC_4H_8O, R=H, R^1=CH_3O.

On the basis of the results, Gevorgyan et al.[9] concluded that the replacement of the hydrogen atom in the *p*-position in the benzene ring by the methoxy-group, as in compound (Ia, Am = NC_4H_8; R = CH_3O; R^1 = H), reduces the rate of elimination. However, it has been noted that, on further increase in the length of the alkyl group, as in compounds (Ia, Am = NC_4H_8; R = CH_3O, ..., $C_7H_{15}O$; R^1 = H), the influence of the latter diminishes, which entails an increase of the rate of elimination. An analogous behaviour has been observed also after the introduction of the propoxy-group in the *p*-position in the benzene ring at the α-carbon atom, as in compound (Ic, R = H, R^1 = C_3H_7O).[11]

It has been established that[8,9] the rate of elimination increases with increase of temperature and the pH of the medium. The rate of elimination is appreciably influenced also by the basicity of the amino-group.[8] Thus it has been shown in relation to the hydrochlorides of β-amino-α-phenyl-4-butoxypropiophenones (I, a and b) that derivatives of

piperidine (with the basicity constant $K_b = 1.6 \times 10^{-3}$) are much more stable than those of morpholine ($K_b = 2.44 \times 10^{-6}$). The pyrrolidine derivatives occupy an intermediate position in terms of their stability ($K_b = 1.3 \times 10^{-3}$).

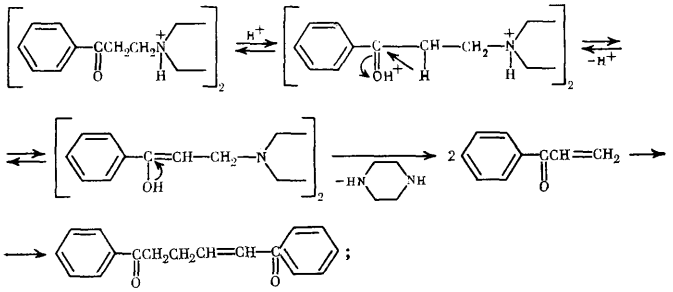
The kinetics of the elimination reaction of the dihydrochloride of 3-(4-*o*-methoxyphenyl-1-piperazinyl)-4-morpholinopropiophenone (II) have been investigated in the pH range 1–10.[13]



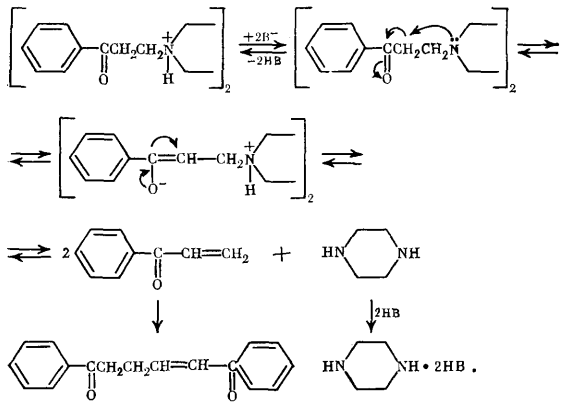
(II)

It was established that the elimination is reversible and that the degree of reaction depends on the pH. The reaction does not lead to equilibrium, since it is accompanied by a series of consecutive-parallel stages such as deaminomethylation, hydration, and dimerisation. In highly acid media the elimination reaction of the protonated form of the Mannich base (II) is an acid-catalysed process. A study has also been made[14–16] of the kinetics of the elimination reaction of the dihydrochloride of 1,4-bis(β-benzoylethyl)piperazine (III) as a function of the nature of the solvent, the pH, the ionic strength of the medium, and the buffer concentration. It has been established that compound (III) exhibits the highest stability at pH 4.5, while at pH 5.1 the main process is the elimination of the amine; at pH 6.0 a cleavage-addition process takes place. Two mechanisms have been proposed for the elimination reaction at pH < 3.5 and pH > 3.5:

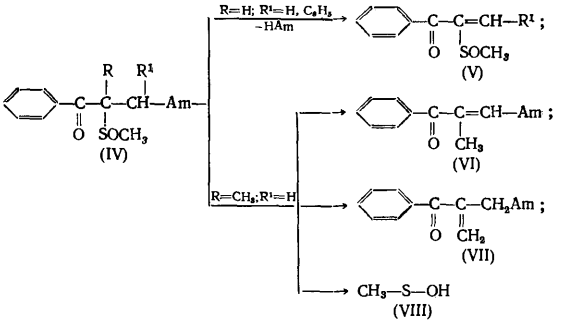
(1) at pH < 3.5:



(2) at pH > 3.5:



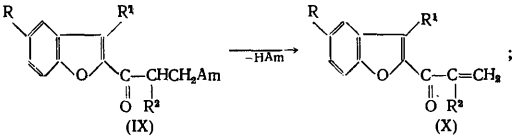
Depending on whether there are substituents in the α- and β-positions, the β-amino-α-methanesulphinylpropiophenones (IV) undergo the elimination reaction in different ways: compounds (IV) with R = R^1 = H decompose at room temperature, while those with R = H and $R^1 = C_6H_5$ distil at t = 180 °C under a pressure of 10^{-2} mmHg with formation of the vinyl ketone (V) and an amine. On the other hand, distillation of the aminoketone (IV, R = CH_3; R^1 = H) gives rise to a mixture of the products (VI), (VII), and (VIII)[17,18] whose structures have been established by physicochemical methods of analysis.



(a) R=H, CH_3; R^1=H; Am=N$(CH_3)_2$, N$(C_2H_5)_2$, NC_4H_8, NC_5H_{10}; (b) R=H; R^1=C_6H_5; Am=N$(CH_3)_2$, NC_4H_8, NC_5H_{10}.

Other studies on the synthesis of vinyl ketones from β-aminoketones have also been carried out.[19–23]

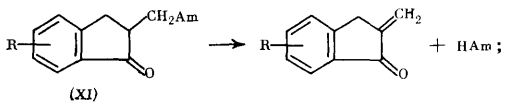
According to the data of Faure and Mattioda,[24] the deamination of 3-amino-1-(substituted 2'-benzofuryl)-1-propanones (IX) by one of four methods (pyrolysis, heating in an aqueous alkaline medium, steam distillation, and treatment of the quaternary ammonium slats in an aqueous alkaline medium) leads to the vinyl ketones (X).



R=R^1=R^2=H, Am=N$(CH_3)_2$, NC_5H_{10};
R=Cl, Br, CH_3O, R^1=R^2=H,
Am=N$(CH_3)_2$, N$(C_2H_5)_2$, NC_5H_{10};
R=H, R^1=R^2=CH_3, Am=N$(CH_3)_2$;
R=H, CH_3O, R^1=CH_3, R^2=C_2H_5, Am=N$(CH_3)_2$.

Owing to their instability, the latter can be isolated in a pure form only when there are alkyl substituents in the 3-position at the α-carbon atom relative to the carbonyl group.

The possibility of the polarographic monitoring of the decomposition reaction of the β-aminoketone has been demonstrated in relation to 2-piperidinomethyl-5-propyl- and 6-ethyl-2-morpholinomethyl-1-indanones (XI). The elimination reaction was carried out in aqueous solution at pH 7 and 37 °C.[25]

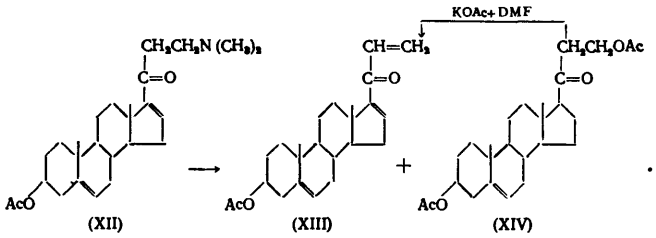


(XI)

Am=N$(CH_3)_2$, NC_4H_9, NC_5H_{10}; R=CH_3, ..., C_3H_7, iso-C_3H_7, CH_3O; Am=NC_4H_8O; R=CH_3, ..., C_3H_7, iso-C_3H_7, CH_3O, Cl, Br.

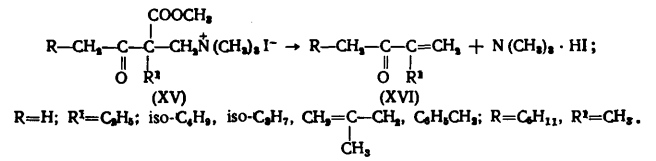
A mixture of acetic acid and acetic anhydride was used to elininate dimethylamine from 3β-hydroxy-21-dimethylaminomethylpregna-5,6-dien-20-one (XII).[26] However, the main reaction product was not the required 3-acetate of 3β-hydroxy-21-homopregna-5,16,21-trien-20-one (XIII) but

the 3,21-diacetate of 3β,21a-dihydroxy-21-homopregna-5,16-dien-20-one (XIV):

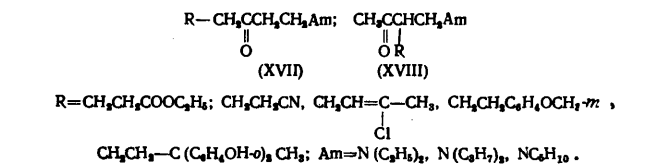


The attempts to eliminate the amine from compound (XII) by treatment with toluenesulphonic acid or phlorizil [phlorizin? (Ed. of Trans.)] were unsuccessful and led merely to an insignificant yield of compound (XIII). A solution to the problem was found by employing potassium acetate and dimethylformamide (DMF). The yield of compound (XIII) was then 65% of theoretical.

Aliphatic aminoketones also undergo the elimination reaction.[27-31] Thus a convenient method of synthesis of the vinyl ketones (XVI) in DMF at 75 °C in the course of 48 h was developed on the basis of the quaternary salts of the β-aminoketones (XV):[27]

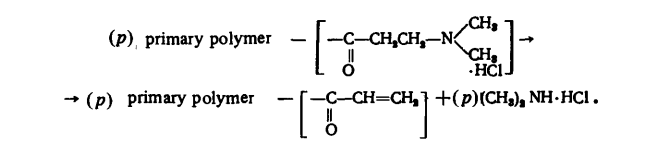


When a mixture of the isomeric aminoketones (XVII) and (XVIII) is heated at 60–120 °C, only compound (XVIII) undergoes the elimination reaction, while compound (XVII) is entirely stable under these conditions:[28]

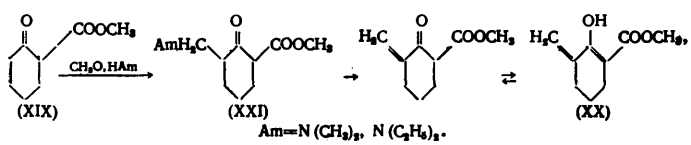


A method has been proposed for the determination of 1-diethylamino-3-butanone in the synthesis of methyl vinyl ketone.[29]

An example of the formation of a vinyl ketone also from a β-aminoketone containing a polymeric fragment has been described:[30]

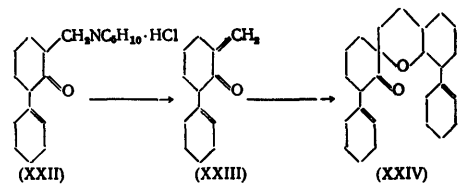


The aminomethylation of 2-methoxycarbonyl-1-cyclohexanone (XIX) by reaction with paraformaldehyde and dialkylamines in dioxan at 80 °C in the course of 8 h leads to the enolic form of 2-methoxycarbonyl-6-methylene-1-cyclohexanone (XX) with a yield of 37%:[32]



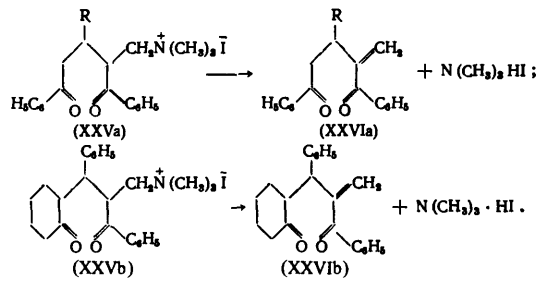
The authors explained the formation of compound (XX) by the initial appearance of 2-dialkylaminomethyl-2-methoxycarbonyl-1-cyclohexanone (XXI) followed by the elimination of the amine.

The pyrolysis of the hydrochloride of 6-cyclohex-1^1-enyl-2-piperidinomethyl-1-cyclohexanone (XXIII) at 230–250 °C for 30 min leads to a 52.6% yield of 6-cyclohex-1^1-enyl-2-methylene-1-cyclohexanone (XXIII), which subsequently dimerises to spiro-[(3-cyclohexenyl-2-oxocyclohexano)-1,2^1-(8^1-cyclohexenyl-3^1,4^1,5^1,6^1,7^1,8^1-hexahydrochroman)] (XXIV):[33]

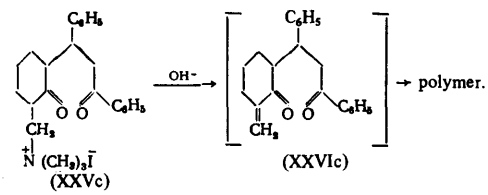


The elimination reaction involving β-aminoketones has also been described in other communications.[34-36]

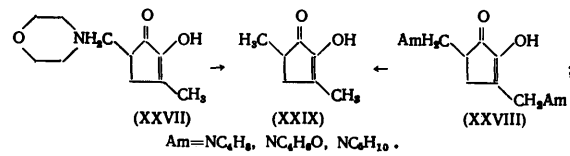
It has been shown[37-42] that the aminomethyl derivatives of diketones also tend to eliminate the amine. Thus the methiodides of dimethylaminomethyldiketones (XXV, a–c) give rise to quantitative yields of the substituted vinyldiketones (XXVI, a–c) in the presence of sodium carbonate either at room temperature or on heating (to 60–70 °C) in DMF:



In the case of the aminodiketone (XXVc) the deamination should have produced the vinyldiketone (XXVIc), but the latter readily polymerises even at room temperature to give a hardening gelatin-like product:[39]



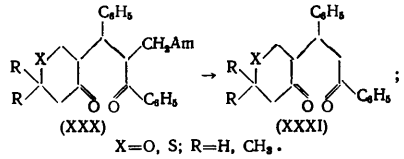
When 2-hydroxy-3-methyl-5-morpholinomethylcyclopent-2-en-1-one (XXVII) or 3,5-bisaminomethyl-2-hydroxycyclopent-2-en-1-one (XXVIII) is heated in acetic acid in the presence of zinc at 70–80 °C, 2-hydroxy-3,5-dimethylcyclopent-2-en-1-one (XXIX) is formed:[43,44]



III. DEAMINOMETHYLATION

It is of interest to note that, when the hydrochlorides of the aminomethyl derivatives of the diketone (XXX) are refluxed in water or ethanol, deaminomethylation and not

deamination is observed, i.e. the initial diketones (XXXI) are obtained in quantitative yields:[40,42]

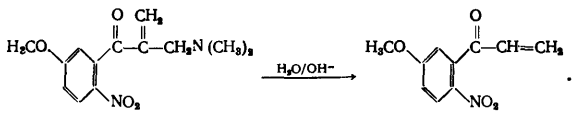


(XXX) (XXXI)

X=O, S; R=H, CH_3.

This fact accounts for the finding that the aminomethylation of the diketones (XXX) in ethanol hardly occurs.

An instance of deaminomethylation in a system where deamination is impossible for structural reasons has been described:[45]



As can be seen from the foregoing, the thermal stabilities of β-aminoketones are various: some of them undergo the elimination reaction at room temperature[17,18,36,37] but the majority undergo this reaction at an elevated temperature.[21,24,26,28,29,31,32,35-41] In a series of cases the elimination reaction is promoted by an acid medium[13-16,26] whereas in others an alkaline medium favours the reaction.[13,26,37]

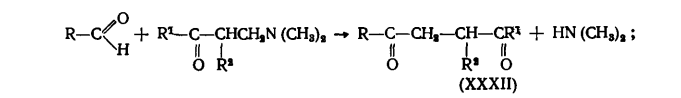
IV. ALKYLATION BY β-AMINOKETONES

Various nucleophiles ($-\rangle$ CH, $\rangle$ NH, -SH, $\rangle$ PH, -OH)

are readily alkylated by β-aminoketones. The reaction can proceed in two directions and in their treatment of the mechanism of the alkylation reaction all investigators start with the hypothesis of the initial elimination of the amine and the formation of the corresponding vinyl derivative. The subsequent interaction is regarded as one with the activated double bond formed.

(a) C-Alkylation

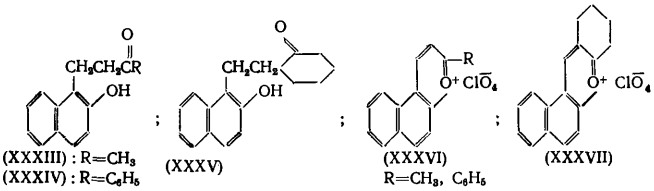
Aromatic and heterocyclic aldehydes interact with β-aminoketones in the presence of sodium cyanide or 3-ethyl-5-(2-hydroxyethyl)-4-methylthiazolidinium bromide as the catalyst with formation of the corresponding 1,4-diketones (XXXII):[46]



(XXXII)

R=CH_3, C_6H_5, 2-thienyl, 3-pyridyl, $CH_3(CH_2)_2$—, $(CH_3)_2C{=}CH$—; R^1=CH_3, C_6H_5, $(CH_3)_2C$—, —$CH{=}C(CH_3)_2$, —$C(CH_3){=}CH$—CH_3, 1-cyclopent-1-enyl, or 1-cyclohex-1-enyl; R^2=H, CH_3, C_6H_5.

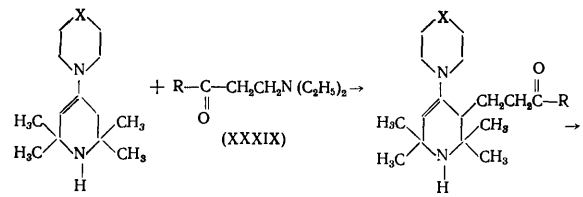
The alkylation of 2-naphthol by the β-aminoketones synthesised from acetone, acetophenone, or cyclohexanone yielded the alkyl(aryl) β-(2-hydroxy-1-naphthyl)ethyl ketones (XXXIII)–(XXXV), which were subsequently converted into the pyrylium salts (XXXVI) and (XXXVII).[47]



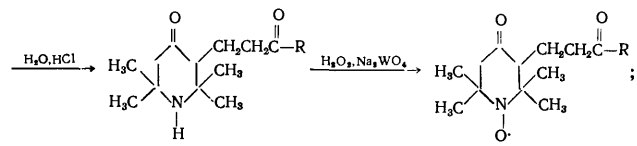
(XXXIII): R=CH_3
(XXXIV): R=C_6H_5 (XXXV) (XXXVI) (XXXVII)
R=CH_3, C_6H_5

The authors were able to alkylate only the 2-naphthol. Resorcinol does not react with β-diethylaminopropiophenone, while the interaction with 4-diethylamine-2-butanone gives rise to high-molecular-weight compounds. Phenol cannot be alkylated by β-aminoketones even in the presence of sodium hydroxide and sodium ethoxide.

Alkylation of the enamines (XXXVIII) by the β-aminoketones (XXXIX) afforded 3-(2-acylethyl-2,2,6,6-tetramethyl-4-oxopiperidines (XL), which were converted into the corresponding nitroxy-radicals (XLI) by oxidation with the H_2O_2–Na_2WO_4 mixture in accordance with the scheme[48]



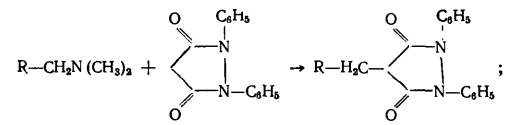
(XXXVIII) (XXXIX)



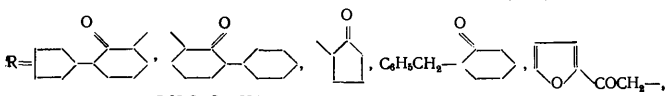
(XL) (XLI)

X=O, CH_2, R=C_6H_5, p-$CH_3OC_6H_4$, $C_6H_5CH{=}CH_2$.

New 4-substituted pyrazolidines (XLII) have been obtained by alkylating the sodium salt of 3,4-dihydroxy-1,2-diphenylpyrazolidine (XLIII) with β-aminoketones:[49]

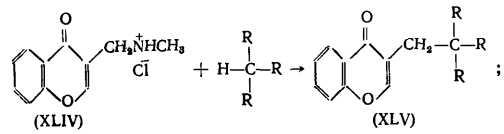


(XLIII) (XLII)

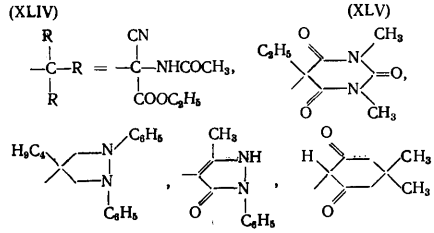


$C_2H_5OCO(CH_2)_2COCH_2$—, $HOOC(CH_2)_2COCH_2$—.

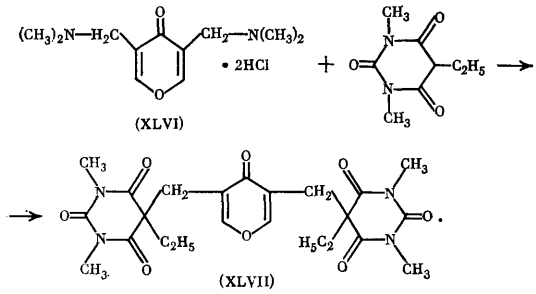
3-Substituted chromones (XLV) have been obtained by the alkylation of various CH-acid components with 3-dimethylaminomethylchromone (XLIV):[50]



(XLIV) (XLV)



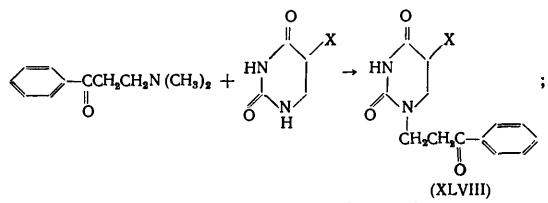
The bisaminomethyl derivatives of ketones have also been used as alkylating agents. Thus the reaction of bis-*NN'*-dimethylaminomethylpyrone (XLVI) with 5-ethyl-1,5-dimethylbarbituric acid gives rise to 3,5-bis(5-ethyl-1,3-dimethyl-2,4,6-trioxotetrahydropyrimidinomethyl)-4-pyrone (XLVII):[51]



(XLVI) (XLVII)

(b) *N*-Alkylation

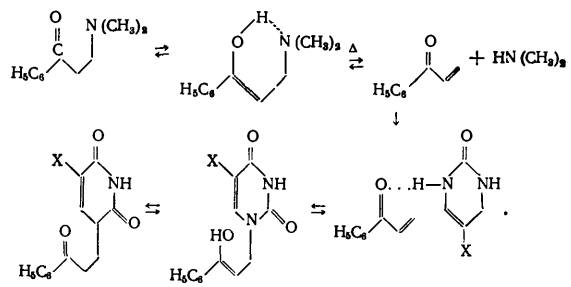
β-Aminoketones interact with 5-alkyl- and 5-halogenouracils to form the corresponding *N*-1-substituted uracils (XLVIII):[19,52]



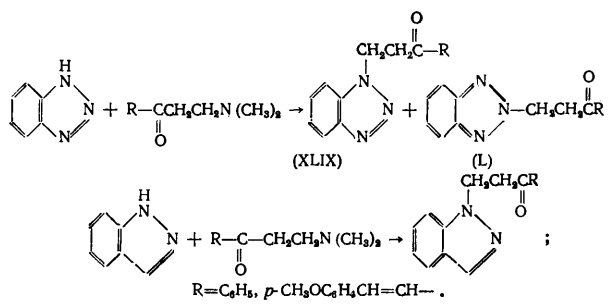
(XLVIII)

X=H, CH_3, C_2H_5, C_3H_7, Br, F.

The possible mechanisms of the alkylation of uracils have been discussed:



Tertiary β-aminoketones have been used as alkylating agents for benzotriazole and indazole:[53,54]

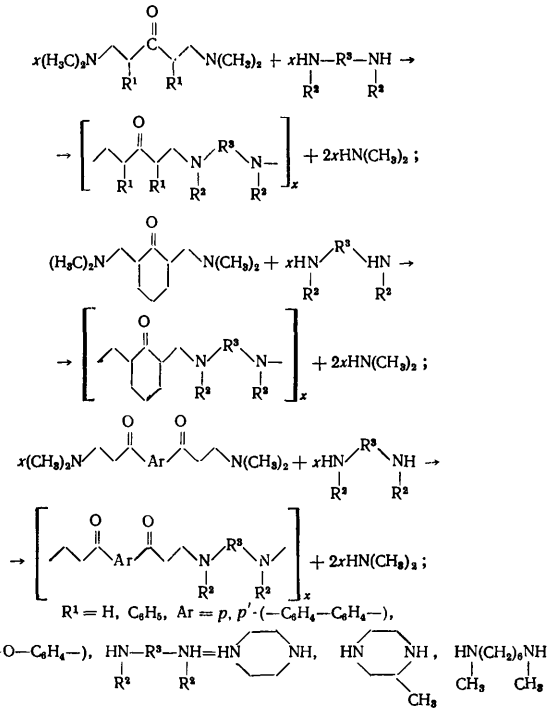


(XLIX) (L)

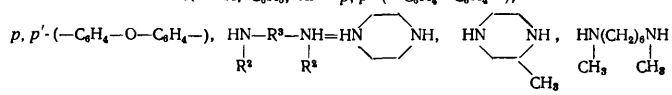
R=C_6H_5, *p*-$CH_3OC_6H_4CH{=}CH{-}$.

The alkylation of benzotriazole yields both the 1- and 2-substituted derivatives (XLIX) and (L).[53]

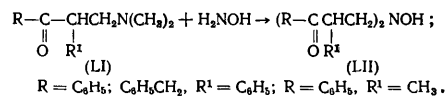
The polycondensation reaction of bisdialkylaminoketones and their methiodides with bis(secondary amines) has been described:[55,56]



R^1 = H, C_6H_5, Ar = *p*, *p'*-($-C_6H_4-C_6H_4-$), *p*, *p'*-($-C_6H_4-O-C_6H_4-$),



The stereochemistry of the resulting polymers has been investigated and a stereochemical comparison of the initial monomers has been carried out.[55,56] A number of studies have been made of the alkylation of morpholine, piperazine, dibenzylamine, and *p*-chloroaniline.[57-59] Treatment of the Mannich bases (LI) with hydroxylamine leads to the formation of compound (LII):



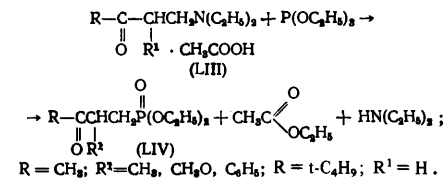
(LI) (LII)

R = C_6H_5; $C_6H_5CH_2$, R^1 = C_6H_5; R = C_6H_5, R^1 = CH_3.

When R^1 = H or CH_3 and R = CH_3, the usual oximes are formed.[60]

(c) *P*- and *As*-Alkylation

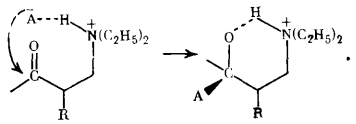
The ability of β-aminoketones to interact with nucleophiles extends also to phosphorous esters.[61,62] In their study of the kinetics of the condensation of trialkyl phosphites with the β-aminoketones (LIII), Ivanov and co-workers[63,64] concluded that a necessary condition for the interaction is the conversion of the nitrogen into the ammonium form. They selected alkyl halides, hydrochloric acid, acetic acid, water, phenol, etc. as the salt forming agents:



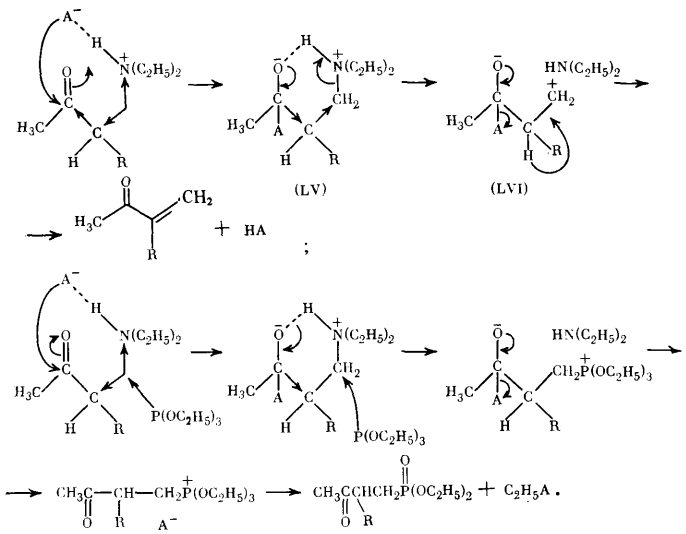
(LIII) (LIV)

R = CH_3; R^2=CH_3, CH_3O, C_6H_5; R = t-C_4H_9; R^1 = H.

As stated above, the amino-group is substituted via an elimination-addition mechanism, but the experimental data obtained in the above studies[63,64] conflict with this scheme. In all cases, on interaction with trialkyl phosphites, the β-aminoketones give rise solely to esters of ketophosphonic acids (LIV). Analysis of the results enabled the authors to conclude that the nature of the activating influence of the carbonyl group is as follows:[64]

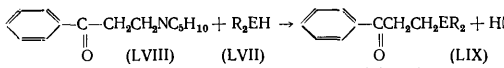


β-Aminoketones are typical ambident electrophiles and have two reaction centres with a reduced electron density: the α-carbon atom and the carbonyl carbon atom. In addition, two nucleophiles are involved in the reaction: the acid anion and triethyl phosphite. The nucleophilicity of the anion is greater than that of the phosphite and one can therefore postulate that the first reaction step is the addition of the acid anion to the carbonyl group with formation of the intermediate (LV) via the mechanism



Subsequent refinement of the reaction mechanism showed that the elimination proceeds via the intermediate (VLI) and that the stage involving the transition from compound (LV) to (LVI) should proceed at a lower rate than the stage in which compound (LV) is formed. The substitution reaction takes place via the solvation of the C(1) carbon atom by triethyl phosphite. The latter gives up its unshared electron pair in the course of the dissociation of the C–N bond to be used to form the C–P bond. The authors concluded that solvation plays a major role in accelerating the decomposition of Mannich bases.

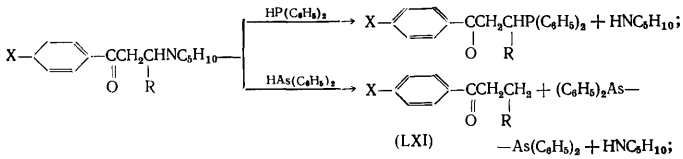
The reactions of β-aminoketones with secondary arsines and phosphines have also been investigated.[65,66] When secondary phosphines and arsines (LVII) interact with β-piperidinopropiophenone (LVIII) the corresponding phosphines and arsines (LIX) are formed smoothly in 80% yield:



E = P, As, R = C_6H_5, cyclohexyl.

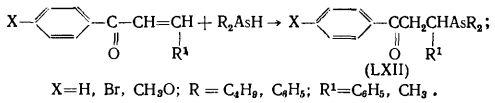
A quantitative comparison of the rates of formation of different phosphines and arsines has shown that phosphines react in ethanol faster than arsines and that the nucleophilicity of the compounds and steric factors and not the acidity of the compounds evidently play a decisive role.

The interaction of the *p*- and α-substituted β-aminoketones (LX) with diphenylphosphine and diphenylarsine leads to the formation of various products. In the latter case the hydride transfer reaction takes place, as shown by the formation of the ketone (LXI) and tetraphenyldiarsine:



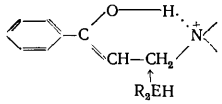
X=Br, Cl, CH_3O, R=H; X=H, R=CH_3, C_6H_5.

The ketoarsines (LXII) can be obtained by the addition of secondary arsines to unsaturated ketones:[65,66]



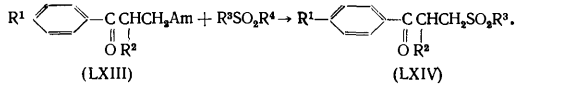
X=H, Br, CH_3O; R = C_4H_9, C_6H_5; R^1=C_6H_5, CH_3.

On this basis, the authors conclude that the alkylation evidently proceeds via a nucleophilic substitution reaction and not via vinyl ketones. They believe that a cyclic transition state of the Mannich base is formed, in which a positive charge is located at the α-carbon atom, which facilitates nucleophilic substitution.



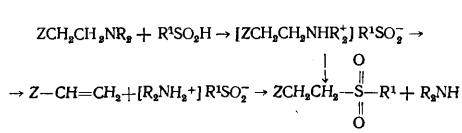
(d) *S*-Alkylation

The β-aminoketones (LXIII) react with sulphinic acids or their sodium salts to form the sulphoketones (LXIV)[67–72] (Table 1):

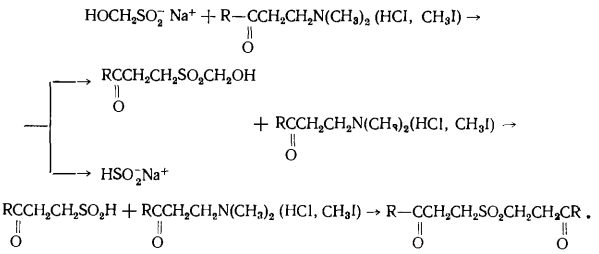


(LXIII) (LXIV)

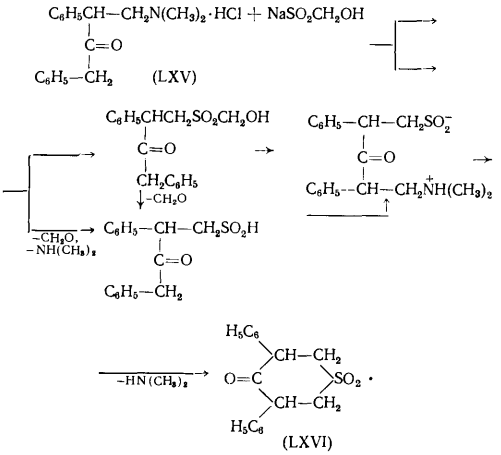
It is believed[67] that the reaction mechanism is as follows:



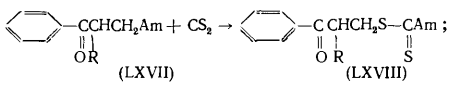
Symmetrical dialkyl sulphones have been obtained in accordance with the following scheme:[68]



The β-aminoketone (LXV) has been converted into 3,5-diphenyltetrahydrothiopyran-4-one 1,1-dioxide (LXVI):[70]

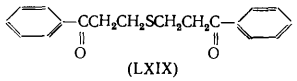


The reaction of the β-aminoketones (LXVII) with carbon disulphide leads to the formation of the substituted dithiourethanes (LXVIII):[73]



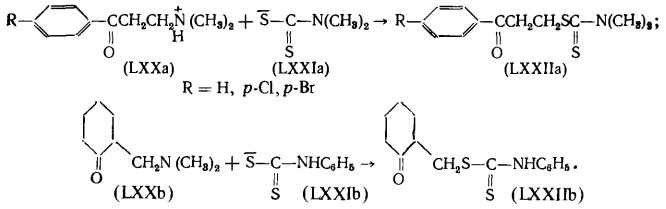
R=H, C_6H_5; Am=NC_4H_8O, NC_6H_{10}.

The same β-aminopropiophenones react with carbon disulphide in aqueous ammonia to form di(2-benzoylethyl) sulphide (LXIX):[74]



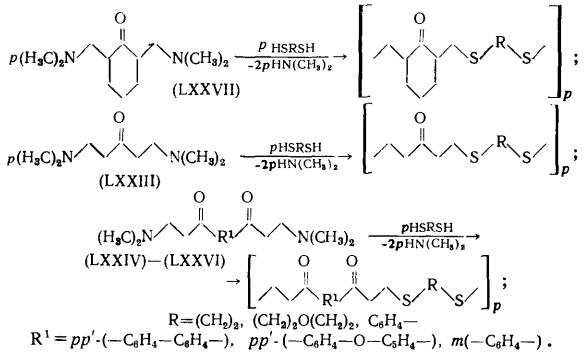
(LXIX)

The interaction of the Mannich bases (LXX, a and b) with the dithiocarbamates (LXXI, a and b) results in the elimination of the amine from the aminoketone molecule and the formation of *S*-(2-acetyl)dithiocarbamates (LXXIII, a and b):[74]



R = H, *p*-Cl, *p*-Br

The bis-Mannich bases (LXXIII)–(LXXVII), obtained from acetone, 4,4-diacetylbiphenyl, di(4-acetylphenyl) ether, 1,3-diacetylbenzene, and cyclohexanone, have been introduced into the polycondensation reaction with ethane-1,2-dithiol, oxydiethanedithiol, and 1,3-dimercaptobenzene. The reaction products are the corresponding poly(β-ketothioethers) (LXXVIII, a–d):[75,76]

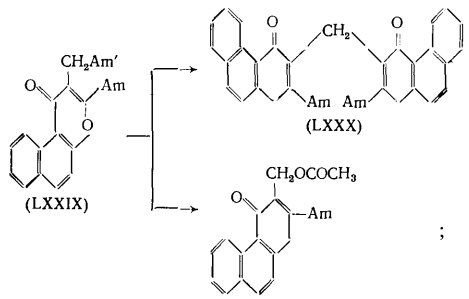


R=$(CH_2)_2$, $(CH_2)_2O(CH_2)_2$, C_6H_4—

R^1 = *pp'*-(—C_6H_4—C_6H_4—), *pp'*-(—C_6H_4—O—C_6H_4—), *m*-(C_6H_4).

(e) *O*-Alkylation

On heating in acetic anhydride at 95°–100 °C for 3–6 h, 3-dialkylamino-2-dialkylaminomethyl-1-oxo-1*H*-naphtho[2,1-*c*]pyrans (LXXIX) are converted into 2,2'-methylenebis{3-dialkylamino-1-oxo-1*H*-naphtho[2,1-*c*]pyrans} (LXXX) in satisfactory yields:[77]



(LXXIX) (LXXX) (LXXXI)

Am=$N(CH_3)_2$, $N(C_2H_5)_2$, NC_4H_8, NC_5H_{10}, $N(CH_3)(CH_2C_6H_5)$, $N(iso\text{-}C_3H_7)_2$, $N(CH_2—CH=CH_2)_2$; Am'=NC_4H_8O, NC_5H_{10}.

When Am = Am' = NC_5H_{10}, the *O*-alkylation product, namely 2-acetoxymethyl-1-oxo-3-(*N*-piperidyl)-1*H*-naphtho[1,2-*c*]pyran (LXXXI), is obtained in 34% yield together with compound (LXXX).

V. CYCLISATION

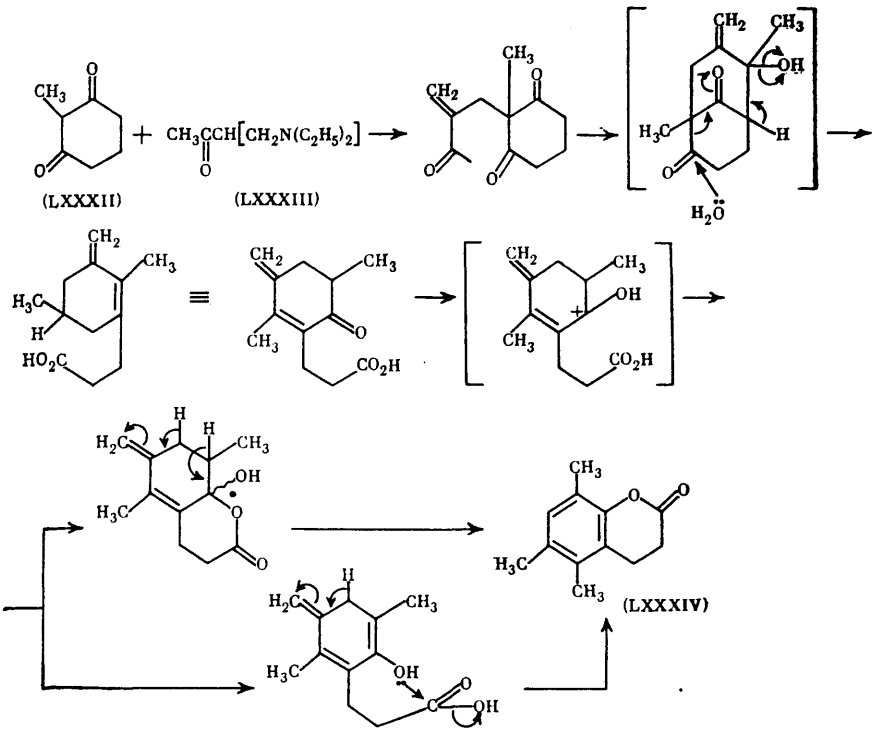
It is known that Mannich bases (β-aminoketones) can serve as intermediates in the synthesis of various heterocyclic compounds via cyclisation reactions. The latter can be

Table 1. *S*-Alkylation.

Alkylating compound (Mannich base)	Alkylated compound	Reaction product	Yield, %	Refs.
			16—83	[67, 71, 72]
			57—79	[67]
			19—57	[69]
			53.0	[68]
			14.0 32.0	[70]

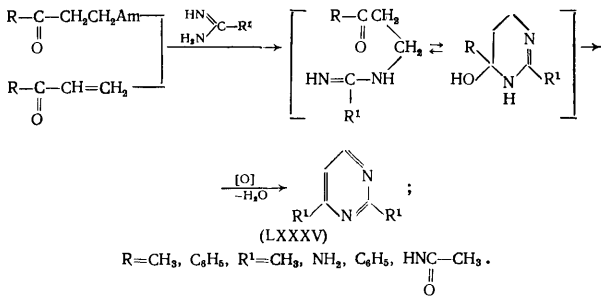
divided into two types: (1) reactions occurring with elimination of the amino-group; (2) reactions occurring without the elimination of the amino-group.

In most cases cyclisation with participation of β-amino-ketones is of the first type. In particular, when equimolar amounts of 2-methylcyclohexane-1,3-dione (LXXXII), *N*-bis-diethylaminomethylacetone (LXXXIII), and pyridine are refluxed in benzene, the dihydrocoumarin (LXXXIV) is obtained in 60% yield.[78] The ethyl analogue of compound (LXXXII) reacts analogously to the latter:



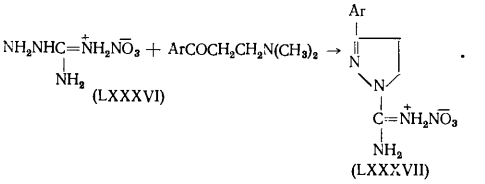
It is of interest to note that a bicyclic ketone is formed under the same conditions from 2-methylcyclopentane-1,3-dione, but its structure has not been stated.[78]

The interaction of the keto-derivatives of Mannich bases with amidines and guanidine leads to the pyrimidines (LXXXV).[79] The yield of the latter is then significantly higher than in the analogous condensation using the corresponding vinyl ketones:



The quaternary slats of β-aminoketones have also been used in this reaction, but this does not increase the yield of the corresponding pyrimidines.

Aminoguanidinium nitrate (LXXXVI) reacts with arylaminoketones in alcoholic solutions at pH 10 to form 1-amidino-Δ^2-pyrazolines (LXXXVII):[80]



The mechanism of the formation of the pyrazoline (LXXXVII) proposed by the authors includes the conversion of the aminoketone into the vinyl ketone and its subsequent conversion into a hydrazone, which cyclises to the pyrazoline. The authors demonstrated that, depending on the pH of the medium, the reaction products can also be di-β-ketohydrazines and the dinitrates of amidinohydrazones.

2-(*N*-Aminomethyl)cycloalkanones (LXXXVIII) have been converted into the diastereoisomeric spiro-pyrazolines (LXXXIX, a and b) and (XC, a and b) with the aid of an ethereal solution of diazomethane or diazoethane.[81] The

Table 2. The synthesis of heterocycles from β-aminoketones.

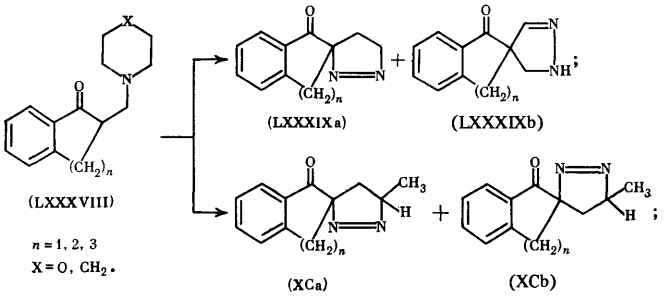
authors proposed a probable reaction mechanism:



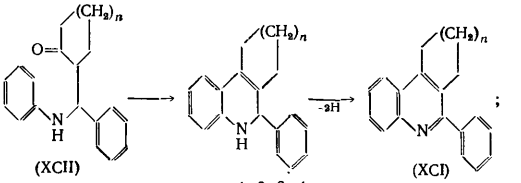
(LXXXVIII)

$n = 1, 2, 3$
$X = O, CH_2$.

(LXXXIXa) (LXXXIXb)

(XCa) (XCb)

Substituted quinolines (XCI) have been obtained by the cyclisation of 2-(1-anilinomethyl-1-phenyl)cycloalkanones (XCII) by refluxing the latter with a 9 : 1 mixture of acetic and sulphuric acids:[82]

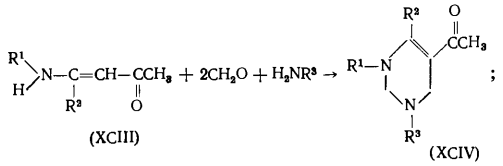


(XCII) (XCI)

$n = 1, 2, 3, 4$.

The synthesis of certain heterocyclic systems from various β-aminoketones has been described[83–88] (Table 2).

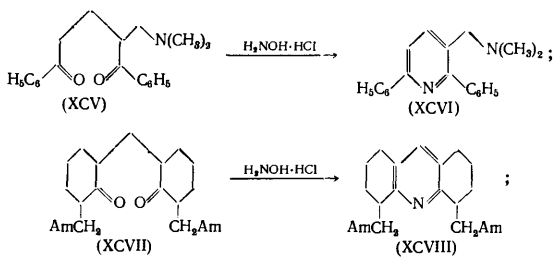
Under the conditions of the Mannich reaction with one mole of a primary amine and two moles of formaldehyde, the enaminoketones (XCIII) cyclise to the tetrahydropyrimidino-derivatives (XCIV):[89,90]



(XCIII) (XCIV)

R^1=CH_3, C_6H_5, $CH_2C_6H_5$, R^2 = H, CH_3, R^3=CH_3, $C(CH_3)_3$.

The interactions of β-aminoketones with hydroxylamine hydrochloride, formaldehyde, and other compounds are reactions of the second type.[91-95] Thus 1,3-dibenzoyl-3-dimethylaminomethylpropane (XCV) has been converted into 3-dimethylaminomethyl-2,6-diphenylpyridine (XCVI) with the aid of hydroxylamine hydrochloride, while bis(3-diamino-methyl-2-oxo-1-cyclohexyl)methane (XCVII) has been converted into 4,5-bis(aminomethyl)-*sym*-octahydroacridine (XCVIII):[91-93]

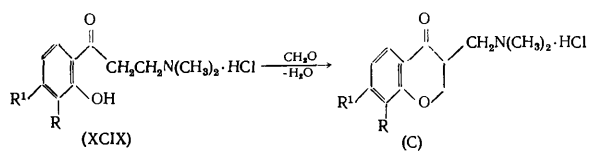


(XCV) (XCVI)

(XCVII) (XCVIII)

Am=$N(CH_3)_2$, $N(C_2H_5)_2$.

Substituted chromanones (C) have been obtained by cyclising the β-aminoketones (XCIX) with formaldehyde:[94]

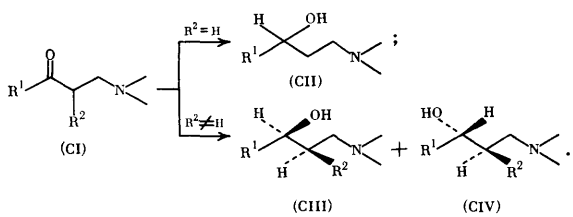


(XCIX) (C)

R, R^1 = H, CH_3O,

VI. REDUCTION

The carbonyl group of β-aminoketones can be readily converted into the hydroxy-group by reducing agents such as complex metal hydrides (lithium tetrahydroaluminate and sodium tetrahydroborate)[53,54,96-117] (Table 3), sodium amalgam,[118] and others.[106-111,119] The reduction products (γ-aminoalcohols) are of interest as biologically active substances:[97,100-102,120]

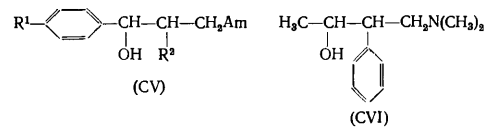


(CI) (CII) (CIII) (CIV)

It can be seen from the above scheme that the reduction of the aminoketones (CI, R^2 = H) leads to the formation of only one aminoalcohol (CII),† while the reduction of the aminoketones (CII, $R^2 \neq$ H) having an α-asymmetric centre gives rise to two diastereoisomeric aminoalcohols (CIII) and CIV).#

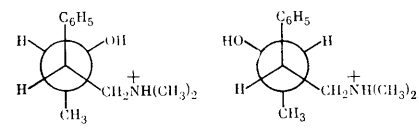
The absolute and relative configurations as well as the predominant conformations of the diastereoisomeric aminoalcohols have been determined by infrared and NMR spectroscopy and by mass-spectrometry.[98,100,105-114]

The aminoalcohols (CV) and (CVI) have been resolved into the diastereoisomers by fractional crystallisation.[98,100,112]



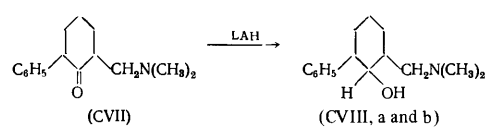
(CV) (CVI)

It has been shown[98] that the conformers (CVIa) and (CVIb) of compound (CVI) predominate.



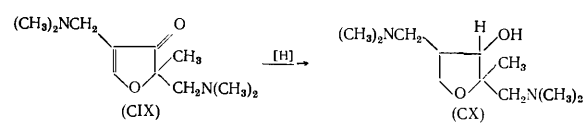
(CVIa) (*threo*) (CVIb) (*erythro*)

The reduction of the β-aminoketone (CVII), which is a derivative of phenylcyclohexanone, leads to a mixture of the stereoisomeric aminoalcohols (CVIIIa) and (CVIIIb), which has been resolved[114] into its components on a chromatographic column to give (CVIa) : (CVIb) = 3 : 1:



(CVII) (CVIII, a and b)

Whereas the reduction of 2,4-bisdimethylaminomethyl-2-methylfuran-3(2*H*)-one (CIX) with the aid of palladium on charcoal involves only the double bond, when rhodium on charcoal or sodium tetrahydroborate is used, the aminoalcohol (CX) is formed:[119]



(CIX) (CX)

†A case is known in which achiral β-dialkylaminopropiophenones were reduced to the optically active aminoalcohols by treatment with lithium tetrahydroaluminate/(−)-menthol.[121]

#The stereochemistry of the reduction of the β-asymmetric β-aminoketones has been described.[122,123] In particular, the reaction between lithium tetrahydroaluminate and a series of β-asymmetric β-aminoketones has been investigated.[123] It has been shown that the stereoselectivity of the reduction of *NN*-dialkylamino-derivatives is greater than that of the reduction of *N*-monoalkylamino-derivatives.

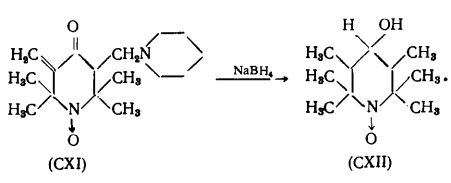
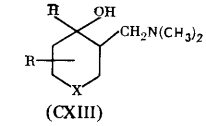
The αβ-unsaturated ketone (CXI) has been reduced to the 2,2,3,5,6,6-hexamethyl-4-hydroxypiperidin-1-yloxy-radical (CXII) with sodium tetrahydroborate:[124]



(CXI) (CXII)

Deamination takes place simultaneously.

A number of studies have been devoted to the stereochemical characteristics of the reduction of the aminomethyl derivatives of tetrahydropyran-4-ones and tetrahydrothiopyran-4-ones to the aminoalcohols (CXIII).[106-111]

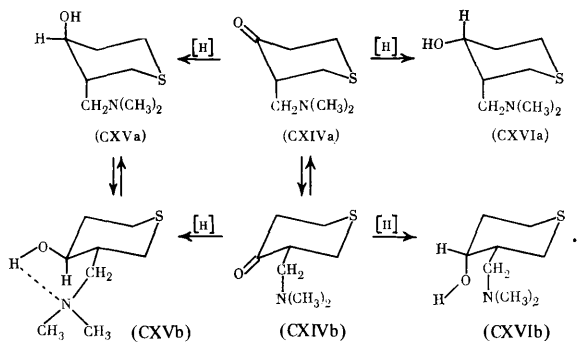


(CXIII)

R = CH_3, $(CH_3)_2$, $(CH_3)_3$, $CH_2N(CH_3)_2$, X = O, S.

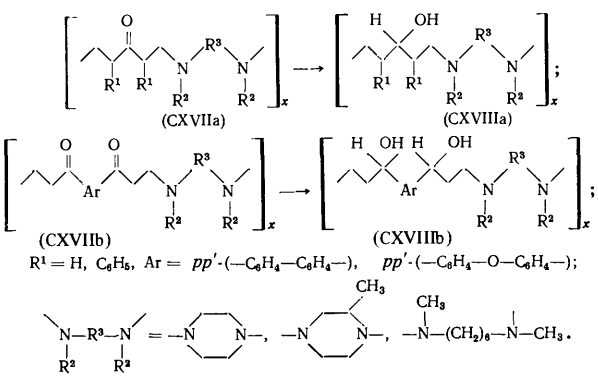
The quantitative ratios, the steric configurations, and the predominant conformations of the stereoisomeric aminoalcohols have been established by gas-liquid chromatography (GLC) and infrared and ^1H NMR spectroscopy and the steric specificity of the test reactions has been elucidated. It has been shown in a number of instances[107,110,111] that the quantitative ratio of the stereoisomeric aminoalcohols depends on the character of the reducing agent and the reaction conditions.

It has been noted that the equatorial isomers of the corresponding alcohols predominate in the reduction of the unhindered and conformationally stable 4-oxotetrahydro-1-thiopyrans (CXIV) with lithium tetrahydroaluminate, while in the reduction with aluminium isopropoxide the axial isomers are the dominant ones,[107] which agrees with the available data.[125] The individual isomers (CXV) and (CXVI) have been isolated by crystallising the mixture:



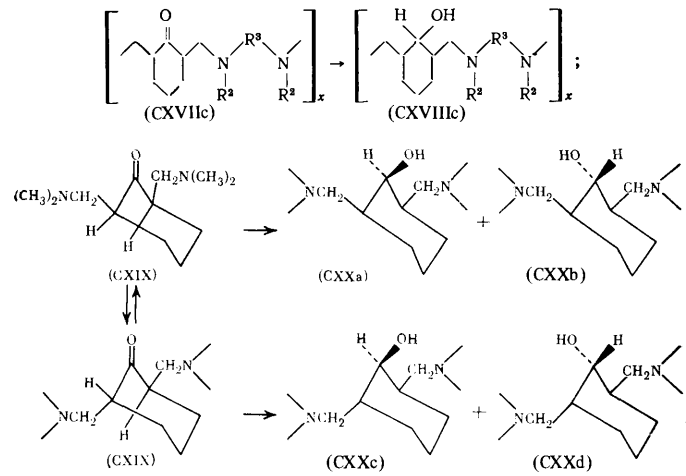
The authors[107] concluded that the aminoketone (CXIV) is reduced preferentially in the conformation (CXIVb), which should be promoted by the formation of a cyclic complex of the chelate type with participation of the metal hydride and the carbonyl amino-groups.[125] The reduction with participation of the conformation (CXIVa) followed by the conversion of the aminoalcohol conformers (CXVa) and (CXVIa) formed initially into compounds (CXVb) and (CXVIb) respectively is less likely, since this involves breaking the stereochemical rules governing the reduction of six-membered cyclic ketones.[126]

Data concerning the reduction of poly-β-dialkylaminoketones (CXVII) to the corresponding poly-γ-aminoalcohols (CXVIII) have been published:[127]



$R^1 = H, C_6H_5$, Ar = *pp'*-(—C_6H_4—C_6H_4—), *pp'*-(—C_6H_4—O—C_6H_4—);

For comparison, a study has also been made of the reduction of the corresponding monomeric aminoketones. The stereochemistry of the reduction products (both polymeric and monomeric) has been investigated. The reduction has been carried out both with lithium tetrahydroaluminate and catalytically:[127]



The reduction of the bis-Mannich base (CXIX) with lithium tetrahydroaluminate leads to the formation of all the possible stereoisomeric aminoalcohols (CXX, a–d). It has been established[127] that fragments having three configurations alternate in the polymeric γ-aminoalcohols:

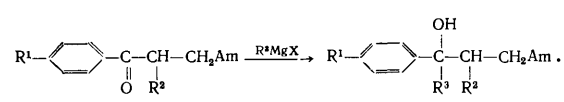
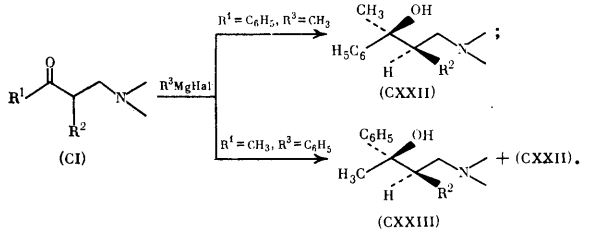
VII. REACTIONS WITH ORGANOMETALLIC COMPOUNDS

The tertiary γ-aminoalcohols (CXXI) have been obtained by the reaction of the β-aminoketones (CI) with a Grignard reagent or organolithium compounds[99–104,108,109,112,128–130] (Table 4):



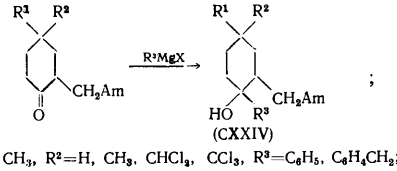
The stereochemistry of the reactions of aryl and methyl 2-aminoalkyl ketones substituted in the α-position, with Grignard reagents has been studied in detail.§ The configurations and the ratios of the diastereoisomers have been determined.[131,132]

The reaction with the phenyl-substituted aminoketones (CI, $R^1 = C_6H_5$) is 100% stereospecific and leads to the amino-alcohol (CXXII), while the reaction of the methyl-substituted ketobases (CI, $R^1 = CH_3$) takes place with the preferential formation of the diastereoisomer (CXXIII) (the optical yields are 86–100%).[133]



(CI) (CXXII) (CXXIII)

A large series of 4-substituted 2-aminomethyl-1-phenyl-(benzyl)cyclohexanols (CXXIV) have been synthesised by the interaction of cyclic Mannich bases with a Grignard reagent;[129] depending on the structure of the reactants, the yields are 30–80%. In particular, a relation is observed between the yields and the character of the amino-group: the best results have been obtained for the pyrrolidino- and morpholino-derivatives:

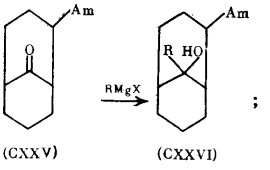


(CXXIV)

R^1=H, CH_3, R^2=H, CH_3, $CHCl_2$, CCl_3, R^3=C_6H_5, $C_6H_4CH_2$;

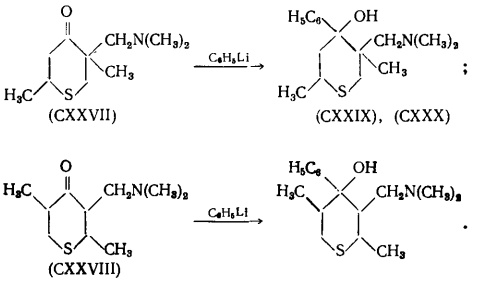
Am=NC_4H_8, NC_4H_8O, NC_6H_{10},  .

The reactions of the bicyclic Mannich bases (CXXV) with a Grignard reagent lead to the formation of the aminoalcohol (CXXVI); for R = C_6H_5, only one isomer of the aminoalcohol was isolated and its configuration established:[128]



(CXXV) (CXXVI)

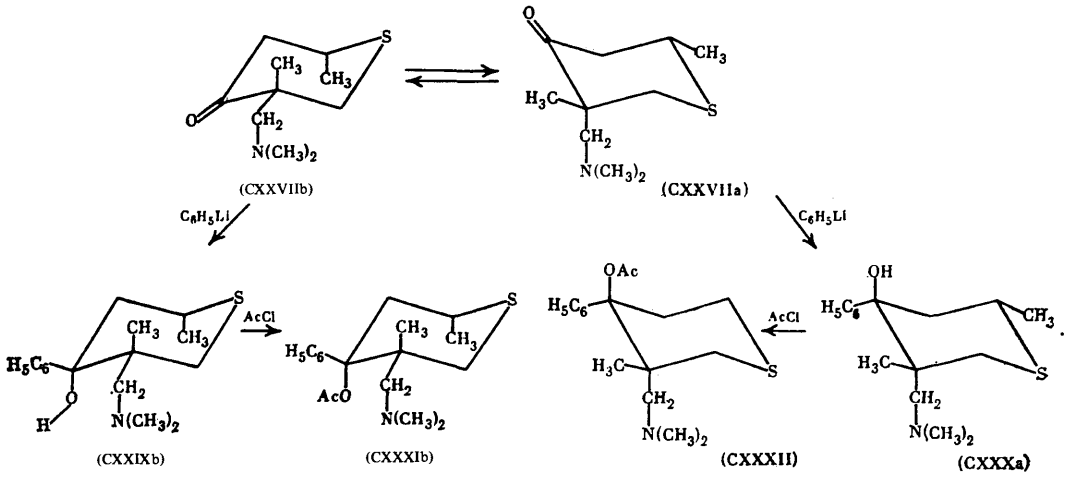
R=C_6H_5; *p*-FC_6H_4, $C_6H_5CH_2$, CH_3; Am= 
A strong predominance of one of two conformers has been observed in the synthesis of tertiary aminoalcohols from the aminomethyl derivatives of γ-ketones, in particular compounds (CXXVII) and (CXXVIII):[108,109,111,130]



(CXXVII) (CXXIX), (CXXX)

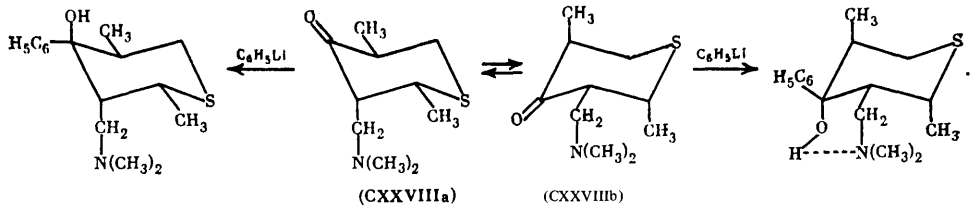
(CXXVIII)

The aminoalcohols (CXXIX) and (CXXX), which are formed as the dominant components from the aminoketone (CXXVII), have respectively the *cis*- and *trans*-configurations relative to the hydroxy- and aminomethyl group, but in solutions the conformational equilibrium is displaced towards the conformers (CXXIXb) and (CXXXa):



(CXXVIIb) (CXXVIIa) (CXXIXb) (CXXXIb) (CXXXII) (CXXXa)

§ The interaction of a Grignard reagent with β-aminoketones having an asymmetric carbon atom in the β-position or in the alkylamino-group also proceeds with a high degree of stereospecificity.[122,133,134]

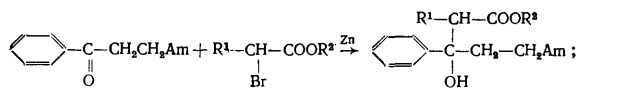


(CXXVIIIa) (CXXVIIIb)

The steric orientation of the hydroxy-groups of the amino-alcohols (CXXIX) and (CXXX) has also been confirmed by the character of the bands of the acetoxy-groups in the infrared spectra of solutions of the corresponding acetates (CXXXI) and (CXXXII).

The authors[109] concluded that the aminoketones (CXXVII) and (CXXVIII) interact with phenyl-lithium in the form of the conformers (CXXVIIb) and (CXXVIIIb) via a cyclic chelate complex with subsequent attack on the carbonyl group by the organometallic compound from the equatorial region leading to the *cis*-alcohols (CXXIXb) and (CXXXb), as shown above.

A number of studies[135-138] have been devoted to the reaction of β-aminopropiophenones (CXXXIII) with Reformatskii's reagent:



(CXXXIII)

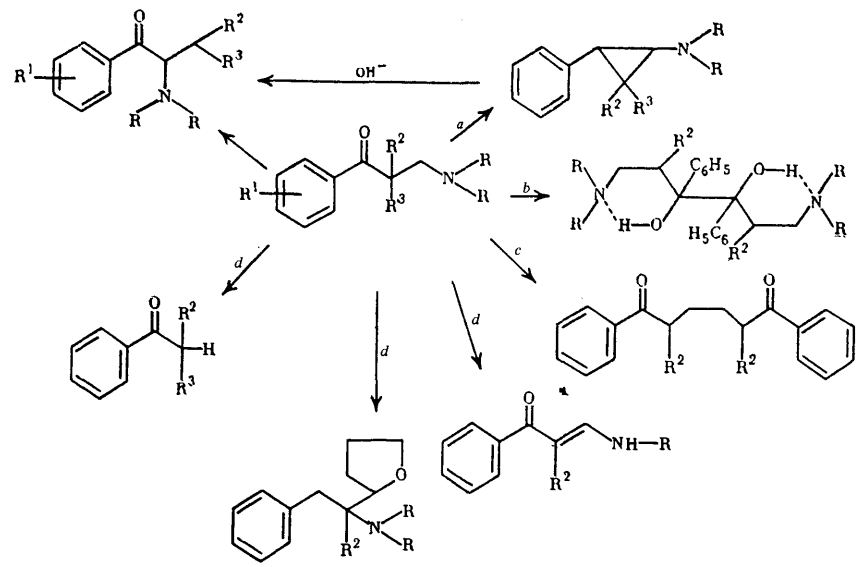
R^1=CH_3, C_2H_5, iso-C_3H_7, t-C_4H_9, R^2=CH_3, C_2H_5, Am=$N(CH_3)_2$, NC_4H_8O, NC_5H_{10}.

The yields for all R^1, except t-C_4H_9, amount to 81%. The steric hindrance in the case of the t-butyl derivative results in a considerable decrease of the yield (not above 10%).

A stereochemical study of the course of the reaction[136-138] showed that compound (CXXXIV) is a mixture of the *erythro*- and *threo*-forms.[133-135] The relative configurations of the diastereoisomers have been established.[137] The authors suggest that the reaction proceeds via a bicyclic transition state in which the nitrogen atom participates and that this is the reason for the observed asymmetric induction.[138] The question of the stability of the transition state is discussed.

VIII. PHOTOCHEMICAL REACTIONS

The authors of a large number of communications[139-153] investigated the photochemistry of β-aminoketones (Mannich bases). The reactions undergone by the latter on irradiation can be divided into the following groups: cyclisations (a), dimerisations (b), isomerisations (c), and other reactions (d). The reactions are shown in the scheme below:



(a) R^1 = H, CH_3, iso-C_3H_7, R^2 = CH_3, C_2H_5, C_6H_5, R^3 = H, CH_3 (for R^2 = CH_3);

(b) R^1 = R^3 = H, R^2 = H, C_6H_5, R^3 = 4-CH_3O, for R^1  ;

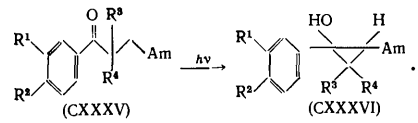
(c) R^1 = R^3 = H, R^2 = H, C_6H_5;

(d) R^1 = H, CH_3, R^2 = R^3 = CH_3;

R^1 = H, R^2 = R^3 = CH_3; $N\begin{smallmatrix}R\\R\end{smallmatrix}$ = $HN(C_3H_7$-iso), $HN(C_4H_9$-t), HNC_6H_{11}; $NHCH_2C_6H_5$,

$NHCH_2CH_2C_6H_5$, NC_4H_8O, NC_5H_{10}, HN—Ad (Ad = adamantyl),  .

The photochemical cyclisation of β-aminopropiophenones (CXXXV) has been reported;[140,142] cyclopropanols were obtained for the first time by this procedure. The cyclisation products (CXXXVI) are indicated in Table 5.

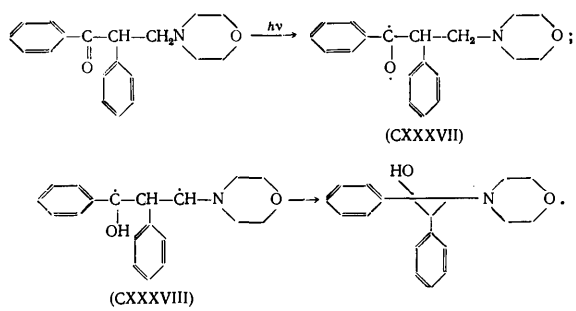


(CXXXV) (CXXXVI)

Table 5. Products of the cyclisation of β-aminopropiophenones (CXXXVI).

R^1	R^2	R^3	R^4	Am	Yield, %	Refs.
H H, CH_3	H H, CH_3, $CH(CH_3)_2$	H CH_3	CH_3, C_6H_5 CH_3	NC_4H_9O $NHCH_3$, NHC_6H_5, $NHCH_2C_6H_5$ $NHCH_2CH_2C_6H_5$	85—98 25—72	[115] [117]

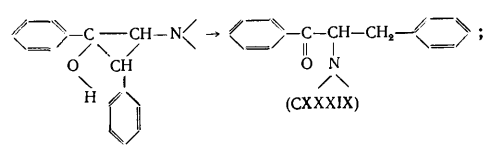
It has been suggested that the excitation of the C = O group results in the initial formation of the C—O biradicals (CXXXVII) which abstract a hydrogen atom from the β-position with the simultaneous formation of the OH group and the C—C biradical (CXXXVIII), which is converted, by intermolecular recombination, into the cyclopropane ring in accordance with the scheme[140]



(CXXXVII)

(CXXXVIII)

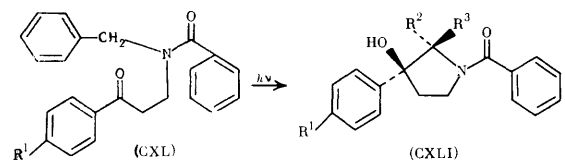
It is of interest that the cyclopropanols (CXXXVI) isomerise to 2-amino-1,3-diphenylpropanones on treatment with alkali or pyridine (CXXXIX):[140,142,143]



(CXXXVI) (CXXXIX)

$N\langle = NC_5H_{10}$, NC_4H_9O.

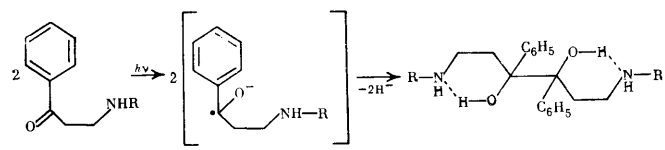
Irradiation of the aminoketones (CXL) in ether gives rise to 1-benzoyl-2-phenyl-3-(4-R-phenyl)pyrrolidin-3-ols (CXLI), which have been resolved into the stereoisomers (2*R*, 3*S*) and (2*S*, 3*R*) by preparative thin-layer chromatography:[144]



(CXL) (CXLI)

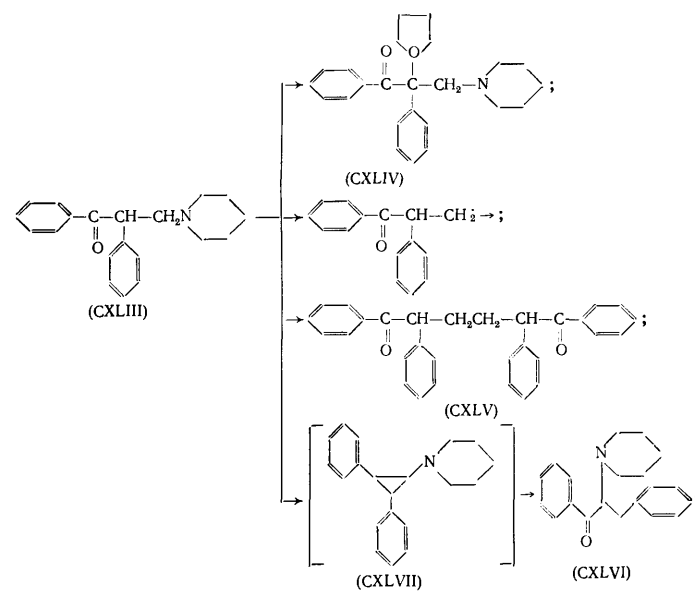
$R^1 = H$, $R^2 = H$, $R^3 = C_6H_5$; $R^1 = Cl$, $R^2 = H$, $R^3 = C_6H_5$;
$R^1 = Cl$, $R^2 = C_6H_5$, $R^3 = H$; $R^1 = Br$, $R^2 = H$, $R^3 = C_6H_5$;
$R^1 = Br$, $R^2 = C_6H_5$, $R^3 = H$ $R^1 = CH_3O$, $R^2 = H$, $R^3 = C_6H_5$.

It is believed[146,147] that photodimerisation with formation of pinacols (the so-called "pinacolisation" reaction) proceeds via the radical-anion(CXLII):



(CXLII)

On irradiation, 2-phenyl-3-piperidinopropiophenone (CXLIII) undergoes different photochemical reactions depending on the solvent:[149]

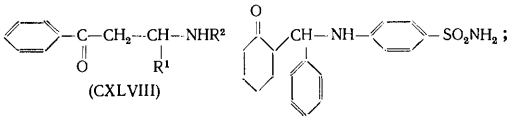


(CXLIII) (CXLIV) (CXLV) (CXLVII) (CXLVI)

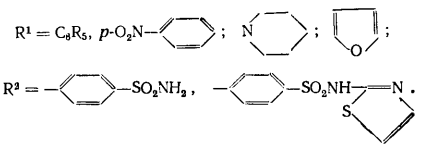
Thus 1,2-diphenyl-3-piperidino-2-(2-tetrahydrofuryl)1-propanone (CXLIV) is formed in tetrahydrofuran (THF). In dioxan, tetrahydropyran, and their mixtures with benzene or in a THF—benzene mixture, compound (CXLIII) gives rise to 1,2,5,6-tetraphenyl-1,6-hexanedione (CXLV) and 1,3-diphenyl-2-piperidino-1-propanone (CXLVI).

The symmetrical diketone (CXLV) is the product of the dimerisation of the radical formed on protolytic elimination of the amine from the initial compound. It is believed[149] that the isomerisation with formation of the α-aminoketone (CXLVI) proceeds via the intermediate cyclopropanol (CXLVII).

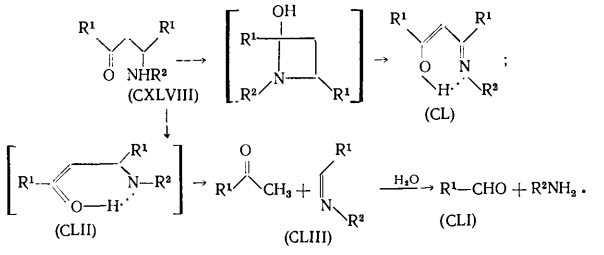
The photochemistry of the sulphamide Mannich bases of the type of compounds (CXLVIII) and (CXLIX) has been investigated:[150]



(CXLVIII) (CXLIX)



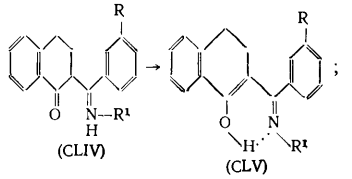
Ultraviolet irradiation of compounds (CXLVIII) in methanol results in the occurrence of two reactions: dehydrogenation to the corresponding β-iminoketones (CL), which exist in the enolic form, and cleavage to the amine, acetophenone, and the aldehyde (CLI):



(CLII) (CLIII) (CLI)

The cyclic intermediate state (CLII), from which acetophenone and the corresponding azomethines (CLIII) are formed, has been proposed for the photolytic cleavage of the aminoketone (CXLVIII).

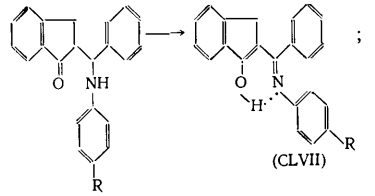
Irradiation of the Mannich bases (CLIV) with ultraviolet light leads to 2-[(*N*-R^1-imino)(4′-R-phenyl)]methyl-3,4-dihydro-1-naphthols (CLV):[152]



(CLIV) (CLV)

R=H, NO_2, R^1=C_6H_5, *p*-$CH_3OC_6H_4$, α-naphthyl.

2-[(4′-R-Phenylimino)phenyl]methyl-1-indenols have been obtained from compounds (CLVI) under analogous conditions:



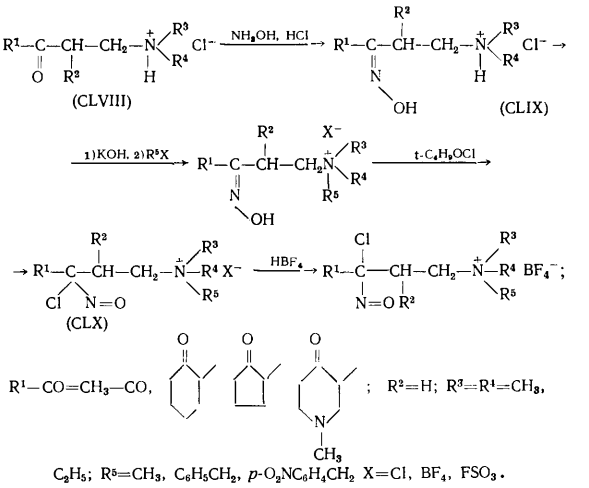
(CLVI) (CLVII)

R=H, CH_3O.

IX. OTHER REACTIONS

It has been shown[154] that the β-aminoketones obtained by the aminomethylation of 1-tetralone, 3,3,6,7-tetramethyl-1-tetralone, acetophenone, 1-chromanone, and *N*-methyl-4-piperidinone with piperidine are capable of producing on acetolysis unsaturated ketones, which are slowly converted into dimers.

The Mannich bases (CLVIII) have been converted into the oximes (CLIX), which were then oxidised to the *gem*-chloro-nitroso-derivatives (CLX) by the chloronium ion:[155]



(CLVIII) (CLIX) (CLX)

C_2H_5; R^5=CH_3, $C_6H_5CH_2$, *p*-$O_2NC_6H_4CH_2$ X=Cl, BF_4, FSO_3.

Complexes with lanthanide metal ions have been obtained from β(α)-naphthylamino-2,4,6-dihydroxypropiophenones;[156] a "metal–metal" bond has not been observed in these complexes, which indicates their monomeric nature.

The influence of 5-substituted 2-hydroxy-β-morpholinopropiophenones and *NN*-bis[β-(2-hydroxy-5R-benzoyl)ethyl]-piperazines on the resistance of polyethylene to the action of the atmosphere under the conditions of accelerated ageing has been investigated.[157] Despite their low effectiveness as thermal stabilisers, they are good light stabilisers of polyethylene.

Aminoketones have been finding applications also in the preparation of various polymers.[3c,55,56,75,76,127,158]

Metallocarbaboranes. Structural Studies in Recent Years

A. I. Yanovskii

Structural studies on metallocarbaboranes (MCB) are surveyed and modern theoretical ideas about the electronic structure of cluster and particularly polyhedral MCB systems are discussed. The characteristic features of the geometry of the polyhedra in specific MCB are examined in connection with the specific features of their electronic structure.
The bibliography includes 78 references.

I. INTRODUCTION

Metallocarbaboranes (MCB) constitute a large class of polyhedral compounds which contain, together with boron and carbon atoms, also several metal atoms in the polyhedron. These compounds, which occupy an intermediate position at the junction between organoelemental and organometallic chemistry, have become in recent years the objects of vigorous research. As frequently happens, the results obtained in this boundary field of science are not only of independent importance but to a large extent they have enriched the ideas which have arisen in adjacent disciplines and have frequently stimulated their development. Such a stimulating role in relation to the chemistry of cluster compounds was played at one time by MCB, which became, as early as the middle of the 1960's, one of the first examples of metal-containing polyhedral systems. The studies in this field have made it possible to combine successfully the researches into the complex and unexpected reactions and far-reaching thermal rearrangements with the synthesis of a large number of extremely stable compounds which are promising from the practical standpoint.

The specific features of MCB are determined in the first place by their unusual polyhedral structures, which are distinguished by an usually wide variety and frequently by their aesthetic perfection. It is therefore natural that in the investigation of these compounds structural studies (these are carried out almost exclusively by X-ray diffraction) occupy in a certain sense a central position, because, on the one hand, they provide the necessary information without which it would be impossible to plan and achieve the synthesis of MCB and, on the other hand, they serve as a basis for the development and improvement of theoretical ideas about their structure.

The following figures reveal the rate of growth of the number of structural studies on MCB in recent years. Thus the exhaustive review by Grimes,[1] which covers the literature up to 1975, quotes a list of more than 400 compounds synthesised by that time, of which only 46 have been subjected to structural studies; at the beginning of 1981, 95 X-ray

diffraction studies on MCB had been performed and during the last 1.5–2 years a further 25 studies concerned with this field have been published.

As a result of the wide variety of the structures of MCB, in many of these studies not only was the structure of the newly synthesised compound established but also new types of polyhedra, unusual modes of coordination of the metal atoms, or hitherto unknown motifs in the disposition of the atoms in the polyhedron were discovered. Although less than 20 years have elapsed since the synthesis of the first MCB by Hawthorne and co-workers[2] in 1965, definite theoretical ideas have already been formulated, which, while they do not always possess an adequate predictive power, at any rate make it possible to generalise and arrange systematically the experimental data accumulated at the present time. Here we have in view the rules for the evaluation of the numbers of skeletal electrons (i.e. the electrons responsible for the bonding in the polyhedron), sometimes referred to as Wade's rules, or the "$2n + 2$" rules.[3] The important role of these rules for the elucidation of the structures of cluster compounds in general and the wide variety of polyhedral boron derivatives in particular has been examined in a number of studies (see, for example, Refs. 3–7). The essential features of Wade's ideas are briefly described in this review in order to employ them subsequently in considering the MCB structures.

II. MODERN IDEAS ABOUT THE ELECTRONIC STRUCTURE OF METALLOCARBABORANES

The ideas underlying the "$2n + 2$" rule have been described in a most logical and readily understood form in the book of King and Rouvray,[5] who consider the structure of cluster systems from the standpoint of the topology of the polyhedron. According to their description, each boron or carbon atom (for simplicity, we shall consider initially a purely carbaborane polyhedron) in an n-vertex polyhedron have an outer atomic orbital (AO), which is used to form the exopolyhedral bond, two tangential orbitals directed along the tangent to the envelope of the polyhedron, and one internal orbital directed towards the centre of the polyhedron (the inner and outer orbitals can be regarded, for example, as two sp-hybrid orbitals). When a cluster is formed, the exopolyhedral orbitals (n orbitals) are not involved and the interaction of $2n$ tangential AO leads to n bonding and n antibonding cluster orbitals.[5] It remains to explain what happens to the n inner orbitals.

In comparing "superaromatic" three-dimensional clusters with planar aromatic systems (here a comparison is made of the sp^2-hybrid orbitals involved in the formation of the σ-bonds of the aromatic ring with the tangential orbitals and of the unhybridised p orbitals with the inner orbitals of the cluster atoms), King and Rouvray[5] emphasise the important topological difference between these two types of aromatic systems. The planar systems are characterised by cyclic graphs C in which each atom is linked to only two neighbours, while the so-called complete graphs K_n, in which each atom is assumed to be bound to all the remaining atoms, are characteristic of the cluster polyhedra. This topological difference is responsible for the different forms of the quantum-chemical equations—for example, the different matrices of the linear equations in the simple Hückel method (only the non-diagonal elements in these matrices, which correspond to pairs of atoms between which there is a chemical bond, are known to be non-zero). The solution of these equations shows that, in contrast to planar molecules, for example, those of benzene (where the interaction of six "inner" p orbitals gives rise to three bonding and three antibonding π orbitals), in the three-dimensional systems the interaction of the n inner orbitals leads to only one non-bonding cluster orbital and $n - 1$ antibonding orbitals.

Thus the total number of the bonding MO in an n-vertex cluster is $n + 1$ (n orbitals formed by the tengential AO and one formed by the inner AO). This approach provides a clear explanation of the experimental rule[3] according to which the most stable carbaboranes, with the maximum delocalisation of electron density, have $2n + 2$ skeletal electrons, which are responsible for the bonding in the polyhedron. Such polyhedra have only triangular faces; they are referred to as *closo*(closed)-polyhedra or deltahedra.

When one of the vertices of the *closo*-polyhedron is removed, one (open) (non-triangular) face arises in the latter. The resulting polyhedron can be regarded as a combination of two complete graphs, one of which includes only inner vertices i.e. those not located on the "open" face, and the other only the boundary vertices (belonging to the "open" face). The interaction of the inner orbitals of the atoms belonging to each graph results in the formation of one additional bonding orbital in each instance. Thus the total number of binding orbitals formed by the interaction of both tangential and inner orbitals in such instances is $n + 2$, where n is the number of vertices of the polyhedron. Such polyhedra with one "open" face are referred to as *nido*-polyhedra (from the Greek "nido"—nest). The so-called *arachno*-structures (from the Greek "arachne"—cobweb) with $2n + 6$ skeletal electrons can be obtained by the removal of two vertices from *closo*-systems.

Thus the opening of the polyhedron, namely the formation of *nido*- and *arachno*-systems, corresponds to an excess of skeletal electrons (relative to $2n + 2$). A deficiency of skeletal electrons can also affect the character of the cluster polyhedron, leading to the formation of extremely unusual structures in which one or several triangular faces have over their centres additional vertices (caps). These polyhedra can also be formally classified as *closo*-systems, because they contain only triangular faces. However, in contrast to the polyhedra representing "normal" $2n + 2$ electron clusters, polyhedra with additional vertices can be subdivided into two smaller *closo*-polyhedra (for example, along the planes of the faces over which the caps are centred). Certain "super-electron-deficient" systems of this kind will be discussed below.

Table 1. The numbers of electrons supplied to the MCB polyhedron by various groups.

Group	No. of electrons	Group	No. of electrons
BH	3—1=2	$Fe(CO)_3$	8+6—12=2
CH	4—1=3	CoCp	9+5—12=2
PMe	5—1=4	$RhH(PPh_3)_2$	9+1+4—12=2
$Re(CO)_3$	7+6—12=1	$NiC_2B_9H_{11}$	10+4—12=2
FeCp *	8+5—12=1	$Pt(PPh_3)_2$	10+4—12=2
$CoC_2B_9H_{11}$	9+4—12=1	NiCp	10+5—12=3
$Rh(PPh_3)_2$	9+4—12=1	$AuC_2B_9H_{11}$	11+4—12=3

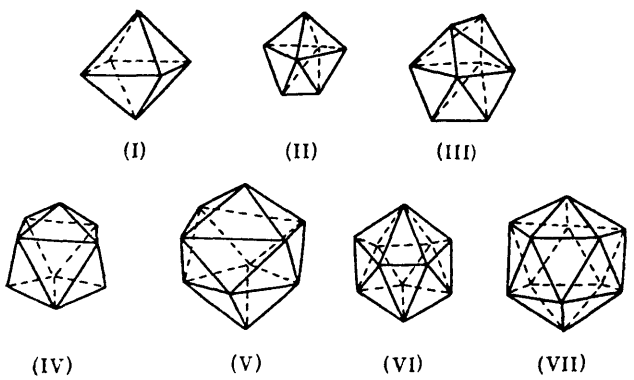
*Here and henceforth Cp = cyclopentadienyl.

In conclusion of this Section, one may indicate how the numbers of skeletal electrons in specific, particularly polyhedral, MCB systems should be evaluated (Table 1). It is

evident from the foregoing that the BH and CH groups each supply three orbitals and correspondingly two and three electrons to the polyhedron. When a transition metal atom is incorporated in the polyhedron, it is assumed that, of the nine of its orbitals, it employs three for bonding in the polyhedron, while the remaining six are used to form bonds with external ligands. It is assumed that the electrons of the metal and the ligands fill in the first place the orbital not involved in the bonding within the polyhedron, i.e. the six outer orbitals. The ML_n group therefore supplies to the polyhedron x electrons of the metal and k electrons of the n ligands, while 12 electrons are distributed among the exopolyhedral orbitals. Thus, overall, the group ML_n supplies $x + k - 12$ skeletal electrons to the polyhedron. For example the $Fe(CO)_3$, CoCp, $Pt(PR_3)_2$, etc. groups function, like the BH group, as donors of two electrons, while the NiCp group, like the CH group, supplies three electrons to the polyhedron.

III. THE STRUCTURES OF METALLOCARBABORANES

We shall now proceed directly to the discussion of the structures of the MCB. The ideal *closo*-polyhedra characteristic of the $B_nH_n^{2-}$ ions and carbaboranes with $n = 6 - 12$ are presented below (Table 2).



The polyhedra of the MCB and carbaboranes having the same number of vertices are usually analogous, although the introduction of a metal atom normally reduces the symmetry of the polyhedron relative to the corresponding carbaboranes. In a number of instances new skeletons, without analogues in the structural chemistry of boranes and carbaboranes, have been discovered in MCB: however, for their description it is frequently also convenient to begin with the *closo*-systems listed in Table 2.

Table 2. *closo*-Polyhedra characteristic of the $B_nH_n^{2-}$ ions and the carbaboranes $C_2B_{n-2}H_n$.

No.	Ion	Polyhedron	Symmetry group	No. of vertices	No. of edges	No. of faces
(I)	$B_6H_6^{2-}$	Octahedron	O_h	6	12	8
(II)	$B_7H_7^{2-}$	Pentagonal bipyramid	D_{5h}	7	15	10
(III)	$B_8H_8^{2-}$	Dodecahedron	D_{2d}	8	18	12
(IV)	$B_9H_9^{2-}$	Three-cap trigonal prism	D_{3h}	9	21	14
(V)	$B_{10}H_{10}^{2-}$	Two-cap square antiprism	D_{4d}	10	24	16
(VI)	$B_{11}H_{11}^{2-}$	Octadecahedron	C_{2v}	11	27	18
(VII)	$B_{12}H_{12}^{2-}$	Eicosahedron	I_h	12	30	20

We shall next consider MCB structures with different numbers n of vertices in the polyhedron; only the most characteristic and typical examples, and not all the structures investigated, are quoted for each value of n. A more complete idea about the MCB structures can be obtained from a number of previous reviews.[1,8-15]

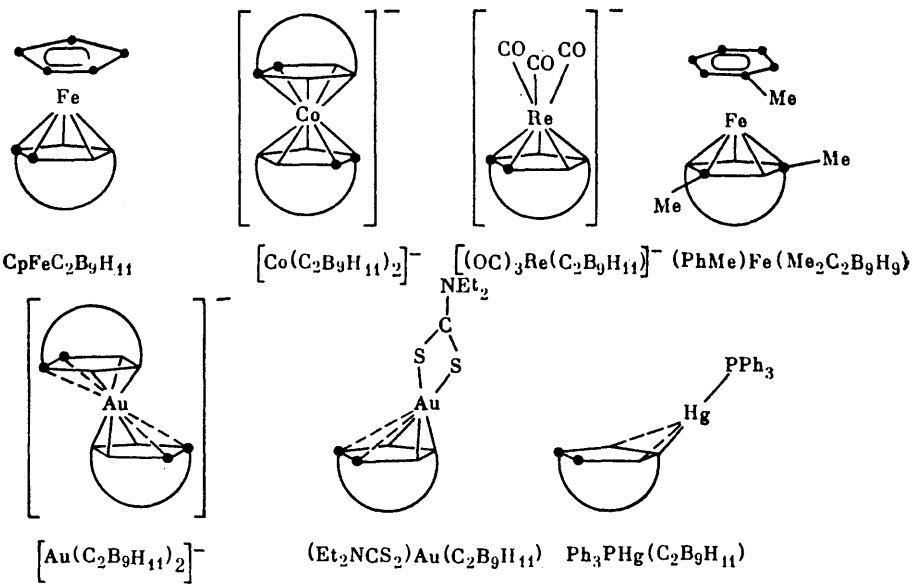


Figure 1. 12-Vertex MCB;[16-23] for simplicity, the *nido*-eicosahedral fragments are represented by half-circles.

1. The Highest (12- and 13-Vertex) Metallocarbaboranes

The most extensive and most widely investigated class of MCB comprises the eicosahedral 12-vertex MCB (Fig.1)†. The first MCB whose structure has been investigated, namely $CpFeC_2B_9H_{11}$, which has a sandwich structure, belongs to this class.[16] Its iron atom is symetrically coordinated to the cyclopentadienyl ligand and to the "open" pentagonal C_2B_3 face of the dicarbollide $(C_2B_9H_{11})^{2-}$ ligand; the Fe–C and Fe–B distances are identical within the limits of the accuracy of the measurement and amount to 2.04 Å.

Subsequently a large number of 12-vertex MCB, incorporating the metals of almost all the Groups in the Periodic System, were synthesised; more than 40 of these have been studied by X-ray diffraction. Almost all the 12-vertex metallocarbaboranes have a more or less strongly distorted eicosahedral structure and, in contrast to the iron derivatives menticned above, in most cases are diamagnetic complexes satisfying Wade's rule. As an example, one may quote two MCB investigated in the form of caesium salts—the anions $[Co(C_2B_9H_{11})_2]^-$ [17] and $[(OC)_3Re(C_2B_9H_{11})]^-$,[18] which belong to the class of MCB known for the longest time, and also the π-arene complex of bivalent iron $(MePh)Fe(Me_2C_2B_9H_9)$ synthesised several years ago.[19] A fully symmetrical coordination of the metal atom to the π-dicarbollide ligand was observed in these compounds. However, such symmetrical coordination is by no means always observed in the 12-vertex MCB. Thus, on passing from the d^6 and d^7 complexes of iron(II), cobalt(III), and rhenium(I), etc. to the d^8 complexes of palladium(II), platinum(II), and gold(III) and further to the d^{10} derivatives of mercury(II), considerable distortion of the symmetrical coordination is observed, being reflected in a shift of the metal atom towards the B atoms of the "open" face and in the breakdown of its planarity, which promotes a shift of carbon atoms away from the metal atom and a shortening of the C–C bond in the *ortho*-dicarbollide ligand. Such distortion of the coordination of the carbaborane ligand can be called the "shift" distortion and in the case of the *ortho*-dicarbollide ligand the "pseudo-π-allyl" distortion.

For example, the difference between the Au–B and Au–C distances in the anion $[Au(C_2B_9H_{11})_2]^-$ [20] reaches approximately 0.5 Å, the angle of inflection in the "open" face along the B...B line is 13.6°, and the C–C bond is shortened to 1.46 Å. As a result of the further "opening" of the MCB polyhedron on passing to the mercury derivative $Ph_3PHg(C_2B_9H_{11})$,[21] the metal atom is bound to only one B atom in the "open" face (the Hg–B distance is 2.20 Å), while the binding to its neighbours in the face assumes the character of weak interaction (with Hg...B distances of 2.50 and 2.53 Å). Finally, the thallium complex can be regarded as the double salt $[R_4P]^+Tl^+[C_2B_9H_{11}]^{2-}$ rather than the phosphonium slat of the thallium-carbaborane anion (Tl...B = 2.664–2.744 Å and Tl...C = 2.915 Å[22]).

It must be emphasised that the above distortions of the *closo*-structure are observed under conditions where the "$2n + 2$" rule formally holds and are independent of whether or not the 18-electron rule holds for the coordination of the metal atom. This is indicated by the structural data for the two gold complexes presented in Fig.1, namely $[(Et_2NCS_2)_2Au]^+[(Au(C_2B_9H_{11})_2]^-$ [20] and $(Et_2NCS_2).Au(C_2B_9H_{11})$,[23] in which identical pseudo-π-allyl distortions are observed, although in the former the Au atom has a 20-electron shell whereas in the latter it has an 18-electron shell. The only structural investigation of the platinacarbaborane $Pt(C_2B_9H_{11})_2$, incorporating the Pt atom in the +4 oxidation state, carried out hitherto[24] has shown that the distortions in the polyhedron are determined evidently solely by its electronic configuration and not by the presence in it of a specific metal atom. Indeed, in the d^6 complex indicated the platinum atom is included in two eicosahedra which are actually symmetrical: the average Pt–C and Pt–B distances are 2.24 and 2.20 Å respectively.

The nature of the "shift" distortions in the symmetrical coordination of the metal in the 12-vertex MCB has been studied in two investigations,[25,26] in which calculations were carried out for the interaction of the $Pt(PH_3)_2$ fragment with the borate anion $B_{11}H_{11}^{2-}$ and its carbaborane analogues by the extended Hückel method (Fig.2). The calculation showed that the character of the coordination of the metal atom as well as the orientation of the PtP_2 group relative to the ligand are determined by the interaction between the highest occupied molecular orbital (HOMO) in this group (i.e. the hybridised d_{xz}-p_x orbital localised in the plane of the Pt–P bonds) and the lowest unoccupied MO (LUMO) of the ligand. In the borate anion $B_{11}H_{11}^{2-}$ two electrons are located at the doubly degenerate $5e_1$ level. As a result of the replacement of one or two B atoms in the "open" face by C atoms, the degeneracy is removed and the location of the nodal plane of the LUMO depends on the positions of the carbon atoms in the carbaborane ligand. The optimum overlap of the HOMO of the metal and the LUMO of the ligand occurs for the orientation in which their nodal planes coincide.

The HOMO nodal plane of the $Pt(PH_3)_2$ fragment is perpendicular to the PtP_2 plane and the ML_2 fragment should therefore be at right angles to the symmetry plane of the $CB_{10}H_{11}$ (I) and *ortho*-$C_2B_9H_{11}$ (III) ligands (Fig.2) and parallel to this plane in the case of the *meta*-$C_2B_9H_{11}$ (II) ligand. Such orientation does actually obtain in the three palladium and platinum complexes whose structures have been investigated: $(Me_3CNC)_2Pd(1\text{-}Me_3NCB_{10}H_{10})$,[27] $(PhMe_2P)_2Pt(2,5\text{-}Me_2C_2B_9H_9)$,[28] and $(Et_3P)_2Pt(3,4\text{-}C_2B_9H_{11})$.[25]

Fig.2 illustrates yet another, perhaps even more important conclusion reached in the above studies.[25,26] Calculation has shown that the LUMO of the carbaborane ligand is localised at the B atoms to a much greater extent than at the C atoms. This factor explains qualitatively the "shift" distortions of the MCB eicosahedra observed for the 12-vertex complexes of metals with the d^8–d^{10} electron configuration.

The most realistic prospects, at the present time, for the practical application of the MCB are also associated with the largest and most thoroughly investigated class of MCB, namely the 12-vertex complexes. Several years ago a structural study was made[29] on the rhodium hydride complex $(Ph_3P)_2PhH(C_2B_9H_{11})$—an effective homogeneous catalyst for the hydrogenation of olefins. A study of the catalytic properties of this complex established that the rate of the hydrogenation reaction diminishes after the addition of free triphenylphosphine to the reaction mixture. The authors[29] suggested that the catalytic hydrogenation reaction takes place with participation of a coordination-unsaturated metal atom and that the first, rate-limiting stage of the catalytic process involves the elimination of the Ph_3P ligand.

These ideas were used for the specific synthesis of a new rhodiacarbaborane complex with a still higher catalytic activity. In the new compound $(Ph_3P)HRhC_2B_9H_{10}C_4H_7)$, whose structure has also been studied,[30] the rhodium atom is involved in η^2-type coordination to the double bond of the butenyl substituent of the dicarbollide ligand (Fig.3). The η^2-coordinated double bond, activated by the interaction with the rhodium atom, is hydrogenated in the first place

†The carbon atoms in Fig.1 and also in some of the subsequent figures are designated by filled circles.

under the conditions of the hydrogenation reaction. Subsequently the metal atom becomes coordination-unsaturated, which in fact determines the catalytic properties of the complex. Indeed the complex described proved to be one of the most effective catalysts for the homogeneous hydrogenation of olefins known at the present time. The related alkene-substituted carbaborane rhodium hydride complex $(PH_3P)_2HRhC_2B_9H_9C_8H_{14}$), with an unsaturated exopolyhedral nine-membered ring, whose double bond is coordinated to the metal atom (Fig. 3), exhibits a somewhat smaller catalytic activity.[31]

Yet another rhodium complex showing a catalytic activity, namely $(Ph_3P)_2HRhC_2B_{10}H_{12}$ (Fig. 4),[32] belongs to the group of the very few structurally characterised 13-vertex MCB.

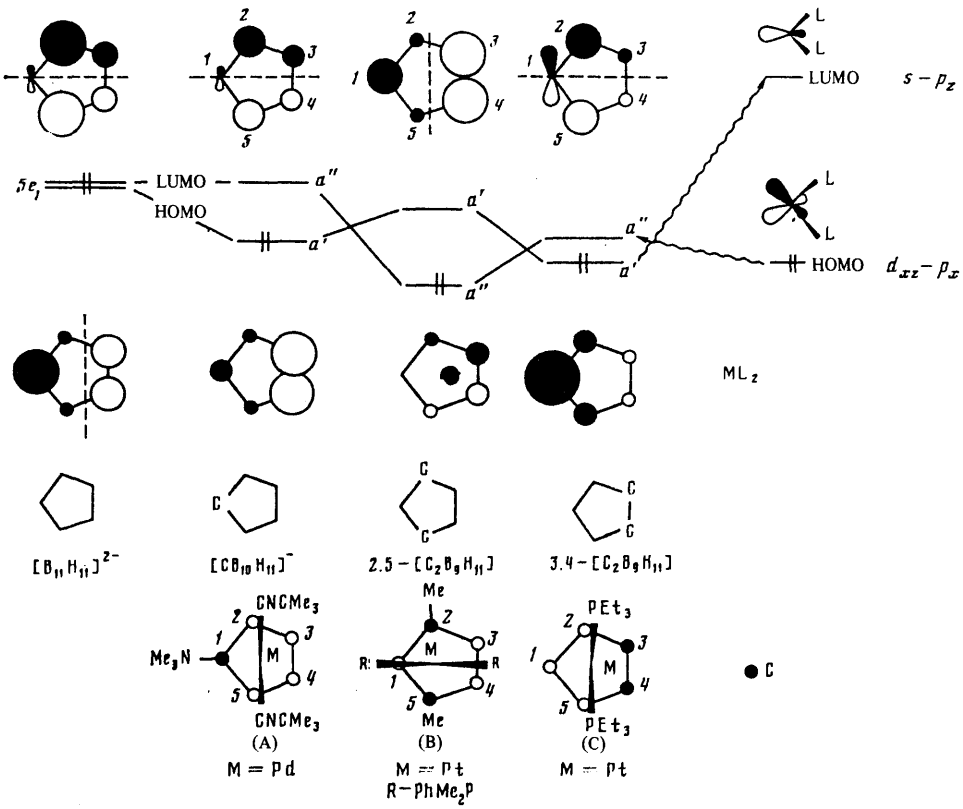

Figure 2. Comparison of the results of theoretical[25,26] and experimental[25,27,28] studies of the geometrical features of the molecules of 12-vertex MCB.

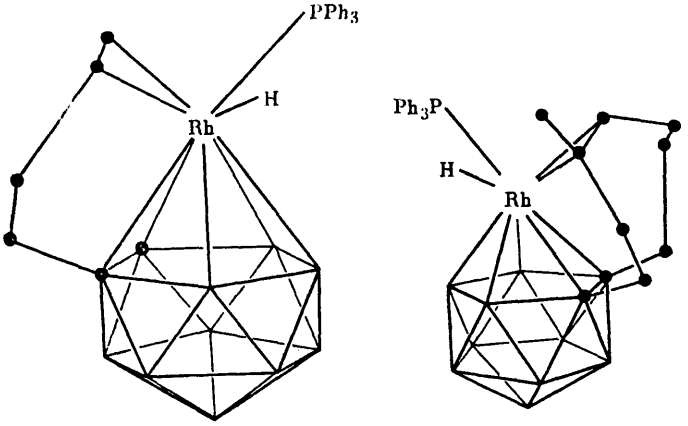
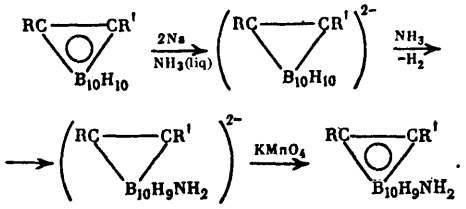
These complexes contain the so-called docosahedral polyhedron in which, in contrast to the eicosahedron, the "open" pentagonal face coordinating the metal atom has been replaced by a hexagonal face. Structural studies on the 13-vertex complexes of cobalt, i.e. $CpCoC_2B_{10}H_{12}$,[33] and titanium, i.e. $[Me_4N]_2[Ti(Me_2C_2B_{10}H_{10})_2]$,[34] with a docosahedral structure are important for the understanding of the mechanisms of certain reactions of the series of *o*- and *m*-carbaborane derivatives.



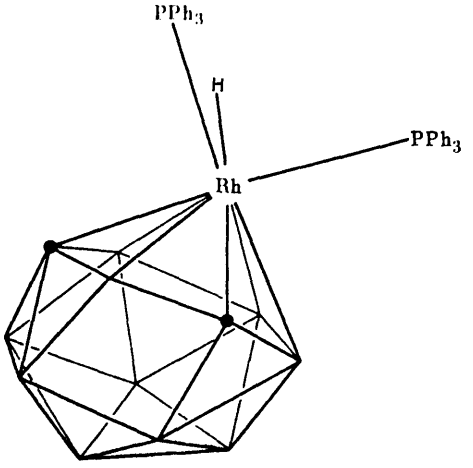
$(Ph_3P)HRhC_2B_9H_{10}C_4H_7$ $(Ph_3P)HRhC_2B_9H_9C_8H_{14}$

Figure 3. The structures of 12-vertex alkenerhodium hydride complexes—catalysts of the homogeneous hydrogenation of olefins.[30,31]

In 1967 Soviet workers proposed an effective method of synthesis of B-substituted derivatives of *o*-carbaborane by treating with nucleophiles the products of the reduction of *o*- and *m*-carbaborane derivatives with a solution of sodium in liquid ammonia (see Kalinin's review[35]). It is suggested that this process proceeds via the intermediate stage of dicarbadodecaborate(14) dianions:



The dicarbadodecaborate anion is also formed on reduction of *o*-carbaborane by metallic sodium in THF in the presence of catalytic amounts of naphthalene. The introduction of transition metal salts ($CoCl_2$ and $TiCl_4$) into the reaction mixture made it possible to isolate the derivatives of the dicarbadodecaborate anion in a pure form and to investigate their structure.[33,34] It may be hoped that detailed studies of the 13-vertex MCB will lead in the future to the possibility for a more detailed investigation of the mechanism of this reaction, which is exceptionally important for the chemistry of *o*- and *m*-carbaboranes and also will make it possible to explain the preferential formation of only some of the isomers of its final complex which are possible in principle.



$(Ph_3P)_2HRhC_2B_{10}H_{12}$

Figure 4. The structure of $(Ph_3P)_2RhH(C_2B_{10}H_{12})$.[32]

2. 11-Vertex MCB

The geometry of the octahedron is characteristic of 11-vertex *closo*-MCB (Fig.5). Many 11-vertex MCB, whose structures have been investigated, for example, the cobaltacarbaborane $CpCoC_2B_8H_9Br$ which we have studied,[36] can be regarded as resulting from the coordination of the metal atom to the non-planar hexagonal "open" face of the boron–carbon skeleton, which resembles a basket and is well-known in the chemistry of boron as the decaborane-14 ($B_{10}H_{14}$) skeleton. In contrast to the eicosahedron, in which each vertex has five nearest neighbours in the polyhedron, in the octadecahedron with pentacoordination (here and henceforth the coordination number C.N. is understood as the number of nearest neighbours in the polyhedron) there are two tetracoordinate and one hexacoordinate vertices. Numerous studies of the structures of MCB with polyhedra having non-isotypical vertices and also investigation of the thermal rearrangements in these systems[9] have shown that the isomers in which the carbon atoms occupy the vertices with the lowest C.N. and the metal atoms occupy those with the highest C.N. are as a rule thermodynamically most stable. A good illustration of this finding is provided by the structure of the bimetallic 11-vertex MCB $Cp_2FeCoC_2B_7H_9$ in the octadecahedral polyhedron of which two carbon atoms occupy tetracoordinate vertices and the iron and cobalt atoms occupy respectively hexacoordinate and pentacoordinate vertices. In this molecule there are 23 skeletal electrons instead of the 24 expected for *closo*-MCB, which causes, according to the authors of the structural study,[37] certain geometrical distortions (differences between the lengths of chemically equivalent B–B bonds amounting to approximately 0.10 Å have been observed), which leads to the loss of a plane of

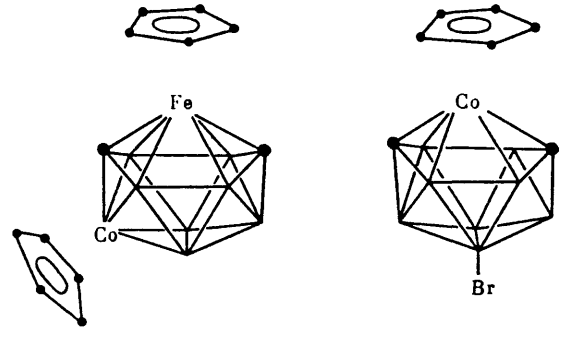
symmetry by the $FeCoC_2B_7$ polyhedron. However, it is noteworthy that the lack of one electron does not affect the geometry of the iron cyclopentadienyldicarbollyl complex $CpFeC_2B_9H_{11}$.[16]

The difference between the C.N. of the atoms in the polyhedron influences the lengths of the bonds in which they are involved. This difference makes it possible, for example, to account for the significant (up to approximately 0.3 Å) difference between the Co–C and Co–B distances in $CpCoC_2B_8H_9Br$. On the other hand, the increase of the Pt–B distance to 2.60–2.66 Å compared with the Pt–C bond, which is 2.17 Å long in the complex $(Ph_3P)_2PtC_2B_8H_{10}$,[38] can be hardly accounted for solely by the influence of the difference between the C.N. of the B and C atoms. This becomes even more evident in relation to another 11-vertex platinacarbaborane, namely $(Me_3P)_2PtC_2B_8H_{10}$.[39] Although this complex contains 24 skeletal electrons, it has in fact a *nido*-eicosahedral structure and not an octadecahedral structure, but its polyhedron can in fact be regarded as a highly distorted octadecahedron in which the metal atom is very markedly displaced relative to the symmetry plane of the polyhedron. As a result, the distances from the platinum atom to the most remote boron and carbon atoms in the "formally open face" of the octadecahedron (3.10 and 2.82 Å) altogether do not correspond to a valence interaction.

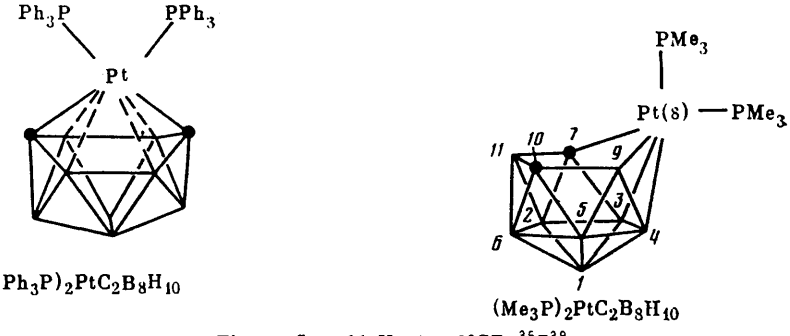
Although the 11-vertex MCB have been investigated in much less detail than the 12-vertex compounds, the few examples examined have already shown that here too the same rule apparently holds as for the eicosahedral MCB: the incorporation of a metal atom with a d^8 configuration leads to the "loosening" of the polyhedron and sometimes, as, for example, in the last platinacarbaborane considered above,[39] also to a decrease of its symmetry. It will be shown below that this rule holds likewise for the lowest MCB.

3. 10-Vertex MCB

The 10-vertex *nido*-carbaboranes, having the decaborane-14 skeleton, which have been investigated in fair detail, are structurally very close to the 11-vertex MCB with an octadecahedral polyhedron. Like each of the BH groups, the



$Cp_2FeCoC_2B_7H_9$ $CpCoC_2B_8H_9Br$



$(Ph_3P)_2PtC_2B_8H_{10}$ $(Me_3P)_2PtC_2B_8H_{10}$

Figure 5. 11-Vertex MCB.[36–39]

CpCo group in the cobaltacarbaborane $CpCo(C_2B_7H_{11})$[40] (Fig.6) behaves, as usual, as the donor of two electrons, while the two CH groups supply three electrons each to the polyhedron; the bridging hydride atoms, whose location has been objectively identified in a structural study,[40] serve as a source of further two electrons. Overall, the complex contains 24 skeletal electrons and has the structure of a 10-vertex *nido*-polyhedron.

Whereas the metal atom in the cobalt complex occupies, as was to be expected, a high-coordination site in the "open" face, in the nickel derivative $(Et_3P)_2Ni(Me_2C_2B_7H_9)$[41] and the platinum derivative $(Ph_3P)_2Pt(CB_8H_{12})$[42] with an analogous skeleton the metal atom occupies a low-coordination site. The coordination of the metal atom in this low-coordination site in the "open" face constitutes a model in a certain sense (assuming that the metal atom is coordinated to the centres of the edges of the polyhedron) of the square-planar environment characteristic of the usual nickel(II) and platinum(II) complexes.

The second low-coordination site in the "open" face of 10-vertex *nido*-complexes of nickel and platinum is occupied by a carbon atom, which, together with the exopolyhedral ligand (the Me group in the nickel complex and the hydrogen atom in the platinum compound), turned "to the outside" of the polyhedron, contains also the so-called "axial" hydrogen atom directed towards the centre of the "open " face. The question arises how one should take into account this carbon atom in calculating the number of skeletal electrons. If both its substituents are regarded as exopolyhedral, then the given carbon atom should serve as a donor of two (4−2 = 2) electrons. In this case the 10-vertex *nido*-polyhedron contains 22 skeletal electrons, i.e. two electrons less than would be necessary to satisfy Wade's "2*n* + 4" rule. This discrepancy is entirely reasonable because, according to Wade's rule, each atom employs three orbitals for the bonding in the polyhedron (see above), while the above discussion assumes that the C(9) and C(6) atoms in the nickel and platinum complexes respectively employ only two orbitals for the bonding in the polyhedron. If, on the other hand, it is assumed that the H_{ax} atom is not an exo-substituent in the full sense of the term and is involved in the bonding within the polyhedron (for example, in the weak interaction with the neighbouring, in relation to the carbon atom, boron atoms in the "open" face), then in this instance both electrons of the $C-H_{ax}$ bond can be classified as the skeletal electrons of the complex. Thus the total number of skeletal electrons

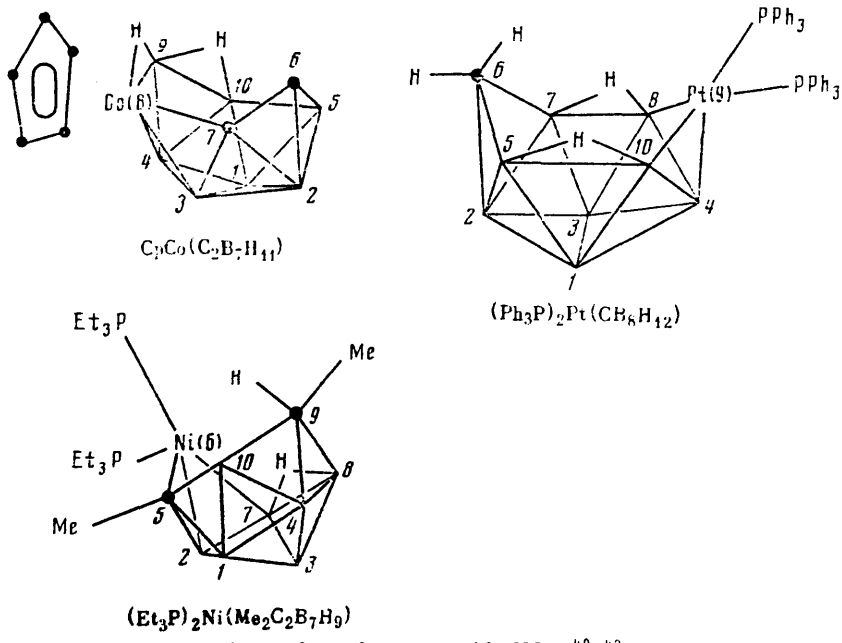


Figure 6. 10-Vertex *nido*-MCB.[40–42]

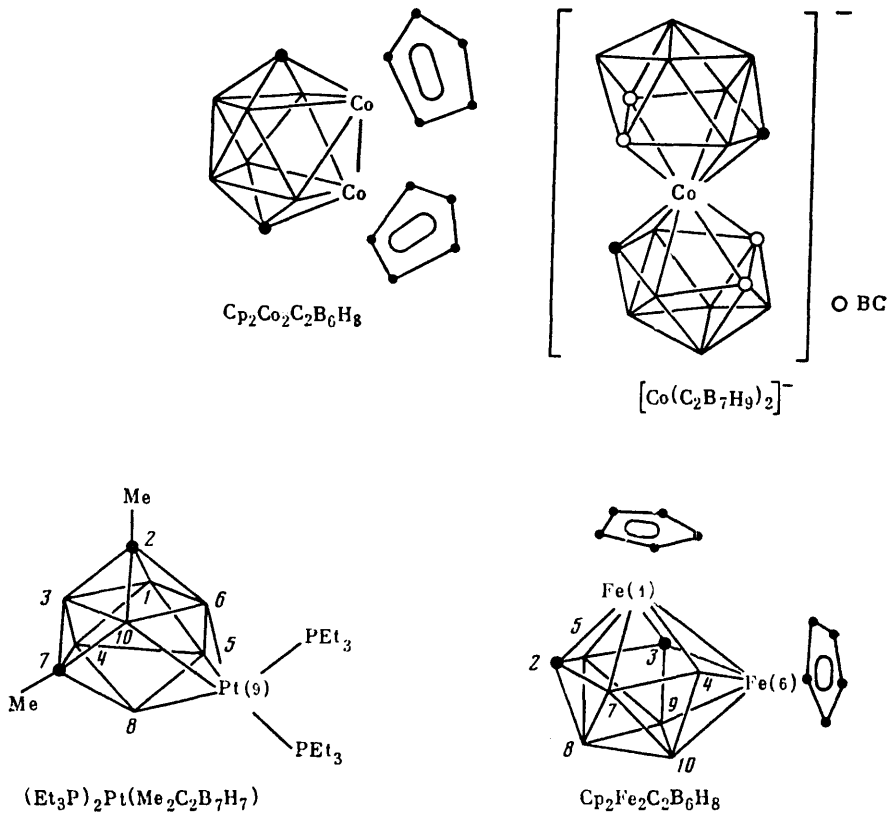

Figure 7. 10-Vertex *closo*-MCB.[43–46]

in the nickel and platinum derivatives under discussion is 24 and is consistent with the *nido*-geometry of the 10-vertex complex.

The "basic" polyhedron in 10-vertex *closo*-MCB is the so-called two-cap square antiprism centred with respect to the faces of both bases (Fig. 7). Polyhedra having this structure have been found in structural studies on cobaltacarbaboranes—the bimetallic complex $Cp_2Co_2C_2B_6H_8$ [43] and a *commo*-MCB—the $[Co(C_2B_7H_9)_2]^-$ anion#.[44] It is striking that the metal atoms in both compounds occupy vertices in the "equatorial" belt of the antiprism, whiole the low-coordination positions in the "caps" are occupied preferentially by carbon atoms.

As in the MCB with a larger number of vertices discussed above, the 10-vertex cobaltacarbaboranes (with a d^6 configuration of the metal atom) have a fairly symmetrical structure. On the other hand, in the platinacarbaborane $(Et_3P)_2Pt(Me_2C_2B_7H_7)$[45] ($d^8$ configuration), which, like its cobalt analogues, satisfies Wade's rule, appreciable distortions of the polyhedron are observed. They are expressed in the formation of a tetragonal open face C(7)B(8)Pt(9)B(10), which arises as a result of the dissociation of one of the "equatorial" bonds [Pt(9)...C(7) bonds 2.83 Å long] in a two-cap square antiprism.

In discussing the structure of 10-vertex MCB, one must not fail to mention the structure of the very interesting bimetallic iron complex $Cp_2Fe_2C_2B_6H_8$.[46] The geometry of the diamagnetic molecule can be described only approximately as one corresponding to a two-cap square antiprism. For the purpose of this description, one must imagine that one "equatorial" bond C(3)–B(4) in the antiprism has been broken and one of the "caps" [Fe(6)] is linked directly to the metal atom in the "equatorial" belt remote from it [the Fe(6)–Fe(1) bond 2.571 Å long].

Such structural anomalies are evidently due to the insufficiency of skeletal electrons for the construction of a 10-vertex *closo*-system. In the given complex there are 20 (instead of 22) electrons, which is the reason for their unusual structure. Although formally this compound belongs to the class of 10-vertex *closo*-MCB (with all the faces triangular), in fact it does not have the geometry characteristic of these systems. Furthermore, its polyhedron can be regarded as a three-cap trigonal prism [with the C(3)B(5)B(9) and B(4)B(7)B(10) bases and the Fe(1), Fe(6), and B(8) "caps"] having one additional vertex at C(2), which corresponds to 9-vertex *closo*-MCB (20 electrons).

A number of interesting 10-vertex MCB and metalloborane complexes have been described by Crook and co-workers,[47–50] who investigated the reactions of the iridium complex *trans*-$[Ir(CO)Cl(PPh_3)_2]$ with the *closo*-$B_{10}H_{10}^{2-}$ borate dianion in

#According to the IUPAC nomenclature, the term *commo*-MCB is given to complexes in which the polyhedra are linked together via a common metal atom.

methanol. In the course of the formation of two of the products investigated, namely $(MeCOO)(Ph_3P)HIrCB_8H_7 \cdot (PPh_2)$[47] and $IrC(OH)B_8H_6(OMe)(C_6H_4PPh_2)(PPh_3)$[48] (Fig. 8), a carbon atom from the solvent as well as the metal atom was inserted in the borane skeleton during the reaction, which resulted in the formation of 10-vertex iridacarbaboranes. The first of these complexes has 22 skeletal electrons (in calculating the number of electrons one must take into account the Zwitter-ionic character of the molecule—the positive charge of the P atom linked to the B atom and the negative charge on the polyhedral skeleton) and possesses the geometry of a fairly symmetrical (the Ir^{III} atom has the d^6 configuration) two-cap square antiprism, which is characteristic of 10-vertex *closo*-MCB.

The second complex investigated contains two skeletal electrons less, because, firstly, it has no hydride ligand and, secondly, its polyhedron does not carry a negative charge. The Ir(7)...B(9) distance in this complex is fairly large (2.82 Å) and the authors[48] characterised it as a *nido*-MCB and the Ir(7)B(8)B(9)C(10) face is regarded as open. Furthermore, the similarity of the polyhedra of this iridacarbaborane and the bimetallic iron complex discussed above is striking. The similarity appears entirely reasonable because both complexes are, as it were, "superelectron-deficient" (see above) 10-vertex classical systems and each has 20 skeletal electrons. As in the iron derivative, in the polyhedron of the iridium complex there is one "additional" vertex, which in this instance is occupied by the B(3) boron atom. It must also be emphasised that the purely boron hydride complex $(Ph_3P)(Ph_2PC_6H_4)HIrB_9H_8$, obtained by the reaction of $IrCl(PPh_3)_3$ with $B_9H_{12}^-$, which is isoelectronic with the above compounds, has an analogous structure, which has been characterised[49] (Fig. 8).

The reaction involving the formation of iridium complexes, mentioned above, has an interesting feature: in these processes the *ortho*-boration of one of the benzene rings of the Ph_3P ligand takes place simultaneously with the insertion of the metal atom in the borane polyhedron. It has been found that similar processes play an important role in the chemistry of MCB and metalloboranes containing triphenylphosphine ligands. Thus, apart from the products mentioned above, the octahedra of the metalloborane $(OC)_3(Ph_3P) \cdot (Ph_2PC_6H_4)_2Ir_2B_4H_2$,[50] in which the metal atoms occupy two neighbouring vertices, have been isolated and structurally characterised in the reaction of $Ir(CO)Cl(PPh_3)_2$ with *closo*-$B_{10}H_{10}^{2-}$, apart from the products mentioned above. Here the benzene rings of the two phosphine ligands at one of the metal atoms have undergone *ortho*-boration. The authors[49,50] suggest that the *ortho*-boration process is not simply a concomitant reaction, involving the elimination of hydrogen atoms in the formation of C–B bonds in the polyhedral skeleton already present, but constitutes an important stage involving the insertion of the metal atom into the polyhedron. In their view the CH group in the benzene ring can serve during the reaction as a source of an additional electron pair, which is supplied to the borane polyhedron and initiates its decomposition.

Incidentally, this view can be open to a definite objection, particularly if one takes into account the results obtained in a structural study[51] of the products of the thermal rearrangement of the 10-vertex *nido*-platinacarbaborane $(Ph_3P)_2 \cdot Pt(CB_8H_{12})$ discussed above (Fig. 6). When this complex is heated, two moles of H_2 are evolved and bonds are formed between the *ortho*-carbon atoms of two benzene rings in different Ph_3P groups and the boron atoms in the 8- and 10-positions.

Thus the *ortho*-boration of the benzene rings of the triphenylphosphine ligands need not necessarily be accompanied by rearrangements in the polyhedral skeleton. It may be that the specific features of the reaction are associated with the enforced geometrical proximity in the C–H (benzene ring) and B–H (carbaborane ligand) bonds, which are characterised by the opposite polarisations of the hydrogen atoms.

4. 9-Vertex MCB

As a rule, 9-vertex MCB consist of a polyhedron having the form of a three-cap trigonal prism. Such geometry is characteristic of, for example, the MCB anion $[CpCoCB_7H_8]^-$, whose structure has been investigated[52] using its caesium salt (Fig. 9). Here the carbon atom occupies a low-coordination position in one of the "caps", while the cobalt atom is located at one of the vertices of the base. The differences between the Co–B(5) and Co–B(6) distances (on average

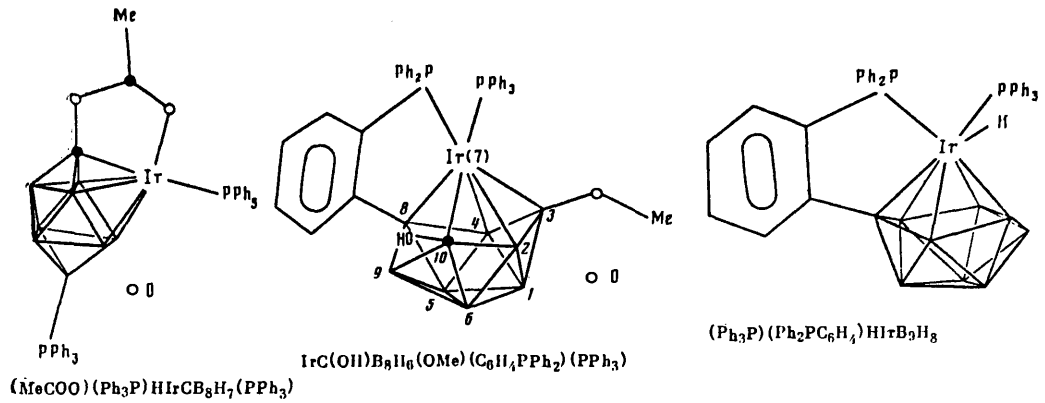

Figure 8. Borane and carbaborane complexes of iridium.[47–49]

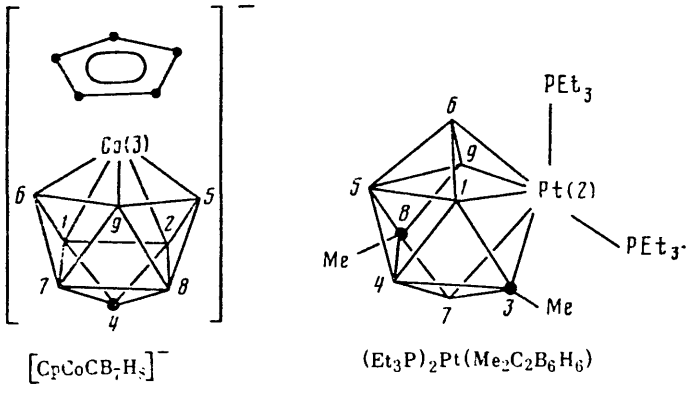
1.98 Å) and between the Co–B(1), Co–B(2), and Co–B(9) distances (on average 2.16 Å) can be explained by the lower C.N. of the B(5) and B(6) atoms in the "caps" of the polyhedron.



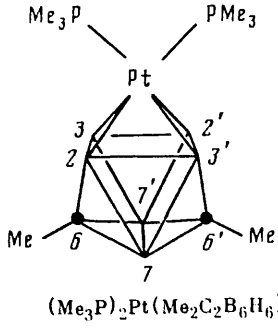


Figure 9. 9-Vertex MCB.[52–54]

Two 9-vertex platinacarbaboranes with analogous compositions, namely $(Et_3P)_2Pt(Me_2C_2B_6H_6)$[53] and $(Me_3P)_2.Pt(Me_2C_2B_6H_6)$,[54] have appreciably different structures. In the first compound, where the platinum atom occupies one of the vertices in the base of the prism, as in the platinum(II) complexes discussed above, appreciable distortions of the polyhedron are observed: the platinum atom forms two short Pt(2)–B(6) (2.17 Å) and Pt(2)–C(3) (2.18 Å) bonds (which, together with the PEt_3 ligands, build up its environment to a square) and three long bonds with the boron atoms in the 1-, 7-, and 9-positions having an average length of 2.48 Å. The B(7)...B(9) distance in the base of the prism does not correspond to the formation of a bond and the Pt(2)B(7)C(8).B(9) face is "open".

On the other hand, the polyhedron ot the triphenylphosphine derivative of platinum is actually symmetrical: four Pt–B bonds are 2.19–2.24 Å long. Thus this complex infringes the rule, mentioned above, concerning the appearance of appreciable distortions in the polyhedron following the introduction of an atom with a d^8 configuration. The only anomaly in the structure consists, in this instance only, in the location of the metal atom at a low-coordination vertex of the polyhedron.

5. 8-Vertex MCB

The 8-vertex *closo*-MCB should have the structure of a dodecahedron with triangular faces according to the general scheme (Table 2). This very interesting polyhedron can be regarded as a combination of two distorted tetrahedra (it is sometimes referred to as a "Siamese" polyhedron. Indeed, in order to obtain this polyhedron, it is necessary to extend one tetrahedron and to compress the other along the $\bar{4}$ symmetry axis and then insert one in the other.

In the cobaltacarbaborane $(C_5Me_5)_2Co_3Me_4C_4B_8H_7$ [55] the two dodecahedral fragments are combined not only via the carbon metal atom in a *commo*-type arrangement but also via a B–B bond 1.758 Å long, which is exopolyhedral in relation to both MCB skeletons (Fig. 10). Both crystallographically independent dodecahedra have virtually identical geometries and a fairly symmetrical structure: the breakdowns in symmetry are evidently associated with the different radii and C.N. of the atoms forming part of the polyhedron. The molecule as a whole has an approximate symmetry plane perpendicular to the B(8)–B(8′) bond. The absence of a second possible mirror plane is associated with the small but significant rotation of the dodecahedral fragments relative to one another as a result of which the C(1)...C(1′) distance is shorter by approximately 0.1 Å than the C(2)...C(2′) distance. This rotation has been attributed[55] to the influence of the additional H atom [apart from the terminal H atoms at the B(4), B(5), and B(6) atoms], which was not detected in the structural study and which is apparently located in the vicinity of the Co(3), B(6), B(8), B(6′), and B(8′) atoms.

The only 8-vertex MCB with an isolated polyhedron, whose structure has been investigated hitherto, namely $(Et_3P)_2.Pt(Me_2C_2B_5H_5)$,[56] is a platinum(II) derivative and its polyhedron is highly distorted as was to be expected. The coordination of the platinum atom can be regarded as of the "square-planar" type [involving the P atoms in the centres of the B(2)–B(6) and B(6)–B(8) edges]. On the other hand, the formation of a bond along any of the two diagonals of the "open" Pt(4)C(1)B(5)B(8) face [Pt(4)...B(5) = 3.105 Å; C(1)...B(8) = 2.896 Å] would have led to a *closo*-dodecahedral structure.

Although the number of structural studies of 8-vertex MCB has been extremely small, the dodecahedral borate dianion $B_8H_8^{2-}$ has been known for a fairly long time.[57] The dodecahedral metalloboranes $Cp_4Co_4B_4H_4$ [58] and $Cp_4Ni_4B_4H_4$ [59] have been obtained recently and their structures characterised (Fig. 10). These compounds are interesting because they have a symmetrical *closo*-structure, although the former has two electrons less and the latter two electrons more than required by Wade's rule. It is natural therefore that the studies of these structures were immediately followed by a whole series of theoretical investigations in which attempts were made to account for the causes responsible for the breakdown of the "2n + 2" rule for the dodecahedron.

It has been noted in the study of Wade and co-workers[60] that the HOMO and the LUMO of the cluster system having the dodecahedral structure are non-degenerate, in contrast to the frontier orbitals of almost all the remaining *closo*-polyhedra. Therefore, although the introduction of two additional electrons into the dodecahedral system or conversely the removal of an electron pair leads to some loosening of the bond in the polyhedron, nevertheless it does not cause appreciable distortions in the latter. On the other hand, a change in the number of skeletal electron pairs in the majority of other *closo*-systems with degenerate frontier orbitals would have led to the appearance of an unstable paramagentic complex, which is distorted as a consequence of the Jahn–Teller effect. This qualitative study has been

confirmed by quantum-chemical calculations for dodecahedral borane and metalloborane systems by the extended Hückel method.[61] The calculation not only justified the stability of the dodecahedral systems not satisfying Wade's rule but also made it possible to explain why the metal atoms in the nickel dodecahedron with an "electron excess" occupy the vertices of an extended tetrahedron or why those in the cobalt complex with an "electron deficiency" are located at the vertices of a compressed tetrahedron.

6. Small (7- and 6-Vertex) MCB

Among the small MCB, the compounds with a 7-vertex polyhedron, having the geometry of a pentagonal bipyramid have been studied in greatest detail. The metal atom in such polyhedra usually occupies a high coordination apical site, as happens, for example in the cobaltacarbaborane $CpCo(Me_2C_2B_4H_4)$[62] (Fig.11), which can serve as an example of a complex with a symmetrical structure typical for 7-vertex MCB. The cobalt atom is located at the high-coordination apical site and is linked symmetrically to the atoms in the equatorial plane (Co–C = 2.031 Å; Co–B = 2.092 Å); the carbon atoms occupy the neighbouring vertices in this plane and the length of the C–C bond (1.461 Å) is close to that found in the dodecahedral fragments of the cobaltacarbaborane $(C_5Me_5)_2Co_3Me_4C_4B_8H_7$ (on average 1.448 Å[55]), mentioned above, and are much shorter than in the analogous eicosahedral systems. This difference is evidently associated with the differences between the C.N. of the carbon atoms in the dodecahedron and the pentagonal bipyramid (C.N. = 4), on the one hand, and in the eicosahedron (C.N. = 5), on the other.

Having examined the structure of a symmetrical cobaltacarbaborane (with the d^6 configuration), we shall now turn to the discussion of the structure of the analogous platinum(II) derivative (with the d^8 configuration). As in all the derivatives of d^8 metals examined above, significant distortions of the geometry of the polyhedron were observed in this instance. The distortions in the 7-vertex MCB have the character of a "shift" deformation analogous to those observed for the eicosahedral MCB. Thus the platinum atom in the complex $(Et_3P)_2Pt(Me_2C_2B_4H_6)$[63] is much closer to the boron atoms (the average Pt–B distance is 2.21 Å) than for the carbon atoms (the average Pt–C distance is 2.855 Å); the angle of inflection of the "open" face along the B...B line,

which tends to shift the carbon atoms away from the metal atom, is 21.4° [in the corresponding 12-vertex complex $(Et_3P)_2PtC_2B_9H_{11}$ [28] the average Pt...C distance is 2.572 Å and the ange of inflection of the "open" face is 9.1°].

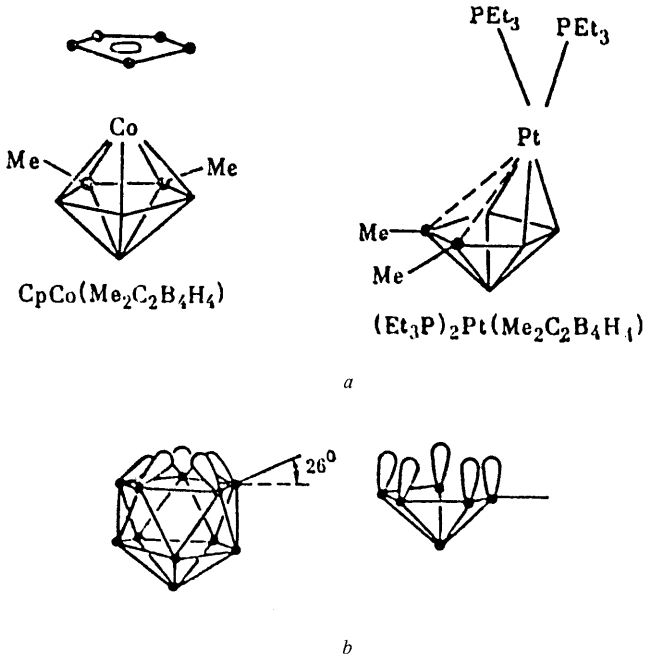

Figure 11. *a*) 7-Vertex MCB;[62,63] *b*) the orientation of the "lobes" of the frontier orbitals of *nido*-carbaborane ligands.[64]

Comparison of these geometrical parameters shows that, although the "shift" distortions in the 7- and 12-vertex polyhedra are of the same type, in the case of the small MCB they are more distinct. This difference is linked directly to the different directions of the exopolyhedral bond in the eicosahedron and in the pentagonal bipyramid. Indeed, in the eicosahedron the exopolyhedral bond emerges from the plane of the pentagonal face in the direction of the vertex centred above it (the angle between the direction of this bond and the plane of the face is 26°), while in the pentagonal bipyramid the exopolyhderal bond is in the equatorial plane. Calculations by the extended Hückel method[64] have shown that this difference leads to different orientations of the "lobes" of the frontier orbitals of the carbaborane ligand: in the eicosahedral fragment the long axes of the "lobes" form a much smaller angle with the plane of the "open" face than in the pentagonal bipyramidal fragment (Fig.11). Bearing in mind that the "shift" distortions in the coordination of the dicarbollide ligand are caused by the preferential localisation of the frontier orbitals at the boron atoms, it becomes understandable why the different orientation of the "lobes" of the orbitals in the pentagonal bipyramid requires a more significant shift of the metal atom in the direction of the boron atoms to achieve a more effective overlap. Such orientation in the orbitals also explains the weaker bonding of the metal atom in the 7-vertex polyhedra compared with the 12-vertex polyhedra, which leads to different barriers to the rotation of the PtP_2 fragment relative to the carbaborane ligand.

Thus two singlets are observed in the ^{31}P NMR spectrum of the platinum dicarbollide complex even at room temperature, while in the spectrum of the pentagonal bipyramidal complex this splitting of the signal is observed only when the temperature is reduced.[63]

A whole series of structural studies on 7-vertex MCB have been undertaken to investigate the unusual chemical properties of derivatives of their hydride *commo*-MCB $(Me_2C_2B_4H_4)_2FeH_2$ (Fig.12). The hydride hydrogen atoms could not be located in a study[65] of the structure of the initial complex. These atoms are apparently disordered and are alternately centred above the four FeB_2 faces of the two pentagonal bipyramidal polyhedra. The presence of the hydrogen atoms is responsible for the appreciable mutual inclination of the pentagonal faces (the dihedral angle is 7.8°), which leads to the appearance of the energetically unfavourable short intramolecular contact Me...Me = 3.53 Å.

Each polyhedron of the complex $(Me_2C_2B_4H_4)_2FeH_2$ contains $2n + 2$ skeletal electrons and satisfies Wade's rule. This can be readily demonstrated by taking into account the fact that the "neutral" carbaborane ligand $Me_2C_2B_4H_4$ serves as a donor of four electrons, while the hydride hydrogen atoms can be regarded, for simplicity, as bound only to the metal atom (in this case the iron atom contributes two electrons to the polyhedron).

For an alternative description of the bonding in the complex under discussion, one can resort, as in the case of other MCB systems with giant polyhedra, to the topological model of a superaromatic cluster proposed by Slovokhotov and Struchkov.[66] In this model the total number of skeletal electrons and the number of vertices in both giant polyhedra are evaluated and the atoms belonging to the two skeletons are taken into account only in the determination of the number of electrons and are not included in the total number of vertices. In the *commo*-complex considered each MCB group serves as a rule as a donor of two electrons and the MCB groups each contribute three electrons to the polyhedron; on the other hand, the presence of the iron atom in this system leads in essence to a decrease of the number of skeletal electrons (the contribution of the iron atom is $8 + 2 - 12 = -2$). Thus the total number of electrons in the complex $(Me_2C_2B_4H_4)_2FeH_2$ is 26, which corresponds to 12 (without taking into account the iron atom) vertices of the polyhedron.

The specific features of the chemical behaviour of the complex $(Me_2C_2B_4H_4)_2FeH_2$ are associated with its ability to lose readily the hydride hydrogen atoms and to combine with metal-containing groups. This result in the formation of compounds in the molecules of which two carbaborane ligands are combined not only via the common central metal atom but also via yet another, additional atom occupying the position of a "cap" in relation to one of the triangular faces in each polyhedron. Such compounds can be called "wedged" *commo*-MCB.

Thus the interaction of the initial iron hydride complex with $CpCo(CO)_2$ and $Co(PEt_3)_4$ leads to the formation of mixed bimetallic MCB having the compositions $CpCoFe(Me_4C_4B_8H_8)$[67] and $(Et_3P)_2CoFe(Me_4C_4B_8H_8)$,[68] which have been investigated by X-ray diffraction. In the study of the electronic structures of these compounds it is convenient to employ the topological model of joined polyhedral systems.[66] In the cyclopentadienylcobalt complex, which incorporates, apart from the CpCo group, four CMe groups, eight BH groups, and the iron atom, there are 26 electrons corresponding to 12 "outer" (disregarding the iron atom and the "additional" BH group) vertices of the joined polyhedron. As a consequence of the replacement of the Cp ligand in the phosphine complex by two Et_3P groups, the number of skeletal electrons

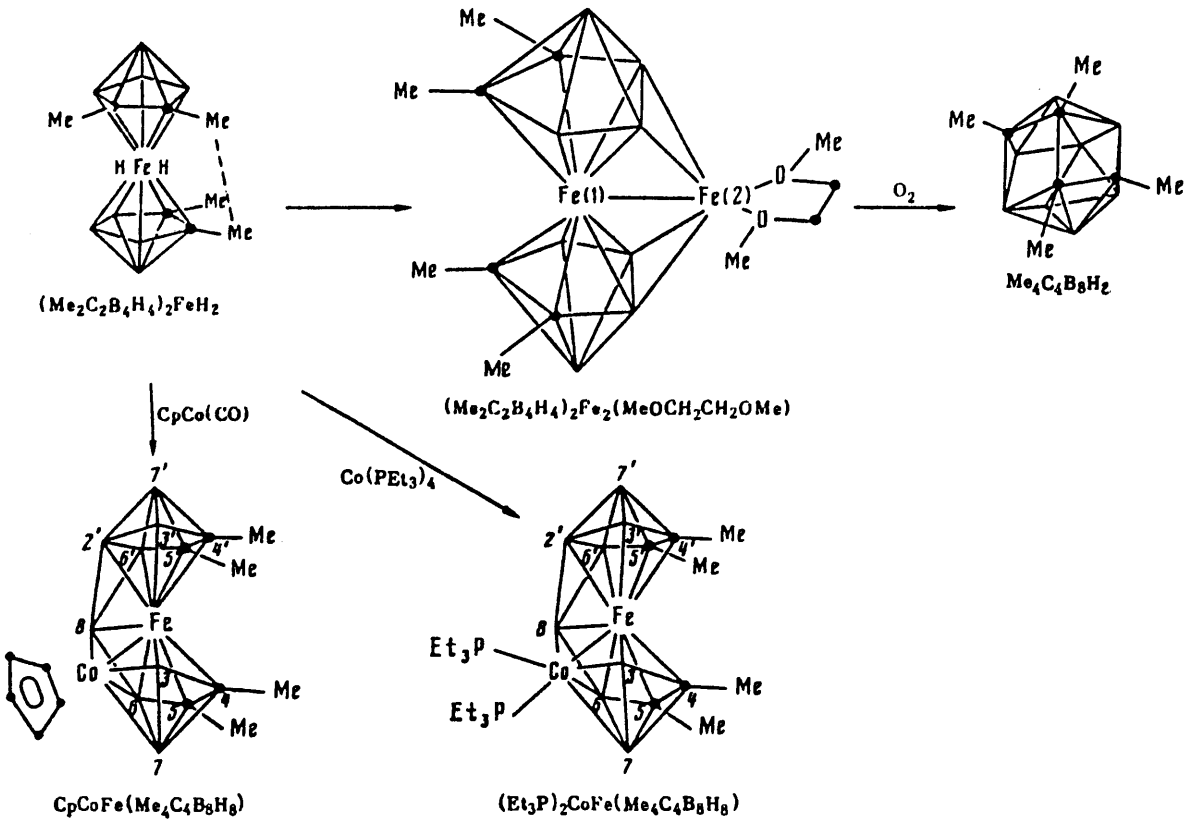

Figure 12. The structure of $(Me_2C_2B_4H_4)_2FeH_2$ and its reaction products.[65,67,68,71,72]

should be one less. This difference in the atomic structure influences in the given instance also the geometrical characteristics: almost all the bonds involving the cobalt atom and the boron atom located at the "additional" vertex in the phosphine complex are longer (on average by 0.08–0.10 Å) than the corresponding distances in the cyclopentadienyl derivative.

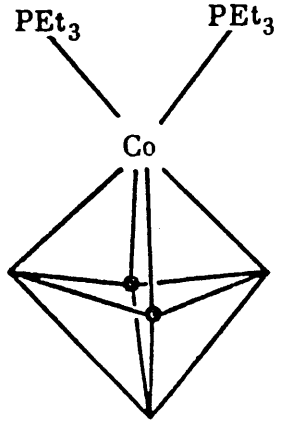
This explanation of the difference between bond lengths in the complexes described appears somewhat more correct than the remark by Barket et al[68] concerning the difference between the polyhedral radii of the cobalt(II) (in the Et_3P complex) and cobalt(III) (in the Cp derivative) atoms. Naturally the "deficit" of electron density (−1e) in such cluster systems is not localised solely at the metal atom but is distributed to a greater or lesser degree throughout the polyhedron. Precisely as a consequence of such delocalisation, not only the bond involving the Co atom but also others (for example, the edges connecting the additional BH group to the Fe and B atoms) are lengthened in the polyhedron of the phosphine complex.

An interesting feature of the iron and cobalt complexes is the asymmetric disposition of the "additional" BH group relative to the coordination planes of the carbaborane and MCB ligands, which is expressed by greatly increased (by approximately 0.3 Å) B(8)–B(2′) and B(8)–B(6′) distances compared with the B(8)–B(6) bond. This provided the authors[69] with a basis for the hypothesis that the "additional" BH group is linked only to the polyhedron containing the cobalt atom and that the relatively short distances to the boron atoms in the other polyhedral fragment are determined solely by the geometrical requirements—the repulsion of the Me groups to the "opposite" side of the polyhedron. In this case the "wedged" complexes can be represented as the usual *commo* MCB in which the 7- and 8-vertex polyhedra are combined via the common iron atom.

However, this view was disproved in a study[70] where a quantum-chemical calculation was carried out on the "wedged" metalloboranes and MCB by the extended Hückel method. The calculations showed that in the model borate anion $[Fe(BH)(B_6H_6)_2]^{4-}$ a symmetrical disposition of the "additional" boron atom relative to the coordinating faces of the *nido*-borane ligands corresponds to an energy minimum and the overlap of the frontier orbitals of each ligand with those of the "additional" BH group is equally important for the bonding in the polyhedron. It has been shown by the methods of perturbation theory that the introduction of the CoCp group instead of one of the BH groups of the borane ligand alters the character of the frontier orbitals of this ligand, which creates more favourable conditions for the overlap with the orbitals of the "additional" BH group. However, such substitution cannot lead to the complete dissociation of the bond between this group and the second, frequently borane, fragment.

The structure of a MCB of the "wedged" type, which constitutes an intermediate in the "oxidative cross-linking" of the ligands in the initial hydride complex $(Me_4C_2B_4H_4)_2FeH_2$, has also been investigated (Fig.12). This process, which proceeds readily in the presence of oxidants and leads to the formation of the tetracarbon carbaborane $Me_2C_4B_8H_8$, has been studied in detail.[71,72] The investigation of mixtures of the complexes $(R_2C_2B_4H_4)_2FeH_2$ with various alkyl radicals R

established that the "cross-linking" of the carbaborane groups does not entail the intermolecular exchange of ligands. In the presence of oxygen or rather oxidants, the "cross-linking" process in the tetrahydrofuran or dimethoxyethane solutions of the hydride complexes takes place almost instantaneously. However, in an inert atmosphere these solutions can persist for a short time (several hours) and the colour changes from dark-red to violet only gradually. The introduction of even trace amounts of oxidants into such a solution induces the instantaneous formation of the tetracarbon carbaborane $R_4C_4B_8H_8$.



$(Et_3P)_2CoC_2B_3H_5$

Figure 13. The structure of $(Et_3P)_2CoC_2B_3H_5$.[77]

The crystals of the intermediate in the "cross-linking" process isolated from the violet solution proved, however, to be fairly stable in air and were investigated by X-ray diffraction.[72] It was found that the molecule of the bimetallic complex $(Me_2C_2B_4H_4)_2Fe_2(MeOCH_2CH_2OMe)$ (Fig.12) contains one of the iron atoms at the "additional" vertex of the "wedged" *commo*-MCB. In contrast to the compounds examined above, the "additional" vertex in this complex [the Fe(2) atom] is located symmetrically relative to the two identical carbaborane ligands. Although the Fe(1)–Fe(2) distance in this structure (2.414 Å) is appreciably smaller than the lengths of the analogous bonds in the other MCB polyhedra (see above, for example), the authors[72] conclude that there is no direct Fe–Fe interaction on the basis of the results of magnetic measurements and the EPR spectra of this paramagnetic complex. Bearing in mind the short Fe–Fe distance, this conclusion appears to us extremely controversial. Thus the electronic structure of this unusual complex, which does not satisfy any of the rules for the evaluation of the number of skeletal electrons employed above, is not as yet entirely clear.

In conclusion of the discussion of the 7-vertex MCB, we may mention bimetallic monopolyhedral pentagonal-bipyramidal complexes. Such compounds, for example, the cobaltacarborane $Cp_2Co_2MeC_2B_3H_4$,[73] can be regarded, on the one hand, as the usual *closo*-MCB systems satisfying the "$2n + 2$" rule and, on the other hand, they can be formally treated as "three-decker" sandwiches made up of the Co^{3+} cations and the $C_5H_5^-$ and $C_2B_3H_5^{4-}$ anions, because these molecules contain a planar carborane face to which two metal atoms are coordinated simultaneously. Although this treatment proved to be extremely useful and stimulated to a considerable extent very interesting studies on the synthesis[74,75] of "multidecker" systems as well as their theoretical investigation,[76] the cluster model of delocalised interactions is undoubtedly more important for the description of the nature of the bonding in MCB of this kind. This is indicated, in particular, also by the stability of such complexes, which distinguishes them from the unstable purely cyclopentadienyl "multidecker" derivatives.

The results of the first structural investigation of the 6-vertex octahedral MCB complex $(Et_3P)_2CoC_2B_3H_5$ were not published until 1980.[77] This complex (Fig.13) belongs to the class of the paramagnetic *closo*-MCB, mentioned above, which contain one skeletal electron less than is required by the "$2n + 2$" rule. As mentioned above, it is as yet not entirely clear how this anomaly in the electronic structure influences the geometry of the polyhedron. One can only note that appreciable differences between the Co–C (2.112 Å) and Co–B (1.955 Å) distances as well as appreciable deviations from planarity in the equatorial belt of the octahedron (the angle of inflection along the B...B line is 19°) are observed in the given structure

---o0o---

In a brief review, it is naturally impossible to dwell on a whole series of other aspects of the structural chemistry of the MCB. We disregarded many structures of *closo*- and *nido*-MCB, did not consider at all complexes with the *arachno*-structure, and did not discuss the extensive class of tetracarbon MCB, which is being vigorously investigated. All these questions undoubtedly merit additional consideration. Here we concentrated attention on compounds with *closo*-polyhedra containing between six and twelve vertices.

In conclusion of the discussion of these compounds, it must be emphasised yet again that the entire wide variety of these structures can be classified and interpreted on the basis of the rules for the counting of skeletal electrons widely employed in cluster chemistry. The overall geometry of the MCB molecules obeys these rules fairly rigorously.

On the other hand, small and sometimes also not very small distortions in the geometry of the polyhedra depend to a large extent on the nature of the metal and primarily on its electronic configuration. Thus, as the *d* sublevels of the metal atoms in the series of transition and post-transition elements are filled, geometrical distortions arise in the MCB systems and become increasingly more marked, being expressed by a decrease of symmetry and a loosening of the polyhedron. Analysis[78] of structural data on the cyclopentadienyl derivatives of post-transition elements has shown that this trend, namely the enhancement of coordination distortions as the *d* sublevels of the metal atoms are filled, is extremely general: it is manifested in complexes of transition and post-transition elements with both planar aromatic and polyhedral "superaromatic" ligands.

Yet another comment may be made on this subject. In all the MCB complexes of bivalent platinum mentioned above, the distortions of the polyhedron lead to a disposition of the strongest bonds involving the metal atom which imitates the square planar coordination characteristic of the usual classical platinum(II) complexes. In considering this question in a wider sense, one may stress that symmetrical MCB *closo*-polyhedra are observed only for metals with the electronic configuration for which an octahedral environment is typical (Fe^{II}, Fe^{III}, Co^{III}, Pt^{IV}, etc.). The introduction into the

carbaborane polyhedron of metals having a less symmetrical coordination [tetragonally distorted octahedral (Cu^{II}), square planar (Pt^{II}, Pd^{II}), and linear (Hg^{II})] leads as a rule to a considerable loosening and (or) decrease of the symmetry of the polyhedron.

Advances in the Study of the Mechanism of the Gas-phase Oxidation of Aldehydes

I.A.Vardanyan and A.B.Nalbandyan

The results of studies of the kinetics and mechanism of the gas-phase oxidation of aliphatic aldehydes are examined in relation to CH_2O, CH_3CHO, and C_2H_5CHO, which are intermediates in the oxidation of hydrocarbons and the general rules governing the course of these degenerate-branched chain processes are established. Attention has been concentrated on the role of heterogeneous factors. It is shown that heterogeneous chain branching as a consequence of the radical decomposition of CH_3CO_3H or $C_2H_5CO_3H$ takes place in the low-temperature oxidation of acetaldehyde and propionaldehyde; the experimental data on the heterogeneous radical decomposition of organic peroxy-compounds are considered.
The bibliography includes 163 references.

I. INTRODUCTION

Aldehydes are the main intermediates in the oxidation of hydrocarbons and the study of the mechanisms of their oxidation can help in determining such mechanisms. The characteristic features of the oxidation of aldehydes are described satisfactorily from the standpoint of the concept of degenerate branched chain reactions.[1-9] The determination of the true mechanism of these processes constitutes an important stage in the further development of the theory of chain reactions and also in the development of the scientific principles of the direct preparation of the compounds involved such as peroxyacids, acids, hydrogen peroxide, etc. which are widely used in various branches of the national economy.

Recent studies of the dependence of the kinetics of the oxidation of CH_3CHO and C_2H_5CHO on the nature of the surface of the reaction vessel over a wide temperature range revealed a number of unusual features.[10-14] This led to the revision of the ideas concerning the character of certain elementary stages, in particular the chain branching stage.

One of the important problems in the kinetics of the gas-phase oxidation reactions involves the elucidation of the causes of the appreciable rate of oxidation of acetaldehyde and propionaldehyde at temperatures below 473 K down to room temperature and the inertness of formaldehyde at these temperatures,[13,14] although the C–H bond energies in the CHO groups of the above compounds are identical.

The negative temperature coefficient (NTC) of the maximum rate of oxidation of aldehydes (CH_3CHO and C_2H_5CHO) observed comparatively recently,[15,16] stimulated studies whose aim was to elucidate the causes of the appearance of this coefficient both in the case of aldehydes and hydrocarbons.

The present state of the experimental and theoretical investigations is analysed in the present review in relation to the oxidation reactions of CH_2O, CH_3CHO, and C_2H_5CHO and the development of ideas concerning the mechanism of these reactions, particularly from the standpoint of allowance for the role of heterogeneous factors, is traced. The characteristic features and the general rules governing these processes have been elucidated and an approach to the development of a method for the selective gas-phase oxidation of aldehydes to acids and peroxyacids by appropriate treatment of the surface of the reaction vessel (treatment with a particular substance) or by altering the surface to volume (S/V) ratio has been formulated on their basis.

II. CHARACTERISTIC FEATURES OF THE KINETICS OF THE OXIDATION OF ALDEHYDES

The oxidation reactions of formaldehyde and acetaldehyde have now been investigated in detail. The conclusions reached have been extended to propionaldehyde, which is legitimate in view of the experimental demonstration of common features[5] of the oxidation of CH_3CHO and C_2H_5CHO. The principal results of the kinetic studies for formaldehyde have been discussed in review articles[6-9] and in a communication.[17] Studies devoted to acetaldehyde and propionaldehyde have been described in Refs.5–9 and 18–25 and Refs.5–9, 12, 14, 26, and 27 respectively.

The principal result of these investigations, common to all the aldehydes, is that the reactions proceed via a degenerate branched chain mechanism with autoacceleration. It has been shown for the photochemical oxidation of acetaldehyde and propionaldehyde that the chains in these reactions are long (~1000 units).[28-31] The chain character of the process is indicated also by the inhibition of the reaction by the addition of small amounts of a number of compounds.[32-35] The chain mechanism of the reaction involving formaldehyde has been demonstrated by the decreased rate of the process with increase of the S/V ratio.[36]

The product responsible for chain branching is a peroxy-compound—hydrogen peroxide in the high-temperature oxidation of formaldehyde and a peroxyacid in the oxidation of acetaldehyde and propionaldehyde. This conclusion is based on the acceleration of the reaction following the addition of RCO_3H [37-40] and also by the results of experiments[5] using the "quenching" method. After rapid cooling to 298 K, the acetaldehyde–oxygen mixture which has partly reacted at 488 K ignites spontaneously at a lower temperature on reheating. A similar phenomenon has been observed also for synthetic $CH_3CHO + O_2$ mixtures with added peroxyacetic acid. The degenerate chain branching has been attributed[5] to peroxyacetic acid and its existence in two forms has been

suggested—more and less stable forms, the former being partly converted into the latter during quenching.

The chain branching stage was initially attributed to the reactions of the peroxyacid, namely the decomposition of the peroxy-complex [$RCO_3H.RCHO$][8,27,39,41,42] or the homogeneous decomposition of RCO_3H.[32,33,43,44] The formation of a peroxy-complex was claimed on the basis of the inconsistency observed in a number of instances between the decrease of pressure in the system and the pressure of the RCO_3H formed, which was particularly clearly manifested at $T <$ 353 K.[39] The only criterion of the occurrence of the branching stage with participation of the peroxy-complex below 423 K is believed to be[39] the dependence of the maximum rate of the oxidation reaction on the square of the aldehyde concentration, which follows from the mechanism adopted (on the assumption of long chains and the neglect of the rate of initiation in mixtures with a high aldehyde content):

$$RCHO + O_2 \rightarrow R\dot{C}O + H\dot{O}_2,$$
$$R\dot{C}O + O_2 \rightarrow RC\dot{O}_3,$$
$$RC\dot{O}_3 + RCHO \rightarrow RCO_3H + R\dot{C}O$$
$$\left.\begin{array}{l} 2R\dot{C}O \rightarrow \\ R\dot{C}O + RC\dot{O}_3 \rightarrow \\ 2RC\dot{O}_3 \rightarrow \end{array}\right\} \text{chain termination},$$
$$RCO_3H \rightarrow RC\dot{O}_2 + \dot{O}H$$
$$RCO_3H + RCHO \rightarrow \text{radicals},$$
$$R = CH_3,\ C_2H_5.$$

It has been stated[45] that the maximum rate calculated from the $p-t$ curves (p is the pressure and t the time) cannot serve as criterion of the correctness of the choice of a particular branching reaction in view of the low accuracy of its determination.

The hypothesis that a peroxy-complex is formed in a gas phase with subsequent decomposition into radicals in space or on the reactor surface is relatively unjustified and has been put forward mainly by analogy with the situation observed in the liquid-phase oxidation.[46] A number of studies have been devoted to the question of the existence of the peroxy-complex in the gas phase.[47-50] Solely on the basis of the iodometric analysis of the reaction products, the formation of the aldehydomonoperacetate (AMP) via the following pathway has been claimed:

$$CH_3CHO + CH_3CO_3H \rightarrow CH_3-\underset{\displaystyle OO}{\overset{\displaystyle OH}{C}}-H \quad \overset{\displaystyle O}{C}-CH_3.$$

AMP then decomposes:

$$AMP \rightarrow \begin{cases} \rightarrow CH_3CHO + CH_3CO_3H; \\ \rightarrow 2CH_3CO_2H. \end{cases}$$

In contrast to the liquid-phase acetaldehyde oxidation reaction, in which the presence of an adduct has been confirmed by NMR,[51,52] no such convincing evidence is available for the gas-phase process.

As regards the homogeneous decomposition of RCO_3H its contribution to the branching process at temperatures up to 473 K is low owing to the high activation energy[53-55] and it is difficult to account for the higher rates of oxidation of CH_3CHO at low temperatures by its formation.

The involvement of hydrogen peroxide in chain branching in the high-temperature oxidation of formaldehyde has been demonstrated[56] by the disappearance of the induction period following the addition of the maximum amount of H_2O_2 observed in the course of the reaction.

There has been no unanimous view concerning the mechanism of the low-temperature oxidation. The nature of the peroxy-compounds, i.e. H_2O_2[7,57,58] or HCOOOH,[4,8,59,60] has been the subject of controversy for a long time. This uncertainty was caused, on the one hand, by the deficiencies of the method of iodometric analysis used by the authors, which failed to yield an unambiguous answer and has been criticised at one time,[3] and, on the other hand, by the possibility of the formation of an organic peroxide, in particular dioxymethyl peroxide, on interaction of CH_2O with H_2O_2 outside the reaction zone.[61]

The formation of HCO_3H has been postulated[60] solely on the basis of the presence of peaks corresponding to masses of 60, 61, and 62 in the mass spectrum of the CH_2O oxidation products, which is unjustified without a comparison with the mass spectrum of the authentic compound. A recent communication[62] quotes the mass spectrum of HCO_3H and presents a comparison with the results of the mass-spectrometric analysis of the products of the low-temperature oxidation of formaldehyde and a mixture containing CH_2O and H_2O_2. In the last two stages the spectra hardly differed. On this basis, it was concluded that the presence of peaks with m/e 60–62 in the analysis of the formaldehyde oxidation products is associated with the products of the interaction of CH_2O and H_2O_2 outside the reaction zone and not with the presence of HCO_3H.

The absence of HCO_3H from the low-temperature formaldehyde oxidation products in a reactor treated with boric acid has been established by analysing the organic peroxyacid in the presence of H_2O_2 using a photoelectric colorimeter (PEC) with the aid of benzidine[63] and *o*-toluidine[64] hydrochlorides. The kinetics of the consumption of CH_2O and the accumulation of H_2O_2 have shown that the chain branching in the low-temperature oxidation of CH_2O is caused by the bimolecular homogeneous decomposition of H_2O_2 into two $\dot{O}H$ radicals.[17]

An important factor in the determination of the mechanism of a chain reaction is the elucidation of the nature of the chain propagating active centre. Progress in this direction has been associated with the employment in the investigations of the kinetic method involving the freezing out of the radicals combined with EPR spectroscopy.[65]

According to published data, the chain propagating active centres in the oxidation of aldehydes are the peroxy-radicals $RC\dot{O}_3$ for acetaldehyde and propionaldehyde and $H\dot{O}_2$ for CH_2O. This conclusion has been based on the presence of acetyl peroxide in the products of the photochemical oxidation of acetaldehyde[66] and also the direct detection of peroxy-radicals by EPR in the thermal oxidation of CH_3CHO [18] and C_2H_5CHO.[12] The observation of the EPR signals due to the peroxy-radicals at low degrees of conversion of acetaldehyde and propionaldehyde (~10%) and the high selectivity of the reaction with respect to peroxyacids (~90%)[67] as well as the parallel course of the peroxy-radical and RCO_3H accumulation curves[18] served to identify the $RC\dot{O}_3$ radicals. An appreciable contribution to the EPR spectrum by radicals of the type $R\dot{O}_2$ was ruled out by the observation that the kinetics of the accumulation of their radicals were inconsistent with the kinetics of the accumulation of ethyl hydroperoxide.[26] Under the experimental conditions, the radicals accumulated in accordance with the rate law characteristic of an intermediate, while the yield of the hydroperoxide increased continuously.

The presence of $H\dot{O}_2$ radicals in the high-temperature oxidation of formaldehyde was indicated by the detection of hydrogen peroxide in the reaction products[57,61,68-71] and by the direct recording of the EPR spectra of the $H\dot{O}_2$ radical.[72]

The identification was based on a comparison of the spectra with the EPR spectra of the $HO_2^{\cdot}$ radicals quoted in the literature[73-76] and on the basis of the parallel behaviour of the radical and H_2O_2 accumulation curves.

The question of the nature of the chain propagating species under the conditions of the low-temperature oxidation of formaldehyde has been discussed[4] as a function of the actual pathway of the reaction of the HĊO radical with O_2 leading to the formation of HO_2 or $HCO_3^{\cdot}$ radicals.

$$\dot{HCO} + O_2 \begin{cases} \longrightarrow HO_2^{\cdot} + CO; & (1a) \\ \longrightarrow HCO_3^{\cdot}; & (1b) \\ \longrightarrow \cdot OH + CO_2. & (1c) \end{cases}$$

The results of studies in recent years of the reactions of the HĊO radicals with oxygen by infrared spectroscopy,[77] mass spectrometry,[78] and intracavity laser spectroscopy (ICLS) combined with flash photolysis,[79] as well as the direct detection of the $HO_2^{\cdot}$ radicals by EPR[80] indicate the preferential formation of $HO_2^{\cdot}$ radicals. The source of the HĊO radicals was either the reaction of formaldehyde with H atoms obtained by a high-frequency discharge in hydrogen or the photolysis of CH_2O.[81]

On the assumption that reaction (1a) takes place, its rate constant has been determined[78] by following directly the concentration of the HĊO radicals and on the basis of data concerning the competition of the reactions of the HĊO radicals with O_2 and O. In another study[77] a band corresponding solely to the $HO_2^{\cdot}$ radical was observed in the infrared spectrum of the products of the reaction of the HĊO radicals with oxygen at room temperature and no bands were found which could be attributed to the $HCO_3^{\cdot}$ radical. The study of the kinetics of the destruction of the HĊO radicals in the photolysis of CH_2O and CH_3CHO in the presence of O_2 by the ICLS method[79] made it possible to determine the rate constants for the overall reaction (1). On the basis of the lack of a dependence of k_1 on pressure in the range 0.2–76 kPa, it was concluded that either the $HO_2^{\cdot}$ radicals are formed preferentially or that the $HCO_3^{\cdot}$ radicals formed decompose rapidly into $CO(CO_2)$ and $HO_2^{\cdot}(\dot{O}H)$. Calculations by the LCAO method have shown[82] that an excited $HCO_3^{\cdot}$ radical is formed in reaction (1b) and can rapidly decompose into ȮH and CO_2. In view of the fact that the yield of CO_2 in the photolysis of CH_2O is low, it has been suggested that at room temperature reaction (1a) competes successfully with the stage (1b) indicated above.

The study of Osif and Heicklen[83] showed that $k_{1b}/k_{1a} = 5 \pm 1$ in the determination of the rates of reactions (1a) and (1b) from the known concentrations of CO, CO_2 and HCO_2H. However, other pathways leading to the formation of HCO_2H,[84] which differ from the reaction sequence $HCO_3^{\cdot} \rightarrow HCO_3H \rightarrow HCO_2H$ and associated, in particular, with secondary processes occurring in the system owing to the presence of CH_2O and H_2O_2 were not ruled out.[61]

The kinetics of the photolysis of CH_2O in a mixture containing O_2 and in the presence of CO_2 have been investigated at 298 K.[84] The quantum yields of H_2, CO, and CO_2 and the consumption of O_2 were determined. Since $\Phi_{H_2} \gg 1$ and $\Phi_{CO} \gg 1$ (Φ is the quantum yield), the authors proposed a reaction mechanism on the basis of which the following expression was obtained for the ratio of the rate constants (M is any kind of species):

$$\frac{k_{1b}[M]}{k_{1b}[M] + k_{1a}} \geqslant 0.049 \pm 0.017.$$

The question of the nature of the chain propagating active centre in the low-temperature oxidation of CH_2O was finally resolved after the direct detection of the $HO_2^{\cdot}$ radicals.[17]

Convincing evidence that peroxy-radicals are the chain propagating active centres was obtained by analysing the kinetics of the thermal oxidation of aldehydes and the following of its features: (1) the attainment of the maximum concentration of the $RCO_3^{\cdot}$ or $HO_2^{\cdot}$ radicals (depending on the object of study) simultaneously with the attainment of the maximum rate of consumption of the aldehyde; (2) the quantitative correspondence between the change in the rates of consumption of the aldehyde and the concentrations of the corresponding peroxy-radicals as the experimental conditions are varies.[12,17,18,26,67,72]

Information concerning the elementary rate-limiting reaction

$$RCO_3^{\cdot} + RCHO \rightarrow RCO_3H + R\dot{C}O$$

obtained indirectly by analysing the molecular products, has been published[31,85] and is presented in Table 1. The rate constants for this reaction have been determined[67] by measuring the concentration of the $RCO_3^{\cdot}$ radicals by EPR and the rate of accumulation of the peroxyacid in the gas-phase oxidation of CH_3CHO or C_2H_5CHO at low degrees of conversion. The rate constants are listed in Table 1.

Data concerning the elementary step

$$HO_2^{\cdot} + CH_2O \rightarrow H_2O_2 + \dot{HCO}$$

have been obtained[86,87] and are also presented in Table 1.

Table 1. The rate constants for the reactions of peroxy-radicals with aldehydes.

Notation: A is the pre-exponential factor, E_a the activation energy, k the rate constant, and T the temperature.

On the basis of data showing a decrease of the induction period and the slow hydrogen oxidation reaction in the presence of added formaldehyde, the reaction mechanism, involving the reactions of the active species with CH_2O has been analysed with the aid of a computer, which made it possible to estimate the rate constant at 773 K.[86] The rate constant for this reaction has been measured by EPR.[87] The approach was similar to that used by Paronikyan et al;[67] the source of the $HO_2^{\cdot}$ radicals was the CH_2O oxidation reaction.

III. THE ROLE OF HETEROGENEOUS FACTORS IN THE OXIDATION OF ALDEHYDES

In the early studies of the oxidation of formaldehyde, few data were published concerning the influence of heterogeneous factors.[36,88,89] A decrease of the reaction rate[36] or a change in the composition of the products with increase of the S/V ratio was noted. In particular, a sharp increase in the yield of CO_2 compared with CO has been observed.[88]

Experiments in a reactor which had been treated with boric acid, inert with respect to decomposition of peroxy-compounds, leads to an appreciable increase in their yield.[59,90]

The observed discrepancies between results obtained by different workers (for example, the presence of an induction period and peroxides[59,89-91] or their absence[92]) has been attributed[60] to differences between the rates of the heterogeneous decomposition of the peroxy-compound, namely HCO_3H, in different experiments. Despite the lack of clear-cut evidence for the formation of HCO_3H, the above study[60] is valuable because the influence of the nature of the surface on the character of the kinetics of the oxidation of formaldehyde was noted in it for the first time.

Studies[93,94] whose authors noted that the treatment of the reactor surface with KCl leads to the inhibition of the homogeneous reaction and did not assume that both the formation and destruction of the active species proceed heterogeneously merit attention.

The influence of the surface of the reaction vessel on the CH_2O oxidation reaction was studied in greater detail by Markevich and Filippova.[68] in clean reactors the reaction proceeds with formation of a considerable amount of hydrogen peroxide (~27% of the initial aldehyde), while in reactors treated with various substances (KCl, CsCl, and $K_2B_4O_7$) the peroxide is not observed and the reaction proceeds at an almost constant rate. A similar dependence of the yield of H_2O_2 on the nature of the surface has been observed in other investigations.[71,72,95,96] The different data obtained have been accounted for in terms of different rate constants for the heterogeneous destruction of hydrogen peroxide and $HO_2^{\cdot}$ radicals on different surfaces.

Thus the variable data definitely indicate the dependence of the yield of H_2O_2 on the nature of the surface. As regards radicals, the first experimental proof of their formation has been obtained by Vardanyan and co-workers.[72,87] In the high-temperature oxidation of CH_2O in an untreated reactor and a reactor treated with boric acid, the $HO_2^{\cdot}$ radicals,[72] whose concentration reached 0.1% of the initial aldehyde, were detected together with considerable amounts of hydrogen peroxide. In reactors treated with salts, hydrogen peroxide and the $HO_2^{\cdot}$ radicals were not detected. Direct experiments have shown[87] that the rate of the heterogeneous destruction of the $HO_2^{\cdot}$ radicals in an untreated reactor and in a reactor treated with boric acid is low but increases appreciably on passing to reactors treated with salts.

In terms of their influence on the rate of the formaldehyde oxidation reaction and the composition of its products, the surfaces investigated have been divided into two groups.[97] A similar subdivision has also been carried out in another study.[98] In the reactors of the first group (reactors pretreated by the reaction taking place or treated with boric acid) the rate of reaction is high and the oxidation proceeds via a degenerate branched chain mechanism and the agent responsible for the chain branching is hydrogen peroxide. The effective activation energies, determined from the maximum rate of consumption of formaldehyde, are 109–125 kJ mol^{-1}. In the reactors of the second group (reactors treated with a salt) the rate of reaction is almost constant and is appreciably lower; no hydrogen peroxide has been detected in the products. The influence of the surface is reflected in a sharp increase of the effective activation energies (209 kJ mol^{-1}) compared with the reactors of the first group. Similar characteristics of the dependence on the nature of the surface have been observed also in the low-temperature oxidation of formaldehyde in reactors treated with boric acid and CsCl.[17]

On the basis of experimental studies and the analysis of the available literature data, the following mechanism has been proposed[56,97] for the oxidation of CH_2O:

$$CH_2O + O_2 \rightarrow H\dot{C}O + HO_2^{\cdot},$$
$$H\dot{C}O + O_2 \rightarrow HO_2^{\cdot} + CO,$$
$$HO_2^{\cdot} + CH_2O \rightarrow H_2O_2 + H\dot{C}O,$$
$$H_2O_2 + M \rightarrow 2OH + M,$$
$$\dot{O}H + CH_2O \rightarrow H_2O + H\dot{C}O,$$
$$\dot{O}H + H_2O_2 \rightarrow H_2O + HO_2^{\cdot},$$
$$H_2O_2 \xrightarrow{\text{wall}} \text{destruction},$$
$$HO_2^{\cdot} \xrightarrow{\text{wall}} \text{destruction},$$
$$HO_2^{\cdot} + HO_2^{\cdot} \rightarrow H_2O_2 + O_2.$$

Extremely convincing evidence for the alteration of the rate of the heterogeneous destruction of peroxy-radicals on passing from reactors of the first group to those of the second has been obtained by EPR.[87,99-101] The heterogeneous decomposition of hydrogen peroxide follows from the comparative analysis of data obtained in a study of the gas-phase decomposition of hydrogen peroxide as a function of the nature of the surface in glass reactors, both thoroughly cleaned[102] and treated with boric,[103,104] phosphoric,[105] and hydrofluoric acids[106] in the temperature range 573–873 K. It has been noted that at approximately 693–698 K a transition from a heterogeneous to a homogeneous reaction is observed. The homogeneous reaction mechanism is indicated, in particular, by the sharp increase of the effective activation energy—from 42 to 230 kJ mol^{-1}.[105] An increase of the reactor diameter leads to a decrease in the rate of decomposition of radicals.[104] In a reactor treated with boric acid,[103,104] the decomposition of H_2O_2 is difficult, and, according to the authors of one of the investigations,[102] a thoroughly clean glass surface is more effective for the conservation of H_2O_2.

The need to include the homogeneous recombination of the $HO_2^{\cdot}$ radicals arises from the experimentally observed dependence of the maximum $HO_2^{\cdot}$ radical concentration on the concentration of the initial aldehyde; this dependence is described by a curve which tends to a limit.[72]

The validity of the proposed mechanism and the characteristic features of the dependence of the reaction kinetics on the nature of the surface which follow from it have been confirmed with the aid of a mathematical model.[107]

There is very little information about the influence of the nature and state of the surface of the reaction vessel on the kinetics of the oxidation of acetaldehyde and propionaldehyde

under static conditions. According to published data, the effective activation energies for the oxidation of CH_3CHO and C_2H_5CHO are much lower (37.6–83.6 kJ mol^{-1}) than for the oxidation of CH_2O, where the effective activation energy is 117–209 kJ mol^{-1}.[5,8]

Pease's study[108] merits special attention because of the novelty of the conclusions reached on the basis of extremely limited information concerning the influence of the nature of the surface on the composition of the products and the rate of the low-temperature oxidation of acetaldehyde. He showed that the rate of reaction is 4–5 times higher in a reactor treated with KCl than in one washed with nitric acid. The maximum yield of CH_3CO_3H was observed in a reactor washed with nitric acid, while the highest yield of CO_2 was noted in a reactor treated with KCl. The amount of CO_2 formed in packed reactors was appreciably higher. By analogy with formaldehyde[96] and H_2,[108] a sharp decrease in the rate of reaction was to be expected in the reactor treated with KCl, since it is known that in this case the rate of destruction of active centres is higher.[87,98]

On the basis of these experimental results, Pease[108] suggested that, in the gas-phase oxidation of CH_3CHO, the chains are initiated on the surface as a consequence of the decomposition of CH_3CO_3H or the $CH_3CO_3^{\cdot}$ radical. Later, the observed dependence of pressure pulsations on the nature of the surface of the reaction vessel in the oxidation of acetaldehyde was also attributed[41] to the heterogeneous decomposition of RCO_3H but this time via a molecular mechanism. According to the authors,[41] the heat evolved in this process initiates a cold flame. However, it has been shown recently that the initiation of the flame is more likely to be the cause rather than the consequence of thermal heating.[110]

Studies[111,112] of the influence of the nature of the surface of a reactor treated with metal halides on the oxidation of acetaldehyde have led to the conclusion that the surfaces catalysing the decomposition of RCO_2H also catalyse the oxidation of CH_3CHO.

A relation has been established in a number of studies[32,108,113] between S/V and the rate of oxidation of CH_3CHO. The proposed explanations are contradictory. Heterogeneous initiation and chain termination have been suggested by Pease,[108] while McDowell and Thomas[32] postulated only a homogeneous process as did their earlier investigation[114] and the study of Combe et al.[39]

Since the calculated activation energies proved to depend on S/V, it was suggested that the corresponding stage is heterogeneous. If the initiation had been homogeneous, one might expect an activation energy of 171.4 kJ mol^{-1},[115] while the value actually obtained[116] is 121.2 kJ mol^{-1}. The possibility of the heterogeneous chain initiation in the oxidation of acetaldehyde has been demonstrated by EPR.[117] The available data show that at low temperatures heterogeneous initiation can predominate over homogeneous initiation.

Data on the influence of the nature and cleanliness of the reactor surface on the rate of the process and its activation energy, obtained in two investigations,[24,44] also merit attention. A marked dependence of the rate of reaction and of the ratio of the yields of the products of the low-temperature oxidation of acetaldehyde (peroxyacetic and acetic acids) on the specific concentration of the substance deposited on the reactor surface has been established recently.[112] The maximum yield of CH_3CO_3H was observed in the reactor treated with a 0.1% KCl solution, while the yield of CH_3CO_2H changed only slightly.

Using the above set of reactions (see Section II) for the description of the acetaldehyde oxidation process, Dixon et al.[22] obtained activation energies ranging from 0 to 66.9 kJ mol^{-1} in the temperature range 318–393 K, on the basis of which they concluded that the branching process is heterogeneous. A similar hypothesis has been put forward by Hardacre et al.[44]

Inspection of the available experimental data obtained under static conditions establishes that a detailed analysis of the products has been carried out only for acetaldehyde. The complete absence of detailed kinetic results concerning the oxidation of propionaldehyde is noteworthy. The sensitivity of the reaction to the nature and state of the surface of the reaction vessel observed in a number of investigations has not been reflected in the proposed mechanisms, which in essence describe a homogeneous process. The conclusion concerning the proposed elementary stages has been reached only on the basis of the analysis of the molecular products. There are no clearly well-founded data concerning the nature of the chain branching stage. The mechanisms of the gas-phase oxidation of CH_3CHO and C_2H_5CHO have been constructed formally by analogy with the liquid-phase oxidation,[46,118,119] which has been studied in greater detail.

Notation: c_0 is the initial concentration of the aldehyde in air at atmospheric pressure, w_{max} the maximum reaction rate, c_r the maximum concentration of radicals, and c_p the maximum concentration of the peroxide.

The first detailed investigation of the kinetics of the oxidation of CH_3CHO and C_2H_5CHO as a function of the nature of the surface has been carried out by Oganesyan and coworkers[18–21] and by Oganesyan[26] respectively. At 448 K the rate of oxidation of CH_3CHO in a reactor of the second group is ~4–5 times higher than in a reactor of the first group; a 40% conversion of acetaldehyde in a reactor of the second group was observed for t = 25 s (t is the residence time of the reaction mixture in the reactor) and for t = 90 s in a

reactor of the first group. The maximum yields of the peroxyacids also differ. The yield in a reactor treated with a salt amounts to 5–7% relative to the initial aldehyde, while in a reactor conditioned by the reaction itself it is 18–20%. An increase of temperature to 499 K results in an interesting phenomenon: the rates of the process in reactors of both types are similar. Up to 25% conversion of acetaldehyde, its consumption in the two cases is described virtually by the same S-shaped curve. The yield of CH_3CO_3H is appreciable in reactors of the first group (17–18%) and low in those of the second group (a fraction of one per cent). Considerable amounts of CH_3CO_3H have been observed[19] in the temperature range 598–648 K in a reactor treated with boric acid, the amount diminishing with increase of temperature: the maximum yields of CH_3CO_3H are 10–11% at 598 K and only 2% of the initial aldehyde at 648 K. In a reactor treated with a salt the amount of CH_3CO_3H is apparently below the sensitivity of the analysis.

The fact that the reaction proceeds autocatalytically in reactors of both types merits attention. However, in contrast to the low-temperature range, the rate of consumption of the aldehyde in a reactor of the first group is ~3–4 times greater (at 623 K) than in a reactor of the second group. The concentrations of the peroxy-radicals are correspondingly greater in a reactor treated with boric acid; Table 2 presents certain characteristic data.

The decreased yield of the organic peroxide with increase of temperature is explained by the increased rate of decomposition of both RCO_3H and the CH_3CO and $CH_3CO_3^{\cdot}$ radicals. It has been established by EPR[10] that the rate of decomposition of the peroxide on a surface treated with a salt is much higher than on one treated with boric acid. In contrast to the low-temperature range, in a reactor treated with boric acid hydrogen peroxide is detected in the CH_3CHO oxidation products, the shape of its accumulation curve differing from that for RCO_3H. Measurable amounts of H_2O_2 are detected at a later stage in the reaction than is RCO_3H. For example, at 623 K and for $t = 0.3$ s the CH_3CO_3H concentration is 2%, while that of hydrogen peroxide is only 0.1%.

Studies of the kinetics of the low-temperature oxidation of propionaldehyde[12] showed that the kinetic behaviour of the system in reactors of both groups is similar to that observed for acetaldehyde. As before, the reaction takes place with autoacceleration, the rate of consumption of the aldehyde and the maximum concentration of the $RCO_3^{\cdot}$ radicals being higher in reactors of the second group. The yields of peroxypropionic acid also differ appreciably: at 423 K and for $t = 2$ min its yield is 1.7% in a reactor treated with KCl and 4.7% of the initial aldehyde in one treated with boric acid.

It has been established[12] that, although the yield of $C_2H_5.CO_3H$ in a reactor treated with KCl is lower, a new organic peroxide, namely ethyl hydroperoxide, as well as ethanol are detected in the reaction product; furthermore, ethylene, detected in a reactor treated with boric acid, is absent. It was concluded that, under conditions favourable for the decomposition of the peroxyacid, the $C_2H_5^{\cdot}$ radicals formed react with oxygen, giving rise to the $C_2H_5O_2^{\cdot}$ radicals, whose subsequent reaction with the aldehyde leads to the formation of ethyl hydroperoxide. The experimentally established influence of the nature of the surface on the yield of the products C_2H_4 and $C_2H_5O_2H$ led to the hypothesis that the reactions $C_2H_5^{\cdot} + O_2 \rightarrow C_2H_4 + HO_2^{\cdot}$ and $C_2H_5^{\cdot} + O_2 \rightarrow C_2H_5O_2^{\cdot}$ take place partly on the reactor surface under the experimental conditions.

With increase of the experimental temperature to 431–531 K, a change in the ratio of the rates of consumption of C_2H_5CHO and of the concentrations of the radicals is observed in reactors of both types, as in the case of acetaldehyde; the ratios are higher in a reactor of the first group (Table 2). It has been established that the yields of $C_2H_5CO_3H$ and $C_2H_5.O_2H$ depend on the nature of the surface of the reaction vessel. In the case of a surface which is effective for the decomposition of peroxides and radicals, the yield of the peroxyacid is lower and that of the hydroperoxide is higher. This has been explained by the fact that the formation of the hydroperoxide is due to the reactions of the $C_2H_5^{\cdot}$ radicals arising in the course of the decomposition of the C_2H_5CO radicals and the peroxyacid.

Analysis of experimental data (Table 2) has shown that, whereas from the standpoint of the involvement of the peroxy-compound in the chain-branching stage the oxidation reactions of formaldehyde, acetaldehyde, and propionaldehyde are similar, in terms of the influence of the nature of the reactor surface they are different. The oxidation of CH_3CHO and C_2H_5CHO proceeds with autoacceleration in reactors of all types. The main intermediate, responsible for the branching, is the corresponding peroxyacid RCO_3H, while the chain propagating active centres are the $RCO_3^{\cdot}$ radicals. The fact that in the low-temperature range the rate of reaction and the concentration of the chain propagating species are low in reactors treated with salts, which are effective inhibitors[3] of the epoxidation processes, despite the intense destruction of the radicals merits attention.

It has been shown for formaldehyde that the rate of reaction in reactors treated with salt is greatly reduced, while the concentration of the active centres becomes lower than the sensitivity of the analysis. The opposite behaviour has been observed for acetaldehyde and propionaldehyde. This is due to the fundamental difference between the natures of the chain branching stages in the oxidation of formaldehyde, on the one hand, and acetaldehyde and propionaldehyde, on the other. This is also indicated by the appreciable difference between the effective activation energies for the processes and the compositions of the reaction products as a function of the nature of the surface. Whereas in the case of CH_2O the activation energy varies from 108.7 kJ mol^{-1} for a surface treated with an acid to 209 kJ mol^{-1} for a surface treated with a salt, in the case of acetaldehyde and propionaldehyde, the activation energy is 37.6–83.6 kJ mol^{-1}, being smaller for a surface treated with a salt.

The kinetic manifestation of the influence of the nature of the surface on the formaldehyde oxidation reaction does not conflict with the idea that there is a stage involving the heterogeneous destruction of the $HO_2^{\cdot}$ radicals and H_2O_2—the product responsible for the branching. For two successive representatives of aliphatic aldehydes, this explanation is invalid. If the decomposition of the intermediate (the peroxyacid) were heterogeneous and involved the formation of molecular products only, the CH_3CHO and C_2H_5CHO oxidation reactions should have been retarded in reactors of the second group in the low-temperature range. Clearly, apart from the heterogeneous chain termination stage, a surface reaction which generates active centres in the gas phase must also occur. This reaction is the decomposition of the peroxyacid on the surface via a radical mechanism with liberation of some of the radicals into the gas phase.

The occurrence of the heterogeneous chain branching has been confirmed with adequate reliability by the autocatalytic character of the process observed regardless of the nature of the surface, the high rates of reaction, and the high concentrations of the active centres in a reactor whose surface (treated with a salt) is effective in the destruction of radicals.

The heterogeneous chain branching is also supported by the results of experiments involving adsorption on the cold surface of the reactor of small amounts of CH_3CO_3H, which leads to the auto-ignition of the acetaldehyde–oxygen mixture

on reheating as a consequence of the heterogeneous decomposition of CH_3CO_3H.[120,121] The temperature of the induced auto-ignition then depends both on the amount of the adsorbed CH_3CO_3H and on the S/V ratio; with increase of S/V, the auto-ignition temperature falls sharply.

According to the available data,[1-3] the increase of S/V leads as a rule to a decrease in the rate of the chain process, which indicates heterogeneous chain termination. However, the influence of the surface is not exhausted by this finding. In early investigations[122-131] the possibility of heterogeneous chain initiation and branching was assumed. The latter possibility was subjected to theoretical analysis in a number of investigations.[1,131-133] So far, there are few experimental data concerning heterogeneous branching. One may note studies[126-130] which dealt with the low-temperature oxidation of hydrocarbons: propane, ethane, and methane. The observed anomalous influence of the surface on the rate of the corresponding stage of the chain process, namely the increase of the rate with increase of S/V, was attributed to heterogeneous chain branching.

Yet another experimental piece of evidence for heterogeneous chain branching in the CH_3CHO and C_2H_5CHO oxidation reactions is provided by the discovery of the radical decomposition of the vapours of the organic peroxides CH_3CO_3H, HCO_3H, CH_3OOH, $C_2H_5CO_3H$, and $(CH_3)_3COOH$ on a solid surface with liberation of some of the radicals from the surface to the gas phase.[134-147] The experiments on the decomposition of the peroxy-compounds were performed mainly at atmospheric pressure in a stream of nitrogen containing small amounts of O_2 at temperatures from ambient up to 498 K. In a number of instances at low pressure the peroxyacid was supplied to the catalyst without dilution with an inert gas. The solid surfaces were those of the reactors of the first and second groups and also metallic platinum, gold, and silver. The residence time in the reactor was varied from several seconds to 10^{-3}–10^{-4} s. In the course of the experiments it was established that, in the absence of catalysts, the decomposition proceeds via a first-order reaction with respect to the peroxy-compound with formation of radicals, which are partly transferred to the gas phase. The detection of peroxy-radicals in the cold trap, placed in the EPR cavity, serves as experimental evidence for the radical decomposition. The heterogeneous character of the decomposition of the peroxy-compounds has also been confirmed by the low effective activation energies, not exceeding 54.3 kJ mol^{-1}.

The general character of the radical decomposition on many solid surfaces has been established in relation to peroxyacetic acid. The detection of the $CH_3CO_3^{\cdot}$ radicals[134] and analysis of the molecular products in the course of the decomposition on platinum[143] led to the conclusion that the peroxyacid dissociates with homolysis of the peroxide bond. This is supported by the finding that the amount of CO_2 formed reached 90% of the initial peroxide. The formation (in the course of the decomposition of organic peroxy-compounds) of OH_{ads} radicals adsorbed on the surface has been demonstrated as a result of the investigation of the methyl hydroperoxide decomposition reaction on a platinum wire in the presence of small amounts of added CO.[143] Under conditions ruling out homogeneous reactions, the formation of additional amounts of CO_2, attributed to the interaction of OH_{ads} with CO, has been observed.

It has been shown that, from the standpoint of the generation of radicals on the surface and their transfer into space, the activities of the catalysts decrease in the following sequence of metals:[141] Pt > Au > Ag, and in the following sequence of alkali metal chlorides:[144] LiCl > NaCl > KCl > RbCl > CsCl.

Comparison of the kinetics of the decomposition reactions of peroxyacetic acid on silver and potassium chloride led to the conclusion that the metallic catalyst is more effective, particularly as regards the generation of radicals and their transfer into the gas phase. Analysis[139] of the ratio of the concentrations of the molecular products of the decomposition of peroxypropionic acid (C_2H_4 and C_2H_4O) made it possible to exclude the transfer of the radicals R from the surface into space.

In a number of instances[134-139] the yield of radicals is appreciable, amounting to 10% of the amount of the decomposed peroxide. A recent study of the radical decomposition of t-butyl hydroperoxide showed that the yield of the $CH_3OO^{\cdot}$ radicals reaches 90% of the decomposed hydroperoxide.[147]

It has been suggested that the heterogeneous decomposition of organic peroxides be used as a source of peroxy-radicals and OH_{ads} radicals for the initiation of the low-temperature oxidation reactions of organic compounds in order to investigate radical reactions.[148]

On the basis of data for the decomposition of organic peroxides on a solid surface, the kinetic curves for the accumulation of the $RO_2^{\cdot}$ radicals, and the analysis of molecular products, the following fundamental elementary steps leading to the formation of radicals have been proposed:[14]

$$CH_3CO_3H_{ads} \rightarrow CH_3CO_{2\,ads}^{\cdot} + \dot{O}H_{ads},$$
$$CH_3CO_{2\,ads}^{\cdot} \rightarrow CH_{3\,ads}^{\cdot} + CO_2,$$
$$CH_{3\,ads}^{\cdot} + O_2 \rightarrow CH_3O_{2\,ads}^{\cdot}$$
$$CH_3O_{2\,ads}^{\cdot} \rightarrow \text{partial transfer of radicals into gas phase.}$$

An important result of the experimental study of the kinetics of the heterogeneous radical decomposition of a peroxy-compound (a peroxyacid) is that the rate of the decomposition reaction on the surface of glass treated with a salt (second group) exceeds that in a reactor treated with boric acid (first group). This result agrees with the observed higher rate of oxidation of acetaldehyde and propionaldehyde in reactors treated with a salt, supporting the view that the branching stage is heterogeneous.

The establishment of the fact that the chain branching is heterogeneous has a number of consequences necessitating a detailed specification of the mechanism presented above by introducing certain possible surface processes involving the radicals formed. The following reactions may be included among them:

$$OH_{ads} + RCHO \rightarrow RCO_{ads} + H_2O, \quad (2)$$

$$RCO_{2\,ads} + RCHO \rightarrow RCO_2H + RCO_{ads}, \quad (3)$$

$$RCO_{ads} \rightarrow R_{ads} + CO, \quad (4)$$

$$RCO_{2\,ads} \rightarrow R_{ads} + CO_2. \quad (5)$$

Information concerning the possibility of the occurrence of reactions (4) and (5) has been published in a communication,[26] where it is shown that the yields of CO, CO_2, as well as C_2H_4 and $C_2H_5O_2H$ depend on the nature of the surface and increase with increase of S/V. The possibility of the occurrence of reaction (2) follows from the possibility of the reaction $OH_{ads} + CO \rightarrow CO_2 + H^{\cdot}$.[143] Depending on the experimental conditions (on the nature of the surface and the values of S/V), the ratio of the contributions of the heterogeneous and homogeneous stages can vary.

Modern ideas about the mechanism of the oxidation of acetaldehyde and propionaldehyde and, in particular, about the pathway leading to the formation of the products can be

formulated mainly in the form of the following sequence of elementary stages without claiming that it is complete:[21,26]

$$RCHO + O_2 \rightarrow R\dot{C}O + HO_2^{\cdot}, \quad (6)$$

$$R\dot{C}O + O_2 \rightarrow RCO_3^{\cdot}, \quad (7)$$

$$RCO_3^{\cdot} + RCHO \rightarrow RCO_3H + R\dot{C}O, \quad (8)$$

$$RCO_3H \xrightarrow{\text{wall}} RCO_2^{\cdot} + \dot{O}H, \quad (9)$$

$$RCO_3H \rightarrow RCO_2^{\cdot} + OH, \quad (10)$$

$$RCO_2^{\cdot} + RCHO \rightarrow RCO_2H + R\dot{C}O, \quad (11)$$

$$\dot{O}H + RCHO \rightarrow H_2O + R\dot{C}O, \quad (12)$$

$$RCO_3^{\cdot} \xrightarrow{\text{wall}} \text{destruction}, \quad (13)$$

$$2RCO_2^{\cdot} \rightarrow \text{products}, \quad (14)$$

$$RCO_3^{\cdot} \rightarrow RO^{\cdot} + CO_2, \quad (15)$$

$$RO^{\cdot} + RCHO \rightarrow ROH + R\dot{C}O, \quad (16)$$

$$R\dot{C}O \rightarrow R^{\cdot} + CO, \quad (17)$$

$$RCO_2^{\cdot} \rightarrow R^{\cdot} + CO_2, \quad (18)$$

$$RO^{\cdot} + O_2 \leftrightarrow RCHO + HO_2^{\cdot}, \quad (19)$$

$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot}, \quad (20)$$

$$RO_2^{\cdot} + RCHO \rightarrow RO_2H + R\dot{C}O, \quad (21)$$

$$R^{\cdot} + O_2 \rightarrow \text{olefin} + HO_2^{\cdot}, \quad (22)$$

$$RO_2^{\cdot} \rightarrow \text{olefin} + HO_2, \quad (23)$$

$$HO_2^{\cdot} + RCHO \rightarrow H_2O_2 + R\dot{C}O, \quad (24)$$

$$HO_2^{\cdot} + \dot{C}H_2O \rightarrow H_2O_2 + H\dot{C}O, \quad (25)$$

$$H_2O_2 + M \rightarrow 2\dot{O}H + M. \quad (26)$$

As already mentioned above, it is assumed that reactions (6), (9), (11), (12), (17), (18), (22), and (23) proceed both on the surface and in the gas phase.

The possibility of the homogeneous recombination of the $RCO_3^{\cdot}$ radicals is justified by experiments[66] in which acetyl peroxide was detected in the RCHO oxidation products and also by the tendency of the maximum concentration of the $RCO_3^{\cdot}$ radicals to reach a plateau with increase in the initial concentration of acetaldehyde.[18] The need to include reactions (24)–(26) arises from the direct detection of the $HO_2^{\cdot}$ radicals and hydrogen peroxide in the high-temperature oxidation of acetaldehyde and propionaldehyde.[26] Direct proof of the occurrence of the heterogeneous chain propagation stages can be provided by the study of the corresponding process at low pressures and temperatures under conditions ruling out homogeneous reactions.

Thus, whereas the mechanism of the oxidation of CH_2O can be regarded as in the main established, that of the oxidation of aliphatic aldehydes of the type RCHO requires further refinement in view of the observation that heterogeneous chain branching takes place.

IV. THE NEGATIVE TEMPERATURE COEFFICIENT OF THE MAXIMUM RATE OF REACTION

Studies devoted to the phenomenon of the negative temperature coefficient (NTC) of the maximum rate of reaction have been surveyed mainly in monographs.[2–4] The principal conclusion which follows from these investigations is that the phenomenon of the NTC is due to the thermal instability of a "critical" intermediate; however, the nature of this species is still controversial. The explanation proposed in a study,[149] where the competition of the reactions of radicals of the type $RO_2^{\cdot}$, $RO^{\cdot}$, $CH_3CO_3^{\cdot}$, and CH_3CO and of the interaction of the radicals $RO_2^{\cdot}$ and $CH_3CO_3^{\cdot}$ with acetaldehyde and the hydrocarbon respectively, leading to the formation of peroxy-compounds, in particular the peroxyacid responsible for the chain branching, merits special attention. With increase of temperature, the rate of formation of the peroxyacid diminishes, causing a fall in the overall rate of the reaction. Other workers adhere to a similar point of view.[150–151] The phenomenon of the NTC has been explained[152] by the competition between the chain propagation and isomerisation reactions of the radicals $RO_2^{\cdot}$ or $RCO_3^{\cdot}$.

The application of the EPR method to the study of the oxidation of propane made it possible to discover the chain propagating species for the reaction,[153,154] and to conclude that the phenomenon of the NTC is due to a change in the chain propagating species and the intermediates responsible for chain branching.[153] $RO_2^{\cdot}$ radicals and ROOH have been detected in the low-temperature range, while $HO_2^{\cdot}$ radicals and H_2O_2 have been found in the high-temperature range.

The phenomenon of the NTC in the aldehyde oxidation reactions has been investigated.[15,16] In the case of acetaldehyde the authors explained it by the contribution of the reverse reaction involving the decomposition of the $CH_3O_2^{\cdot}$ radicals; in the case of propionaldehyde the authors merely stated the fact of its existence. The kinetics of the oxidation of propionaldehyde at atmospheric pressure under flow conditions and at temperatures corresponding to the fall, the minimum, and the increase to a maximum reaction rate, namely 623, 683, and 803 K respectively, have been investigated comparatively recently by EPR.[155] In all cases the EPR spectra of peroxy-radicals were recorded. At 623 K considerable amounts of ethyl hydroperoxide and small amounts of peroxypropionic acid, formed from the peroxy-compounds, were found.

Analysis of the kinetics of the accumulation of C_2H_5OOH and peroxy-radicals enabled the authors[155] to conclude that the main contribution to the EPR spectrum comes from radicals of the type of $C_2H_5CO_3^{\cdot}$. The maximum concentration of the latter is attained (within the limits of experimental error) simultaneously with the attainment of the maximum rate of consumption of the aldehyde. This experimental finding served as proof that the chain propagating active centres in this temperature range are precisely the $RCO_3^{\cdot}$ radicals. The discovery of large amounts of CO and $C_2H_5.O_2H$ and the fact that the ratio $[CO]/[CO_2] > 1$ permitted the conclusion that the $R\dot{C}O$ decomposition stage makes a significant contribution. The decrease in the rate of consumption of the aldehyde at 683 K is accompanied by a decrease in the concentration of the peroxy-radicals and peroxy-compounds. A sharp increase of the concentration ratio $[CO]/[CO_2]$, which becomes ~10, is noteworthy. Such a sharp change in the ratio of the product concentrations has been explained[155] by the decrease of the rates of formation of the $C_2H_5CO_3^{\cdot}$ radical and organic peroxy-compounds as a consequence of the increase of the rate of decomposition of the $\dot{C}_2H_5CO$ radical, leading to a fall of the rate of the C_2H_5CHO oxidation reaction. At 803 K the $HO_2^{\cdot}$ radicals and

H_2O_2 were detected as intermediates, the maximum concentrations of the radicals and the rate of decomposition of propionaldehyde being attained almost simultaneously.

Analysis of the experimental data led the authors[155] to the conclusion that the chain propagating active centres in the region of the NTC consist predominantly of the $C_2H_5CO_3^{\cdot}$ radicals, whose concentration increases sharply with increase of temperature owing to their thermal instability and the thermal instability of the $C_2H_5\dot{C}O$ radicals. This causes an appreciable decrease of the concentration of the peroxy-compounds $C_2H_5CO_3H$ and C_2H_5OOH, which leads to a decrease in the rate of the process. On further increase of temperature, the rate of reaction again begins to rise, since the contribution by the degenerate chain branching process, responsible for the bimolecular decomposition reactions of hydrogen peroxide, begins to increase anew.

The results obtained permitted the conclusion that the phenomenon of the NTC in the oxidation of propionaldehyde is caused by the competition between the $C_2H_5\dot{C}O$ radical decomposition and oxidation reactions. As a consequence of this, the reaction mechanism changes, namely the nature of the chain propagating active centres and the peroxy-compounds responsible for the degenerate branching changes. In the region of the NTC these are the peroxy-radicals and organic peroxides, while at high temperatures the corresponding species are the $HO_2^{\cdot}$ radicals and hydrogen peroxide.

On the basis of the available information about the possibility of the heterogeneous decomposition of the $C_2H_5\dot{C}O$ radical,[26] one may expect an appreciable influence of the nature of the surface on the phenomenon of the NTC.[156] Depending on the change in the rate of decomposition of $C_2H_5\dot{C}O$, there is a possibility of narrowing or expanding the region of the negative temperature coefficient of the maximum rate of reaction.

In view of the fundamental similarity of the mechanisms of the oxidation of propionaldehyde and acetaldehyde, the above conclusions can be extended also to the oxidation of acetaldehyde in the region of the NTC of the maximum rate of reaction. The absence of the phenomenon of the NTC in the oxidation of CH_2O may be associated precisely with the fact that neither the $HCO_3^{\cdot}$ radicals nor HCO_3H are formed and the oxidation proceeds with formation of the $HO_2^{\cdot}$ radicals and hydrogen peroxide, albeit an appreciably lower rate, which however increases continuously with temperature, as a consequence of which the causes of the change in mechanism do not apply.

The ideas developed and the experimental data described above can help also in the understanding of the NTC phenomenon in the oxidation of hydrocarbons, in the course of which aldehydes and the corresponding peroxyacids are produced. The possibility of the formation of the latter at comparatively high temperatures (from 598 to 723 K) follows from experiments[19] carried out under flow conditions at atmospheric pressure and for short residence times of the reaction mixture in the reactor, i.e. under conditions which make it possible to remove relatively unstable products fairly rapidly from the reaction zone and to accumulate them until they attain concentrations susceptible to measurement.

V. CONCLUSION

Analysis of the experimental data on the oxidation of aldehydes makes it possible to explain the greater ease of the oxidation of CH_3CHO and C_2H_5CHO compared with CH_2O. This is associated in the first place with the fundamental difference in the character of the branching stage from the standpoint of both the nature of the products responsible for the branching and the site at which this reaction is localised (surface or space).

In the CH_3CHO and C_2H_5CHO oxidation reactions chain branching is caused by the heterogeneous radical decomposition of the corresponding peroxyacid, while in the CH_2O oxidation reaction it is due to the homogeneous bimolecular decomposition of hydrogen peroxide. As regards the behaviour of these two peroxy-compounds under corresponding conditions, it is known that peroxyacids decompose at a much higher rate and with a lower activation energy[134] than hydrogen peroxide.[157] The possibility of the heterogeneous radical decomposition of hydrogen peroxide has been demonstrated.[158–161] However, in the oxidation of formaldehyde at atmospheric pressure the rate of the heterogeneous radical decomposition of hydrogen peroxide is lower than the rate of its homogeneous bimolecular decomposition.

One cause of the low rates of oxidation of formaldehyde is the fact that the reaction chains are short,[2] in contrast to CH_3CHO and C_2H_5CHO, and that the chain propagating species in the reaction is the $HO_2^{\cdot}$ radical, whose interaction with the aldehyde proceeds with an activation energy of 46 kJ mol^{-1},[87] which is appreciably higher than the activation energies for the interaction of the $RCO_3^{\cdot}$ radicals with $CH_3.\dot{C}HO$ and C_2H_5CHO, amounting to 33.4 and 32.2 kJ mol^{-1} respectively.[67]

The formation of the peroxyacid in the oxidation of acetaldehyde and propionaldehyde and its absence in the oxidation of formaldehyde are caused by the different reactivities of the $H\dot{C}O$ and $R\dot{C}O$ radicals towards oxygen. The former reaction leads mainly to the formation of the $HO_2^{\cdot}$ radicals and the latter to the formation of the $RCO_3^{\cdot}$ radicals. Ultimately this is the reason why the formaldehyde oxidation reaction is somewhat isolated in the series of aliphatic aldehydes.

The experimental evidence for heterogeneous chain branching is important not only for the determination of the mechanism of the thermal oxidation of acetaldehyde and propionaldehyde but also for the further development of the theory of degenerate branched chain reactions, indicating the existence of a similar heterogeneous stage in many reactions exhibiting an "anomalous" sensitivity to the nature and state of the surface of the reaction vessel.

The survey of the experimental data permits the conclusion that the heterogeneous branching of homogeneous chains in the oxidation reactions of organic compounds proceeds more effectively at low temperatures and in the presence of long chains. From this standpoint, it is desirable to revise the existing schemes for the gas-phase oxidation of organic substances and to introduce, as far as possible, corrections to their mechanism, since in practice a corresponding reaction was not taken into account in constructing the mechanism, although the influence of the surface on these processes has not been denied in the literature.

The detection of peroxy-compounds in the high-temperature oxidation of aldehydes also indicates their involvement in chain branching in the oxidation reactions of hydrocarbons.

The results of studies[10,11,18–21,26] have led to a series of important practical conclusions, providing explanations of certain fundamental phenomena, which had been incomprehensible until recently. The observed[108] acceleration of the acetaldehyde oxidation reaction in reactors treated with KCl, as well as the influence of S/V and of the specific concentration of the KCl (deposited on the surface) on the rate and direction of the CH_3CHO oxidation reaction, the spontaneous inflammation of $CH_3CHO + O_2$ mixtures which have partly reacted at a lower temperature after their "quenching", and the spontaneous inflammation of artificial mixtures with added

peroxy-acetic acid[5] are explained by the degenerate chain branching. The observed pressure pulsations in the reactor treated with KCl at a lower temperature in the cold-flame oxidation of acetaldehyde are also caused by the radical decomposition of peroxyacetic acid, specifically by the increase of its rate on a given surface.

Thus the results of the study of the gas-phase oxidation of aldehydes obtained in recent years have significantly altered the existing ideas about the mechanisms of these processes. This has promoted the development of theoretical bases for technological processes for the preparation of valuable oxygen-containing compounds by treating the surface of the reactor or by altering the S/V ratio. In particular, ways have been found for increasing the selectivity in the oxidation of propionaldehyde to propionic[162] and peroxypropionic[12] acids and of acetaldehyde to peroxyacetic acid.[163]

The Reactions of Acetals with Ozone

D.L.Rakhmankulov, E.M.Kuramshin, and S.S.Zlotskii

Data concerning the composition of the products of the ozonisation of acetals, the stoichiometry of the process, and the influence of substituents and the structure of acetals on their reactivity, the effect of the polarity of the medium, the activation parameters for the process, and the kinetic isotope effects are surveyed and analysed. At lowered temperatures the process proceeds via a heterolytic mechanism, while with increase of temperature the fraction of ozone consumed due to the formation of free radicals rises.
The bibliography includes 60 references.

I. INTRODUCTION

The reactions of organic compounds with ozone, leading to various polyfunctional oxygen-containing compounds, are of considerable theoretical and practical interest.[1-3] However, the available information about the reactions of saturated hetero-organic compounds with ozone has not so far been surveyed or described systematically. It is known that, in the course of the ozonolysis of saturated oxygen compounds, substances containing carboxy-, carbonyl, and hydroxy-groups are formed.[4-9] The ozonolysis of acetals with linear and cyclic structures proceeds smoothly under mild conditions and with a high selectivity.[10-19] Since acetals can be readily obtained from cheap easily available petrochemical products, their use as the starting materials in organic synthesis is extremely promising. The ozonolysis of 1,1-dialkoxyalkanes and 1,3-dioxacyclanes leads to the formation of esters, alcohols, and glycol monoethers, ozone attacking only the methylene (or methylidyne) group adjoining two heteroatoms.[12,18] The principal publications devoted to this process are summarised and analysed in this review.

II. THE PRODUCTS OF THE OZONOLYSIS OF ACETALS AND RELATED COMPOUNDS

The first communication[11] stating that the reaction of ozones with acetals is rigorously specific, giving rise to quantitative yields of the corresponding esters of alcohols or glycol monoesters, was published in 1971. In later studies by the same workers,[12-16,20-23] a relation was established between the conformation of the acetal group and its reactivity towards ozone. It was shown that the reaction considered is general for acetals having linear and cyclic structures (Table 1).

The nature of the alkyl substituents in acyclic acetals does not influence the composition of the reaction products. However, significant differences are observed between the rates of oxidation; cyclic acetals react much faster than acyclic acetals (Table 1). Thus the complete oxidation of 1,3-dioxolans (I) and (II) required only 10 min, whereas exhaustive ozonolysis of the dimethoxyacetals (VI) and (VII) takes place in 13–15 h. Under these conditions, one mole of ozone reacts with one mole of the acetal, giving rise to one mole of the ester and one mole of oxygen.

The interaction of ozone with linear-cyclic acetals has been studied in relation to tetrahydropyranyl and tetrahydrofuryl ethers.[12,13]

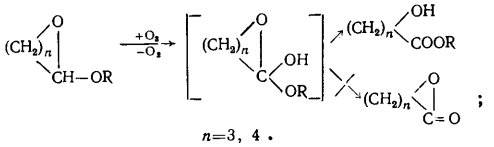
Treatment of 2-alkoxyoxacyclanes with ozone (Table 1) results in the exclusivie formation of esters of ω-hydroxy-acids; lactones and other products were not detected in the reaction mixture.[12,13]

Table 1. Ozonolysis of acetals at −18 °C in ethyl acetate.[11]

No.	Acetal	Product	Reaction time, h	Yield, %
(I)		$C_6H_5COOCH_2CH_2OH$	10*	100
(II)		$C_6H_{13}COOCH_2CH_2OH$	10*	98
(III)		$C_6H_{13}COOCH_2\overset{\displaystyle CH_3}{\overset{\vert}{C}}H_2OH$	1	98
(IV)		$C_6H_{13}COOCH_2CH_2CH_2OH$	2	97
(V)	$C_6H_{13}CH(OC_2H_5)_2$	$C_6H_{13}COOC_2H_5$	8	97
(VI)	cyclo-$C_6H_{11}CH(OCH_3)_2$	cyclo-$C_6H_{11}COOCH_3$	13	98
(VII)	$C_6H_{13}CH(OCH_3)_2$	$C_6H_{13}COOCH_3$	15	91
(VIII)			2	99
(IX)			1	91
(X)			3	91
(XI)			2	95
(XII)			6	85
(XIII)			6	87

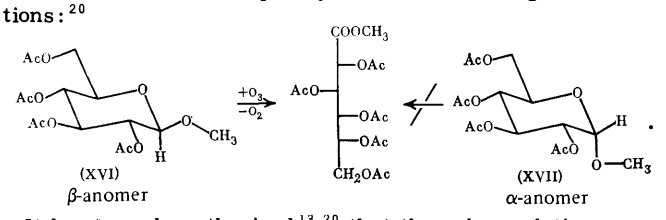
*The reaction time is given in minutes.

The formation of the products of this process is explained by the following scheme:[13]



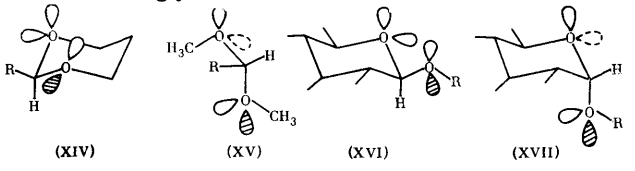
$n=3, 4$.

Subsequently the oxidation of a series of conformationally rigid α- and β-methylglucopyranosides was investigated.[12,20] The β-anomers were oxidised smoothly with ozone, while the α-anomers did not react. For example, methyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (XVI) is converted into methyl 2,3,4,5,6-penta-*O*-acetylgluconate, while the corresponding α-anomer (XVII) is completely inert under analogous conditions:[20]



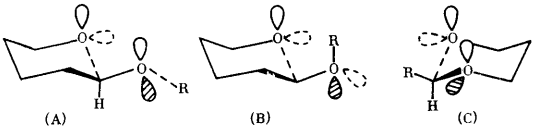
(XVI) β-anomer (XVII) α-anomer

It has been hypothesised[13,20] that there is a relation between the configuration of the acetal group and its reactivity with respect to ozone. For the successful occurrence of the reaction, there should be at each oxygen atom in the acetal an unshared electron pair such that its free orbital is oriented perpendicular to the plane including the C–H bond to be dissociated. This requirement is satisfied by acetals with a dioxan structure (XIV) and the most stable rotational isomers of the β-glycosides (XVI).



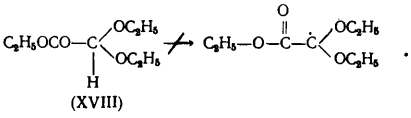
(XIV) (XV) (XVI) (XVII)

In the α-glycosides (XVII), the preferred conformation is that where the orbitals of the oxygen atoms in the ring are not oriented perpendicular to the plane containing the C–H bond and only the second oxygen atom has an orbital with the appropriate orientation; the oxidation with ozone does not therefore occur at an appreciate rate. For the preferred conformation of the linear acetal (XV),[13] the orientation of the oxygen orbitals is analogous to that in the α-glycosides (XVII). In order to interact with ozone, the dialkoxyalkane needs to assume another conformation, which ensures the required orientation of the orbitals (this is impossible for α-glycoside with their rigid chair conformation). However, the equilibrium concentration of any reactive conformer of a dialkoxyalkane is extremely insignificant, because the anomeric effect must be overcome for its formation and the rate of reaction, which depends on the concentration of this conformer, is extremely low. All the possible skewed conformers possible for the acetal group have been examined[20] and for each of them a rigid chemical model was selected and its reactivity with respect to ozone was determined. The experimental results obtained, summarised in a number of studies,[13,20,22,23] established that, of the six *gauche*-conformations possible for the acetal group, only three, namely (A), (B), and (C), are reactive with respect to ozone:



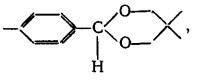
(A) (B) (C)

In these conformers the orbital of the unshared electron pair of each oxygen atom is oriented perpendicular to the plane containing the C–H bond. The results suggested[13] that a positive charge on the carbon atom of the acetal group should be generated in the transition state of the reaction. The appropriate disposition of the orbitals of the free electron pairs of each oxygen atom can readily stabilise such a positive charge. In the presence of the ethoxycarbonyl group this type of stabilisation is impossible and ethyl diethoxyacetate (XVIII) proved to be completely inert with respect to ozone. This rules out the possibility of a free-radical reaction mechanism because the presence of the ethoxycarbonyl group should facilitate the formation of the intermediate dialkoxyethoxycarbonylmethyl radical:



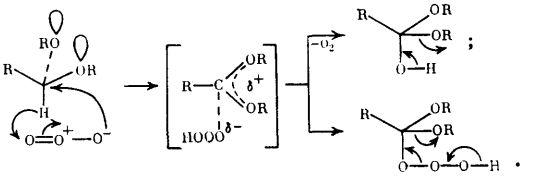
(XVIII)

The study of the reactivities of the acetals of *p*-substituted benzaldehydes



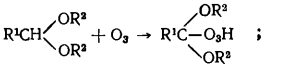
where R = OCH_3, H, or NO_2, showed that electron-donating groups accelerate the reaction, while electron-accepting groups retard it.

The set of the results obtained suggested the following process mechanism[13,20] [see also Section (V)]. Ozone reacts with the C–H acetal bond by a 1,3-insertion mechanism, forming either an α-hydroxyacetal and molecular oxygen or a hydrotrioxide:



These products decompose to an ester of an alcohol. It must be emphasised that ozone is inserted only for the conformation of the acetal group in which the orbital of the free electron pair of each oxygen atom has the antiperiplanar orientation in relation to the C–H bond.

In most investigations it has been suggested that the labile intermediates in the ozonolysis of unsaturated compounds are the corresponding hydrotrioxides.[13,20,24] The first spectroscopic evidence for the existence of hydrotrioxides was obtained in the study of the ozonolysis of ethers.[24] It has been observed recently[17,28] that the interaction of acetals with ozone results in the formation of hydrotrioxides, stable at −50 °C, which have been identified by ^{1}H NMR:



(XIX)—(XXII)

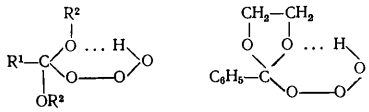
(XIX): $R^1=R^2=CH_3$

(XX): $R^1=CH_3$, $R^2=C_2H_5$

(XXI): $R^1=C_6H_5$, $R^2=CH_3$

(XXII): $R^1=C_6H_5$, $R^2R^2=(CH_2)_2$.

The ^{1}H NMR spectra contain two signals in the region of δ = 13 p.p.m. relative to Me_4Si. Since the position of the signals did not change appreciably on dilution, they were preferentially attributed to the proton of the OOOH group combined into six-membered rings by an intramolecular hydrogen bond:[28]



Although the origin of two signals of the proton in the O_3H group remains obscure, it is of interest to note that a similar observation has been made for the hydrotrioxide of 2-methyltetrahydrofuran.[24] With increase of temperature, both signals tend to merge and broaden. It has been suggested[28] that this splitting may be caused by the presence of two conformations of the hydrotrioxides of acyclic acetals, which is a result of the non-equivalence of the two oxygen atoms in acetals. The acetal hydroperoxides can be used as effective oxidants for organic compounds. It has been shown[25] that the reaction of 1,1-diethoxyethane hydrotrioxide with diphenylamine and 2,2,6,6-tetramethylpiperidine leads to the formation of the corresponding hydroxy-radicals (the diphenylnitroxy-radical and the 2,6,6,6-tetramethylpiperidin-1-yloxy-radical). Under mild conditions, 1,1-diethoxyethane hydrotrioxide rapidly oxidises pyridine to the *N*-oxide and dipropyl sulphide to dipropyl sulphoxide.[26,27]

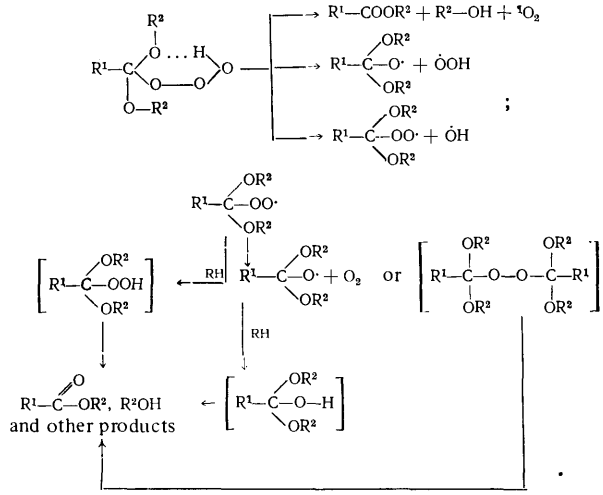
The kinetics of the thermal decomposition of acetal hydroperoxides have been investigated both for the pure substances and for their solutions in diethyl ether and methylene chloride.[17,28] The decomposition follows first-order kinetics. The expressions for the rate constants $k(s^{-1})$ for the thermal decomposition of the hydrotrioxides investigated have the following forms:

$$\begin{array}{ll} \text{(XIX)} & \lg k = 11.8-67.5/\theta, \\ \text{(XX)} & \lg k = 11.1-60.8/\theta, \\ \text{(XXI)} & \lg k = 15.8-79.6/\theta, \\ \text{(XXII)} & \lg k = 12.2-62.3/\theta, \end{array} \qquad \theta = 2.3RT .$$

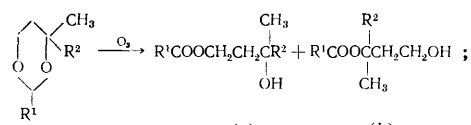
Table 2. The composition of the products of the ozonolysis of 1,3-dioxacyclanes at different temperatures.[29]

Initial compound	Isomer ratio (*a*)/(*b*)		
	−50° C	15° C	50° C
(XXIII)	2:1	2:1	2:1
(XXIV)	2.5:1	2:1	2:1
(XXV)	7:1	3:1	2:1

The low pre-exponential factors for compounds (XIX), (XX), and (XXII) apparently indicate a chain mechanism for the decomposition reaction. All the hydrotrioxides investigated decompose in the temperature range from −40° to +40 °C with formation of singlet oxygen, whose yield (relative to the amount of ozone absorbed) varies from 45 to 80% and depends on the initial compound. In the case of 1,1-diethoxyethane hydrotrioxide (XX), ethyl acetate (0.80–0.85 mole per mole of the ozone absorbed), ethanol (0.70–0.75 mole), water, acetaldehyde, acetic acid, ethyl formate, diethyl carbonate, as well as small amounts of gaseous substances, probably ethane and methane, were detected among the reaction products. The presence of two types of peroxy-compounds, which were not finally identified but are tentatively believed to be an alkyl hydroperoxide and a dialkyl peroxide, was also observed. Apparently the formation of a considerable proportion of ethyl acetate and ethanol together with singlet oxygen is due to the non-radical decomposition of the hydrotrioxide, while the presence of the other two products in the reaction mixture can be accounted for by a free-radical decomposition mechanism:[17]



The reactions of asymmetric 1,3-dioxacyclanes with ozone have been studied in relation to 4-methyl-1,3-dioxan (XXIII), 2,4-dimethyl-1,3-dioxan (XXIV), and 4,4-dimethyl-1,3-dioxan (XXV) in the temperature range from −50° to +50 °C.[29] The reaction products (Table 2) consist of a mixture of the isomeric monoethers (*a*) and (*b*), whose yield relative to the ozone and the substrate which have been consumed reaches 95%:

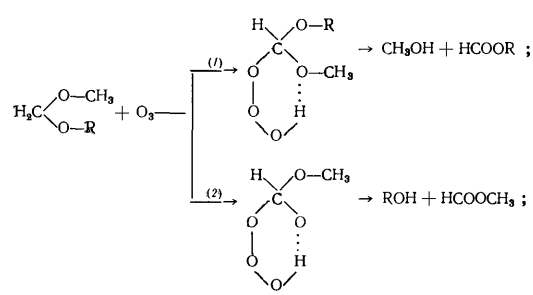


(*a*) (*b*)

R^1, R^2=H (XXIII); R^1=CH_3, R^2=H (XXIV); R^1=H, R^2=CH_3 (XXV) .

In all cases the main products are substances with an acylated primary hydroxy-group (*a*). These results can be accounted for by the preferential dissociation of the C(2)–O(3) bond in the intermediate hydrotrioxide,[29] which is caused by the steric repulsion between the hydrotrioxide group and the axial CH_3 group attached to the C(4) atom in the ring.

The interaction of asymmetric linear acetals with ozone has been studied in relation to methoxyalkoxymethanes at −60 °C.[30] Butyl formate, methyl alcohol, butyl alcohol, and methyl formate accumulate simultaneously in the interaction of ozone with butoxymethoxymethane (XXVI). The ozonolysis of methoxypentoxymethane (XXVII) leads analogously to pentyl formate, methyl alcohol, pentyl alcohol, and methyl formate. The results have been explained within the framework of the following mechanism:



R=C_4H_9 (XXVI), C_5H_{11} (XXVII); (*1*):(*2*)=4:1 .

The observed ratio of pathways (*1*) : (*2*) = 4 : 1 can be explained by the preferential formation of an intramolecular hydrogen bond involving the oxygen atom of the OCH_3 group in the intermediate hydrotrioxide, while the steric hindrance due to the C_4H_9 and C_5H_{11} groups diminishes the probability of the formation of a hydrogen bond involving the OR group.

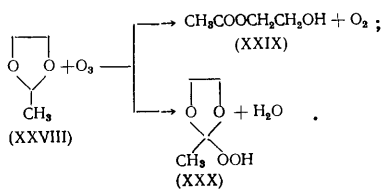
The behaviour of the C–H bond adjoining the three oxygen atoms in relation to ozone has been investigated.[31] Ethyl orthoformate, which is regarded as a derivative of diethoxymethane in which the hydrogen atom has been replaced by the ethoxy-group, was chosen as the object of study. It was established that the main ozonolysis products are diethyl carbonate, ethyl formate, and ethyl alcohol, which accumulate simultaneously:

$$HC(OC_2H_5)_3 + O_3 \begin{cases} \longrightarrow HO_3C(OC_2H_5)_3 \xrightarrow{-O_2} OC(OC_2H_5)_2 + C_2H_5OH \\ \longrightarrow HC(OC_2H_5)_2OCH(O_3H)CH_3 \xrightarrow{-O_2} HCOOC_2H_5 + C_2H_5OH + CH_3CHO \end{cases}.$$

The attack by ozone on the C–H bond adjoining the three oxygen atoms is the main pathway in the process. The reactivity of ethyl orthoformate towards ozone is close to that of diethoxymethane, is twice as high as the reactivity of ethyl alcohol, and is much less than the reactivity of 1,1-diethoxyethane.

III. THE CONTRIBUTION OF RADICAL REACTIONS IN THE OZONOLYSIS OF ACETALS

The results of the ozonolysis of acetals at reduced temperatures (between −78° and 20 °C)[13,29,32,33] clearly demonstrate that the reaction is general and leads to the formation of esters or glycol monoesters with a selectivity not less than 90%. It has been shown[32] that, in the temperature range 20–60 °C, water and organic hydroperoxides, identical to the products obtained in the initiated oxidation of acetals by molecular oxygen, are formed together with the products indicated above. It has also been demonstrated that the reaction of 2-methyl-1,3-dioxolan (XXVIII) with ozone between 20° and 40 °C involves the simultaneous accumulation of the monoester of ethylene glycol (XXIX), the corresponding hydroperoxide (XXX), and water, while at temperatures ≤5° the monoester (XXIX) is virtually the only reaction product (Table 3):



It has also been found[32] that, when 1,1-diethoxyethane (XXXI) is treated with ozone at 20–60 °C, the corresponding hydroperoxide (XXXIII) and water are formed simultaneously with ethyl acetate (XXXII) and ethyl alcohol (Table 3):

$$CH_3CH(OC_2H_5)_2 + O_3 \begin{cases} \longrightarrow CH_3COOC_2H_5 + C_2H_5OH + O_2 \ ; \\ (XXXII) \\ \longrightarrow CH_3C(OOH)(OC_2H_5)_2 + H_2O \ . \\ (XXXIII) \end{cases}$$

With increase of temperature, the yield of the hydroperoxide and water with respect to the ozone consumed increases and at 50–60 °C reaches 30–40%. The presence of considerable amounts of hydroperoxides and water in the products of the ozonolysis of acetals is believed[32–35] to indicate the formation of radicals in the primary reaction of ozone with acetals.

The extent of formation of free radicals in the primary reaction between ozone and acetals has been estimated from the amount of hydroperoxides and water formed and also from the amount of ozone consumed under the conditions of non-chain formation of hydroperoxides.[32] It has been shown that the reactions involving free radicals are more characteristic of linear acetals (~50% at 60 °C), but, with decrease of temperature (<10 °C), the contribution of the radical pathway to the overall process becomes negligible.

Table 3. The influence of temperature on the composition of the products of the reaction of ozone with 1,1-diethoxyethane and 2-methyl-1,3-dioxolan at advanced stages of the reaction in the absence of a solvent.[32]

Reaction temperature, °C	Amount of initial compounds which have reacted, mmol		Yield of products, mmol			
	O_3	acetal	the ester (XXIX) or (XXXII)	C_2H_5OH	the hydroperoxide (XXX) or (XXXIII)	H_2O
			(XXXI)			
60	5.0	11.4	11.1	8.0	1.8	2.1
40	5.0	10.5	10.2	8.2	1.2	2.0
20	10.0	17.5	16.6	14.2	1.7	2.2
5	10.0	12.8	11.8	10.2	0.6	0.7
			(XXVIII)			
40	5.0	10.4	10.0	—	1.3	1.0
20	5.0	6.1	5.7	—	0.9	0.9
5	10.0	10.8	10.6	—	0	0

The rate of formation of free radicals in the reaction of ozone with 1,1-diethoxyethane has been investigated[35] using the results on the liquid-phase chain oxidation of the latter initiated by ozone. With continuous supply of an ozone–oxygen mixture to the reaction mixture, the initial rates of accumulation of the hydroperoxide (v_{AOOH}) and of consumption of ozone (v_{O_3}) were determined (Table 4).

Table 4. The rates of accumulation of the hydroperoxide (XXXIII) (v_{AOOH}), of the consumption of ozone (v_{O_3}), and of initiation (v_i) as a function of the ozone concentration in the gas mixture c_{O_3} in the reaction of ozone with the acetal (XXX) at T = 50 °C.[32,35]

$10^5 c_{O_3}$, M	$10^6 v_{O_3}$, mol litre^{-1} s^{-1}	$10^5 v_{AOOH}$, mol litre^{-1} s^{-1}	$10^6 v_i$, mol litre^{-1} s^{-1}	v_i/v_{O_3}
4.0	2.2	0.7	0.7	0.3
6.6	3.7	1.1	1.3	0.4
11.7	8.5	1.7	3.4	0.4
32.1	23.2	3.3	13.0	0.6
55.8	15.5	2.2	6.0	0.4
84.4	34.6	3.3	13.5	0.4

The rate v_{O_3} is directly proportional to a concentration of ozone in the gas mixture c_{O_3}, while the rates v_{AOOH} vary linearly with $v_{O_3}^{1/2}$ and $v_{AOOH}/v_{O_3} \geq 1$, which agrees with the mechanism of the radical process in which the hydroperoxide

appears in the step involving the abstraction of hydrogen from the substrate by the peroxy-radical:[10]

$$CH_3CH(OC_2H_5)_2 + O_2 \xrightarrow{k_1} CH_3\dot{C}(OC_2H_5)_2,$$
$$CH_3\dot{C}(OC_2H_5)_2 + O_2 \xrightarrow{k_2} CH_3C(O\dot{O})(OC_2H_5)_2,$$
$$CH_3C(O\dot{O})(OC_2H_5)_2 + CH_3CH(OC_2H_5)_2 \xrightarrow{k_3} CH_3C(OOH)(OC_2H_5)_2 + CH_3\dot{C}(OC_2H_5)_2,$$
$$2CH_3C(O\dot{O})(OC_2H_5)_2 \xrightarrow{k_4} \text{non-radical products.}$$

According to the mechanism proposed, the rate of formation of the hydroperoxide AOOH is given by the formula $v_{AOOH} = k_2 k_3^{-1/2}[AH]v_i^{1/2}$, where v_i is the rate of formation of radicals in the system in the stage involving initiation by the reaction of O_3 with the acetal.[35] These results (Table 4) made it possible to determine the ratio v_i/v_{O_3}, characterising the fraction of ozone consumed in the formation of free radicals, which is 0.45 ± 0.15. This permitted the hypothesis that the ozonolysis of acetals takes place simultaneously via molecular and radical pathways:[32,35]

$$CH_3CH(OC_2H_5)_2 + O_3 \text{ (AH)} \begin{cases} \xrightarrow{(a)} CH_3C(O_3H)(OC_2H_5)_2 \xrightarrow{-O_2} CH_3COOC_2H_5 + C_2H_5OH; \\ \xrightarrow{(b)} CH_3\dot{C}(OC_2H_5)_2 + O_2 + \dot{O}H \rightarrow \text{radicals;} \end{cases}$$
$$AH + \dot{O}H \rightarrow \dot{A} + H_2O; \quad \dot{A} + O_2 \rightarrow A\dot{O}_2; \quad A\dot{O}_2 + AH \rightarrow AOOH + \dot{A};$$
$$A\dot{O}_2 + A\dot{O}_2 \rightarrow \text{non-radical products.}$$

At temperatures below 10 °C the fraction of ozone consumed in the formation of free radicals [pathway (*b*)] is negligible and the reaction proceeds almost entirely via the formation of the unstable hydrotrioxide [pathway (*a*)]. With increase of temperature (above 10 °C), the fraction of ozone consumed in the formation of free radicals increases and conditions are created for oxidation by oxygen.

Table 5. The stoichiometry of the reaction of ozone with the dioxolans –R at 0 °C.[36]

R	Amount of acetal mmol		Amount of ozone absorbed, mmol	Solvent	α*
	initial	final			
CH_3	22.8	19.7	3.18	CH_2Cl_2	1.0
	17.4	13.8	3.46	ditto	0.94
	13.6	8.3	5.84	»	1.09
C_6H_5	16.2	11.5	5.00	»	1.06
	12.3	9.4	2.69	»	0.95
	9.2	4.4	4.70	»	1.01
p-$CH_3C_6H_4$	12.3	9.3	2.92	CCl_4	0.92
	9.1	2.6	6.68	ditto	1.03

*α is the ratio of the amount of ozone absorbed and the acetal which has been consumed.

IV. THE INFLUENCE OF THE STRUCTURE OF ACETALS AND THE CONDITIONS IN THEIR REACTION WITH OZONE ON THE RATE OF THE PROCESS

The stoichiometry of the reaction of ozone with acetals was first investigated in relation to 2-phenyl-1,3-dioxolan (I) at −78 °C in methyl acetate.[36] It was established that treatment of one mole of the acetal with ozone results in the formation of one mole of oxygen and one mole of glycol monoester. The results of further studies,[36] carried out in relation to 1,3-dioxolans substituted in 2-position at 0 °C, have shown that the stoichiometric ozone : acetal ratio is close to unity and is almost independent of the initial concentrations of the reactants (Tables 5 and 6).

When the reaction was carried out in the pure substrate (1,1-diethoxyethane or 2-methyl-1,3-dioxan) in the temperature range betwee −20° and 60 °C, it was found[32] that the stoichiometry of the reaction (O_3 : OH) changes from 1 : 1 (between −20° and 0 °C) to 1 : 2 (40–60 °C), which is associated with the occurrence of chain oxidation at temperatures ≥40 °C. On the other hand, when the concentrations of the acetal are close to those of ozone, the stoichiometric ratio of the reactants at 20 °C is close to unity.

Table 6. The stoichiometry of the reaction of ozone with the dioxolans –R in CCl_4 at 0 °C.[36]

R	c_{AH}, 10^{-4} M	c_1, 10^{-4} M	c_2, 10^{-4} M	$\alpha = \frac{c_1 - c_2}{c_{AH}}$
C_6H_5	7.1	9.4	2.3	1.00
	5.0	6.4	1.5	0.98
	3.7	5.8	2.0	1.03
CH_3	5.0	6.0	1.2	0.96
	3.0	6.2	3.3	0.97
	3.0	3.6	0.5	1.03

Notation: c_{AH} is the initial concentration of the acetal, c_1 the initial concentration of O_3, c_2 the final concentration of O_3.

This made it possible to investigate the reactivity of acetals with different structures in relation to ozone at 20 °C, the rate of consumption of ozone being followed spectrophotometrically. For all the compounds investigated, the kinetic O_3 consumption curves have the same form and, when [AH] ≫ [O_3], can be satisfactorily represented in a linear form by plotting $\ln [O_3]_0/[O_3]$ against time; under these conditions, ozone is consumed via a pseudounimolecular process with a rate constant $k' = v_{O_3}/[O_3]_0$.[18,29,31–37,40] With increase of the acetal concentration in solution, the rate constant k' increases linearly[32] and the initial rate of consumption of ozone obeys a second-order equation: $v_{O_3} = k[AH][O_3]$; the constant k reflects the overall reactivity of the acetal with respect to ozone and in the temperature range between −78° and 20 °C the process proceeds mainly via the molecular pathway.

The reactivity of 1,3-dioxacyclanes is determined by the ring size and the nature of the substituent at the C(2) carbon atom. The influence of ring size on the reactivity of acetals has been investigated.[18] Comparison of the bimolecular rate constants for the reactions of ozone with five-, seven-, and six-membered 1,3-dioxacyclanes has shown that the reactivity decreases in the sequence 1,3-dioxolan > 1,3-dioxepan > 1,3-dioxan. The dependence of $\lg(k_n/k_0)$ on n, where n (ring size) assumes values of 5, 6, and 7, is analogous to that for the solvolysis of chlorocycloalkanes and the thermal decomposition of cyclic diazoalkanes.[18] This enabled the authors to postulate the appearance in the transition state of a deficiency of electron density at the C(2) atom. The increase of reactivity after the introduction of alkyl and particularly phenyl substituents in the 2-position, which are capable of compensating for the decrease of electron density, has been explained[36] by the stabilisation of the positively charged species produced in which a p_z orbital is formed. The necessary effect is a maximum for 1,3-dioxans, since six-membered rings are less strained, resulting in an intermediate species which has a planar structure with the p_z orbital in

the same plane as the electron pairs of the oxygen atoms and the π orbitals of the phenyl substituent. The transition state in the case of seven- and particularly five-membered 1,3-dioxacyclanes largely deviates from the planar structure, as a result of which the conjugation with the p_z orbital is less effective.

Table 7. Correlation between the rates of reaction with ozone and the Taft substituent constants.

Acetal	Solvent	T, °C	ρ	Correlation coefficient
	CCl_4	0	−1.16	0.995
	C_2H_5OAc	−78	−1.27	0.998
	C_2H_5OAc	−78	−1.58	0.980
	C_2H_5OAc	−78	−1.31	0.910

In order to determine the quantitative relations between the structure of the acetal and its reactivity towards ozone, a study has been made of the influence of substituents on the variation of the rate constants in series differing from one another only in the substituent. The experiments were performed at different temperatures (−78°, 0°, and 20 °C) and in solvents of different polarity (CCl_4,[36,37,40] ethyl acetate[37]).

Taft and Hammett inductive constants have been compared[36] with the relative rate constants for the reaction of ozone with 2-alkyl- or 2-aryl-1,3-dioxolans, which were determined by a competitive method at 0 °C in CCl_4, and also with the pseudo-unimolecular rate constants for the interaction of ozone with 2-alkyl-1,3-dioxans and 1,1-dimethoxyalkanes measured in ethyl acetates at −78 °C. These results showed that electron-donating substituents increase and electron-accepting substituents diminish the reactivity of acetals, the latter increasing by a factor of ~2 following the replacement of a non-polar solvent (hexane) by a polar solvent (ethyl acetate or acetic anhydride). The reaction paramters ρ, the absolute magnitude and sign of which characterises the change in the charge density in the reaction centre on passing from the ground to the transition state, are listed in Table 7. The increase in the negative value of ρ following the replacement of a non-polar solvent (CCl_4) by a more polar solvent (ethyl acetate) is noteworthy.

The quantitative relations between the structure of the acetals and their reactivity in the interaction with ozone in CCl_4 at 20 °C have been investigated taking into account the inductive (σ^*) and steric (E_S) effects of the substituents.[40] For this purpose measurements were made of the rate constants for the reaction of ozone with linear formals and acetals having symmetrical and asymmetric structures, 2-alkyl-1,3-dioxolans and 2-alkyl-1,3-dioxans (Table 8). It has been established that the reactivities of the compounds investigated diminish in the sequence 1,3-dioxolans > 1,3-dioxans > 1,1-dialkoxyalkanes > dialkoxymethanes. The reaction rates constants correlate satisfactorily with the Taft inductive constant σ^*; the sign of ρ is negative and its absolute magnitude varies in the sequence 1.0–1.6 (Table 9). The negative values of ρ in all the examples considered show that a partial positive charge is generated on the acetal carbon atom in the trantision state and the rate of ozonolysis is limited by the hydride transfer stage.[43,44] The characteristic influence of the nature of the solvent on the rate of the process, noted above, confirms the polarity of the transition state. In order to take into account simultaneously the influence of the inductive and steric effects[45] of the substituents

Table 8. The rate constants k (litre mol^{-1} s^{-1}) for reactions of the acetals $H_2C(OR)_2$, $R^1CH(OR^2)(OR^3)$,  , and  with ozone in the liquid phase.[40]

Remarks: 25 °C; solvent—CCl_4; $[O_3] = 1.6 \times 10^{-4}$–$1.6 \times 10^{-3}$ M; [acetal] = 10^{-3}–10^{-2} M; [a] $R^2 = CH_3$, $R^3 = C_4H_9$; [b] $R^2 = CH_3$, $R^3 = iso\text{-}C_5H_{11}$; [c] $R^2 = R^3 = C_2H_5$.

on the rate of ozonolysis of acetals, relations of the type $\lg(k/k_0) = \rho\sigma^* + \delta E_S$ were investigated.[40] The two-parameter correlation (Table 9) describes the best reactivities of the compounds studied. The alkyl substituents R in the alcoholic component of the dialkoxymethanes do not manifest an appreciable steric effect (the steric constant for the reaction series is $\delta = -0.054$) because of their remoteness from the reaction centre, since the reactivities of compounds of this series are mainly determined by the inductive effect of the substituents ($\rho = -2.42$). The reactivities of 1,1-diethoxyalkanes, like those of dialkoxymethanes, are determined mainly by the inductive effect ($\rho = -2.30$). The positive sign of the steric constant δ for this reaction series is noteworthy, indicating a decrease of the reaction rate with increased bulk of the substituent at the reaction centre. The substituents in the reaction series involving the ozonolysis of 2-alkyl-1,3-dioxolans and 2-alkyl-1,3-dioxans (Table 8) exert an appreciable influence on the reactivity.[36,37] Analysis of the constants ρ and δ (Table 9) shows that the rate of the process is determined by the inductive and steric effects of the substituents and that the influence of the latter becomes decisive for 2-alkyl-1,3-dioxans. The observed difference between the five- and six-membered rings can be explained[40] by the conformational characteristics of the molecules considered. It is known that the introduction of a substituent into 1,3-dioxan fixes the chair confirmation,[46] while the C–H bond attacked is in a conformation favourable for reaction because its orientation is antiperiplanar relative to the orbitals of the free electron pairs of the oxygen atoms.[20] The five-membered ring does not have quite such a distinct conformational minimum[47,48] and the steric influence of the substituents in the 2-position is therefore smaller.

Table 9. The inductive (ρ) and steric (δ) constants for the reaction series involving the reaction of ozone with acetals.[40]

Compound	$\lg(k/k_0) = \rho\sigma^*$		$\lg(k/k_0) = \rho\sigma^* + \delta E_S$			
	ρ	r	ρ	δ	r	s
	−1.55	0.973	−2.42	−0.054	0.975	$0.4 \cdot 10^{-2}$
	−1.32	0.991	−2.30	0.38	0.998	$2.6 \cdot 10^{-4}$
	−1.02	0.937	0.68	−0.58	0.992	$0.4 \cdot 10^{-2}$
	−1.6	0.994	5.89	−2.92	0.990	$1.6 \cdot 10^{-2}$

Notation: r is the correlation coefficient and s the variance.

The activation parameters for the ozonolysis of linear and cyclic acetals determined in two investigations[36,37] are listed in Table 10. The high negative entropies of activation $\Delta S^{\neq}$ ($\Delta S^{\neq} = -141$ to -106 J mol^{-1} K^{-1} [36]) and the anomalous relation between the reactivities of linear acetals and the corresponding enthalpies of activation, namely the fact that the increase of the reactivity of the acetal is accompanied by an increase of the enthalpy of activation,[37] are noteworthy. It has also been established[37] that the enthalpy of activation $\Delta H^{\neq}$ and the entropy of activation $\Delta S^{\neq}$ are linked by a linear relation, so that a compensation effect is observed ($\Delta H^{\neq} = \beta\Delta S^{\neq} + h_0$; β is the isokinetic temperature and h_0 is a constant).[37] For linear acetals, the isokinetic temperature is much below the experimental temperature range and the reactivity is determined by the entropy factor.[37] Since, according to Deslongchamps et al.[22], linear acetals exist in a conformation which is inert towards ozone, in order to become reactive the acetal molecules must assume a favourable conformation[20] in which the C–H bond attacked is oriented antiperiplanarly relative to the unshared electron pairs of the oxygen atoms. For cyclic acetals, which exist in a favourable conformation,[22] β lies at higher temperatures than the working range[37] and the enthalpy factor determines the reactivity.

V. THE MECHANISM OF THE INTERACTION OF OZONE WITH ACETALS

The reaction of ozone with a saturated C–H bond can proceed via homolytic, concerted, and heterolytic mechanisms.[36,49,50]

The homolytic mechanism can operate in principle in several ways.[50] It can involve a chain reaction initiated by oxygen atoms, which are formed on reversible dissociation of ozone:

$$O_3 \rightleftarrows O_2 + O \quad (\Delta H = 107 \text{ kJ mol}^{-1} \text{ (Ref.50)}).$$

Analysis by Denisov[50] indicated a low probability of the occurrence of the chain reaction at reduced temperatures. This agrees with the finding that the initiating effect of ozone on the gas-phase oxidation of hydrocarbons is observed only at temperatures above 100 °C, where ozone decomposes at an appreciable rate.[50] In the liquid phase at moderate temperatures the radicals can be generated via a bimolecular reaction. However, the mechanism involving abstraction of a hydrogen atom is believed to be unlikely in view of the high endothermicity of the reaction:

$$RH + O_3 \rightarrow R^{\cdot} + HO_3^{\cdot} - q \quad (q = Q_{R-H} - 255 \text{ [56]}),$$

which does not agree with experimental data.[36] For example, $Q_{R-H} \cong 340$ kJ mol^{-1} [10] and $q \cong 85$ kJ mol^{-1} for 1,3-dioxacyclanes, while the activation energy for the ozonolysis of acetals varies in the range 22–35 kJ mol^{-1}.[36]

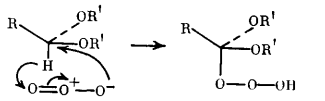
The formation of radicals is a result of the attack by ozone on the C and H atoms in the C–H bond, while the mechanisms $RH + O_3 \rightarrow R\dot{O} + H\dot{O}_2$ [54,55] and $RH + O_3 \rightarrow R\dot{O}_2 + H\dot{O}$ [57,58] are also unlikely, because it is known that this should lead to a high activation energy (above 100 kJ mol^{-1}) and to a high negative entropy of activation. Denisov pointed out[50] that the reaction

$$RH + O_3 \rightarrow R^{\cdot} + HO^{\cdot} + O_2 - q \quad (q = Q_{R-H} - 320 \text{ kJ mol}^{-1} \text{ (Refs.59, 60)})$$

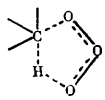
is thermodynamically the most favourable among homolytic reactions. For example, the endothermicity of this reaction for 1,3-dioxacyclanes is only 20 kJ mol^{-1}, which agrees well with the activation energy $E = 22$–35 kJ mol^{-1} [36] (for endothermic reactions, $E > |q|$ [50]). The above analysis shows that the homolytic interaction of ozone with a saturated C–H bond can proceed at the experimentally observed rate at elevated temperatures, provided that the energy of the C–H bond attacked does not exceed 340 kJ mol^{-1}. This is consistent with the finding that, under conditions suitable for a chain reaction, namely [RH] > 5 M and $T > 50$ °C, ozone initiates the chain oxidation of acetals.[32,35] Below 0 °C, the probability of the formation of free radicals as a result of the primary reaction of ozone with acetals is low.

The observed high rates of reaction of ozone with acetals at reduced temperatures (Table 1) indicate the possibility of the concerted and heterolytic reaction mechanisms.

The concerted mechanism involving the 1,3-dipolar insertion of ozone in the C–H bond with formation of an intermediate hydrotrioxide can be represented by the following scheme accordingly to Nagia and Benson:[49]



In the case of a concerted reaction, the insertion of O_3 in the C–H bond takes place tentatively via a five-membered cyclic transition state of the following form:[49]



Calculations have shown that the formation of the cyclic transition state, involving a marked extension of the C–H bond and a considerable change in the O–O–O valence angle in the ozone molecule, leads to a high activation energy (above 100 kJ mol^{-1}) [51] and to a high negative entropy of activation.[50] Consequently the mechanism involving the 1,3-dipolar insertion of ozone is also unlikely.

The primary reaction of ozone with an acetal apparently takes place heterolytically via the transfer of a hydride ion to the O_3 molecule with formation of a close ion pair in a solvent cage, which then recombines to form the hydrotrioxide:[36,49]

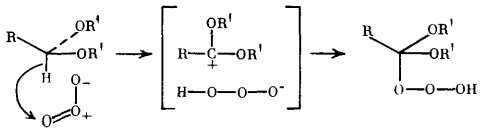


Table 10. The activation parameters for the reactions of ozone with various acetals.

No.	Acetal	Solvent	$\Delta H^{\neq}$, kJ mol^{-1}	$\Delta S^{\neq}$, J mol^{-1} K^{-1}
(XXVIII)	 R=CH_3	CCl_4	22.6±2.9	−141±10
(I)	R=C_6H_5	CCl_4	24.9±0.4	−125±2
(III)		Hexane	34.3±3.5	−106±17
(III)	ditto	C_2H_5OAc	33.2±2.5	−106±12
(LV)	iso-C_3H_7–C(OCH$_3$)(OCH$_3$)–H	C_2H_5OAc	37.4±0.7	−110±3
(VII)	C_6H_{17}–C(OCH$_3$)(OCH$_3$)–H	C_2H_5OAc	35.2±1.6	−121±7

Under these conditions, a partial positive charge is generated on the acetal carbon atom in the transition state. The validity of this hypothesis is confirmed by the results of a study of the reactivity of acetals using the Taft correlation equation (Table 9),[36,40] the study of the influence of the ring size and of the nature of the substituent at the acetal carbon atom on the reactivity of acetals,[18] and the high negative activation entropies $\Delta S^{\neq}$ for the ozonolysis of acetals (Table 10).[36] It is known[52] that the appearance of a pair of charges in the transition state leads to a significant decrease of the entropy and $\Delta S^{\neq}$ can reach −120 J mol^{-1} K^{-1}.[52] The results of Benson's thermochemical calculations[49] support the heterolytic reaction pathway.

Additional data concerning the primary reaction of ozone with acetals have been obtained in a study of the kinetic isotope effect (KIE).[53] Experiments on the reaction of ozone with the deuterio-acetals of acetaldehyde, benzaldehyde, and formaldehyde demonstrate unambiguously that in acetals the attack by ozone is directed to the C–H bond adjoining two heteroatoms (Table 11). Estimation of the absolute values of the KIE and their comparison with the known $\Delta S^{\neq}$ for the corresponding acetals[36] make it possible to infer the degree of charge separation in the transition state. Since the KIE is manifested when the hydride ion has been partially transferred to the ozone molecule in the transition state, its magnitude increases with increase of the degree of transfer and reaches its maximum value ($k_H/k_D \cong 6.9$ at 25 °C [52]) for complete symmetry of the transition state when the C–H bond ruptured and the H–O bond formed have similar strengths.[52] Consequently, the increase of the KIE on passing from formals and linear acetals to cyclic acetals (Table 11), accompanied by a decrease of the corresponding $\Delta S^{\neq}$, indicates an increase in the degree if charge separation in the transition state of the reaction between acetals and ozone.

Table 11. The kinetic isotope effects and entropies of activation in the reactions of ozone with acetals at 20 °C [53] ($v_{O_3} = kc_{ac}c_{O_3}$).

Compound	k, litre mol^{-1} s^{-1}		k_H/k_D	$\Delta S^{\neq}$, J mol^{-1} K^{-1} (X = H)
	X=H	X=D		
	22.8	4.8	4.9	−141
	53.6	12.4	4.3	−125
$CX_3CX(OC_3H_7)_2$	2.0	0.55	3.6	−104
	1.3	0.4	3.0	−94.3
	5.6	1.9	2.9	—
$X_2C(OC_3H_7)_2$	0.60	0.28	2.1	—

Thus analysis of data on the composition of the products of the reactions of ozone with acetals,[20,29,32] the stoichiometry of the reaction,[32,36] and the influence of the nature of the substituents and the structure of the acetals on their reactivity over a wide temperature range (between −78° and 60 °C),[18,40] allowance for the polarity of the medium,[37] and analysis of the activation parameters for the process and of the KIE [36,53] permit the conclusion that the nature of the primary reaction of ozone with acetals is complex. At reduced temperatures the process proceeds via a heterolytic mechanism with transfer of the hydride ion and the formation of an ion pair in a solvent cage: its recombination leads to an intermediate highly unstable hydrotrioxide whose decomposition leads to the formation of the observed reaction products.

Under these conditions (between −70° and 20 °C), the probability of the homolytic reaction pathway is insignificant. With increase of temperature (>20 °C), the fraction of ozone consumed in the formation of free radicals increases, reaching ~40–50% at 50 °C.[32,35]

Thioalkylation Reactions

V.I.Dronov and Yu.E.Nikitin

A systematic account is given of data on thioalkylation reactions—reactions involving the substitution of mobile hydrogen atoms by an alkylthiomethyl (or another alkylthioalkyl) group on treatment with formaldehyde (or other aldehydes) and a thiol.
The bibliography includes 51 references.

CONTENTS

I. Introduction 554
II. Thioalkylation reactions 554

I. INTRODUCTION

The aminomethylation reaction (the Mannich reaction) is widely known and has been described in detail in reviews and monographs.[1-6] It consists of the treatment of certain compounds containing mobile protons (ketones, phenols, various heterocycles, etc.) with formaldehyde and primary or secondary amines (or ammonia) whereby it is possible to introduce the alkylaminomethyl group into such compounds:

$$RH + CH_2O + HN\!\!\!\diagup\!\!\!\diagdown \rightarrow RCH_2N\!\!\!\diagup\!\!\!\diagdown + H_2O .$$

In the course of the investigation of the condensation of ketones with formaldehyde and thiols, we introduced the term "thioalkylation" for this reaction by analogy with the Mannich reaction.[7] We include among thioalkylation reactions all those in which treatment of compounds having mobile protons with formaldehyde (or other aldehydes) and a thiol results in the substitution of these protons by an alkylthiomethyl (or another alkylthioalkyl) group:

$$RH + CH_2O + R'SH \rightarrow RCH_2SR' + H_2O .$$

These reactions are analogues of the Mannich reaction and constitute a special case of the more general thiomethylation reaction [sic (Ed.of Translation)].[8]

A series of such reactions have been described in the literature long before we investigated the thioalkylation of ketones. In this communication we give a systematic account of such reactions and have combined them under a common name (such combination without taking into account the reaction mechanism is to some extent rather formal).

II. THIOALKYLATION REACTIONS

1. Thioalkylation of ammonia and amines

The familiar reaction involving the aminomethylation of thiols can be formally regarded as thioalkylation in which amines or ammonia function as compounds with mobile protons:

$$R_2NH + CH_2O + R'SH \rightarrow R_2NCH_2SR' + H_2O .$$

Since this reaction has been described in the literature only very briefly,[6] we decided to carry out a more detailed survey.

Tris(arylthiomethyl)amines were obtained for the first time[9] by refluxing arenethiols and hexamethylenetetramine in anhydrous dioxan in a nitrogen atmosphere (toluene-α-thiol reacts analogously):

$$(CH_2)_6N_4 + 6RSH \rightarrow 2N(CH_2SR)_3 + 2NH_3 ;$$
$$R=C_6H_5,\ p\text{-}BrC_6H_4,\ p\text{-}O_2NC_6H_4,\ p\text{-}CH_3C_6H_4,\ C_6H_5CH_2 .$$

The attempt to obtain tris(pentylthiomethyl)amines by this procedure was unsuccessful.

Analogous results have been obtained[10] on refluxing (for 15–30 min) arenethiol (or toluene-α-thiol), a 37% solution of formaldehyde, and aqueous ammonia (in molar proportions of 3 : 3 : 1) in alcohols. The reaction with benzenethiol was carried out for 2 h without heating:

$$NH_3 + 3CH_2O + 3RSH \rightarrow N(CH_2SR)_3 + 3H_2O ;$$
$$R=C_6H_5;\quad p\text{-}t\text{-}C_4H_9C_6H_4;\ p\text{-}ClC_6H_4;\ m\text{-}CH_3C_6H_4;\ p\text{-}O_2NC_6H_4;\ 2,4,6\text{-}(CH_3)_3C_6H_2;$$
$$2\text{-}C_{10}H_7;\ C_6H_5CH_2 .$$

The yields of tris(arylthiomethyl)amines were 21.5–80.5%.

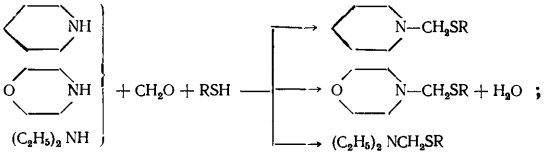
Bis(ethylthiomethyl)amine was synthesised by the reaction of ammonium chloride, a 37% aqueous solution of formaldehyde, and ethanethiol in molar proportions of 3.96 : 9.87 : 6.46 at pH < 6 and subsequent treatment of the reaction mixture with an excess of a dilute solution of sodium hydroxide.[11]

The thioalkylation of amines was first described by McLeod and Robinson.[12] The reaction of diethylamine with 35% aqueous formaldehyde solution and ethanethiol afforded diethyl(ethylthiomethyl)amine in 53% yield:

$$(C_2H_5)_2NH + CH_2O + C_2H_5SH \rightarrow (C_2H_5)_2NCH_2SC_2H_5 + H_2O .$$

Diethyl(isopropylthiomethyl)amine was obtained analogously.

A more detailed study of the thioalkylation of secondary aliphatic amines showed[13] that, in contrast to phenols, the reaction of arenethiols with formaldehyde and secondary aliphatic amines results in the formation of aryl dialkylaminomethyl sulphides and not Mannich bases. Thus a series of aryl piperidinomethyl, aryl morpholinomethyl, or aryl diethylaminomethyl sulphides have been obtained from the corresponding amines, aqueous formaldehyde, and various arenethiols:



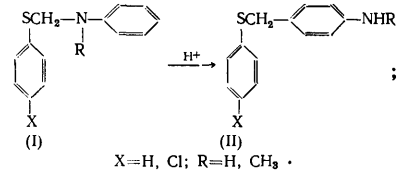
$$R=C_6H_5;\ o\text{-}CH_3C_6H_4;\ m\text{-}CH_3C_6H_4;\ 2\text{-}C_{10}H_7;\ 1\text{-}C_{10}H_7;\ p\text{-}O_2NC_6H_4;\ p\text{-}ClC_6H_4;$$
$$p\text{-}BrC_6H_4;\ 2,5\text{-}Br_2C_6H_3;\ p\text{-}CH_3OC_6H_4;\ 2,4,6\text{-}(CH_3)_3C_6H_2 .$$

The secondary amine was added to an equimolar amount of the arenethiol at a temperature not exceeding 20 °C and the mixture was then treated with an equimolar amount of aqueous formaldehyde (37%), the mixture was heated to 80 °C, and was maintained at this temperature for 2 h. The yields were 22–89% of aryl piperidinomethyl sulphides, 33–96% of aryl morpholinomethyl sulphides, and 31–71% of aryl diethylaminomethyl sulphides.

The thioalkylation of secondary aliphatic amines has been investigated[14] and it has been established that, when a solution of 0.1 mole of an arenethiol, 0.1 mole of aryl methylamine, and 0.10–0.17 mole of a 35–40% aqueous solution of formaldehyde are heated in 20 ml of alcohol at 80 °C for 2 h, *N*-aryl-*N*-methylaminomethyl sulphides are obtained in 66–93% yield:

$$R'NHCH_3 + CH_2O + R^2SH \rightarrow R'(CH_3)NCH_2SR^2 + H_2O;$$
$$R' = C_6H_5;\ R^2 = C_6H_5,\ p\text{-}ClC_6H_4;\ 2,4,6\text{-}(CH_3)_3C_6H_2;\ C_6Cl_5;$$
$$R' = p\text{-}O_2NC_6H_4;\ R^2 = p\text{-}ClC_6H_4;\ R' = p\text{-}CH_3OC_6H_4;\ R^2 = p\text{-}ClC_6H_4.$$

The aryl *N*-arylthiomethyl sulphides (I), obtained by the thioalkylation of aromatic amines in the presence of strong acids, readily rearrange in high yields into the isomeric aryl *p*-aminobenzylsulphides (II):[14]

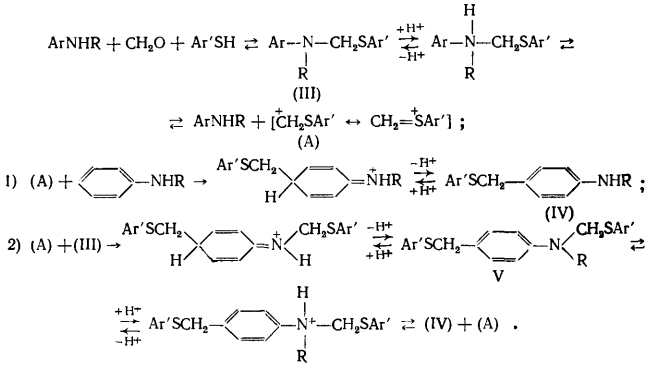


(I) (II)

X=H, Cl; R=H, CH_3.

In order to obtain compound (II), the sulphide (I) is refluxed with an equimolar amount of concentrated hydrochloric acid in 95% alcohol. Under analogous conditions, the sulphides (II) can be obtained in one stage by condensing aromatic amines and thiols with formaldehyde in the presence of strong acids (HCl, HBr, H_2SO_4). The aromatic thiols employed were C_6H_5SH, $p\text{-}ClC_6H_4SH$, $p\text{-}CH_3C_6H_4SH$, $p\text{-}O_2NC_6H_4SH$, and 2,4-$(CH_3)_3C_6H_2SH$, while the aromatic amines were $C_6H_5NH_2$, $2\text{-}C_{10}H_7NH_2$, $m\text{-}ClC_6H_4NH_2$, $p\text{-}CH_3C_6H_4NH_2$, and *N*-methylaniline. The yields of the products were 39–90%.

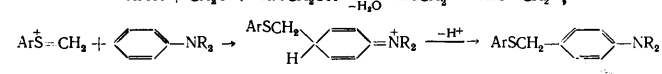
The mechanism of this reaction evidently involves the protonation of aryl *N*-alkyl-*N*-arylaminomethyl sulphide (III) at the nitrogen atom and subsequent decomposition into the initial amine and the resonance-stabilised carbonium-sulphonium ions (A).[16] The latter can then alkylate either the alkylarylamine or the sulphide (III); in the former case *N*-alkyl-*p*-aminobenzyl aryl sulphide(IV) is formed immediately after deprotonation while in the latter the intermediate *N*-alkyl-*N*-arylthiomethyl-*p*-aminobenzyl aryl sulphide (V) is produced and is then converted into the aryl benzyl sulphide (IV) with regeneration of the ion (A):



The second hypothesis is supported by the fact that the intermediate (V) can be isolated in a satisfactory yield when the reaction of *p*-chlorobenzenethiol and formaldehyde with *N*-methylamine is carried out in the presence of concentrated hydrochloric acid at 40 °C; this product is fully converted into the sulphide (IV) on raising the temperature to 80 °C. This mechanism is also confirmed by the finding that the *ortho*-product of the condensation reaction was not obtained even in those cases where the *p*-position in the aromatic amine is occupied (with the exception of the reaction with $2\text{-}C_{10}H_7NH_2$ [15]); it has been noted that the large size of the arylthiomethyl group prevents the entry of the substituent into the *ortho*-position.

Apart from the primary and secondary amines, tertiary aromatic amines also enter into the reaction described above, but the yields of products are then low (15–33%):[16]

The mechanism involving the intermediate formation of arylthiomethanol, whose protonation and subsequent elimination of the water molecule yield a carbonium-sulphonium ion, has been proposed for this reaction. The ion reacts with an arylamine to form aryl *NN*-dialkyl-*p*-aminobenzyl sulphide:[16]



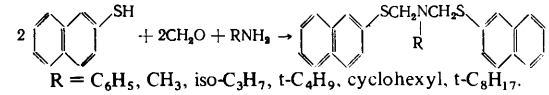
A study of the thioalkylation of primary aromatic amines[14] established that, in contrast to primary aliphatic amines and benzylamines, which usually give rise to a mixture of secondary and tertiary amines via the Mannich reaction, aromatic amines condense with arenethiols and formaldehyde (in molar proportions of 1 : 1 : 1) to form almost exclusively aryl *N*-arylaminomethyl sulphides:

$$RNH_2 + CH_2O + R'SH \rightarrow RNHCH_2SR' + H_2O$$
$$R = C_6H_5;\ R' = C_6H_5;\ p\text{-}ClC_6H_4;\ 2,4,6\text{-}(CH_3)_3C_6H_2;\ R' = p\text{-}ClC_6H_4;$$
$$R\ m\text{-}ClC_6H_4;\ p\text{-}ClC_6H_4;\ p\text{-}CH_3OC_6H_4;\ p\text{-}O_2NC_6H_4.$$

The yields of the reaction products are 16–86%, when the thiol : amine : formaldehyde molar ratios are 2 : 1 : 2, 1,3,5-triaryl-1,5-dithia-2-azapentanes are obtained:

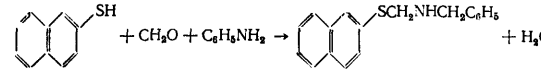
$$RNH_2 + 2CH_2O + 2R'SH \rightarrow R'SCH_2{-}\underset{\displaystyle R}{N}{-}CH_2SR' + 2H_2O;$$
$$R' = C_6H_5,\ R = C_6H_5,\ p\text{-}ClC_6H_4.$$

The thioalkylation of various aliphatic amines with naphthalene-2-thiol and formaldehyde in molar proportions of 1 : 2 : 2 (in ethyl acetate at 25–28 °C for 48 h) leads to analogous results:[17,18]



R = C_6H_5, CH_3, iso-C_3H_7, t-C_4H_9, cyclohexyl, t-C_8H_{17}.

The yields of the reaction products are 55–95%. The condensation of naphthalene-2-thiol, formaldehyde, and benzylamine also yielded benzylaminomethyl-2-naphthyl sulphide:



The following reaction mechanism has been proposed:[18]

$$C_{10}H_7SH \rightleftarrows C_{10}H_7S^- + H^+;$$
$$RNH_2 + CH_2O \rightarrow RNHCH_2OH;$$
$$RNHCH_2OH + H^+ \rightarrow RNHCH_2^+ \leftrightarrow R\overset{+}{N}H{=}CH_2;$$
$$C_{10}H_7S^- + R\overset{+}{N}H{=}CH_2 \rightarrow C_{10}H_7SCH_2NHR;$$
$$C_{10}H_7SCH_2NHR + CH_2O \rightarrow C_{10}H_7SCH_2{-}\underset{\displaystyle R}{N}{-}CH_2OH \text{ etc.} \rightarrow C_{10}H_7SCH_2{-}\underset{\displaystyle R}{N}{-}CH_2SC_{10}H_7.$$

2. Thioalkylation of Hydrogen Halides

The familiar reaction involving the chloromethylation of thiols can be regarded as a thiomethylation reaction in which hydrogen chloride behaves as a compound with a mobile proton:

$$HCl + CH_2O + RSH \rightleftarrows RSCH_2Cl + H_2O.$$

Böhme[19] obtained chloromethyl ethyl sulphide by this reaction for the first time by passing hydrogen chlorides into a mixture of ethanethiol and paraformaldehyde cooled to −15 °C:

$$n\,C_2H_5SH + (CH_2O)_n + n\,HCl \rightleftarrows n\,C_2H_5SCH_2Cl + n\,H_2O.$$

Alkyl and aryl chloromethyl sulphides $RSCH_2Cl$, where R = CH_3,[20,22] C_2H_5,[19,22,26] C_3H_7,[20,22] iso-C_3H_7,[22] n-C_4H_9, iso-C_4H_9, s-C_4H_9, t-C_4H_9, n-C_5H_{11}, s-C_5H_{11},[22,23] C_6H_{13},[22,28] 2-ethylbutyl, 1-methylheptyl,[23] C_8H_{17},[28,29] $C_{12}H_{25}$, $C_{14}H_{20}$,[28] cyclohexyl,[22] C_6H_5, p-ClC_6H_4, or $C_6H_5CH_2$ [20] having different structures were subsequently obtained with the aid of this procedure. The yields of alkyl chloromethyl sulphides are 43–85%.

When paraldehyde was used instead of paraformaldehyde, a series of alkyl and aryl α-chloroethyl sulphides were obtained:

$$3RSH + (CH_3CHO)_3 + 3HCl \rightleftarrows 3RSCHCl + 3H_2O;$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad CH_3$$

R = CH_3 (Refs.20, 21), C_2H_5 (Refs.20–22, 24, 26), t-C_4H_9 (Ref.27), C_6H_5 (Ref.21), iso-C_3H_7 (Refs.22, 24), alkyl (Refs.24, 25), C_4H_9, C_5H_{11} (Refs.22, 24).

The yields of the products are 30–90%.

Other aldehydes have also been used:

$$RSH + R'CHO + HCl \rightleftarrows RSCHCl + H_2O;$$
$$\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\quad R'$$

R = CH_3, R′ = C_6H_5 (Ref.20); R = R′ = C_2H_5 (Ref.21); R = C_2H_5, R′ = n-C_3H_7, iso-C_3H_7, C_6H_5 (Ref.26).

The yields of the α-chloroalkyl sulphides in these syntheses are 40–81%.

In one investigation acetone was used in the thioalkylation of hydrogen chloride instead of an aldehyde and α-chloroisopropyl ethyl sulphide was then obtained in 20% yield:

$$C_2H_5SH + CH_3COCH_3 + HCl \rightleftarrows CH_3C(Cl)SC_2H_5 + H_2O.$$
$$\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\quad CH_3$$

The thioalkylation of hydrogen chloride in a solvent (CH_2Cl_2) using anhydrous calcium or magnesium sulphate to absorb the water formed in the reaction[30] did not result in an increase of the yield of the required product. The yields were 50% of $C_2H_5SCH_2Cl$, 63% of iso-$C_3H_7SCH_2Cl$, and 45% of $CH_3SCH(Cl)CH_3$. In the syntheses by Böhme's method the yields are 43–60% of the first product,[19,20,22,26] 85% of the second product,[22] and 30–59% of the third product.[20,21]

In the thioalkylation of hydrogen chloride in benzene[28,31] the yields of alkyl chloromethyl sulphide are independent of the length of the hydrocarbon group in the thiol and depend mainly on the reaction temperature and the amount of solvent employed. The highest yields (>70%) are reached at 0–10 °C when CH_2O and RSH are employed in molar proportions of 1.2 : 1 (the benzene : thiol ratio is 4.5 : 1).

There has been one study on the thioalkylation of hydrogen bromide[20] in which bromomethyl ethyl sulphide was obtained by Böhme's method in 44% yield.

The data on the mechanism of the thioalkylation of *NN*-dialkylanilines suggest the following most probable mechanism of the thioalkylation of hydrogen halides:

$$RSH + CH_2O \rightleftarrows RSCH_2OH;$$
$$HX \rightleftarrows H^+ + X^-;$$
$$RSCH_2OH + H^+ \rightarrow RSCH_2\overset{+}{O}H_2 \xrightarrow{-H_2O} RSCH_2^+ \leftrightarrow R\overset{+}{S}{=}CH_2;$$
$$RSCH_2^+ + X^- \rightarrow RSCH_2X;$$
$$X = Cl, Br.$$

3. Thioalkylation of Ketones

The thioalkylation of ketones was investigated for the first time by the authors of the present review.[32] It was established[33] that the reaction proceeds readily in the presence of alkalis; calcium carbonate weakly catalyses the reaction, while triethylamine has no catalytic effect. When piperidine is added to a mixture of a ketone, a thiol, and formaldehyde, *N*-alkylthiomethylpiperidine is formed but does not catalyse the reaction. The reaction in the presence of alkalies is exothermic and in many cases reaches completion very rapidly at room temperature. In the remaining instances heating of the mixture to 50 °C is sufficient to complete the reaction.

Aliphatic, cyclic, and aliphatic-aromatic ketones and all thiols other than aromatic thiols enter into the thioalkylation reaction. The methylene group adjoining the carbonyl group in alkyl methyl ketone is the most reactive.

When a fivefold excess of the ketone is treated with equimolar amounts of a thiol, formaldehyde, and sodium hydroxide, mono(alkylthiomethyl)-substituted ketones are obtained:[7,33,34]

$$R^1COCH_2R^2 + CH_2O + R^3SH \rightarrow R'COCH(R^2)CH_2SR^3 + H_2O;$$
$R^1{=}R^2{=}CH_3$; $R^3{=}C_2H_5$; n-C_4H_9; t-C_4H_9; C_8H_{17}, cyclohexyl; $C_6H_5CH_2$; $R^1{=}CH_3$; $R^2{=}C_3H_7$; $R^3{=}C_4H_9$; $R'{=}C_6H_5$, $R^2{=}CH_3$, $R^3{=}C_6H_5$, n-C_4H_9, t-C_4H_9, cyclohexyl; $R^1R^2{=}(CH_2)_4$; R^3-n-C_4H_9; t-C_4H_9; cyclohexyl; $R^1{=}CH_3$; $R^2{=}H$; $R^3{=}C_4H_9$; $R'{=}C_6H_5$; $R^2{=}H$; $R^3{=}C_4H_9$, C_8H_{17}.

The yields of the reaction products are 50.2–100%.

When equimolar amounts of acetone, butanethiol, formaldehyde, and sodium hydroxide interact, 61% of bis(butylthiomethyl)acetone and only 10.5% of mono(butylthiomethyl)acetone are obtained. The reaction involving acetophenone produces analogously under these conditions 64.2% of bis(butylthiomethyl)acetophenone and 25.9% of the mono-(butylthiomethyl) derivative.[35] This can be explained by the fact that the methylene group, which is more reactive than the methyl group, appears next to the carbonyl group in the mono(butylthiomethyl) derivatives formed:

$$CH_3COCH_3 + CH_2O + C_4H_9SH \rightarrow CH_3COCH_2CH_2SC_4H_9 + H_2O;$$
$$CH_3COCH_2CH_2SC_4H_9 + CH_2O + C_4H_9SH \rightarrow CH_3COCH(CH_2SC_4H_9)_2 + H_2O.$$

When ketones were allowed to react with twice the molar amounts of a thiol, formaldehyde, and sodium hydroxide in an aqueous alcoholic medium at 20–50 °C, bis(alkylthiomethyl)-substituted ketones were obtained in 38–93% yields:[33,35]

$$R^1COCH_2R^2 + 2\,CH_2O + 2\,R^3SH \rightarrow R^1COC(R^2)(CH_2SR^3)_2 + 2\,H_2O;$$
$R^1{=}CH_3$; $R^2{=}H$; $R^3{=}C_2H_5$; C_4H_9; $R^1{=}C_6H_5$; $R^2{=}H$; $R^3{=}C_2H_5$; C_4H_9; C_6H_{13}; cyclohexyl; $C_6H_5CH_2$; $R^1R^2{=}(CH_2)_3CH$; $R^3{=}C_4H_9$.

It is noteworthy that the introduction of the first $RSCH_2$ group into the ketone molecule, with the exception of acetone and acetophenone, takes place readily, while the introduction of the second $RSCH_2$ group is difficult. This fact is manifested particularly clearly in the thioalkylation of cyclohexanone with butanethiol. The introduction of the

first $C_4H_9SCH_2$ group into the cyclohexanone molecule proceeds via an exothermic reaction and is completed in 2 h, while the introduction of the second $C_4H_9SCH_2$ group requires prolonged (10 h) heating at 50 °C.[35]

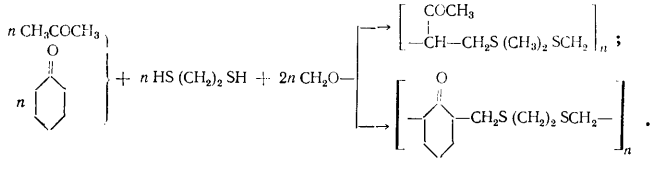
When butanone is thioalkylated with two moles of butanethiol and formaldehyde, 1,3-bis(butylthiomethyl)-2-butanone is obtained, while the reaction with three moles of ethanethiol and formaldehyde gives rise to 1,3,3-tris(ethylthiomethyl)-2-butanone. The third $C_2H_5SCH_2$ group enters the sterically more hindered 3-position rather than the 1-position.[35]

The thioalkylation of acetone by four moles of a thiol, formaldehyde, and sodium hydroxide results in the formation of 1,1,3,3-tetrakis(alkylthiomethyl)-2-propanones:[33]

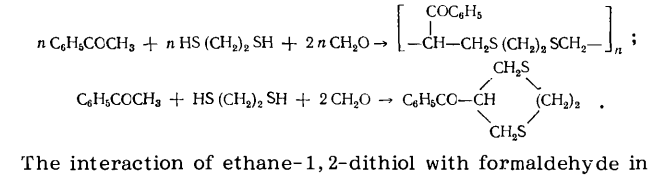
$$CH_3COCH_3 + 4CH_2O + 4RSH \rightarrow (RSCH_2)_2CHCOCH(CH_2SR)_2 + 4H_2O;$$
$$R = C_2H_5;\ C_4H_9;\ C_6H_{11};\ C_{12}H_{25};\quad t\text{-}C_{12}H_{25};\ \text{cyclohexyl},\ C_6H_5CH_2\ .$$

The yields of the required products are 77–93%.

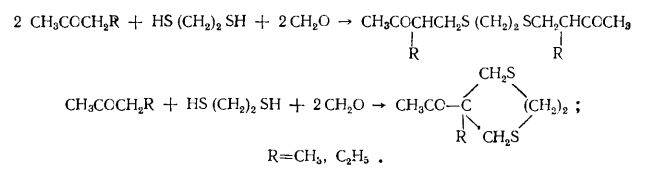
The thioalkylation of ketones by dihydric thiols, particularly by ethane-1,2-dithiol, has been investigated.[36] The condensation of acetone and cyclohexanone with formaldehyde and ethane-1,2-dithiol in molar proportions of 1 : 2 and 4 : 1 in the presence of alkali at room temperature gives rise to polymeric ketobis-sulphides in yields of 92.2 and 94% respectively:



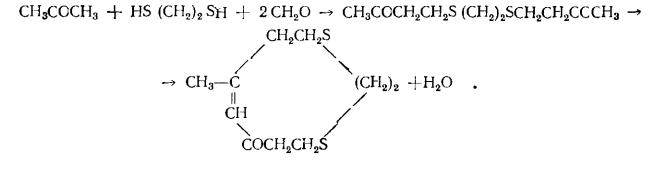
The yield of the polymeric ketobis-sulphides obtained from acetophenone under these conditions is 16.7% and the main reaction product is 6-benzoyl-1,4-dithiacycloheptane (71.4%):[36]



The interaction of ethane-1,2-dithiol with formaldehyde in molar proportions of 1 : 2.4 with a 20-fold excess of butanone or 2-pentanone at 20 °C in the presence of alkali yields 3,10-dimethyl- and 3,10-diethyl-5,8-dithiadodecane-2,11-diones respectively together with small amounts of 6-methyl- and 6-ethyl-6-acetyl-1,4-dithiacycloheptanes respectively:[36]

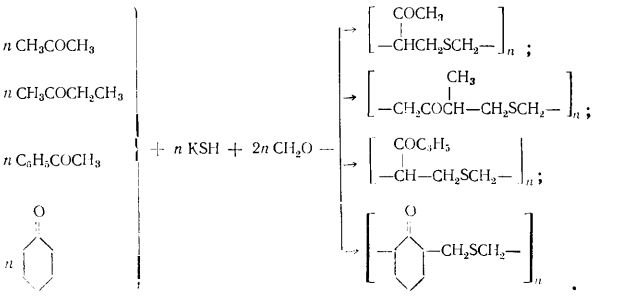


6-Benzoyl-1,4-dithiacycloheptane and 3-methyl-6,9-dithiacycloundec-2-en-1-one are obtained from acetophenone and acetone respectively under analogous conditions:[36]

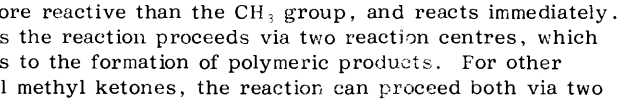


The thioalkylation reaction where hydrogen sulphide is used instead of a thiol can be compared with the Mannich reaction in which ammonia is used instead of an amine. The thioalkylation of ketones by potassium hydrogen sulphide and formaldehyde[37] is close to the thioalkylation of ketones by ethane-1,2-dithiol and formaldehyde as regards the character of the products obtained.[36]

The condensation of acetone, butanone, cyclohexanone, or acetophenone with potassium hydrogen sulphide and formaldehyde in molar proportions of 1 : 2 : 2.2 at room temperature affords polymeric ketosulphides in almost quantitative yields:

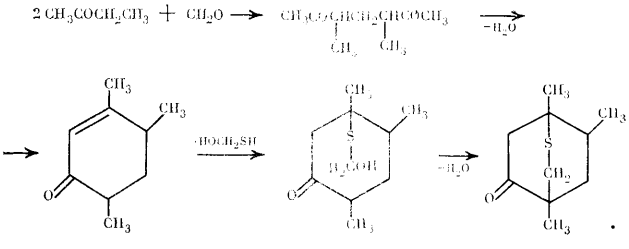


The interaction of butanone, 2-pentanone, or 2-hexanone with potassium hydrogen sulphide and formaldehyde in molar proportions of 2 : 0.5 : 1.23 at room temperature produces respectively 3,7-dimethyl-, 3,7-diethyl-, and 3,7-dipropyl-5-thianonane-2,8-diones in 15–49% yields:



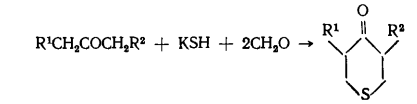
Only polymrtic products are obtained from acetone under these conditions, which can be explained by the fact that, after the substitution of one proton, the methylene group appears in the acetone molecule next to the carbonyl group, is more reactive than the CH_3 group, and reacts immediately. Thus the reaction proceeds via two reaction centres, which leads to the formation of polymeric products. For other alkyl methyl ketones, the reaction can proceed both via two reaction centres and one reaction centre (in the latter case via the most reactive methylene group with formation of 3,7-dialkyl-5-thianonane-2,8-diones).

Together with polymeric products, 1,4,5-trimethyl-7-thiabicyclo[2.2.2]octan-2-one is obtained in 20% yield on condensation of butanone with potassium hydrogen sulphide and formaldehyde in molar proportions of 1 : 0.15 : 0.36 at 50 °C:



The condensation of potassium hydrogen sulphide and formaldehyde with ketones containing two methylene groups with identical reactivities next to the carbonyl group can yield cyclic γ-ketosulphides. Thus a series of 2,6-dialkyl-4-thiacyclohexanones have been obtained in the form of mixtures of *cis*- and *trans*-isomers, with the former predominating slightly, in the course of one month at room temperature or 20–30 h at 50 °C using ketone : potassium

hydrogen sulphide : formaldehyde molar ratios of 1 : 1 : 2 in alcohol:[33]



$R^1=R^2=C_2H_5$; C_3H_7; C_4H_9; C_7H_{15}; $R^1=C_6H_5$, $R^2=CH_3$.

The yields of the cyclic γ-ketosulphides are 23–72.5%.

Amino-derivatives of ketosulphides have been obtained by the condensation of ketones with formaldehyde and aminothiols in the presence of sodium hydroxide.[33] A series of mono(dialkylaminoethylthiomethyl)-substituted ketones have been obtained from equimolar amounts of *N*-(2-mercaptoethyl)-amines, formaldehyde, and sodium hydroxide with a fivefold excess of the ketone:

$$RCOCH_2R^1 + HSCH_2CH_2NR_2^2 + CH_2O \rightarrow RCOCH(R^1)CH_2SCH_2CH_2NR_2^2 ;$$

$RR^1=(CH_2)_4$; $R_2^2=(CH_2)_5$; $R=C_6H_5$; $R^1=CH_3$; $R_2^2=(C_2H_5)_2$; $(CH_2)_5$; $(CH_2)_2O(CH_2)_2$.

The reaction of acetophenone with twice the molar amounts of *N*-(2-mercaptoethyl)amine, formaldehyde, and sodium hydroxide gave rise to a series of bis(dialkylaminoethylthiomethyl)-substituted ketones:

$$C_6H_5COCH_3 + 2HSCH_2CH_2NR_2 + 2CH_2O \rightarrow C_6H_5COCH(CH_2SCH_2CH_2NR_2)_2 ;$$

$R_2=(C_2H_5)_2$; $(CH_2)_5$; $(CH_2)_2O(CH_2)_2$.

Tetrakis(dialkylaminoethylthiomethyl)-substituted ketones have been synthesised from acetone with four molar amounts of *N*-(2-mercaptoethyl)amine, formaldehyde, and sodium hydroxide:

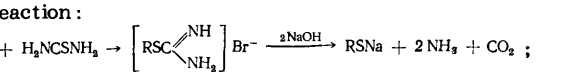
$$CH_3COCH_3 + 4HSCH_2CH_2NR_2 + 4CH_2O \rightarrow$$
$$\rightarrow (R_2NCH_2CH_2SCH_2)_2CHCOCH(CH_2SCH_2CH_2NR_2)_2 ;$$
$$R_2=(C_2H_5)_2, (CH_2)_5 .$$

3-Ethylthiomethyl-2-butanone has been obtained[38] in 80% yield by thioalkylating butanone with ethanethiol using the method which we have described:

$$CH_3COCH_2CH_3 + C_2H_5SH + CH_2O \rightarrow CH_3COCH(CH_3)CH_2SC_2H_5 + H_2O .$$

The vacuum distillation of the reaction products led to the isolation of high-molecular-weight fractions of the hydroxymethyl derivative of 3-ethylthiomethyl-2-butanone in 80% yield, but the position of the hydroxymethyl group in this compound was not established.

In the thioalkylation of ketones, Babakhanova et al.[39] used as a thiol component alkaline solution of *S*-alkylisothiuronium salts, which were obtained by the reaction of alkyl bromides with thiourea. They established that the side products resulting from the alkaline decomposition of *S*-alkylisothiuronium salts do not affect the yield of the ketosulphides, which amount to 80–90% relative to the alkyl bromides used in the reaction:



$$RSNa + CH_3COCH_2CH_3 + CH_2O \rightarrow CH_3COCH(CH_3)CH_2SR ;$$
$$R=C_2H_5, C_3H_7, C_4H_9 .$$

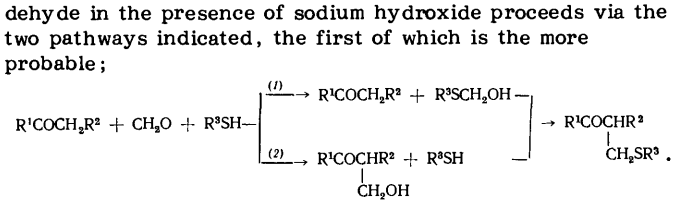
Ketosulphides have been obtained by the condensation of ketones, 1,3-diketones, or β-ketoacids esters with thiols and aldehydes in THF at 70 °C in the course of 5 h in the presence of catalytic amounts of concentrated sulphuric acid:[40]

$$RCOCH_2R^1 + R^2CHO + R^3SH \xrightarrow{H^+} RCOCH(R^1)CH(R^2)SR^3 + H_2O ;$$

$R=CH_3$; $R^1=CH_3CO$; $R^2=R^3=C_2H_5$; $RR^1=(CH_2)_4$; $R^2=H$; $R^3=C_2H_5$; C_6H_5; $RR^1=(CH_2)_5$; $(CH_2)_3$; $R^2=H$; $R^3=C_3H_5$; $R=CH_3$, $R^1=CH_3CO$; C_3H_5CO; $COOC_2H_5$; $R^2=H$; $R^3=C_3H_5$; $R=C_6H_5$; $R^1=COOC_2H_5$; $R^2=H$; $R^3=C_6H_5$.

The yields of the ketosulphides amount to 31–92%.

It has been established experimentally[33] that the reaction involving the thioalkylation of ketones by thiols and formaldehyde in the presence of sodium hydroxide proceeds via the two pathways indicated, the first of which is the more probable;



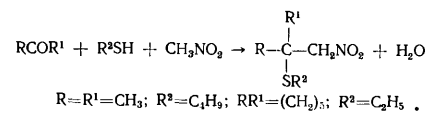
The condensation of ketones with thiols and aldehydes in the presence of strong acids[40] apparently proceeds via the formation of a carbonium-sulphonium ion as an intermediate. Thus the mechanism of this reaction is analogous to that of the Mannich reaction.[6]

4. Thioalkylation of Nitroalkanes

When a mixture of propanol, toluene-α-thiol, and nitromethane was heated at 100 °C for 30 min in the presence of catalytic amounts of piperidine, 2-(benzylthio)nitrobutane was obtained in 76% yield; 2-(benzylthio)-2-phenylnitroethane has been obtained analogously from benzaldehyde (4 h, 100 °C, yield 53%; 20 days, approximately 20 °C, yield 64%):[41]

$$RCHO + R'SH + CH_3NO_2 \rightarrow RCH(SR')CH_2NO_2 + H_2O ;$$
$$R=C_2H_5, C_6H_5, R'=C_6H_5CH_2 .$$

Ketones have also been used in this reaction instead of aldehydes, but they proved to be less reactive. On refluxing in the presence of piperidine (for 24 h), 1-(ethylthio)-1-nitromethylcyclohexane has been obtained in 50% yield from cyclohexanone, ethanethiol, and nitromethane, while 2-(butylthio)-2-methylnitropropane has been synthesised in 58% yield from acetone, butanethiol, and nitromethane:

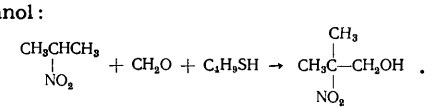


$R=R^1=CH_3$; $R^2=C_4H_9$; $RR^1=(CH_2)_5$; $R^2=C_2H_5$.

It has been suggested[41] that the condensation of nitroalkanes with aldehydes or ketones proceeds via the intermediate formation of nitro-olefins to which thiols then add:

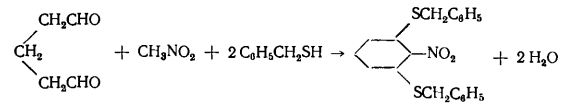
$$RCHO + CH_3NO_2 \rightarrow RCH(OH)CH_2NO_2 \xrightarrow{-H_2O} RCH=CHNO_2 \rightarrow$$
$$\xrightarrow{R'SH} RCH(SR')CH_2NO_2 .$$

The interaction of 2-nitropropane, formaldehyde, and butanethiol in the presence of piperidine yields 2-methyl-2-nitropropanol:

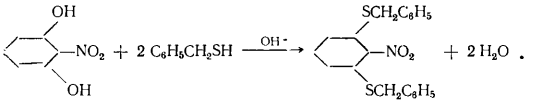


The latter is not dehydrated with formation of a nitro-olefin and the thioalkylation reaction does not take place. The behaviour of other nitroalkanes in this reaction has not so far been investigated.

1,3-Bis(benzylthio)-2-nitrocyclohexane has been obtained from glutaraldehyde, nitromethane, and toluene-α-thiol in the presence of sodium hydroxide:[42]



The same product is obtained under analogous conditions from toluene-α-thiol and 2-nitrocyclohexane-1,3-diol:



The latter is apparently an intermediate in the reaction described above.

Thus the condensation of nitromethane with thiols and aldehydes (or ketones) results in the substitution of the mobile proton of nitromethane by the thioalkyl group and the reaction can be formally classified as a thioalkylation reaction although the mechanism is different from that of other such reactions.

5. Thioalkylation of 1,3-Disulphones

The thioalkylation of sulphones was first investigated by the authors of the present review.[43] Benzyl phenyl sulphone, bis(phenylsulphonyl)methane, and bis(butylsulphonyl)-methane were used as the sulphones, whilst the thiols were butanethiol, 2-methylpropane-2-thiol, cyclohexanethiol, and benzenethiol. It was established that the above sulphones and thiols can be arranged in the following sequences in terms of their reactivity in the thioalkylation reaction:

$$(C_6H_5SO_2)_2CH_2 > (C_4H_9SO_2)_2CH_2 > C_6H_5SO_2CH_2C_6H_5 ;$$
$$t\text{-}C_4H_9SH > \text{cyclo-}C_6H_{11}SH > C_4H_9SH > C_6H_5SH .$$

The sulphone thioalkylation products have been obtained in 9–93% yields from equimolar amounts of the sulphone, the thiol, a 34% aqueous solution of formaldehyde, and sodium hydroxide in alcoholic solution with heating (to 50–55 °C; 78 °C in the case of benzyl phenyl sulphone) until the qualitative test for the thiol was negative (c.f. Houben-Weyl[44]):

$$RSO_2CH_2R^1 + R^2SH + CH_2O \rightarrow RSO_2CH(R^1)CH_2SR^2 + H_2O ;$$
$$R = C_6H_5;\ R^1 = SO_2C_6H_5;\ R^2 = C_4H_9;\ \text{cyclohexyl};\ C_6H_5;$$
$$R = C_4H_9;\ R^1 = SO_2C_4H_9;\ R^2 = C_4H_9;\ \text{cyclohexyl};$$
$$R = R^1 = C_6H_5;\ R^2 = C_4H_9;\quad t\text{-}C_4H_9;\ \text{cyclohexyl} .$$

The thioalkylation of 1,3-disulphones with formaldehyde and potassium hydrogen sulphide has also been investigated.[45] The reaction was carried out in a mixture of dioxan and methanol at room temperature using the molar ratios 1 : 3-disulphone : KSH : CH_2O = 2 : 1 : 2. 1,1,5-5-Tetrakis-(butanesulphonyl)-3-thiapentane, 1,1,5,5-tetrakis(cyclo-hexanesulphonyl)-3-thiapentane, 1,1,5,5,-tetrakis(benzene-sulphonyl)-3-thiapentane, and 1,2,6,7-tetrakis(benzene-sulphonyl)-4-thiaheptane have been obtained from bis(butanesulphonyl)methane, bis(cyclohexanesulphonyl)-methane, bis(benzenesulphonyl)methane, and 1,2-bis-(benzenesulphonyl)ethane respectively:

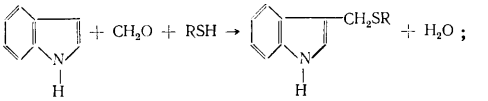
$$2(RSO_2)_2CH_2 + 2CH_2O + KSH \rightarrow (RSO_2)_2CHCH_2SCH_2CH(SO_2R)_2 ;$$
$$R = C_4H_9;\ \text{cyclohexyl};\ C_6H_5 ;$$
$$2C_6H_5SO_2CH_2CH_2SO_2C_6H_5 + 2CH_2O + KSH \rightarrow$$
$$\rightarrow C_6H_5CH_2\underset{\displaystyle SO_2C_6H_5}{\underset{|}{C}}HCH_2SCH_2\underset{\displaystyle SO_2C_6H_5}{\underset{|}{C}}HCH_2SO_2C_6H_5 .$$

The yields of the reaction products are 30–50%.

6. Thioalkylation of Other Compounds

It has been established[46] that the thioalkylation of indole, antipyrine, and 2-naphthol proceeds satisfactorily under conditions very similar to those necessary for the optimum yields of Mannich bases. The weak bases, namely indole and antipyrine, are thioalkylated in weakly acid media, while the weakly acidic 2-naphthol is thioalkylated only in a basic medium.

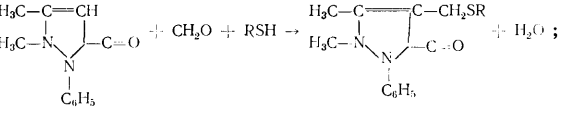
Thus the condensation of indole, a 40% aqueous solution of formaldehyde, and alkanethiols (or toluene-α-thiol) in aqueous acetic acid in the course of six days at room temperature gives rise to the corresponding 3-(alkylthiomethyl)indoles:



R = C_2H_5; C_3H_7; C_4H_9; $C_6H_5CH_2$.

The yields of the products of the reactions of alkane thiols are approximately 25%, while the reaction of toluene-α-thiol gives rise to 14% of the product; under these conditions, benzenethiol does not react.

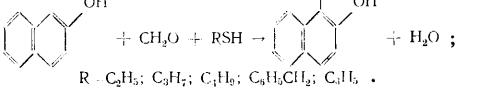
The thiolalkylation of antipyrine with paraformaldehyde and thiols in aqueous acetic acid takes place at 100 °C in the course of 23–47 h, the corresponding 4-(alkylthiomethyl)-antipyrines being obtained:



R = C_2H_5; C_3H_7; C_4H_9; $C_6H_5CH_2$; C_6H_5 .

In the reactions involving benzenethiol and toluene-α-thiol the yields of products are approximately 80%, while in the reactions of propane- and butane-thiols they are 42 and 62% respectively. Owing to its low boiling point, ethanethiol does not react satisfactorily under these conditions. 4-(Ethyl-thiomethyl)antipyrine has been obtained in 17% yield on condensing ethanediol, a 40% aqueous solution of formalde-hyde, and antipyrine in aqueous acetic acid at room tempera-ture for 14 days.

The corresponding 1-alkylthiomethyl-2-naphthols have been obtained from 2-naphthol, a 40% aqueous solution of formaldehyde, and thiols in alcohol in the presence of tri-ethylamine (6 days at room temperature):



R = C_2H_5; C_3H_7; C_4H_9; $C_6H_5CH_2$; C_6H_5 .

The yields of the condensation products are 76–79%. On decrease of the reaction time to three days, the yields are halved.

It is believed[46] that the first stage of the reaction which they investigated involves the addition of the thiols to formaldehyde with formation of alkylthiomethanols, which then react with indole, antipyrine, or 2-naphthol. This has been demonstrated by the fact that the reactions of phenyl-thiomethanol with antipyrine give rise to 4-(phenylthio-methyl)antipyrine, while the reaction of ethylthiomethanol and 2-naphthol gives rise to 1-ethylthiomethyl-2-naphthol in approximately the same yield as in the reactions of anti-pyrine or 2-naphthol with a thiol and formaldehyde. The authors do not rule out the possibility of an alternative mechanism involving the addition of indole, antipyrine, or 2-naphthol to formaldehyde with subsequent interaction of the resulting hydroxymethyl derivatives with the thiols, but they do not state that this mechanism has been confirmed experimentally.

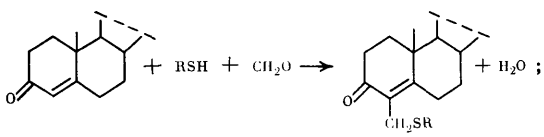
Certain compounds containing in the molecule a double bond conjugated with the carbon group, namely CO–CH=X (X = C or N), undergo the thioalkylation reaction. Thus it has been established[47] that treatment of α-ketoaldehyde ω-monoarylhydrazones with thiols and formaldehyde in acetic acid in an atmosphere of nitrogen results in the substitution of the proton in the α-position relative to the carbonyl group:

$$RCOCH{=}N{-}NHAr + R'SH + CH_2O \rightarrow \underset{\displaystyle CH_2SR'}{RCOC{=}N{-}NHAr} + H_2O;$$

R=R′=C_6H_5; Ar=C_6H_5; *p*-ClC_6H_4; *m*-ClC_6H_4; *m*-$O_2NC_6H_4$; R=CH_3; R′=CH_2CO_2H; Ar=C_6H_5.

The yields of the reaction products are 20–50%. It is believed[47] that the reaction proceeds via the intermediate formation of hemimercaptals.

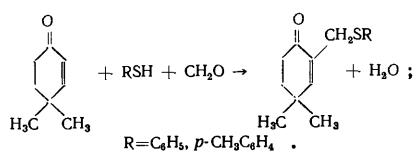
When a mixture of a 3-oxo-Δ^4-steroid, a thiol, aqueous formaldehyde (40%), triethylamine, and alcohol in proportions of 5 : 4 : 3 : 3 : 10–30 by weight (depending on the solubility of the steroid) is heated (60 °C, 30–50 h), 4-alkylthiomethyl-3-oxo-Δ^4-steroids are obtained in a satisfactory yield:[48,49]



R=C_2H_5; C_4H_9; C_6H_{11}; $C_6H_5CH_2$; C_6H_5, *p*-$CH_3C_6H_4$, furfuryl, CH_2CH_2OH; $(CH_2)_2CO_2CH_3$.

When triethanolamine is used as the catalyst and solvent and the mixture is heated to 110–150 °C, the reaction time is reduced to 8–16 h. Paraformaldehyde can be used in this reaction instead of aqueous formaldehyde and triethylamine can be replaced by other tertiary amines: trimethylamine, tri(n-propyl)amine, and *N*-methylpiperidine.

The corresponding 2-(alkylthiomethyl)substituted products are obtained in 70–72% yields by an analogous method on heating in alcohol a mixture of 4,4-dimethylcyclohex-2-en-1-one, a thiol, a 37% aqueous formaldehyde solution, and triethylamine in molar proportions of 1 : 1.5 : 1.6 : 1.4:[50]



R=C_6H_5, *p*-$CH_3C_6H_4$.

---o0o---

It follows from the foregoing that the thioalkylation reactions have been little investigated. The thioalkylation of amines, hydrogen chloride, and ketones has been most thoroughly investigated hitherto, but only isolated studies have been made of the thioalkylation of other compounds.

With the exception of the thioalkylation of amines, the mechanisms of other reactions have also been little studied. All the reactions described in this review, apart from the thioalkylation of nitroalkanes, apparently proceed via a similar mechanism. The thioalkylation of nitroalkanes takes place via the intermediate formation of nitroalkenes with subsequent addition of thiols to the latter. The thioalkylation of primary and secondary amines proceeds via the mechanism of the Mannich reaction:[6] via the intermediate formation of aminomethanols $>N{-}CH_2OH$ in alkaline media or carbonium-immonium ions $>N{-}CH_2^+ \leftrightarrow >\overset{+}{N}{=}CH_2$ in acid media.

The mechanism of the thioalkylation of *NN*-dialkylanilines, ketones, indole, antipyrine, 2-naphthol, α-ketoaldehyde ω-monoarylhydrazones, and hydrogen halides is apparently analogous to the mechanism of the Mannich reaction (it involves the intermediate formation of the thiomethanols $RSCH_2OH$ in alkaline media and the carbonium-sulphonium ions $RSCH_2^+ \leftrightarrow R\overset{+}{S}{=}CH_2$ in acid media). However, one should not assume that all the compounds undergoing the Mannich reaction undergo thioalkylation or conversely. These reactions have their own specific features. For example, phenol readily undergoes the Mannich reaction but does not undergo the thioalkylation reaction. Conversely, bis(benzenesulphonyl)methane readily undergoes thioalkylation but does not produce Mannich bases.[51]

The Solid-phase Polymerisation of Monomers with Conjugated Acetylenic Groups

V.M.Misin and M.I.Cherkashin

Published data on the solid-phase topochemical polymerisation of linear and cyclic monomers containing conjugated acetylenic groups are surveyed and the boundary conditions in this process are discussed. The structure of the monomers, is the intramolecular and supermolecular structures of the polymers, and the specific features of their chemical, physicochemical, physicomechanical, and optical properties are examined.
The bibliography includes 300 references.

I. INTRODUCTION

Fundamental synthetic studies on the solid-phase polymerisation of diacetylenic monomers containing the $-(C\equiv C)_2-$ (DA) groups were published a fairly long time ago.[1-5] At the present time such investigations have undergone a considerable development in connection with the discovery of a series of unique properties in the polymeric single crystals obtained by this procedure: thermochromism, high mechanical strength, non-linear optical properties, and a considerable anisotropy of the mechanical, optical, electrophysical, etc. properties. The available reviews on this subject, including those which were published during the preparation of this report, are devoted mainly to problems of the kinetics and mechanism of the polymerisation of DA and the magnetic, spectroscopic, and electrophysical properties of polydiacetylenes (PDA).[6-9]

In the present review attention has been concentrated on the characteristics of the structure, crystal chemistry, and morphology of the initial crystalline monomers having the general formula $R-(C\equiv C)_n-R$ ($n = 2-4$) and the corresponding polymers, the characteristic features of the mechanical and chemical properties of the polymeric crystals, and the specific features of the synthesis of soluble polydiacetylenes and DA copolymers. In addition, the reactions of various compounds containing separated $-(C\equiv C)_2-$ groups are considered. In writing this review, the authors endeavoured to cover fairly fully the available literature, reflecting at the same time the chronology of the varying and sometimes contradictory points of view on certain aspects of the solid-phase topochemical polymerisation (TPM) of acetylenes and the properties of the resulting products.

It must be emphasised that by the term topochemical polymerisation we understand a process which consists in a direct transition from the molecules of the crystalline monomer to crystallised polymer chains with retention of the crystallographic centre of gravity and symmetry of the monomeric units. The crystal lattice of the monomer is not disrupted in this process and non-crystalline intermediates are not produced. In the course of the polymerisation of such monomers, a solid solution of polymer chains in the monomer matrix is formed, i.e. the polymerisation is homogeneous.[10-12]

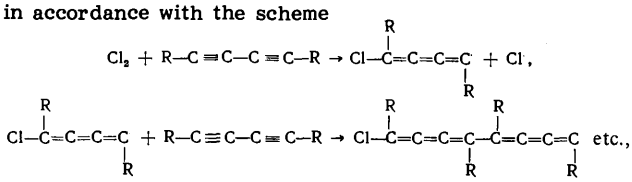
Instances of the breakdown of the crystal lattice with a corresponding change in the monomer polymerisation process are observed in real DA–PDA systems and special attention will be devoted to this aspect.

II. THE SOLID-PHASE POLYMERISATION OF LINEAR SYMMETRICAL DIACETYLENIC MONOMERS

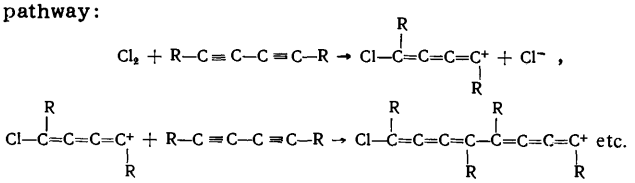
1. General Information

The acquisition of green, red, blue, or other colours by certain solid derivatives of diacetylene, for example, diols and mono- and di-carboxylic acids with a metallic lustre, which has been observed in early investigations[13-15] on illumination or heating, was subsequently interpreted as the topochemical polymerisation of these compounds.[14-16] A study of the infrared spectra of the polymers of deca-4,6-diyne-1,10-diol and its bisnaphthylurethane, the study of the electronic absorption and fluorescence spectra of the hexa-2,4-diyne-1,6-dicarboxylic acid polymer, and the detection of phthalic acid in the products of the decarboxylation and oxidation of this polymer by chromic acid (the material balance of the reaction products has not been published)[17,18] suggested[16-18] that parallel diyne molecules are converted into a polyacene macromolecule. The impossibility of the polymerisation of diynes in solution and in the melt has been explained by the absence of this type of seed outside the crystal.[14,16] Without taking into account the character of the substituents in the DA, this view was in fact reflected in the early reviews.[19-21] Subsequently the above concept was revised. Wegner[1-5] showed that the solid-phase polymerisation of DA (photochemical, radiation-induced, and mechanically initiated or thermopolymerisation at a temperature below the melting point), which proceeds in accordance with the laws of a topochemical reaction, leads to the formation of conjugated linear but not acene polymers. The polymerisation then proceeds only in those DA where the substituents contain groups capable of forming hydrogen bonds or of dipole–dipole interaction.[1,2] The attempts to polymerise such monomers in the liquid phase frequently fail. It has been shown[22] that the polymerisation of DA can be initiated by chemical initiators—gases capable

of forming radicals on the surface or in the bulk of the crystals (Cl_2, Br_2, O_3, NO_2, NOCl, PF_3, or I_2), for example, in accordance with the scheme



although the authors do not rule out an alternative reaction pathway:



Numerous symmetrical conjugated DA of different classes, examples of which are presented in Table 1, have been investigated as the monomers. However, the vast majority of the kinetic studies as well as the investigations of the structures and physicochemical and electrophysical properties of PDA have been carried out on the basis of a fairly limited range of symmetrically substituted monomers with R = CH_2OH (HD), $CH_2OC(O)NHC_6H_5$ (HDDU), $CH_2OSO_2C_6H_4.CH_3$-*p* (TS), CH_3-*N*-carbazolyl (DCHD), and $(CH_2)_nOC(O)NHCH_2C(O)O(CH_2)_mCH_3$, where $m = 1$ and $n = 3$ (3ECMU), $m = 3$ and $n = 3$ (3BCMU), $m = 1$ and $n = 4$ (4ECMU), and $m = 3$ and $n = 4$ (4BCMU), as well as a cyclic DA:

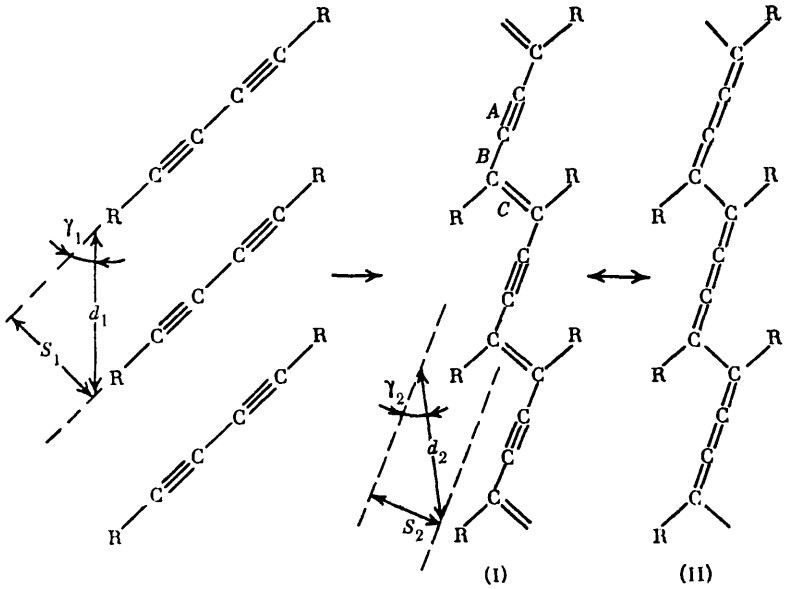

Figure 1. Schematic illustration of the solid-phase polymerisation of monomers with the $-C\equiv C-C\equiv C-$ groups: (I) and (II) are respectively the enyne and butatriene mesomeric forms of the polymer chains; the parameters d, S, and γ describe the topology of the monomer molecules and the polymer chain; B, C, and A are the length of single, double, and triple bonds.[9]

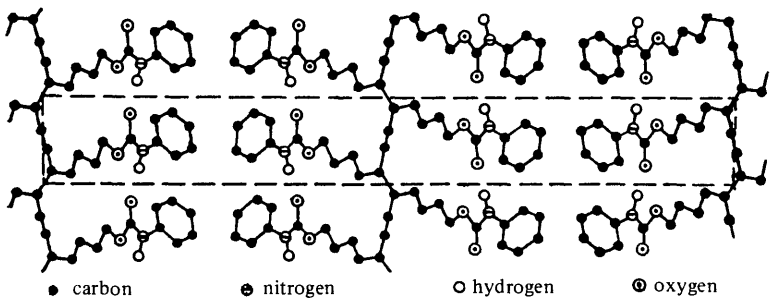

Figure 2. Schematic illustration of the packing of DA [R = $(CH_2)_4OCONHC_6H_5$] in the crystallographic cell. Projection on to the *bc* plane.[81]

Various specially synthesised deuterio-derivatives of TS have been used in the study of the isotope effects in the polymerisation of this DA.[79,80]

2. The Essential Conditions in the Polymerisation of Diacetylenes

The requirements which must be met by the DA polymerising via the TPM mechanism have been discussed in a review.[9] In the present communication the factual data on which these requirements are based have been extended. The changes occurring in the monomer–polymer transition, in conformity with the principles of a topochemical polymerisation of DA, are illustrated in Fig.1. The polymerisation reaction involves the 1,4-*trans*-addition and proceeds via specific rotations of the monomer units about the centres of gravity and via shifts of the centres of gravity. It is determined by the characteristic features of the packing of the monomer in the crystal lattice and proceeds without the evolution of side products and with formation of polymer chains extended parallel to the crystallographic *b* direction (Fig.2).[81]

The absence of the polymerisation of DA molecules in solution and in the melt has in fact been explained by the disordered nature of its molecules.[1,37] However, the presence of polar or interacting (Fig.2) side groups is not a sufficient condition for the occurrence of solid-phase polymerisation, since certain types of substituent hinder it. Indeed, diphenylbutadiyne (DPB) does not polymerise in the

solid phase, since large shifts and rotations of the molecules are required for this purpose.[5,27,28,81] All the symmetrical diamino-derivatives of DPB are also inactive. Nitro-, phenylureido-, acetamido-, or benzamido-groups in the 4- and 4'-positions in DPB hinder the topochemical polymerisation, while those in the 2- and 2'-positions and particularly 3- and 3'-positions of the corresponding DA promote it.[5]

In a series of DA with the substituents R = $CH_2OC(O).(CH_2)_nCH_3$ (n = 4, 6, 8, 10, 12, 14, 16), the rate of polymerisation increases with increasing length of the paraffinic side group, reaching a maximum for n = 8 and then falling owing to the characteristics of the packing of the paraffinic side chains in each member of the series considered.[63]

The presence of α-substituents at the $-(C\equiv C)_2-$ group gives rise to steric hindrance in topochemical polymerisation. Diyne monomers with the substituents R = $CH(CH_3)OC(O).NHC_6H_5$ or $C(CH_3)_2OC(O)NHC_4H_9$ do not therefore polymerise, in contrast to the extremely reactive monomers with the substituents R = $CH_2OC(O)NHC_6H_5$ or $CH_2OC(O)NHC_4H_9$.[1,2,4,23,25]

In view of the need to create a suitable crystal structure in the solid monomer, the polymorphism of the DA assumes a special importance. Thus HDDU, recrystallised from various solvents or their mixtures, has several different crystalline modifications among which only one exhibits a high reactivity.[1,10,82,83] This is caused by the fact that only the monomer recrystallised from a dioxan–water mixture has the necessary packing as a result of the presence of dioxan molecules in the centre of the unit cell forming hydrogen-bonded chains with other neighbouring DA molecules.[84] When dioxan is removed by evacuating the specimens, the monomer loses its reactivity.[84]

Polymerised DA with R = $CH_2OCONHC_6H_4CH_3$-m can be obtained in the form of "orange" and "blue" modifications, whose colour is associated with a small admixture of PDA. After being kept in dioxan vapour, the "orange" modification undergoes a "solvatochromic" solid-phase transition to the more reactive "blue" phase, which is accompanied by an increase of the size of the crystals in one of the directions by ~25%. This is associated with the insertion of dioxan in the single crystal, the formation of hydrogen bonds, and the assumption of a planar conformation by the PDA formed. Extraction of the non-polymerised monomer from the "blue" modification (λ_{max} = 650 nm) leads to the appearance of a red residue (λ_{max} = 550 nm) as a result of the reverse process: the removal of strain from the crystal and the transition of the monomer to a non-planar conformation having different electronic structures.[85]

After being kept in the vapours of polar solvents, the inactive modifications of other urethane DA are also able to undergo a transition into reactive modifications. The transition is accompanied by the appearance of an intense colour associated with the formation of polymer chains in the crystal matrix of the DA and depending on both the structure of the DA and on the type of solvent.[85]

A strong influence of the substituents on the capacity for polymerisation, associated with the packing of the monomer, has been observed also in a series of symmetrical DA (III):

$$RC_6H_4SO_2OCH_2C\equiv C-C\equiv CCH_2OSO_2C_6H_4R \quad \text{(III)}$$

R = H, m-CF_3, p-CH_3, p-OCH_3, p-F, p-Cl, p-Br.

Thus the p-bromo-,[46,47] p-fluoro-,[46] and p-chloro-derivatives of compound (III)[46,47,86] are inactive in solid-phase polymerisation. X-Ray diffraction studies have shown that the lack of reactivity of the chloro-derivative is associated with the unsuitable packing of the monomer.[86] However, a crystalline modification of the p-fluoro-substituted sulphonate, less reactive than TS, has been found.[47] Reactive modifications of compound (III) with R = p-Cl or p-Br, whose melting points are ~50° lower than those of the corresponding inactive forms, have been obtained by crystallisation from a highly supersaturated ethereal solution†. The diacetylenes (III) with R = H, p-OCH_3, or m-CF_3 polymerise in the solid phase and the p-methoxy-derivatives can be obtained in both reactive and inactive forms.[46,47] According to X-ray diffraction studies,[46,47] the side groups in the inactive form rotate above the –O– bond, so that the distance between neighbouring molecules is much greater than that necessary for solid-phase polymerisation. TS (R = p-CH_3) is the most reactive.

The influence of not only the nature of the substituent in the side groups of DA but also of its isotopic composition on reactivity in TPM has been observed. Thus the infrared spectroscopic and differential scanning calorimetric (DSC) studies of the kinetics of the thermal topochemical polymerisation of a series of TS derivatives revealed a decrease of the rate of the autocatalytic stage in a series of DA with different substituents, i.e.

$$CH_2OSO_2C_6H_4CH_3\text{-}p > CH_2OSO_2C_6H_4CD_3\text{-}p > {}^{13}CH_2OSO_2C_6H_4CH_3\text{-}p > CD_2OSO_2C_6D_4CD_3\text{-}p > CD_2OSO_2C_6H_4CH_3\text{-}p,$$

while E_a remained unchanged. During the induction period, the opposite isotope effect was observed. The difference between the rates of reaction has been explained by the variation of the pre-exponential factor for the rate constant, which is attributed to the different lifetimes of the excited state responsible for the chain initiation.[79,80] A decrease of the rate of reaction has also been observed for DA with other substituents: $CH_2OCONHC_6H_5 > CD_2OCONHC_6H_5$.[79]

In order to determine the reactivities of crystallised DA, it is necessary to take into account the contribution of the strain energy of the crystal and the change in chemical energy in the monomer–polymer transition. An estimate of the free energy barrier to molecular movement, required for topochemical polymerisation, is essential in determining the contribution of the energy of the crystal. However, the exact determination of the magnitude of this barrier is very difficult. Allowance for the limitations examined above, arising in the solid-phase polymerisation of DA, led to the development of the principle of the minimum mean square atomic displacement (MMAD) necessary for polymerisation,[81,87] which makes it possible to predict the possibility of the topochemical polymerisation of both different DA and their different crystalline modifications. Parameters most suitable for the description of the topology of the reacting monomer molecules and the resulting polymer chain were selected for this purpose. Such parameters are the vector d_1 and the angle γ_1 in the monomer and the vector d_2 and the angle γ_2 in the polymer, linked by the relation $a = S/\sin\gamma$ (Fig.1). The values of d_1 and γ_1 have been determined for a large number of monomers (Table 2) and have been found to vary in the ranges d_1 = 4.1–8.5 Å and γ_1 = 41–90°. For the polymers, d_2, γ_2, and S_2 are respectively 4.9 Å, 13.4°, and 1.2 Å.

For the most reactive modifications, the monomer parameter S_1 should be ~3.4 Å (twice the van der Waals radius of the carbon atom which can obtain in monomers of the type $HC\equiv C-C\equiv CH$ and $NC-C\equiv C-C\equiv C-CN$). However, owing to the large bulk of the substituent side groups, it actually assumes larger values, reaching ~4.7 Å for the very bulky t-butyl substituents. A polyconjugated chain with the corresponding changes in the geometrical dimensions by the

†V.Enkelmann, J.Mater.Sci., 1980, 50, 951.

amounts Δd and $\Delta\gamma$ is formed in the course of the topochemical polymerisation. The mean square displacements necessary for the polymerisation reaction in solid DPB, HD, and its benzoate were determined by a formula[81]

$$\text{HCAC} = {}^1/_2\left\{\sum_{i=1}^{4}\left[\int_{\gamma_1}^{\gamma_2}(A_i + B_i\sin\theta)^{1/2}\,d\theta\right]^2\right\}^{1/2},$$

where

$$A_i = r_i^2 + {}^1/_4[(d_2-d_1)/(\gamma_2-\gamma_1)]^2;\quad B_i = r_i[(d_2-d_1)/(\gamma_2-\gamma_1)],$$

r_i is the length of the vector joining the centre of the molecule to the ith carbon atom in the linear group $C\equiv C-C\equiv C$ in the monomer, and θ varies from γ_1 to γ_2.

Although the above analysis does not include certain details, for example, the anisotropy of the intermolecular forces and the allowance for the difference between the lengths of the polymer chain and between the numbers of the initial monomer molecules (i.e. the principle holds best for low degrees of conversion), nevertheless the calculations yielded a satisfactory agreement with the experimental result: the mean square displacements increased with decrease of the polymerisation capacity of the monomers estimated in the investigations.[81]

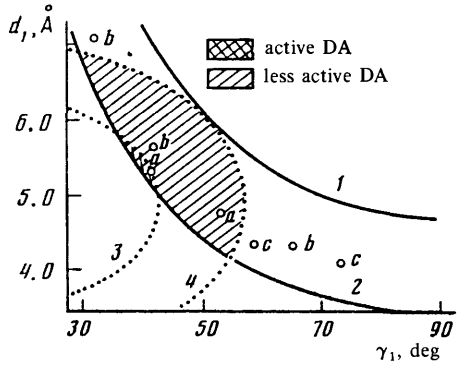

Figure 3. Determination of the ranges of the structural parameters, d_1 and γ_1 corresponding to the reactive and inactive modifications of DA: *a*) hexadiynediol; *b*) hexadiyne; *c*) hexadiyne dibenzoate; 1) S_1 = 4.7 Å; 2) S_1 = 3.4 Å; 3) MMAD = 0.72 Å; 4) MMAD = 1.08 Å.[81]

Fig.3 [81] presents as an example the structural parameters (dashed lines) for two values of MMAD: 0.72 Å (corresponds to the most reactive crystalline HD phase) and 1.08 Å (corresponds to crystalline DPB which is almost inactive in topochemical polymerisation; although the crystals become coloured, the polymer can be isolated). The crystalline modifications of monomers with coordinates lying to the right of the MMAD = 1.08 Å curve are inactive in topochemical polymerisation, which agrees with experimental observations. In addition, curves (continuous lines) representing the $d_1 = S_1/\sin\gamma_1$ relation for two values of S_1 are plotted in Fig.3. The circles in Fig.3 denote the coordinates of d_1 and γ_1 observed for the crystalline modifications of monomers with approximately the same minimum separations S_1. Thus the curves plotting in Fig.3 make it possible to determine the regions in which the parameters d_1 and γ_1 correspond to high (narrower region) and low (broader region) reactivities.

For example, in the case where S = 3.4 Å (curve *2*) the region of the parameters corresponding to a very high reactivity is bounded by the ranges $\gamma_1 \cong 36$–$42°$ and $d_1 \cong 5.0$–5.9 Å, while the region corresponding to a lower reactivity is bounded by the broader ranges of the parameters $\gamma_1 \cong 29$–$55°$ and $d_1 \cong 4.2$–6.9 Å.

Analysis of Fig.3 shows that one cannot except an appreciable topochemical polymerisation of monomers with $S_1 \geq 4.7$ Å, since the curves corresponding to the MMAD and S_1 = 4.7 Å (curve *1*) are hardly overlapped. Indeed, reactive phases of DA of the type $R-C(CH_3)_2-C\equiv C-C\equiv C-C(CH_3)_2-R$ are unknown.[2,31]

Table 2. Specific features of the packing in the single crystals of the DA $R^1-C\equiv C-C\equiv C-R^2$ and the possibility of topochemical polymerisation ($R^1 = R^2$).

Remarks: [1]$R^2 = CH_3$. [2]$R^2 = CH_2$(9-anthryl). [3]$R^2 = (CH_2)_8COOH$. [4]Complete conversion is not attained. [5]Topochemical polymerisation is impossible according to the MMAD principle. [6]Reactive under pressure. [7]Phase transition in the course of topochemical polymerisation.

It has been suggested that this principle for the determination and comparison of the reactivities in topochemical polymerisation with the aid of the MMAD principle can be extended also to other systems as well. It has been shown experimentally that the most reactive DA are those which have the following parameters: $d_1 \cong 5$ Å, $\gamma_1 \cong 45°$, and S_1 in the range $3.4 < S_1 < 4.0$ Å (Table 2). For example, the non-polymerising DA (III) with R = *p*-Cl has $d_1 \cong 5$ Å, which corresponds to a high reactivity of the monomer.[86] However, $\gamma_1 \cong 67.0°$ is outside the limits corresponding to a reactive modification of DA.[81] On the other hand, in one of the modifications of DA with R = $CH_2OC(O)NHC_6H_4CH_3$-*m* the vectors of the neighbouring molecules are not parallel, intersecting at an angle of 72°, which is inconsistent with the mechanism of topochemical polymerisation. However, the short distance between the neighbouring terminal carbon atoms is sufficient for the reaction to occur albeit with a low yield. The exposure of this modification to dioxan vapour leads to the formation of a highly reactive modification containing the solvent.[85]

The second factor influencing the specific features of the topochemical polymerisation of the monomers and the morphology of the resulting PDA is the inconsistency between the parameters of the crystal cells of the monomer and the polymer, which leads to strain and hence to defects in the single crystal on polymerisation of the monomer, which diminished the degree of conversion of DA and prevents the formation of a polymer having a high molecular weight.

The influence of this factor has been observed by means of X-ray diffraction for HD [27] in the course of the polymerisation of which (^{60}Co γ-radiation, dose 5–100 Mrad, dose rate 1 Mrad h^{-1}) the linear parameters and the angle γ of the unit cell varied continuously with the corresponding variation of the density of the crystal (Fig.4). The distance between the centres of the reacting monomer molecules then diminished by 0.44 Å and the axis of the conjugated C≡C–C≡C bonds was rotated by an angle of ~28°.

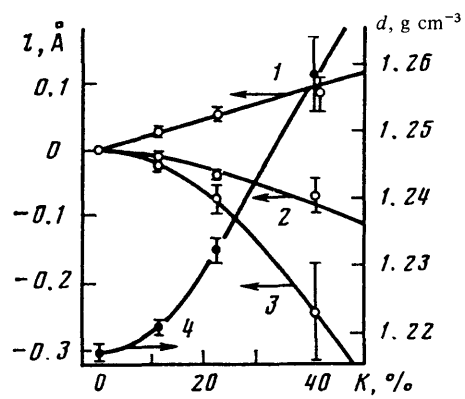

Figure 4. Variation of the parameters *l* of the unit cell [1) Δ*a*; 2) Δ*c*; 3) Δ*b*] and the density *d* (curve 4) as a function of the degree of conversion *K* of hexa-2,4-diyne-1,6-diol.[27]

The polymerisation reaction results in the formation of a solid solution of the polymer chains in the monomer matrix. However, when a specimen of this kind polymerised up to low degrees of conversion (50 Mrad) is kept for two months at room temperature, phase separation takes place, yielding separately the monomer and the amorphous phase of the polymer.[27] The conversion of PDA into the amorphous form also takes place on topochemical polymerisation of the monoclinic HD phase up to high degrees of conversion. The reason for this is the deviation of the centre of the monomer unit of the polymer chain from the centre of the corresponding monomer molecule as a result of a continuous translational movement initially over a distance $d_1 - d_2 = 0.44$ Å and then, as the polymer chain grows, over a longer distance. The enhancement of the amorphous X-ray scattering with increasing conversion in the range 0–69% corresponds experimentally to this process. A similar inhomogeneous course of the solid-phase polymerisation has been observed by Raman spectroscopy for HD biscaprilate.[45] A similar behaviour is observed on thermal polymerisation of HD.[30] Because the shifts are $d_1 - d_2 \cong 0$ for the HDDU phase containing dioxan, appreciable amorphous scattering does not occur up to quantitative conversion.[10,83]

Since the distribution of well-separated polymer chains along their lengths is irregular for long $d_1 - d_2$ distances and high degrees of conversion, the synthesis of PDA single crystals with $d_1 - d_2 \neq 0$ should probably be carried out at a suitable higher temperature where the molecular mobility essential for the longitudinal rearrangement of the system increases.

Another example of the synthesis of amorphous PDA is provided by the solid-phase polymerisation of HD bis-stearylurethane with subsequent extraction of the monomer which has not reacted and the isolation of the polymer having the character of a nematic liquid crystal.[3] The authors believe that the thermodynamically unfavourable strained or kinetically stable polymer conformation having a high free energy can exist only in the presence of a monomer lattice, ensuring thereby an "enforced" isomorphism of the polymer and monomer. The isolation of such a polymer leads to its conversion into an amorphous form with the corresponding decrease in its free energy.

However, for example, in the case of poly-TS, an increase of the degree of crystallisation of the extracted PDA with increasing degree of conversion has been noted.[36] This phenomenon is caused by the isolation of the polymer chains in the polymer matrix at lower conversions. With increase of the amount of polymer, neighbouring chains appear. Calculations based on the random formation of nuclei have demonstrated a significant increase in the number of adjoining chains and hence of the degree of crystallinity in the extracted polymer for conversions in excess of 10%, which has in fact been observed.[36]

In a general form, the criteria of phase stability have been examined[81] from the standpoint of the dependence of the overall free energy of the system on the degree of conversion. Here it is assumed that the overall free energy is made up of intramolecular and intermolecular components and should decrease with increased degree of conversion. Since the intramolecular contribution can be represented as a linearly diminishing function of the monomer–polymer transformation (both the monomer and the polymer must then exist in conformations with the minimum free energy), the change in the overall free energy of the system is influenced significantly by the character of the variation in the intermolecular contribution. Fig.5 presents an example of a free energy diagram, conforming to these general postulates, for the case where topochemical polymerisation proceeds with phase separation.[64]

The third general condition governing the possibility of topochemical polymerisation is the correspondence between the symmetries of the structural units in the monomer and

polymer crystals. In conformity with the possible types of symmetry for the monomer units in PDA and with the retention of the specificity of the solid-phase reaction, there exist specific types of symmetry of the monomer necessary for the synthesis of specific PDA chains: the monomer symmetries are of the 1, $\bar{1}$, 2, *m*, 2/*m* types for the synthesis of *trans*, *trans*-polymers and 1, 2, *m*, *mm*2 for the synthesis of *cis*, *trans*-polymers. Examination of the types of symmetry for a series of DA (HDDU and HD) and DA with R = $CH_2OC(O)C_6H_5$ and C_6H_5 has shown that their topochemical polymerisation can proceed with formation of *trans*,*trans*-PDA. Furthermore, in theory the type of symmetry of the crystalline HDDU phase should enable it to polymerise with formation of *cis*,*trans*-PDA single crystals (it has been established experimentally that this monomer polymerises with formation of only *trans*,*trans*-PDA).[84] However, in practice all the conjugated DA, including cyclic DA, are packed in crystals in such a way that the solid-phase polymerisation yields either the *trans*, *trans*-polymer or the monomer does not polymerise.[103]

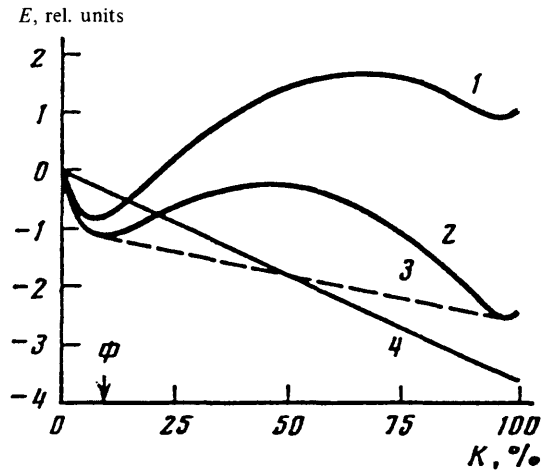

Figure 5. The free energy (E) diagram for the case where the solid-phase polymerisation cannot occur up to high degrees of conversion K owing to phase separation into isomorphous or non-isomorphous phases: 1) intermolecular contribution (one phase); 2) total free energy (one phase); 3) total free energy (two phases); 4) intramolecular contribution. The point Φ denotes the limiting conversion without phase separation.[64]

It has been observed that polymerisation with formation of a single crystal does really occur in the case of HDDU but not for TPB and HD dibenzoate,[1,5,23,27] since in the last two cases polymerisation requires excessive molecular displacements. In other words, the topochemical polymerisation of TPB and HD dibenzoate is allowed by symmetry conditions but is prohibited by the minimum displacement principle. The solid-phase polymerisation of HD is likewise not prohibited by the symmetry criterion and occurs in practice at least up to low degrees of conversion.[27] However, as reported above, owing to the displacement of the centres of the monomer units (by $d_1 - d_2$), the correspondence between the topologies of the polymer chain in the monomer units subsequently breaks down and the final polymer is amorphous. In such cases the "recrystallisation" of the reactive form in the direction of the PDA chains is necessary to increase the degree of conversion and the degree of crystallinity.

Thus the set of the specific requirements mentioned above which must be met by the topochemical polymerisation of diacetylenes may be formulated as the following criteria:[81,87] the occurrence of the minimum displacements of the atoms of the reacting molecules, phase stability of PDA in the DA matrix, and the retention of crystallographic symmetry elements in the DA → PDA transition. Only the simultaneous fulfillment of these criteria permits the actual occurrence of the topochemical polymerisation of the monomers.

The solid-phase polymerisation (γ-irradiation; 6.3 Mra; −78 °C) of thin films of butadiyne, i.e. DA having the smallest R = H substituents, has been described. However, the infrared spectra indicate the aromatic character of the monomer which implies, according to the authors,[104] the isotactic linear 1,2-addition to the C≡C bond and subsequent cyclisation.

The characteristic features of the DA polymerisation processes as well as the specificity of the structure and properties of the intermediate compounds and the final PDA have been investigated by various methods: gravimetrically with extraction of the monomer,[11,25,35–38,79,105,106] contraction of single crystals,[76,107,108] flash photolysis,[102] method employing X-ray diffraction,[27,30,35] proton spin–lattice relaxation,[110] DSC,[25,27,76,77,105,111–115] Brillouin scattering,[56,116] photoacoustic methods,[117–119] optical spectroscopy,[35,82,105,120–123] scattered reflected light spectroscopy,[35,38,46,124] EPR,[30,125–132] infrared spectroscopy,[80,133] Raman spectroscopy,[31,35,41,45,46,134,135] and molecular weight distribution.[136] When particular conditions are met, various methods for the investigation of the topochemical polymerisation kinetics (for example, the gravimetric method, DSC, and electronic spectroscopy) yield satisfactorily concordant results.[105]

3. The Crystal and Molecular Structures of Diacetylenes and Their Polymers

The solid-phase reactions of DA which satisfy the criteria for topochemical polymerisation result in the formation of crystalline linear polymers. Well formed acicular crystals up to 5 cm long have been obtained by the method described on the basis of HDDU,[53] while large crystals weighing more than 1 g have been synthesised from TS.[125,137] The possibility of obtaining larger PDA crystals (up to 15 cm long and weighing up to 10 g) has been reported.[87]

Studies by optical and electron microscopy of the etched characteristic surfaces of the preferred cleavage planes of TS single crystals[36,138,139] revealed specific ellipsoidal pits, caused by dislocations, arranged in certain preferred directions having a long axis in the [010] direction, which subsequently becomes the direction of the principal PDA chain. Photographs and schemes for different types of the observed defects have been published[138,139] and the possible role of active centres (chain propagation initiators) has been discussed. Thermal polymerisation, in which dislocations play an important role, then begins at localised sites corresponding to the centres of the elliptical pits, while all the polymer chains grow in only one direction—"plus" or "minus" depending on the sign of the Burgers vector of the dislocation lines. This hypothesis is confirmed by the additional appearance near the deformation zones of numerous characteristic dislocations, which arise as a consequence of the compression of TS in the [010] direction and at which polymerisation begins.[36,139] Evidence for the occurrence of localised polymerisation either at the dislocation sites or at the sites of macroscopic deformation, for example, scratches,

has not been obtained for a photoinitiated reaction. Thus the defects do not control the photopolymerisation, since each absorbed photon of energy should lead to reaction regardless of the presence of defects in the crystal.[138,139] As a consequence of this, the energy of the photon initiating the topochemical polymerisation (~370 kJ mol^{-1}) should be much higher than the energy stored in the dislocation centres (not more than 90–180 kJ mol^{-1} according to calculations) and should be comparable to the activation energy for thermal polymerisation (80–120 kJ mol^{-1}).[139]

All the PDA crystals synthesised are cleaved in specific directions. For example, HDDU is cleaved along the (100) and (102) planes, forming smooth surfaces suitable for spectroscopic and electrophysical studies. Various types of dislocations have been observed on these surfaces although it is not clear whether they appear in the course of cleavage, or whether they are already present in the single crystal, or whether they arise in the course of the topochemical polymerisation.[138] Detailed microscopic studies of single crystals of poly-TS taking into account the crystal structure[35,36,138–140] permitted the solution of a number of problems: a scheme has been devised for the slip systems, deformation twinning of the crystals has been observed, and the characteristics of the distribution of the polymer chains and defects in the single crystals have been determined. The results of studies of the morphology of poly-TS in a number of investigations have been examined critically.[141]

The structure of the dislocations in TS and poly-TS has been investigated in detail with the aid of Laue diagrams. The growth of dislocations in the TS crystal during topochemical polymerisation and the influence of dislocations on the polymerisation process have been analysed.[142] The characteristic features of the optical spectra of a specially synthesised high-defect poly-TS have been attributed to the presence of dislocations at which short polymer chains have been terminated.[143] It is believed[144] that dislocations are present in the TS crystals and are then fixed during polymerisation, affecting the topochemical polymerisation process and mechanical and electrical properties. For example, the anisotropy of the mobilities of the current carriers in the direction of the polymer chains and at right angles to them is associated with the one-dimensional character of the PDA. However, the difference between the ratios of the corresponding mobilities $\mu_\parallel/\mu_\perp$, which are 10 [145] and $(8 \pm 3) \times 10^2$,[146] can be attributed to dislocations.

Furthermore, the mobilities of current carriers $\mu_\parallel$, determined in different studies, differ in magnitude (1 – 5 $cm^2 V^{-1} s^{-1}$,[147–149] 6×10^3 $cm^2 V^{-1} s^{-1}$,[150] and 2×10^5 $cm^2 V^{-1} s^{-1}$ [151]) and can also be attributed to different contents of dislocations functioning as current carrier traps.[144] Indeed the edge dislocations in poly-TS with the Burgers vector parallel to the direction of the chain are present in an amount of 10^{13} m^{-2}.[144] An approximate calculation showed the following: if each dislocation (with a density of 10^{12}–10^{13} m^{-2}) disrupts a chain when the chain passes through a dislocation nucleus, the length of the undeformed section of the chain is 0.1 – 1 mm, which corresponds to the distance traversed by an electron in poly-TS.[151] Dislocations can be arranged in lines at right angles to the direction of the chain. When the density of the dislocations along the line become sufficiently great, low-angle grain boundaries are formed.[144]

Fibrillar crystals with a diameter not exceeding 1000 Å and having a length of several μm have been obtained by the crystallisation from solution of partly polymerised TS. The direction of the molecules in the crystals have not been determined, but it has been noted that the crystal structure of fibrillar crystals differs from that of lamellar crystals obtained by the polymerisation of DA single crystals.[152,153]

The conversion into an amorphous form of the poly-TS crystals formed by forging and rolling is not caused by chemical changes but is due to the chain defects (loops and bends), leading to the appearance of segments with different conjugation lengths along the chain.[154,155]

The deformations along the crystal lattice defects have been discovered with the aid of asymmetric high-resolution X-ray topography in DA and PDA with $R = (CH_2)_4OCONHC_6H_5$. The defects are preserved in the course of topochemical polymerisation and the degree of deformation along them does not increase.[156]

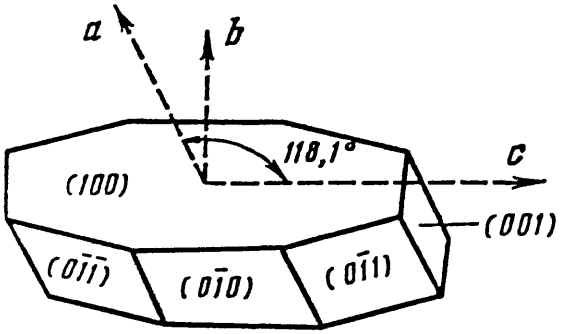

Figure 6. A TS crystal for dilatometric measurements; the (010) and (001) surfaces have been obtained by polishing.[108]

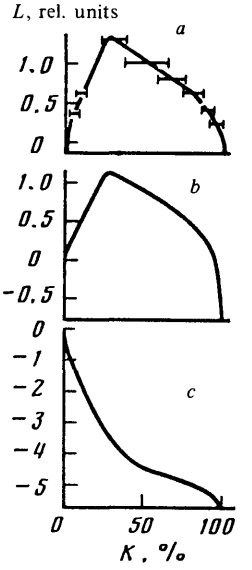

Figure 7. Variation of the dimensions L of a TS crystal with the degree of conversion K: *a*) $100\Delta d_{(100)}/d_{(100)}$; *b*) $100\Delta d_{(001)}/d_{(001)}$; *c*) $100\Delta b/b$.

The presence of a well formed TS crystal made it possible to investigate dilatometrically the kinetics of thermal (at 333.2 K) topochemical polymerisation. Direct measurements of the geometrical dimensions of the crystal (Fig.6)[108] at 276 and 294 K on the basis of the formulae

$$\frac{\Delta d_{(100)}}{d_{(100)}} = \frac{\Delta a}{a} + \Delta\beta \cot \beta,$$
$$\frac{d\Delta_{(010)}}{d_{(010)}} = \frac{\Delta b}{b},$$
$$\frac{\Delta d_{(001)}}{d_{(001)}} = \frac{\Delta c}{c} + \Delta\beta \cot \beta$$

were used to calculate the varying unit cell parameters. The existence of maxima in the parameter a and c in the region of 30% conversion has been observed, while the parameter b diminishes continuously (Fig.7).[108] The continuous variation of the parameter b during topochemical polymerisation has also been noted in another study.[116] However, examination of the unit cell parameters derived from X-ray diffraction data showed that the thermal polymerisation of TS (59.4 °C) is accompanied by a jump in b for the unit cell in the region of the transition from the induction period in topochemical polymerisation to the autocatalytic stage (~15% conversion) with a corresponding alteration of the reaction rate constant from 4.8×10^{-7} to 1.6×10^{-4} s^{-1}.[157,158]

X-Ray diffraction analysis of the products of the low-temperature phototopochemical polymerisation of symmetrical DA with R = $(CH_2)_4OSO_2$– –CH_3, carried out at T = 110 K, revealed the homogeneous character of the polymerisation up to 20% conversion of the monomer.[159]

On the other hand, in the case of the γ-initiated topochemical polymerisation at 20 °C all the DCHD unit cell parameters vary in jumps (see above) in the range of conversions of the monomer 30–50%, which is believed[98,160] to be a consequence of a phase transition.

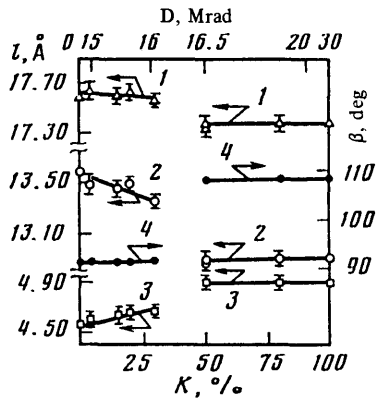

Figure 8. Variation of the parameters l of the DCHD crystal unit cell with the degree of conversion K and the γ-radiation dose D: 1) c; 2) a; 3) b; 4) β.[98]

The study of a poly-TS crystal by wide angle X-ray diffraction under a pressure $p \leq 16.5$ kbar revealed the variation of the parameters a and c as well as the angle β of the monoclinic unit cell with increasing pressure.[161] The compressibilities obtained have the following values:

Parameter	a	b	c	β
Compressibility, $kbar^{-1}$	$2.6 \cdot 10^{-3}$	0.0	$3.2 \cdot 10^{-3}$	$2.4 \cdot 10^{-4}$

The formation of PDA single crystals makes possible their complete X-ray diffraction analysis together with the calculation of the coordinates of all the atoms, the lengths of the valence bonds, and the angles, which means that one can determine the type of unit in the main chain. At the beginning of the development of the research into the solid-phase polymerisation, the isomorphism of the monomeric and polymeric crystals enabled the authors to regard the polymerisation process as one involving the rupture of two C≡C bonds via a mechanism involving the 1,4-addition of monomeric units to the polymer chain (Fig.1) with formation of an enyne (I) structure, or the cumulene (II) structure mesomeric relative to the former, which some workers[1-3,5,34,37] have found to be preferable.

However, calculations of bond length based on the results of the X-ray diffraction analysis of the HDDU,[84] TS,[162] and DCHD[163] polymers were found to agree better with the concept of the polymer chain as a flat zig-zag containing conjugated C=C and C≡C bonds. Not only in these but also in all other polymers investigated, the existence of only the *trans*-confugurations of a macromolecule relative to the C=C bond has been noted. Later X-ray diffraction analysis showed that the cumulene structure makes a greater contribution at least for PDA with R = $(CH_2)_4OCONHC_6H_5$ and for BPG.[164-166] Crystallographic data for a series of DA and PDA as well as the bond lengths in the PDA main chains are listed in Table 3.

Differences have been detected between the expansion coefficients of a crystal of a BPG monomer and the polymer chain in the study of the temperature variation of the position of the maximum in the electronic transition.[181]

The study of the reflection spectra of PDA with R = $(CH_2)_4$.$OC(O)NHC_2H_5$ deposited on ceramic discs with a high thermal expansion coefficient revealed a phase transition between liquid helium temperature to room temperature, induced by the removal of mechanical stress and accompanied by the structural change (II) → (I).[182] The thermochromic transition (green → red) observed for the same PDA at temperatures in the range 115–130 °C has been explained by a first-order phase transition accompanied by the structural change (I) → (II). The reverse process occurs in the region of 70 °C.[60]

A phase transition, caused by a rearrangement of the side groups at 142 K, has been observed for a carbazolyl-containing PDA with the aid of ultraviolet and Raman spectroscopy.[71]

X-Ray diffraction studies on poly-TS crystals revealed a reversible second-order phase transition below 170 K. The unit cell of the high-temperature phase

($P2_1/c$, a=14.493; b=4.910, c=14.930 Å; β=118.14°; Z=2)

contains two symmetrically arranged polymer chains extended along the b direction.[162] The transition to the low-temperature phase is characterised by the rotation of the side group in the neighbouring polymer chains in the opposite directions. Although the bond lengths and angles in the main chain are not altered in this process, two varieties of polymer chains appear in the unit cell and the latter is in fact doubled without change in the perfection of the single crystal

($P2_1/c$; a=14.92; b=4.910; c=25.56 Å; β=92°; Z=4).

The low-temperature splitting in the optical and Raman spectra of poly-TS has been explained by the existence of two types of polymer chain.[183-187] The monomeric TS undergoes two phase transitions.[158]

	calculation for the ideal enyne PDA chain									1.20	1.45	1.34	[180]
										1.21	1.43	1.34	[84]
	calculation for the ideal cumulene PDA chain									1.26	1.35	1.48	[180]
										1.28	1.32	1.46	[84]

Remarks: [1]The monomer is inactive or its activity is low. [2]T = 110 K. [3]Polymerises at high pressure. [4]T < 170 K. [5]T = 110 K. [6]Crystallised from anisole. [7]Crystallised from the dioxan–water system. [8]T = 120 K. [9]The angle γ is quoted. [10]T < 142 K. [11]2:1 complex with phenazine. [12]Macromonomer. [13]Cross-linked macromonomer. [14]Polymer washed free of monomer.

The study of the polymerisation of TS led to the hypothesis[38] that the structure (II) obtains in the polymer for a low degree of conversion owing to the discrepancies between the unit cells of the monomer and polymer in the direction of the chain (the TS chain should increase in length by ~5%). The absorption spectra of TS at low conversions resemble those of PDA having the cumulene structure (II).[56] With increase of the degree of conversion, the strain energy diminishes and the enyne structure (I) becomes preferable. The induction period is then replaced by the autocatalytic stage involving an increase of the topochemical polymerisation rate constant by a factor of 100–400.[36,112,113] It is expected that only enyne structures are formed in the autocatalytic stage, while the cumulene structures are converted into the enyne structures. The consecutive transition of the structures is confirmed by the results of optical and EPR spectroscopic measurements.[130,155]# The results of the investigation of poly-TS by resonance Raman spectroscopy can apparently be accounted for by the contributions of different types of structures.[137] It has been suggested that, apart from the main *trans*-structure, there is another impurity structure which consists of a perturbed planar fully *trans*-structure and not a *cis*-structure.[137]

The majority of the workers who have investigated the optical infrared and Raman spectra of PDA have described the structure of their chains in terms of a mesomeric structure, the extreme manifestations of which are the cumulene and enyne units.[23,56,133] For example, in conformity with

#H.Gross and H.Sixl, Mol.Cryst.and Liquid Cryst., 1983, 93, 261.

the calculation for the Coulson and Dewar models, the fraction of the cumulene structure in poly-HDDU is 8–25% and diminishes when the chain conformation deviates from the planar zig-zag as a result of structural disorder.[23] The contributions of structures of different types depend on the chemical structure of the substituent in the monomer and also on the conditions in the preparation and state of the monomer whose variation can entail the reversible interconversion of these structures. However, regardless of the electronic structure of the chain, all the PDA have one common feature: a marked anisotropy of the physicochemical, electrolphysical, and other properties associated with the orientation of the polymer chain along the crystallographic *b* direction (Fig. 9).[7]

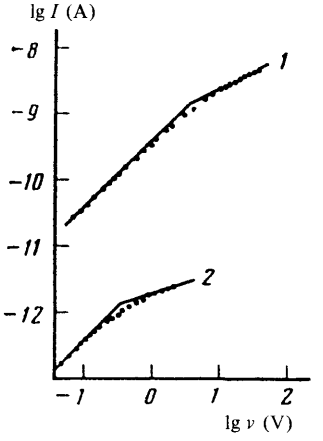

Figure 9. Variation of the photocurrent with the stress in a poly-TS single crystal; the light is polarised parallel (curve *1*) and at right angles (curve *2*) to the polymer chains (to the crystallographic *b* axis).[7]

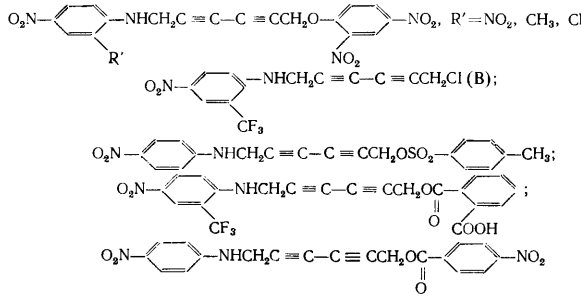
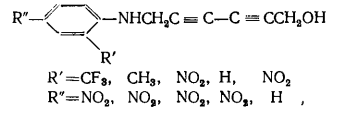
III. SPECIAL CASES OF THE SOLID-PHASE POLYMERISATION OF MONOMERS WITH $-(C\equiv C)_n-$ GROUPS

1. Polymerisation of Asymmetric Diacetylenes

A large number of polymeric single crystals have been synthesised from asymmetric DA of the type $R^1-C\equiv C-C\equiv C-R^2$ (Table 4). The study of the polymerisation of nitroanilino-substituted DA having the structure



has shown that only the monomers (A) and (B) are reactive in the solid phase. The monomer (A) polymerises on heating and under the influence of ultraviolet radiation and X-rays, while the monomer (B) polymerises only under the influence of X-rays.[195] Among a series of asymmetric DA having the general formula



only those with $R' = CF_3$ and $R'' = NO_2$ polymerise under the influence of ultraviolet light and X-rays ($Cu K_\alpha$, 3 days, 73% conversion), although all the monomers are electronically and sterically similar.[196]

Table 4. The asymmetric DA $R^1-C\equiv C-C\equiv C-R^2$ investigated in the solid-phase polymerisation.

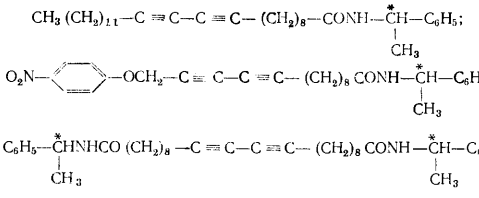
Polymerisation in single crystals and monolayers of DA having the structures $CH_3(CH_2)_{17}C\equiv C-C\equiv CCOOM$ ($M = H^+$, Cu^+, or Ag^+) and $HC\equiv C-C\equiv(CH_2)_{17}COOH$ led to the formation of blue and red polymers respectively.[197] The instability of the copper salt in the crystalline state has been noted.

DA with chiral substituents, derivatives of *d*(+)-α-methylbenzylamine, are highly sensitive to ultraviolet light and X-rays:

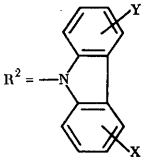


It has been observed that the asymmetric DA with the $CH_3(CH_2)_{11}$ end groups has a higher quantum efficiency (1×10^{12}) than the corresponding pentacosa-10,12-diynoic acid (1.6×10^{11}). It has been suggested that it be used to cross-link polymeric materials (for example glycidyl methacrylate) and also in photography and lithography.[198]

Carbozole-containing polymers based on the monomers

$$R^1(CH_2)_mC{\equiv}C{-}C{\equiv}C(CH_2)_nR^2,$$

in which m and n = 0–10 and $R^1 = CH_3$, OH, OC(O)NHR^3 [R^3 = alkyl (C_1–C_{18}), phenyl, tolyl, naphthyl, or $CH_2OC(O)C_qH_{2q+1}$ (q = 2–4)] have been proposed as materials with non-linear optical properties:[194]



X and Y = H, Cl, Br, NO_2.

The photopolymerisation of the tetrachlorocadmates $(RNH_3)_2CdCl_4$ (where R = $CH_2C{\equiv}CC{\equiv}CCH_2Cl$) with organic cations is known.[199] The use of asymmetric DA containing simultaneously hydrophilic and hydrophobic substituents made it possible to obtain and investigate polymeric monolayers and multilayers with unique structures.[200]

Infrared spectroscopic study of the blue products of the polymerisation of hepta-2,4-diynoic acids[133] (^{60}Co γ-radiation: 120 Mrad; 0.135 Mrad h^{-1}) showed that during solid-phase polymerisation a single crystal contains three components (the monomer, the insoluble polymer, and a segregated soluble oligomer), which give rise to two individual solid solutions over the entire range of conversions: the phase enriched in the monomer [with frequencies 1420, 905, and 600 cm^{-1} for the $(CH_2)_n$ groups], which is converted into a phase enriched in the polymer [with frequencies 1350 and 835 cm^{-1} for the $(CH_2)_n$ groups]. It is of interest that the authors proposed a cumulene structure of the chain unit for the intermediate oligomer.

The presence of two different non-chiral substituents in the monomeric molecule makes possible the existence of additional, compared with symmetrical diacetylenes, types of structure in the PDA molecules: "head to tail", "head to head", or both simultaneously. For the polymers obtained (using ^{60}Co γ-radiation) from the asymmetric diacetylenes

$$CH_3C{\equiv}C{-}C{\equiv}CCH_2OCONHC_6H_5;\ HOCH_2C{\equiv}C{-}C{\equiv}CCH_2OCONHC_6H_5;$$
$$CH_3NHCOOCH_2C{\equiv}C{-}C{\equiv}C{-}CH_2OCONHC_6H_5$$

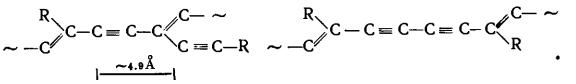
only the first type of addition has been observed with a regular alternation of "head–tail" side groups and the occurrence of entirely the *trans*-conformation in the polymer chain.[87]

Being formally symmetrical, a DA having chiral groups can give rise to several types of addition of units. The mixture of the DA $R{-}C{\equiv}C{-}C{\equiv}C{-}R$, $S{-}C{\equiv}C{-}C{\equiv}C{-}S$, and $R{-}C{\equiv}C{-}C{\equiv}C{-}S$ [R and S are the chiral groups $-CH_2\overset{*}{C}H(CH_2CH_3)-OCONHC_6H_5$ of different sign], synthesised by Wilson et al.,[173] crystallises in two crystallographic modifications one of which is a racemic mixture, while the other is optically inactive. Their polymerisation leads to the corresponding PDA having the structures $[{=}C(R)C{\equiv}CC(R){-}C(S)C{\equiv}CC(S){=}]_n$ and $[{=}C(R)C{\equiv}CC(S){=}]_n$.

Certain general criteria of the solid-phase polymerisation of asymmetric diacetylenes have been stated by Baughman and Yee.[87]

2. Polymerisation of Linear Monomers with the $-(C{\equiv}C)_n-$ Groups

The polymerisation of triynes having the general formula $R{-}(C{\equiv}C)_3{-}R$ can proceed via a 1,4-addition reaction with formation of asymmetric side substituents R and $C{\equiv}C{-}R$ and via the 1,6-addition reaction with formation of symmetrical substituents R or, via a combination of both processes:



Examination of the MMAD principle in relation to triynes demonstrated a higher probability of the formation of fully *trans*-polymers in the case of both 1,4- and 1,6-addition than that of the formation of the corresponding *cis*-polymers. Furthermore, it has been noted that higher MMAD are required for the 1,6-addition reaction than for the 1,4-addition.[87] It must be emphasised that the polymer formed can have the type of symmetry corresponding to the monomer type of symmetry, which agrees with the specificity of both the 1,6-addition reaction of triynes and the 1,4-addition of symmetrical diynes. However, for the topochemical asymmetric 1,4-addition reaction of triynes, which should be preferred in conformity with the MMAD principle, the monomer type of symmetry corresponding to the possible occurrence of such topochemical polymerisation is 1 or m, which has in fact been observed.[87] The absence of the topochemical polymerisation of dimethyltriacetylene, the molecular symmetry of which ($\bar{3}m$) [81,201] rules out the occurrence of a specific reaction of this monomer via both 1,4- and 1,6-additions in agreement with the criteria concerning the type of symmetry formulated above.

Table 5. Polymerisation of the triynes $R{-}(C{\equiv}C)_3{-}R$.[193]

R	Photopolymerisation[1]		Thermal polymerisation		
	yield[2] of polymer	colour[3]	T, °C	τ, h	yield of polymer, %
CH_2OH	+++	purple-red	60	52	87
			100	0—1	—[4]

			83	40	—[5]
			100	1	—[5]

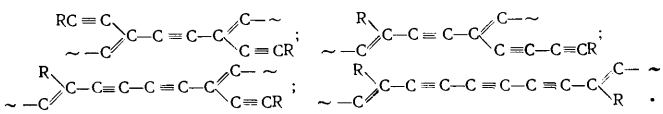
Remarks. [1]Moderate-pressure mercury lamp, room temperature, 3 h. [2]– = no polymerisation, + = low yield (<1%), ++ = moderate yield (<10%), +++ = high yield (>20%). [3]Unresolved polymer–monomer mixture. [4]Rapid carbonisation takes place. [5]Elimination of sulphonate groups (according to infrared spectroscopic data).

Examination of the polymerisation reactivity of octa-2,4,6-triyne-1,8-diol and some of its derivatives in topochemical polymerisation showed that the diol is the most reactive monomer (it polymerises readily even on recrystallisation in the dark at room temperature). The diphenylurethane of the diol polymerises to a crystalline polymer on heating and also on irradiation with ultraviolet light and X-rays, but its reactivity is lower. The dibutylurethane and the dibenzoate

are inactive in the photochemical reaction, although heating of the dibenzoate at 100 °C gives rise to a black polymer in 88% yield. On the other hand, the bistoluenesulphonate is photochemically reactive but does not undergo thermal polymerisation. The reactivity of triynes in photopolymerisation thus diminishes in the sequence diol > phenylurethane > toluenesulphonate > butylurethane > benzoate, the most reactive form of the phenylurethane derivative having been obtained by recrystallising the monomer from a petroleum ether–benzene mixture (Table 5). Triynes with large α-substituents [R = $C(CH_3)_2OH$] do not photopolymerise.[175]

Depending on the structure of the macromolecules, the repeat period of the chain may range from 1 (~4.9 Å) to 4 (19.6 Å) monomer units. The study of the structure of the polymers synthesised (Table 3)[87,175] showed that *trans*-polymerisation does indeed take place fully, while 1,4-addition with formation of structure (I) in the topochemical polymerisation of the biphenylurethane of octatriynediol leads to a crystalline polymer, while the polymerisation of octatriynediol up to a high degree of conversion results in a polymer with a perturbed three-dimensional order.

In the polymerisation of tetraynes the PDA chains can have four types of units and can also consist of a combination of two or more structures:

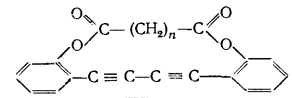


in the presence of asymmetric substituents in the main PDA chain [for example, R and RC≡C] there is a possibility of the "head to head" and "head to tail" addition of the monomer molecules which increases the number of possible variants of the polytetrayne structure. The structure becomes still more complicated when the substituents possess optical activity.

According to infrared and Raman spectroscopic and X-ray diffraction data (Table 3), the symmetrical tetrayne with $R=CH_2OCONHC_2H_5$ polymerises thermally and under the influence of γ-radiation without changes in the side groups forming the polymeric skeleton $(=RC-C\equiv C-CR'=)_n$, in which the length of the repeating fragment is 4.75 Å. Nevertheless it has not been established whether symmetrical polymerisation with formation of C≡C–R side groups or asymmetric polymerisation with formation of the R and $C\equiv C)_2$–R side groups takes place.[87] X-Ray diffraction has shown that the unit cell parameters vary gradually during the reaction with increasing degree of conversion and that a new phase does not appear. Such absence of phase separation is a necessary condition for the solid-phase synthesis of polymeric single crystals. However, the three-dimensional order of the monomeric phase is not retained in the polymer from which the monomer has been extracted and depends on the method of initiation of the reaction: the γ-initiated reaction leads to an amorphous polymer with extended chains, while the thermal reaction results in the formation of a polymer having two-dimensional order but a perturbed periodicity in the direction of the chain.[87] The γ-initiated topochemical polymerisation of the symmetrical diol $HO-CH_2-(C\equiv C)_4CH_2-OH$, which crystallises as an isomorphous phase with triacetylenic and diacetylenic diols, breaks up the three-dimensional order in the monomeric phase. This results in the formation of a monomer having an extended chain in which the repeating fragment is 4.9 Å long, in good agreement with the 1,4-addition of the monomer molecules involving the formation of a fully *trans*-polymer.[87]

3. Polymerisation of Cyclic Monomers

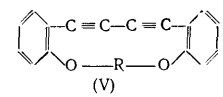
The synthesis of cyclic compounds containing conjugated C–C bonds established that some of these compounds are just as unstable in the solid phase as linear diacetylenes although they are fairly stable in solutions.[202–204] In both cyclic and linear diynes, the structure of the substituents R has been found to have a stong influence on the reactivity of the monomer.



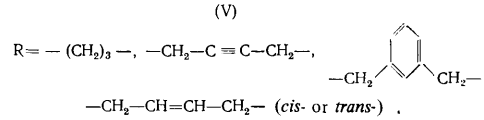
(IV)

$n = 3, 4, 5, 7$.

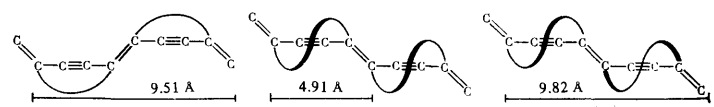
Monomers of type (IV) are sensitive to light only for $n = 3$.[202] The strongly strained ethers (V) are fairly stable in the solid state under illumination but are sensitive to heating:[203]



(V)



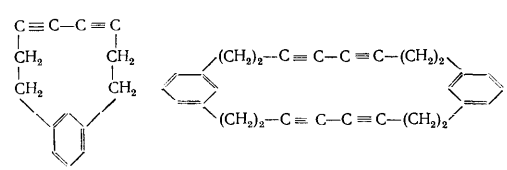
The polymerisation of *oo*-buta-1,3-diynylenediphenyl glutarate (BPG) (IV) ($n = 3$) under the influence of ultraviolet light or γ-radiation affords, after the extraction of the monomer which failed to react, an asbestos-like infusible insoluble PDA in yields up to 35–40%.[57,103,164,181] The non-extracted product of the polymerisation reaction is a solid solution of the polymer in the monomer matrix, the axis of the monomer being rotated by 33° in the course of the topochemical polymerisation and the side groups undergoing a change in orientation. The structure of poly-BPG can be represented by the following units:



(VI)

It has been established by X-ray diffraction (Table 3), optical dichroism, and infrared and Raman spectroscopy[103,164,205] that the macromolecules consist of a flat zig-zag (fully *trans*-polymer) with helically coiled substituents [structure (VI)]. The repeating interval in the achiral chain then consists of a double unit (~9.7 Å), which is satisfactorily consistent with calculations carried out taking into account the valence angles and bond lengths (9.82 Å).[103] Studies have shown[103, 181,206] that the polymer contains conjugated C≡C– and C≡C– (*trans*) bonds, although there is a possibility of a contribution by the cumulene structure.

The exceptionally unstable compound (VII) polymerises in several seconds to give an insoluble red polymer even in the dark, while the cyclic compound (VIII) is stable.[203]



(VII) (VIII)

The macrocyclic compounds (IX) have been proposed for the synthesis of three-dimensional polymers having fully conjugated parallel chains and hence exhibiting a strong dichroism.[207]

(IX)

The ladder polymers based on compound (IX) should have had higher moduli of elasticity and thermal stabilities than the linear PDA.

The study of a series of cyclic monomers (IX) ($n = 4$, $m = 2$–4), obtained by the oxidative dehydrocondensation of octa-1,7-diyne,[208] showed that the monomer with $m = 4$ exhibits the greatest capacity for topochemical polymerisation. Crystalline modifications both photochemically inert and reactive polymerising under the influence of γ-radiation, ultraviolet light, heat, or mechanical action, with formation of pink polymeric crystals, have been obtained from different solvents.[179,208] Elemental analysis has shown that the "active" form crystallises with inclusion of 1 mole of chloroform per cyclotetrameric unit. It is of interest that the "inactive" crystals contain 1 mole of benzene per mole of the cyclotetramer according to infrared spectroscopic and ^1H NMR data. When the "active" colourless acicular crystals are kept in the dark *in vacuo*, chloroform is removed and the crystals are converted into a yellow amorphous modification with a melting point close to that of the monomer but do not undergo solid-phase polymerisation. Accordingly, it is recommended that the monomer be polymerised under pressure of chloroform vapour in order to prevent the evaporation of chloroform from the single crystal. The infusible, insoluble polymer obtained retains the form of the crystals of the initial monomer and exhibits a strong dichroism with the dichroism axis parallel to the axis of the acicular crystal. According to Raman spectroscopic data, the polymerisation occurred as a 1,4-addition reaction of the diacetylenic groups of the monomer.[179,207,208] The unit cell of the polymer incorporating two monomeric units and two chloroform molecules has the parameters $a = 12.4$ Å, $b = 24.8$ Å, and $c = 4.8$ Å, where c represents the direction of the polymer chain. Comparison of these results with molecular models made it possible to assume that the most preferred of the three possible conformations (crown, boat, and chair) is the chair conformation, which is less strained and has a repeat period of ~4.9 Å.[179]

The total insolubility of the polymerised specimen shows that the cyclotetramer polymerises (γ-radiation, 50 Mrad) quantitatively. However, the low degree of crystallinity (40%), the positive temperature coefficient of linear expansion, and a lower mechanical strength than that of the linear PDA showed that the polymer might have contained $-(C\equiv C)_2-$ groups which failed to react. It has been established that resonance Raman spectroscopy does not always make it possible to determine the degree of conversion of the monomer, since, for example, the characteristic band of PDA with $R = (CH_2)_3OCONHC_6H_5$ might not have been observed in the spectrum of a mixture containing 75% DA and 25% of its polymer. In addition, the DSC curve for the polycyclic compound revealed an exothermic peak with a maximum at 197 °C corresponding to the exothermic 1,4-addition reaction of the $-(C\equiv C)_2-$ groups which failed to react in the course of the polymerisation, whose heat overlaps the endothermic heat of evolution of the solvent.[179]

4. Polymerisation at High Pressure

Diacetylenes in the single crystals where the distances between the terminal carbon atoms of the C≡C bonds in neighbouring molecules are greater than a certain critical value do not polymerise. A factor promoting the polymerisation of such monomers is an increase of pressure. A typical example of DA which is difficult to polymerise is provided by HD dibenzoate, which crystallises in two forms which are and are not capable of polymerising under high pressure.[23,96] X-Ray diffraction studies of the two forms have shown that this is caused by a difference between the distances separating the carbon atoms in the C≡C bonds in neighbouring reacting molecules (4.02 and 5.36 Å respectively).[96]

The study of the solid-phase polymerisation of DPB, HD, and hexadiyne under a pressure of 75 kbar (the specimen was placed in a solid medium which transmitted the pressure) and at temperatures up to 260 °C showed that the smallest amount of polymer detectable at 21 °C after 1 h is obtained at minimum pressures of 60, 20, and 60 kbar respectively.[24] Assuming that the compressibilities of the monomer crystals are identical, the authors believe that the crystal lattices of the monomers are distorted in the course of topochemical polymerisation until the attainment of the structural parameters optimal for polymerisation. The polymers from which the monomer has been removed by extraction are amorphous. The remaining hydrogen bonds in the partly polymerised HD are disrupted on extraction of the monomer. The infrared spectra of PDA indicate the occurrence of 1,4-addition with formation of units of type (II) in poly-DPB and of type (I) in the HD and hexadiyne polymers. Ogo and Okuri attributed the same structure to poly-HD.[209]

The sterically hindered α-substituted DA, such as octa-3,5-diyne-2,7-diol and its bisphenylurethane and bistoluenesulphonate, become capable of polymerising with increase of pressure to 30 kbar. The yield of the polymers depends more on the pressure than on time and temperature. A structure of type (II) has been proposed for the main chain.[210]

Detailed study of the kinetics of the thermal topochemical polymerisation of TS under hydrostatic pressure[107,211] demonstrated the disappearance of the autocatalytic effect at a pressure $p \geq 2$–4 kbar. Since the autocatalytic effect has been attributed to the difference between the dimensions of the monomeric and polymeric crystals, the influence of pressure was explained by the equalisation of the monomeric and polymeric lattices with its aid; at $p = 1$ kbar the length of the repeating fragment in PDA single crystals is smaller by 0.25 Å (~5%) than in the monomer single crystals, while the corresponding length at $p \geq 4$–2 kbar is smaller by 0.1 Å.[211]

The photopolymerisation of TS, carried out in an optical cuvette under a hydrostatic pressure up to 4 kbar, and also the study of the resulting specimens by scanning electron microscopy showed that the size of the polymerised sections increases with increasing pressure.[122] The solid-phase polymerisation takes place along the entire surface of the crystal and breaks arise as a result of contraction in the direction of the chain. In the non-irradiated regions of the crystal, secondary chain initiation by the primary growing chains has been observed.

5. The Joint Crystallisation of Diacetylenes and Their Polymerisation

The photoinitiated polymerisation of DA take place when the single crystals are irradiated with light having a wavelength within the absorption band of the monomer. The photosensitised polymerisation of 2,4-diynoic acids $R^1-C\equiv C-C\equiv C-R^2$ [$R^1 = COOH$, $R^2 = (CH_2)_nCH_3$, $n = 11$, 13, or 15], cocrystallised with phenazine, has been reported.[174,212] Mixed crystals of DA and phenazine having the dimensions 10 × 2 × 0.5 mm have been obtained from an alcoholic solution

containing both substances by slow evaporation of the solvent. The crystals have the stoichiometric composition of a complex comprising two molecules of the diynoic acid and one phenazine molecule and exhibit the fluorescence observed for pure phenazine crystals. According to infrared spectroscopic data, there is no formation of a salt (?complex) of any kind between the diynoic acid and phenazine. Polymerisation takes place readily in the mixed crystals under the influence of visible light ($\lambda \leqslant 450$ nm), while the pure diynoic acid is not polymerised by light with $\lambda > 300$ nm. It has been noted that, when $\lambda = 400$–430 nm, the quantum yield ϕ of the sensitised photopolymerisation of the cocrystallised material is approximately 10 times smaller than the ϕ observed on direct irradiation of the acetylenic chromophore.[212] The rate of polymerisation of the pure acid is initially higher than that of the cocrystallised compound, but a lower limiting degree of conversion has been noted in the former case.[174]

The crystal structures of the acids and their cocrystallised mixtures with phenazine have been studied (Table 3), which has led to a model capable of explaining the characteristic features of the topochemical polymerisation of the acid and its complex. According to the model, the acid molecules are packed in the single crystals in layers of the "head–head–tail–tail" type (Fig.10). The authors[174] regard the crystal structure of the complex as intermediate between the structures of the pure compounds and explain thereby why acridine and pyrazine do not form analogous complexes. On the other hand, the 4,6- and 10,12-diynoic acids do not cocrystallise with phenazine, unlike the 2,4-diynoic acids, probably because the latter have a higher pK_a owing to the strong electron-accepting character of the $C\equiv C-C\equiv C$ group, which means that they have a greater capacity for the formation of complexes with phenazine. Phenazine is removed by extraction from the coloured polymeric crystals obtained by topochemical polymerisation, after which the latter assume a fibrous form. Other substances can be introduced into the space produced by the removal of phenazine.[174] In the PDA chains the monomer units are linked "head to tail".[174]

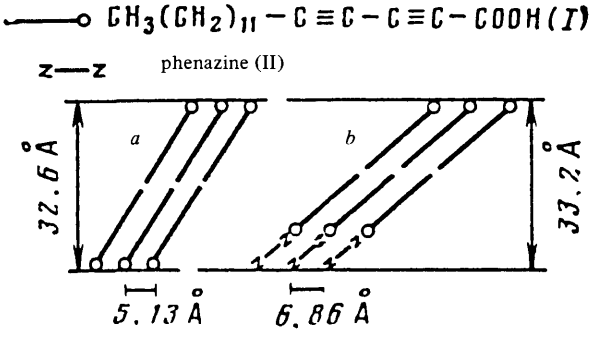


Figure 10. Structural models of DA (*a*) and of the cocrystallised DA–phenazine mixture (*b*) in the (100) projection i.e. at right angles to the direction of the PDA chains.[174]

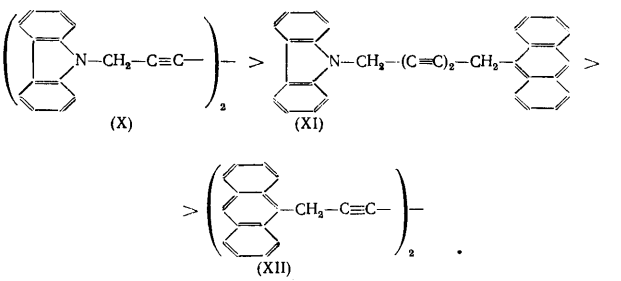
The study of the photoinduced topochemical polymerisation using the light corresponding to the optical excitation band of phenazine ($\lambda = 420$ nm) or DA ($\lambda = 280$ nm) revealed differences between the corresponding quantum yields ($\phi_{420} = 0.1$ and $\phi_{280} = 0.5$) and activation energies ($E_{420} = 0.21$ eV and $E_{280} = 0.17$ eV). It is believed that there is no electron transfer from the excited phenazine molecule to DA.[213]

Another aspect of the use of the mixed crystals is the solid-phase copolymerisation of various cocrystallising diacetylenic monomers, for example, those containing the urethane groups $R = CH_2OCONCH_6H_4X$, where X = H, *p*-Cl, or *p*-Br.[214] The relatively unreactive HD bis(*m*-trifluoromethylbenzenesulphonate) cocrystallises with the isomorphous TS. Thermal polymerisation of DA takes place in the jointly crystallised material, the duration of the induction period, which is also observed in the topochemical polymerisation of pure TS, depending on the ratio of the comonomers.[47,48]

It has been observed that the monomers (III) with R = *p*-Cl or *p*-CH_3 give rise to a series of mixed single crystals owing to the similarity of the van der Waals radii of the substituents Cl and CH_3.[215,216] The formation of solid solutions has been observed also for the symmetrical diacetylenes with $R = CH_2OCONHC_6H_5$ or CH_2OCONH-2-thienyl.[216] The diacetylene (III) with R = *p*-OCH_3 (there is no induction period[44,46,134,169,170]) and DA with R = naphthalene-2-sulphonyloxy (inactive in topochemical polymerisation[51]) also cocrystallise with TS, the composition of the crystals having been determined from the absorption spectra. Ideal solid solutions are formed when the content of the naphthalenesulphonates is 0–50%. The induction period in the topochemical polymerisation in the mixed crystals of TS with compound (III) (R = *p*-OCH_3) or DA with R = naphthalene-2-sulphonyloxy diminishes with decreasing fraction of TS in the crystal.[215]

It has been shown that the crystals produced by the cocrystallisation of TS and the inactive compounds (III) (where R = *p*-Cl [217,218] or R = *p*-Br [218]) form both reactive and unreactive modifications. A significant rearrangement of the TS crystal lattice does not occur when the content of the chloro-derivative is up to 20%, while in the mixed crystals of the bromo-derivative perturbations of the lattice are observed at lower concentrations of the latter as a consequence of the greater bulk of the bromine atom. The parameter *b* of the cocrystallised material diminishes monotonically with increasing content of the chloro- or bromo-derivative in the mixture with TS with a simultaneous decrease of the melting point. The copolymerisation of TS with compound (III) (R = *p*-Cl or *p*-Br) proceeds up to total conversion and is characterised by an induction period whose duration increases with increasing fraction of the inactive halogen-containing DA. However, in the case of the chloro-derivative an initial decrease of the induction period with increasing mole fraction of the chlorine-containing DA and the cocrystallised material in the range 0–0.05% has been observed, which is difficult to explain. The activation energy E_a for the copolymerisation reaction is identical with E_a for the homopolymerisation of TS, but the rate of topochemical polymerisation is lower than that for the pure TS.[218] Phase separation has never been observed in the course of topochemical polymerisation regardless of the composition of the cocrystallised material.[217,218] The comonomer units are distributed statistically.[218]

The capacity of DA with polynuclear aromatic substituents for polymerisation diminishes in the sequence[69,216]



The diacetylene (XI) undergoes thermal polymerisation (with decomposition) only near the melting point of the monomer and does not undergo radiation-induced polymerisation. The monomers (XI) and (XII) and certain DA derivatives of quinoline, phenothiazine, and acridine in various proportions cocrystallise with DCHD (X) (Fig.11), the mixed crystals polymerising not only thermally but also under the influence of γ-radiation. The ratio of the monomers in the non-polymerised cocrystallised material differs from that in the solution from which the crystal of the cocrystallised material has been grown. Compounds (XI) and (XII) have an inhibiting effect on the photoinitiated copolymerisation of compound (X) using light with λ = 250 and 350 nm, the wavelength corresponding to the absorption bands of the diacetylenic and carbazolyl fragments. When the crystals obtained by cocrystallising compound (X) with compound (XI) or (XII) are illuminated with light corresponding to the absorption band of the anthryl group (λ = 400 nm), the process is sensitised. This has been explained by the effective transfer of the excitation energy to the active centres in the crystals obtained by cocrystallisation.[99] As in the case of other types of cocrystallised crystals, the decrease of the fraction of the relatively inactive DA in the crystal obtained by crystallisation with an active DA [compound (X)][25,71] increases the rate of topochemical polymerisation with a simultaneous decrease of the induction period (Fig.12). This finding can be accounted for by the gradual approach by the parameter *b* of the crystal, along which the topochemical polymerisation takes place, to the optimum values characteristic of the pure compound (X) (Fig.11 and Table 2). Chemical and spectroscopic analysis of single crystals of the copolymers have shown that their composition is analogous to that of the initial comonomeric crystals.[99]

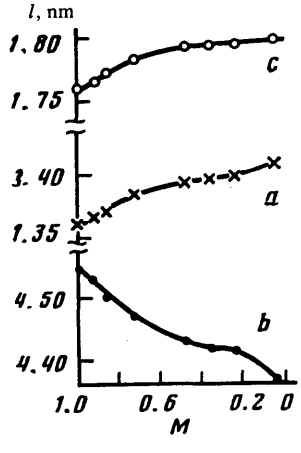


Figure 11. The influence of the DCHD mole fraction *M* in the crystal obtained by cocrystallising

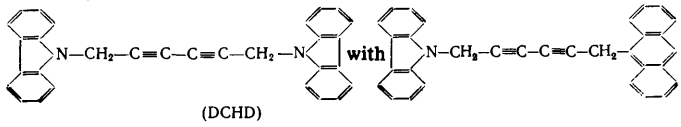

(DCHD)

on the unit cell parameters.[99]

It has been observed that mixtures of different DA show a greater contrast in colour changes on heating or irradiation than the individual DA. The cocrystallised crystals of two and more linear or cyclic monomers of different structure have therefore been suggested as thermal indicators or γ-radiation dose indicators on the basis of changes over their colour range.[219]

The cocrystallised crystallisation and copolymerisation of symmetrical monomers of similar structure, namely DA with R = $CH_2OCONH(CH_2)_3CH_3$ and $CH_2OCONHCH_2CH_3$ as well as DA with R = $(CH_2)_2OH$ and $C(CH_3)_2OH$, have been investigated with the aid of optical spectroscopy and DSC.[220]

as a function of the DCHD mole fraction in the cocrystallised material: 1) 1.000; 2) 0.989; 3) 0.978; 4) 0.945.[99]

IV. SOLUBLE DIACETYLENE POLYMERS AND THEIR PROPERTIES

The polymers obtained by the topochemical polymerisation of DA are as a rule insoluble in the usual organic solvents. However, it has been noted that many polymers based on the urethane derivatives of HD [2] and substituted DPB [5] dissolve in hexamethylphosphoramide (HMP). The polymers of 2,2-bis(acetamido)- and 3,3-bis(phenylureido)-diphenyldiacetylene dissolve in addition in concentrated sulphuric acid.[5]

Poly-TS dissolves in hot nitrobenzene, dimethylformamide (DMF), HMP, and butyrolactone, crystallising anew after the solutions have been allowed to stand.[37] The same polymer synthesised up to 12% conversion dissolves in DMF.[221] The yellow colour of the solution remains unchanged after reducing the temperature and adding the solvent. The electronic absorption spectrum of the solution has a broad maximum with $\lambda_{max} \cong 450$ nm and the extinction coefficient $\varepsilon = 5.6 \times 10^3$ litre mol^{-1} cm^{-1}, as well as a long-wavelength low-intensity downward slope. A gel permeation chromatogram demonstrated a broad molecular weight distribution (MWD) of poly-TS ($\bar{M}_n = 0.98 \times 10^5$, $\bar{M}_w = 4.80 \times 10^5$), it does not change as the degree of conversion increases to 12%, which demonstrates an increase in the number of oligomeric chains while their length remains unaltered. The average degree of

polymerisation of the soluble oligomer is $\bar{n} \cong 20$, while the chains with $\bar{n} \cong 100-200$, present in a small amount, are slowly precipitated at room temperature.[221] With increased degree of conversion of TS, the polymer chain length increases markedly. However, it is not clear whether this is a consequence of the growth of the chains formed during the induction period or whether it occurs as a result of the initiation of longer chains in the autocatalytic stage.

The results of a theoretical study of the thermal topochemical polymerisation of TS, which showed[157] that the growth of strained PDA chains is greatly hindered during the induction period (the rate constant is $k = 7.8 \times 10^{-7}$ s^{-1}), is in good agreement with experiment. Short chains [~100 Å ($\bar{n} = 20$)] are formed. After the attainment of a degree of conversion of ~15%, the chain length reaches 200 Å, In the autocatalytic stage ($k = 1.6 \times 10^{-4}$ s^{-1}) the length of the chains formed is greater than 700 Å.[222] An indirect estimate of the size of the poly-TS chains at high conversions of the monomer yielded the following values: $\bar{n} \cong 4200$ and a chain length $L \cong 2$ μm were found in a study of the kinetics of thermal topochemical polymerisation;[111] $100 < \bar{n} < 10000$ was found in a Brillouin scattering study;[116] $L \cong 5$ μm was found in an electron microscopic investigation of the etching profile of photopolymerised TS.[222]

Polydiacetylene with R = $(CH_2)_4OSO_2C_6H_4CH_3$-*p*, obtained by the γ-radiation-induced polymerisation of the monomer (42% conversion—1 Mrad; 68% conversion—3 Mrad) dissolves at room temperature in many polar solvents (chloroform, dichloroethane, DHF, DMF, acetone, nitrobenzene, and nitromethane).[43] The yellow-orange solution has λ_{max} = 466 nm and $\varepsilon_{max} = 16.7 \times 10^3$ litre mol^{-1} cm^{-1}. The addition of a precipitant alters the colour to red with formation of a deposit. The study of PDA solutions by the light scattering and gel permeation chromatographic (GPC) methods has been shown that the macromolecules in solution have a helical conformation and that $\bar{M}_w = 7.4 \times 10^5$ and $\bar{M}_w/\bar{M}_n = 2$.[43] A broadening and shift of the MWD maximum towards higher values of $\bar{M}_n$ ($\bar{n} = 60-2000$) with increase in the degree of conversion from 2 to 10% has been observed for this PDA. Subsequently the position of the MWD curve hardly changes.[136] According to light scattering and osmometric data,[223] the shape of rigid rodlike helices, consisting of linear segments, is also characteristic of the molecules of PDA with R = $(CH_2)_2$. .OCOR′ (R′ = isopropyl, benzyl, or 1-naphthyl) in solution in $CHCl_3$, for which $\bar{M}_w = (8-13.4) \times 10^5$, $\bar{M}_n = (2.4-3.4) \times 10^5$, and $\bar{M}_w/\bar{M}_n = 3.33-3.94$.

It has been observed that soluble oligomers of hepta-2,4-diynoic acid[133] and the DA (IX) ($m = n = 4$) have the cumulene structure (II) according to infrared spectroscopic data.

The readily soluble PDA with R′ = $(CH_2)_{11}CH_3$ and $R^2 = CH_2OH$ (decalin, 100 °C) and also with $R^1 = (CH_2)_{11}CH_3$ and R^2 = COOH (nitrobenzene, DMF, HMP, 100 °C; pyridine, 20 °C) have $\lambda_{max} \cong 460$ nm in solution and $\lambda_{max} \cong 550$ nm in the single crystal, which can be explained by the altered conformation of the macromolecular skeleton.[224]

In order to investigate the conformational transitions of the polymer chains in solutions, polymers of symmetrical DA, containing in the long side substituents a large number of polar (−CO−, −NH−) and flexible (−O−, $-CH_2-$) groups have been specially synthesised.[65] The degree of interaction of the side substituents with the solvent via such groups increases and hence also the solubility of the PDA molecules. Diacetylenes with R = $(CH_2)_nOCONHCH_2COO(CH_2)_mCH_3$ are relatively inactive for $n = 2$ and are totally inactive for $n = 1$ in topochemical polymerisation. The crystals of the 3BCMU, 3ECMU, and 4ECMU monomers became coloured on heating and γ-irradiation. According to X-ray diffraction data, the specimens of poly-3BCMU, obtained with a low degree of conversion, are in the main amorphous, which has been explained[66] by the existence of only a small number of the polymer chains which determine the crystallinity of the specimen. With increase in the degree of conversion, the degree of crystallinity also increases, because an increasing number of the polmer chains become parallel to one another. The PDA of this type, obtained with degrees of conversion up to 50–92% on γ-irradiation are readily soluble in chloroform, THF, and DMF.[65] According to the GPC data (solvent—DMF), all the polymers obtained are characterised by the following features: (a) there are no intermediate oligomeric compounds, (b) the MWD is wide for all degrees of conversion, and (c) there is almost no increase in the molecular weight in the range of degrees of conversion 7–68%.[225] For example, $\bar{M}_n = 0.98 \times 10^5$, $\bar{M}_w = 4.9 \times 10^5$, and $\bar{M}_w/\bar{M}_n = 5$ for the poly-3BCMU obtained by the γ-irradiation (50 Mrad) of the monomer. The study of the viscosity of its 0.05% solutions in variable-composition solvent–precipitant mixtures (chloroform–hexane, DMF–*o*-dichlorobenzene) demonstrated the absence of an influence by the fraction of the solvent in the mixture on the viscosity of the solution, which indicated the existence of an extended conformation of the rigid polymer chains in all the solutions investigated. The extended conformation of the macromolecule is also retained on extraction of the monomer which failed to react from the partly polymerised PDA single crystal or on fusion of the single crystal.[225] Since the number of units in the polymeric 3BCMU and 4BCMU molecules is known, amounting to 10^3 and 2.4×10^3 respectively,[225–227] the length of such rigid chains was determined and was found to be ~5×10^3 and 12×10^3 Å. The same number of units in poly-4BCMU has been found by the actinometric method.[120] The electronic absorption spectra of solutions of poly-BCMU in DMF have λ_{max} = 470–475 nm and $\varepsilon \cong 17.5 \times 10^3$ litre mol^{-1} cm^{-1}.[221]

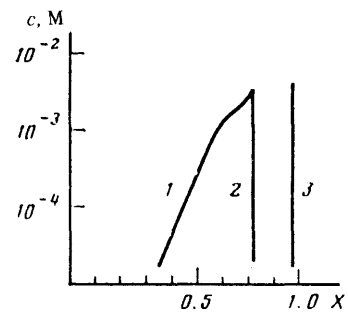

Figure 13. The phase diagram of poly-3BCMU in the chloroform–hecane system; the regions of the blue deposit (curve *1*), the blue solution (curve *2*), and the yellow solution (curve *3*) are designated as a function of the molar concentration of PDA (c) and the mole fraction of $CHCl_3$ (X).[228]

It has been observed that the addition of hexane (a precipitant) to yellow solutions of BCMU and ECMU in chloroform leads to a sharp reversible change of the colour of the solution to blue (3BCMU) or red (4BCMU). The coloured solutions are stable and do not give rise to a precipitate on standing after ultracentrifugation. An increase of the

fraction of hexane leads to the precipitation of the polymers.[105,225,227-230] The precipitation point of the deposit is strongly dependent on the polymer concentration, while the colour transition point is independent of the polymer concentration but is specific to each polymer of the series considered (Fig. 13 and Table 6).[228] Direct titration and back titration lead to different values of the $CHCl_3$ fraction (X and X') at the colour transition point. The quantity X (titration of the chloroform solution with hexane) is then always smaller than X' (titration of the blue solution with chloroform) (Table 7).[229] The solvatochromic phenomenon observed had been explained by conformational transitions of the polyconjugated PDA molecules whose optical spectrum is determined by the length of the continuous conjugation and not the chain length. In the yellow solutions the planarity of the polymer chains is perturbed by the rupture of the intermolecular hydrogen bonds, the interactions of the side substituents with the solvent ($CHCl_3$), and the rotation of the molecules about the C–C bond. The addition of a precipitant (hexane) weakens the PDA–solvent interaction and leads to a conformational transition in the macromolecules with the formation of a planar zig-zag structure of the polymer chains, fixed by hydrogen bonds, with a high effective conjugation length.[105,228-231]

Table 6. Solvatochromic and thermochromic properties of a PDA solution.[228,233,234]

PDA	K, %	X	Q, kJ mol^{-1}	T_p		
				o-dichlorobenzene	nitromethane	ethyl methyl ketone
Poly-4BCMU	92	0.55	35±2	49, 58*	52, 60	42, 47
Poly-4ECMU	75	0.65	25±2	85, 97	60, 71	72, 85
Poly-3BCMU	53	0.71	27±2	93, 102	—, 92	—
Poly-3ECMU	50	0.91	—	**	**	**

Notation: K is the degree of conversion, X the mole fraction of $CHCl_3$ at the solvatochromic transition point, Q the heat of solution, and T_p the temperature of the rupture of the hydrogen bonds of PDA in various solvents.

*The first figure denotes the dissociation of the intermolecular bonds and the second the dissociation of the intramolecular bonds.

**Poly-3ECMU dissolves only in highly polar solvents (DMF) to form a yellow solution immediately.

The effectiveness of the formation of hydrogen bonds in the 3BCMU polymers is greater than in the 4BCMU polymers owing to the difference between the lengths of the side substituents (the values of n in the side substituents).[226] Indeed construction of models taking into account the hydrogen bonds showed that the capacity of 4BCMU for polymerisation is higher, which has been reflected in the kinetics of the polymerisation of these two monomers.[105,227,228] The difference between the absorption band shifts of the 3BCMU and 4BCMU polymers in the course of conformational transitions has been accounted for by the difference between the densities of the hydrogen bond networks.[227] The strong influence of hydrogen bonds on the physicochemical processes in PDA has been demonstrated by adding small amounts of trifluoroacetic acid (acetic acid is ineffective) to the blue or red solution of poly-BGMU, which resulted in an instantaneous alteration of the colour to yellow. This colour transition is associated with the rupture of the intramolecular hydrogen bonds in the PDA network, the formation of hydrogen bonds between the added acid and the ether and urethane groups of PDA, and finally the subsequent conformational transition of the polyconjugated macromolecules.[227,228,231]

The solvatochromism of solutions of sparingly soluble (~10^{-4} mol litre^{-1} in DMF) PDA with R = $(CH_2)_nOCONHC_6H_5$ (n = 3, 4) when a precipitant is added to them can be accounted for by a similar intramolecular hydrogen bond formation process.[232]

Table 7. Solvatochromic transition points for solutions of poly-3BCMU.[229]

Dose, Mrad	K, %	Molecular weight			T_t, °C	Mole fraction of $CHCl_3$ at the colour transition points	
		$10^{-6}\overline{M}_n$	$10^{-6}\overline{M}_w$	$\overline{M}_w/\overline{M}_n$		X	X'
0.09	20.9	1.33	3.90	2.93	20	0.66	0.80
0.09	20.9	1.33	3.90	2.93	0	0.68	0.84
45	57.5	0.0802	3.18	39.7	22	0.70	0.89
45	57.5	0.0802	3.18	39.7	0	0.73	0.96

Notation: K is the degree of conversion, T_t the transition temperature, X the mole fraction obtained by titrating the yellow chloroform solution with hexane, and X' the mole fraction obtained by titrating the blue solution with chloroform.

Poly-BCMU and poly-ECMU are sparingly soluble in xylene, *o*-dichlorobenzene, ethyl methyl ketone, and certain other solvents. However, with increase of temperature, they dissolve and this is accompanied by sharp and reversible (hysteresis) colour changes. For example, the yellow solution of poly-3BCMU in *o*-dichlorobenzene (t = 106 °C) becomes blue at t < 80 °C, while the yellow solution of poly-4-BCMU (t > 68 °C) becomes red at t < 40 °C.[233] Heating PDA in a poor solvent leads to the reverse process. Thus, when red fibrillar particles of poly-4BCMU are stirred for 0.5 h at 49 °C, a red solution is formed in *o*-dichlorobenzene. Rapid heating (for less than a minute) at 58 °C gives rise to a yellow solution of PDA. Regardless of the solvent employed, the crystals of poly-4BCMU and poly-4ECMU initially form a red solution and then, on raising the temperature, a yellow solution (Table 6).[234] The heat of solution of each PDA is almost independent of the solvent.[233,234] A study of solutions and gels of these PDA by infrared spectroscopy, ^{13}C NMR, and DSC made it possible to explain the colour transitions occurring on raising the temperature by the successive dissociation of initially intermolecular and then intramolecular hydrogen bonds with formation of a non-planar conformational structure in yellow solutions at a higher temperature.[226,232-235] A decrease of temperature is accompanied by the reverse processes. The narrow temperature ranges of the thermochromic transitions indicate the cooperative character of the processes. The presence of isobestic points in the electronic spectra at 510 and 490 nm indicates the presence of a conformational equilibrium planar structure (red or blue solution or gel)–non-planar structure (yellow solution).[233]

The latest studies on poly-3(4)BCMU have shown§ that coloured solutions (blue or red) in a poor solvent are not true solutions. Thus the explanation of the colour change in the PDA solution by a conformational transition in individual rod-like conjugated macromolecules, leading to a change in the effective conjugation block is not correct and final¶.[225]

The thermochromic transition in solution has also been observed for PDA with R = $(CH_2)_4OCONHCH_2CH_3$. Its solution in DMF at 100 °C has the yellow colour characteristic of a non-planar conformation of the macrochains (λ_{max} = 470 nm), while at room temperature it has the orange colour of the planar conformation (λ_{max} = 520 nm). However, this phenomenon was not observed for the phenyl-containing DA with a similar structure [R = $(CH_2)_m$. .$OCONHC_6H_5$, where m = 3, 4] even in the presence of a precipitant.[232]

It has been reported that, on treatment with ultrasound in water, DA with R = $(CH_2)_8CH_2OP(O)(OH)_2$ dissolves and polymerises (irradiation with ultraviolet light) with formation of a dark-blue thermochromic solution.[236] However, in this case a true solution is apparently not formed, since the topochemical polymerisation of DA cannot take place in it.

A visible conformational transition has been observed in aqueous solutions of PDA with the symmetrical substituents $(CH_2)_nCOO^-K^+$ (n = 2, 3) and $(CH_2)_3OCONHCH_2COO^-K^+$.[67,68] The solution of the first polymer has a yellow colour at pH ≥ 7. The maximum in its absorption spectrum shifts from 462 to 535 nm when the pH is reduced from 9.5 to 3,, while at low pH (after the addition of HCl) an absorption band with λ_{max} = 575 nm appears in addition. The change in the colour of the solution to red or purple takes place because the planar conformation of the macrochain, which obtains for polymers with the COO^-K^+ groups at pH < 7, is perturbed with increase of the pH by virtue of the formation of the ionic groups COO^-, between which there is a powerful electrostatic repulsion. At pH < 2 a blue-black polymer is precipitated. The introduction of an electrolyte (LiCl, NaCl, KCl) into the solution, leading to a suppression of the dissociation of the ionogenic COO^-K^+ groups and the subsequent decrease of the repulsion between then, has a lesser influence on the conformation. It is of interest that, when the concentration of the electrolyte was altered, the existence of an isosbestic point was noted but the latter vanished when the pH of the medium was altered.[68] The character of the influence of the pH and the electrolyte on solutions of two other polymers is analogous and the difference observed in the shift of the maxima of the absorption spectra of the solutions has been explained by the different distances of the terminal COO^-K^+ groups from the main chain.[68] The salt-like PDA of this class can be synthesised only via the corresponding polymeric acids with subsequent formation of their salts in

the presence of alkalis. The monomeric potassium and sodium salts of the DA acids are incapable of topochemical polymerisation.[67]

V. MONOMOLECULAR AND POLYMOLECULAR LAYERS BASED ON DIACETYLENES

The principles of the topochemical polymerisation of diacetylenes in single crystals examined earlier are also valid in the solid-phase polymerisation of DA packed into thin layers. Studies in this field have been vigorously prosecuted[237] in connection with the extensive possibilities for the practical application of such layers.

Monomeric monolayers were first obtained using tricosa-10,12-diynoic acid $C_{10}H_{21}C\equiv C-C\equiv C(CH_2)_8COOH$.[192] It was noted that, from the standpoint of the solubility of the layers, the cadmium salt of this acid, forming in the mono-layer a polymer whose structure is illustrated in Fig.14, is more suitable as regards the stability of the layers. The method of preparation of the monomolecular and polymolecular layers has been described†.[238] the monomolecular or polymolecular layers of the monomers satisfied the criteria for topochemical polymerisation and polymerised under ultraviolet irradiation via 1,4-addition without breakdown of the layer structure and with formation of ultrathin films, which are stable under laboratory storage conditions (oxygen, light, etc.).[192,239] The polymerisation of the macromolecular and polymolecular layers, like that of single crystals, can proceed thermally (below the melting point) and under the influence of high-energy radiation.[224]

Subsequently layers based on a whole series of asymmetrically substituted DA (XIII) were obtained similarly and then investigated:

$$CH_3(CH_2)_m-C\equiv C-C\equiv C-(CH_2)_nCOOH\ ;$$
(XIII)

m = 4, 7, 9, 11, 13, or 15, n = 8;[190,191,240,241] m = 2–15, n = 0, 2, 3, or 8:[242] DA with $R^1 = (CH_2)_{11}CH_2$ and R^2 = CH_2OH or COOH.[224] The monomers synthesised exhibit different capacities for the formation of monolayers and for polymerisation in the latter (Table 8).[216,239] It has been observed that the polymerisation of DA in monolayers, initiated by ultraviolet radiation, must be carried out in an inert atmosphere, since the reaction in oxygen leads to the formation of ozone under the influence of which the polymer chains are ruptured.[190,243] As a result of this, the side chains replace the main chains and thereby expand the monolayer, disrupting it.[190] It has been noted that the stability of layers increases with increase in the m/n ratio in compound (XIII). The layers are stronger when the aqueous phase on which the film is formed contains the Cd^{2+}, Ba^{2+}, Ca^{2+}, Fe^{3+}, or Al^{3+} ions.[242]

Polymerisation results in contraction, the extent of which makes it possible to infer the degree of conversion. The change in the degree of conversion was compared with the change in the optical density in the electronic spectra and with the position of the maximum in the absorption spectra.[190,191,240] It has been shown[190,191] that diacetylenes having the general formula (XIII) (m = 11, 13, 15; n = 8) polymerise rapidly in a monolayer at 20 °C (ultraviolet radiation). For m = 9, the polymerisation proceeds only at 2 °C, while acids with still shorter chains (m = 4.7) do not polymerise under such conditions. With increase in the pH of the aqueous phase, the rate of polymerisation increases when the lithium, sodium, and potassium salts of the acid are employed. The use of the Be^{2+}, Cd^{2+}, and Ba^{2+} ions[190,191] and Ca^{2+} and Mg^{2+} ions[190,243] perturbs the packing of the monomer molecules in the layer and suppresses the polymerisation process at high pH. With decrease of pH to below 6 (by adding HCl), the polymerisation proceeds to completion also in the presence of bivalent ions.[191]

Remarks: [1]+++ = dark-blue after less than 10 s; ++ = dark-blue after 10–30 s; + = dark-red after more than 2 min; − = no reaction. [2]Phase transition at 46 °C. [3]There are two modifications with different reactivities.

The study of the acid $CH_3(CH_2)_{17}C\equiv C-C\equiv C-COOH$ and of a series of its salts (NH_4^+, Ag^+, Na^+, Cd^{2+}, Cu^{2+}, Hg^{2+}, and Mn^{2+}) with the aid of optical and infrared spectroscopy and EPR showed that the acid itself and its silver and ammonium salts polymerise in the polymolecular layers (the PDA have respectively λ_{max} = 670 and 635 nm), the topochemical polymerisation of the cadmium, sodium, and manganese salts does not occur, while the polymerisation of the copper and mercury salts is accompanied by the decarboxylation of the DA.[244,245] The non-linear optical susceptibility of the blue polymeric ammonium salt is the same as that of the PDA with a $-(C\equiv C)_2-$ group in the centre of the aliphatic chain.[245]

In the polymolecular layers the alkyl side substituents of the monomers (XIII) (m = 2–15, n = 0, 2, 3, 8) are inclined at an angle of 48–63° relative to the support in each monolayer. During polymerisation, the substituents become almost perpendicular to the surface of the support, which results in the observation of the phase transition accompanied by a hypsochromic shift of the maximum in the absorption spectrum.[242]

According to X-ray diffraction and electron microscope data, the PDA chains are extended in the monolayer parallel to the support, while the layers have the crystalline domain structure and are made up of a mosaic of blocks or crystallites. The average size of the domain in which there is a homogeneous orientation of the main PDA chains depends on the conditions of the preparation of the layers and is of the order of several μm.[190,200,239,246,247] In a two-layer and multilayer membrane both monolayers retain the individual morphology of the crystallites.[248,249] Various modifications of the monomeric and blue polymeric layers as well as the transitions between these modifications have been investigated by electron microscopy (Fig.15).[250]

A crystalline dichroic fibre with a thickness of the order of several micrometers has been obtained by withdrawing from the surface of water a PDA acid monolayer. In these fibres the long lateral paraffinic chains, deviating from the polymer units, are oriented at right angles to the fibre axis and form crystallites which are packed at random across the fibre.[190] The tensile stress in the PDA fibres is comparable to that for the usual non-oriented polymers and the modulus of extension is high, due to the high degree of crystallinity. An increase in the size of the crystallites is then accompanied by an increase of the modulus.[251]

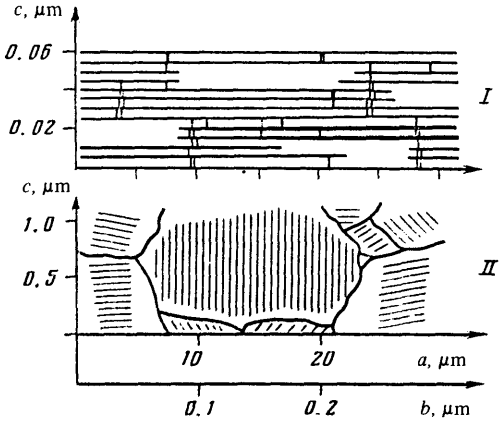

Figure 15. A model of the polymolecular layers based on $CH_3(CH_2)_nC{\equiv}C{-}C{\equiv}C(CH_2)_8COOH$ at right angles (I) and parallel (II) to the specimen; *A*) and *B*) DA; *A'*) and *B'*) PDA; *A*) and *A'*) the low-temperature phase; *B*) and *B'*) the high-temperature phase ($t > 60$ °C). The dimensions of the low-temperature (*A* and *A'*) phase (*a*) and the high-temperature (*B* and *B'*) phase (*b*) are indicated along the horizontal axes. Sections with parallel cross-hatching represent identically oriented planes.[250]

Polymolecular layers have been used to determine the quantum yield ϕ of the photochemical polymerisation of DA. The specimens used were films deposited on quartz plates and consisting of 32 monolayers of the diynoic acids (XIII) ($m = 9$, 11, 13; $n = 8$). The initial value of ϕ (the number of DA molecules which have reacted for each absorbed light quantum) is 10–14, so the polymerisation has the character of a chain reaction. With increased degree of conversion, ϕ falls rapidly for all the monomers investigated.[252]

On the basis of the results of the study of the processes involving the photochemical topochemical polymerisation of diacetylenic acids in polymolecular layers, sensitised by the surface-active cyanine,[246,253] acrydine, and anthraquinone[255] dyes, models have been proposed for the sensitised photochemical polymerisation of DA.[246,253–255] The quantum yield ϕ depends on the amount of sensitiser, depends only slightly on temperature, and is independent of the light intensity.[246] The photochemical topochemical polymerisation is initiated solely by ultraviolet light with $\lambda \leq 313$ nm. After the formation of small amounts of PDA, the polymerisation occurred in the range $400 < \lambda < 500$ nm.[256] The observed effect of the self-sensitisation of the photochemical topochemical polymerisation of the polymolecular layers has been explained by the generation of the PDA chains of highly mobile charge carriers, which activate the centre capable of polymerisation present at the end of the chain, ensuring further chain propagation.[256]

For the polymerised polymolecular layers of the cadmium salts of the DA acid $CH_3(CH_2)_{11}{-}C{\equiv}C{-}C{\equiv}C{-}(CH_2)_8COOH$, a thermochromic transition has been observed (Fig.16).[247]

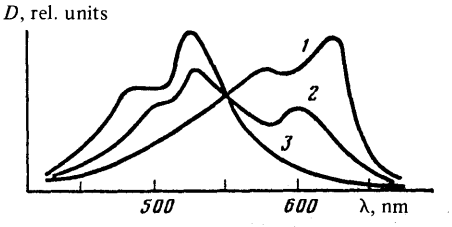

Figure 16. The thermochromic transition in polymolecular layers of the cadmium salts of the PDA acid $CH_3(CH_2)_{11}{-}C{\equiv}C{-}C{\equiv}C{-}(CH_2)_8COOH$; temperature (°C): 1) 23; 2) 52; 3) 91.[247]

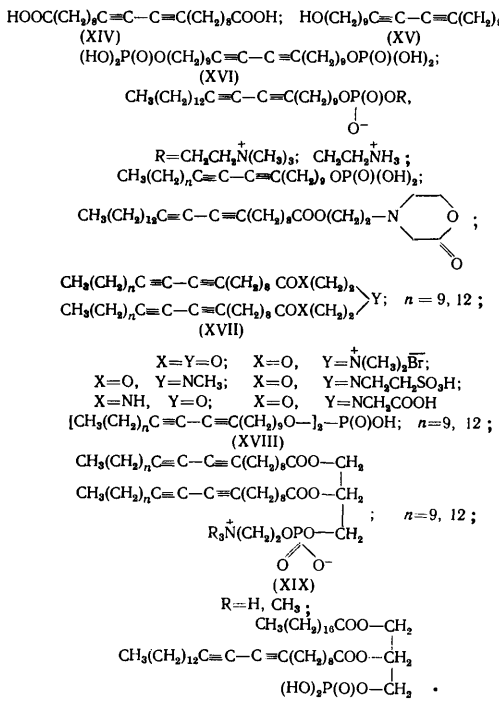
Apart from the monomolecular and polymolecular layers based on individual acids and their salts, polymolecular layers made up of mixtures of different acids and their cadmium salts have been investigated. An increase in the stability of mixed polymolecular layers based on the cadium salts of pentacosa-10,12-diynoic and arachidic acids (the latter is inactive in topochemical polymerisation) has been observed relative to the stability of polymolecular layers of the pure diynoic acid. In mixed layers the components form individual domains whose structure resembles that of the monolayers of the corresponding pure components. At a low concentration pentacosa-10,12-diynoic acid forms domains whose size is <0.1 μm, while the second component forms large domains whose size extends to several μm. It is of interest that, with increase of the concentration of the diynoic acid, the dimensions of its domains also increase but the degree of conversion nevertheless falls.[257] Polymolecular layers of the cadmium salts of tricosa-10,12-diynoic and tricosa-4,6-diynoic (less reactive) acids also separate into phases, but, in contrast to the previous pair of acids, another picture is observed: when the concentration of one of the components exceeds 50%, the polymolecular layer consists of a mixture of domains of this pure component and of domains of a crystalline complex of the acid components in 1 : 1 proportions.[257]

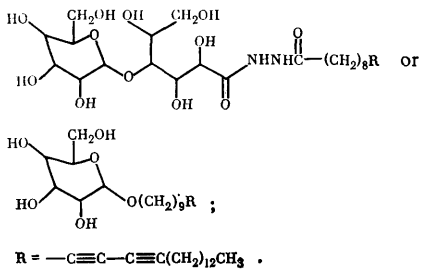
It has been suggested that the thickness of the polymolecular layers based on DA acids could be determined from the standard bond lengths and valence angles. However, the lack of validity of this approach owing to the ambiguity in the conformations of the individual CH_2 groups of the paraffinic moieties of the diacetylenic acids has been demonstrated.[250]

The chiral DA–$CH_3(CH_2)_{11}{-}C{\equiv}C{-}C{\equiv}C{-}(CH_2)_8CONH{-}\overset{*}{C}H(CH_3){-}C_6H_5$ polymerises rapidly in polymolecular layers on irradiation with ultraviolet light and X-rays. Even under the influence of scattered laboratory light, the topochemical polymerisation of layers of this monomer at the air/water interface takes place in seconds.[198]

The development of the principles governing the preparation of strong monomolecular and polymolecular layers based on diacetylenic acids and their salts and the study of the topochemical polymerisation of diacetylenes made it possible to obtain a whole series of polymeric membranes and DA-based liposomes modelling the natural lipids and certain functional compounds:[258-264]



The polymerisation of the diacetylenic phosphorylcholine (XIX) (R = CH_3, n = 12) initiated by ultraviolet light (argon) in a monolayer leads to the formation of a polymeric phospholipid coloured red and exhibiting optical activity.[265-267] The topochemical polymerisation of phospholipids containing one of two residues of tricosa-10,12-diynoic acid has been investigated on the basis of the contraction of the layers and various types of structures corresponding to phospholipid polymers have been examined taking into account the intra- and intermolecular cross-links involving both one and two acyl groups containing the C≡C–C≡C bond.[266,267] Spherical multilayer lipsomes 4000 Å in diameter have been obtained by hydrolysing suspensions of diacetylenic phospholipids.[266] Structures modelling liposomes have been obtained also by treating the DA (XVI) with ultrasound in water in the presence of cholesterol with subsequent ultraviolet irradiation.[236] On the other hand, on treatment with ultrasound, the symmetrical DA (XIV) and (XV) form crystalline suspensions in water, which do not model liposomes.[236]



The phototopochemical polymerisations of the lipid DA (XVII) [n = 9, X = O, Y = $\overset{+}{N}(CH_3)_2Cl^-$], (XVIII) ($n$ = 9), and (XIX) (n = 9, R = CH_3) have been compared. It has been shown that the capacity of compound (XIX) for polymerisation is appreciably lower than that of the other two DA. The quantum yield of the phototopochemical polymerisation of compound (XVII) is ~6500 times higher than for compound (XIX).[268]

Naturally non-polymerising lipids {distearyl- and dioleylphosphatidylcholine and cholesterol combined with lipids having DA groups in the chain, for example (XIX) (n = 9, R = CH_3) and (XVII) (n = 9, X = O, Y = $\overset{+}{N}(CH_3)_2Cl^-$; n = 12, X = O, Y = $\overset{+}{N}(CH_3)_2Br^-$; n = 12, X = O, Y = $-(CH_2)_2O(CH_2)_2O(CH_2)_2O(CH_2)_2-$)} form mixed monomolecular and bimolecular layers, consisting of domains, or homogeneous membranes, depending on the type of the monomeric and natural lipid.[269-272] It has been observed that, when systems of this kind are acted upon by the enzyme phospholipase A_2, only the natural lipids are hydrolysed and in layers with separated phases the rate of cleavage is the same as in layers comprising one of the natural lipids; the rate is much lower in homogeneous layers.[270]

The biological models of two-layer lipid membranes synthesised in this way have been investigated by electronic spectroscopy for chemical analysis (ESCA). The presence on the surface of the layers of the elements (P, N, Br, and C) which enter into the composition of the functional group has been demonstrated. The angle of wetting by water θ, which decreases when the monolayers with a hydrophobic surface are kept in air, has been determined. It has been observed that for hydrophilic polymers the nature of the functional groups has less influence on θ for the monolayer than in the case of a hydrophobic polymer.[273]

The preparation of thin films based on PDA with the aid of other methods without employing the principles governing the formation of Langmuir–Blodgett monolayers has been described. These films also demonstrate the specific character of the properties of the polymers.

Thus a thermochromic colour change (at 455 K) from green to yellow has been observed in amorphous films of poly-3BCMU obtained by precipitation from dilute chloroform solutions of PDA with hexane and subsequent drying. The reverse colour change occurs at 435 K. It has been shown by DSC and infrared spectroscopy that the thermochromism is associated with a one-dimensional order ↔ disorder transition, which is determined by the disruption or formation of hydrogen bonds along the polydiacetylene chain containing the C(O)O and NH groups.[274] This explanation of the phenomenon is similar to that given when the thermochromism of single crystals of the same nature was considered.[65]

Thin PDA films with R = $(CH_2)_nOCONHC_6H_5$ (n = 1, 4) and R = CH_2OH have been obtained by an epitaxial mechanism on the surfaces of alkali metal halide single crystals. It has been shown by electron microscopy and electron diffraction that the films consist of highly oriented lamellar single crystals extended in the direction of their maximum dimension along the [110] crystallographic direction on the support.[275]

VI. MECHANICAL PROPERTIES OF POLYDIACETYLENES

A negative coefficient of thermal expansion α has been observed for a series of PDA single crystals along the direction of the polymer chains. Thus $\alpha = -(1.686 \pm 0.039) \times 10^{-5} - (1.35 \pm 0.18) \times 10^{-7}t$ (t in deg C) for a freshly prepared poly-HDDU specimen[53,276] in the temperature range

$t = -50-100$ °C, diminishing by an order of magnitude after evaporation of the dioxan occluded in the single crystal. The coefficient of thermal expansion of the same polymer in the direction of the chain has been determined in another study[277] as -2.0×10^{-5} K^{-1}. For poly-DCHD, $\alpha = (-2.38 \pm 0.07) \times 10^{-5}$ K^{-1}.[70] The coefficient α for poly-TS is negative below 70 K and positive above this temperature, the change in the coefficient within the range of hydrostatic pressures 0–3.43 kbar not exceeding the error of measurement.[278]

Negative values of α had been observed earlier for certain partly crystalline polymers, for example, polyethylene,[279] only with the aid of X-ray studies, since the negative value of α characteristic of the crystalline phase, is masked by the significantly more positive α for the amorphous component. Explanations of the anomalous behaviour of the coefficient α, involving the use of the principle that the amplitude of the torsional movement (torsional vibration) of the chain increases with temperature,[279] have been put forward.[53,277]

It has been concluded[276] that the sign of the coefficient α is not determined by the change in the delocalisation of π electrons arising owing to the thermal conformational fluctuations or the reversible formation of defects, since the theoretically possible calculated contribution to the coefficient should be much less than the value actually observed. Subsequently[278] the unusual behaviour of the coefficient α was analysed in terms of an equation including the Grueneisen parameter and it was postulated that this behaviour is caused by the characteristic properties of the PDA chain.

The positive value of the coefficient observed solely for the polymer based on compound (IX) ($m = n = 4$) in the temperature range $-50-40$ °C ($\alpha = 4.46 \times 10^{-6}$ K^{-1}) has been attributed[179] to the presence of $-(C\equiv C)_2-$ groups which failed to react, which leads to disordering of the chains and the conversion of the polymer into an amorphous form.

The mechanical properties of traditional polymers are determined to a large extent by the presence in them of structural and phase defects. For very perfect PDA crystals made up of extended macrochains, there is a possibility of particularly high strength properties of the polymer molecules within the macrovolume of the specimen with the simultaneous manifestation of a pronounced anisotropy: the modulus in the direction of chains is much higher than that for the direction at right angles to the chains.[280]

The dynamic and static moduli of extension of the crystalline fibres of poly-HDDU, obtained in the region of elastic deformations, are virtually identical (~4.5×10^4 N mm^{-2}).[52] The observed deviation from Hooke's law (the decrease of the modulus by ~3 and 6% on 3 and 4% deformation respectively) is analogous to the behaviour of other filamental crystals, for example, those of iron, quartz, etc. The tensile strength, reaching 1.7×10^3 N mm^{-2}, usually increases with decrease of the length of the fibre and is approximately proportional to the reciprocal of the fibre diameter. The latter factors can be accounted for by the existence on the surface of the fibre (or in its vicinity) of a small number of defects, which control the disruption process. Indeed photographs obtained with the aid of a scanning electron microscope demonstrated the formation of a crack on the surface of the crystal after the tensile strength has been exceeded, the crack spreading initially to a certain depth and then along the fibre. As a result of this, the crystal is partly cleaved and there is an irreversible slip of its two components relative to one another.[52]

The tensile strength of PDA with R = $CH_2OCONHC_2H_5$ (diameter 10–100 μm, length up to 5 cm) is also proportional to the reciprocal of the fibre diameter. The tensile strength, which increases with increase in the degree of conversion, amounted to $(0.6-1.4) \times 10^3$ N mm^{-2} for a relative elongation of 12–20%, but in a number of instances it reached 6.2×10^4 N mm^{-2}. Creep was not observed in the fibres.[281]

Poly-TS specimens increase in length by 4% before they are ruptured: the corresponding tensile strength is 2.0×10^3 N mm^{-2}.[282] The degree of conversion in the thermal polymerisation of TS (60 °C) has been followed by measuring the frequencies of phonons with wave vectors parallel to the *a*, *b*, and *c* axes of the crystal. It has been shown that the density varies from 1.404 to 1.483 g cm^{-2}, while the modulus of elasticity increases in the direction of the chains from 0.97×10^4 to 4.38×10^4 N mm^{-2} on passing from the monomer to the polymer.[58]

It has been observed that the Raman spectra of the deformed and undeformed regions of poly-TS are identical[280,283] and the *b* axis of the unit cell, which is the direction of the main PDA chain, should therefore remain unchanged. A transition from the monoclinic to the triclinic unit cell has been observed in the deformed regions of poly-TS.[280] Under these conditions, the *a* axis is unchanged, while the *b* axis and the angle β are altered, which diminishes the volume of the cell by ~7% and leads to closer packing of the polymer chains in the deformed regions.[36] The slip planes in the deformation of poly-TS crystals have been determined.[36,52]

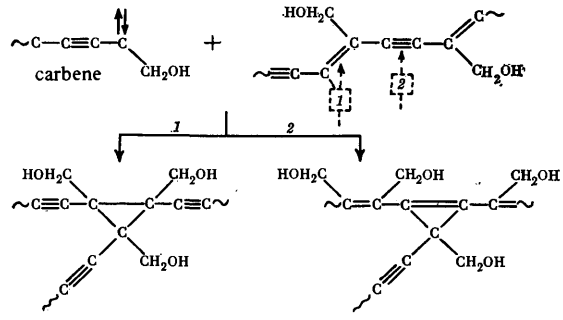
A ladder polymer based on compound (IX) ($m = n = 4$)[179,208] has a low modulus (5.5×10^3 N mm^{-2}) and tensile strength (2.2×10^2 N mm^{-2} (despite the existence of a dense cross-linked network. The reason for this is the disorder in the chains owing to the presence of $-(C\equiv C)_2-$ groups which have reacted incompletely (see Section III).[179] The tensile strength of DCHD is 0.6×10^3 N mm^{-2}.[70]

The morphology and mechanical properties of a fibre obtained from a polymerised DA layer have been investigated[271] (see Section V).

The high mechnical strength of many single-crystal PDA fibres enabled Young and Galiotis[284] to suggest that fibres of this type be used in thermoplastic and thermally hardening composite materials with high strengths and rigidities. A comparative study with the aid of resonance Raman spectroscopy (Kr laser, $\lambda = 676$ nm) of poly-DCHD fibres and fibre joints overed by an epoxy-resin (hardened with an amine) showed that the strength of the bond between the fibres and the epoxy-resin is fairly high and the tensile strength at the joint is comparable to that of a whole fibre.[285]

VII. CHEMICAL PROPERTIES OF POLYDIACETYLENES

According to mass-spectrometric data and elemental analysis, the CH_2OH side groups in the HD polymers obtained in air or in argon exhibit a high chemical stability in the course of polymerisation.[30] However, in the solid-phase polymerisation of HD crystals containing occluded oxygen, the reactive terminal carbene radicals, which propagate the polymerisation reaction, may be oxidised with formation of the ~=C(CH_2OH)–C≡C–C(CH_2OH)=O end groups. The polymerisation of HD in argon leads to a high conversion (>20%) in intermolecular interactions between the terminal carbene radicals and the multiple bonds in the polymer chains, which results in cross-linking of the polymer formed[30] in accordance with the scheme



--[ ]--► possible direction of attack by the carbene and the corresponding reaction products.

A low chemical stability in thermal polymerisation has been observed for the $R-(C\equiv C)_3-R$ polymers ($R = CH_2OH$ or $CH_2OSO_2C_6H_4CH_3$-*p*) (Table 5).[193]

The thermal stabilities of various types of PDA have been investigated. It has been observed that, despite the polyconjugated main chain, the crystalline PDA do not possess a high thermal stability owing to the presence in the macromolecules of side substituents which are unstable at a high temperature. Their thermal decomposition begins as a rule at a temperature not exceeding 200–215 °C. For example, the PDA obtained by the thermal polymerisation of TS at 60 °C would not decompose on rapid heating to 210 °C; prolonged heating induces decomposition at a much lower temperature (110 °C). The thermal decomposition of poly-TS specimens obtained at 70° and 80 °C takes place immediately after the attainment of 110 °C.[36] Mass-spectrometric studies of the molecular structure of poly-TS as well as investigation of its degradation process suggested a mechanism for the low-temperature decomposition.[40] Gas-chromatographic and mass-spectrometric studies of the products of the pyrolysis of this polymer at 400–1000 °C have shown that the main pyrolysis products are triacetylene and toluene-*p*-sulphonic acid.[40]

The poly-BPG, whose polyconjugated main chain is doubled by the chain of the side substituent coiled around it, has a higher thermal stability. The polymer loses 2 wt.% at 350 °C, 13 wt.% at 400 °C, 30 wt.% at 450 °C, and 39 wt.% at 500 °C.[103] A cyclo-ladder polymer based on compound (IX) ($m = n = 4$), possessing a dense cross-linked network, has been synthesised.[179] However, an improvement in thermal stability was not achieved primarily because of additional weight loss due to the evolution at 150 °C of the solvent cocrystallised with the initial monomer. Apart from the weight loss mentioned above at 150 °C (9 wt.%), the thermogravimetric curve shows a sharp weight loss beginning at 400 °C and reaching a maximum (48 wt.%) at 470 °C.[179]

Poly-DCHD exhibits a higher thermal stability, probably owing to the aromatic carbazolyl nuclei, being stable to 300 °C and losing 6.5 wt.% at 400 °C. However, exothermic decomposition, leading to a weight loss of 62% at 475 °C, begins between 400° and 450 °C.[70]

As in the case of polyalkynes, obtained by liquid-phase polymerisation, the polyhexa-2,4-diyne synthesised by topochemical polymerisation is vigorously oxidised by oxygen.[24] Accoring to Chance et al.,[286] the hypsochromic shift in the optical spectrum of a solution of poly-3BCMU arises partly owing to chemical defects which perturb the conjugation and appear as a result of the slow (in the course of months) oxidation of the PDA chains.

In addition, like other polyacetylenes having multiple bonds within the chain, the PDA can combine with ozone. For example, it has been observed that ultraviolet radiation causes the disruption of PDA monolayers[190,243] and decolorisation of PDA solutions[287] owing to the interaction of the main polyconjugated chains of the polymers with the ozone formed and subsequent decomposition of the ozonides.

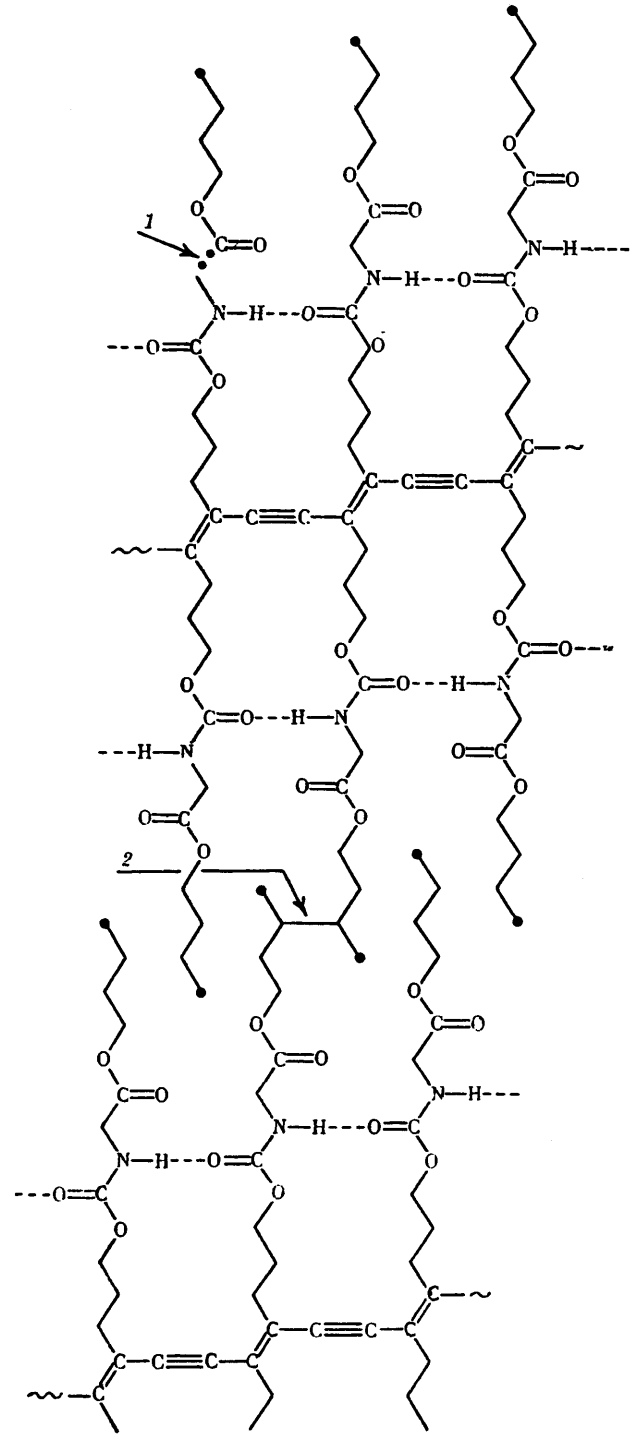


Figure 17. Schematic illustration of the decomposition of poly-3BCMU under the influence of γ-radiation: 1) disruption; 2) cross-linking.[290]

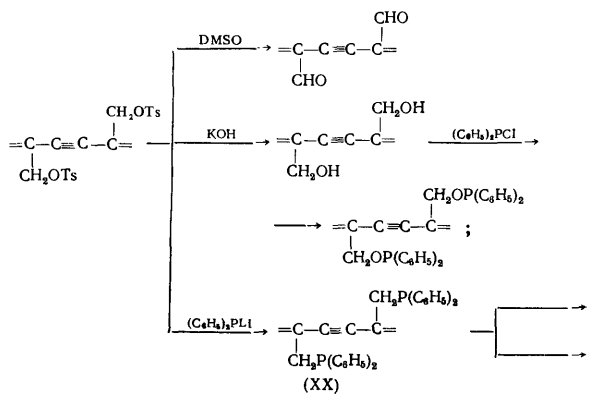
PDA washed free of monomers,[193] PDA double layers,[288] and a TS single crystal, subsequently polymerised via a topochemical polymerisation mechanism,[289] have been doped with iodine. The conductivity of the specimens then increases by several orders of magnitude but neither the mechanism of the doping process nor the structure of the products of the interaction of PDA with iodine have been studied in detail.

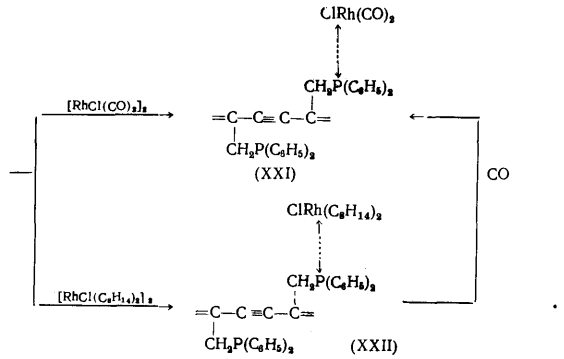
Investigation of the radiation stability of poly-3BCMU (^{60}Co γ-radiation, 20 °C, vacuum) showed that crystalline PDA remains soluble after irradiation with a dose of 50 Mrad. In amorphous PDA, obtained by dissolving and precipitating crystalline PDA, the gel fraction is formed at 3 Mrad, while for a dose of 200 Mrad the polymer loses its solubility completely.[290] It has been noted that the highly conjugated main chains do not undergo cross linking, while irradiation leads to the degradation of the side chains and their cross linking by intermolecular bonds (Fig.17). The marked decrease of $\bar{M}_n$ and the widening of the MWD with increase in the degree of conversion from 20.9 to 57.7% probably take place as a result of degradation in the course of polymerisation (Table 7).[229]

Using the chemical structure of the side substituents, PDA has been modified. Charge-transfer complexes between electron acceptors and the monomeric DA containing the anthryl or carbazolyl groups have been obtained.[69] However, it has been shown[64] that the monomeric charge-transfer complexes based on 1,6-bis(3-pyrenyloxy)hexa-2,4-diyne and electron acceptors (tetracyanoquinodimethane, tetracyanoethylene, trinitrofluorenone, etc.) do not polymerise in the solid phase. Nor are charge transfer complexes formed on treating a suspension of PDA in CH_2Cl_2 with a solution of tetracyanoquinodimethane. Only on mixing solutions of a pyrene-containing PDA and acceptors, diluted with HMP, are intensely coloured 1:1 or 1:2 complexes (depending on the type of acceptors) precipitated.[64] The equilibrium constants for the formation of the charge-transfer complexes investigated are higher than for the model charge-transfer complexes with the corresponding monofunctional compounds.

The presence of labile toluene-*p*-sulphonyl groups made it possible to carry out reactions between poly-TS and $LiP(C_6H_5)_2$ with formation of a fully phosphinated dark-brown amorphous polymer (XX) having $CH_2P(C_6H_5)_2$ side groups.[291, 292] The photomicrographs obtained with the aid of a scanning electron microscope showed a loose surface of the specimen with its area not quite so large as that of silica gel. The toluene-*p*-sulphonyloxymethyl groups have been replaced via polymer-analogue reactions by CHO, CH_2OH, and $CH_2OP(C_6H_5)_2$ groups.[292]

The study of the EPR spectra of a dry specimen of poly-TS with an attached spin label as well as specimens wetted with benzene and CCl_4 did not reveal a difference between the shapes of the spectra obtained.





Thus, in the given instance the nature of the solvent did not influence the behaviour of other molecules attached to the polymer chains.[277] The polymeric complexes $RhCl(CO)_2R'$ (XXI) and $RhCl(C_8H_{14})_2R'$ (XXII) (R' is one phosphine group in PDA)[291] have been obtained respectively by the reaction of compound (XX) with $[RhCl(CO)_2]_2$ and $[RhCl(C_8H_{14})_2]_2$ (C_8H_{14} is cyclo-octene).[291] In the presence of the complex (XXI) mono-olefins are hydrogenated by cyclohexa-1,3-diene is relatively inactive. In the presence of the complex (XXII) cyclohexa-1,3-diene is hydrogenated more rapidly to acrylonitrile than are α-olefins. Benzene is also hydrogenated at a measurable rate at atmospheric pressure. On the other hand, the "monomeric" complex $RhCl[P(C_6H_5)_3]_3$ does not catalyse the hydrogenation of conjugated olefins at atmospheric pressure. The high reactivity of the phosphinated polymeric complex is apparently associated with the increased rigidity of the polymer chains, which ensures the stabilisation of two coordination sites and prevents the formation of the chelate. Thus the possibility arises of activating both hydrogen atoms and the conjugated olefin.[291]

VIII. POLYMERISATION OF LINEAR COMPOUNDS WITH SEPARATED $-C\equiv C-C\equiv C-$ GROUPS

Linear DA of the types

$$R-C\equiv C-C\equiv C-(CH_2)_2-C\equiv C-C\equiv C-R,$$
$$R-C\equiv C-C\equiv C-(CH_2)_2-C\equiv C-C\equiv C-(CH_2)_2-C\equiv C-C\equiv C-R,$$
$$R-C\equiv C-C\equiv C-(CH_2)_2-C\equiv C-C\equiv C-C\equiv C-C\equiv C-(CH_2)_2-C\equiv C-C\equiv C-R,$$
$$R=CH_2OSO_2C_6H_4CH_3\text{-}p,\ CH_2OCONHR'(R'=CH_3,\ C_2H_5,\ C_6H_5),$$

have been proposed as temperature–time indicators.[219–293]

At 100–200 °C or under the influence of ultraviolet light, the crystalline $H_3C-C\equiv C-C\equiv C-Hg-C\equiv C-C\equiv C-C\equiv C-CH_3$ polymerises up to 100% conversion (the yield has been determined gravimetrically) with formation of violet, blue, and even red-brown insoluble crystals. The S-shaped conversion curves show an induction period, as in the case of the solid-phase polymerisation of TS. The authors[294] believe that this involves the formation reaction of a ladder polymer (Fig.18).

The presence of the $C\equiv C-C\equiv C$ groups in the long polymer chains does not rule out the possibility of the reaction involving the 1,4-cleavage of the diacetylenic groups in such chains via the mechanism described above for low-molecular-weight DA. Indeed, the oxidative condensation of nona-1,7-diyne[176,295] and dodeca-1,11-diyne[176,177,296] yielded the corresponding crystalline macromers containing reactive groups in the chain.

$$HC\equiv C[(CH_2)_mC\equiv C-C\equiv C]_n(CH_2)_mC\equiv CH;$$
$$m=5,\ 8.$$

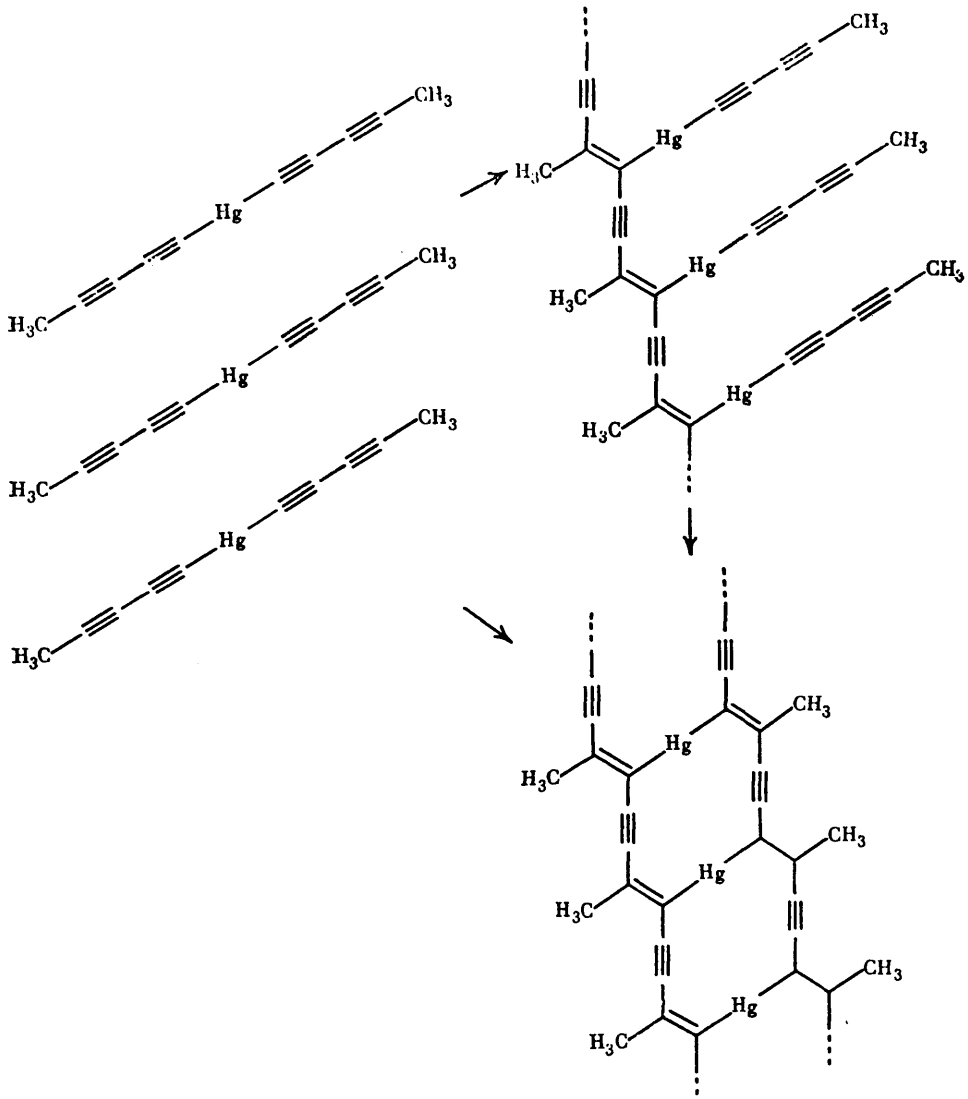


Figure 18.

A cross-linked polymer is formed under the influence of ^{60}Co γ-radiation in the crystals of these macromonomers via the topochemical polymerisation mechanism. The crystal unit cell parameters of the initial macromonomer and the cross-linked product have been determined (Table 3) and the possible polymer structure have been examined. It has been shown by ^{13}C NMR that the cross-linking is incomplete and that $=C-C\equiv C-C=$ bridges are formed during the reaction, since the signals characteristic of the butatrienes $C=C=C=C$ have not been observed in the range 200–220 p.p.m.[297]

An analogous reaction occurs also in less ordered polymeric systems. Thus the reactions of glycols containing DA groups with di-isocyanates or adipic acid dichloride gave rise to the corresponding soluble polyurethanes and a polyester (Table 9).[298,299] Owing to the presence of the reactive DA groups, the films made up of the heterochain polymer synthesised are coloured under the influence of ultraviolet light or heating to give red or orange tints with formation of a three-dimensional network. Polyurethanes based on hexamethylene di-isocyanate show the highest reactivity (Table 8), being coloured even when the specimens are merely pressed (at a pressure of 100–200 kg cm^{-2}).[299] Proof of the occurrence of the reaction in the more ordered regions is provided by the formation of a coloured gel from a precipitate of polyurethanes several seconds after the start of ultraviolet irradiation, while irradiation of solutions of these polymers leads to the appearance of only a weak brown colour after 30 min. It has been observed that the cross-linking of solid polymers is catalysed by radical initiators (benzoyl peroxide, azobisisobutyronitrile) and is inhibited by hydroquinone. Solutions of polymers do not exhibit this type of behaviour.[299]

The polyurethane $-[-NH(CH_2)_6-NH-\overset{\overset{O}{\|}}{C}-O-CH_2-(C\equiv C)_3-CH_2-O-\overset{\overset{O}{\|}}{C}-]_n-$, obtained from octa-2,4,6-triyne-1,8-diol and hexamethylene di-isocyanate, also gives rise to cross-linked products in yields of 75 and 13% respectively on heating (70 °C, 48 h) or ultraviolet irradiation (3 h).[300]

Table 9. The properties of heterochain polymers with the $-(C\equiv C)_2-$ groups in the main chain.[298,299]

Polymer	M.p., °C[1]	Appearance of colour	
		u.v. irradiation	heating
	~150	yellow	colourless
	~130	yellow	colourless
	138	purple	purple
	149	red	red
	~130	orange	yellow-red

[1]With decomposition; DSC, 32 K min^{-1}. [2]After 1 h at 110 °C.

---o0o---

The data examined indicate a vigorous development of the research into the polymerisation of monomers with conjugated diacetylenic groups and also the wide-scale investigation of a whole set of specific properties of the polymers. The fact that the methods employed to obtain the polydiacetylenes are in essence the methods for the synthesis of polyconjugated polymers with small numbers of defects or no defects at all, which serve as effective models for the study of the physics of one-dimensional systems, is of special interest. The synthesis of tens of monomeric and oligomeric compounds of different classes, the study of their capacity for topochemical polymerisation, and the study of the structure of the polymerisation products formed revealed general rules obeyed by the polymerisation of compounds containing the $-(C\equiv C)_2-$ groups.

Nevertheless many problems, for example, the elucidation of the causes of the manifestiation of different reactivities of DA having similar electronic and steric structures, have remained unsolved. There is no doubt that further development of studies in the field of the solid-phase polymerisation of diacetylenes will lead to the creation of new types of oligomeric-polymeric materials with a specific structure and to a considerable expansion of their practical applications.

Physical Chemistry of the Polycondensation of Polyfunctional Nucleophilic Compounds with Polycarboxylic Acid Derivatives

N.V.Karyakin, I.B.Rabinovich, and A.L.Rusanov

The literature data on the kinetic and thermodynamic characteristics of the polycondensation of aromatic diols, diamines, tetramines, and their derivatives with tetracarboxylic acid dianhydrides and dicarboxylic acid dihalides in amide solvents are surveyed. Attention is concentrated on the analysis of the dependence of the physicochemical parameters of the polycondensation on the nature of the nucleophile and electrophile.
The bibliography includes 157 references.

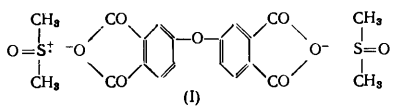
I. INTRODUCTION

Polycondensation in solution is nowadays widely used in industrial practice; as regards the industrial application of various polycondensation processes, this procedure is inferior only to polycondensation in the melt[1] (p.130). Aromatic polyamides, polyarylates, and other thermostable polymers are synthesised in solution by low-temperature polycondensation methods. This type of polycondensation began to be widely employed also in connection with the development of a two-stage method for the synthesis of polyheteroarylenes. In this synthesis, intermediate or so-called prepolymers are obtained in the first stage by the polycondensation of aromatic diamines and their derivatives with carboxylic acid dianhydrides or dihalides and are then converted into the final heterocyclochain polymers in the second stage of the process by solid-phase cyclodehydration at elevated temperatures.

Numerous studies of the low-temperature polycondensation processes in solution have been described in the literature; in the present review an attempt is made to give a systematic account and a survey of the results of these investigations.

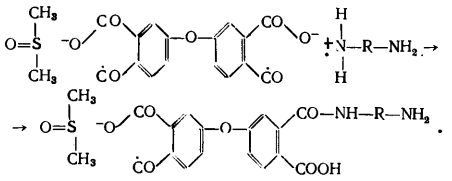
II. THE INFLUENCE OF SOLVENTS ON LOW-TEMPERATURE POLYCONDENSATION PROCESSES

In considering the mechanism of polycondensation in solution, many workers have suggested the formation of complexes between the polycarboxylic acid dianhydrides, and particularly dicarboxylic acid dihalides, with polar solvents.[2-8] For example, in a study of the reactions of benzidine, di(4-aminophenyl)methane, and di(4-aminophenyl)-ether with the dianhydride of oxydi(3,4-dicarboxybenzene) in solution in dimethylsulphoxide (DMSO), Kolesnikov et al.[8] suggested the formation of an anhydride–solvent adduct having the structure



(I)

The higher the nucleophilicity of the solvent, the more stable is the complex of this kind and the higher its concentration in solution. This can apparently explain the difference between the molecular weights of the polyamidoacids obtained in different solvents other conditions being equal, which has been observed in two investigations.[2,7] The above complex reacts with a diamine to form a new adduct:

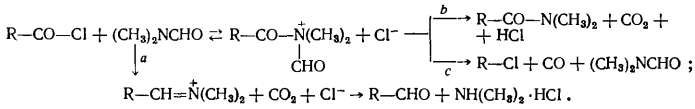


The transfer of one of the protons is responsible for the appearance of the amide bond and the formation of the polyamidoacid molecule.[5]

Boiko and Zhubanov[9] and Efimova et al.[10] pointed out the possibility of isolating such complexes, and presented the results of comparative studies of the rates of their interaction with diamines in polar solvents. Complexes of the dianhydrides of pyromellitic acid (PMDA) and 3,6-endoethene-9-bicyclo-2,4-octane-1,2,9,10-tetracarboxylicacid {3,6-(9-endoethene)bicyclo[2.4]octane-1,2,9,10-tetracarboxylic acid?} (AB) with DMSO, *NN*-dimethylformamide (DMF), and *NN*-dimethylacetamide (DMA) were chosen as the objects of study. The amine components selected were *m*-phenylenediamine (*m*-PDA), di(4-aminophenyl)ether (DAPE), and di(4-aminophenyl)methane (DAPM). Both in the case of AB and PMDA (Fig.1), the rate of the process is higher than the rate of interaction of the corresponding complexes. The polarity of the solvent forming part of the complex exerts an appreciable influence under these conditions on the reactivity of the complex. Analogous conclusions have been reached in other studies[10-12] where it was shown by infrared spectroscopy that polyamide–solvent complexes, whose nature influences greatly the molecular weight of the polymer formed, arise in solution in DMSO.

The studies of the reactions involving the synthesis of aromatic polyamides with carboxylic acid dichlorides in solvents of the amide type have shown that DMF is entirely unsuitable for such purposes. The impossibility of obtaining

high-molecular-weight compounds in this solvent[13,14] and the sharp decrease of the viscosity of the reaction solution following the preliminary dissolution of the dihalides in other amide solvents indicates the occurrence of side reactions, the main one being the interaction of the acid dihalide with the amide solvent.[4,15-17] This problem has been examined in fair detail in a number of investigations[16-18] in relation to the interaction of a series of acid dihalides with DMF. Thus it has been established[18] that two types of salts can be formed simultaneously in solution of the carboxylic acid chloride in DMF as a consequence of the attack by the electrophilic centre of the chloride on the oxygen or nitrogen atom in DMF:



If the acid chloride in which the R–C bond is weakened by structural features participates in the reaction of DMF, the corresponding salts of the acid chloride with DMF undergo decarboxylation (pathway *a*) or decarbonylation (pathway *c*), which lead to the formation of an aldehyde or a chloralkane. On the other hand, when the chloride of an acid incapable of decarboxylation is made to react with DMF, then transamidation takes place under more severe conditions and leads to the formation of the dimethylamide of the corresponding acid (pathway *b*).

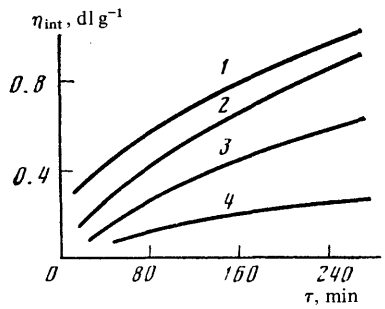


Figure 1. Dependence of the intrinsic viscosities of 0.5% DMF solutions of polyamidoacids obtained at T = 303 K via different reactions: 1) DAPE + AB; 2) DAPE + AB.DMSO; 3) DAPE + AB.DMA; 4) DAPE + AB.DMF (for the significance of the abbreviations, see text).[9]

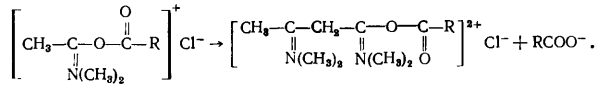
It has been shown[19] in relation to the reaction of aniline with acid halides of different structure in DMF and DMA that at room temperature the acylation of aniline in DMF leads to the formation not only of the corresponding anilides but also of considerable amounts (up to 50%) of *NN*-dimethyl-*N'*-phenylformamidine, which means that, when the reaction was carried out in DMF, it proceeds via the formation of the intermediate adducts (I) (Scheme 1) of the acid halides with DMF and the adduct formation reaction is reversible. When aniline is added to the system, the equilibrium is displaced towards the formation of an adduct the rate constant for the interaction of which with aniline is much higher than that for the acylation of aniline by the acid halide.

The sharp decrease in the molecular weight of the polymer following the preliminary dissolution of the acid halides in DMF and other polar solvents has been explained[20] by the occurrence of side reactions other than those provided for by Scheme (1). For example, such a reaction may be the self-condensation of the adduct of DMA with the acid halide in accordance with the scheme[10]



It has been demonstrated convincingly[16] in relation to the acylation of aniline by the dichloride of isophthalic acid in solution in DMA that the amount of aniline which has not reacted increases the longer the acid dichloride has been kept in DMA and also with increase in the concentration of the salt in the same solvent. Analogous results have been obtained likewise in the analysis of the conditions governing the synthesis of polyterephthalamide based on di(4-aminophenyl)ether.

It is believed[21] that oligoanhydrides can be formed in amide–salt solvents together with other reactions.[14,15] In this case the presence of metal chlorides in solution in the synthesis of aromatic polyamides induces, together with an increase in the solubility of the polymers, an increase in the chemical reactivity of the solvent towards the initial monomers. This diminishes the molecular weight of the polymer formed.[16] In order to obtain polymers with a high molecular weight, it is therefore necessary to seek ways of diminishing the contribution of the reactions involving the formation of complexes between the monomers and the solvent. Thus the possibility of employing reactive solvents has been demonstrated.[1] It has been proposed[22] that the difluorides be used instead of the more reactive dichlorides. In order to diminish the extent of complex formation, it is recommended that preliminary dissolution of the acid dihalides in the amide solvent be avoided.[4]

The conditions in the polycondensation process in the synthesis of aromatic polyamides in amide solvents have been analysed by Ivanov et al,[23] who showed, in particular, that an increase of the rate at which the measured amount of the dichloride is introduced and especially the use of a solid dichloride leads to the formation of a polyamide with a higher molecular weight. Analogous results have been obtained by other workers,[24-26] who found that the polymer with the maximum molecular weight is obtained when the dry dianhydride is added to the solution of the diamine in small portions. Changing the order in which the reactants are added does not make it possible to obtain solutions with a sufficiently high viscosity. Similar conclusions were reached by other investigators[27-29] in relation to the polycondensation reaction of phenolphthalein with terephthalic acid dichloride in various solvents and also by Krongauz et al,[4] who investigated the reaction of the dihydrazide and dichloride of di(4-carboxyphenyl) ether in solution in hexamethylphosphoramide.

Thus, as already mentioned by Sokolov[1] (p.144), a quantitative estimate of the reactivity of the solvent in relation to the initial monomers is very important. Several methods for such estimations have been proposed in the literature. For example, in the study of the characteristics of the low-temperature polyesterification in a series of solvents[30-33] and also in the study of the reaction of 2,2-di(3-chloro-4-hydroxyphenyl)propane with terephthalic acid dichloride in the presence of triethylamine,[34] a tendency towards a decrease of the molecular weight of the polyarylates with increase of the dielectric constant of the solvent was established. Another method for estimations

of this kind involves the study of the reactions with participation of model compounds in various solvents. This problem has been examined in detail in a monograph,[1] where the results of studies of the condensation reactions of aniline with the dichlorides of isophthalic and terephthalic acids are analysed.

According to Sokolov,[1] the thermochemical method is very convenient for the quantitative estimation of the relative reactivities of solvents in complex formation reactions with the starting materials. As an example, Table 1 presents the enthalpies of solution ΔH^0_{solv} of isophthalic acid dichloride in organic solvents obtained in a number of studies.[22,35,36] The markedly different values of ΔH^0_{solv} at 298 K indicate comparatively strong interactions of isophthalic acid dichloride with amide solvents and conversely weak interaction with all others. The latter is indicated also by the results of a study of the viscosity (density)—composition diagrams[35] for the isophthalic acid dichloride–tetrahydrofuran (THF) system at 323 K. Both these relations are linear over the entire composition range, which indicates the absence of a specific interaction between the components. The intrinsic viscosities of solutions of polyisophthalamide obtained in DMA and DMF are 1.5 and 0.07 dl g^{-1} respectively (c = 0.5 wt.%, T = 293 K). These results agree with data[14] obtained in the study of the reaction of aniline with isophthalic acid dichloride in DMF and DMA. It has been shown[14] that, when the reaction is carried out in DMF, up to 70% of the monoanilide is formed, while in DMA the content of the monoanilide does not exceed 2–5% under the same conditions.

Table 1. The enthalpies of solution ΔH^0_{solv} of isophthalic dichloride in organic solvents at 298 K.[35]

Solvent	$-\Delta H^0_{solv}$, kJ mol^{-1}	Solvent	$-\Delta H^0_{solv}$, kJ mol^{-1}
Carbon tetrachloride	27.6	Tetramethylurea	18.0
Nitrobenzene	22.6	*N*-Methylpyrrolidinone	43.9
Methylene chloride	21.3	Dimethylacetamide	57.3
Toluene	20.9	Pyrrolidinone	157.7
Tetrachloroethane	18.4	Dimethylformamide	204.6
Tetrahydrofuran	16.7		

The interaction of acid chlorides with solvents of the amide type depends not only on the nature of the latter but also on the chemical structure of the initial dichloride.[35] The results of Sokolova and Sokolov[36] demonstrate, firstly, the higher reactivity of aromatic carboxylic acid dichlorides compared with those of aliphatic acids and, secondly, that the reactivity of aromatic acid halides in relation to amide solvents decreases in the sequence bromides > chlorides > fluorides. These results are satisfactorily correlated with data concerning the synthesis of polymers: the higher the enthalpy of reaction of the acid halide with the solvent, the lower the molecular weight of the polymer formed[1] (p.148).

It has been shown[37] that aromatic diamines are also capable of interacting with solvents to form side products. Thus, when a solution of di(3-amino-4-dydroxyphenyl) sulphone in DMA is heated, 87.5% of dimethylaniline relative to the theoretical amount is evolved. However, in solutions of benzidine, 3,3'-dihydroxybenzidine, and 2,2-di(3-amino-4-hydroxyphenyl)propane in DMA, dimethylamine in amounts of only 1.9, 2.15, and 5.4% respectively was detected after standing for 2 h at 298 K.[37] However, when DMA is capable of acylating the amino-group of the monomer, then this type of reaction should occur also in later stages of the polycondensation. This conclusion has been confirmed[37] in relation to the synthesis of poly[4,4'-dihydroxy-3,3'-(isophthalamido)diphenyl sulphone] in which not only chain termination but degradation of the polymer takes place.

As an illustration of the foregoing, one may also quote a study of the stability of the intrinsic viscosity of solutions of polyamidoacids based on pyromellitic anhydride and di(4-aminophenyl) ether[3] or bis(4-aminodiphenyl ether) of hydroquinone.[38] It was observed that the stability of the polyaminoacid in solution in DMF and DMSO is approximately the same and is significantly lower than in *N*-methylpyrrolidinone (MP). Comparison of the activation energies for the degradation of the polymers in various solvents (50 kJ mol^{-1} in DMF, 63 kJ mol^{-1} in DMSO, and 83 kJ mol^{-1} in MP) with data for the hydrolysis of the amide bond (75–85 kJ mol^{-1}) permits the conclusion[3,38] that the decomposition of polyamidoacids in amide solvents takes place preferentially as a result of the dissociation of the amide bond.

It follows from the foregoing that the choice of a solvent for the polycondensation of tetracarboxylic acid dianhydride or dicarboxylic acid dihalides with aromatic diamines and diols plays an extremely important role in the synthesis of the corresponding high-molecular-weight compounds. The presence of moisture in the reaction system must be very carefully monitored for such purposes. A detailed study[39] of the kinetics of the hydrolysis of isophthalic and terephthalic acid dichlorides has shown that in the temperature range 283–323 K they interact with water, which leads to the loss of the functional acid chloride groups. The presence of a definite amount of water in the solvent can therefore result in the cessation of polycondensation. Analogous effects of the hydrolysis of tetracarboxylic acid anhydrides have been observed also in the synthesis of polyamidoacids in amide solvents.[40]

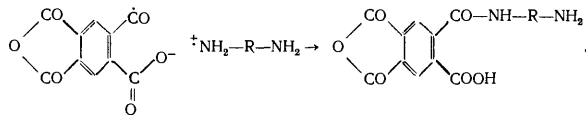
At the same time a number of workers[26,41–45] found in analysing various processes leading to the synthesis of polyamidoacids that the dependence of the molecular weight of the polymer formed on the concentration of water in the solvent always passes through an extremum. In other words, a small water content in the solvent (from 0.5 to 1.5 wt.%) not only does not lead to the hydrolysis of the initial dianhydride but also promotes an increase of the molecular weight of the polymer. The fact that, in conformity with the change in the equivalent conductance of aqueous solutions of aromatic acid dianhydrides on their interaction with the diamine, the rate of polycondensation is many times greater than the rate of hydrolysis agrees with this finding. The positive influence of the presence of water on the polycondensation has been explained[47] by the increased degree of swelling of the polymers in the presence of water, but no rigorous evidence for this is yet available.

III. CHARGE-TRANSFER COMPLEXES IN POLYCONDENSATION REACTIONS

Numerous studies[48–54] dealing with the synthesis and the interpretation of the electronic and infrared spectra of the solid reactants at 77–90 K and their solutions in non-polar

and highly polar solvents have been devoted to the donor-acceptor interaction in the systems carboxylic acid anhydrides–tertiary and primary amines. Analogous data have been obtained by other investigators[55–58] for the systems aromatic acid halides–tertiary and primary amines.

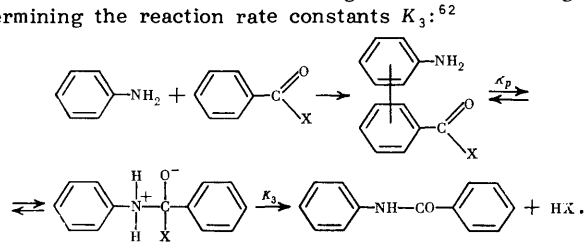
The results of these studies yield the conclusion that the reactions involved in the synthesis of polyamides, polyamidoacids, and their derivatives entail the formation of charge-transfer complexes (CTC) between the reactants. However, under the real conditions of low-temperature polycondensation (253–313 K) such complexes are unstable because their formation is followed by the rapid transfer of a proton from the amine to the anhydride group and the formation of an amide bond:



For a quantitative estimate of the electron-accepting and electron-donating properties of the reactants in acylation reactions, calculations have been made,[54,60–63] of the electron affinities and ionisation potentials of a series of carboxylic acid halides and anhydrides and aromatic diamines. The results of these investigations have been discussed in detail in a review[62] and we shall therefore quote here only the most important conclusions reached on their basis.

In the first place, the energy of charge transfer for the CTC of acid derivatives with the same electron donor increases linearly with their electron affinity. An analogous relation has been observed also for the CTC with the same electron acceptor, for example, with pyromellitic dianhydride for which the charge transfer energy varies in parallel with the variation of the ionisation potential of the aromatic amine.[62] The donor–acceptor interaction of amines with carboxylic acid derivatives, leading to the formation of CTC, is determined both by the electron-donating and electron-accepting properties of the reactants and by the polarity of the reaction medium. For example, bands of the *p*-phenylenediamine radical-cation and the chloranil radical-anion (total electron transfer) have been observed[64,65] in the study of the absorption spectra of this system in methanol.

It is believed[62] that the formation of the CTC of acid anhydrides with aromatic diamines is due mainly to the interaction of the aromatic rings (π-interaction). On the other hand, in the acylation of diamines by acid halides it was possible to detect the formation, together with the π-complex, of an adduct with a zwitter-ionic structure (a σ-complex) which is particularly stable in the case of tertiary amines. A mechanism has been proposed[62] for the acylation reaction including a CTC formation stage and the subsequent total electron transfer, which involves the appearance of a σ-complex in the system; the donor–acceptor properties of the reactant then determine the equilibrium constants K_p of the corresponding reactions. When the σ-complex is converted into the final products, the dissociation of the carbon–halogen bond is the stage determining the reaction rate constants K_3:[62]



Studies in which the energetics of the CTC formation reactions have been determined are therefore extremely interesting. Thus the thermodynamic functions of the CTC of dimethylaniline with phthalic, tetrachlorophthalic, and benzoic acids as well as the chlorides of benzoic, isophthalic, and phthalic acids in solution in acetonitrile have been calculated[66,67] (Table 2). In the CTC formation reactions involving acid chlorides the equilibrium constant is greater than for the formation of the complexes of the corresponding anhydrides. Since the enthalpies of both reactions are almost identical, the difference between the equilibrium constants is caused by the difference between the entropies of the above processes.[66]

Table 2. The energy characteristics of certain CTC formation reactions with participation of dimethylaniline.[66]

Acceptor	λ_{max}, μm	E_t, kJ mol^{-1}	$-\Delta H^0$ (298), kJ mol^{-1}	$-\Delta G^0$ (298), kJ mol^{-1}
TCPA	460	260.7	15.1±7.5	5.94
PA	375	318.8	8.4±6.3	3.51
BA	339	353.5	5.0±0.4	3.14
IPC	360	332.6	7.5±1.3	4.73
BC	338	354.0	4.6±0.8	5.65
PC	330	362.3	8.4±1.3	2.76

Notation. TCPA = tetrachlorophthalic acid anhydride; PA = phthalic anhydride; BA = benzoic acid anhydride; IPC = isophthalic acid dichloride; BC = benzoyl chloride, PC = phthalic acid chloride; E_t = electron transfer energy.

It is noteworthy that the calculated resonance energies and the contribution of the ionic structure of the complex in its ground state (which are 0.25 and 0.41% respectively in the case of benzoic acid anhydride and chloride, for example) did not confirm the conclusion[62] that there is a high contribution by the ionic structure. At the same time one of the principal postulates put forward by the above workers,[62] namely that the kinetics as well as the energetics of the CTC formation reactions and the electron affinity of the electron acceptor vary in parallel, has been confirmed,[66] because it has been found that in a series of anhydrides the decrease of the electron affinity of the acceptor is accompanied also by a decrease of the equilibrium constant for the CTC formation reaction.

Extensive information about the CTC of aromatic diamines with chloranil, which is similar to pyromellitic dianhydride as regards the character of its interaction with π-donors,[68] has been obtained.[57,69] It was found that the complex formation equilibrium constant diminishes with decrease of the basicity of the amine. In addition, a correlation has been observed between the thermodynamic characteristics of the CTC investigated and the rate constant for the reaction of the same diamine with pyromellitic dianhydride. The above workers[71] carried out a spectroscopic-kinetic study of the reaction of *m*-phenylenediamine with pyromellitic dianhydride and dichloropyromellitic dianhydride. The electron phototransfer and thermotransfer in model systems containing primary and substituted aromatic diamines and electron acceptors have been investigated. A mechanism for the elementary stage in the polycondensation reaction, which consists of successive electron and proton transfer from the amino-group to the partially positive centre of the dianhydride, has been proposed on the basis of the results.

Thus analysis of the literature data has shown that interaction involving the formation of CTC is an essential stage in polycondensation reactions with participation of aromatic diamines and carboxylic acid derivatives.

IV. KINETIC CHARACTERISTICS OF THE REACTIONS OF AROMATIC DIOLS, DIAMINES, AND THEIR DERIVATIVES WITH CARBOXYLIC ACID DIANHYDRIDES AND DIHALIDES

The first studies of the polycondensation reactions of aromatic diamines with tetracarboxylic acid dianhydrides already made it possible to establish the series of the relative reactivities of the corresponding nucleophiles[72,73] and electrophiles[72] on the basis of the results of measurements of the viscosities of the solutions of the polymers formed. The same method has been used[74-77] for the analysis of the reactivities of the bisphenols and aromatic acid dichlorides in polyesterification reactions. In particular, it has been shown[76] that the decrease in the reactivity of the dichloride not only diminishes the molecular weight of the polyarylate but also abolishes its temperature dependence.

The influence of the chemical structure of diamines and acid dianhydrides on the molecular weights of the polymers formed has also been examined by other investigators.[78,79] The reactivity of tetracarboxylic acid dianhydrides has been estimated[80] from measurements of the electron conductivities of their aqueous solutions. It has been suggested[81] that the comparative rates of dissolution of the monomers in organic solvents be used for the estimation of their reactivities. For the same purpose, the copolycondensation constants have been compared in a number of studies, in particular by Zhubanov et al,[82] which have been used to determine the relative reactivities of alicyclic tetracarboxylic acid dianhydrides. The reactivities of aromatic diamines have been estimated quantitatively[83-86] from the rate constants for the polycondensation with 1,6-hexamethylene diisocyanate in various solvents. It has been shown that the introduction of electron-accepting substituents into the diamine molecule lowers its reactivity and in many cases the reaction hardly proceeds.[84] As regards dianhydrides, particularly alicyclic acid dianhydrides, their reactivity is significantly influenced by steric factors.[73,87]

In view of the complexity of polycondensation processes, particularly as a consequence of the changed reactivity of the second reaction centre in bifunctional monomers after the first has reacted, many studies have examined the reactivity of the starting materials by using the reactions of model compounds. In one investigation[88] this has been done in relation to the reactions of aromatic amines with *p*-nitrobenzoyl chloride (or picryl chloride) while in another investigation[1] (p. 90) reactions of *p*-anisidine with acyl halides were used.

The reactivities of aromatic acid dichlorides in *p*-nitroaniline acylation reactions have been investigated[89] in solution in DMA at 298 K. It has been shown that the separation of the acid chloride groups by two benzene rings lowers appreciably the reaction rate constant compared with the amination of terephthalic acid dichloride. However, the introduction of powerful electron-accepting groups (for example, SO_2) between the benzene rings increases the rate constant for the above reaction. It is noteworthy that the reactivity of dinuclear acid dichlorides depends much less on the nature of the bridging group in a molecule than the reactivity of diamines with an analogous structure.[60,81,83,84]

The rate constants k_1 and k_2 for the reactions involving the successive addition of aniline derivatives to isophthalic and terephthalic acid dichlorides in various solvents have been determined[90] [see also Sokolov[1] (p. 24)]. It was found that in all cases $k_1 > k_2$. The reduced reactivity of the second COCl group is manifested to a greater extent by terephthalic acid dichloride. For the same acid dichlorides, k_1/k_2 increases with increase of the basicity of the amine and is independent of the nature of the solvent. At the same time in individual instances there is a possibility also of the opposite relation between k_1 and k_2 (Table 3).

Table 3. The rate constants for the reactions of terephthalic acid dichloride with the phenols 
in the presence of triethylamine (dioxan, 303 K).[91]

R	k_1, litre mol^{-1} s^{-1}	k_2, litre mol^{-1} s^{-1}	k_1/k_2	pK_a^*
CH_3	11.5±1.0	4.7±0.3	2.45	14.4
H	10.0±1.0	6.8±0.9	1.47	13.7
Cl	17±1	15±1	1.13	12.7
NO_2	48±2	62±3	0.77	10.1

*The ionisation constant of the phenol.

The acylation[92] of *o*-phenylenediamine by an equimolar amount of *m*-carbaboranedicarboxylic acid monochloride has been investigated[92] in solution in THF at 263 K in the presence of tertiary amines and the quantity $\alpha = k_2/k_1$, characterising the relative reactivities of the amino-groups in the *o*-phenylenediamine molecule, has been calculated from the equation quoted by Emanuel' and Knorre[93] (p. 194). It was found that in all cases $\alpha < 1$ and depends on the nature of the tertiary amine (for example, $\alpha = 0.15$ and 0.018 for reactions involving pyridine and trioctylamine respectively). The marked difference between the reactivities of the amino-groups in the presence of trioctylamine consists also in aromatic tetra-amines, which leads to the formation of linear polyaminoamides (PAA). In the presence of pyridine and quinoline the difference between the reactivities of the amino-groups diminishes ($\alpha = 0.11-0.15$), which results in the formation of soluble PAA with a branched structure. In the presence of triethylamine and dimethylaniline ($\alpha = 0.39$ to 0.47), insoluble cross-linked polymers are formed.[94]

Thus the synthesis of polybenzimidazoles involves difficulties associated primarily with the high probability of the cross-linking of the growing macrochains owing to the low reactivities of all four amino-groups in the tetra-amine molecule. It has been shown[95-97] that this phenomenon can be avoided by using for the reaction with acid dichlorides, aromatic bis(*N*-phenyl-*o*-phenylenediamines) or tetramines in which two amino-groups have been replaced by acetamido-groups.[98]

The possibility of employing indirect methods for the estimation of the reactivities of polycondensation monomers, for example, using the ionisation constants, the stretching vibration frequencies of the reacting bonds, and other properties, has been noted.[7] This postulate has been confirmed for the condensation of benzoyl chloride with aromatic amines[1] (p. 27).

The calculation of molecular diagrams by the LCAO-MO method in terms of the Hückel π-electron approximation has proved extremely useful for such purposes. Calculations of this kind have been carried out for aromatic diamines,[99]

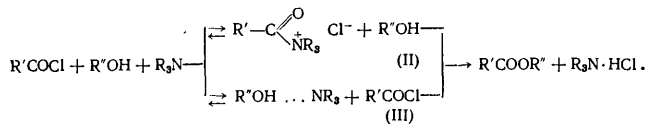
tetramines,[100] dicarboxylic acid bisamidrazones,[101] bisphenols,[102] and carboxylic acid dianhydrides[103] and dichlorides.[104] The calculations showed that the charges on the oxygen atoms in bisphenols and on the carbon atoms in acid dichlorides are linearly related to the Hammett substituent constants. In the case of amines, the electron densities at the nitrogen atom vary in parallel with the basicity of the amines. For example, the data of Bochvar et al[100] have been used to interpret the formation of linear polyaminoamidoacids;[105] the same data[100] agree with the ionisation constants of the tetramines quoted by Balyatinskaya et al.[106] The calculated energies of the lowest valence orbital of acid dianhydrides and their derivatives and the frontier electron densities of the carbonyl carbon atoms[103] made it possible to elucidate the detailed mechanism of acylation reactions, i.e. they determine the direction of nucleophilic attack.

Sokolov and co-workers[1] (pp. 28, 107, 147) were among the first groups of investigators who proposed a method for the estimation of the reactivities of diamines and acid dihalides from the enthalpies of their reactions with organic solvents (DMF, DMA, etc.) or an aqueous hydrochloric acid solution. The quantitative information obtained by this procedure makes it possible to select the reactants for the synthesis of polymers, since the higher the enthalpy of reaction of the acid dichloride with the solvent the lower the molecular weight of the polyamide formed in the corresponding reaction.

The reactivities of monomers depend to a large extent on the nature of the solvent chosen for polycondensation. This has been demonstrated convincingly in relation to the synthesis of poly-*m*-phenyleneisophthalamide[1] (p. 88) and also in the analysis of the kinetics of the acylation of *p*-nitroaniline by terephthaloyl chloride[89] in the following solvents: acetonitrile ($pK_a = 10.13$; $k = 0.03$ litre mol^{-1} s^{-1}); *N*-methylpyrrolidinone ($pK_a = 0.92$; $k = 1.80$ litre mol^{-1} s^{-1}); dimethylacetamide ($pK_a = 0.19$; $k = 2.90$ litre mol^{-1} s^{-1}).[89] Evidently the basicity of the solvent is a significant factor, which influences the rate of polycondensation reactions.

However, one must note that, whilst giving preference to monomers with a higher reactivity in polycondensation reactions, one must rigorously take into account the role of side reactions. Since the more reactive monomer is more actively involved in such reactions, in many instances this can lead to a decrease of the molecular weight of the polymer formed[1] (p. 89).

The most thoroughly investigated branch of the polycondensation kinetics is that of the high-temperature (423–483 K) polyesterification of dicarboxylic acid dichlorides with bisphenols in solution. For a comparatively large number of reactions, the rate constants and activation energies for the synthesis of polyarylates have been determined. The results of these studies are presented and discussed in the monograph of Korshak and Vinogradova[108] (chapter III). The problems of the kinetics and mechanism of the low-temperature condensation of the same reactant in the presence of tertiary amines (acceptor–catalytic polycondensation) have already been examined in detail in reviews.[109–111] In this review we shall only mention that fact that the mechanism of the acceptor-catalytic polyesterification can be represented by two "catalytic fluxes": nucleophilic [the formation of complex (II)] and general basic [the formation of complex (III)]:



The relative contributions of the above mechanism are determined mainly by the basicity of the tertiary amine employed and the acidity of the phenol. Increase in the acidity of the phenol and in the basicity of the tertiary amine creates conditions for reaction via the general base catalytic mechanism. Questions concerning the choice of the catalyst and of its influence on the side reactions in polycondensation processes and the properties of the polymers formed have been examined in very great detail in a review.[112] The kinetic aspects of the reactions in the low-temperature polycondensation of aromatic diamines with tetracarboxylic acid dianhydrides have been analysed in a number of investigations. The kinetics of the formation of polyamidoacid (PAAC) based on pyromellitic dianhydride (PMDA) and *m*-phenylenediamine in solution in DMF have been investigated.[113,114] The kinetics of the polycondensation of PMDA with dinuclear aromatic diamines in the same solvent have been discussed.[115] Quantitative information about the kinetics of the reactions of 9,9-di(4-aminophenyl)fluorene with a series of tetracarboxylic acid dianhydrides in solution in *N*-methylpyrrolidinone has been obtained.[116] The systematic investigations of the kinetics of the formation of DAAC based on the dianhydrides of tricyclodecenetetracarboxylic acids in solution in DMF have been carried out.[117–120] Certain postulates concerning the mechanisms of the above reactions have been published in other communications.[117,118,120,121] Analysis of the experimental results of the above studies permits the following conclusions.

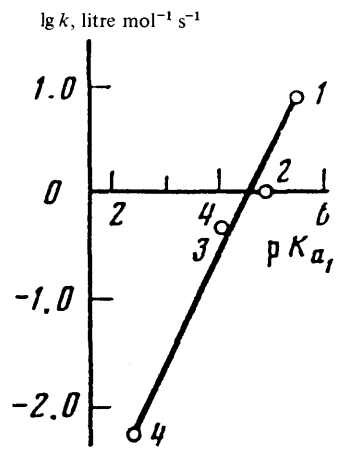


Figure 2. Dependence of the logarithms of the rate constants for the reactions of PMDA with amines on the logarithms of the first ionisation constants of the amines: 1) reaction with di(4-aminophenyl) ether; 2) reaction with *m*-phenylenediamine; 3) reaction with di(4-aminophenyl) sulphide; 4) reaction with di(4-aminophenyl) sulphone; 5) solvent—DMF; 298 K.[70]

Firstly, the rate constants for the polycondensation reactions of the same acid dianhydrides with different aromatic amines increases with increasing basicity of the amine (Fig. 2). In the reactions of the same diamine with different carboxylic acid dianhydrides the rate increases with increasing electrophilic character of the carbon atoms in the anhydride molecule. For example, according to

Vygodskii et al,[116] the rate constants for the polycondensation of 9,9-di(4-aminophenyl)fluorene at 298 K in solution in *N*-methylpyrrolidinone with dinuclear dianhydrides are 0.079, 0.49, and 1.70 litre mol^{-1} s^{-1} for the dianhydrides of tetracarboxylic acids derived from diphenyl ether, benzophenone, and diphenyl sulphone respectively.

Secondly, the reactivities of the dianhydrides of aliphatic and alicyclic acids are lower than those of the dianhydrides of aromatic acids, other conditions in the polycondensation reaction being equal. For example, the rate of reaction of di(4-aminophenyl)ether in solution in DMF with PMDA is 1000 times higher than the rate of polycondensation of the same diamine with the dianhydride of tricyclo[4,2,2,$0^{2,6}$]dec-7-ene-3,4,9,10-tetracarboxylic acid AB[70] and approximately 100 and 50 times greater than the rates of acylation of di(4-aminophenyl)ether by the dianhydrides of mesobutane-1,2,3,4-tetracarboxylic acid (MBTCA) and cyclopentane-1-*cis*, 2-*cis*, 3-*cis*-tetracarboxylic acid (CPTCA) in the same solvent.[121] On the other hand, the activation energies for the last two reactions[121] exceed by factors of 6 and 4.5 respectively the activation energy for the polycondensation of di(4-aminophenyl)ether with PMDA.[122]

Thirdly, the formation of polyamidoacids from aromatic diamines and acid dianhydrides consists of rapid (I) and slow (II) stages (Table 4). Whereas Koton[121] attributes this to the formation of monoacyl derivatives with a reduced basicity of the amino-groups in the first stage, Zhubanov et al[118] explain the above finding by the different reactivities of the dianhydride groups in asymmetric alicyclic acid dianhydrides relative to the reactions of diamines. For example, this can be caused by the different electron-donating properties of the cyclobutane and cyclohexane fragments and also by the shielding of one of the anhydride groups.[123]

Table 4. Kinetic parameters of the interaction of di(4-aminophenol) ether with AB[118] MBTCA, and CPTCA[121] (solvent—DMF; 298 K).

Dianhydride	Rate constant, litre mol^{-1} s^{-1}		E_a, kJ mol^{-1}	
	section I	section II	E_I	E_{II}
AB	$4.15 \cdot 10^{12}$	$4.18 \cdot 10^{-3}$	40.0±2.0	30.5±2.0
MBTCA	$(0.8 \pm 0.3) \cdot 10^{-1}$	$(3.1 \pm 0.5) \cdot 10^{-3}$	—	—
CPTCA	$(1.6 \pm 0.4) \cdot 10^{-1}$	$(3.6 \pm 0.5) \cdot 10^{-3}$	—	—

For the significance of the abbreviations, see text.

Nevertheless, one can agree with the view[121] that the onset of the growth of the macrochain in the synthesis of PAAC is associated with the formation of monoacyl derivatives of diamines and that the chain growth is caused by the preferential reactions of their functional groups. It has also been noted that the kinetics of the reactions involved in the synthesis of polyamidoacids can be successfully described taking into account their autocatalytic and equilibrium character.[120]

The kinetic features of the reactions involved in the single-stage polycondensation of diamines with tetracarboxylic acid dianhydrides have been elucidated in relation to the synthesis of polyimides. The molecular weights of the polymers obtained in solution are higher than those of the same polyimides synthesised by the two-stage method. The factors influencing the rate constants for the reactions involving the single-stage synthesis of polyimides are mainly the same as for the processes in the synthesis of polyamidoacids: the structure of the starting materials,[128,129] the nature of the solvent,[130] and the conditions in the polycondensation process.[113,124]

V. THERMODYNAMICS OF THE REACTIONS

The principal relations between the number-averaged degree of polycondensation $\bar{P}_n$ and the degree of reaction p, between $\bar{P}_n$ and the polycondensation equilibrium constants K_p, and between $\bar{P}_n$ and the molecular weight distribution of the linear polycondensation polymer have been obtained by Flory.[132] Later these postulates were analysed in detail in a number of investigations,[1,133–141] which showed that the study of the polycondensation thermodynamics is important because the equilibrium states in these processes determine the average degree of polycondensation, the molecular weight, and the molecular weight distribution of the polymer formed.

In connection with the development of the two-stage method for the synthesis of polyheteroarylenes, special attention is devoted in the literature to the low-temperature polycondensation processes in solution. Much quantitative information about the thermodynamics of the reactions of phthalic anhydride (PA) with aniline, which models the formation of polyamidoacids, has been published.[142]

The results permit the conclusion that the equilibrium constants for the acylation reaction depend on the structure of the starting materials: whereas the reactions of phthalic anhydride with *p*-nitroaniline and of PMDA with di(4-aminotetrafluorophenyl) ether hardly occured at 313 K, the equilibrium in the phthalic anhydride–aniline and PMDA–*p*-phenylenediamine systems is markedly displaced towards the formation of *o*-carboxyamides under the same conditions. The introduction of the electron-donating substituents CH_3, CH_3O, $(CH_3)_2N$ in the *para*-position in the aniline molecule entails an even greater increase of the equilibrium constants, i.e. its parallel variation with the basicity of the amine employed is observed.

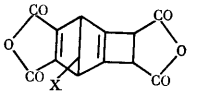
Comparison the equilibrium constants for the same reaction in different solvents has shown that the equilibrium shifts to the right with increasing basicity of the solvent. Thus, on passing from acetonitrile to THF, K_p increases almost by a factor of 10, while in dimethylsulphoxide and diemthylacetamide this constant exceeds 1×10^5. The influence of the basicity of the medium is reflected also in the enthalpy of the process, which amounts to −48.0 kJ mol^{-1} in acetonitrile and −54.5 kJ mol^{-1} in THF. This is believed[142] to be related to the association of the carboxy-groups of the products with the solvent molecules, which has been confirmed by the infrared spectroscopic data for a series of model compounds.

Analogous data concerning the influence of the solvent on the enthalpy of the reaction of phthalic anhydride with 4-aminodiphenyl ether, which models the synthesis of PAAC, were obtained later.[143]

Zhubanov and co-workers[119,144–147] used infrared spectroscopy to investigate the polycondensation reactions of aromatic diamines with the dianhydrides of tricyclodecenetetracarboxylic acid at 298 K in DMF; the results are compiled in Tables 5 and 6. The reactivity series of the dianhydrides has been proposed on the basis of the decreasing absolute Gibbs energy of the reaction (ΔG_r^0, Table 5). The aromatic

diamines investigated can be arranged in a series, based on the absolute values of ΔG_r^0 (298) for the polycondensation reaction with a specific dianhydride (Table 6), which agrees with the series based on their first ionisation constants.

Table 5. Thermodynamic parameters of the reactions of di(4-aminophenyl)ether with the dianhydrides.[146]



X	$-\Delta H_r^0$, kJ mol^{-1}	$-\Delta G_r^0$, kJ mol^{-1}	$-\Delta S_r^0$, kJ mol^{-1} K^{-1}	K_c, litre mol^{-1}

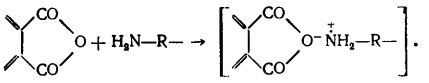
We shall next consider the results of the study of the thermodynamics of the polycondensation reactions of tetracarboxylic acids dianhydrides with aromatic diamines, tetraamines, and their derivatives in solution.[148-157]

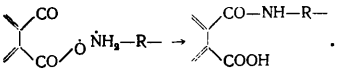
1. Thermodyamics of the Polycondensation Reactions of Tetracarboxylic Acid Dianhydrides with Aromatic Diamines

Tables 7–9 present the results of the determination of the enthalpies of the reactions of the dianhydrides of oxybis-(benzene-3,4-dicarboxylic) acid (OBBDA) and PMDA with mononuclear and dinuclear diamines and also with aromatic diamines containing benzimidazole and triazole groups.

The synthesis of poly(*o*-carboxy)amides proceeds via a bimolecular reaction involving the acylation of amines whose mechanism includes the nucleophilic attack on the amino-group, leading to the opening of the anhydride ring with formation of the amide bond. The attack by the nucleophile on the partially positive centre of the dianhdyride terminates in electron transfer (complete or partial depending on the dielectric constant of the medium) to the acceptor (the dianhydride):



However, this system is unstable, because its formation is followed by the rapid proton transfer from the amine to the anhydride group and by the formation of the amide bond:



This process is accompanied by the dissociation of the N–H and C–O bonds in the diamine and dianhydride molecules respectively and by the formation of new bonds (O–H, C = O, and C–N) in the polymer macromolecule. The fact that interaction of various diamines with the same dianhydrides results in the evolution of unequal amounts of heat is due primarily to the different nucleophilicites of the initial nucleophiles. On the other hand, the nucleophilicities of the amines investigated, determined by the presence of the unshared electron pair at the nitrogen atom of the amino-group, depend on the basicity of these substances.

The present authors[150,151] have attempted to relate the enthalpies of the synthesis of poly(*o*-carboxy)amides to the basicities of the initial diamines. Indeed, the higher the basicity of the amine, i.e. the higher the electron density at the nitrogen atom of the amino-group, the easier the electron transfer to the partially positive centre of the anhydride. This leads in its turn to a relatively greater deficiency of electron density at the nitrogen atom of the amino-group, i.e. promotes the appearance of an excess positive charge. The latter promotes the polarisation of the N–H bond in the amine and facilitates the abstraction of a proton from the amino-group.

Thus an increase of the basicity of the amine diminishes the dissociation energy of the N–H bond in the amine. Since the enthalpy of the chemical reaction is determined by the algebraic sum of the energies of the bonds which have been ruptured and formed, the above fact should diminish the enthalpy with increasing basicity of the amine, bearing in mind that the energies of the other bonds indicated above vary to a lesser extent with the chemical nature of the amine in reactions with the same dianhydride. Indeed, linear relations between the enthalpies and the logarithms of the first ionisation constants of aromatic diamines have been observed for their reactions with OBBDA and PMDA.[151-153,156]

$$\Delta H_r^0(298) = A + B \cdot pK_{b_1}.$$

For the reactions of OBBDA with mononuclear diamines, the quantities ($-A$) and B are 203.0 ± 0.8 and 10.5 ± 0.3 respectively; for the reactions of OBBDA with dinuclear diamines the corresponding quantities are 969.0 ± 1.0 and 89.1 ± 0.8. Finally, the same parameters for the reactions of dinuclear diamines with PMDA are 934.0 ± 1.0 and 87.7 ± 0.7.

The above conclusions agree with the results quoted in Fig. 3, where the dependence of the enthalpies of the polycondensation of four dinuclear diamines with OBBDA and PMDA on the stretching vibration frequency of the amino-groups is presented.[153] On this basis, we suggest that an increase of the stretching vibration frequency indicates an increase of the N–H bond energy in the sequence di(4-aminophenyl) ether < 4,4′-diaminobiphenyl < di(4-aminophenyl) disulphide < di(4-aminophenyl)sulphone. The enthalpies of the corresponding polycondensation reactions vary in the

same direction. For example, the introduction of an electronegative substituent between the benzene rings in the amine molecules (oxygen bridge) diminishes the enthalpy of reaction in solution by 8.0 ± 1.5 kJ mol^{-1} (Tables 8 and 14). The introduction of the electron-accepting CO or SO_2 groups between the benzene rings increases the enthalpy of reaction in solution in DMF by 15 ± 5 and 23 ± 2 kJ mol^{-1} respectively (Tables 8 and 14).

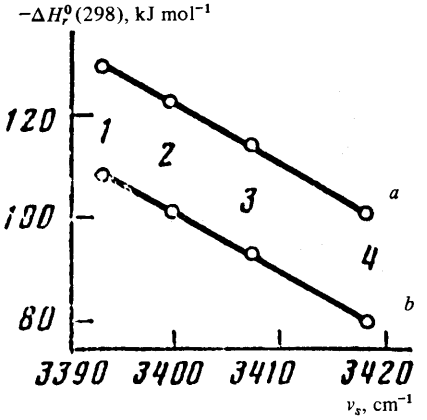


Figure 3. Dependence of the enthalpies of polycondensation of aromatic diamines with OBBDA (*a*) and PMDA (*b*) on the stretching vibration frequency ν_S of the NH_2 groups of the diamines[153]

X = *1*) -O-; 2) -S-S-; 3) $-SO_2-$.

Table 7. The enthalpies of polycondensation reactions of OBBDA with monoculear aromatic diamines (solvent—DMF; 298 K).[157]

Diamine	pK_{b_1} (H_2O)	$-\Delta H_r^0$, kJ mol^{-1}
1,4-Diaminoxylene	7.35	125.9±4.2
p-Phenylenediamine	7.96	119.7±0.4
m-Phenylenediamine	9.12	108.0±1.3
o-Phenylenediamine	9.48	103.3±2.1

In the case of the *para*- and *meta*-derivatives of amines, the lower enthalpy of the polycondensation of the latter with OBBDA refers respectively to *p*-phenylenediamine (−119.7 and −108.0 kJ mol^{-1}, Table 7), bis(*o*-aminophenyl)-*p*-benzoylene-2,2-bistriazole (−83.7 and −95.4 kJ mol^{-1}, Table 9), and the bisamidrazone of terephthalic acid (−116.3 and −128.0 kJ mol^{-1}, Table 9); the corresponding enthalpy difference is 11.7 kJ mol^{-1} in all cases under these conditions.

A linear relation has been established between the enthalpies of polycondensation of aromatic diamines with PMDA in solution in DMF and the logarithms of the rate constants for the same processes:[153]

$$\Delta H_r^0(298),\ (\text{kJ mol}^{-1}) = (-102.0 - 8.45 \lg K) \pm 1{,}0,$$

where K are the rate constants for the corresponding polycondensation reactions expressed in litre mol^{-1} s^{-1}. From this it follows that the variation of the enthalpy of the above reaction with the nature of the amine is correlated with the variation of the activation energy for the reaction.

Table 8. The enthalpies (kJ mol^{-1}) of the reactions of OBBDA, PMDA, and phthalic anhydride (PA) with the diamines $H_2N-C_6H_4-X-C_6H_4-NH_2$ (solvent—DMF; 298 K).[150]

	95.4±1.3
	83.7±2.1
	83.7±2.1

On the basis of the kinetic studies of the reactions of di(4-aminophenyl) ether with carboxylic dianhydrides, it has been suggested[121] that the synthesis of poly-(*o*-carboxy)-amides in solution in polar solvents proceeds via a stage involving the formation of monoacyl derivatives. It is therefore of interest to compare the enthalpies of the reactions for the successive addition of two moles of phthalic anhydride (PA) to one mole of the corresponding diamine. It follows from Table 8 that, for the reactions involving the addition of the second mole of PA to the diamine, $\Delta H_r^0(298)$ is in all cases smaller in absolute magnitude than the analogous values for the reactions of the first mole of PA with the initial diamine: $\Delta H_1^0 > \Delta H_2^0$. It has also been established[154] that ΔH_1^0 and ΔH_2^0 vary in parallel with the variation of the ionisation constants of the amines pK_b, namely for the first and second anhydride addition reactions the following relations have been obtained respectively:

$$\Delta H_1^0, \text{ (kJ mol}^{-1}) = (-338.4 + 28.5 \cdot pK_{b_1}) \pm 1.0 ;$$
$$\Delta H_2^0, \text{ (kJ mol}^{-1}) = (-286.2 + 18.9 \cdot pK_{b_2}) \pm 2.5.$$

Since in practice polyamidoacids are synthesised by adding the solid dianhydride to a solution of the diamine, we shall consider the thermodynamic characteristics of the dissolution of a series of dianhydrides in DMF. These results, which are presented in Table 10, show that the affinity of tetracarboxylic acid dianhydrides for DMF diminishes in the sequence PMDA > TBBDA > OBBDA.

Table 10. Thermodynamic parameters of the dissolution of dianhydrides in DMF at 298 K.[150]

Dianhydride	ΔH^0_{solv}, kJ mol^{-1}	$-\Delta G^0_{solv}$, kJ mol^{-1}	ΔS^0_{solv}, J mol^{-1} K^{-1}
PMDA	—12.96	100.5	288.7
TBBDA	—5.02	96.0	299.2
OBBDA	12.55	92.0	351.5

By adding together the enthalpies of solution of PMDA and OBBTA in DMF to the enthalpies of mixing of the solutions of the dianhydride and a diamine (Table 8), we obtain the enthalpy of reaction of the crystalline dianhydride with the solution of the diamine. Linear relations obtained from calorimetric data for the reactions of mononuclear diamines with crystalline OBBDA are presented below for the calculation of the enthalpies of such reactions of PMDA or OBBTA with other diamines from the enthalpies of reaction of the same anhydrides with the amines which we have investigated:[151–153,156]

$$\Delta H_r^0(298), \text{ (kJ mol}^{-1}) = (-182.1 + 9.48 \cdot pK_{b_1}) \pm 2.0.$$

For the reactions of dinuclear aromatic diamines with a crystalline OBBDA, we have

$$\Delta H_r^0(298), \text{ (kJ mol}^{-1}) = (-953.4 + 88.74 \cdot pK_{b_1}) \pm 2.5.$$

For reactions of dinuclear aromatic diamines with crystalline PMDA, we have

$$\Delta H_r^0(298), \text{ (kJ mol}^{-1}) = (-956.5 + 87.67 \cdot pK_{b_1}) \pm 1.0.$$

Analysis of the enthalpies presented in Table 8 for reactions carried out by mixing solutions of the starting materials established a linear relation between the enthalpies of polycondensation of OBBDA and PMDA with the same amine in DMF:

$$\Delta H_r^0(298, \text{OBBDA}) \text{ (kJ mol}^{-1}) = [-20.2 + 1.0 \Delta H_r^0(298, \text{PMDA}) \pm 1.5.$$

The relation obtained makes it possible to estimate reliably the enthalpy of reaction of a specific amine with one dianhydride from the known enthalpy of polycondensation of the same diamine with another dianhydride. An analogous relation has been obtained also for the enthalpies of polycondensation of the same amines with OBBDA and PMDA by adding the solid dianhydrides to a solution of the diamine in DMF:

$$\Delta H_r^0(298, \text{OBBDA}) \text{ (kJ mol}^{-1}) = [5.4 + 1.0 \times \Delta H_r^0(298, \text{PMDA}) \pm 1.5.$$

The entropies and Gibbs free energies of two processes of the type discussed have been determined calorimetrically for the reactions of OBBDA with di(4-aminophenyl)ether (DAPE) and di(4-aminophenyl) sulphone (DAPS) in DMF.[152] The above polycondensation reactions have been chosen because they are characterised by the maximum and minimum enthalpies respectively for the series of diamines investigated, which have been used to synthesise polyamidoacids. The results presented are listed in Table 11. It follows from these data that the entropies of the reactions investigated are negative and increase in absolute magnitude with increasing temperature. In contrast to ΔH_r^0, ΔS_r^0 is virtually the same for both processes. Consequently the enthalpies of the above processes are the factor which determines the differences between the Gibbs free energies of the acylation of the diamines by the same dianhydride.

Table 11. Thermodynamic parameters and equilibrium constants of the reactions of OBBDA with DAPE and DAPS (solvent—DMF; 101.325 kPa).[152]

T, K	$-\Delta H_r^0$, kJ mol^{-1}		$-\Delta S_r^0$, J mol^{-1} K^{-1}		$-\Delta G_r^0$, kJ mol^{-1}		K_c	
	DAPE	DAPS	DAPE	DAPS	DAPE	DAPS	DAPE	DAPS
240	114.0	69.0	114.0	95.0	87.5	46.5	$1 \cdot 10^{19}$	$1 \cdot 10^{10}$
260	122.0	80.0	145.0	139.0	84.5	44.5	$1 \cdot 10^{17}$	$8 \cdot 10^{8}$
280	129.5	88.0	175.0	169.0	80.5	41.5	$1 \cdot 10^{15}$	$4 \cdot 10^{7}$
300	129.0	88.0	191.5	190.5	72.0	31.0	$4 \cdot 10^{12}$	$3 \cdot 10^{5}$

It follows from the analysis of the dependence of ΔG_r^0 on T that the reactions of DAPE and DAPS with OBBDA in DMF are thermodynamically allowed over the entire temperature range and are characterised by high equilibrium constants. Presumably the equilibrium constants for other diamines at 298 K are also in the range 10^5–10^{12}. Thus the equilibria in the syntheses of poly(*o*-carboxyl)amides are almost completely displaced towards the formation of the polymers. With increase of temperature, their equilibrium constants diminish in conformity with the principle of the displacement of chemical equilibrium.

2. Thermodynamics of the Reactions of the Dianhydrides of Tetracarboxylic Acids with Aromatic Tetramines and Their Derivatives

Table 12 presents the enthalpies of polycondensation of OBBDA with certain bisamidrazones of dicarboxylic acids in dimethyl sulphoxide (DMSO) at 298 K. The enthalpies of the reactions involving the successive addition of two moles of PA to one mole of the corresponding bisamidrazone (Table 12) have also been determined. As in the reactions of PA with aromatic diamines (Table 8), the $\Delta H_r^0(298)$ values for the addition of the second mole of PA to the bisamidrazone are in all cases smaller in absolute magnitude than the analogous value for the reactions of the first mole of PA with the initial bisamidrazone. The difference between the enthalpies of addition at different stages of the process is greater for the bisamidrazone of terephthalic acid than for the bisamidrazone of isophthalic acid.

Table 12. The overall enthalpies of polycondensation of OBBDA with acid bisamidrazones in DMSO and the enthalpies (ΔH_1^0 and ΔH_2^0) of the subsequent addition of two moles of PA to one mole of the bisamidrazone.[150]

Bisamidrazone	$-\Delta H_r^0$ (298), kJ mol^{-1}	$-\Delta H_1^0$, kJ mol^{-1}	$-\Delta H_2^0$, kJ mol^{-1}	$\Delta H_1^0/\Delta H_2^0$
	128.0±1.7	75.7	46.4	1.63
	116.3±2.1	72.0	49.4	1.46
	111.3±2.1	69.5	50.2	1.38

Table 13 lists the values of ΔH_r^0 (298) for the reactions of OBBDA with tetramines. The introduction of electron-accepting substituents, for example, phenyl groups, into the tetramine molecule increases ΔH_r^0 (298 K), which agrees with the above hypothesis concerning the relation between the enthalpies of reaction of the dianhydrides with amines and the basicity of the latter. In particular, such a relation has been established in the following form for the tetramines which we have investigated:

$$\Delta H_r^0(298),\ (\text{kJ mol}^{-1}) = (-302.7 + 13.8 \cdot pK_{b_1}) \pm 2.5.$$

The ΔH_r^0 (298) for the reactions of tetra-aminobiphenyl and its phenyl-substituted analogue with OBBDA and also the ΔH_r^0 (298) for the polycondensation of bis(diaminophenyl) sulphone and its phenyl-substituted derivative with OBBDA differ by ~27 kJ mol^{-1}. The enthalpies of polycondensation of the phenyl-substituted tetramines with OBBDA in solution in DMF then vary in parallel with the variation of the ionisation constants of the amines in the same solvent:[151]

$$\Delta H_r^0(298),\ (\text{kJ mol}^{-1}) = (-354.2 + 19.5 \cdot pK_{b_1}) \pm 3.5.$$

An analogous relation has been obtained also for the reactions of phenyl-substituted tetramines with one mole of PA in DMF:

$$\Delta H_1^0(298),\ (\text{kJ mol}^{-1}) = (-127.9 + 5.2 \cdot pK_{b_1}) \pm 1.0.$$

where the experimental ΔH_1^0 (298) are −76.1, −62.8, and −56.5 kJ mol^{-1} for the phenyl-substituted derivatives of tetra-aminobenzene, tetra-aminobiphenyl, and bis(diaminophenyl) sulphone respectively.[151]

Table 13. The enthalpies (kJ mol^{-1}) of polycondensation of OBBDA with the aromatic tetramines  (solvent—DMF; 298 K; p = 101.325 kPa).[150]

X	pK*	$-\Delta H_r^0$ (298)	X	pK	$-\Delta H_r^0$ (298)
O	11.31	145.6±1.7	—	11.80	136.4±2.1
CH_2	11.58	142.3±0.4	CO	12.87	124.7±0.4
O—Ph—O	11.75	141.0±0.4	SO_2	13.66	115.4±0.4

*The ionisation constants of the tetramines in DMF have been determined by Balyatinskaya et al.[106]

Table 14. The entropies and Gibbs free energies of the polycondensation reactions of BDAPE with acid dianhydrides (solvent—DMF).[151]

T, K	$-\Delta S_r^0$, J mol^{-1} K^{-1}				$-\Delta G_r^0$, kJ mol^{-1}			
	TBBDA	OBBDA	BPDA	PMDA	TBBDA	OBBDA	BPDA	PMDA
240	28.0	73.0	31.5	10.5	171.5	131.8	131.8	106.7
260	33.5	75.5	33.5	17.0	169.5	131.8	129.7	106.7
280	42.0	75.5	42.0	23.0	167.4	129.7	127.6	104.6
300	52.0	77.5	48.0	33.5	165.3	127.6	125.5	102.5

It follows from the above conclusions concerning the thermodynamics of the polycondensation reactions of tetracarboxylic acid dianhydrides with aromatic diamines and their derivatives that a change in the nature of the electron acceptor in the reactions of the same nucleophile with different dianhydrides should exert a significant influence on the enthalpies of formation of the polymers. The determination of ΔH_r^0 (298) for the reactions of bis(3,4-diaminophenyl) ether (BDAPE) with various tetracarboxylic acid dianhydrides in solution in DMF established that in such cases an increase of the strength of the corresponding acid entails an increase of the absolute enthalpy of polycondensation of the dianhydrides with the same tetramine. The fact that the absolute value of ΔH_r^0(298) for the reaction of BDAPE with OBBDA is greater than the corresponding value for the reaction of BDAPE with the dianhydride of benzophenone-3,3′-4,4′-tetracarboxylic acid (BPDA) (−145.6 and −139.3 kJ mol^{-1} [157]) is associated with the fact that the addition of the first anhydride group in the case of BPTA results in a more marked decrease of the enthalpy of addition of the second

anhydride group than for OBBDA:[157]

	$-\Delta H_1^0$, kJ mole^{-1}	$-\Delta H_2^0$, kJ mol^{-1}	$\Delta H_1^0/\Delta H_2^0$
BPDA	60.2	33.1	1.8
OBBDA	57.7	40.2	1.4

The entropies and Gibbs free energies of reaction of a number of dianhdyrides with BDAPE in solution in DMF have been determined (Table 14). As for the polycondensation of dianhydrides with aromatic diamines (Table 11), the entropies of reaction of BDAPE with various dianhydrides are negative at all temperatures. On the other hand, the absolute value of ΔS_r^0 is comparatively small and the entropy component ΔS_r^0 in the expression for the Gibbs free energy is 10–15% of the enthalpy component.[151] The results obtained make it possible to set up the following reactivity series for the dianhydrides in their reactions with aromatic amines: TBBDA > OBBDA > BPDA > PMDA.

The equilibrium constants for the reactions investigated permit the conclusion that the equilibrium is in all cases almost fully shifted towards the formation of the corresponding polymer.

VI. CONCLUSION

Examination of the data described makes it possible to note the following points. The reactions of aromatic diamines, diols, and their derivatives with carboxylic acid dianhydrides and halides in amide solvents proceed in two stages. The first functional groups of these substances interact in the first stage and the activation energy is 30–40 kJ mol^{-1}. The second functional groups of the initial monomers react in the second stage and the rate constant for their interaction is lower by two–three orders of magnitude than the analogous value for the first stage, while the activation energy for the second stage is 20–30 kJ mol^{-1}.

The introduction of electrophiles into the solvent before adding the nucleophile leads to a significant decrease of the molecular weight of the polymer formed compared with that obtained when the reactants are added to the solvent in tbe opposite order or simultaneously.

The transition state in the polycondensation reactions is a charge-transfer complex whose formation can be detected, for example, from the infrared spectra of the solutions at low temperatures (~180 K). The processes involving the formation of such complexes are exothermic and their enthalpies amount to several tens of kJ mol^{-1}; their entropies are negative and amount to tens of J mol^{-1} K^{-1}, which leads to Gibbs free energies ranging from −2 to −10 kJ mol^{-1}.

The enthalpies of the polycondensation reactions with formation of aromatic polyesters, polyamides, or their *ortho*-derivatives in solution are negative and are linearly related to the logarithms of the ionisation constants of the nucelophiles. The entropies of the polycondensation reactions in solution are negative and depend only slightly on the nature of the reactants or are comaratively small in the given reaction series. The variation of the Gibbs free energies of the polycondensation processes with the chemical nature of the amine or the dianhydride is therefore determined mainly by the simultaneous variation of the enthalpy of the process, whose magnitude is significantly influenced by the variation of the dissociation energy of the N–H chemical bond (or the C–O or C–Cl bonds) in the starting materials of the above reactions. In conformity with the equation for the reaction isobar, the equilibrium constants of the polycondensation processes in solution diminish with increasing temperature. From the thermodynamic point of view, it is therefore more convenient to carry them out at a lower temperature, particularly when a weakly basic nucleophile has been selected for their synthesis. The lower limit of the temperature of these reactions is virtually determined by the freezing points of the solutions, which are close to the freezing point of the pure solvent because of the low concentrations of the reactants.

Polymerisation of *N*-Vinylpyrroles

B.A.Trofimov, A.I.Mikhaleva, and L.V.Morozova

Data on the polymerisation of *N*-vinylpyrroles, which have become readily available in recent years as a result of the discovery of their direct synthesis from ketoximes and acetylenes, are described systematically and surveyed. The characteristic features of their radical polymerisation and copolymerisation as well as their copolymerisation with electron-accepting monomers are examined and the mechanism and the unusual nature of the cationic polymerisation processes are discussed.
Attention is concentrated on new examples of the class of *N*-vinylpyrroles, their reactivity, and the structure of the polymers.
The bibliography includes 104 references.

I. INTRODUCTION

There has been a notable increase of interest in the chemistry of pyrroles in recent years. Two comprehensive monographs[1,2] and a review[3] have been published and the number of journal articles[2] dealing with various aspects of the chemistry of pyrrole derivatives has been increasing continually. This has been stimulated by a number of factors, for example, by the presence in natural objects of various pyrrole derivatives[1,2,4] such as antibiotics, pheromones, and toxins, as well as the discovery of new possibilities for the polymerisation of the pyrrole ring[5,6] and the employment of polypyrroles, which exhibit metal-like electronic conductivity, in the conversion of solar energy.[7-10]

N-Vinylpyrroles can be regarded as extremely interesting monomers for polymerisation and as starting compounds for organic synthesis, with the aid of which it is possible to obtain pyrrole-containing products. However, until recently these were regarded as unavailable and virtually unknown compounds.[1] Beside the evident practical value of poly-*N*-vinylpyrroles (in particular, these are potential semiconductors and photosensitive materials for electrophotography, holography, etc.), their synthesis and study were until recently held back by the difficulty of synthesising the initial monomers. The development of a new general method of synthesis of *N*-vinylpyrroles by the reaction of ketoximes with acetylene,[11,12] for which the name Trofimov reaction has been suggested,[13,14] has now led to virtually unlimited possibilities for the synthesis of monomers of this class.

The characteristic features of the polymerisation of *N*-vinyl monomers have been examined in monographs,[15,16] reviews,[17-20] and dissertations, for example, in Refs.21-23. However, they contain little information about the polymerisation of *N*-vinylpyrroles with the exception of a dissertation[21] in which a large section is devoted to this question. The polymerisation of *N*-vinylindoles has been studied to a much greater extent,[18,24,25] mainly in the systematic investigations of Skvortsova.[26-31]

N-Vinylcarbazole is the most reactive and the most thoroughly investigated monomer of the *N*-vinyl series[15,18] but neither indole nor carbazole are typical pyrroles.

The number of studies on the polymerisation of *N*-vinylcarbazoles which have been published is so large that an adequate survey of these is possible only in an independent review. This review is not therefore concerned with questions of the polymerisation of *N*-vinylcarbazole. It deals with the most significant aspects of certain contradictory features of the polymerisation of *N*-vinylpyrroles and *N*-vinylindoles taking into account the conclusions reached in earlier publications.

II. METHODS OF SYNTHESIS OF *N*-VINYLPYRROLES

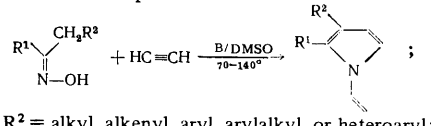
All the methods of synthesis of *N*-vinylpyrroles available until recently were based on the introduction of the vinyl group into compounds containing the pyrrole ring (see Refs.15-18 and the bibliography quoted therein).

NH-Heterocycles are usually vinylated directly with acetylene at elevated temperatures (150-200 °C) and pressures of 15-20 atm in the presence of basic catalysts.[15-18] One of the variants of the vinylation reaction is based on the use of vinyl acetate.[18]

The dehydration of *N*-β-hydroxyethyl derivatives, usually obtained from the corresponding heterocycles and oxiran to give the *N*-vinyl derivatives, takes place in the presence of potassium hydroxide at a reduced pressure and at elevated temperatures.[18]

The elimination of hydrogen halides from *N*-α- and *N*-β-haloethyl derivatives under the influence of bases is also used to synthesise *N*-vinyl monomers.[18]

The method of synthesis of *N*-vinylpyrroles based on the cyclisation of ketoximes with acetylene in a strong base—dimethyl sulphoxide (DMSO)—system has been developing most vigorously. *N*-Vinylpyrroles can be obtained by this reaction, by-passing the pyrroles themselves, from cheap and readily available compounds:[11,12]

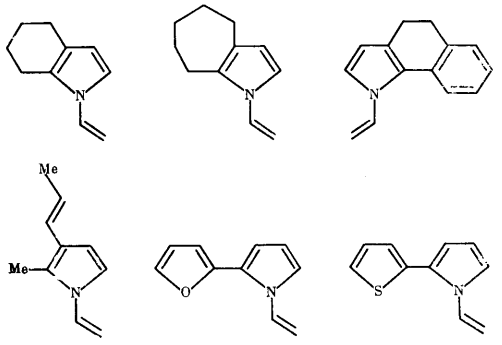


R^1, R^2 = alkyl, alkenyl, aryl, arylalkyl, or heteroaryl;
R^1-R^2 = $(CH_2)_n$, n = 3-5; B = strong base.

The yields of *N*-vinylpyrroles are 70-95% under the optimum conditions.

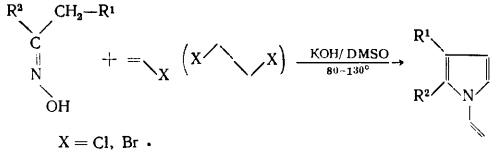
Even *N*-vinylpyrroles in which the initial pyrroles had been difficult to obtain previously by the usual methods or were completely unknown, for example, annelated pyrroles

derived from the oximes of cyclohexanone, suberone, and tetralones, or various alkenyl-, furyl-, and thienyl-pyrroles, became available together with simple alkyl- and aryl-substituted *N*-vinylpyrroles:[12,32-36]



Virtually all ketoximes containing at least one reactive methyl or methylene group in the α-position relative to the oxime functional group undergo this reaction.

A new effective procedure for the direct vinylation of pyrroles in a strong base–DMSO system has been developed.[37,38] *N*-Vinylpyrrole was obtained by this method in high yields under mild conditions at atmospheric pressure and temperatures in the range 80–100 °V (previously NH-heterocycles were vinylated under a pressure of 10–20 atm). Trofimov and co-workers[39-41] showed for the first time that the interaction of ketoximes with vinyl halides or halogenoethane in the same KOH–DMSO system also leads to *N*-vinylpyrroles:



X = Cl, Br .

Depending on the structure of the reactant and the conditions, this reaction can be directed towards the preferential formation of vinylated or non-vinylated pyrroles.[39-41]

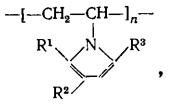
Thus effective, safe, and technologically viable methods of synthesis of *N*-vinylpyrroles, based on the use of cheap and readily available starting materials, namely ketoximes and ultimately ketones and also acetylenes, vinyl halides, and halogenoethane, have now been developed, which creates conditions for their wide-scale employment as monomers.

III. RADICAL POLYMERISATION OF *N*-VINYLPYRROLES

The study of the radical homopolymerisation of a series of *N*-vinylpyrroles has been undertaken.[21,42-44] Its aim was to seek the optimum conditions for the synthesis of the polymers, the analysis of their structure, and also the estimation of the reactivities of the monomers and the properties of the polymers.

It was established beforehand that hydrogen peroxide and benzoyl peroxide do not initiate the polymerisation of *N*-vinylpyrroles, but induce a deep colour in the monomers. It may be that the inertness of hydrogen peroxide under the given conditions is associated with the tendency of *N*-vinylpyrroles, indole, and some of their derivatives to oxidise.[45] The inability of benzoyl peroxide to initiate the polymerisation of certain vinyl monomers is usually explained by the rapid decomposition of the peroxide in the presence of these compounds[46] or by the addition of the products of its decomposition to the monomer, as happens for enamines,[47] ethyl vinyl sulphide,[48] and vinyl ethers.[49]

The homopolymers of substituted *N*-vinylpyrroles having the structure



where R^1 = H, Me, or Ph; R^2 = H or Me; R^3 = H or $COCF_3$; and $R^1 - R^3 = (CH_2)_4$, have been synthesised under conditions of radical initiation by azobisisobutyronitrile (ABIN).[42-44]

The occurrence of polymerisation involving the vinyl double bond has been demonstrated by ^{1}H NMR and infrared spectroscopic data. The absorption bands of the N–CH=CH_2 groups (at 582, 859, 946, 1582, and 1640 cm^{-1}) disappear from the infrared spectra of the polymers, but the characteristic bands of the pyrrole ring remain at 708, 1300, 1490, and 1540 cm^{-1}. The ^{1}H NMR spectra of the polymer contain no signals of the protons of the vinyl group (4.78 and 4.30 p.p.m.) and there are no significant perturbations in the resonance of the protons of the pyrrole rings, although a broadening of the signals characteristic of the polymers is observed.[42-44]

Solutions of the polymers in chloroform and carbon tetrachloride are intensely coloured, which is probably due to the ability of the test compounds to form charge-transfer complexes (CTC) with various halogens, hydrogen halides, and halohydrocarbons, which also happens for *N*-vinylindole[26] and *N*-vinylcarbazole.[20] The possibility of a formation of such complexes has been demonstrated in relation to poly-*N*-vinyl-4,5,6,7-tetrahydroindole.[44] When this polymer has been treated with a hot 1% aqueous HCl solution, its EPR spectrum contains a singlet with a width of 22 G, which can be due to centres of the CTC type (the concentration of unpaired electrons is 3×10^{17} spins g^{-1}). The appearance of a colour on prolonged contact with air justifies the hypothesis of the possible formation of complexes of these polymers with atmospheric oxygen. A freshly prepared polymer is virtually diamagnetic *in vacuo* (10^{-4} mmHg) and contains only traces of a paramagnetic admixture. Heating of the specimen at 150 °C for 5 h does not induce any changes in the EPR spectrum. However, when the polymer has been subjected to an analogous treatment in air after evacuation, its spectrum shows a low-intensity singlet with a width of about 10 g (the concentration of paramagnetic centres is 4.5×10^{16} spins g^{-1}).[44] Consequently the complex is formed precisely with oxygen and is not due to temperature-induced changes in the structure of the polymer leading to an expansion of the conjugation system. CTC of this type are readily decomposed on heating in a high vacuum. The intensity of the EPR signal then falls almost to zero.

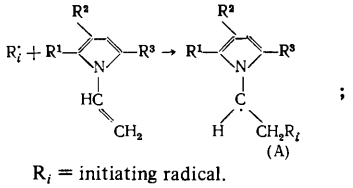
The results of the study of the polymerisation of *N*-vinylpyrroles justify their arrangement in the following sequence in terms of decreasing reactivity: 2-methyl-*N*-vinylpyrrole (I) > *N*-vinyl-4,5,6,7-tetrahydroindole (II) > 2,3-dimethyl-*N*-vinylpyrrole (III) > 2-phenyl-5-trifluoroacetyl-*N*-vinylpyrrole (IV) > 2-phenyl-*N*-vinylpyrrole (V).[42,43]

Conjugation between the pyrrole ring and the N-vinyl group has been demonstrated in *N*-vinylpyrroles by infrared[50] and ultraviolet[51] spectroscopy, NMR,[52,53] and the study of the relative basicities.[54]

According to ^{13}C NMR data,[52,53] the intensity of the $p-\pi$ conjugation in the *N*-vinyl group in the ground state of the series of compounds investigated falls in the sequence (II) ≥ (III) > (I) > (V) > (IV). Consequently the observed sequence of the monomers based on their reactivities in radical polymerisation is not associated directly with the effect of conjugation. Steric factors, namely the decreased probability of collisions with the growing radical and the

steric blocking of the active radical centre for the less compact monomers (III), (IV), and (V), apparently play an important role in the chain propagation stage.

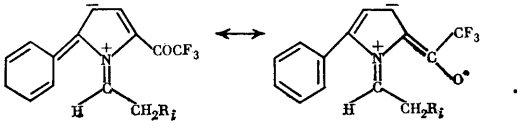
Another important factor influencing the character of the polymerisation should be the relative stability of the radical (A) responsible for chain propagation



(A)

R_i = initiating radical.

The stabilisation and may be the loss of reactivity of the radical (A) owing to the interaction with a neighbouring heteroatomic system will be more pronounced the greater the number of electron-donating substituents or substituents capable of conjugations are present in the ring, which has in fact been observed. Thus the unpaired electron in 2-phenyl-5-trifluoroacetyl-*N*-vinylpyrrole can be effectively distributed via a mechanism involving conjugation with participation of both substituents. For example, one may quote two of the large number of possible canonical structures:



Thus compounds (IV) and (V) should tend to form the most stable and perhaps also the least reactive radical, which in all probability explains their low reactivity in radical polymerisation.[44]

The kinetic parameters of the polymerisation of *N*-vinyl-4,5,6,7-tetrahydroindole have been estimated.[55] It has been established that polymerisation in bulk and in solution in benzene proceeds in the initial stages as a steady-state process at rates which depend on the concentrations of the reactants and the experimental temperature and is described by the equations

$$\lg V_0 = (-3.75 \pm 0.05) + (0.52 \pm 0.02) \lg[I],$$
$$\lg V_0 = (-5.22 \pm 0.02) + (0.98 \pm 0.03) \lg[M],$$

where [I] and [M] are the concentrations of the initiator of the monomer.

The kinetic reaction orders with respect to the monomer and the initiator have been determined together with the effective rate constant for the polymerisation K_{eff}, whose value proved to be virtually identical with K_{eff} for polymerisation in bulk found from the dependence of lg [M] on the reaction time. Thus the initial rate of polymerisation is described by a concentration dependence typical for the polymerisation of vinyl polymers with bimolecular termination of the kinetic chains.

The temperature dependence of the effective rate constant for the polymerisation in bulk is described satisfactorily by the Arrhenius equation

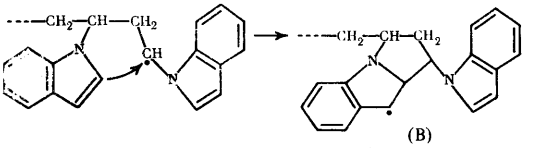
$$\lg K_{eff} = (9.5 \pm 0.4) - (4635 \pm 152) T^{-1}.$$

The effective activation energy and the pre-exponential factor are respectively 88.7 ± 2.9 kJ mol^{-1} and (3.0 ± 1.1) × 10^9 litre$^{1/2}$ $mol^{-1/2}$ s^{-1}. The average rate of initiation is 2.16×10^{-7} mol $litre^{-1}$ s^{-1}.

According to kinetic calculations,[55] the comparatively low chain propagation rate constants in the radical polymerisation of *N*-vinyl-4,5,6,7-tetrahydroindole compared with other vinyl monomers, where the activation energies are approximately the same, are caused by the influence of entropy factors, namely by the steric hindrance induced by the presence of the bulky tetrahydroindole substituents.

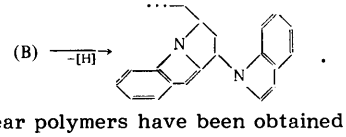
The average length of the kinetic chain ($\bar{\nu}$ = 42–107) greatly exceeds the experimentally observed length of the polymer chain ($\bar{P}$ = 20–33) for the same rate of initiation, which indicates a significant role of transfer processes in the termination of the growing chain. It was demonstrated by special experiments that there is no chain transfer to benzene. Another chain self-transfer constant obtained, which amounts to 1.49×10^{-2}, led to the conclusion that at 60 °C it is impossible to obtain polymers of *N*-vinyl-4,5,6,7-tetrahydroindole with $M_n > 10\,000$.[55]

A possible cause of the oligomeric character of the polymerisation products is intramolecular cyclisation of the macroradical as a result of the attack by the vinyl radical centre on a neighbouring pyrrole ring accompanied by its dearomatisation, the loss of hydrogen, and the subsequent chain transfer to the monomer analogous to that which occurs in the case of *N*-vinylindole:[56]

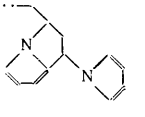


(B)

On the basis of the analysis of the ^{13}C NMR spectra using model compounds, it has been concluded[56] that the radical polymerisation of *N*-vinylindole involves partly the C(2)–C(3) bond of the indole ring and the formation of tricyclic condensed indoline structures, whose content in the polymer is about 25% judging from the intensity of the corresponding ^{13}C signals. Polycyclic radicals of type (B) should evidently exhibit a reduced reactivity as a consequence of stabilisation by the π-electron system and also the enhanced tendency towards chain termination as a result of the abstraction of a hydrogen atom and aromatisation:



The usual linear polymers have been obtained only for the *N*-vinyl derivatives of 2-methyl- and 2,3-dimethylindoles, i.e. compounds in which the 2-position has been substituted. As in the 3-methyl-*N*-vinylindole macromolecules, anomalous indoline structures have been detected in these polymers.[56] On the other hand, there are no anomalous signals in the ^{13}C NMR spectrum of poly-*N*-vinylpyrrole.[56] However, bearing in mind the limited sensitivity of the method, one cannot fully exclude the possibility that the polymer contains (albeit in the form of end fragments) small amounts of the corresponding bicyclic structures:



The formation of additional cyclic structures in the polymerisation of *N*-vinylpyrroles agrees with data obtained in the study of cyclopolymerisation as a phenomenon.[57] Intramolecular cyclisation of this kind can prove to be in a number of instances a thermodynamically more favourable process than intermolecular chain propagation reactions.

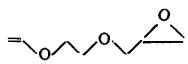
The maximum yield in the radical polymerisation of *N*-vinylindoles reaches 79% (for 2-methyl-*N*-vinylindole), while the minimum yield is 6% (for 2,3-dimethyl-*N*-vinylindole). The molecular weight of the polymers is 4000–10 100.[46]

Thus the reactivity of the monomers and the structure of the polymers formed depend strongly on the positions and numbers of the methyl groups in the pyrrole ring. However, in the series of *N*-vinylpyrroles (I)–(V), it is at present impossible to establish a clear-cut dependence of the reactivity of the monomers on their structure, because the structure is determined not only by different electronic and steric effects but also by the fundamental difference between the chain propagation and chain termination pathways.

IV. COPOLYMERISATION OF *N*-VINYLPYRROLES

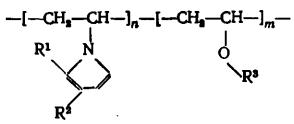
The majority of the known polymers obtained on the basis of monomers with pyrrole rings (mainly as part of the carbazole and indole systems) do not contain functional groups permitting a specific modification of their properties. Interesting possibilities of this kind have arisen from the copolymerisation of *N*-vinylpyrroles with vinyl compounds containing reactive groups such as the oxiran ring.

The copolymerisation of a series of substituted *N*-vinylpyrroles, namely 2-methyl-*N*-vinylpyrrole,[58,59] *N*-vinyl-4,5,6,7-tetrahydroindole,[60,61] and 2-phenyl-*N*-vinylpyrrole[58,59] with the glycidyl vinyl diether of ethylene glycol, called vinylox,[11] has now been investigated:



There are literature data showing that in some cases the copolymerisation of *N*-vinylindole[28] and *N*-vinylcarbazole[20] with various monomers entails the formation of the homopolymers of the initial compounds together with the copolymers. However, the character of the curves for the turbidimetric titration of the copolymerisation products indicates the formation of true copolymers in the given instance.[58,59] This conclusion is supported also by data obtained by fractionating the copolymers in which all the fractions show identical compositions close to that of the initial copolymer.[58,59]

The infrared and ^{1}H NMR spectra of the copolymerisation products confirmed the disappearance of the vinyl groups of the pyrroles and vinylox, the signals of the epoxy-groups in the pyrrole rings remaining unaltered.[58,61] Thus it has been shown that the copolymerisation involves the double bond of the vinyloxy- and *N*-vinyl groups:



R^1 = Me, Ph, $R^1 = R^3 = (CH_2)_4$, $R^3 = (CH_2)_3OCH_2CH{-}CH_2$ (O)

The copolymers are formed for any initial ratios of the monomers and are always enriched in pyrrole units. The initial composition is the main factor which determines the overall rate of reaction and the characteristics of the polymers.

A method for the determination of the content of pyrrole groups in the copolymers from ^{1}H NMR data has been developed in order to estimate quantitatively the composition of the copolymers.[62] The specific activity and polarity factors (see Table) have been determined from the quantitative estimation of the reactivities of *N*-vinylpyrroles within the framework of the *Q*–*l* scheme. The quantities $Q_2 = 0.021$ and $l_2 = -1.44$ for vinylox were used in the calculation.[63] The negative polarity of *N*-vinylpyrroles indicates the electron-donating character of the nitrogen atom in the radical formed. The quantities obtained within the framework of the *Q*–*l* scheme indicate a weaker conjugation (compared with the vinyloxy-group) between the double bond and the heteroatom.

It has been established in the course of partition chromatography that all the copolymers have a unimodal distribution and that their molecular weight is fairly homogeneous.[59]

The "copolymerisation limit", calculated by the method of Prokof'ev et al.[64] for the *N*-vinyltetrahydroindole and vinylox copolymers, is reached when the indole monomer has been consumed, regardless of the composition of the initial mixture, but the degree of conversion is determined by the initial composition.[66]

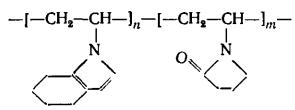
Calculation of the distribution of the copolymer units by the method of Gindin et al.[65] showed that, whatever the initial content of *N*-vinyl-4,5,6,7-tetrahydroindole, large blocks of the given monomer separated by one or two vinylox units predominate in the chain.

The copolymerisation constants (r) and the parameters of the specific activity (Q) and polarity (l) of *N*-vinylpyrroles.[62]

M_1	r_1	r_2	Q_1	l_1
2-Methyl-*N*-vinylpyrrole	6.5	0.05	0.024	−2.86
N-Vinyl-4,5,6,7-tetrahydroindole	5.2	0.06	0.020	−2 45
2-Phenyl-*N*-vinylpyrrole	3.4	0.32	0.013	−1.59

Note. M_1 = *N*-vinylpyrrole and M_2 = vinylox; $Q_2 = 0.21$ and $l_2 = 1.44$.[63]

A method has been developed for the preparation of the copolymers of *N*-vinyl-4,5,6,7-tetrahydroindole with *N*-vinylpyrrolidinone:[44,67]



The copolymerisation was carried out in a solvent or in its absence in the presence of ABIN and the yield of the copolymers reached 66–94%.

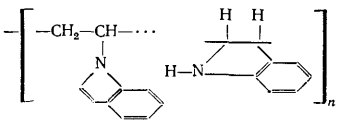
The possibility of using the absorption band of the carbonyl group of *N*-vinylpyrrolidinone at 1690 cm^{-1} for the quantitative determination of the composition of its copolymers was demonstrated previously.[68] The above method has been used also to estimate the composition of *N*-vinyl-4,5,6,7-tetrahydroindole copolymers.[44]

Under the conditions investigated, the maximum content of the tetrahydroindole fragments in the copolymers is 68% and the molecular weight diminishes with increasing fraction of the indole component from 20 000 to 2000. The use of benzene as the solvent reduces the molecular weight of the products without affecting significantly the composition of the copolymers.[44,67,69,70]

Like the *N*-vinyl-4,5,6,7-tetrahydroindole homopolymer, the copolymers are capable of forming complexes of the CTC type with atmospheric oxygen and hydrochloric acid.[44]

Studies[71–73] of the polymerisation of *N*-vinylindole and its 2- and 2,3-methylated analogues established that all the monomers readily polymerise under the influence of free radicals, cationic catalysts, radical-cations, and Ziegler–Natta catalysts and also thermally in the absence of catalysts.

Copolymers with indole, methylindole, indene, and coumarin with equimolar proportions of the monomeric fragments have been obtained under the conditions of thermal initiation:[71–73]



The yield of the polymers is 45% (indole)–78% (coumarin) and the intrinsic viscosity does not exceed 0.2 dl g^{-1}.

The attempts to synthesise the homopolymers of the above comonomers under identical conditions (thermopolymerisation at 150–200 °C) were unsuccessful.[71]

According to gel-chromatographic data, all the copolymers have a unimodal molecular weight distribution.[71] However, the structure of the copolymers has been demonstrated on the basis of infrared spectroscopic data.[71] The intensity of the bands of the indole ring (at 1539 and 714 cm^{-1}) in the infrared spectra of the copolymers is reduced, the band due to the N–H bond (at 3448 cm^{-1}) is present, and the characteristic frequencies of the C=C bond of *N*-vinylindole (at 1612 and 850–820 cm^{-1}) disappear.

The ^1H NMR spectra in deuteriobenzene yield a minimal amount of information as a consequence of the poor solubility of the copolymers but the ratio of the signal intensities of the aromatic and aliphatic protons confirmed the proposed structures.[71]

V. COPOLYMERISATION OF *N*-VINYLPYRROLES WITH ELECTRON-ACCEPTING MONOMERS

The copolymerisation of *N*-vinyl compounds with electron-accepting monomers usually leads to copolymers with a specific structure and properties and also yields interesting information about the formation of charge-transfer complexes and about their role in polymerisation processes. Unfortunately no information about the behaviour of simple *N*-vinylpyrroles in copolymerisation of this kind is as yet available in the literature. It has been stated[74,75] that the copolymerisation of *N*-vinylcarbazole with maleic anhydride is impossible, since the radical-ions formed as a result of the interaction of the monomers induce the kinetically more favourable homopolymerisation of *N*-vinylcarbazole. However, it was later shown that the copolymerisation of these monomers is possible in the presence of free-radical initiators, although some poly-*N*-vinylcarbazole is nevertheless always formed.[76]

A detailed study of the copolymerisation of *N*-vinylindole with maleic anhydride has been published recently.[77] The formation of alternating copolymers of *N*-vinylindole with the acceptor indicated had been published earlier,[51] but no structural characteristics of the products were indicated.

It has also been reported that *N*-vinylindole does not polymerise in acetonitrile at 40 °C in the presence of small amounts of maleic anhydride.[25] On the other hand, under the influence of free-radical initiators, *N*-vinylindole copolymerises with fumaronitrile and diethyl fumarate and the copolymers have a distinct alternating structure.[78–79] As a rule, the monomeric units of the acceptor predominate in the macromolecules of such copolymers as a result of side reactions involving the 3-position of the indole ring.

When *N*-vinylindole and maleic anhydride dissolve in chloroform, a pale-yellow colour appears, which indicates the electronic interaction of the monomers according to the data of Priola et al.[77] However, a distinct upfield shift of the signal of the protons of maleic anhydride is observed in its ^1H NMR spectrum when *N*-vinylindole is added. The shift has been attributed[77] to the reversible complex formation reaction between *N*-vinylindole and maleic anhydride. The equilibrium constant K_e, found[77] by Hanna's method,[80] is 0.25 litre mol^{-1} (in chlorform at 25 °C), which is extremely close to the value K_e = 0.28 litre mol^{-1} obtained for the maleic anhydride–indole system[81] (in chloroform at 20 °C). It is of interest that the same equilibrium constant (0.28) has been found[77] also for the *N*-methylindole–maleic anhydride system. This finding indicates complex formation mainly via the indole ring. Comparison[77] of the data obtained with the values of K_e for the copolymerisation of maleic anhydride with styrene, vinyl acetate, trimethylvinylsilane, ethyl vinyl ether, and ethyl vinyl sulphide leads to the conclusion that the electron-donating properties of *N*-vinylindole and styrene[82] in relation to maleic anhydride are similar and one can therefore expect alternating copolymers with the given acceptor, as for *N*-vinylindole, which is in fact observed in reality. If the copolymerisation is carried out in the absence of an initiator, then thermo- or photo-activation is required for the attainment of an acceptable degree of conversion.[77] Polymers obtained in the presence of free-radical initiators have comparatively high molecular weights (of the order of 56 000).

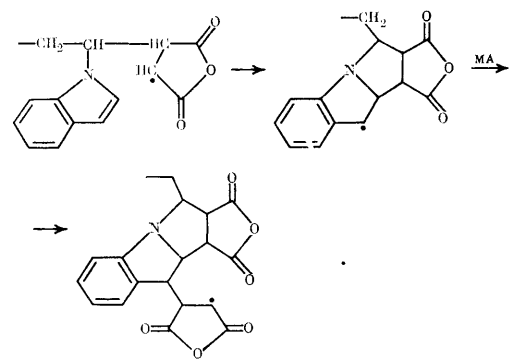
The spontaneous copolymerisation of *N*-vinylindole in the absence of free-radical initiators or Lewis acids suggests that the monomers can form CTC in the initiation stage.

The degree of conversion, the molecular weights, and the composition of the copolymers depend appreciably on the type of solvent in which the copolymerisation is carried out. Highly polar solvents such as acetonitrile or dimethylformamide promote the exclusive formation of the *N*-vinylindole homopolymer. This is explained by the fact that the equilibrium:

$$D + A \rightleftarrows [D \rightarrow A] \rightleftarrows [D^{+\cdot} A^{-\cdot}] \rightleftarrows D^{+\cdot} + A^{-\cdot},$$

where D is the monomer-donor and A the monomer-acceptor, is displaced to the right with increase in the ability of the solvent to solvate the ions.[77]

Analysis of the ^{13}C NMR spectra and the composition of the copolymers led to the conclusion[77] that the copolymerisation is complicated by cyclisation involving the 2-position in the indole ring and additional molecules of maleic anhydride (MA) in accordance with the scheme



The possibility of the participation of the C(2)–C(3) bond of the indole ring in copolymerisation with maleic anhydride has been confirmed by the synthesis of alternating copolymers of unsubstituted indole with the same comonomer-acceptor.[81]

The copolymerisation of maleic anhydride with methylindoles has also been investigated.[77] The fact that the composition of the copolymers does not change significantly as the composition of the initial mixture is varied is regarded as evidence in support of the mechanism of the alternating copolymerisation of *N*-vinylindole and its 2-, 2,3-, and 3-methyl derivatives. It is of interest that 2,3-dimethyl-*N*-vinylindole, for which reactions involving the C(2)–C(3) bond should be difficult, gives rise to 1:1 copolymers. On the

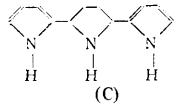
other hand, the dependences of the degree of conversion and of the intrinsic viscosity on the composition of the initial mixture are extremely complex and cannot be interpreted solely on the basis of the idea that the CTC formed undergoes homopolymerisation.

VI. CATIONIC POLYMERISATION

The cationic polymerisation of *N*-vinylpyrroles has been studied to a much lesser extent than the radical polymerisation. If one disregards the vinyl derivatives of carbazole and indole, then there exist apparently only two brief mentions of the polymerisation of pyrroles proper.[17,83] In one of these[83] *N*-vinylpyrrole and vinylindole were mentioned among a large number of vinylamines subjected to polymerisation in the presence of Lewis acids and their complexes with ether such as $ZnCl_2$, BF_3, $BF_3.OEt_2$, $AlBr_3$, $SnCl_4$, and $AlCl(Et_2)$. The polymerisation is carried out without a solvent or in an organic solvent, preferably an aromatic hydrocarbon or ether, in the temperature range from −100° to 100 °C and at a catalyst concentration of 10^{-3} mole per mole of the monomer.

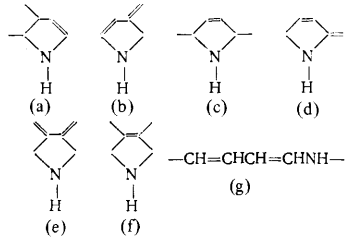
The synthesis of a specimen of poly-*N*-vinylpyrrole by the cationic polymerisation in the presence of $BF_3.OEt_2$, for comparison with the polymer obtained under the influence of an excess of CCl_4 (the polymers proved to be identical according to the infrared spectra), has been described.[25] The conditions of the cationic polymerisation and the yield are not quoted.

In general, bearing in mind the high sensitivity of the pyrrole ring to the action of various acid agents, one can hardly hope for the smooth polymerisation of *N*-vinylpyrroles under the conditions of cationic catalysis. In fact, the pyrroles and oligomers obtained under the influence of strong acids have been known for more than 100 years (quoted after Lamb and Kovachic[84]). In particular pyrrole was trimerised with the aid of HCl as early as 1888. Although different structures were attributed to the trimer formed,[84] only the formula (C), proposed in 1957,[85] satisfies all the available experimental data.

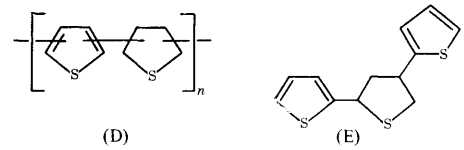


(C)

The polymerisation of pyrrole under the influence of trichloroacetic acid has been studied.[86] However, no data have been presented concerning the structure of the insoluble polymer formed. Later several non-aromatic structures (a)–(g) were proposed for the repeating units of the oligomer chain in the pyrrole oligomer obtained with the aid of the same catalyst:[87]



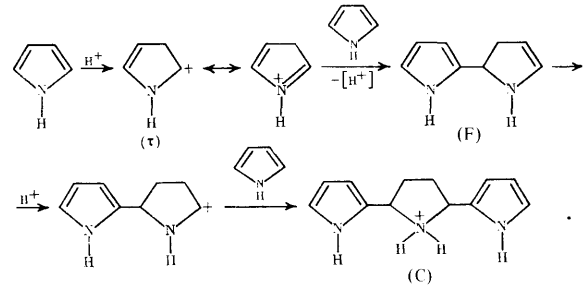
It is known that, on treatment with aluminium chloride or trifluoroacetic acid, thiophen is converted into a polymeric product whose characteristics are closest to formula (B):[88,89]



(D) (E)

The liquid trimer (E) can be obtained by bringing thiophen into contact with phosphoric acid.[90,91] These data as well as the structure of the pyrrole trimer (C) justify the hypothesis that the chain formed in the oligomerisation of pyrrole under cationic conditions has alternating aromatic and non-aromatic structures by analogy with thiophen oligomers.

On the basis of ^{13}C and ^{1}H NMR, infrared and ultraviolet spectroscopic data, the results of mass-spectromatic studies, and the determinations of molecular weights, it has been recently confirmed[84] that the bulk of the pyrrole oligomer obtained in the presence of acids has the trimeric structure (C). The pyrrole ring is known to be protonated mainly in the 2-position.[1,2] This fact gives rise to certain difficulties when attempts are made to account for the formation of the trimer having the structure indicated. In order to obviate such difficulties, it is assumed[85] that, although the 2-protonated pyrrole does in fact predominate in the reaction mixture, its 3-protonated isomer is the more reactive electrophile. Protonation in the 3-position leads to the cation (τ) which in its turn reacts with pyrrole to form the dimer (F). Subsequent attack by its protonated form on the pyrrole ring leads to the protonated trimer (C):[84]



The positive charge on the nitrogen atom of the pyrrolidine ring lowers the reactivity of the neighbouring pyrrole rings with respect to the subsequent electrophilic attack. This is used to explain the relative stability of the trimer compared with other trimerisation products.[85]

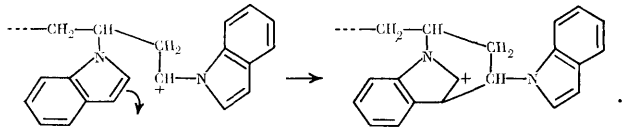
Together with the trimer (A), a coloured insoluble polymer, known for a long time as red pyrrole, is formed when pyrrole is acted upon by strong acids.[84] Its composition is variable, since it is continuously oxidised in air. In terms of its instability, it resembles the trimer. It has been suggested that the formation of "red pyrrole" can entail also ring opening.[84]

The involvement of the pyrrole ring in the formation of the macromolecule has been observed recently in the polymerisation of *N*-vinylindole and its methyl derivatives in the presence of $BF_3.OEt_2$.[56] As in radical polymerisation, the methyl groups in the pyrrole ring influence very significantly the yield, the molecular weight, and the structure of the polymers formed.

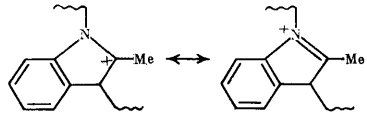
According to ^{13}C NMR spectroscopic data, cyclisation takes place in this case also, although its mechanism differs from that observed in radical polymerisation.[56] The character of the reactivity of the methyl derivatives of *N*-vinylindole is directly opposite to that noted for polymerisation in the presence of radical initiators. Among the methylated *N*-vinylindoles, the 2-methyl derivative gives rise to only

traces of a polymer, while the 3-methyl and 2,3-dimethyl-derivatives are very reactive and readily form polymers with a regular polyvinyl structure and there is no cyclisation side reaction.[56] The polymerisation of unsubstituted *N*-vinylindole leads to products with a partly cyclised structure where the molecular weight and degree of conversion are appreciably lower than for 3-methyl and 2,3-dimethyl derivatives.

It has been suggested[56] that in the cationic polymerisation of *N*-vinylindole the cyclisation reaction proceeds as a result of the attack by the growing cation on the C(3) carbon atom of the indole ring with formation of a six-membered ring in accordance with the following scheme:



The cause of the attack on the 3-position is the high electron density at this carbon atom, typical for indole compounds. All the electrophilic substitution reactions therefore usually proceed precisely in this position.[92] The very low reactivity of 2-methyl-*N*-vinylindole in cationic polymerisation can be explained by the fact that, as a result of intermolecular cyclisation, it forms a more stable tertiary cation, which should therefore be less reactive in the chain propagation stage:[56]



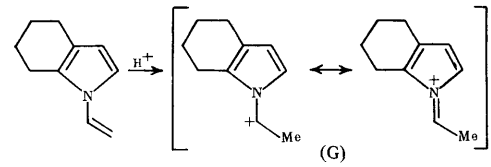
It is well known that, in the presence of halogens, hydrogen halides, alkyl halides, organochlorosilanes, and other electron acceptors, *N*-vinylindole polymerises via the double bond or produces polymeric charge-transfer complexes.[18,26,93,94]

According to Nomori et al.,[25] *N*-vinyl monomers can be arranged in the following sequence in terms of their reactivity towards polymerisation under the influence of electron acceptors: *N*-vinylcarbazole, *N*-vinylindole, *N*-vinylpyrrole. The ionisation potentials of these monomers decrease in the same sequence and hence the ease of their oxidation increases likewise, which is evidently inconsistent with the initiation mechanism postulating electron transfer as the key stage. At the same time, electron acceptors can be arranged in the following sequence in terms of their reactivity in polymerisation: dichlorodicyanobenzoquinone > *p*-chloranil > dichloro-*p*-benzoquinone > tetracyanoethylene > maleic anhydride. This sequence of electron acceptors is consistent with the sequence of the electron affinities and hence with the proposed polymerisation mechanism.

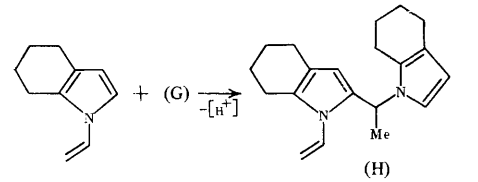
An *N*-vinylpyrrole polymer has been obtained in the presence of excess CCl_4 and the infrared spectrum of the product was consistent with the spectrum of the poly-*N*-vinylpyrrole synthesised in the presence of boron trifluoride etherate.[25]

It must be emphasised that the mechanism of polymerisation in the presence of carbon tetrachloride is not regarded as ultimately elucidated even for *N*-vinylcarbazole, despite the large number of studies devoted to this question.[20]

When *N*-vinyl-4,5,6,7-tetrahydroindole was acted upon by hydrochloric acid, a dimer, the product of electrophilic attack by the immonium cation on the pyrrole ring, was obtained together with the polymer:[95]



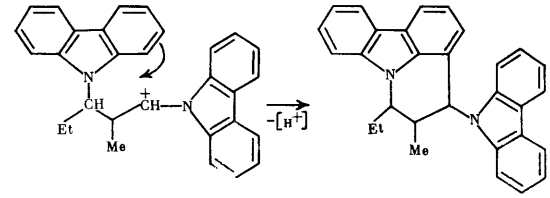
(G)



(H)

When hydrochloric acid is replaced by chlorotrimethylsilane, the yield of the dimer increases to 70%. This reaction leads to interesting possibilities for the synthesis of new *N*-vinylpyrroles.

Even the benzene fragments of the carbazole ring can be subjected to intramolecular attack by the growing cation. This has been demonstrated[22] for *N*-alkenylcarbazoles, which do not form high-molecular-weight products under the influence of acids (H_2SO_4 and $BF_3.OEt_2$), the main reaction being dimerisation. Thus the dimer of *N*-*trans*-propenylcarbazole gives rise to a cyclic product having the following structure:



VII. APPLICATIONS OF POLY-*N*-VINYLPYRROLES

Until recently, *N*-vinylcarbazole was the only widely available representative of the series of *N*-vinylpyrroles. A whole series of promising applications of this polymer have already been discovered: as insulating materials for the electrotechnical industry, particularly in high-frequency technology, and as components for the modification of synthetic rubbers.[15]

Poly-*N*-vinylcarbazole is one of the first and most vigorously investigated photosensitive polymeric systems, the interest in which is due primarily to their possible technological application in non-silver image recording processes—electrophotography, photothermoplastic recording, etc.[96,97]

The stream of publications on the properties and applications of *N*-vinylcarbazole is so great (see, for example, the relevant reviews[96-99]) that the problem indicated apparently requires special consideration and will not therefore be analysed in this article.

A photoconducting polymeric material has been obtained from the copolymers of *N*-vinylindole and its 2- and 3-methyl derivatives with *N*-vinylcarbazole or styrene.[72] These copolymers could be used as solutions or melts forming photosensitive layers for electrophotography.

The thermal copolymerisation of *N*-vinylindole with indole or other heterocyclic compounds having an endocyclic double bond leads to copolymers containing 2,3-indoline fragments in the main chain and indole rings in the side chain.[71-73] These polymers can also be used in electrophotography.

Poly-*N*-vinylpyrroles with high melting points have been synthesised in liquid SO_2 at −10° to −70 °C.[100]

Polyvinylindole has been investigated as a catalyst of photochemical polymerisation using its ability to form radical-ions.[101]

Polymers of *N*-vinylpyrroles having a stable colour have been described in patents.[102,103] The copolymers of *N*-vinyl-4,5,6,7-tetrahydroindole with vinylox sensitised by trinitrofluorenone are photosensitive and are capable of being hardened by polyamines like the usual epoxyresins.[61,66]

The study of the thermal stability of these copolymers by differential thermal analysis demonstrated the possibility of extending the temperature range of the use of the copolymers by introducing the indole component.[60]

In order to increase the assortment of reactive polymeric materials for the synthesis of medicinal drugs, a method has been developed for the preparation of the copolymers of *N*-vinyl-4,5,6,7-tetrahydroindole with *N*-vinylpyrrolidinone.[44,67] Water-soluble copolymers enriched in *N*-vinylpyrrolidinone exhibit an antisilicosis activity in model pneumoconiotic processes,[70] while the *N*-vinylpyrrolidinone homopolymer does not show such an activity.[104]

Products based on annelated pyrroles have been employed for the enrichment of polymetallic ores by flotation.[69] The polymeric flotation agent exhibits effective foam-producing properties when employed in amounts as low as 10 g per tonne of ore and the overall extraction of zinc and lead under these conditions reaches 175% [sic., Ed.], while under analogous conditions industrial foaming agents extract only 90% of the metals.[69]

Overall, the chemistry of *N*-vinylpyrroles is too new to compete successfully as regards practical applications with the chemistry of other pyrroles and even with that of *N*-vinylcarbazole. The examples quoted illustrate only the first advances achieved in the applied employment of *N*-vinylpyrroles.

Thus it follows from the literature data quoted that the chemistry of *N*-vinylpyrroles is developing very vigorously. At the same time some of its aspects have only been outlined for possible investigation. These include the cationic polymerisation whose key stage is the electrophilic substitution of hydrogen in the pyrrole ring by the immonium cation. This reaction can lead to new condensed polycyclic systems.

A characteristic feature of the present state of the chemistry of *N*-vinylpyrroles is the virtually complete absence of quantitative data concerning the polymerisation process and hence the absence of a clear-cut correlation between the structure of the monomers and their reactivity.

In the next few years one may expect the synthesis of new polyvinylpyrroles with properties of practical value both as a result of the use of new monomers of this series and as a result of the chemical modification of the highly reactive pyrrole ring in the polymers already known.

Reactions in Organic Crystals

V.E.Shklover and T.V.Timofeeva

Structural investigations of two types of chemical reactions occurring in organic crystals on heating and irradiation are examined, namely intermolecular rearrangements (including the rearrangement of molecules via the transfer of individual atoms and groups of atoms, isomerisation, stereo-isomerisation, etc.) and reactions with elimination of small molecules (N_2, CO_2, H_2O, HHal). Solid-phase processes are discussed in terms of topochemical reactions and reactions in non-crystalline (amorphous) regions.
The bibliography includes 195 references.

III. Reactions with elimination of small molecules 634

I. INTRODUCTION

Reactions occurring in the solid phase have been known for a long time but they have attracted increasing attention recently, because of two main factors. The first of these is that the occurrence of reactions in the solid phase imposes significant limitations on the mobility of the reacting molecules. This not only facilitates the experimental and theoretical study of chemical reactions in the crystal but frequently creates completely new (compared with traditional liquid-phase reactions) possibilities for their investigation. The combined use of various techniques for the investigation of solid-phase reactions makes it possible to follow the entire chain of molecular transformations taking place and in a number of instances to achieve a well-founded characterisation of their mechanism. The first advances on these lines have already been made as regards the mechanisms of intramolecular rearrangements, reactions with elimination of small molecules, etc. The second factor is that the practical use of the possibilities of solid-phase synthesis which cannot be achieved in liquid- or gas-phase reactions (for example, the preparation of crystalline polymers with chains having a regular structure, the formation of enantiomerically pure products with the configuration of asymmetric centres specified beforehand, etc.) was initiated in recent years.

It is possible to differentiate two main types of solid-phase reactions: topochemical reactions and reactions in non-crystalline regions.[1,2]† The topochemical character of the

†Topochemical reactions consist in the conversion of the molecules of the initial substance into those of the product without the disturbance of the crystal lattice and without the formation of non-crystalline intermediates.[1-4] The relation between the crystallographic directions of the product of the solid-phase process and the initial substance is then referred to as topotaxy.[1]

process makes it possible to predict the structure of the product formed, which is by no means possible in all non-topochemical reactions.

The essential condition for the occurrence of intermolecular solid-phase topochemical reactions is that the shifts in the equilibrium positions of the atoms in the interacting molecules are small, while the thermal vibrations of the molecules themselves are fairly strong. This general principle, formulated by Schmidt,[5-7] can be specified in a more concrete form for solid-phase reactions of the most varied types. For example, it has been established empirically that, in the photochemical interaction of unsaturated molecules in the crystal via their C=C π bonds, topochemical control requires that these bonds should be oriented in parallel and that the atoms formed should be separated from one another by not more than 4.0 Å.[8] In order to stimulate chemical reactions in the solid phase, one employs nowadays virtually all the procedures for the usual chemical reactions, but it is entirely clear that the maximum topochemical control is possible when the solid-phase reactions are carried out with photoirradiation, which makes it possible to create the optimum conditions for the realisation of the principle indicated above. Schmidt's principle has been somewhat modified.[9] The preferred reaction in the crystal is that which requires the minimum change in the form of the "reaction cavity" (the space incorporating the reacting molecule before the reaction and the molecule of the reaction product). The principle of the conservation of the shape of the reaction cavity is especially useful for the explanation of chemical reactions in clathrates and for the description of the reactivities of excimers in crystals.

It must be emphasised that topochemical factors operate also in solid-phase intramolecular reactions, creating in this instance a kind of external limitation to the atomic shift necessary for the occurrence of the reaction (when the internal limitations are defined as those caused by the structure of the molecule itself).[10]

A disposition of the molecules suitable for the reaction is sometimes not inherent in the periodic lattice of the crystal but arises only when defects or dislocations are formed in the latter. However, in this instance too, as in topochemical reactions, the process actually occurs under the control of the lattice, since its direction and mechanism are determined by the fixed disposition of the interacting molecules.

The most important method for the investigation of solid-phase reactions is X-ray diffraction analysis, since it enables one to establish vigorously and quantitatively all the structural and geometrical parameters of the starting materials and final products (the valence and dihedral angles and the bond lengths), so that the process occurring can be adequately characterised when a topochemical mechanism operates. Under the conditions of a non-topochemical mechanism, information about the defects and dislocations and about their number and the principal reaction pathways can be obtained with the aid of electron microscopy. However, this is insufficient for the establishment of the orientation of the molecules at the dislocation boundaries. Computational methods, whereby one can model both the character of the relative disposition of the molecules and the possibility of their displacements in the course of a reaction, are frequently employed in such instances.

An important characteristic of solid-phase processes is their homogeneity or heterogeneity. By a homogeneous process one understands in this instance one whose product forms a solid solution in the lattice of the initial compound. In the corresponding heterogeneous process the product forms its own lattice and does not give rise to solid solutions in the initial compound. In a homogeneous mechanism a transition of the single crystal → single crystal type takes place, while in a heterogeneous mechanism the single crystal of the initial compound disintegrates. One must note that in a number of instances solid-phase reactions are investigated in polycrystalline specimens, which hinders their X-ray diffraction study. Since data concerning the structure of the crystal obtained from an X-ray diffraction study are averaged both in space (throughout the crystal) and in time, it is difficult to characterise by this method the homogeneity and heterogeneity of the process (with the exception of cases of the so-called dynamic X-ray diffraction analysis used for comparatively slow processes). Important additional information about the character of solid-phase processes and about the movement of the molecules involved in the reaction can be obtained from Raman phonon spectra. Thus a sufficiently complete picture of solid-phase processes can be obtained solely by a combined study of the structure and reactivity of the organic crystals using the entire set of the methods indicated above.

Investigation of chemical reactions in solid crystals (see the relevant reviews[1,9-17]) led to the development of a new scientific discipline, which arose recently at the frontier between organic chemistry and organic crystal chemistry (crystal engineering). The aim of this new discipline is to understand and formulate the main rules and principles governing the structure of the packing of potentially reactive molecules in crystals such that the most favourable conditions are created for the participation of the molecules in particular chemical reactions and rearrangements without the need for diffusion and requiring only a slight rearrangement of the crystal packing with topochemical control of the process.[17]

This paper represents a review of the structural investigations of chemical reactions in organic crystals published mainly after the appearance in 1977 of our previous review on this topic.[1] The review includes various types of thermal and photochemical intramolecular rearrangements and reactions involving the elimination of small molecules in crystals of organic compounds. In order to demonstrate the wide-scale occurrence of solid-phase reactions, several types of solid-phase processes in molecular crystals formed by complex compounds have also been examined.

The proposed subdivision of the reactions considered in the review into intramolecular rearrangements and reactions involving the elimination of small molecules is to some extent arbitrary. The first of the above two types includes processes in which the overall composition of the molecules of the initial substances and final products is the same. The character of the rearrangements taking place under these conditions is fairly varied. They can be intramolecular, whereupon only proton transfer can lead to a significantly different result: for example, it can lead to a significant alteration of the molecular skeleton, which entails a change in the chemical properties of the compound or to insignificant geometrical changes (the transfer of a hydrogen atom via a hydrogen bond and small conformational changes), as a consequence of which a significant alteration of the physical characteristics of the specimen, particularly its colour, takes place.

The rearrangements of molecules can also take place via the transfer of larger atomic fragments, in particular, methyl or phenyl groups. Together with the instances of intramolecular mechanism, such as, for example, that operating in the stereoisomerisation of metal complexes, there is also a possibility in this case of intermolecular processes. It must be emphasised that all the processes involving the transfer of atoms or groups of atoms mentioned above take place in the manner stated only by virtue of their suitable disposition in the crystal and such disposition can be both inherent in the structure of the crystal itself and can be "created" at its defects or dislocations.

The character of reactions of the second type (with elimination of small molecules) is in most cases predetermined not only by the very disposition of the molecules but also by their interactions in the crystal, in particular, by the existence of a system of intermolecular hydrogen bonds whose chains provide a pathway for the reaction. A striking manifestation of the role of such interactions is provided by the differences between the reactions on different faces and along different directions in crystals.

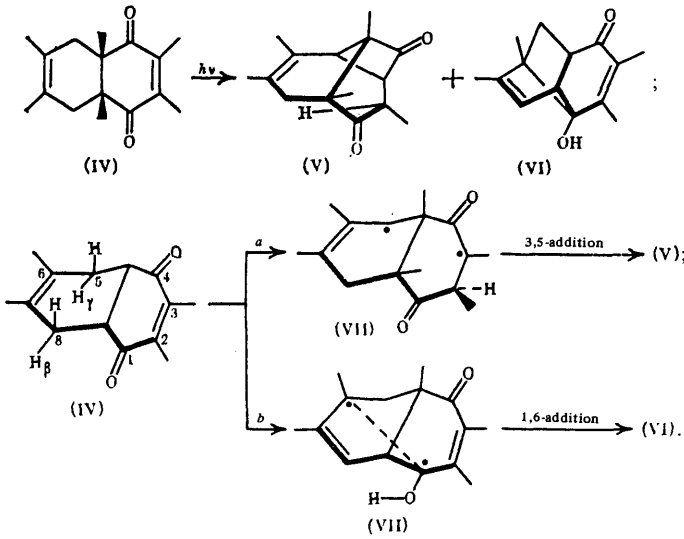
II. INTERMOLECULAR REARRANGEMENTS

The study of the controlling influence of molecular packing in the crystal and the photochemical behaviour of organic systems undergoing unimolecular photo-rearrangements in solution was initiated, according to Scheffer,[10] by investigations of the photoreactions of santonin (I) in the solid phase. It was observed that the photolysis of crystalline santonin results in the formation of a product whose appearance can be accounted for by the formation and subsequent dimerisation of cyclopentadienone (III) and not of luminosanton (II), as in solution (scheme 1). However, the relation between the structure and reactivity remained unelucidated in this instance and required further study.

1. Isomerisation of Naphthoquinone Derivatives

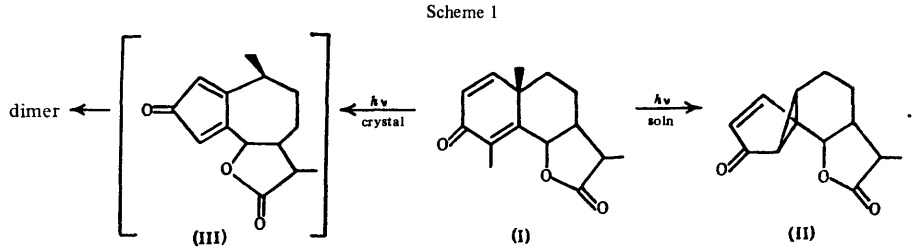
Studies of the photochemical reactions of solutions of Diels-Alder adducts of non-cyclic 1,3-dienes with *p*-quinones have shown that two main types of reactions, which depend on the character of the substituents in the initial adduct, are characteristic of these systems.[18,19] The interaction of a quinone and 1,3-dienes [for example, of the 2,3-dimethylbutadiene adduct (IV) (Scheme 2)] on irradiation of the solution, leads to the formation of cyclobutanones of type (V) as the main product, while compound (VI) has been detected as the side product [with the ratio (V):(VI) = 2:1]. The formation of these photoproducts requires at first sight a very major molecular rearrangement of compound (IV), but it was found that irradiation of crystals of compound (IV) yields the same products and in the same proportions (2:1) as in solution.[20,21]

Scheme 2



The cyclohexane ring of the molecule of compound (IV) has the half-chair conformation in the crystal and has a *cis*-junction with the approximately planar enedione ring. The formation of cyclobutanone (V) (reactions *a* in Scheme 2) takes place as a result of the transfer of the allyl hydrogen atom H_γ to the C(2) atom of the enedione chromophore and the subsequent formation of a bond between the C(3) and C(5) atoms in the biradical (VII) produced. The mechanism of the formation of the dienol (VI) (reaction *b* in Scheme 2) should include the initial excitation of the molecule with subsequent transfer of the H_β atom to the O atom of the carbonyl group at C(1) with formation of the intermediate biradical (VIII). The occurrence of these two competing solid-phase

Scheme 1



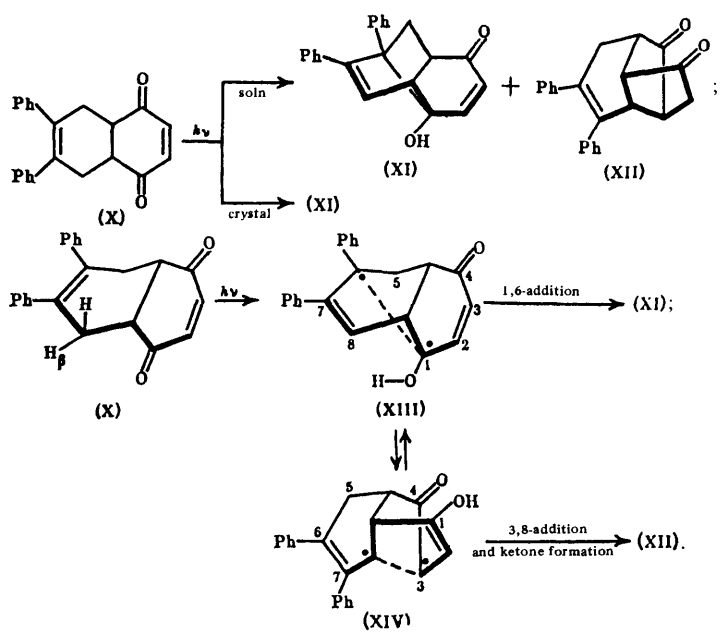
photoprocesses is determined by two factors: (1) the geometry of the initial molecules is extremely favourable for intramolecular transfers of hydrogen atoms; (2) the intermediate states arising in the transfer of H atoms are ideally suitable for the subsequent intramolecular interaction of the biradicals produced. The form of the molecules of the photo-products (V) and (VI) is then extremely similar to that of the initial molecule of compound (IV).[6] Analogous data have also been obtained for the adducts produced in the Diels-Alder reaction between duroquinone and *trans,trans*-hexa-2,4-diene (IX).[10]

Photolysis of the Diels-Alder adduct of *p*-benzoquinone with 2,3-diphenylbutadiene (X) in solution affords the products (XI) and (XII) in proportions of 3:1 (Scheme 3);[10] in this case photoproducts of the type of cyclobutanone are not formed. Photolysis of compound (X) in the solid phase leads to the unsaturated alcohol (XI), which can be regarded as an analogue of compound (VI); the diketone (XII) is not formed. An answer to the question of the causes of the differences between the reaction products in different media was provided by an X-ray diffraction study of compound (X).[22] Since the overall twist-conformation of the molecule of compound (X) found in the crystal apparently predominates also in solution, presumably the reaction in both liquid and solid phases begins with the same conformation as that of the initial molecule of compound (X) and the differences between the reaction products are determined by the conformational flexibility of the biradical intermediate (XIII) produced when a β-hydrogen atom is transferred. In fact the biradical (XIII) has the same conformation as its precursor (X) and can undergo biradical condensation to the dienone alcohol (XI) both in solution and in the solid phase. The direct formation of the diketone (XII) and the biradical (XIII) is sterically impossible[10] and requires a conformational rearrangement of the rings with transition to the biradical (XIV). Naturally, such a transition, which is permissible in solution, is no longer possible in a crystal, so that the photoproduct (XII) is formed only when the reaction is carried out in the liquid phase.

Another example of the different course of a chemical reaction in the crystal and in solution, due to the different possibilities for the necessary conformational rearrangements of the reacting molecules in the liquid and solid phases, is provided by the intramolecular rearrangement in the crystals of 1,3-diphenylindan-2-dione and *NN*-dialkyl-α-oxoamide.[23,24] If the molecular structure limits the possible conformational rearrangements, then the reaction products in solution and in the crystal are as a rule identical; for example, the presence of the axial CH_3 group in the molecule of compound (IV) prevents the rearrangement of the intermediates (VII) and (VIII) and leads to identical products of the photochemical reaction of compound (IV) in both phases investigated.

All the photochemical reactions considered begin with the intramolecular abstraction of a hydrogen atom. Table 1 presents data for the geometry of five compounds, in which photoinitiated solid phase abstraction of a β-hydrogen atom by the carbonyl oxygen atom (leading to the formation of an enone alcohol) has been observed, as well as two adducts produced by the Diels-Alder reaction in which a γ-hydrogen atom is abstracted by the enone carbon atom with formation of photoproducts of the cyclobutane type. Although the data in Table 1 do not refer to the real geometry of the molecule at the instant of photochemical reaction (X-ray diffraction study has yielded the parameters for only the ground electronic state), they nevertheless can reveal the factors which favour such reactions. This applies particularly to the transfer of a β-hydrogen atom to oxygen, since it is quite likely[25-32] that the carbonyl fragment in enones (and apparently also in enediones) retains the geometry of

Scheme 3



its ground state on photochemical excitation. Even when a H_β atom is transferred to the enone C atom, the X-ray diffraction data for the relative positions of the H_γ and C(2) atoms reproduce fairly exactly the geometry of the excited state, because the twisting of the enone C=C π-bond on formation of the activated state alters mainly the parameter τ_C [25-32] (data concerning the possible planarity of the enone molecules in the activated state are quoted by Dyxtra[33] and Jones and Kearns[34]). We may note that such twisting can facilitate the abstraction as a result of the more exact alignment of the 2p orbital of the C(2) atom with the direction of the H_γ atom, i.e. as a result of the increase of the angle τ_C in the direction of the ideal value of 90°.[10]

Table 1. Intramolecular solid-phase reactions accompanied by the transfer of a hydrogen atom.[15]

Initial compound	Product containing the enone fragment	$R(H_\beta...O(1))$, Å	τ_O, deg	Δ_O, deg	Product containing the enedione fragment*	$R(H_\gamma...C(2))$, Å	τ_C, deg	Δ_C, deg
	(XI)	2.46	3	81.3	*	—	—	—
		2.57	5	80.7	*	—	—	—
		2.58	8	83.6	*	—	—	—
	(VI)	2.47	0	85.1	(V)	2.89	52	72.6
		2.26	1	86.4		2.66	50	74.4

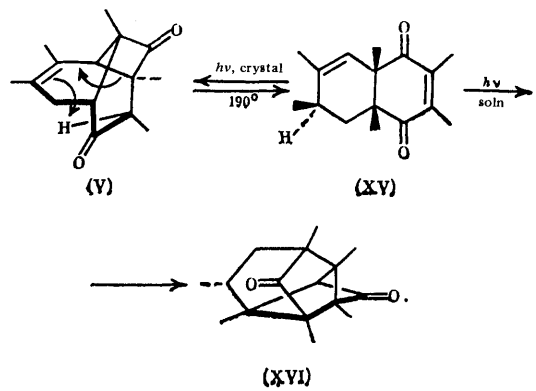
Notation: τ_O is the deviation of the H_β atom from the plane of the carbonyl group at the C(1) atom, Δ_O is the angle $C(1)O(1)H_\beta$, τ_C is the deviation of the H_γ atom from the plane of the C(2)=C(3) double bond, and Δ_C is the angle $C(3)C(2)H_\gamma$.

*Does not form.

The distances between the hydrogen atom and the "abstracting" atom over which the transfer of a hydrogen atom is observed vary from 2.26 to 2.58 Å for abstraction by oxygen and from 2.66 to 2.89 Å for abstraction by carbon, which agrees with the difference between the van der Waals radii of the oxygen and carbon atoms (1.52 and 1.70 Å).[35,36] It is believed[10] that the intramolecular transfer of a hydrogen atom is feasible over distances comparable to the sum of the van der Waals radii of the interacting atoms. If one begins with the postulate that the radius of the hydrogen atom is 1.20 Å,[36] these sums are 2.72 Å for the H and O atoms and 2.90 Å for the H and C atoms. These values are appreciably higher than those proposed earlier on the basis of calculations and/or molecular models. For example, a spherical "activated volume" of the carbonyl group, whose radius has been estimated as 1.7–2.1 Å, has been proposed[37] for the intramolecular photochemical hydrogen atom transfer reactions.

The relative orientation of the orbitals of the "abstracting" atom and the hydrogen atom is no less important. Table 1 shows that the β-hydrogen atom is located in all cases (within the limits of several degrees) in the mean-square plane of the "abstracting" carbonyl group, which favours the thoroughly investigated[38] transfer of a hydrogen atom to the excited carbonyl fragment located in the same plane. The values of Δ_O for these systems are close to 90° (Table 1) and are almost ideal for the transfer considered.[10]

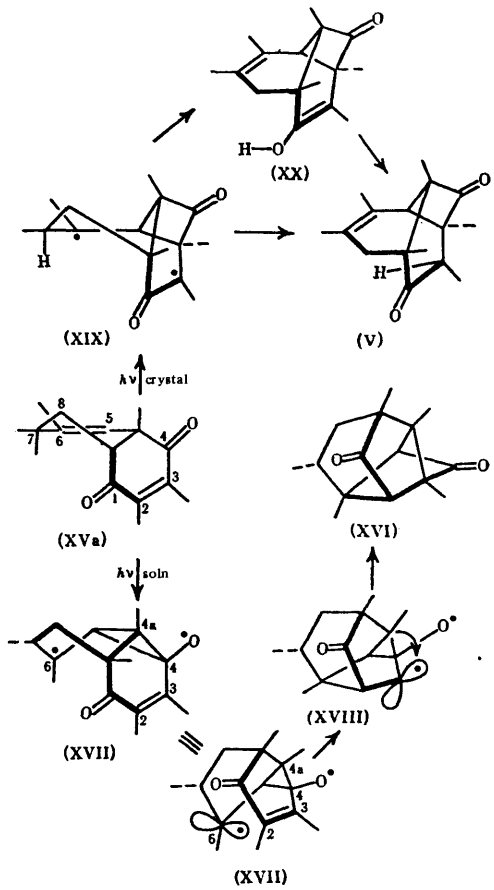
Scheme 4



In the course of thermolysis at 190 °C cyclobutanone undergoes the retroene reaction (Scheme 4), giving a satisfactory yield of the crystalline β,γ-unsaturated ketone (XV),[18] whose further photochemical reactions in solution and in the crystal proceed in entirely different ways. Whereas the explosive photoproduct (XVI) is formed in solution, the initial cyclobutanone (V) is regenerated almost quantitatively in the crystal.[39] According to X-ray diffraction data, the ketone (XV) has the conformation (XVa) in the crystal (Scheme 5) and the bulky CH_3 substituent at the C(7) atom occupies a pseudoequatorial position in this instance. If it is assumed that compound (XVa) behaves as a typical $^3(\pi,\pi^*)$-excited βγ-unsaturated ketone, then in the first stage it should undergo the well known oxadi-π-methane rearrangement[40-43] consisting in the formation of a bridge between the carbonyl carbon atom and the vinyl group, which leads to the product (XVII). The transition to compound

(XVI) requires then the rupture of the C(4)–C(4a) bond with formation of the C(4a)–C(3) and C(6)–C(2) bonds (Scheme 5).

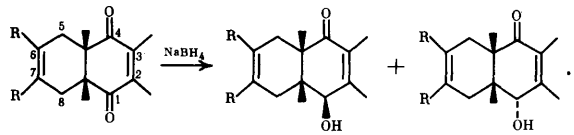
Scheme 5



It has been noted[10] that each stage of the transition (XV) → (XVI) involves a significant displacement of the atoms and deformation of the molecule and leads ultimately to a product, the form of the molecule of which has very little in common with that of the initial molecule. This is not observed in the solid-phase rearrangement, which constitutes a radical difference between the reactivities of compound (XV) in the two different phase states examined.

A detailed comparison has shown that the molecular shapes of compound (XV) and of its photoproduct (V) are very similar. Compound (V) is formed as a result of the appearance of the C(3)–C(5) bond [the 2*p* orbitals of the C(3) and C(5) atoms are directed towards one another; the C(3)...C(5) distance is 3.12 Å, which is less than twice the van der Waals radius of the C atom (3.40 Å)[20]] via the intermediate compound (XIX), which is followed by the intramolecular transfer of the pseudoaxial hydrogen atom from the C(7) atom to the C(2) atom, which takes place either directly or via the enol (XX). The configuration of the C(7) atom in compound (XVa) is extremely favourable for such transfer: the H(7)...O(1) distance is 2.64 Å and we have the angles $\tau_C = 28.5°$ and $\Delta_O = 84.7°$. The mechanism of the solid-phase transition described requires a minimum displacement of the atoms from the initial positions: the C(2), C(3), C(5), and C(7) atoms are rehybridised and the C(3) and C(5) atoms approach one another, but the overall molecular shape is retained. Another mechanism of the (XV) → (V) transformation, differing from the foregoing by the sequence of stages, has also been proposed.[15]

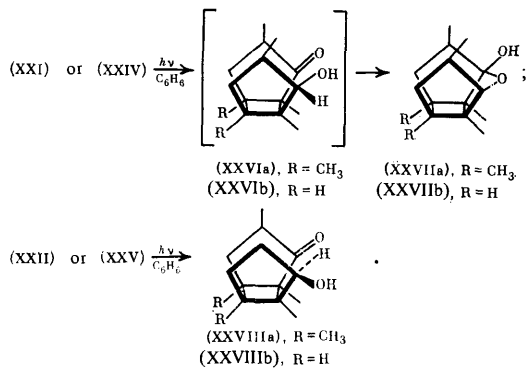
Scheme 6



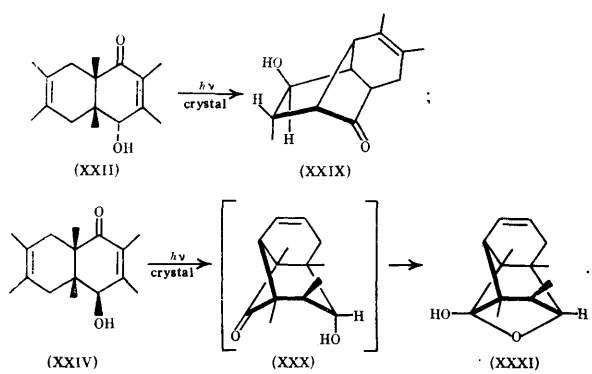
(IV), R = CH_3 (XXI), R = CH_3 (XXII), R = CH_3
(XXIII), R = H (XXIV), R = H (XXV), R = H

The reduction of the duroquinone–butadiene Diels-Alder adduct (IV) leads to a mixture of the alcohols (XXI) (50%) and (XXII) (35%) (Scheme 6). Analogously, the reduction of the duroquinone–butadiene adduct (XXIII) affords the products (XXIV) (63%) and (XXV) (31%). The photochemical behaviour of these products in the solid phase differs sharply from that observed in solution.[44,45] Irradiation at $\lambda > 330$ nm of benzene solutions of all four tetrahydronaphthoquinones (Scheme 7) leads to products of the intramolecular [2 + 2]-cycloaddition having the tetracyclo[5.3.0.$0^{2,6}$.$0^{4,9}$] decane skeleton. In compounds (XXI) and (XXIV) the configuration of the carbon atom to which the OH group is attached is such that the ketoalcohols (XXVIa) and (XXVIb) formed initially cyclise to the internal hemiacetals (XXVIIa) and (XXVIIb). At the same time the formation of similar acetals from the photoproducts (XXVIIIa) and (XXVIIIb) is not observed.

Scheme 7



Scheme 8

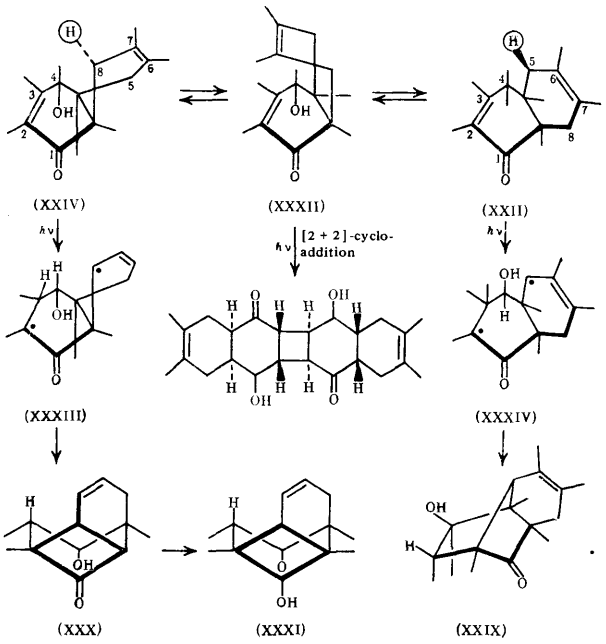


Irradiation of the same substances in the solid phase does not lead to the formation of products with a skeletal structure. The character of the photoproducts formed in the

solid phase is determined, as in solution, by the disposition of the hydroxy-groups in the substrate molecule; a typical picture is presented in Scheme 8. We may note that irradiation of the polycrystalline specimens of compound (XXII) is used to obtain the ketoalcohol (XXIX); the photolysis of the polycrystalline compound (XXIV) is used in exactly the same way for the quantitative formation of the hemiacetals (XXXI) (a structural scheme for this process has been published[31]).

Scheme 9 illustrates the conformation of the molecules of the cyclohexenones (XXII) and (XXIV) in the crystal;[46] the cyclohexenone ring in the half-chair conformation has a *cis*-junction with the cyclohexene fragment (also in the half-chair conformation). Since the carbon atoms attached to the OH substituents have the opposite configurations in compounds (XXII) and (XXIV), these molecules are characterised by the opposite directions of the twist of the second ring. The photoproduct (XXXI) is formed from the conformer (XXIV) as a result of the transfer of the allyl hydrogen atom from C(8) to C(3) and the subsequent formation of the C(2)–C(8) bond in the biradical (XXXIII). The photoproduct (XXIX) is formed via the conformer (XXII) as a result of the C(5) → C(3) transfer of the allyl hydrogen atom and subsequent formation of the C(2)–C(5) bond in the biradical (XXXIV) produced.

Scheme 9



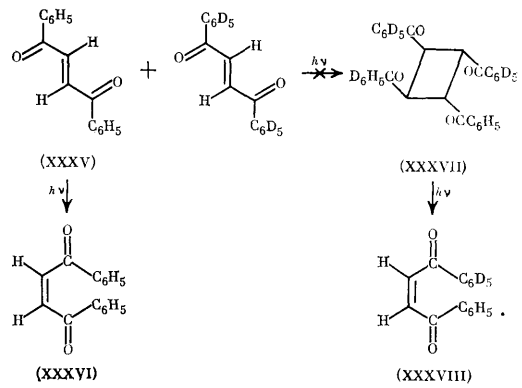
As in the other cases described above, the reactions of compounds (XXII) and (XXIV) proceed with minimal deformations of the molecules. The transfer of a hydrogen atom is achieved over a distance of 2.72 Å in compound (XXII) and 2.84 Å in compound (XXIV), which is less than the limiting distance of 2.90 Å required for the transfer to a carbon atom. The conformational similarity of the biradicals (XXXIII) and (XXXIV) with the products (XXXI) and (XXIX) is also significant.

Comparative analysis of the reactivities of the isomers (XXI) and XXII) in the solid phase, carried out on the basis of their X-ray diffraction study,[47] has shown that the molecules have different conformations in the crystal and the distances from the H_γ atoms to the C(2) and C(3) atoms in compound (XXII) are somewhat smaller than in compound (XXI) (2.78 and 2.72 Å in the former case and 2.88 and 2.92 Å in the latter), which accounts for the reactivity of compound (XXII) [and the lack of reactivity of compound (XXI)] in a solid-phase reaction proceeding via the transfer of a H_γ atom to the β-enone C(3) atom. We may note that the angles Δ_C and τ_C (Table 1) in compounds (XXI) and (XXII) proved to be similar: 75.2° and 78.5° in the former case and 49.3° and 53.2° in the latter.

2. Isomerisation of 1,2-Dibenzoylethylene

Crystalline *trans*-1,2-dibenzoylethylene (XXXV) is gradually converted into the *cis*-isomer (XXXVI) in the light.[48] Since the corresponding cross-product, namely benzoyl(pentadeuteriobenzoyl)ethylene (XXXVIII), was not detected by the mass spectrometry of a solid solution of the bispentadeuteriated analogue of compound (XXXV) and the non-deuteriated compound (XXXV) was used in this reaction, it is suggested that the above isomerisation does not include a stage involving the intermediate formation of the cyclobutane derivative (XXXVII) (Scheme 10).[49]

Scheme 10



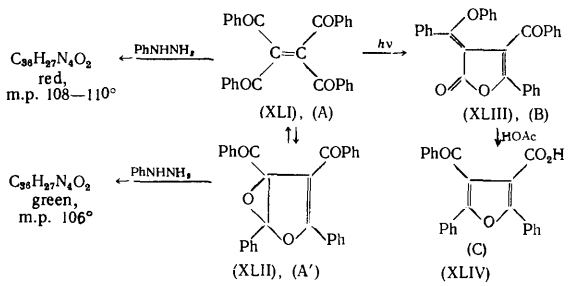
In order to investigate the factors influencing the solid-phase *cis–trans* transformations of compounds of the class considered, the structures of compound (XXXV), *trans*-1,2-ditolylethylene (XXXIX),[48] compound (XXXVI), and *cis*-1,2-bis(*p*-chlorobenzoyl)ethylene (XL)[50] were determined. Analysis of the molecular parameters indicates an appreciable loss of conjugation between the carbonyl and phenyl groups in compound (XXXV) compared with compound (XXXIX). The molecular packing in the crystals of compounds (XXXV) and (XXXIX) is of the stacked type and is not determined by the mutual contacts of the carbonyl group as in the *cis*-isomers (XXXVI) and (XL). The large distances between the centres of the double bonds [5.0 Å in compound (XXXV) and 5.4 Å in compound (XXXIX)] preclude the occurrence in this instance of solid-phase dimerisation reactions with formation of cyclobutane derivatives, which agrees with the data of Griffin et al.[49] The mutual orientation of the crystallographic axes of the phases (XXXV) and (XXXVI) has been determined from the X-ray diffraction pattern of compound (XXXV), on which reflections characteristic of compound (XXXVI) appear.[49] The packing density in the *cis*-isomer is somewhat smaller (the unit cell volumes are V_{cis} = 608.9 A^3 and V_{trans} = 596.1 A^3). The transition (XXXV) → (XXXVI) is accompanied by the loss of the centre of symmetry and leads to a change in the space group ($P2_1/c \rightarrow P2_1$). Even in the imperfect crystals of compound (XXXV)

the rate of rearrangement is low, i.e. the photoisomerisation apparently takes place in defective regions and is propagated via the dislocations formed around the nuclei of the *cis*-isomer.[48]

3. Isomerisation of Tetrabenzoylethylene

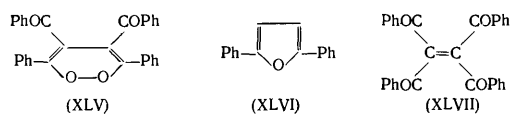
Tetrabenzoylethylene exists in three crystalline forms: two colourless forms (A) and (A') and in the yellow form (B), to which structures (XLI), (XLII), and (XLIII) respectively have been ascribed (Scheme 11).[51–55]

Scheme 11



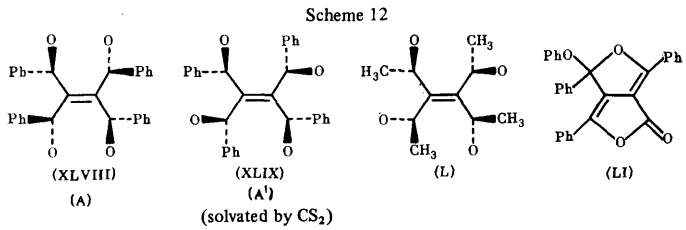
In daylight form (A), produced on crystallisation from a large amount of organic solvents, is irreversibly converted into form (B), whose treatment with acetic acid affords the product (C), to which the structure (XLIV) has been attributed. Crystals of compound (A') are obtained by crystallisation from CS_2 and are resistant to the action of light.

In addition, the structure (XLV) has been proposed[54] for compound (A'). The structure (XLIV) of the product (C) has been confirmed[55] by the formation of 2,5-diphenylfuran (XLVI) on its decomposition. Data for the tetra-acetyl derivative (XLVII) have been used in the analysis of the possible structure of tetrabenzoylethylene.[51–55]



It has been established by X-ray diffraction studies[56] that compounds (A) and (A') do indeed represent different crystalline modifications of tetrabenzoylethylene, the different types of behaviour of which on irradiation with visible light being explained by the difference between the conformations of their molecules and in their packing in the crystals. The conformations (XLVIII) and (XLIX) correspond to forms (A) and (A') respectively (Scheme 12). The related tetra-acetylethylene molecule has the conformation (L) in the crystal. In addition, X-ray diffraction study[57] has shown that the product (B) of the photolysis of (A) has the structure (LI) and not the structure (XLIII) proposed previously.[52]

Scheme 12

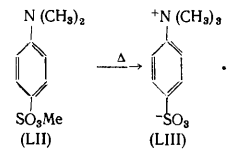


Intermolecular contact between the carbonyl oxygen atom and the hydrogen atoms in the *o*-positions in the ring has been observed in the crystal (A), its length being 2.62(8) Å, which is close to the sum of their van der Waals radii (2.72 Å).[35,36] A series of fairly short contacts involving the hydrogen atoms in the *m*-positions in the same ring have also been found. It may be that the intermolecular interaction in the direction of this O...H contact leads to the formation of a phenyl radical whose attack on a neighbouring molecule gives rise to the product (B); the generation of the next phenyl radical then leads to the propagation of reaction via chain mechanism along the *a* crystallographic axis.[42]

At the same time the authors[57] do not rule out the possibility of an intramolecular rearrangement of compound (XLVIII) to compound (LI). As a consequence of the alternation of the deviations of the parallel groups from the plane of the ethylene fragment in the molecule of compound (XLVIII), there is a possibility of forming hydrogen bonds between the carbonyl oxygen atoms and the *o*-hydrogen atoms of the neighbouring benzoyl groups. In addition, the alternating disposition of the benzoyl groups in compound (XLVIII) relative to the plane of the ethylene group prevents a concerted intramolecular movement of the phenyl groups. The disposition of the oxygen atoms in compound (XLVIII) favours the formation of the condensed furo[3,4-*c*]furan system (LI).

4. Rearrangement of Methyl *p*-Dimethylaminobenzenesulphonate

Methyl *p*-dimethylaminobenzenesulphonate (LII) rearranges in the solid phase to the betaine (LIII), the rate of reaction increasing with temperature until the attainment of the melting point, after which it falls sharply:[58]



An X-ray diffraction study showed[58] that the crystals of compound (LII) is made up of stacks of molecules, whose arrangement is convenient for the transfer of the CH_3 group along the molecular chain. The impossibility of an intramolecular rearrangement has been demonstrated experimentally using the corresponding deuterio-derivatives.

The CH_3 transfer process has been modelled by calculating the energy of the interaction of the molecule of compound (LII) with the CH_3 group approaching it,[59] using the extended Hückel method. The initial molecular geometry was taken from X-ray diffraction data. The extent to which the CH_3 and $(CH_3)_2N$ groups are pyramidal was varied as a function of the increasing distance from the N and O atoms; it was assumed that the CH_3 group is planar and is located between the N and O atoms at equal distances from the latter.

Fig.1 presents the dependence of the energy of the system described on the O–CH_3 and N–CH_3 distances and the extent to which the CH_3 group has been withdrawn (λ_1 and λ_2). The energy surface was of the kind usual for reactions of the type X + YZ = XY + Z, but the presence of a minimum in the lower left-hand region, where a saddle point is normally present, is striking. The dashed line indicates the path corresponding to the formation of an adduct with subsequent abstraction of the ether CH_3 group. The mechanism of the formation of a new bond with simultaneous dissociation of the old one would correspond to a diagonal path on the energy surface. The need to overcome a significant energy barrier

in this path suggests a two-stage process mechanism involving the formation of the corresponding intermediate compound. The total activation energy for the process along this reaction path is low and the relative thermodynamic advantage of the product molecule compared with the initial molecule is equivalent to ~12 kcal mol^{-1}.

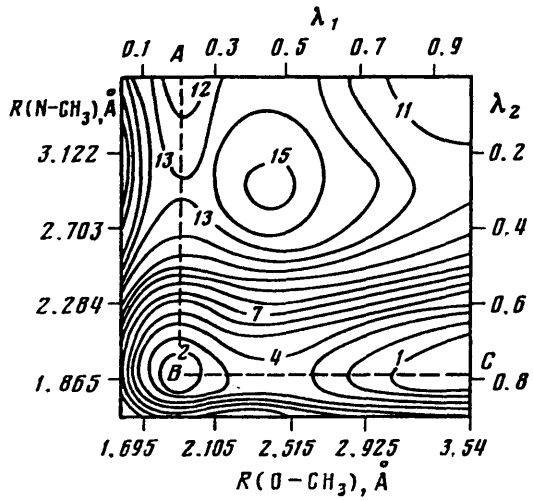


Figure 1. The energy surface for the reaction as a function of the distance to which the CH_3 groups are removed (λ_1 and λ_2) on dissociation of the O–CH_3 and N–CH_3 bonds. The energy contours are drawn at 1 kcal mol^{-1} intervals. Stage *A* corresponds to $^{+}CH_3 + (CH_3)_2NC_6H_4SO_3CH_3$, stage *B* corresponds to $(CH_3)_3\overset{+}{N}C_6H_4SO_3CH_3$, and stage *C* corresponds to $(CH_3)_3NC_6H_4SO_3^{-} + \dot{C}H_3$.[59]

The charges on the atoms and the Mulliken bond orders have been calculated for the molecules of the initial compound and the product. The CH_3 group abstracted has a large positive charge, which is partly transferred to the remaining CH_3 group. In the course of this rearrangement the negative charge on the N atoms becomes smaller and that on the O atom increases. The migrating CH_3 group leaves behind a bonding electron on the O atom, but at the same time it captures an electron from the N atom, which is used to form a new bond, so that the total change in the charge of the CH_3 groups should be small. The reaction involving the formation of methyl radicals does not then occur, since such a pathway would have involved a greater activation energy.

The change in the energy of the crystal structure as the CH_3 group moves towards a neighbouring molecule (and also as the character of the coordination of the N atoms is altered) in the course of the migration of the CH_3 group in the crystal was estimated by the method of atom–atom potentials,[68] taking into account the electrostatic component. The calculation showed that the displacement of the CH_3 group by 1 Å changes the energy of the crystal structure by only 7 kcal mol^{-1}. For the $(CH_3)_2N$ group, the deviation of the substituents towards the approaching CH_3 group is unfavourable, while that in the opposite direction is free (within the limits of 40°).

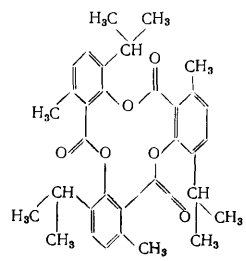
In order to elucidate the character of the changes in the molecular packing energy in the crystal on passing from compound (LII) to compound (LIII), the energy of the structure of compound (LII) was also calculated using the coordinates taken from the results of its X-ray diffraction study[58] together with the energy of a model crystal made up of molecules of compound (LIII) but packed in the (LII) lattice.[59] It was found that this hypothetical structure is significantly less favourable than the real structure of compound (LII). This is apparently in fact one of the reasons why the transformation described above does not proceed via a single crystal–single crystal mechanism.

Additional information about the mechanism of the reaction considered has been obtained from Raman phonon spectra,[60–62] which yield information both about the structure and the dynamics of the lattice, by means of which it is possible to obtain the characteristics of the homogeneity or heterogeneity of the solid-phase processes. The dynamics of the crystal lattice in which solid-phase reactions take place can favour their occurrence (the so-called "phonon enhancement"). In order to detect the possibility of such an enhancement, one considers the temperature dependence of the phonon spectra, where it is possible to observe a softening of certain modes, which indicates an increase in the amplitudes of the molecular movements precisely in the crystallographic directions along which solid-phase reactions can occur.

Analysis of the phonon spectra of crystals of compound (LII)[61] led to the conclusion that in this instance the solid-phase reaction is heterogeneous, which is consistent with the conclusions of Gavezzotti and Simonetta.[59] A study of the temperature dependence of the phonon spectrum revealed a softening of one of the modes (27 cm^{-1}), which indicates the possibility of the phonon enhancement of the reaction considered.

5. Geometrical Isomerisation of *cis*-Stilbene in Clathrate Complexes

The intramolecular solid-phase rearrangements in crystals made up of identical molecules were discussed above. Naturally, such reactions are possible also in clathrate compounds, where the reacting molecules are enclosed within cavities of the crystal lattice of the "host" molecules. Among the numerous known clathrate-forming compounds, the one which attracts most attention as regards the topic of the present review is tri-o-thymotide (TOT), which forms clathrates of different type,[63] a common feature of which is their chiral structure.[64] In particular, this gives rise to the possibility of the asymmetric synthesis in the reactions of prochiral "guest" molecules enclosed in the chiral TOT crystals.[65]



The first example of the photoinduced stereoisomerisation in crystals of TOT clathrates is the solid-phase rearrangement *cis*-stilbene.TOT–*trans*-stilbene.TOT under the influence of ultraviolet irradiation.[63] The reverse transition

in the crystal has not so far been observed, although in solution both processes are possible.[66] The quantitative *cis–trans* photoisomerisation has been thoroughly investigated also for crystalline olefins (for example, for cinnamic acid derivatives) in the absence of clathrate-forming compounds[7,67] and a common feature of all these processes is the absence of the reverse conversion of the *trans*-isomers into the *cis*-isomers. This constitutes the fundamental difference between the solid-phase processes of this kind and liquid-phase processes, although the rearrangements can take place in both directions.[63]

The conformations of the TOT molecules in crystals of the *cis*-stilbene.TOT (LIV) and *trans*-stilbene.TOT (LV) clathrates are very similar.[63] In the crystal of compound (LV) two symmetrically independent (i.e. not linked by the symmetry elements of the space group) stilbene molecules are located at the centre of symmetry, fill the non-intersecting channels parallel to the *a* and *b* crystallographic axes respectively, and are disordered (statistically or dynamically), which is manifested by high thermal parameters of their atoms. The characteristic features of the molecules incorporated in various inclusion complexes are in general either complete orientational disorder, which can be detected in certain cases by NMR in the solid state,[64] or a fairly high order, the extent of which, for example in the case of compound (XL), can be reliably determined by X-ray diffraction.

The packing of symmetrically independent *trans*-stilbene molecules in the above two types of channels of one (LV) crystal differs as regards the C...C distances between neighbouring molecules in the channel of each given type (4.60 and 3.83 Å) and the distances between the planes passing through the aromatic rings of neighbouring molecules (0.6 and 2.0 Å). The *cis*-stilbene molecules in the crystal of compound (LIV) are disordered with respect to two positions (linked by a centre of symmetry), the overall population of which is lower than that of the populations of the positions of the *trans*-stilbene in the crystal of compound (LV).

Table 2. The volume of the channels in the clathrates (LIV) and (LV).[63]

Channel	V_f, Å^3	V_u, Å^3
a-Channel (LV)	570	94
a-Channel (LIV)	570	72
b-Channel (LV)	826	56
b-Channel (LIV)	887	103

Notation: V_f is the free volume in the TOT matrix and V_u the useful volume (accessible to the "guest" molecules).

The reactions of the occluded molecules in clathrates require a preliminary alteration of the shape and volume of the channels; the very similar densities and unit cell parameters of the clathrates (LIV) and (LV) indicate an insignificant alteration of the free volume in the TOT matrix. Table 2 shows that, whereas the overall volume of all the cavities (the free volume) in the TOT matrix changes insignificantly in the (LIV) → (LV) transition, its component in which the "guest" molecules can be accommodated (the useful volume) undergoes an appreciable change (namely there is a sharp alteration in the *b* channels and a smaller alteration in the *a* channels), which can be accounted for by a change in the shape of the channels, while the volume remains unaltered.

The reason why *trans*-stilbene is preferentially incorporated in TOT may be associated with the mutual correspondence of the symmetries of the "guest" molecule and of the cavity in the matrix of the "host" molecule. The absence of a centre of symmetry in the *cis*-stilbene molecules creates less favourable conditions for their packing in a centrosymmetrical cavity, as a result of which the corresponding clathrate is less stable. It is useful to take this into account in seeking suitable molecules for inclusion in the lattice of the given "host". For example, one may expect that, for a "host" forming centrosymmetrical cavities, the *meso*-(*R*,*S*)-diastereoisomers are preferable to the D- or L-(*RR* or *SS*)-stereoisomers, while the inclusion of molecules of the second type will be preferable in cavities having the C_2 symmetry.

When any solid-phase chemical reaction is considered, provided that it differs from the corresponding reaction in solution, the question arises in what way and at what stages does the crystalline medium exert its influence on the course of the reaction. Thermal solid-phase reactions can therefore be usefully subdivided into four stages: the initial "loosening" of the molecular packing in the "reaction centre" of the crystal, their subsequent intra- or inter-molecular chemical transformation, then the formation of a solid solution of the product in the initial substrate, and finally the concluding separation of the product phase.[10] In photochemical solid-phase reactions the first stage as such is naturally absent, its role being assumed by the photoexcitation of the crystal system.

The photoisomerisation reactions in TOT clathrates can be regarded as processes occurring in the closed volume of the "reaction cavity" of the clathrate. An alternative explanation is that the molecules can diffuse from the closed cavities of the clathrate into its less "constrained" positions, in which they initially undergo chemical transformations and this is followed by the recrystallisation of TOT and the reaction product (*trans*-stilbene) with formation of the final clathrate. Although the second pathway cannot in fact be fully ruled out, preference has been given[63] to the process in the "reaction cavity".

As regards the solid-phase transition (LIV) → (LV), it has been concluded[63] that the transformation of a molecule with C_1 symmetry into one with a C_i point group within the cavity having the same C_i symmetry is the main factor which determines the observed photochemical reaction. Since the *cis–trans* isomerisation of stilbene requires the internal rotation of one fragment of the molecule relative to the other by 180° and therefore presupposes a definite deformation of the reaction cavity, it has been suggested that this kind of deformation takes place readily in TOT clathrates, which has been confirmed, in particular, by the wide variety of molecules which can be incorporated in such clathrates.[63,67] The manifestation in the crystal of compound (LV) of a temperature dependence of the rate of the *cis–trans* isomerisation of stilbene, is apparently associated with a kind of activation of the "loosening" of the molecular packing in the corresponding cavity,[10,63] which promotes a freer internal rotation, necessary for the *cis–trans* isomerisation indicated. The breakdown of the ordered disposition of the molecules in TOT clathrates following this kind of loosening of the packing is not always reversible and, when the molecules do not return to their initial positions or when the concerted nature of their migration in various parts of the crystal is disturbed, then a transition of the single crystal–single crystal type does not take place and individual crystallites of the new phase are formed.

6. Isomerisation of the Monoadduct of 11-Cyano-1,6-Methano[10]Annulene and 4-Methyl-1,2,4-Triazoline-3,5-Dione

In the study of the liquid-phase Diels–Alder reactions between bridge [10]annulenes and *N*-methyl- and *N*-phenyltriazoindolines,[69] isomers of the *exo*-type [compounds (LVI)] and the *endo*-type [compounds (LVII)] of the monoadducts of 11-cyano-1,6-methano[10]annulene with 4-methyl-1,2,4-triazoline-3,5-dione were isolated (Fig. 2).[70] It was found that the interaction of compounds (LVI) and (LVII) with a second mole of 4-methyl-1,2,4-triazoline-3,5-dione leads to only one isomer of the bisadduct (LVIII), namely one having the *endo,endo*-configuration. Thus the initial monoadduct of the *exo*-type undergoes the configurational transformation (LVI) → (LVII) into the isomer of the *endo*-type before or in the course of the reaction with the dienophile.[69,71]

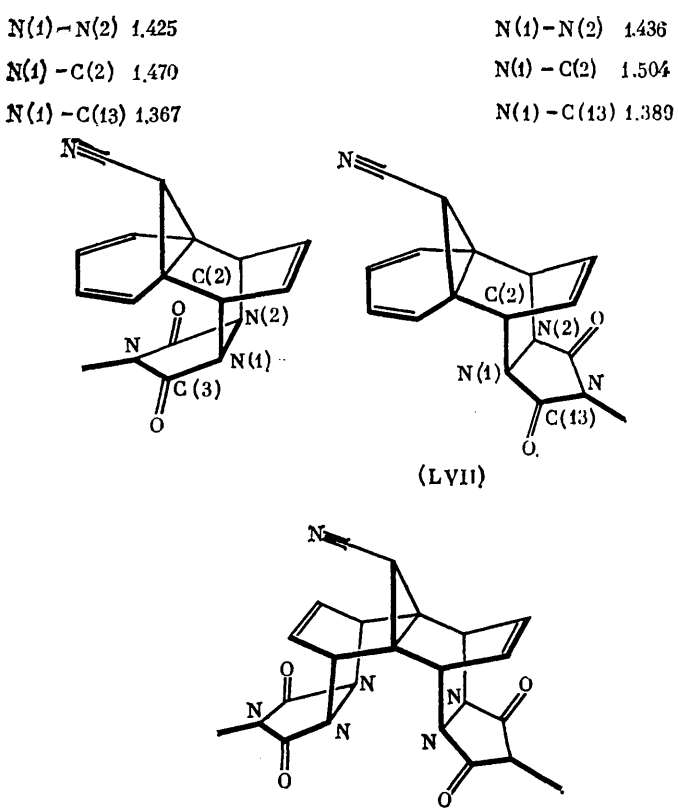


Figure 2. The structures of the *exo*- and *endo*-isomers (LVI) and (LVII) of the monoadduct and also of the *endo,endo*-isomer of the bisadduct (LVIII) of 11-cyano-1,6-methano-[10]annulene and 4-methyl-1,2,4-triazoline-3,5-dione.[71]

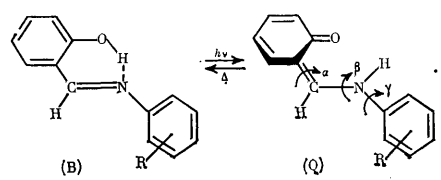
A similar study of the analogous solid-phase rearrangement (LVI) → (LVII) showed[71] that, on heating to 75 °C, dark bands appear within the (LVI) single crystal, although its outer form does not change. The complete transition (LVI) → (LVII) takes place at a temperature close to 175 °C: the X-ray diffraction patterns of compounds (LVI) and (LVII) become identical (when the powder method is used), and the reaction in the single crystal leads to the polycrystalline product (LVII). Of the two possible mechanisms of this process proposed for the solution, namely the Diels–Alder retro-reaction or or inversion relative to the N–N bridge in the primary adduct, the latter appears more probable. The barrier to the Diels–Alder retro-reaction of the model adduct of cyclopentadiene and maleic anhydride is 37.5 kcal mol^{-1}.[72] Since the C–N bond present in the molecule of compound (LVI) is only slightly weaker than the C–C bond in the model adduct, for compound (LVI) this barrier should be not less than 30 kcal mol^{-1}. In the case of double inversion the barrier should in its turn be only approximately 7 kcal mol^{-1} [for the (LVI) → (LVII) inversion] and ~9 kcal mol^{-1} [for the inversion (LVII) → (LVI)].[71] The experimental value is ~11.9 kcal mol^{-1},[71,73] which thus confirms the double N-inversion mechanism of the process under consideration.

Comparison of the geometrical parameters of the isomers (LVI) and (LVII) also confirms that the observed rearrangement proceeds via the mechanism involving the inversion of the N–N bridge. The less stable *exo*-isomer has a geometry closer to the flattened transition state of the isomerisation reaction considered. In fact, the dihedral angle between the planar fragments intersecting along the N–N bond in compound (LVI) (152.1°) is greater than in compound (LVII) (137.0°). The shortening of the bond between the hydrazine N atom and the C atom of the carbonyl group in the *exo*-isomer (LVI) thus also confirms the hypothesis that the planar transition state is stabilised by the conjugation of the diazo-group with the carbonyl group, which lowers the barrier to the inversion process.[71]

7. Chromotropic Reactions

Yet another large class of organic reactions which differ fundamentally when they are carried out in the liquid and crystalline phases comprises chromotropic transformations, in which the rearrangement is accompanied by a change in the colour of the reacting compounds. The arylimines of substituted salicylaldehydes are the most thoroughly investigated organic photochromic compounds in relation to this reaction (Scheme 13):[74,75]

Scheme 13



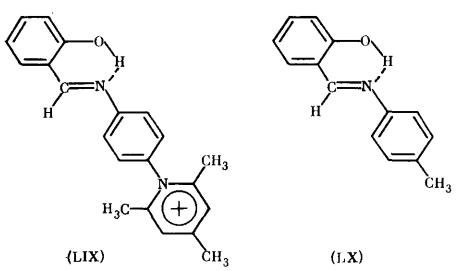
In solutions they are almost all photochromic, which is due to their ability to undergo on irradiation ($\lambda \cong 340–360$ nm) a rearrangement with phototransfer of a proton via the hydrogen bond from the O atom of the hydroxy-group to the imine N atom with transition of the planar benzenoid structure (B) into the quinonoid NH form (Q). As a consequence of the easier internal rotation of the fragments in the resulting (Q) molecule (with a change in the angles α and β and the rupture of the NH...O hydrogen bond), it now has a non-planar structure and is characterised by the appearance of the so-called "photochromic" absorption bands due to the different angles of rotation of the aldehyde ring in different molecules ($\lambda = 480$ nm, $\alpha \cong 50–55°$; $\lambda = 540$ nm, $\alpha \cong 65–70°$).[75–78]

The extremely short lifetimes of such (Q) structures in condensed phases ($\tau_{1/2} \cong 10^{-6}$ s) significantly hinder their study in solutions. However, in polymer matrices, frozen solutions, and in the crystalline phase, their lifetime is significantly increased, which explains the special advantages of the solid-phase methods for the investigation of chromotropic reactions compared with the liquid-phase methods.

Crystalline salicylidenearylamines (which are photochromic in solution) have been subdivided into two classes, which differ from one another as regards the character of physical influences inducing a change in their colour:[75] (1) photochromic non-fluorescent crystals which are coloured like the solutions, with the appearance in the absorption spectrum of bands at 485 and 540 nm, and which do not change colour when the temperature is altered; (2) thermochromic crystals which do not exhibit photochromic properties on irradiation but do fluoresce with a large Stokes shift at 77 K and are capable of acquiring a colour only on raising the temperature, whereupon a broad absorption band appears in their spectrum with a somewhat shorter wavelength in the range 400–470 nm.

Different types of behaviour of the compounds considered in solution and in the crystal justify the assumption that their photochromic and thermochromic properties in the crystalline state should be determined to a large extent by the influence of the packing.[75,79,80] This is confirmed by the formation of polymorphic photochromic and thermochromic modifications of salicylideneaniline[81] and salicylidene-*m*-chloroaniline[82] (depending on the rate of cooling of the solution on crystallisation) and also the photochromic and thermochromic solid solutions of compounds of this class, whose properties are determined exclusively by the crystal lattice of the "host".[83]

In order to elucidate the influence of intermolecular interactions and the nature of the phenomenon of chromotropism, the crystal structures of the photochromic (compound (LIX)] and thermochromic [compound (LX)] salicylidenearylamines have been compared.[75]



(LIX) (LX)

In the molecule of compound (LIX) $\alpha = 4°$, $\gamma = 51°$, and the angle of rotation of the trimethylpyridinium ring relative to the aniline ring is 87.2°. The molecules of compound (LX) in the crystal are planar and are packed in stacks along the c axis; the interplanar distance is ~3.4 Å. These data agree well with the results of other structural studies on compounds of this class[79,80,84–87] and show that the stacked close packing of the planar molecules is characteristic of thermochromic crystals and its absence and a non-planar molecular structure are characteristic of photochromic crystals.[75] Quantum-chemical calculation by the CNDO/2 method for the planar and non-planar ($\gamma = 60°$) molecules showed that the non-planar structure is preferable to the planar-structure only to the extent of ~2.5 kcal mol^{-1} [75] and the conformation of the molecules of compound (LIX) in the crystal can be fully determined by the packing effects.

The increased electron density at the N atom in the planar structure, which follows from the above calculation, strengthens the N...H–O hydrogen bonds, lowers the activation energy for the transfer of a proton from the O atom to the N atom in the ground state, and leads to the formation of the quinonoid form on raising the temperature. The formation of non-planar (in terms of the angles α and β) quinonoid forms of thermochromic compounds can be hindered by the stacked close packing of the planar molecules. Indeed calculation of the intermolecular interaction in the crystal of compound (LXX) by the method of atom–atom potentials yields 10.0 kcal mol^{-1} as the energy of the interaction between the molecules in the stacks, while the energy of interaction between the stacks does not exceed 2.5 kcal mol^{-1}.[75]

The non-planar photochromic molecules do not form close-packed stacks in the crystals, because the intermolecular interaction energy in such stacks does not exceed 1–3 kcal mol^{-1}. The non-planar molecular structure resulting from the decreased electron density at an N atom leads to an increased activation energy for the proton transfer in the ground state and the absence of thermochromism. However, on photoexcitation to the S_1 state, adiabatic proton transfer does occur.[75] In contrast to thermochromic crystals, in the photochromic structures the absence of a stacked structure in the latter entails the occurrence of an adiabatic non-coplanarisation process (with respect to the angles α and β), after the proton transfer, which no longer leads to fluorescence but to the formation of coloured forms with long-wavelength absorption at ~480 and 540 nm. The additional appearance in the spectra of thermochromic crystals of a long-wavelength absorption band at ~470 nm on raising the temperature can be associated with the formation of a certain amount of non-planar quinonoid forms, for example, on the surface of the crystal, as a result of an increase in the thermal vibrations of the atoms.

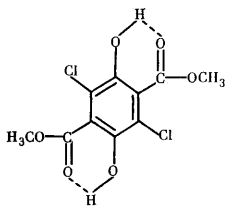
According to Aldoshin et al.,[75] the difference between the energies of the planar and non-planar forms of the free molecules of salicylidenearylamines is insignificant and is close to the intermolecular interaction energy in the crystal. If the gain in the crystal lattice energy is greater than the gain in the energy of the free molecule in one or other of the possible conformations, a structure arises in the crystal whose conformation ensures a minimum crystal lattice energy. Thus, by altering the ratio between the free energy of the molecule and the crystal lattice energy (by introducing various substituents), it is possible to regulate the structure and properties of the crystals.

A structural study[88] of the photochromic α_1- and α_2-forms of *N*-salicylidenepentafluoroaniline [compounds (LXI) and (LXII)], the α-form of *N*-salicylidene-4-bromoaniline (LXIII), and the thermochromic β-form of *N*-salicylidene-4-chloroaniline (LXIV) [the molecules of compounds (LXI)–(LXIII) are non-planar while those of compound (LXIV) are planar and packed in stacks] led to a mechanism of both types of chromotropic transitions based on the idea of the formation of intermolecular charge-transfer complexes (IRCTC). Thermochromic crystals are regarded in this case as an equilibrium mixture of tautomers, forming the corresponding IRCTC (the rate of equilibration depends on temperature). As regards photochromic crystals, their irradiation with ultraviolet light induces tautomerisation with formation of IRCTC [the crystals of compounds (LXI) and (LXII) have structures of the IRCTC type].

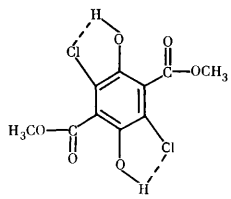
Investigations of solid-phase processes, which are close to phase transitions and in particular are close to the so-called conformational polymorphism in which a change in the conformation of the molecules in the crystal is accompanied by the

simultaneous alteration of structural and/or electronic characteristics of the system (intra- and inter-molecular hydrogen bonds, the colour of the crystal, etc.), can also be included among studies of intramolecular rearrangements.

The transition of the yellow form (LXV) of dimethyl 3,6-dichloro-2,5-dihydroxyterephthalate into the colourless form or, in the terminology of Curtin et al.,[89] the white form (LXVI), occurring on heating compound (LXV) to 140°, which is significantly below the melting point of compound (LXVI), is an example of this kind. The difference between the yellow and white forms, established by X-ray diffraction,[89] consists in the different dispositions of the intermolecular hydrogen bonds and also in the different orientations of the methoxycarbonyl groups relative to the plane of the benzene ring—in the yellow form these groups are in the plane of the benzene ring, while in the white form they are almost at right angles to it.



(LXV) yellow form



(LXVI) white form

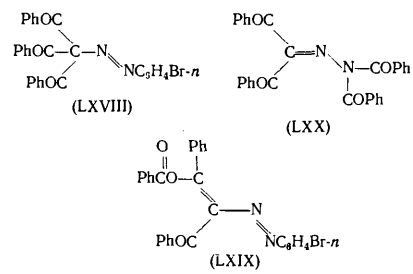
The difference between the characters of the intermolecular hydrogen bonds makes it possible to classify the molecules of the above two forms as isomers. Although the two forms crystallise in the same space group $P\bar{1}$, in the yellow form $Z = 1$ (one system of centres is occupied), while in the white form $Z = 2$ (two systems of centres are occupied), as a result of which the volume of the unit cell increases by a factor of two. The packing in the crystals of the yellow form consists of stacks of translationally linked molecules; the rearrangement of the packing occurring on transition to the white form can be described as the rotation of alternate molecules in the stack by 180° about the axis joining the Cl atom.

The rate of transformation of one form into the other depends significantly in this instance on temperature. Thus, whereas at room temperature both forms can coexist indefinitely, at 140° the transition takes place in several minutes. The transition can begin over a wide temperature range. Having been initiated at any point in the crystal, the new phase spreads in the [110] direction. When viewed through an optical microscope, this process appears to be a transition of the single crystal–single crystal type, but X-ray diffraction data show that the specimen obtained is polycrystalline, although it can consist of fine single crystals having similar orientations.

For a more complete investigation of the kind of processes occurring in the transition considered, the recently proposed technique of Ramon phonon spectroscopy in the solid state was used.[60–62] The Raman spectra confirmed the presence of different systems of hydrogen bonds in compounds (LXV) and (LXVI).[62] It was observed that only in the initial stages, when the content of the white form is low, does the process proceed as a homogeneous reaction, after which it acquires a heterogeneous character. The study of the temperature dependence of the phonon spectrum did not reveal a soft mode in the latter, which might have indicated the occurrence of lattice vibrations favouring the process via a topochemical mechanism. It was therefore concluded[62] that the thermal rearrangement is of a dislocation type although its mechanism at the molecular level still remains obscure.

Other examples of solid-phase conformational transformations are the transition of 2-(4-methoxyphenyl)-1,4-benzoquinone (LXVII) from the yellow to the red form (in which the rings undergo a mutual rotation by 110° and an overall reorientation of the molecule takes place with appearance of an intermolecular donor–acceptor interaction[90]) and the thermochromic polymorphic transitions of naphthazarine[91–93] and diaminoterephthalic acid esters.[94]

The structural rearrangement in the thermochromic transitions (observed both in solution and in the crystal) of the yellow azotriketone [compound (LXVIII)] to the red (compound (LXIX)] and colourless [compound (LXX)] products is more significant.[95] These processes consist in the competing migration of the acyl group from the C atom to the O atom [the (LXVIII) → (LXIX) transition] and from the C atom to the N atom [the (LXVIII) → (LXX) transition].



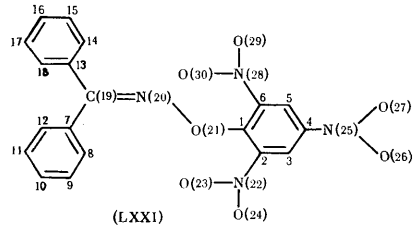
(LXVIII)

(LXX)

(LXIX)

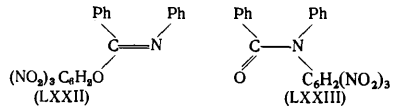
The ratio of the isomerisation products in the crystal and in the solution (dioxan) should then be fairly similar [(LXIX):(LXX) is 0.85 and 1.05 respectively]. The rate of reaction in the crystal is 100–400 times lower than in solution and diminishes as the quality of the crystals of compound (LXVIII) improves. If a more volatile solvent ($CHCl_3$) is used for crystallisation, then, when the resulting crystal of compound (LXVIII) is allowed to stand, the solvent diffuses from it and the rate of the thermochromic rearrangement increases (although the ratio of the red and white products is also altered).[96] Analysis of the non-valence contacts in the molecule of compound (LXVIII) did not reveal a structural preference for the migration of any particular acyl groups to the O or N atoms. At the same time the absence of intermolecular contacts from the crystal of compound (LXVIII) and the corresponding N, O, and C atoms in neighbouring molecules makes it impossible to attribute an intermolecular mechanism to the observed solid-phase thermochromism.[96]

An appreciable rearrangement of the molecule is observed also in the solid-phase thermochromic (≤70 °C) transformation of the colourless picryloxime (LXXI):



(LXXI)

and of its derivatives via the intermediate (LXXII) into the yellow amide (LXXIII):[96,97]

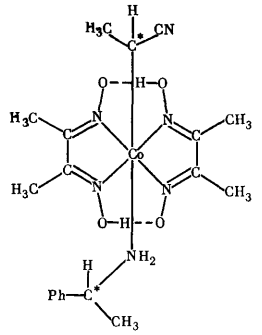


Steric strain is observed in the molecule of compound (LXXI) in the region of the O–Ph bond [C(1–6)], where the O(21), N(22), and N(28) atoms deviate from the plane of the benzene ring by −0.095, 0.144, and −0.134 Å respectively, while the N(25) atom in the *p*-position is located exactly in this plane. The C(6)C(1)O(21) and C(2)C(1)O(21) valence angles differ markedly (129.0° and 114.5°). The above geometrical distortions are caused by the intramolecular steric interaction of the N(20) atom and the nitro-group at the N(28) atom, on the one hand, and between the O(21) atom and the nitro-group at the N(22) atom, on the other [the N(20)...N(28), N(20)... O(30), O(21)...N(22), and O(21)...O(23) distances are 2.668, 2.859, 2.676, and 2.766 Å]. The aromatic C(7–12) ring in the *syn*-position relative to the picryl group has been rotated by a larger angle in the plane of the $C_2C{=}N(-O)$ group compared with the C(13–18) ring (60.5° and 18.6° respectively). The distance between the O(21) atom and the C(19) atom to which it migrates is 2.213 Å. Intermolecular distances less than 4 Å between the potentially reactive atoms in the crystal compound (LXXI) were not observed.[97]

8. Rearrangements of Metal Complexes

A structural study of *R*-α-cyanoethyl-(*S*-α-methylbenzylamino)cobaloxime (LXXIV) revealed a change in the unit cell parameters in the course of the X-ray diffraction which was not accompanied by the disruption of the single crystal.[98] After exposure for 22 days, a crystal of compound (LXXIV) [a = 8.665(2) Å, b = 13.485(3) Å, c = 9.584(3) Å, β = 96.95(3)°, V = 1111.6(5) Å^3; space group $P2_1$] is converted into a crystal of compound (LXXV) [a = 8.637(2) Å, b = 13.833(3) Å, c = 9.539(2) Å, β = 99.07(3)°, and V = 1125.5(4) Å^3]. A similar change in the unit cell parameters in the formation of a crystal of compound (LXXV) in the course of irradiation with X-rays has been established also for crystals of the second enantiomorphic form of compound (LXXIV).

Despite the retention of the non-centrosymmetric space group $P2_1$ of the initial compound for both types of crystals of compound (LXXV) formed, the two processes investigated represent the racemisation of the enantiomorphic forms of compound (LXXIV). An X-ray diffraction study[98] showed that, after the transition, the CH_3 groups of the cyanoethyl ligand occupy with equal probabilities two positions corresponding to the *R*- and *S*-configurations. It has been suggested[98] that this process proceeds via the dissociation of the Co–C bond and the appearance of the planar cyanoethyl radical capable of further recombination to reform the initial structures with equally probable attack on both sides in this reaction. This hypothesis has been confirmed by direct EPR observations of the homolytic cleavage of the Co–C bond in alkylaminocobaloximes when they are irradiated with visible light (λ > 420 nm).[99,100] The energy liberated on dissociation of the bonds can induce the formation of local zones consisting of the melt. The appearance of the racemic structure on re-formation of the bonds is apparently to be explained by its greater thermodynamic stability. The retention of the single crystal structure can be accounted for by the identity of the crystal-structure parameters of both enantiomers.



(LXXIV) and (LXXV)

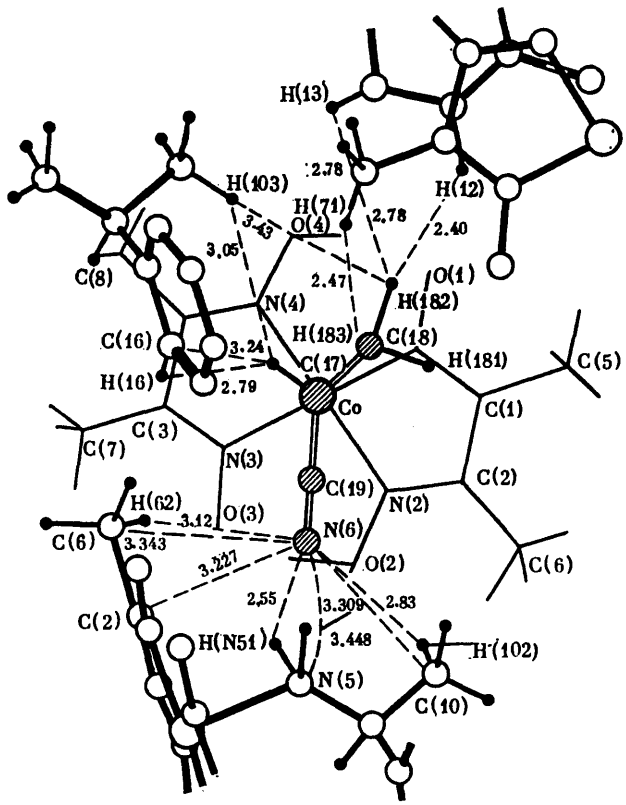


Figure 3. The environment of the atoms of the α-cyanoethyl group (shaded circles) in a crystal of compound (LXXIV); the C(17) atom is projected on to the Co atom.[98]

In order to investigate the dependence of the rate of the solid-phase racemisation of compound (LXXIV) on temperature, measurements have been made of the unit cell parameters of this compound at 133 K [a = 8.791(2) Å, b = 13.516(2) Å, c = 9.161(2) Å, and β = 98.31(3)°] and also their variation with increase of temperature to 293 K.[101] The difference between the parameters at 133 and 293 K is

unusual; on the one hand, it does not indicate the occurrence the (LXXIV) → (LXXV) transition, while, on the other hand, the explanation cannot be reduced to the thermal expansion of the crystals of compound (LXXIV) (the linear thermal expansion coefficients are -1.00×10^{-4}, -0.10×10^{4}, and 2.95×10^{-4} K^{-1} along the *a*, *b*, and *c* axes respectively). For the crystal of the racemate (LXXII) under the same conditions, the linear expansion coefficients are similar (-1.00×10^{-4}, 0.25×10^{-4}, and 2.50×10^{-4} K^{-1}), whence it follows that the thermal expansion of compound (LXXIV) [and possibly also of compound (LXXII)] is reversible.

Comparison of the crystal structures of compound (LXXIV) at 173 and 293 K has shown that cooling leads to the contraction of the crystal owing to the compaction of the structure in the region of the H(17) atom (Fig. 3). The most significant changes are in the H(17)...H(103) = 3.05 Å, H(17)...H(16) = 2.79 Å, and H(182)...H(103) = 3.43 Å, distances which diminish to 2.47, 2.53, and 2.56 Å respectively, i.e. the values corresponding to the normal van der Waals contacts. This compaction does in fact explain the retardation of the racemisation of compound (LXXI) at low temperatures.

Racemisation in the course of X-ray irradiation and its retardation on reducing the temperature to 133 K are also characteristic of crystals of the diastereoisomeric [in relation to compound (LXXIV)] complex *S*-α-cyanoethyl(*S*-α-methylbenzylamine)cobaloxime (LXXVI).[102] The crystals of compounds (LXXIV) and (LXXVI) have two features in common: (1) the molecules in the crystal have a bond which is sensitive to irradiation by X-rays and to exposure to electromagnetic radiation with a higher wavelength; (2) this bond is located in the region of loose packing (with increased intermolecular distances). However, in the case of the crystals of *R*-α-(methoxycarbonyl)ethyl(*R*-α-methylbenzylamine)bis(dimethylglyoximato(cobalt(III) racemisation is no longer observed, which is caused by the failure of the second of the conditions indicated in this instance.[103] Nevertheless, it is believed[101,103] that the number of crystalline complexes which satisfy both conditions should be large and that varied solid-phase reactions should be observed in them.

In contrast to compounds (LXXIV) and (LXXVI), the racemisation which takes place on irradiation of crystals of [(*S*)-1-cyanoethyl](pyridine)cobaloxime (LXXVII)[104] and [(*R*)-1-cyanoethyl](pyridine-4-carbonitrile)cobaloxime (LXXVIII),[105] which proceeds via the inversion of the configuration of the cyanoethyl group in one of the two [(A) and (B)] symmetrically independent molecules (in both cases the space group is P_1 with $Z = 2$), gives rise to the racemate (A'), whose molecules are characterised by an ordered disposition of the cyanoethyl groups (with a centrosymmetric space group $P\bar{1}$, Z = 1).

The volumes of the reaction cavities of the cyanoethyl groups in the enantiomorphic crystals of compounds (LXXVII) and (LXXVIII) and the crystals of the corresponding racemates are compared in Table 3 with the rate constants for racemisation in the crystal. The cyanoethyl group of the molecule (B), which undergoes inversion in racemisation, occupies a larger volume than the cyanoethyl group in the molecule (A). Evidently the greater the volume of such cavities, the higher the reaction rate. The retardation of the racemisation of the crystal of compound (LXXIV) at 173 K can also be attributed to a decrease of the volume of the cavity of the cyanoethyl group from 14.53 $Å^3$ at 273 K to 12.95 $Å^3$ at 173 K.[105] In the crystal of [(*R*)-1-cyanoethyl]-(4-methylpyridine)cobaltoxime, for which racemisation is also observed on irradiation, the cavities occupied by the reactive groups have a larger volume than those incorporating inactive groups.[105]

Yet another example of racemisation in the crystal has been described for the solid-phase transition on irradiation with X-rays of [(*R*)-1-methoxycarbonylethyl](pyridine)cobaloxime (LXXIX) containing the methoxycarbonylethyl groups $CH(CH_3)CO_2CH$ instead of the cyanoethyl groups.[106] The rate of racemisation of compound (LXXIX) (space group $P2_1$) is in this case so high that it has been possible to investigate by X-ray diffraction only the racemates of compound (LXXX) (space group $P2_1/n$).[105]

Table 3. The volume v of the cavities occupied by the cyanoethyl groups before (A and B) and after (A') the racemisation of compounds (LXXVII) and (LXXVIII) together with the rate constants *k* for the racemisation.[105]

Parameter	(LXXVII)	(LXXVIII)
v(A), Å³	7.97	8.89
v(B), Å³	10.37	11.34
v(A'), Å³	10.52	10.52
v(A+B), Å³	27.95	25.58
v(2A'), Å³	26.41	26.49
k, s^{-1}	$1.65 \cdot 10^{-6}$	$2.83 \cdot 10^{-6}$

9. Spin Isomerism

Many chemically and biologically important processes involving iron(II) and iron(III) complexes are accompanied by a change in the spin state of the metal atom. Such changes cause a sharp alteration in the strength of the donor ligand–metal ion bond and hence in the chemical properties of the complex; however, compounds manifesting the properties of "spin equilibrium", i.e. capable of existing in the form of an equilibrium mixture of spin isomers, have so far been little investigated.[107–112]

The crystallographic approach to the description of spin transitions both in the crystal and in solution involves the measurement at room temperature of the geometrical parameters of complexes with similar structures but with different spin states. For example, a study at room temperature of the low-spin complexes $[Fe(sal)_2trien]Cl.2H_2O$ and $[Fe(sal)_2.trien]NO_3.H_2O$ and the high-spin complexes $[Fe(acac)_2Cl_2.trien]PF_6$ and $[Fe(acac)_2trien]PF_6$(sal = salicylaldehyde, trien = triethylenetetramine, and acac = acetylacetone) revealed a difference of 0.12 Å between the average metal–ligand bond lengths.[113]

A more complete structural description of the spin isomers is provided by the X-ray diffraction study of the same object at high and low temperatures. Thus investigation of $Fe(2,2'\text{-bipy})_2.(NCS)_2$ (β-modification) at temperatures above and below the spin transition established a change in the Fe–N bond length from 2.02 Å in the state $^1A_1$ to 2.14 Å in the state $^5T_2$.[114] For the iron(II) complex with the hexadentate [4-(6-*R*)-2,2'-bipyridyl]-3-aza-3-butenylamine ligand,[115] the expected increase (by ~0.12 Å) of the average of the six Fe–N distances was observed on passing from the high-spin state at 300 K to a mixture of the high- and low-spin states at 205 K. The structure of iron(III) trisdithiocarbamate was determined at 79 K, where the complex exists predominantly in the low-spin state, and at room temperature, where there are approximately equal contents of iron in the high- and low-spin states.[116]

When the investigations are carried out at temperatures such that two or more isomers are present in large amounts, in all cases it is possible to observe only the "average" structure, i.e. the spin isomers are crystallographically indistinguishable. Crystallographic studies carried out at several temperatures, where the disorder caused by the presence of spin isomers can be experimentally differentiated, are therefore of greatest interest. We shall consider the X-ray diffraction study of the methanol solvate of tris(2-picolinylamine)iron(II) dichloride (LXXXI) carried out at five temperatures (115, 148, 171, 199, and 227 K).[117] The high- and low-spin isomers of this compound are well resolved at four temperatures in the range 148–227 K. The differences between the spin isomers are evident also from a comparison of the structural parameters of compound (LXXXI) at 148–171 K (where both spin isomers are present in appreciable amounts) with the parameters obtained at the highest and lowest of the selected temperatures of their measurements. The average distances between the low-spin iron atom and the nitrogen atom at 148 and 171 K are 2.01(1) and 2.02(2) Å respectively, whereas at 115 K, when the substance consists of 98% of the low-spin isomer, the difference is 2.016(3) Å. The average distances between the high-spin iron atom and the nitrogen atom at 148 and 171 K are in their turn 2.18(1) and 2.19(1) Å, while at 227 K, where compound (LXXXI) consists of 84% of the high-spin complex, the average distance is 2.198(6) Å.

Another criterion which makes it possible to distinguish the spin isomers is the presence of correlations between the thermal parameters of the corresponding ligand atoms in the low- and high-spin forms. The structure of compound (LXXXI) (at 148 and 171 K)[117] was refined on the assumption that the isotropic thermal parameters of all the atoms are independent. The physically reasonable values of these parameters even in those cases where the distances between the atoms of the low- and high-spin isomers are small is remarkable. In the crystal of compound (LXXXI) there exists a two-dimensional system of the Cl...H–N and Cl...H–O hydrogen bonds. Although it has been remarked that the nature of the hydrogen bonds in the spin-isomeric compounds can influence appreciably the spin equilibrium, a detailed analysis of the change in the system of hydrogen bonds in the crystal of compound (LXXXI) at different temperatures has not been carried out.[117]

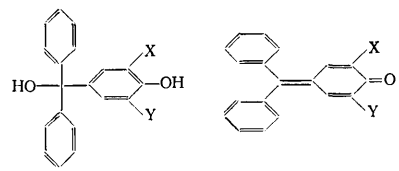
Estimates of the equilibrium constants for the spin transitions, obtained for compound (LXXXI) by X-ray diffraction[117] and by studying the Mössbauer effect,[118,119] have shown that the spin transitions in compound (LXXXI) are significantly non-cooperative; ΔH and ΔS are then 2.35(8) kcal mol^{-1} and 15.3(8) e.u. respectively, which may be compared, for example, with 4 kcal mol^{-1} and 10 e.u. for the spin transition in the complex tris [4-(6-*R*-2,2-bipyridyl)-3-azabutenylamine]iron(II) in the solid phase and in solution.[115] The above enthalpy change is apparently associated with the proximity of the spin transition temperature in these complexes to room temperature. In general the enthalpy change in the spin transition in the crystal is very sensitive to "specific" intermolecular interactions. On the other hand, one may expect that a change in entropy will not greatly influence the change in the crystal lattice observed during the course of the spin transition.[117]

III. REACTIONS WITH ELIMINATION OF SMALL MOLECULES

Chemical reactions in organic crystals accompanied by the liberation of low-molecular-weight products (in particular gaseous products) are well known. They include the desolvation of crystalline solvates (see, for example, Byrn and Lin[120] and Curtin and Paul[121]), controlled decomposition of explosive substances[122] and solid aza-compounds,[123] decarboxylation of diacyl peroxide,[124,125] and also the decarboxylation of *p*-aminosalicylic[126–129] and benzoic[130] acids.

1. Dehydration of *p*-Hydroxytriarylmethanols

The solid-phase thermal dehydration to the fuchsones (LXXXIII) of certain *p*-hydroxytriarylmethanols (LXXXII),[131,132] whose molecules have functional groups ensuring the presence in the crystal of a system of hydrogen bonds between the phenolic OH group (the proton donor) and the OH group at the sp^3 carbon atom (proton acceptor) in a neighbouring molecule, is well known. The presence of such hydrogen bonds, which link up the molecules into infinite chains, has been demonstrated by an X-ray diffraction study of compound (LXXXIIa) and also by the investigation of the isostructural crystals of compounds (LXXXIIb) and (LXXXIIc)[132,133]



(LXXXII): (a) X, Y=H; (b) X, Y=Br; (c) X, Y=CH_3; (d) X=CH_3, Y=H; (e) X=CH_3, Y=Br.

(LXXXIII): (a) X, Y=H; (b) X, Y=Br; (c) X, Y=CH_3

The thermal solid-phase dehydration of compound (LXXXII) in crystals having two different habits [(LXXXIIc′) and (LXXXIIc″) (Fig.4)] has been investigated.[133] The reactions in crystals of compound (LXXXIIc) proceeds in the same way as in crystals of compounds of a completely different type, namely certain oximes of picryl esters.[134–135] The reaction begins with the development at opposite end-faces of the crystal, namely (001) and (00$\bar{1}$), of readily distinguishable opaque triangular yellow regions, which consist of a solid solution of the reaction product in the initial crystal. The regions which have reacted crack and are then separated from the specimen. The [001] direction, in which the reaction is preferentially propagated, corresponds to the orientation of the hydrogen bond chains in the crystal of compound (LXXXIIc′).

The thermal dehydration of crystals of compound (LXXXIIc″) proceeds in a completely different way and begins immediately throughout the bulk of the crystal. It is striking that the crystal becomes yellow and turbid already at a low degree of conversion. Despite its identical structure, the thermal dehydration of compound (LXXXIIb) is approximately an order of magnitude faster than that of compound (LXXXIIc),[133] which can be attributed to the sharp (by a factor of 10^4) increase of acidity after the substitution of the CH_3 groups in 2,6-dimethylphenol by Br atoms.[136] However, the study of the rate of evolution of water vapour on heating the crystal showed that the monomethyl derivative (LXXXIId) is dehydrated much faster than the monobromo-derivative (LXXXIIe).[137] Unfortunately there are no structural data for compounds (LXXXIId) and (LXXXIIe).

The study of the photochemical dehydration of compound (LXXXII) (under ultraviolet irradiation) demonstrated that the reaction in both the single crystal and in polycrystalline

specimens (its visible manifestation consists in the appearance of a yellow colour and turbidity in the specimen) is observed only in thin surface layers.[133,136]

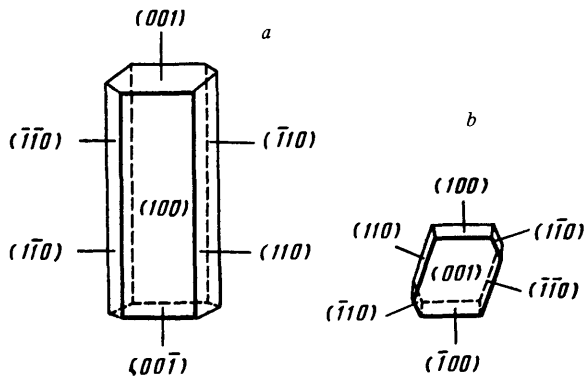


Figure 4. Two habits, (*a*) and (*b*), of crystals of compound (LXXXII).[133]

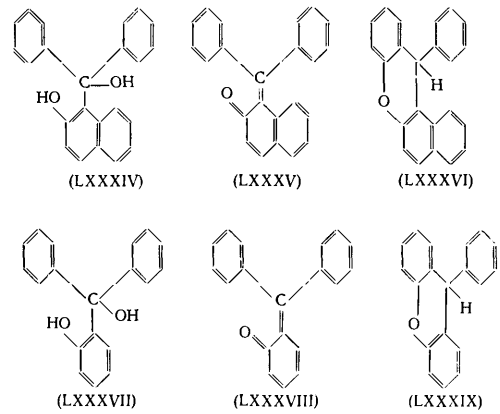
We may note that the crystal of (LXXXIIc) subjected to preliminary ultraviolet irradiation undergoes thermal dehydration much faster.[133] This is apparently caused by the photolytic formation in the crystal of the carbinol (LXXXII) of the nuclei of the fuchsone (LXXXIII) phase. It remains obscure how the fuchsone phase is propagated in the carbinol crystal: chemically, i.e. by transfer of the phenolic proton along the lattice defects, or in some other way.

As already stated, thermal solid-phase reactions in organic crystals have come to be described in terms of two limiting mechanisms, "heterogeneous" and "homogeneous", which have been used by Wegner et al. in the study of the solid-phase polymerisation of diacetylenes.[139] The heterogeneous reaction is characterised by an initial nucleation stage and subsequent migration of the reaction front through the crystal. The stage which determines the operation of one of the two reaction mechanisms is in fact nucleation. Both homogeneous and heterogeneous mechanisms are characteristic of the nucleation of the thermal dehydration of the carbinols (LXXXII), i.e. the process is the first example of a solid-phase reaction where the nucleation stage is under a kind of double control.[133]

The molecules of type (LXXXIII) can acquire chirality as a consequence of the internal rotation of their groups about single bonds. In the liquid phase the rapid interconversion of enantiomers should lead to the disappearance of chirality. However, in the solid phase, where the molecular conformation is frozen, there is a possibility of crystallisation in enantiomorphic space groups, as has been observed for binaphthyl (see, for example, Pincock and coworkers[140,141]).

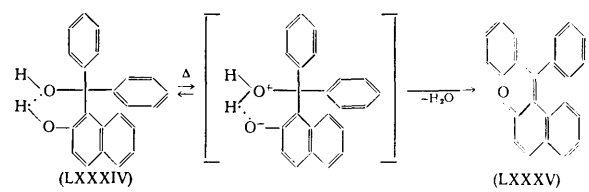
Three polymorphic modifications (α, β, and γ) have been observed for compound (LXXXIIIc), one of which, namely β-(LXXXIIIc), crystallises in the enantiomorphic space group $P2_12_12_1$.[142,143] X-Ray diffraction study revealed three types of deformations of the molecules of compound (LXXXIIc) in the crystals relative to the planar form: distortion of the quinone ring, breakdown of the planarity of the exocyclic double bond, and rotation of the aromatic rings relative to this bond. The crystals of α-(LXXXIIIc) and β-(LXXXIIIc) are made up of layers having similar structures but linked symmetrically to one another in different ways: via the 2_1 axes in β-(LXXXIIIc) and via the slip reflection planes and symmetry centres in α-(LXXXIIIc). The possibility of the thermal solid-phase transition α → β has been demonstrated[142] (by means of a powder diffraction pattern recorded at 383 K) and the changes in the geometry and packing of the molecules of compound (LXXXIIIc) required for this transition have been analysed.

In contrast to compound (LXXXVII), the solid-phase thermal dehydration of compounds (LXXXIV) and (LXXXVII) can proceed both intramolecularly [with formation of the fuchsones (LXXXV) and (LXXXVIII) and intermolecularly [with formation of the xanthenes (LXXXVI) and (LXXXIX).[144,145]



Later investigations[146] of the thermal dehydration of compounds (LXXXIV) and (LXXXVII) by infrared spectroscopy and NMR confirmed only the occurrence of the transitions (LXXXIV) → (LXXXV) and (LXXXVII) → (LXXXIX). X-Ray diffraction study[146] demonstrated the existence of intramolecular hydrogen bonds in crystals of compounds (LXXXIV) and (LXXXVII); thus the thermal dehydration in the crystals of compound (LXXXIV) probably proceeds via Scheme 14:

Scheme 14



An analogous mechanism of the intermolecular transfer of a hydrogen atom has been used to account for the thermochromic and photochromic transitions in crystals of salicylideneanilines (see, for example, Aldoshin and Atovmyan[147] and Cohen et al.[148]).

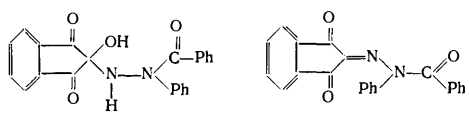
However, the discrepancy between the molecular geometries in the crystals of compounds (LXXXIV) and (LXXXVI) conflicts with the above description of the thermal dehydration of crystals of compound (LXXXIV). In fact the dihedral angle relative to the C(sp^3)–C(naphth.) bond in compound (LXXXIV) [as well as the corresponding angle in compound (LXXXVII)] is close to 80°, while an angle close to 0° (or 180°) would have been ideal for the rearrangement in accordance with Scheme 14. In a molecule of compound (LXXXV) the dihedral angles relative to the central double bond are 10.4° and 13.5° (two values are given in view of the breakdown of the planarity of the two central carbon atoms.[149] It has therefore been suggested[146] that the difference between

the solid-phase reactivities of compounds (LXXXIV) and (LXXXIIb) [the process (LXXXIIb) → (LXXXIIIb) is much faster than (LXXXIV) → (LXXXVI)] cannot be accounted for solely by the difference between the crystal structures of compounds (LXXXIV) and (LXXXVII).

The similarity of the crystal structures and hydrogen bond systems in compounds (LXXXIV) and (LXXXVII) makes it difficult to account for the difference between the products of their solid-phase thermal dehydration. It has been postulated[146] that the greater bulk of the naphthalene ring in the molecule of compound (LXXXIV) compared with that of the phenyl substituent in compound (LXXXVII) results in some flattening of the tetrahedron at the central sp^3-hybridised carbon atom, i.e. leads to a greater amount of sp^2-character in the latter. It may be that this difference between the geometries of the ground states of compounds (LXXXIV) and (LXXXVII) actually determines the difference between their reactivities in solid-phase dehydration processes.

2. Dehydration of (β-Benzoyl-β-Phenylhydrazyl)-2-Hydroxyindan-1,3-Dione

The solid-phase thermal dehydration of the hydrazinocarbinol (XC) proceeds anisotropically:[150] the appearance of the reaction product (XCI) [the acquisition of a red colour by the initial crystal of compound (XC)] begins at the $(10\bar{1})$ and $(\bar{1}01)$ faces and is propagated in the [001] direction.



After 17 days at 65 °C, the degree of conversion in the process (XC) → (XCI) is 10%. The possible sequence of stages in the solid-phase reactions of this type (nucleation, the formation of a solid solution, initiation of the new phase, and its separation) have been examined.[151]

The hydroxy-group O(4)–H in the molecule of compound (XC) in the crystal forms intramolecular hydrogen bonds with the carbonyl O(3) atom (Fig.5). The N(1)–H...O(2) hydrogen bonds between the molecules of compound (XC), linked by 2_1 axes, combine them into chains along the *b* axis of the crystal. Attack by a proton from the outer side of the chain (Fig.6) leads to the elimination of the OH group from the molecule of (A), which promotes also the subsequent abstraction of the OH group from a neighbouring molecule of (B) by the H(N) group. However, the H(N) atom forms a hydrogen bond with the O(1) carbonyl group of the molecule of (B) and not with the OH group; the H(N)...O(2) distance is 3.01 Å. The low rate of the reaction (XC) → (XCI) is apparently due precisely to the complexity of the rearrangement of the hydrogen bond formed by the N–H group. This hypothesis has been confirmed by the initiation of the reaction when a thin layer of the hydrate of toluene-*p*-sulphonic acid is deposited on the faces of the crystal of compound (XC),[151] the acceleration effect diminishing as the reaction front moves away from the region where the crystal is in contact with the acid. Fig.5 shows that the conformation of the molecule of compound (XC) is close to that necessary for the elimination of the H_2O molecule. During the reaction, there is an appreciable change in the geometry of the molecule of compound (XC), because its (H)OC(2)N(1)H(N) torsional angle is 36°, while in the indandione molecule the >C(2)=N(1) fragment should be planar.

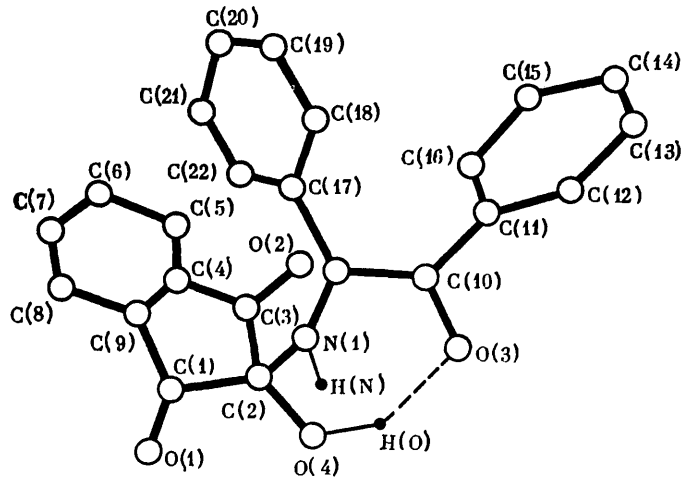


Figure 5. The structure of the molecule of compound (XC).[150]

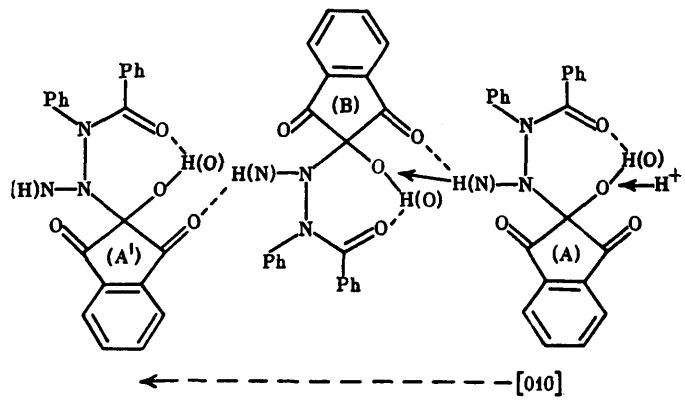

Figure 6. The possible mechanism of the solid-phase dehydration of compound (XC); the preferred direction [010] of dehydration is shown by a dashed line.[150]

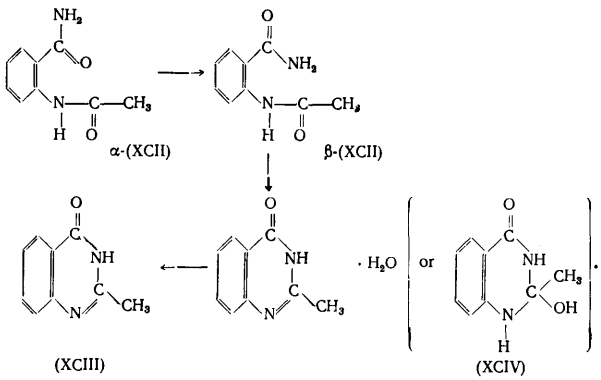
3. Dehydration of *o*-Acetamidobenzamide

o-Acetamidobenzamide crystallises in two polymorphic modifications, α-(XCII) and β-(XCII), the solid-phase thermal transformation of which leads to anhydro-2-methyl-4-quinazolinone (XCIII).[152] Spectroscopic data and differential

scanning calorimetry indicate the following sequence of stages in the reaction (XCII) → (XCIII):



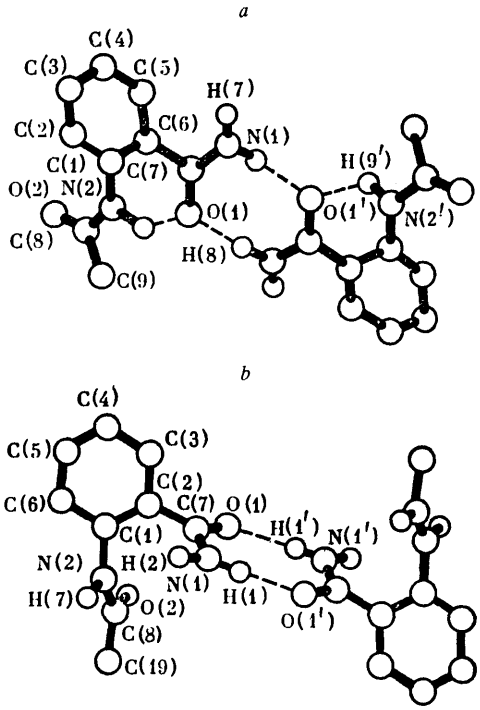


Figure 7. The structure of the centrosymmetric dimers in the crystals of α-(XCII) (*a*) and β-(XCII) (*b*).[152]

The crystals of α-(XCII) and β-(XCII) are made up of centrosymmetric molecular dimers (Fig.7) formed via a hydrogen bond with participation of the primary amido-group, the plane of the amide fragment in the structure β-(XCII) being inclined at 52° relative to the plane of the benzene ring, while in α-(XCII) the angle of inclination is only 8°. The appreciable difference of these angles from the energetically optimum value of 25° [152] has been explained by the simultaneous involvement of secondary *o*-amido-substituents in hydrogen bonds: the secondary amido-group in α-(XCII) participates in the intramolecular hydrogen bond with the primary amido-group, while in β-(XCII) it is involved in the intermolecular hydrogen bond between molecules linked only via the 2_1 axis. Fig.8 illustrates schematically the conformational transition α-(XCII) → β-(XCII) which is necessary for the formation of the system of hydrogen bonds observed in β-(XCII) crystals. Primary structural data for compound (XCIII) and the postulated structure of compound (XCIV) permit the conclusion that the main role in the destabilisation of the structure of β-(XCII), which leads to the solid-phase dehydration and the formation of compound (XCIII), is due to the hydrogen bonds combining the molecules of compound β-(XCII) into dimers.[151]

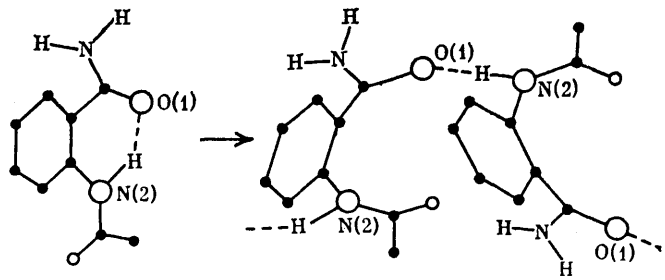

Figure 8. Schematic illustration of the conformational changes in the transition α-(XCII) → β-(XCII).[152]

X-Ray diffraction study of compound (XCIII) permitted hypotheses concerning the mechanism of its solid-phase hydrolysis with formation of compound (XCII).[153] The crystal structures of compounds (XCII) and (XCIII) are similar—the carbonyl groups in the molecules of compound (XCIII), linked via the 2_1 axis, form hydrophilic cavities parallel to the (001) plane. It has been suggested that the solid-phase hydrolysis of compound (XLIV) takes place precisely in the hydrophilic cavities along the *a* axis.

4. Dehydration of Copper Formate Hydrates

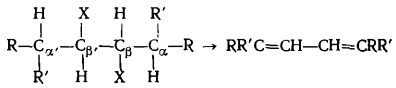
Crystals of copper(II) formate hydrates are known to be capable of thermal dehydration.[154–157] The structural treatment of this process, which is topotactic in character and leads to well oriented pseudomorphic anhydrous phases as products,[154,155,157] has been held back by the lack of structural data for such phases although the crystal structures of the initial copper(II) formate hydrates are known.[158–161]

The pale-blue crystals of copper(II) formate tetrahydrate $Cu(HCOO)_2.4H_2O$ (XCV) lose the water of crystallisation on drying in air and become opaque, being converted into the anhydrous phase $Cu(HCOO)_2$.[162] Comparison of the crystallographic parameters of compounds (XCV) and (XCVI) indicates the similarity of the structures in the *ab* planes and considerable differences between them in the direction of the *c* axis, which suggests the topotactic character of the dehydration of compound (XCV). A crystal of this compound is made up of layers, parallel to the (001) face, in which the copper atoms have a square planar environment consisting of four formate anions, each of which links two copper atoms. The H_2O molecules are distributed between these layers, half of them augmenting the coordination of the copper atoms to the octahedral coordination; the remaining water molecules are not coordinated at the metal atoms but form hydrogen

bonds with the H_2O molecules coordinated to the copper atoms.[162] The crystal of compound (XCVI) is also made up of layers of tetracoordinate copper atoms, analogous to those found in compound (XCV); the fifth and sixth coordination sites of the copper atom are occupied by the O atoms of the formate groups. Both types of molecules of water of crystallisation in the crystal of compound (XCV) have a relatively large amount of freedom as regards diffusion parallel to the layers. The removal of water should alter the coordination of the copper atoms and should lead to the mutual approach of the layers. Some structural rearrangement should occur also within the layers themselves.

5. Dehydrobromination of *meso*-dibromobutane Derivatives

Crystalline *meso*-dibromobutanes undergo double dehydrobromination on treatment with gaseous ammonia or amines, giving rise to quantitative yields of the corresponding buta-1,3-dienes[163]

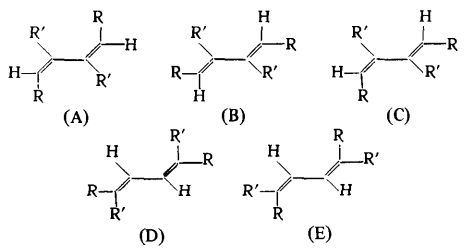


(XCVII)–(CI)

where (XCVII) = *meso*-β β′-dibromoadiponitrile, (XCVIII) = (*R*, *S*, *R*, *S*)-αα′-dimethyl-ββ′-dibromoadiponitrile, (XCIXa), (XCIXb) = (*R*, *R*, *S*, *S*)-αα′-dimethyl-ββ′-dibromoadiponitrile, (C) = dimethyl (*R*, *S*, *R*, *S*)-αα′-dimethyl-ββ′-dibromoadipate, and (CI) = dimethyl (*R*, *R*, *S*, *S*)-αα′-dimethyl-ββ′-dibromoadipate.

Apart from the van der Waals interactions, the molecular packing in crystals of compounds (XCVII)–(CI) is determined by the Br...N≡C and C...N≡C donor acceptor interactions.[164,165] The Br...N distances in the crystals of compounds (XCVII), (XCVIII), and (XCIXb) (3.20, 3.26, 3.22 Å respectively), which are significantly smaller than the sum of the van der Waals radii (3.45 Å),[35,36] can be regarded as corresponding to weak interactions between a Lewis acid and a Lewis base.[166] A weak interaction of the type C...N≡C is observed also in the crystal of compound (XCVII) (the corresponding C...N distance is 3.27 Å).

The solid-phase dehydrobromination of compound (XCVII) gives rise to a mixture of the isomeric butadienes (A)–(C) in the proportions 2:3:5, while the dehydrobromination of crystals of compounds (XCVIII), (XCIX), (C), and (CI) yields the pure products (B), (A), (D), and (E) respectively.[164,167]

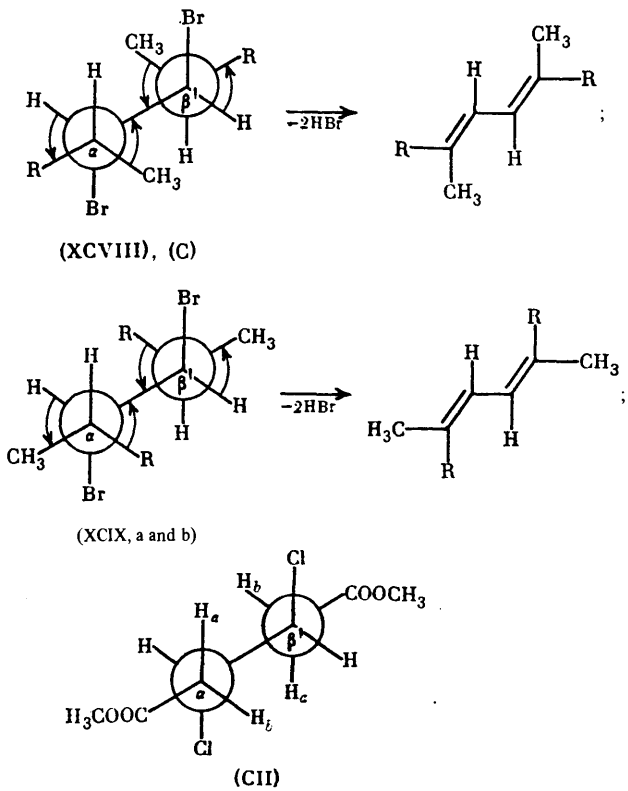


(A) (B) (C) (D) (E)

The reaction of the crystals of compound (XCIXa) is faster than in another polymorphic modification (XCIXb) of this compound.

In the crystals of the αα′-dimethyl derivatives of compounds (XCVIII), (XCIXa), (XCIXb), (C), and (CI), in which there is a possibility of the elimination of only one hydrogen atom from each C_α atom, all the H_α atoms are in the antiperiplanar positions relative to the Br atom. Assuming an *anti*-elimination mechanism, which requires a minimal rearrangement of the geometry of the carbon atoms for transition to the sp^2-hybridised state, one should expect the formation of the corresponding *trans,trans*-butadienes from the molecules of compounds (XCVIII) and (C) having the *R*, *S*, *R*, *S*-configuration and of *cis*-butadienes from the molecules of compounds (XCIX, a and b) and (CI) having the *R*, *R*, *S*, *S*-configuration (Scheme 15). This hypothesis has been confirmed experimentally[164,167] and it has demonstrated that the *anti*-elimination processes and the configuration of the products under the conditions of the heterogeneous gas–crystal reaction are controlled by the conformation of the initial molecules.

Scheme 15



(XCVIII), (C)

(XCIX, a and b)

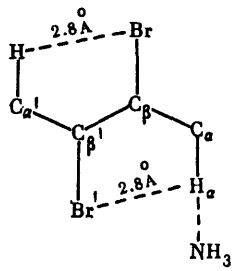
(CII)

The mechanism for the elimination reaction in molecules with two hydrogen atoms at each C_α atom is more complex. In the nitrile (XCVII) and the ester (CII) the H_a atom is antiperiplanar relative to the Br atom, while the H_b atom has a *gauche*-orientation. Since the *anti*-elimination mechanism applies also to the nitriles and esters, presumably the *cis,cis*-butadiene and the *trans,trans*-butadiene are formed respectively from compounds (XCVII) and (C). This course for the elimination process is consistent with the experimental data for compound (C),[164] but has not been confirmed for compound (XCVII). The formation in the latter case of a mixture of butadiene isomers shows that the elimination was preceded by rotation about the C_α–C_β bond in some of the molecules of compound (XCVII). Such rotation, which requires an energy expenditure of 5 kcal mol^{-1} according to conformational calculations,[168] is impossible in the crystal matrix, but, on the crystal surface and at the dislocations, where the reaction is initiated, the lattice is somewhat "staggered" and this barrier can be overcome.

We shall consider how, within the framework of the steric control of the *anti*-elimination in the crystal, the NH_4^+ ion is formed on one side of the molecule and a halide ion is

removed on the other (charge separation). It may be that, by virtue of the relatively short distance between the H_α and Br atom (~2.8 Å), the NH_4^+ ion, formed on the side of the C_α atom, induces the elimination of the Br′ atom linked to the C'_β atom, while the non-solvated Br^- anion, formed at the C_β atom, behaves as a strong base capable of abstracting the hydrogen atom linked to the C'_α atom (Scheme 16). The closeness of the oppositely charged ions leads to the subsequent rapid interaction.

Scheme 16



The induction period, frequently observed in reactions of the gas–crystal type,[169] as well as the influence of defects on the rate of these solid-phase processes[168,169] have shown that they begin with the diffusion of gas molecules to the existing nucleation centres (for example, to dislocations and impurities) at which the reaction is initiated and is then propagated throughout the bulk of the crystal.

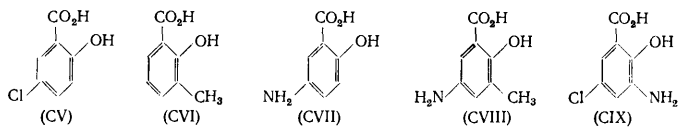
The difference between the types of packing should lead to a difference between the rates of diffusion and it is to be expected that the reaction should be faster in the less dense crystalline forms where the crystal field hindering diffusion is usually weaker. Apparently this is the explanation of the higher rate of dehydrobromination in crystals of compound (XCIXa) compared with (XCIXb), since the density of compound (XCIXa) is less than that of (XCIXb) (d = 1.84 and 1.90 g cm^{-3} respectively), while the intermolecular forces in the former case are weaker, which can be seen from the greater intensity of the thermal movement of atoms in the crystals of compound (XCIXa) at room temperature. The difference between the rates of diffusion of Br atoms, which is a consequence of the anisotropy of the crystal packing, has also been invoked to account for the different rates of bromination reactions of the gas–crystal type of the polymorphic forms of mesaconic acid.[169]

According to microscopic studies, reactions of the gas–crystal type are heterogeneous,[168,170,171] beginning on the surface of the crystal, while the process determining their rate is the "unpacking" of the layer formed, which hinders the movement of gas to the next layer. The observed difference between the rates of reaction in different crystallographic directions is usually interpreted on the basis of the idea that the reacting groups are unequally accessible to the diffusing gas molecules on different crystal faces. The anisotropy of the propagation of the reaction front is also observed in solid-phase rearrangements with thermal initiation.

We shall consider the possibilities of access to the potentially reactive hydrogen atoms on different faces of (XCIXa) and (XCIXb) crystals. The approach of NH_3 molecules to the H_α atoms can be blocked by the CH_3, CN, and C_β groups. The molecules in the crystal of compound (XCIXa) form layers perpendicular to the *b* axis and in each layer they are linked solely by *a* and *c* translations. The C_α–H bonds are perpendicular to the plane of the layer, while all the remaining bonds of the tetrahedral C_α atom are located approximately in the plane of the layer. In such a structure of the crystal, the neighbouring molecules located in a single layer do not hinder the approach of NH_3 molecules to the H_α atoms. The initial elimination of one H_α atom, which leads to the formation of NH_4^+ and Br^-, induces the elimination of a second H_α atom and results in a weakening of the fixation of the reacting molecule within the plane of the layer. The rate of the second process depends on the crystal forces, which are weaker in compound (XCIXa) than in (XCIXb). The partial "unpacking" of the layer ensures the access of NH_3 molecules to the next molecular layer. The H_α atoms of the molecular layer in compound (XCIXb) are much less accessible than in (XCIXa), which explains the lower rate of dehydrohalogenation of this crystalline modification.

6. Dehydrochlorination and Decarboxylation of *p*-Substituted Derivatives of Salicylic Acid

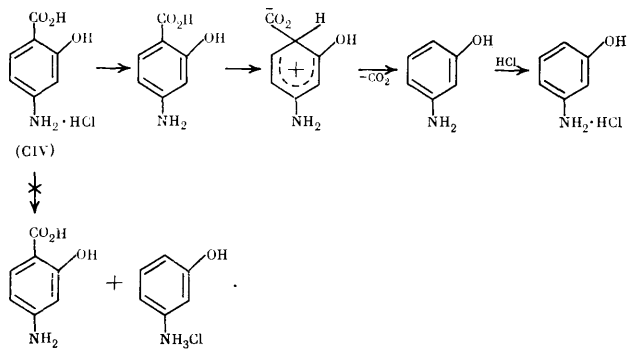
The kinetics and mechanism of the decarboxylation of *p*-substituted derivatives of salicylic acid in solution have been thoroughly investigated.[126–129] Solid *p*-aminosalicylic acid (CIII) decomposes at 70 °C, while its hydrochloride (CIV) decomposes at 100 °C. On heating to 100 °C, compound (CIV) is fully converted into *m*-aminophenol in 10 h. The salicylic acids (CV)–(CIX) did not decompose appreciably on heating to 100 °C for a week.



On the basis of kinetic data, a carbanionic mechanism of the decarboxylation reaction, similar to that observed for the decarboxylation of trinitrobenzoic acid, has been suggested.[172]

The decarboxylation of compound (CIV) involves the initial loss of HCl, which is followed by the decarboxylation, the sublimation of *m*-aminophenol, and finally its reverse interaction with HCl (Scheme 17). This sequence of stages agrees with the absence of a reaction of the crystal–crystal type between *m*-aminophenol and compound (CIV) when they come into direct contact.

Scheme 17



It has been stated[172] that this mechanism agrees with the characteristic features of the molecular packing in the crystals of compound (CIV). In conformity with the idea that solid-phase photochemical interaction between C=C bonds separated by a distance of ~4 Å is possible,[173] there exist four intermolecular contacts in the crystals of compound (CIV) between the acid proton and the unco-atom of the carbon ring attached to the carboxy-group, whose lengths are 3.98, 4.99, 4.60, and 4.42(3) Å, which gives rise to the possibility

of the propagation of the reaction in the crystal in several directions. The reaction is initiated on the $(10\bar{2})$ faces. Layers of polar carboxy-groups and non-polar aromatic groups, arranged parallel to the (100) face, are approximately perpendicular to the $(10\bar{2})$ faces. Thus the evolution of the CO_2 formed is to be expected from the side of the $(10\bar{2})$ face and not the (100) face.[169]

The solid-phase thermal (at 95 °C) decarboxylation of crystals of compound (CIV) having different habits (A, B, and C) has been investigated;[174] for this purpose, the development of the region of turbidity in the crystal (which corresponds to the disordering induced by the loss of HCl preceding the decarboxylation) was observed. In a crystal of compound (CIV) having the A habit, HCl is evolved along the *b* axis. The reaction along the *c* axis is slower. The loss of HCl by crystals of compound (CIV) having the B habit takes place in the direction of the *a* axis. If we now turn to the molecular packing in the crystal of compound (CIV), it is found that the HCl molecules can leave the crystal along the *a* and *b* directions without involving the non-polar functional groups and interacting only with the amino- and carboxy-groups. The evolution of HCl along the *c* direction is also possible, although in this case Cl^- ions and OH and NH_2 groups as well as hydrocarbon radicals may be encountered in the path of the HCl molecules.

Thus, the characteristics of the molecular packing suggest that the dehydrochlorination reaction should proceed along the *a* and *b* directions. The authors[174] were unable to explain the observed course of the reaction, which started from the $(0\bar{1}1)$, (011), and $(10\bar{2})$ faces of the form A of the (CIV) crystal. The attempts to explain the characteristic directions of propagation of the solid-phase reaction in a crystal of compound (CIV) having the B habit on the basis of the characteristic features of the molecular packing in the crystal were also unsuccessful.# Apparently the anisotropic loss of HCl by (CIII) and (CIV) crystals is associated with the characteristic features of the initiation of the reaction. The zone of the reaction initiated on a certain face of the crystal (having the A or B habit) migrates to its centre, and HCl is most easily removed via the regions which have reacted or been disrupted.[174]§

According to microscopic observations, the reaction in the *a* direction of the (CIV) crystal is faster than in the *b* direction, in conformity with the calculated cross-section of the tunnel for the release of HCl, which amounts to 3.23 $Å^2$ along the *a* axis and to 1.60 $Å^2$ along the *b* axis. The distance between the rings in the direction of the *a* axis is also smaller than in the direction of the *b* axis (5.316 and 4.232 Å respectively).[174]

The interaction of (CIV) crystals having the A and B habits with gaseous primary, secondary, and tertiary amines has been investigated.[174] The interaction with primary and secondary amines proceeds rapidly and leads to liquid products. However, hexamethylenetetramine reacts at the (001) face in the A crystal habit (in the course of 30 min), while crystals having the B habit [with (001) and (100) faces having a large area] do not decompose even after 72 h. Different rates of reaction with hexamethylenetetramine are also characteristic of the different faces of the acetylsalicylic acid crystal. There exist data demonstrating different rates of interaction of crystalline aminoacid enantiomers with optically active amines.[177]

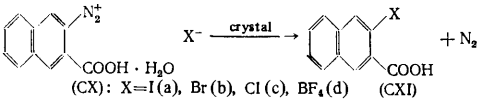
Crystals of compound (CIV) with all three habits are involved in an interaction of the crystal–crystal type with Na_2CO_3. This reaction always begins at the site of contact between the crystals of the acid and the carbonate and is fairly slow (it is completed after 40 days at 60 °C).[174] If the reaction occurs at room temperature, drops of water are formed. Compound (CIII) is formed as the product and *p*-aminosalicylate anions have also been detected. The low rate of reactions of the crystal–crystal type compared with those in solution can be accounted for by the low rates of diffusion of ions in the crystal lattice in compound (CIV).[178–182] If the solid-phase thermal decomposition of compound (CIV) in the absence of contact with Na_2CO_3 involves the loss of HCl by diffusion, then the reaction of the crystal–crystal type (acid–base) considered above consists either in the diffusion of HCl to Na_2CO_3 or in the counterdiffusion of H^+ or Na^+ ions with formation of H_2CO_3 in the lattice of the base and of NaCl in the lattice of the acid.

Reactions of the crystal–crystal type are relatively rare and have been thoroughly investigated only in relation to the formation of spinels from metal oxides (for example, Al_2O_3 and MgO) at high temperatures.[178–182] The most probable mechanism of these reactions is based precisely on the counterdiffusion of cations.

7. Decomposition of 3-Carboxynaphthalene-2-Diazonium Halides with Evolution of Nitrogen

Studies of the solid-phase reactions of aromatic diazonium salts began with the investigation of the thermal decomposition of solid benzenediazonium fluoroborate.[183] Aromatic diazonium salts readily explode and are isolated only rarely; nevertheless, a series of diazonium salts with weakly nucleophilic anions have been investigated by X-ray diffraction.[184–192]

We shall consider the mechanism of the decomposition of these salts in relation to the monohydrate (CX). The orange crystals of compound (CXa) rapidly acquire a blue colour on standing at room temperature, evolve nitrogen as a result of the substitution of its diazo-group by an I atom, and are converted into the polycrystalline acid (CXIa).[193–195] The intensity of the 2250 cm^{-1} band of the RN_2^+ group in the infrared spectrum diminishes rapidly. The topotaxy of crystals of compounds (CXa) and (CXIa) has not been observed.



(CX): X=I(a), Br(b), Cl(c), BF_4(d) (CXI)

The crystals of compounds (CXb) and (CXc) are isostructural and, like compound (CXd), crystallise as monohydrates. Data obtained by differential scanning calorimetry, thermogravimetric analysis, and X-ray diffraction indicate the ability of the triclinic crystals of compound (CXb) to lose water topotactically on heating about 65 °C and to be converted into an intermediate α-phase which is in itself then converted into the β-phase at 90 °C. The thermal decomposition of the β-phase (at ~100 °C) is accompanied by the evolution of nitrogen and the formation of 3-bromo-3-naphthoic acid (CXIb).[193–195]

#An analogous description of the propagation of a solid-phase reaction has also been resorted to to explain the loss of the water of solvation from the crystalline hydrates when the latter are cut by a razor blade[175] and in the solid-phase reaction of dimethyl 3,6-dichloro-2,5-dihydroxyterephthalate,[176] which begins at one end of the crystal and passes through the entire crystal in a direction which cannot be accounted for by the character of the molecular packing.

§Crystals of compound (XXIII) having the C habit have not been investigated by X-ray diffraction.

Although the molecular packing of the molecules in crystals of compounds (CXIa) and (CXIb) is of different types, the direct environment of the diazonium group in these compounds is similar: all the 15 C, N, and O atoms in the cations are approximately coplanar and there exists one shorter intramolecular O(13)...N(14) contact, whose length is 2.5 Å. The shortest intermolecular contact (2.9 Å) has been observed between the "outer" N(15) atom and the O(13) atom of the carbonyl group. The shortest contacts involving the halogen atom, namely I...N(15), which is 3.4 Å long in compound (CXIa), and Br...N(15), which is 3.27 Å long in compound (CXIb), also involve the outer N atom and are significantly shorter than the sum of the van der Waals radii (3.53 and 3.40 Å respectively[35,36]). The distances between the halogen atom and the "inner" N atom are 3.80 Å for compound (CXIa) and 3.50 Å for compound (CXb).

Each halogen atom is coordinated via two diazonium groups and is also involved in hydrogen bonds with the two solvating H_2O molecules [the Hal...OH_2 distances are 3.4 and 3.6 Å in compound (CXa) and 3.27 and 3.29 Å in compound (CXb)]. In addition, the H_2O molecule [O(16)] forms hydrogen bonds with carboxy-groups over O(12)...O(16) distances of 2.6 Å in compound (CXa) and 2.54 Å in compound (CXb) and is located opposite the C(2)–N(1) bond at a distance of 3.3 Å in compound (CXa) and 3.39 Å in compound (CXb) from the C(2) atom [the shortest intermolecular contact involving the C(2) atom].

The difference between the immediate environments of the diazonium groups in compounds (CXa) and (CXb) is determined by the van der Waals radii of the halogen atoms whose non-identity is manifested by the small differences between the corresponding Hal...N distances and also by the different intermolecular coordinations of the carbonyl O(13) atom.[193–195]

One may assume that the reactivity of compounds (CXa) and (CXb) is determined by the initial disposition of the halide and diazonium ions; N_2 is then evolved by a mechanism involving substitution as a result of attack by the halide ion. However, the discrepancy between the similarity of the environments of the diazonium group and the different stabilities of compounds (CXa) and (CXb) conflicts with this mechanism. The stability of the diazonium group in the β-phase (CXb) (~2 h at 95 °C) also conflicts with the alternative unimolecular mechanism involving the reversible loss of molecular nitrogen and the formation of aryl cations and relatively rapid cooling of compound (CXa) at 30–60 °C. The difference between the stabilities of the diazonium group combined with the similar environments in compounds (CXa) and (CXb) probably reflects the greater ease of oxidation of I^- ions compared with Br^- ions when an electron is transferred to the diazonium cation.[193–195]

The difference indicated between compounds (CXa) and (CXb) is intensified by virtue of the different character of the hydrogen bonds in the two structures, which link each halide ion to two molecules of water of crystallisation and also each water molecule to two halide ions. In the crystals of compounds (CXb) two bromide ions and two H_2O molecules are linked into rings around the centres of symmetry, while in compound (CXa) the hydrogen bonds form chains along the *c* axis made up of alternating iodide ions and H_2O molecules. The disruptions in the structure due to the absence of an H_2O molecule or the removal of a halide ion transmitted along the chain of hydrogen bonds [although it had not been possible to isolate the preferred direction of the disruption of the crystal of compound (CXa)]. When compound (CXb) is subjected to analogous disruption, there is a greater probability of the localisation of point defects, i.e. they do not spread throughout the bulk of the crystal.

The O–H...O hydrogen bonds and the short N(15)...O(13) intermolecular contacts in the crystals of compound (CXb) combine the cations into layers parallel to the $(1\bar{1}1)$ face; the shortest Br...N contacts are between the layers. The cracks appearing in the crystal of compound (CXb) in the transition (CXb) → α-(CXb) are perpendicular to the (001) face of the initial crystal of compound (CXb). It has been possible to establish a topotactic relation only with the fairly well ordered β-(CXb) phase, the volume of the unit cell of which proved to be smaller than for its hydrated precursor (CXb) (570 and 593 A^3). The $(\bar{1}1\bar{1})$ plane of the β-(CXb) crystal is inclined only at an angle of 14° to the $(1\bar{1}1)$ plane of the layers in the crystal of compound (CXb) and they both determine the direction of the cracks on dehydration of compound (CXb). It has therefore been suggested[190] that the layer structure of the crystals of compound (CXb) is preserved in the dehydration process and that the change (the disruption of the hydrogen bond system) takes place between the layers.

- - - o 0 o - - -

Thus the intramolecular rearrangements and reactions with evolution of a low-molecular-weight product are characteristic of crystals of organic and complex compounds of a fairly wide variety of types. The degree of control of the course of these solid-phase reactions by the crystal lattices of the initial compounds in different reaction stages can be various.

The high selectivity of the majority of the reactions considered and the possibility of regulating them, at least in some cases, by altering the character of the molecular packing of the crystals of the initial compounds (crystal engineering) leads to extensive prospects for specific synthesis under the control of the lattice.

Stabilisation of Disperse Systems by Water-soluble Polymers

A. A. Baran

The stabilisation of disperse systems by the addition of uncharged and partly charged water-soluble polymers is considered. The influence of the adsorbed non-ionic polymers on various components of the interaction energy of the colloidal particles as well as the results of direct measurements of the repulsion forces between the adsorbed macromolecules are analysed. The mechanism of the stabilisation of real dispersions by adsorbed layers of uncharged macromolecular substances is discussed. The bibliography includes 141 references.

IV. The mechanism of the stabilisation of real dispersions by non-ionic polymers 655

I. INTRODUCTION

High-molecular weight compounds (HMC) are effective stabilisers of disperse systems and extremely small amounts of these substances can radically increase the stability of colloidal solutions as regards sedimentation and aggregation. This is used widely in various branches of modern technology: for the stabilisation of emulsions in the food, pharmaceutical, and cosmetic industries, in the manufacture of varnishes, dyes, paper, and photographic emulsions, in medicine, etc.

As early as the beginning of the 20th century, a study was made of the stabilising (protective) effect of the addition of hydrophilic substances (gelatine, starch, albumen, haemoglobin, etc.) on the hydrophobic sols of gold, silver, sulphur, and other colloids. Such substances are characterised by "gold", "silver", and other numbers.[1] Since the 1950s, synthetic polymers have been used on an increasingly wide scale for the stabilisation of dispersions, which led to an appreciable increase of the number of publications in this field during the last 15–20 years. Although many aspects of the influence of added HMC on the stability of colloidal solutions have been thoroughly investigated, the mechanism of the stabilising effect of polymers has not been finally elucidated and the theoretical principles of their selection for such purposes are in the initial stage of development. This is caused by the great complexity of the polymer-containing disperse systems and the multiplicity of factors responsible for their stability.

The stabilising effect of polymers in colloidal systems is directly related to their adsorption on the surface of the disperse phase. As a result of the adsorption of macromolecules or their aggregates,[2] the properties (including rheological properties[3]) of the interface and the intensity of the interaction between the surface and the intermicellar liquid are radically altered. This leads to a modification of the previous factors or to the appearance of new factors governing the stabilisation of the disperse systems; both effects are usually manifested. For a correct understanding of the mechanism of the action of HMC on the stability of colloidal solutions, it is necessary to have data on the adsorption of polymers by the disperse phase and the parameters of the adsorbed layers formed on the surface and on the influence of the adsorption of high-molecular-weight substances on the structure of the electrical double layer and on the hydration condition of the particles. Examination of the rules governing the adsorption of HMC by disperse particles and the structure of the electrical double layer is outside the framework of the present review; a discussion of these questions can be found, for example, in Refs. 4 and 5. Detailed information about the influence of the adsorption of HMC on the double layer and about the electro-surface methods for the determination of the parameters of the polymeric adsorption layers has been published.[6]

This review surveys the results of experimental and theoretical studies devoted to the elucidation of the rules and mechanism of the stabilisation of disperse systems by the addition of uncharged and partly charged water-soluble polymers, which have been published mainly during the last ten years. In particular, the methods for the measurement and for the theoretical calculation of the forces which determine the interaction of the polymer-containing particles have been examined.

II. RULES GOVERNING THE STABILISATION OF DISPERSE SYSTEMS BY WATER-SOLUBLE POLYMERS

As already mentioned, the influence of HMC on the stability of colloidal solutions is due to the characteristic features of the adsorption on the particles of the disperse phase and of the structure of the adsorbed layers formed under these conditions. However, the relation between the adsorption of the polymer and its influence on the stability was not considered in the vast majority of investigations, particularly in the earlier ones. The dependence of the stabilising effect of HMC on the nature and amount of the added reactant, its

molecular weight, the conditions in its introduction, the presence of electrolytes in the system, and other factors has been mainly investigated. We shall analyse briefly the influence of the above factors on the stabilisation of dispersions by high-molecular-weight substances.

1. The Nature of the Stabiliser

High-molecular-weight compounds, which, on the one hand, are adsorbed by the particles, and, on the other, readily dissolve in the dispersion medium, serve as stabilisers of dispersions. These are frequently copolymers, one of the components (A) of which is bound to the surface via chemical interactions, hydrogen bonds, etc., while the second component (B) exhibits a high affinity for the intermicellar liquid. For example, two polymers in which the role of component A is assumed by the substance which forms the disperse phase exhibit an effective stabilising activity towards latex dispersions. The inclusion in the composition of A of ionogenic groups bearing a charge opposite to that of the particles or highly polar functional groups significantly improves the bond between component A and the surface.[7] A polymer readily soluble in the dispersion medium and exhibiting a weak affinity for the surface is selected as component B. For aqueous media, such polymers are, for example, poly(ethylene oxide), poly(vinyl alcohol), poly(acrylic acid), etc., while for aliphatic hydrocarbons polyisobutylene, poly(lauryl methacrylate), etc. are used.[8]

In the systems considered component B forms a steric energy barrier necessary for stabilisation, while substance A ensures a bond with the surface. The ratio of the molecular weights of components A and B (M_A and M_B) is important for copolymers. As an approximation, one can assume that $M_A \cong nM_B$, where n is the number of polymer chains of B linked to the skeleton of A.[9] As a rule, M_A is in the range 10^4–10^5 and M_B is in the range 10^3–10^4.[8] The higher the adsorption energy of an elementary unit, the lower the value of M_A necessary to attain a satisfactory stabilising effect. M_B must be sufficiently large to ensure steric hindrance over distances ranging from several to several tens of nanometers from the surface; it depends on the size and chemical nature of the particles.

Substances with comparatively low molecular weights were used initially as stabilisers, namely carboxylic acids, alkylbenzenes, etc.—they were employed to obtain stable suspensions of carbon black, titanium oxides, iron, and other substances in organic solvents which are of practical importance.[8] High-molecular-weight compounds such as, for example, poly(vinyl alcohol) (PVA), poly(ethylene oxide) (PEO), methylcellulose (MC), non-hydrolysed and hydrolysed polyacrylamide (PAA and PAA-H), poly(acrylic acid) (PAAC), poly(methacrylic acid) (PMAAC) and its salts, polyethyleneimine (PEI), salts of carboxymethylcellulose (CMC) and polyvinylpyrrolidinone (PVP) and copolymers based on them, gelatine, and many others have been used recently to stabilise hydrodispersions. Table 1 lists examples of the employment of water-soluble polymers for the stabilisation of many model practically important dispersions.

As yet, it is difficult to formulate unambiguous criteria which would make it possible to decide which particular HMC would be the most effective stabilisers of a particular colloidal system. On the basis of theoretical considerations (see Section III) and the available experimental data, one can assume that, among non-ionic polymers, high-molecular-weight specimens which form fairly thick or fairly dense adsorbed layers on the surface of the particles will exhibit an effective stabilising activity. In the case of charged HMC, polyelectrolytes bearing like charges and having a high charge density on the macrochain would be more effective. The influence of the nature of the polymer on the stabilisation is to a large extent determined by the structure of the adsorbed layers formed on the surface, which depends on interactions of different types in the complex polymer-containing systems polymer–surface, polymer–solvent, polymer–polymer, and surface–solvent.[5,9] The stabilising effect of HMC depends not only on the degree of their polymerisation and the type and number of functional groups in the macromolecule but also on the character of the distribution of the latter along the polymer chain. Copolymers are as a rule more effective regulators of stability than homopolymers.[8]

Table 1. Water-soluble polymers used to stabilise disperse systems.

Polymer	Dispersion	
	of negatively charged particles	of positively charged particles
Non-ionic polymers		
Poly(ethylene oxide)	Au [10—13], AgI [14, 15], Sb_2S_3 [16]	AgI [14], Fe_2O_3 [12]
Poly(vinyl alcohol)	AgI [17, 18], AgBr [19], Sb_2S_3 [20], o/w [21, 22]	—
Poly(vinyl acetate)	AgBr [19]	—
Gelatine	AgI [23, 24], AgBr [19, 25], Au [1], SiO_2 [26]	AgBr [25, 27]
Methylcellulose	AgI [28], AgBr [25], Sb_2S_3 [28], latex [29], carbon black [30]	AgBr [25]
Unhydrolysed polyacrylamide	$Ca_3(PO_4)_2$ [31], SiO_2 [32]; kaolinite [32], MnO_2 [33]	CaF_2 [34]
Anionic polyelectrolytes		
Hydrolysed polyacrylamide	AgBr [35], MnO_2 [33], SiO_2 [36], latexes [37]	—
Sodium polystyrenesulphonate	Au [12], AgBr [35], latexes [39], montmorillonite [38]	Fe_2O_3 [12]
Poly(acrylic acid) and its salts	AgI [40], AgBr [35], SiO_2 [41], ZnS [43, 44], kaolin [45]	AgI [40], Al_2O_3 [41]
Sodium salt of carboxymethylcellulose	AgI [46], Sb_2S_3 [46], montmorillonite [47]	Fe_2O_3 [48]
Cationic polyelectrolytes		
Polyethyleneimine	SiO_2 [37], latexes [49]	—
Polyamines	SiO_2 [37], latexes [37]	—
Vinylpyridine-butyl methacrylate copolymers	AgI [50], latexes [51]	—
Poly[dimethyl aminoethylmethacrylate (methyl acrylate)]	Latexes [39, 52]	—

Note. The numbers in square brackets denote refences (Ed. of Translation).

2. Methods of Investigation

The stabilising effect of polymers can be inferred by various methods: from the change in the coagulation thresholds of the sols under the influence of electrolytes determined by measurements of the optical density or light scattering in the system[11,14–20,24,28,33,43,48] or on the basis of direct ultramicroscopic determinations of the number of particles per unit volume,[13,50,51] from the change in the rate of sedimentation of suspensions and of the volume of the deposits,[31,32,34,44,52,53–56] or from the change in the rheological characteristics of the dispersion.[47] Measurements of the dielectric parameters[57] and of the relative electrical conductivities of the dispersions,[58] measurements of light scattering at low angles (below 1°),[59] and laser Doppler spectroscopy[49,60] are promising but as yet little used methods for the study of

the degree of aggregation of particles in disperse systems. A more detailed analysis of the methods for the study of the stability of disperse systems is described in other communications.[8,53]

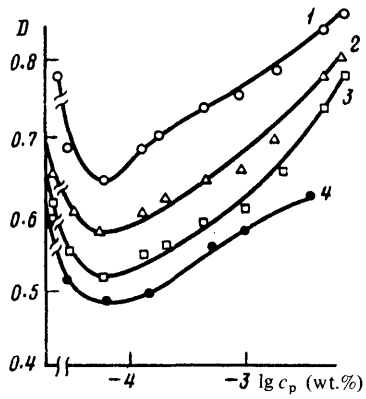

Figure 1. Dependence of the optical density D of a manganite suspension on the concentration c_p of the unhydrolysed (curves *1–3*) and hydrolysed (curve *4*) PAA dispersed in it. Time from onset of precipitation of the dispersion (min): 1) 10; 2) 20; 3) and 4) 30; concentration of the disperse phase $c_{d.p.}$ = 1 g dm^{-3}.[33]

3. The Stabiliser Dose

The processes involving the stabilisation or coagulation of dispersions by high-molecular-weight substances are interrelated. Usually, with increase of the content of the polymer in the system its stability initially falls (flocculation) and the increases (stabilisation). This is illustrated by the variation of the optical density of suspensions of manganite as a function of their content of different polyacrylamide specimens (Fig.1)[33] or by the dependence of the thresholds in the coagulation of silver iodide sol by sodium ions on the concentration of the added poly(ethylene oxide) (Fig.2).[61] Analogous changes in stability have been observed after the addition of poly(vinyl alcohol),[17–20] poly(ethylene oxide),[14–16] and methylcellulose[28] to Au, AgBr, AgI, and Sb_2S_3 sols, of poly(ethylene oxide)[8] and a number of cationic polyelectrolytes[51,52] to a polystyrene latex, of poly(methacrylic acid) to dispersions of a zinc sulphide phosphor,[43,44] etc.

The width of the stabilisation and destabilisation regions depends on a large number of a wide variety of factors: the chemical composition and molecular weight (M) of the reactant, the degree of ionisation of the polyelectrolyte macromolecules, the concentration of the solid phase, the electrolyte content of the system, the duration of contact between the macromolecules and the particles of the disperse phase, and also the method used to estimate the stabilising activity of the HMC. The latter is due to the fact that the vast majority of procedures used to measure the stability are indirect methods sensitive not only to the degree of aggregation of the particles but also to experimental factors, for example, to the wavelength in optical measurements, to the shape of the particles in conductimetric and rheological methods, to the density and type of packing of the particles in the deposits in filtration methods, etc. With the exception of the rapid coagulation thresholds found with the aid of direct ultramicroscopic studies of coagulation kinetics, the threshold in the coagulation of sols by an electrolyte is also a conventional quantity which depends on the duration of the observation and on the composition of the added electrolyte (the thresholds for coagulation by different electrolytes can characterise different degrees of aggregation). In the study of the stabilisation of dispersions by polyelectrolytes one must take into account the influence of the possible chemical interactions of multicharged ions with the functional groups of the stabiliser,[46,62] which alters the coagulation thresholds. It is believed[8] that the "pseudostability" zone observed by Levi and Stepanova[19] before the region of the flocculation of AgBr sols in the presence of PVA and poly(vinyl acetate) is a result of the employment of an unsuitable method for the measurement of the degree of aggregation.

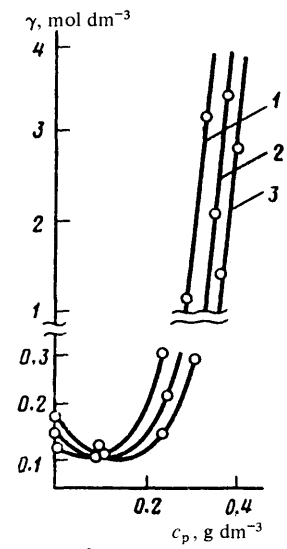

Figure 2. Dependence of the coagulating concentration γ of NaCl for a silver iodide sol on its content of PEO with $M = 1.7 \times 10^4$ and in the presence of different concentrations of KI in the system (mol dm^{-3}): 1) 10^{-2}; 2) 10^{-3}; 3) 10^{-4}; $c_{d.p.}$ = 0.42 g dm^{-3}.[61]

Studies of the influence of the addition of non-ionic polymers (PEO, PVA, and MC) on the stability of hydrophobic gold, silver iodide, antimony sulphide, and polystyrene sols, which was measured in terms of the coagulating concentrations of the counterions, indicate the rules governing the stabilisation of colloidal solutions by uncharged HMC and have much in common:[14–16,18,20,28,61,63] after the attainment of a specific HMC concentration, the dispersion obtains its limiting stability and does not coagulate in the presence of any realistically attainable electrolyte contents in the system: a sharp increase of stability takes place over a narrow range of polymer contents in solution; the thresholds in coagulation by counterions of different charge are gradually levelled out as the concentration of the polymer in the colloidal solution increases; there is a linear relation between the concentration of the solid phase in the sol and the minimum amount of stabiliser necessary for the attainment of a given stability.

Some of these relations are illustrated in Fig.3. The results of adsorption experiments have shown that, in the region of polymer additives corresponding to an abrupt increase of stability, the HMC introduced into the system is wholly absorbed by the disperse phase.[17,28,63-65]

In the studies mentioned above, it has also been shown that small amounts of added non-ionic polymers lower the stability of sols relative to singly charged counterions but not multicharged counterions (see Fig.3); stabilisation takes place only after a fairly broad destabilisation zone. We believe that the appearance of the latter is due to the sensitisation of the system as a result of the interaction of dipolar units of the macromolecule involved in an arrangement of the same type on the opposite walls of the particles. It has been shown theoretically[66] that such interaction leads to the appearance in the system of a negative wedging pressure, i.e. to an additional attraction between the particles. Clearly this mechanism can operate only for low degrees of adsorption of the HMC when the polymer is distributed on the surfaces of the particles in a monomolecular layer and for low values of the "critical gap" between the particles in the coagulation of the sol by singly charged counterions.

When PEO and PVA were added to a sol made up of positively charged AgI particles, an unusual phenomenon was observed—a change in the charge on the particles manifested both by a change in the sign of the electrokinetic potential[67] and by the appearance of a sensitivity of the protected sol to cations,[14] as can be seen from the data in Fig.4. We explained this effect by the occurrence in the oriented layer of adsorbed dipolar segments of the macrmolecules with appreciable "adsorption potential jumps" ψ_a, which are superimposed on the ionic potential of the double layer ψ_i (for $\psi_a > \psi_i$) and can alter the sign of the surface charge of the particle (see also below).

The addition of polyelectrolytes to dispersions sometimes leads to dependences of the stability on the concentration of the reactant more complex than those described above. For example, it has been shown[43,44] that the dependences of the rate of sedimentation and of the optical density of suspensions of the zinc sulphide phosphor on the amount of added poly(methacrylic acid) exhibit a series of minima and maxima (Fig.5); the authors explained this by the simultaneous alteration of the electrokinetic potential of the particles and of the thickness of the adsorption layer with increased degree of adsorption of the stabiliser macromolecules.

4. The Influence of the Molecular Weight

As a rule the stabilising effect of the HMC increases with increase of *M*. In other words, a sharp increase of stability is attained at a lower concentration of the polymer in the system the higher the degree of its polymerisation. This dependence can be clearly traced after the addition of PEO to gold[11-13] and silver iodide[14,15] sols and to polystyrene latex,[8,63] of PVA to silver iodide[17,18] and antimony sulphide[20] sols and an o/w (oil in water) emulsion,[21] of CMC and MC to colloidal AgI and Sb_2S_3 solutions,[28,46] of PAA to kaolinite suspensions,[8] etc.

It has been shown[11,14] that low-molecular-weight specimens of poly(ethylene glycols) ($M < 2 \times 10^3$) do not alter the thresholds in the coagulation of gold and silver iodide sols by an electrolyte. At the same time it has been observed that the variations of the stabilising and flocculating effects of PEO on calcium carbonate suspensions[68] and of the effect of PAA on calcium phosphate dispersions[69] with the molecular weight of the HMC pass through a maximum. After the addition of non-ionic polymers to hydrophobic sols by the "double addition" method (the reactant is added to half the volume of the dispersion and after a time this solution is mixed with a second portion of the initial colloidal solution[12,13,17]), the optimum dose of the flocculant and stabiliser depends little on its molecular weight, which was explained by the weak dependence of the equilibrium thickness of the adsorbed layer of flexible-chain polymers on the degree of their polymerisation. We believe[53] that the different dependences of the flocculating and stabilising effects of polymers on *M* are determined by a series of factors: the degree of approach to the HMC adsorption equilibrium, the dependence of the thickness of the adsorbed polymer layer and of the character of

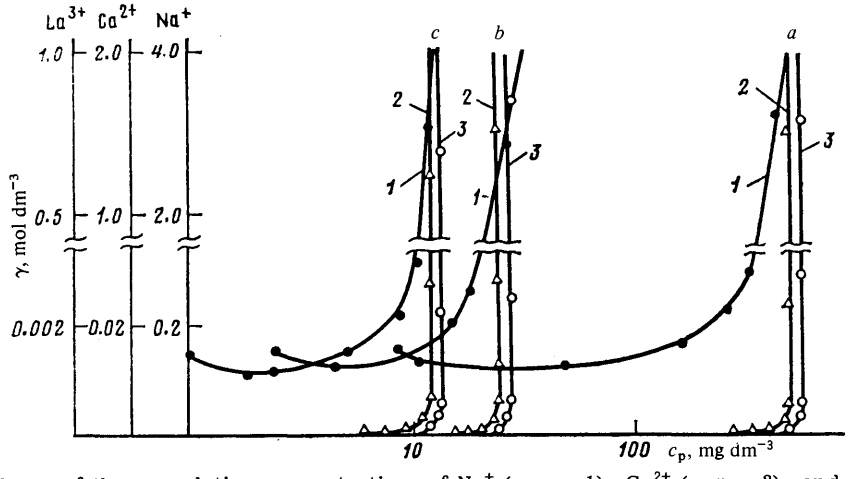

Figure 3. Dependence of the coagulating concentrations of Na^+ (curve *1*), Ca^{2+} (curve *2*), and La^{3+} (curve *3*) ions for an antimony sulphide sol on the content in the system of PEO having different molecular weights: *a*) 2.3×10^5; *b*) 1.3×10^6; *c*) 2.6×10^6.[16]

the distribution in the latter of the macromolecular segments on the degree of polymerisation, and also the mechanism of the stabilisation or flocculation processes.

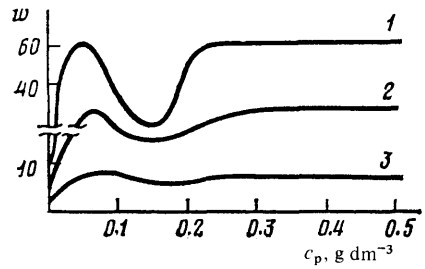

Figure 5. Dependence of the coagulation retardation coefficient w for a suspension of the zinc sulphide phosphor on the content of added poly(methacrylic acid) for different $c_{d.p.}$ (g dm^{-3}): 1) 0.1; 2) 0.25; 3) 2.0.[44]

5. The Influence of the Concentration of the Solid Phase

In most cases it has been observed that the higher the content of the solid phase in the system the higher the HMC concentration at which the same stabilisation effect is attained. For dilute sols, there is a linear relation between the concentration of the disperse phase and the minimum amount of the polymer necessary to attain a specified stability (i.e. approximately equal thresholds in coagulation by an electrolyte).[14-16,18,20,28,62] A similar dependence for the coagulation of AgI and Sb_2S_3 salts containing added poly(ethylene oxide), proportional to the concentration of the solid phase, is illustrated by the data in Table 2..

The above dependence indicates indirectly the complete adsorption of the polymer in the experimental concentration range and shows that, in order to attain a given degree of stabilisation, the same surface coverage of the particles by the high-molecular-weight substance is required. Within the framework of these ideas, the increased stability of AgI sols containing the same amount of added PEO with increase of their age, which we have observed,[61] can be explained by the decrease in the area of the adsorbing surface and by the accompanying increase of the amount of HMC corresponding to a unit surface area.

Table 2. Dependence of the thresholds in the coagulation of AgI and Sb_2S_3 sols by sodium chloride (γ_{NaCl}) on the content of the solid phase in the presence of added poly(ethylene oxide).[16]

$c_{d.p.}$, g dm^{-3}	c_{PEO}, mg dm^{-3} ($M = 1.7 \times 10^4$)	γ_{NaCl}, mmol dm^{-3}	c_{PEO}, mg dm^{-3} ($M = 1.3 \times 10^6$)	γ_{NaCl}, mmol dm^{-3}
		AgI sol		
0.5	3.2	140	1.7	240
1.0	6.4	145	3.4	250
2.0	9.6	140	5.1	250
		Sb_2S_3 sol		
0.2	12.8	60	1.7	350
0.4	25.6	65	3.4	325
0.6	36.4	65	5.1	340

6. The Influence of Particle Size

There are few literatue data concerning the influence of this factor on the conditions in the stabilisation of dispersions by polymers. It has been shown[56] that the form of the influence of the same amounts of added PEO on the rate of sedimentation of silica suspensions (for a constant $c_{d.p.}$) depends on the size of their particles: a gradual stabilisation of the systems has been observed for the coarsest fractions with increase of the HMC concentration, whereas flocculation has been noted for the fine fractions before stabilisation. It has been observed[70] that the flocculating (and stabilising) concentration of polyelectrolytes for fine-particle silica suspensions (particle diameter < 40 mn) is proportional to the specific surface of the particles, i.e. is inversely proportional to their diameter, whereas for large particles it varies

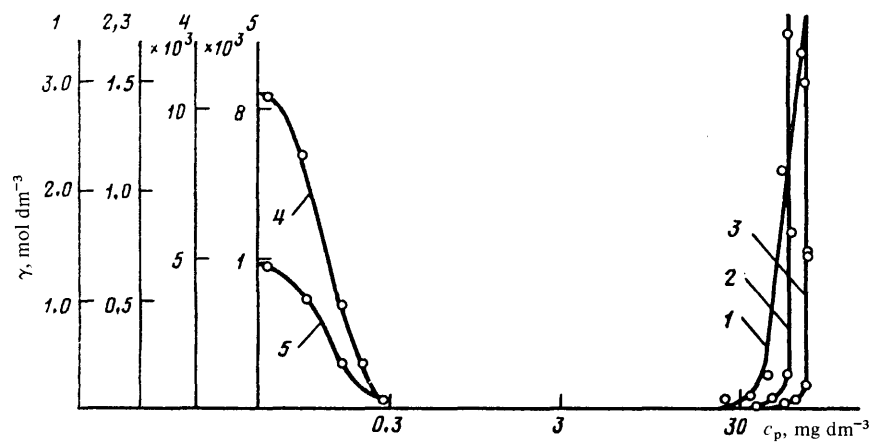

Figure 4. Dependence of the coagulating concentrations of Na^+ (curve 1), Ca^{2+} (curve 2), La^{3+} (curve 3), NO_3^- (curve 4), and SO_4^{2-} (curve 5) ions for a positively charged silver iodide sol on its content of PEO with $M = 2.6 \times 10^6$.[14]

in proportion to the square of the particle diameter. Thus the influence of the particle size on the stabilisation is associated with the variation of the adsorption surface area of the disperse phase. However, here one must also bear in mind the possible influence of the variation of the thickness of the adsorbed polymer layers, for a given specific adsorption, with increasing radius of curvature of the particles.[71]

7. The Influence of Temperature

It has been shown[72,73] that the critical concentrations of the counterions for the Au, AgI, As_2S_3, and Sb_2S_3 sols containing small amounts of added PEO, PEA, CMC, and gelatine diminish significantly with increase of temperature, while in the range 32–40° abrupt changes appear in the $\gamma-T$ curves (Fig.6). For the same sols without polymer additives, anomalous changes in stability with increasing temperature have not been discovered.[74] Therefore the above features of the influence of temperature on the stability can be naturally attributed in the first case to a change in the nature of the surface of the particles as a consequence of the adsorption of hydrophilic substances on the latter. The overall decrease of γ with increase of temperature is caused by the gradual dehydration of the particles and the decrease of the thickness of the lyosphere surrounding them.

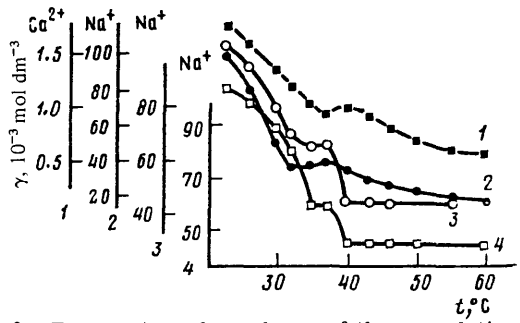

Figure 6. Temperature dependence of the coagulating concentration of the counterions for an antimony sulphide sol when the system contains 9.6 mg dm^{-3} of PEO with $M = 1.7 \times 10^4$ (curve *1*), 20.6 mg dm^{-3} of PEO with $M = 1.1 \times 10^5$ (curve *2*), 7.2 mg dm^{-3} of PEO with $M = 2.6 \times 10^6$ (curve *3*), and 14 mg dm^{-3} of PEO with $M = 1.3 \times 10^6$ (curve *4*).[72]

8. The Influence of the Degree of Surface Coverage

Measurements of the degree of adsorption and of stability carried out on the same object revealed a dependence of the stabilising effect of the HMC on the amount of polymer adsorbed by a unit surface. It has been shown[15,17,18,20,28,56,63] that for each polymer there exists a definite "critical" degree of adsorption Γ_{cr}, the abrupt increase of the stability of the sol being caused by the attainment of this degree of adsorption or its being exceeded (Fig.7); the above degree of absorption usually varies in the range 0.4–1.0 mg m^{-2}. Γ_{cr} depends on the nature and the molecular weight of the polymer, on the charge of the polyelectrolyte macromolecules, and ultimately on the structure of the adsorbed polymer layer on a given surface (see below). For example, it has been shown[15] that an increase of the molecular weight of PEO from 2.3×10^5 to 2.6×10^6 results in a diminution of Γ_{cr} for silver iodide sol particles from 1.0 to 0.5 mg m^{-2}. The increase of the fraction of non-hydrolysed acetate groups in the poly(vinyl alcohol) molecule from 2 to 18% gives rise to a decrease of the degree of surface coverage of the AgI particles, corresponding to a sharp increase of the stability of the sol, from ~0.8 to 0.4 mg m^{-2} (Fig.7).

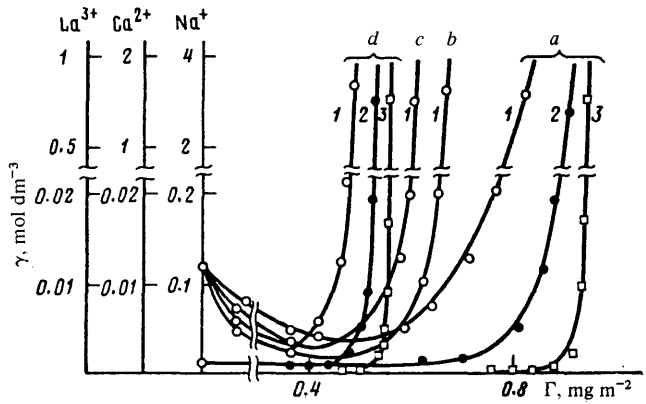

Figure 7. Dependence of the coagulating concentrations of Na^+ (curve *1*), Ca^{2+} (curve *2*), and La^{3+} (curve *3*) ions for a AgI sol on the degree of adsorption of PVA; *a*) $M = 2.2 \times 10^4$, 12% of acetate groups; *b*) $M = 4.1 \times 10^4$, 2% of acetate groups; *c*) $M = 5.9 \times 10^4$, 12% of acetate groups; *d*) $M = 6.5 \times$ *d*) $M = 6.5 \times 10^4$, 18% of acetate groups.[18]

One must note that in a system as complex as a hydrophobic sol–polymer solution–electrolyte solution system an increase of temperature not only disrupts the boundary solvation layers but also alters the solid phase–HMC solution adsorption equilibrium and the conformation of the adsorbed macromolecules and causes a rearrangement of the water structure in the surface hydrate layers. On the basis of general theoretical considerations and the experimental data obtained,[72,73] one can assume that none of the factors enumerated, except the last, can undergo abrupt changes over a narrow temperature range. This is also indicated by numerous data concerning the anomalous changes in many properties of adsorbed water precisely in the temperature range indicated.[75]

However, comparison of the results of the adsorption and coagulation measurements requires caution. This is because measurements of the degree of adsorption of HMC are carried out on colloidal deposits (sol coagulates) and those of stability are performed on "live" dispersions. It may be expected that a smaller surface area is available for the adsorption of macromolecules in the coagulates than in the sols and suspensions owing to the possible aggregation of particles on coagulation. According to Koopal and Lyklema,[76] ~35% of the surface of the particles in silver iodide suspensions and deposits is inaccessible to the adsorption of PVA. As a result of the aggregation of the particles in the presence of the polymer (partial flocculation), the specific adsorption of HMC at a given equilibrium concentration becomes a function of the content of the solid phase in the dispersion, as has been

shown for the adsorption of poly(vinyl alcohol) in suspensions of montmorillonite,[77] silver iodide,[76] and other systems.[78] This is reflected in its turn in the stability of the sol.

It has been observed in a number of studies that the addition of electrolytes decreases the degree of adsorption of non-ionic polymers by the disperse particles[64,65] and increases the degree of adsorption of polyelectrolytes.[79,80] This complicating effect must also be taken into account in devising a relation between the stability and the degree of adsorption of HMC on the basis of the determination of the concentrations of the electrolytes at the coagulation point.

III. THEORETICAL IDEAS CONCERNING THE STABILISATION OF COLLOIDAL SOLUTIONS BY ADSORBED LAYERS OF NON-IONIC POLYMERS

According to modern ideas, the stability of disperse systems is determined by the balance of the attraction and repulsion forces between the particles. In ion-stabilised dispersions, these are van der Waals attraction and repulsion forces in electrical double layers.[1,4] The adsorption of water-soluble polymers by charged particles alters the above forces by changing simultaneously the effective Hamaker constant and the structure of the electrical double layers of the particles. Moreover, the adsorption gives rise to the appearance of additional repulsion forces during the interaction of the adsorbed macromolcules and the appearance (or the enhancement of the role) of the solvation stability factor—the so-called structural component of the wedging pressure.[81] In real disperse systems the above factors are manifested simultaneously, i.e. the stability is determined by the joint action of several of these. Hence it is evident that the theoretical interpretation of the mechanism of the stabilisation of dispersions by high-molecular-weight substances and the search for theoretically well-founded criteria governing the application of a particular HMC for this purpose are complex.

In considering the contribution of the above components to the overall interaction energy of polymer-containing particles (ΔF), it is necessary to bear in mind that the influence of the adsorption of the HMC on ΔF is determined not only by the degree of adsorption of the polymer but also by the structure of the adsorbed layers formed on the surface of the particles—their thickness, the form of the distribution of the density of the segments along the normal to the surface $\rho(x)$, and the number and length of the "tails" and "loops" bound to a unit surface. The determination of these characteristics requires the application of special research techniques[5,6,8,17,63] and some of these, for example, the character of the functions $\rho(x)$, can be estimated only theoretically.[17,82,83]

In this review we are unable to consider the modern ideas about the adsorption of HMC on a solid surface and about the structure of the adsorbed polymer layer; these questions have been discussed in a number of communications.[2,5,6,8,17,82,83] We shall only mention the principal features necessary for the understanding of the problem under consideration.

The structure of the polymer shell on a solid surface depends on many factors—on the amount of the adsorbed substance and its molecular weight, the adsorption energy of an elementary unity, the quality of the solvent, the flexibility of the polymer chain, and, for polyelectrolytes, also the density of the electric charges on the latter. Various models of the adsorbed HMC layers have been discussed and justified: in the form of a thin layer with a large number of contacts between the macromolecule and the surface[84]—this obtains when the affinity of the polymer for the surface is high, i.e. in the presence of chemisorption interactions between the HMC and the adsorbent; in the form of an undeformed polymer coil (when the interaction between the rigid macromolecule and the surface is relatively weak);[28,85] in the form of supermolecular formations transferred to the surface from concentrated HMC solutions;[2,5] in the form of loops and tails of equal or different sizes[6,15,17,18,63–65,76] and (for polyelectrolytes) in the form of ellipsoids of rotation for different degrees of deformation.[79,80]

At the present time the stabilisation of hydrophobic dispersions by the addition of non-ionic flexible-chain water-soluble polymers is most readily susceptible to theoretical interpretation. The adsorption layer is in this case usually described in terms of the Bulas–Hoeve–Hesselink model,[82,86] according to which the polymer shell on the surface consists of a denser first layer (with a relatively large number of contacts between the macromolecule and the surface) and a loose layer made up of unequal tails and loops turned towards the liquid whose distribution with respect to size is described by an exponential relation.[17,82] The density of the segments changes abruptly at the boundary between the first and second layers.[86] Depending on the conditions, linear, power, or most frequently, exponential $\rho(x)$ relations have been postulated for the peripheral part of the adsorbed layer.

We shall consider the influence of the adsorption of polymers on various components of the interaction energy of disperse particles.

1. The van der Waals Attraction

The presence of a surfactant or a polymer around part of the layer can diminish the attraction energy ΔF_A between them both as a result of steric considerations (owing to the increase of the minimum distance to which the particles can approach one another) and because the adsorbed layers alter the effective Hamaker constant A. In the expressions describing the relation between ΔF_A and A (see, for example, Fridrikhsberg[4] and Sonntag and Strenge[88]) the attraction energy is a function not only of the interaction constant of the disperse phase (A_1) and the dispersion medium (A_2) and the constant for the interaction of the disperse phase with the medium (A_{12}) but also of the Hamaker constant of the adsorbed layer (A_3).

The influence of the parameters of the adsorption layers of the polymers on the molecular attraction of the disperse particles has been considered theoretically in a study[89] where the following expression for ΔF_A was obtained in the case of unretarded London forces in terms of the microscopic approximation:

$$\Delta F_A = -\frac{1}{12}\left[(A_2^{1/2} - A_3^{1/2})\frac{a+h}{a-2h} + (A_3^{1/2} - A_1^{1/2})\frac{a}{d} + 4(A_2^{1/4} - A_3^{1/4})(A_3^{1/4} - A_1^{1/4})\frac{a+h}{(d-h)(2+h/a)}\right] \quad (1)$$

where a is the radius of the particles, d the distance between them, and h the thickness of the adsorbed HMC layer.

Vincent[90] derived the corresponding equations for retarded London forces and also examined the case of the interaction between plates and a sphere containing a homogeneous adsorbed layer on the surface. Some of his results are illustrated in Fig.8. Deryagin and Churaev[81] and Ninham and Parsegian[92] obtained an analytical expression for the London–van der Waals forces in the case of three-layer films in air and in water on the basis of the macroscopic Lifshits theory of interactions between condensed bodies.

The complex expressions obtained for ΔF_A can be simplified under certain conditions. For example, for emulsions of the water/oil type stabilised by hydrocarbons, one can assume that $A_2 \cong A_3$, since the molecular interaction forces between hydrocarbon chains and between the latter and the oil are similar.[88] In the general case the adsorption of polymers can both diminish and increase the attraction between the particles. Its influence is determined by the results of the combination of Hamaker constants: when a dense particle ($A_1 > A_2$) is "clad" in a light adsorbed layer ($A_3 < A_2$), the effective Hamaker constant for the particle plus adsorbed layer system decreases. Conversely, a heavy coat with a low density diminishes the attraction. However, it has been shown[89] that the change in A owing to the appearance of adsorbed polymer layers never converts attraction into repulsion.

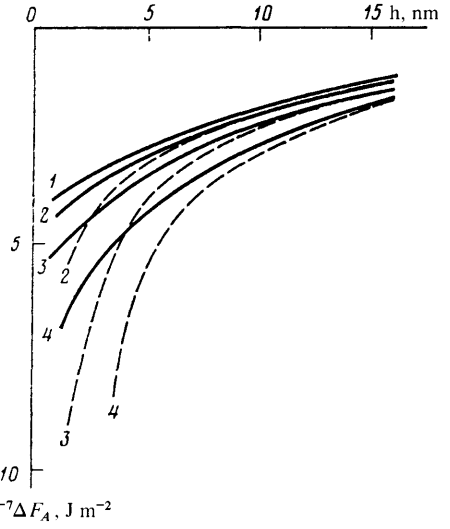

Figure 8. Theoretical variation of the influence of the adsorbed homopolymer on the van der Waals attraction of two plane-parallel plates on the assumption of an exponential (continuous lines) or uniform (dashed lines) distribution of the density of units in the adsorption layer. Average volume fraction of units in the layer: *1*) 0; *2*) 0.03; *3*) 0.1; *4*) 0.2. The Hamaker constant is $20kT$ for the particles, $17.5kT$ for the polymer, and $10kT$ for the solvent; the thickness of the layer is 10 nm.[90]

The influence of the Hamaker constant for the adsorbed layer A_3 on the particle attraction force has been examined[93] and it has been shown that, under the conditions where $A_1 > A_2$, the plot of ΔF_A against A_3 passes through a minimum. In discussing the influence of the adsorption of water-soluble polymers on A, one must bear in mind that the adsorbed layer contains polymer units plus water molecules. According to Fleer and Lyklema[55] and Sonntag and Strenge,[88] when the polymer is strongly hydrated one can assume that $A_2 \cong A_3$, i.e. that the molecular attraction of the particles with the adsorbed layer is the same as the attraction in the pure dispersion medium. In this case the expression for the attraction energy becomes

$$\Delta F_A = -\frac{1}{12}(A_2^{1/2} - A_1^{1/2})^2 \frac{a}{d}. \qquad (2)$$

The character of the distribution of the density of the units in the adsorbed layer influences significantly the $\Delta F_A(A)$ relation, primarily over short interparticle distances.[90,93]

New possibilities for a more exact calculation of the influence of the adsorption of HMC on the molecular attraction of the particles have been provided by Lifshit's macroscopic theory. Without going into the description of this theory here (see, for example, Dzyaloshinskii et al.[94]), we may note that the results of the calculation of ΔF_A by the Lifshits method, particularly for aqueous media, can differ markedly from those based on the London theory,[8,95] because the high polarity of water leads to a greater contribution to A by polarisation interactions at infrared and microwave frequencies than at ultraviolet frequencies (in Hamaker's procedure only the ultraviolet frequencies of the dispersion are used in the calculations of A). Furthermore, allowance for the low-frequency components of the distortion forces in the macroscopic theory leads to a dependence of A on temperature[91,92] and on the presence of salts in the system. All these factors must be considered in discussing the influence of the adsorption of HMC on the molecular attraction of the particles.

2. The Repulsion of Electrical Double Layers

The adsorption of non-ionic polymer macromolecules can alter the parameters of the electrical double layer, which is reflected in its turn in the contribution of the electrical component ΔF_R to the particle interaction energy. These changes reduce mainly to the following.

(a) The accumulation of polymer units in the Stern layer can alter the density of the electrical charges on the surface—either as a result of a change in the dielectric constant and hence of the capacity of the double layer or as a result of the appearance of "adsorption potential jumps" ψ_a in the oriented layer of dipolar segments on the surface. The appearance of ψ_a having the same sign as the ionic potential jump ψ_i, under the conditions of a constant interphase potential jump ($\psi_0 = \psi_i + \psi_a$), inevitably entails a decrease of ψ_i (subject to the condition $\psi_a < \psi_i$) or even alters its sign (when $\psi_a > \psi_i$), which is manifested experimentally as a change in the charge on the particles in the presence of the added non-ionic polymer.[14,63,67]

(b) The adsorbed macromolecules can displace from the Stern layer some of the specifically adsorbed counterions, which increases the ψ_1 potential and hence the stability of the colloidal solution. This explains, for example, the initial increase in the electrokinetic potential of AgI particles in the presence of small amounts of added poly(ethylene oxide)[67] or poly(ethylene glycol).[96]

(c) The formation on the surface of a fairly dense adsorbed polymer layer with a high density of units, in which water loses its solvent power, leads to an increase in the thickness of the Stern layer and to the separation of the components of the double layer, which is again responsible for the growth of the ψ_1 and ζ potentials,[97] i.e. for the stabilisation of the dispersion. These ideas have been evoked to account for the increased stability of hydrophobic sols as a result of the adsorption of diphilic molecules of organic substances[98,99] and can also be used to interpret a wide variety of changes in the stability of disperse systems in the presence of polymeric additives.[8,44]

(d) The formation on the surface of fairly thick hydrodynamically impermeable layers of non-ionic polymers shifts the slip planes into the bulk of the liquid phase, which entails a decrease in the ζ potential and in the contribution of the electrical forces to the repulsion of the polymer-containing particles. These ideas have served as a basis for calculating the effective thickness of the adsorbed layers of non-ionic HMC (for a more detailed description, see Refs.6, 9, and 17).

The addition of oppositely charged polyelectrolytes to a colloidal solution usually leads to a significant decrease in the ζ potential and to a change in the charge of the particles,[48,50-52] which is accompanied by the destabilisation (flocculation) of the system. As a rule, the stability minimum and the isoelectric point of the particles of the dispersion do not coincide.[48,50-53,100] The adsorption of polyelectrolytes bearing charges of the same kind as the particles is in many cases responsible for the increase in the electrokinetic potential and for the stability of the dispersion.[44,46,52,63]

3. Interaction of the Adsorbed Macromolecules

The adsorbed macromolecules are hardly ever located in a planar position on the surface: some of the macrochains in the form of loops and tails are immersed in the surrounding liquid. The interpenetration of two such adsorbed layers gives rise to repulsion forces of two types:[8,101] (1) as a consequence of the decreased number of possible conformations of the polymer chain, which leads to the loss (decrease) of the configurational entropy and hence to an increase in the free energy of the system and (2) owing to a change in the polymer–solvent interaction in the overlap zone and the appearance of a local osmotic pressure under these conditions. In a details study it is possible to differentiate two limiting cases of the "entropic repulsion".[8,101] The first arises when the decrease of the entropy of the system in the interaction of adsorbed molecules entails desorption of the latter. This increases the interfacial free energy, i.e. leads to the repulsion of the particles. This model has been considered theoretically[102,103] in relation to short weakly adsorbable rod-like molecules, which have sufficient time for desorption during the elementary particle collision step. It explains, for example, the stabilisation of dispersions of carbon black in hydrocarbons by alkylbenzenes,[104] the extremum in the dependence of the stabilising effect on the degree of surface coverage by the polymer,[103] etc. For slowly desorbable or altogether non-desorbable high-molecular-weight polymers (i.e. when the simultaneous rupture of a large number of contacts with the surface is unlikely), another mechanism is more suitable, in which it is assumed that, in the course of particle collisions, the polymer–particle adsorption equilibrium does not change and the increased free energy of the system is due to the decrease of its entropy following the redistribution or compression of the adsorbed segments in the overlap zone.

In this constant adsorption model one distinguishes in its turn two limiting cases: the mutual interpenetration of the adsorbed layers without the compression of the adsorbed polymer chains (the "mixing" effect) and compression of the adsorbed layers without their mutual overlapping (the "volume restriction" effect). Naturally both these cases are idealised and there are always difficulties in selecting a model of the interaction in quantitative calculations, because the two contributions mentioned above cannot be separated in real systems. On the basis of general considerations, one can only assume that at a high concentration of units on the surface, in the adsorption of substances with not unduly high molecular weight and when the interacting surfaces have approached one another very closely, the "volume restriction effect" will predominate, while for low degrees of surface coverage, for low degrees of adsorption of low-molecular-weight polymers, and for large interparticle distances, the "mixing" effect is the dominant one.[8,15] Difficulties also arise in the selection of a model of the adsorbed layer in the form of tails or loops. The distribution of the density of units in the loop and in the tail, which determines the interaction between the macromolecules, changes in different ways with increasing distance.[105-107] It has been shown theoretically that in the case of a long-chain homopolymer it is possible to neglect the concentration of the tails compared with that of the loops,[82] but for not an unduly long macromolecule the adsorption in the form of tails is energetically more favourable.

A number of attempts have been made at a quantitative calculation of the repulsion energy of hypothetical particles (plates) with a polymer coating, caused by the "volume restriction" effect (ΔF_{VR}) and the "mixing" effect (ΔF_M). ΔF_{VR} has been calculated[102] for short rigid rodlike molecules on the hypothesis that the increase in the free energy of the system is determined by the decrease of the configurational entropy S as the second surface approaches: $S = k \ln N$ (where N is assumed to be proportional to the area occupied by the free ends of the rods). Mackor's model has been extended[108] to the interaction of a sphere with another sphere, the lateral interaction of the adsorbed chains being considered simultaneously. Using the same concentration, an increase in the entropic repulsion with increasing length of the macromolecular chain, the impossibility of stabilisation of unduly small particles by macromolecules having the specified lengths, etc. have been predicted theoretically.[109] The earlier attempts to calculate ΔF_{VR} are not considered here, since they were based, as shown by Hesselink,[106] on an incorrectly selected distribution of the densities of the adsorbed units as a function of the distance from the surface; furthermore, they have been considered in fair detail in another review.[8]

The "mixing" or osmotic effect was first considered by Fischer.[110] In the derivation of an expression for the calculation of the contribution ΔF_M, arising when two spherical polymer-containing particles approach one another, he suggested that (1) the concentration of the segments in the adsorbed layer is identical throughout, (2) the concentration of the segments in the overlap region is equal to the sum of the concentrations in both interacting adsorbed layers, and (3) that the Flory–Krigbaum theory of dilute solution is applicable to the calculations of ΔF_M. In this theory the free energy of mixing of the polymer units and solvent molecules in a small volume element is expressed as:[111]

$$\delta(\Delta F_M) = kT(\delta n_1 \ln \Phi_1 + \chi \delta n_1 \Phi_2), \qquad (3)$$

where δn_1 is the number of solvent molecules in the volume element δV, Φ_1 and Φ_2 are the volume fractions of the solvent and the polymer respectively, and χ is the Flory–Huggins interaction parameter. The change in the free energy of mixing in the volume V is calculated as the sum of the changes in all the volume elements. Thus an expression has been obtained[110] for calculating the repulsion energy between two particles with an adsorbed layer of a non-ionic polymer:

$$\Delta F_M = \frac{4\pi k T c^2}{3 V_1 \rho^2} (\psi - \chi) \left(h - \frac{d}{2}\right)^2 \left(3a + 2h + \frac{d}{2}\right) \qquad (4)$$

where c is the concentration of the polymer segments per unit volume of the adsorbed layer, ρ the density of the adsorbed

substance, h the thickness of the layer, V_1 the partial molar volume of the solvent, and ψ the entropic parameter of the interaction.

For small overlaps, the hypothesis (2) is entirely reasonable, but for larger overlaps it is not very suitable. It follows from the work of Hesselink[106] that the first assumption also has little justification in this theory. An advantage of Meier's theory[109] is the use in the expression for ΔF_M of the familiar Flory parameter χ in an explicit form, which makes it possible to take into account the contribution of the nature of the solvent to the repulsion. On the other hand, the expression for $\rho(x)$ used by the same investigator is apparently erroneous.[8,106]

The latest advances in this field are associated with the development of statistical methods for the calculation of the number of conformations of adsorbed macromolecules by Hesselink[82,106] and other workers.[112,113] Hesselink[106] quotes an expression for the calculation of the number of conformations of a single loop and a single tail lost following the approach of a second surface, subject to an exponential distribution of the density of units along the normal to the surface. On this basis, Hesselink et al.[114] derived relations suitable for the calculation of the increase in the free energy of the system resulting from the restriction of the volume of the adsorbed polymer chains and their mixing (calculated per unit area of the surface):

$$\Delta F_{VR}=2\nu kTV(\bar{i}, d); \quad (5)$$

$$\Delta F_M=2(2\pi/9)^{3/2}(\alpha^2-1)kT\nu^2\langle r^2\rangle M(\bar{i}, d). \quad (6)$$

In these expressions the terms $V(\bar{i}, d)$ and $M(\bar{i}, d)$ describe the increase in the free energy as a function of the distance d between the surfaces for the average loop; they depend on the mechanism of binding of the macromolecule to the surface and on the average number of units in the loop $\bar{i}$; ν is the number of loops (tails) per unit area, α the swelling coefficient, and $\langle r^2\rangle^{1/2}$ the mean square distance between the ends of the polymer chain.

Relations for the calculation of $V(\bar{i}, d)$ and $M(\bar{i}, d)$ have been published.[114] Various cases of the binding of macromolecules to the surface were then considered, namely adsorption in the form of tails and loops of equal size, in the form of a macromolecule with an exponential distribution of tails and loops with respect to size, or in the form of a homopolymer all the segments of which have equal chances of binding to the surface.

The values of $V(i, d)$ and $M(i, d)$ for a simplified model, frequently used in practice, of the adsorption of a polymer in the form of identical loops and subject to the conditions $d/(il^2)^{1/2} \geq 1$ can be calculated from the following relations with an error up to 2%:[114]

$$V(i, d)=-2(1-12d^2/il^2)\exp(-6d^2/il^2), \quad (7)$$

$$M(i, d)=(3\pi)^{1/2}\{6d^2/il^2-1\}\exp(-3d^2/il^2), \quad (8)$$

where i is the number of units in the loop.

Although the Hesselink–Vrij–Overbeek (HVO) theory yields reasonable values for ΔF_{VR} and ΔF_M and can, as will be shown below, predict many experimental relations, it has a series of weak points. Since it uses the exponential distribution $\rho(x)$, it assumes the existence of the "volume restriction" effect over any interparticle distances, which is naturally incorrect. Nor is the hypothesis that the values of α for macromolecules in the bulk phase and in the adsorbed layer are identical fully justified in the HVO theory. In addition, it suffers from the limitations of the Flory–Krigbaum theory, which constitutes the basis of the calculation of ΔF_M.

The Napper–Evans steric stabilisation theory[115–119] constitutes an expansion and development of the Fischer theory. The main factor determining the stabilisation of HMC dispersions is believed by these authors to be the polymer–solvent interaction, which influences decisively the conformation of the stabiliser in the surface layer of particles. A satisfactory stabilisation is attained when the solvent used is better than a θ-solvent; under these conditions, the polymer–solvent interaction predominates over the polymer–polymer and solvent–solvent interactions. Near the θ-point a transition should be observed from a stable to an unstable state, as follows from Eqn.(4), according to which $\Delta F_M = 0$ under θ-conditions, where $\chi = 0.5$. On passing to solvents inferior to the θ-solvent, the medium–medium and polymer–polymer interactions become energetically more favourable ($\Delta F_M < 0$), which leads to flocculation in the system. Conversely, positive values of ΔF_M ensure the stabilisation of the system.

Numerous experiments whereby Napper and co-workers[115–119] did indeed demonstrate convincingly that, after the attainment of θ-conditions (by altering the temperature or solvent composition), there is an abrupt change in the stability of polymer dispersions stabilised by various block copolymers of type AB. Analysis of stabilisation conditions[118] for ~40 systems has shown that the θ-point is close to the limit of stability of a sterically protected dispersion and that the θ-point and the critical point for flocculation are clearly correlated in both aqueous and non-aqueous media.

Napper introduced the concept of the enthalpic, entropic, and mixed entropic-enthalpic stabilisations. This classification is best examined by dividing the free energy change occurring on mutual interpenetration of the macromolecular chains (the energy of mixing) into the enthalpic (ΔH_M) and entropy (ΔS_M) components:

$$\Delta F_M=\Delta H_M-T\Delta S_M. \quad (9)$$

The generalised Flory–Huggins interaction parameter, characterising the thermodynamics of the polymer–solvent interaction, can be represented in its turn by the sum

$$\chi=\chi_h+\chi_s,$$

where χ_h is the parameter of the enthalpy of mixing (measured calorimetrically) and χ_S is the entropic parameter, which characterises the volume effects of mixing, a change in the structure, dissociation and formation of hydrogen bonds, etc. At infinite dilution, $\Delta H_M \to (-q)$ and $\Delta H_S \to (-\psi)$, where $q = \chi_h$ and $\psi = 1/2 - \chi_S$. On the basis of the above considerations, Napper[120] established the conditions under which a particular type of steric stabilisation predominates (Table 3).

Table 3. Comparison of different types of steric stabilisation (according to Napper).

q	ψ	ΔH_M	ΔS_M	$\Delta H_M/\Delta S_M$	ΔF_M	Type of stabilisation
<0	<0	>0	>0	>1	>0	Enthalpic
>0	>0	<0	<0	<1	>0	Entropic
>0	<0	<0	>0	≷1	>0	Mixed

The majority of solutions of polymers in non-polar media are characterised by positive values of q and ψ and therefore entropic stabilisation is to be expected for them. Negative

values of q and ψ, caused by the rupture of the hydrogen bonds with increased HMC concentration in the system, correspond to many polymers in non-aqueous solutions (for example, a solution of PEO in water). The addition of dioxan to aqueous solutions of surfactants decreases the negative (increases the positive) values of q and ψ, which is accompanied by a transition from the enthalpic to the entropic mechanism of stabilisation.[120]

The type of steric stabilisation can be established from the form of the change in the disperse system with increase of temperature. Napper and co-workers showed[117–119] that colloidal systems, which flocculate on aggregation, undergo enthalpic stabilisation at least below the critical flocculation temperature (c.f.t.), while systems which flocculate on cooling are stabilised entropically at least above the c.f.t. In other words, systems with enthalpic stabilisation tend to lose stability on heating, while entropically stabilised systems flocculate on cooling. According to Napper,[117] the c.f.t. is the minimum temperature causing the flocculation of dispersions stabilised enthalpically or the maximum temperature at which dispersions stabilised entropically flocculate.

A new approach to the problem of the stabilisation of colloids by non-ionic polymers has been developed recently in a study[121] whose authors attribute the appearance of repulsion forces to the presence in the solution of free non-adsorbable HMC. Such a situation can obtain for an inert surface or a surface which repels the polymer and also when all the adsorption centres on the surface have been occupied. The average density of units is assumed to be lower on the surface than in the bulk phase. The appearance of repulsion forces as the surfaces approach one another to distances less than twice the distance between the centres of mass of the macromolecules is attributed to the differences between the free energies of mixing of the polymer with the solvent (calculated by the Flory–Krigbaum procedure) in the initial and final states of the system.

4. Solvation of the Disperse Phase

The adsorption by colloidal particles of water-soluble polymers containing a large number of hydrophilic groups must lead to the hydrophilisation of the surface of the disperse phase and hence to an increased contribution by the solvation stability factors. However, among various aspects of the influence of HMC on the stability of colloidal solutions, this effect has not so far been examined.

Here one should note that the concept of the solvation of the disperse phase as an aggregative stability factor for colloidal systems has been firmly and for a long time incorporated in the literature,[122,123] although neither the structure of the surface solvate layers nor the physical nature of the corresponding repulsion forces have so far been unambiguously established.[124–128] It is believed that the solvation stability factor is determined by the presence on the surface of polymolecular layers of the solvent with an unusual structure (differing from that in the bulk phase) and properties.[124,126–128] The interaction of these layers induces the appearance between them of repulsion forces whose nature has not been finally elucidated. It is most likely that they are caused by a change in the statistical distribution of the water molecules in the overlap zone (by an increase of the degree of their order).[72] The present state of the theory of the liquid state does not permit the calculation of the above forces; they can be estimated only indirectly by subtracting from the experimental force of the interaction of the disperse phases the sums of the theoretically calculated repulsion forces of the double layer and molecular attraction forces.[81] Such estimates have so far been made only for a small number of model systems.[81,129]

The solvation of the disperse phase has been regarded as an important or dominant factor in the stabilisation of not only hydrophilic sols[122,130,131] but also of hydrophobic systems stabilised (hydrophilised) by adsorption layers of low-molecular-weight surfactants.[132,133]

The important role of the structural component of the wedging pressure in the mechanism of the stabilisation of colloidal solutions with a polymer additive is also indicated by data concerning the hydrophilic properties of the stabilised macromolecules as well as the temperature dependence of the stability of polymer-containing dispersions (see Section II). It has been shown[134–136] with the aid of high-resolution NMR and the spin-echo method that three forms of water exist in the PEO–water, PVA–water, and CMC–water systems: the hydration sphere bound firmly to macromolecules and consisting of 2–3 H_2O molecules per unit at the boundary of which there is an abrupt change in many properties of water, the polymolecular hydration layer made up of 16–20 water molecules per unit in which the mobility of water molecules still differs from that in the pure liquid with a gradual transition to the properties of the latter in the bulk phase, and finally water corresponding to the usual liquid in all its properties. Thus, like hydrophilic solid surfaces,[124–128] water-soluble polymers exert a structure-forming effect on several molecular layers of water.

The observed[72,73] abrupt changes in the coagulation thresholds of hydrophobic sols containing water-soluble polymers with increasing temperature can be explained by the influence on the stability by the structural component of the wedging pressure, in particular the structure of water itself in the polymolecular hydrate layers formed on the surface (see Section II). The contribution of this stabilisation factor depends on the degree of adsorption of the HMC by the particles, the degree of hydration of the stabiliser macromolecule, and other factors (see below).

IV. THE MECHANISM OF THE STABILISATION OF REAL DISPERSIONS BY NON-IONIC POLYMERS

It is possible to use two procedures to carry out an experimental test of the theories of the interaction of adsorbed macromolecules and to discover the mechanism of the stabilisation of real HMC dispersions. The first more direct method involves the direct measurement of the repulsion forces of the adsorbed polymer chains and their comparison with the corresponding values calculated theoretically. The second method consists in comparing the experimental characteristics of the stabilisation of dispersions by polymers [the influence on the latter of the degree of adsorption and the molecular weight (MW) of the stabiliser, the ionic strength of the solution, and other factors] with the characteristics predicted on the basis of the analysis of the potential curves for the interaction of polymer-containing particles constructed using the parameters of the electrical double layer and the adsorbed polymer layer, which have been determined by an independent method and which enter into the equations of a particular theory.

1. The Energies of the Interaction of the Particles with the Adsorbed HMC

It follows from the foregoing features described in the previous Section that the overall free energy of the polymer-containing particles is in the general case given by

$$\Delta F = \Delta F_A + \Delta F_R + \Delta F_P + \Delta F_{st} \quad (10)$$

where F_{st} is the contribution of the structural component of the wedging pressure, which cannot be determined quantitatively but which can be neglected, as will be shown below, for high degrees of adsorption of the polymer and $\Delta F_P = \Delta F_{VR} + \Delta F_M$.

Our previous communications[15,16,18,20,22,28,63] present the results of calculation of the component (and their sum) of the interaction energies of silver iodide, antimony sulphide, and styrene particles as well as oil drops in water containing adsorbed PVA, PEO, and MC, using the parameters of the electrical double layer and the adsorbed polymer layer found by independent methods.

The contributions ΔF_{VR} and ΔF_M were calculated from the formulae of the Hesselink–Vrij–Overbeek theory [Eqns.(5) and (6)] for models of the binding of macromolecules to the surface which were most appropriate for a given system: for undeformed statistical coils, i.e. $\langle r^2 \rangle = il^2$ and $\nu = \Gamma N_A/M$, where Γ is the degree of adsorption in g m^{-2} and N_A the Avogadro number (this model is suitable for the adsorption of PVA on the surface of oil in water and of MC on AgI and Sb_2S_3 particles), for loops of equal size, i.e. under conditions where Eqns.(7) and (8) are valid, and, finally, for an adsorbed layer with an exponential distribution of loops with respect to size (the model of adsorbed layers of PVA and PEO on the surface of hydrophobic Sb_2S_3 and AgI particles). For the last two models, the number of loops was found from the relations $\nu = n/\bar{i}$, where n is the number of units in the form of loops bound per unit surface, calculated as the difference between the total degree of adsorption and the degree of adsorption in the first layer. The quantity $\langle r^2 \rangle$ for adsorbed chains was found as $\langle r^2 \rangle = \alpha \bar{i} l^2$, using the quantities $\bar{i}$, l, and α found previously.[6,28,63-65] In conformity with Hesselink's procedure,[82] the concentration of tails compared with that of the loops was neglected for the high-molecular-weight polymers employed.

The attraction energy was found in terms of the microscopic approximation for the model of plane-parallel plates:[88]

$$\Delta F_A = -\frac{A_{12}}{12\pi d^2}. \quad (11)$$

The repulsion energy of the double layer of plates was found from the formula valid when $\kappa d > 1$:[1]

$$\Delta F_R = \frac{\varkappa}{z^2} f(Z); \quad Z = ze\psi_1/kT \quad (12)$$

where z is the charge of the counterion and κ^{-1} the Debye radius.

The Stern potentials ψ_1 for silver iodide and polystyrene particles were determined from the results of dielectric and conductimetric measurements[63] and the surface potential ψ_0, calculated from the charge densities on the surface,[63] was adopted as the effective potential of the Sb_2S_3 particles. The values of the functions $f(Z)$ were taken from the Tables quoted in Kruyt's monograph.[1]

Analysis of the character of the variation of ΔF_{VR} and ΔF_M as a function of the interparticle distance for AgI, Sb_2S_3, or polystyrene containing different amounts of an adsorbed HMC (for example, see Fig.9) leads to the following conclusions.[15,16,18,20,22] Repulsion owing to the overlap and mixing of the adsorbed macrochains is manifested over longer distances than the repulsion induced by the restriction of their volume. This is due to the fact that the former effect arises as soon as the interpenetration of the segments located on the opposite walls begins, while the manifestation of the latter effect (the compression of the flexible polymer chain) requires an adequate approach to the second (restricting) surface.

ΔF_{VR} and ΔF_M increase both with increasing degree of adsorption of the polymer (as a consequence of the lengthening of the adsorbed tails and loops) and as the surfaces approach one another (owing to the involvement in the interaction both of an increasing number of units of the given loop and also of shorter loops). The contribution of osmotic effects is greater in the adsorption of methylcellulose and poly(ethylene oxide) than in the adsorption of poly(vinyl alcohol), because water is a better solvent for the former polymers ($\Delta F_M \propto \alpha^2$). Calculations have also shown that the repulsion of the adsorbed macromolecules increases with increasing molecular weight of the polymer for the same degree of adsorption and the same ionic strength of the solution, despite the fact that the area of the polymer shell is the same under these condition. This is caused by the unequal concentrations of the loops in the adsorbed layer for specimens having different molecular weights. Thus the HVO theory explains the experimentally observed increase of the stabilising effect of polymers with increase of their molecular weight.

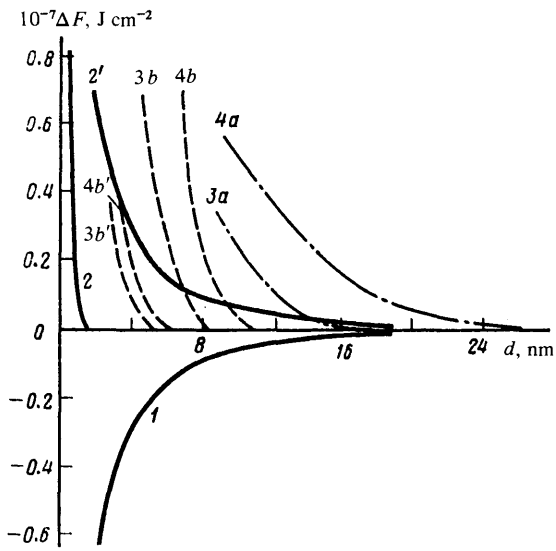

Figure 9. Different components of the interaction energy of Sb_2S_3 particles which have adsorbed 0.4 mg m^{-2} (b') and 1.0 mg m^{-2} (a and b) of PVA with $M = 2.2 \times 10^4$: 1) ΔF_A; 2) ΔF_R in 1 M KCl solution; 2′) ΔF_R in 10^{-3} M KCl solution; 3) ΔF_{VR}; 4) ΔF_M for the model involving adsorption in the form of undeformed coils (a) and with an exponential distribution of loops with respect to size (b).[20]

Comparison of the values of ΔF_R and ΔF_P made it also possible to estimate the contributions of different forces to the repulsion of real particles containing adsorbed HMC. Fig.9 shows that in a concentrated electrolyte solution the stabilisation of the sol is determined in all cases soley by the polymer component, because the double layer is in this case "hidden" within the polymer shell. On the other hand, in the case of dilute electrolyte solutions the contributions ΔF_R and ΔF_P to the repulsion of particles depend on the degree of adsorption of the HMC: with decrease in the salt concentration (with increased thickness of the double layer) and

with decrease of Γ (with a decrease in the length of the loops), the contribution of the repulsion also increases (Fig.10).

Thus the interaction between particles coated by an adsorbed layer of a HMC is not determined solely by the balance of the van der Waals attraction and repulsion forces of the polymer chbins, as has been frequently suggested.[8,107-110,114,121] As a special case, this obtains only in concentrated electrolyte solutions when the thickness of the electrical double layer is much smaller than the effective thickness of the polymer coating; when $\kappa^{-1} > h$, the opposite picture is observed.

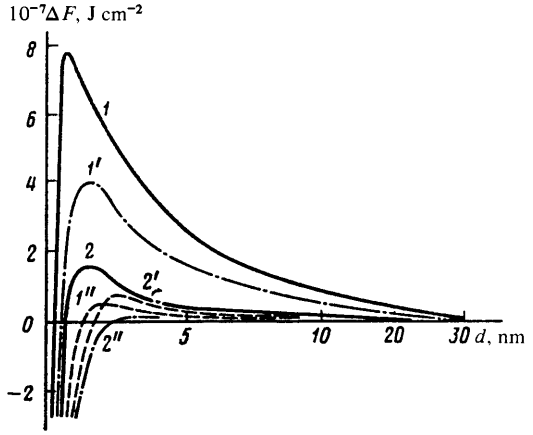

Figure 10. Potential curves for the interaction of Sb_2S_3 particles which have adsorbed 0.4 mg m^{-2} (curves *2*, *2′*, and *2″*) and 1.0 mg m^{-2} (curves *1*, *1′*, and *1″*) of PVA with $M = 2.2 \times 10^4$: 1) and 2) $\Delta F = \Delta F_A + \Delta F_R + \Delta F_{VR} + \Delta F_M$; 1′) and 2′) $\Delta F = \Delta F_A + \Delta F_R + \Delta F_M$; 1″) and 2″) $\Delta F = \Delta F_A + \Delta F_R + \Delta F_{VR}$.[20]

The potential curves for the interaction of the particles with the adsorbed non-ionic polymer have been constructed by adding together ΔF_A, ΔF_R, and ΔF_P.[15,16,18,20,28,63] It has been shown (Fig.10) that, with increase in the degree of adsorption of the HMC, the interaction energy between the particles increases significantly, reaching values amounting to several and several tends of erg cm^{-2}, which explains the formation of highly stable sols in the presence of the PVA, PEO, and MC polymers. Comparison of the results of theoretical calculations by the HVO method with the experimental stabilisation data (see Section II) has shown that the abrupt increase in the stability of the sols occurs for approximately the same degrees of adsorption ($\geqslant$0.5–0.7 mg m^{-2}) as in the case where there is an appreciable barrier preventing the mutual approach of the particles, sufficient for the stabilisation of the colloidal solution. The HVO theory also predicts correctly the dependence of the stabilising effect of polymers on their molecular weight. At the same time this theory in its pure form is unsuitable for the description of the stabilisation of dispersions by the addition of HMC in dilute electrolyte solutions; it does not take into account the change in the interaction of the polymer with the solvent following adsorption and does not allow the separation of the contributions to the interaction caused by the volume restriction and osmotic effects.

Thus, on the basis of the general approach of the physical Deryagin–Landau–Verwey–Overbeek theory of stability (involving the allowance for the balance of the attraction and repulsion forces between the particles) and resorting to the HVO theory, it is possible to interpret many experimental relations obtained in the study of the stabilisation of dispersions by the addition of non-ionic water-soluble polymers and also to determine the contributions of different factors to the stabilisation of these systems.

As already stated, the contribution of the solvation of the particles to the mechanism of the stabilisation of polymer-containing dispersions cannot as yet be estimated quantitatively. However, the set of experimental stabilisation data and their comparison with the results of adsorption measurements permit qualitative estimations. Apparently, in the case of dispersions with a small amount of added polymer, i.e. for small thicknesses of the adsorbed HMC layer, the contribution of the structural component of the wedging pressure is comparable to that of the other stabilisation factors. This is indicated particularly by the results of the study of the temperature dependence of the stability of polymer-containing hydrophobic sols (see Section II). At the same time, in the presence of large amounts of the high-molecular-weight substance in the system, whereupon there is a sharp increase of its stability, the solvation of the disperse phase is a weaker stabilisation factor than the steric repulsion. This is indicated, for example, by the insensitivity to the temperature factor of highly stable polymer-containing sols and the impossibility of achieving their coagulation by adding concentrated salt solutions. This constitutes the radical difference between colloidal solutions protected by low-molecular-weight surfactants, on the one hand, and those protected by water-soluble polymers, on the other. In the former case, the breakdown of the boundary solvate layers (by the addition of dehydrating agents, by an increase of temperature, etc.) leads to the coagulation of the sol[132,133] while in the latter case the same result is not attained.

2. Direct Measurements of the Repulsion Forces Between Adsorbed HMC

The small number of publications on the direct measurement of the repulsion forces between adsorbed macromolecules reflects the difficulty of the experimental study of these systems. Thin aqueous films stabilised by the adsorbed layer of HMC, whose thickness can be measured fairly accurately by optical methods, are convenient objects for study. Furthermore, by altering the hydrostatic pressure, it is possible to determine the dependence of the interaction force between the surfaces (and of its individual components when the remaining components are either constant or small) on the thickness of the gaps separating them. Here it is appropraite to mention that the dependence on interparticle distance of the ionic-electrostatic forces, arising following the overlap of the double layers, was established for the first time precisely in relation to liquid films and the principal conclusions of the DLVO theory were subjected to a quantitative test.[88,137]

The condition for equilibrium in the liquid film is defined thus:[88]

$$P_A + P_R + P_P + P_h = 0 \qquad (13)$$

where P_A is the van der Waals attraction force, P_R the repulsion force of the double layers, P_P the repulsion force of the adsorbed macromolecules, and P_h the hydrostatic force.

The results of the measurement of the equilibrium thicknesses of water films between oil drops stabilised by adsorbed layers of poly(vinyl alcohol) have been published.[21,129,138,139] The thickness of the films h was determined by the light interference method.[88,137] The values of h obtained in relatively concentrated electrolyte solutions (where the thickness of the adsorbed layer is much greater than the effective thickness of the double layer) proved to be much greater than twice the radius of inertia or twice the effective hydrodynamic radius R_h of the spherical macromolecular coils in solution calculated from viscosity measurements. The high thicknesses of the PVA film (up to 80–90 nm) have been explained[138] by the presence in the adsorbed layer of long tails, which produce little change in the hydrodynamic radius of the coil but are strongly manifested as a second surface approaches.

In order to account for the finding that $h > 2R_h$, the author of the present review[129] suggested that the equilibrium thickness of the films is determined not only by the thickness of the adsorbed macromolecules but also by the thickness of the polymolecular hydrate layers bound to them, which can reach several nanometers.[136] It has also been shown[21] that the thickness of the adsorbed PVA layers in emulsion films depends little on the molecular weight of the polymer (for different PVA specimens stabilising emulsions of cyclohexane in water, it amounts to 31–35 nm), but change appreciably when the nature of the non-aqueous phase is altered.

Lyklema and van Vliet[138] measured the hydrostatic force which must be applied to horizontal films stabilised by PVA in order to compensate for the steric repulstion of the adsorbed macromolecules as the surfaces approach one another, subject to the condition that the P_A and P_R contributions are small, i.e. when $P_P = P_h$. The experimental dependences of the equilibrium thickness on the wedging pressure (steric repulsion) (see the dashed curve in Fig.11) show that, with increase in the molecular weight of the polymer, a sharp rise of P_P begins with increasing interparticle distances. The experimental $P_P(d)$ curves for a series of stabiliser specimens are close to the corresponding theoretical relations calculated by the Hesselink–Vrij–Overbeek method on the assumption that (1) the interaction of the adsorbed macromolecules is via long tails and (2) that the distribution of the tails with respect to size is the same in the adsorbed state as in the bulk phase. Hence it was concluded[138] that the long tails extending into the bulk phase play a decisive role in the steric repulsion of adsorbed poly(vinyl alcohol).

Analogous $P_P(d)$ relations have been found also for other PVA specimens stabilising aqueous films in symmetrical emulsions of oil in water.[129,139,140] The sharper increase of P_P observed[129] as the surfaces approach one another compared with the theoretical calculation in terms of the HVO theory was explained by the authors on the grounds that the theory does not take into account the energy consumed in the "expulsion" (at least partial) of water molecules from the gap between the film walls as its thickness decreases, i.e. does not take into account the possible contribution of the structural component of the wedging pressure.

Having expressed the relative change in the film thickness as a function of pressure, Sonntag et al.[139] obtained a linear relation between h/h_0 and P up to $h/h_0 \cong 0.3$. It has also been shown that this relation is relatively insensitive to the molecular weight of the stabiliser (PVA). On further interpenetration of the adsorbed macrmolecules, the repulsion energy rapidly rises. Both in this region and in the linear region, the deformation of the adsorbed layers is reversible and is independent of its duration, i.e. during deformation there is no intertwining of the macromolecules into a coil or their desorption. The linear character of the relation between the pressure and deformation in the initial stage of the interpenetration shows that in the outer regions of the adsorbed layer there are no large segment (unit) concentration gradients, which agrees with Hoeve's model[86] for the distribution of the density of units as a function of distance for macromolecules with a high adsorption energy. In this case there is an appreciable gradient of the density of segments near the interface and a slow decrease in the direction of the bulk solution.

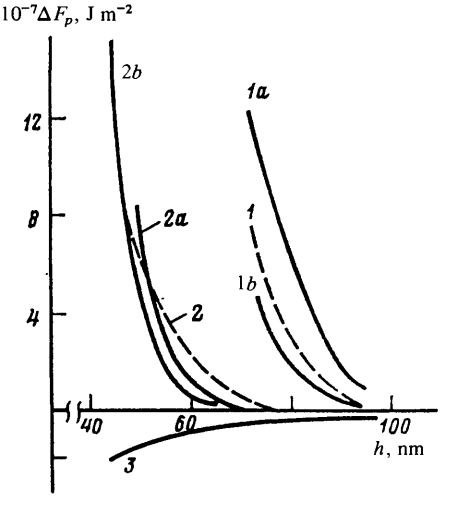

Figure 11. Variation of the steric repulsion of the tails of PVA bound to the oil/water interface and having $M = 1.43 \times 10^5$ (curves *1*) and 4.25×10^4 (curves *2*); dashed curves—experimental data; continuous curves—data calculated by the HVO method for 0.30/1 (curve *1a*), 0.40/2 (curve *1b*), 0.40/1 (curve *2a*), and 0.60/2 (curve *2b*) specimens, where the numerator represents the fraction of units in the form of tails and the denominator the number of tails per polymer molecule; 3) ΔF_A.[138]

It has also been shown[139] that, as the surfaces approach one another, the experimental P_P increases more slowly than would follow from the Hesselink–Vrij–Overbeek theory. This can be attributed to the fact that the real concentration of units in the outer component of the adsorbed HMC layer is higher than is assumed in the theory.

Sonntag et al.[140] measured the steric repulsion of various specimens of poly(vinyl alcohol) adsorbed at the oil/water interface and on quartz filaments as a function of the specific adsorption of the polymer, the molecular weight of the specimen, and the nature and concentration of the added electrolytes. It was concluded that only a small proportion of the tails of the macromolecule (one tail on 30 nm^2 for an average number of units in the tail ($\bar{n} = 500$) or one tail on 20 nm^2 for $\bar{n} = 800$) are responsible for the steric repulsion. With decrease of the number of unhydrolysed acetate groups in the molecule, the thickness of the adsorbed layer also rises, but the steric repulsion diminishes. It has likewise

been observed that, with increase of the KCl concentration in solution from 10^{-3} to 2 M, a sharp rise of P_P begins for increasingly shorter interparticle distances. In conformity with the HVO theory,[114] this shows that the contribution of the osmotic effect to the steric repulsion diminishes with increasing content of the electrolyte in the system. The transition in the lyotropic series from rubidium chloride to lithium chloride leads to the same effect for an unaltered concentration of the added salt.

Cairns et al.[141] developed another approach to the study of the steric repulsion between adsorbed macromolecules; it is based on the idea that this interaction can be characterised as an excess osmotic pressure (Π) in the isotropic disperse system. In other words, the potential energy of the interaction between the particles is expressed in terms of $\Pi = P$. It has been shown that the experimental dependence of Π on the volume fraction Φ_C of poly(methyl methacrylate) particles, stabilised by poly-1,2-stearic acid in dodecane, is close, in the region where $\Phi_C = 0.5-0.6$, to the relation evaluated theoretically from the formula $P = P_A + P_P$, where P_A was calculated by Hamaker's method and P_P was calculated by the statistical Flory–Krigbaum theory [see Eqn.(4)]. For higher values of Φ_C, the experimental Π increase more sharply than the theoretical values, i.e. under these conditions the adsorbed layer is less compressible than predicted by the theory, which assumes a uniform distribution of segments in the adsorbed layer. Hence it is concluded that in fact the concentration of segments in the outer part of the polymer shell is lower than in the inner part.

---o0o---

Thus direct measurements of the repulsion forces between the adsorbed macromolecules make it possible, firstly, to infer the character of the distribution of the polymer segments in the section of the adsorbed HMC layer, secondly, permit the determination of the mechanism of the stabilisation of polymer-containing dispersions under various conditions, and, thirdly, serve as an instrument for the experimental test of the validity of the theories of the interaction of adsorbed polymer chains.

Transition Metal Carbonyls Combined with Hydrogen Donors as Initiators of the Radical Reduction of Trichloromethyl Compounds

R.Kh.Freidlina, R.G.Gasanov, N.A.Kuz'mina, and E.Ts.Chukovskaya

The review is devoted to new redox catalysts of the homolytic reduction of trichloromethyl compounds to dichloromethyl compounds—mononuclear and dinuclear metal carbonyls [$Fe(CO)_5$, $Ni(CO)_4$, $M(CO)_6$ (M = Mo, Cr, W), $Mn_2(CO)_{10}$] in combination with hydrogen donors (secondary alcohols, silicon hydrides, mercaptans, tertiary amines, amides, and tetrahydrofuran).
The results obtained hitherto concerning the development of a new radical-chain method for the reduction of a wide variety of trichloromethyl compounds to the dichloromethyl derivatives are surveyed.
The bibliography includes 78 references.

I. INTRODUCTION

The ability of $Fe(CO)_5$ to initiate the hydrogenolysis of the C–Cl bond in polychloro-derivatives containing the CCl_3 group under the influence of hydrogen donors with the selective formation of the corresponding dichloromethyl derivatives was discovered by the authors of the present review in 1967;[1,2] since then the reaction based on Scheme (1) has been investigated for a wide range of examples using a wide variety of metal carbonyls (MC) and hydrogen donors (HA).

Scheme 1

$$RCCl_3 + HA \xrightarrow{MC} RCCl_2H.$$

The study of the applications of MC as initiators of radical reactions is a comparatively new field in the chemistry of transition metal carbonyls. The first investigations on these lines date back to 1959–61.[3,4] Many examples of radical addition, telomerisation, polymerisation, cyclisation, disproportionation, and others, initiated by metal carbonyls and their complexes with various ligands, are now known.[5] The evidence for the radical mechanism of the reaction based on Scheme (1), obtained particularly by the EPR method using spin trapping agents (see Section IV), is presented below.

The hydrogenolysis of the C–Cl bond in various polychloro-derivatives has significantly extended the range of applications of various MC and their combinations with nucleophiles for the initiation of radical reactions. We call such systems (MC + nucleophile) coordination initiators based on metal carbonyls; they are also referred to as redox catalysts.[6]

The study of the reduction of trichloromethyl compounds led to the discovery of a number of features of the reactions as a function of the nature of the MC and the hydrogen donor and also as a function of the structure of the trichloromethyl compound.

$Fe(CO)_5$, $Mo(CO)_6$, $Cr(CO)_6$, $W(CO)_6$, $Mn_2(CO)_{10}$, and $Re_2(CO)_{10}$ have been used as initiators, while secondary alcohols, silicon hydrides, mercaptans, tertiary amines, acid amides, and tetrahydrofuran have been employed as hydrogen donors. $Ni(CO)_4$, $HMo(CO)_4P(C_6H_5)_3$, and $MoH_2(\eta\text{-}C_5H_5)_2$ have also been used.

It is noteworthy that, apart from its interest for the chemistry of metal carbonyls, the reduction of trichloromethyl compounds to the corresponding dichloromethyl derivatives is an urgent synthetic problem, since in recent years trichloromethyl compounds have become available as a result of the addition of polyhalogenomethanes (CCl_3X; X = H, Cl, Pr) to olefins and telomerisation,[7,8] while compounds with dichloromethyl groups are less readily available. Methods for the selective reduction $RCCl_3 \rightarrow RCHCl_2$ have undergone little development in previous investigations. The reaction which would be of greatest interest for the solution of the problem formulated, namely the catalytic hydrogenation of $RCCl_3$ compounds, proceeds as "reductive dimerisation" and not as hydrogenolysis of the C–Cl bond:[9,10]

$$2RCCl_3 \xrightarrow[Pd/C]{H_2} RCCl_2CCl_2R.$$

Dichloromethyl compounds are of interest not only for chemical and physicochemical studies but also for practical purposes. We may mention the reduction of DDT and related compounds,[11] the reduction of α-trichloromethyl compounds to the corresponding dichloromethyl derivatives.[12] Trichloro- and dichloro-methyl compounds have found extensive applications as insecticides, herbicides, and plasticisers and in the synthesis of medicinal preparations.

This review is devoted to a survey of data on the applications of transition metal carbonyls in the initiation of the hydrogenolysis of the C–Cl bond and the justification of a fundamentally new method for the conversion of trichloromethyl compounds into the dichloromethyl derivatives.

The only other review on this problem[13] is devoted solely to the synthetic aspect of these reactions.

II. SYSTEMS BASED ON METAL CARBONYLS AND VARIOUS HYDROGEN DONORS

1. Alcohols

(a) The Reduction of CCl_4 and $CHCl_3$

Since carbon tetrachloride is reduced more readily than chloroform, in the presence of reductants with moderate activity it is possible to carry out a selective reduction to chloroform. The $Fe(CO)_5$ + iso-C_3H_7OH system is a reductant of this kind (Table 1, experiment 1). $Mo(CO)_6$ and

$Mn_2(CO)_{10}$ combined with iso-C_3H_7OH enter into a non-selective reaction with partial reduction to CH_2Cl_2 (Table 1, experiments 2 and 3).

Chloroform is reduced with greater difficulty than CCl_4 and $RCCl_3$. Thus the $Fe(CO)_5$ + iso-C_3H_7OH system hardly reduces $CHCl_3$ at 120–140 °C (experiments 4 and 5). $Mo(CO)_6$ and $Mn_2(CO)_{10}$ combined with iso-C_3H_7OH reduce $CHCl_3$ to CH_2Cl_2 in 72–73% yields.

Table 1. The reduction of polychloromethanes CCl_3X by isopropyl alcohol in the presence of metal carbonyls (3 h).[12]

No.	MC	X	[CCl_3X] : [iso-C_3H_7OH] : [MC]	T, °C	F*, %	Yield, %	
						$CHCl_3$	CH_2Cl_2
1	$Fe(CO)_5$	Cl	1:8:0.05	120	100	100	0
2	$Mn_2(CO)_{10}$	Cl	1:8:0.05	120	100	90	10
3	$Mo(CO)_6$	Cl	1:8:0.05	140	100	64	36
4	$Fe(CO)_5$	H	1:8:0.05	120	0	—	0
5	$Fe(CO)_5$	H	1:8:0.05	140	10	—	10
6	$Mn_2(CO)_{10}$	H	1:8:0.1	120	72	—	72
7	$Mo(CO)_6$	H	1:8:0.05	140	73	—	73

*F = degree of conversion of the initial polychloroalkane.

The data in Table 1 clearly demonstrate the sequence of the reactivities of MC: $Mo(CO)_6 \geq Mn_2(CO)_{10} \gg Fe(CO)_5$.

Isopropyl alcohol is not an inert medium for the reaction under consideration. Being a hydrogen atom donor, it is oxidised to acetone and in addition it enters into a series of side processes, which lead to the formation of isopropyl chloride, di-isopropyl ether, propene, and water:[14]

$$RCCl_3 + (CH_3)_2CHOH \xrightarrow{MC} RCCl_2H + (CH_3)_2CO + HCl,$$
$$(CH_3)_2CHOH + HCl \rightarrow (CH_3)_2CHCl + H_2O,$$
$$(CH_3)_2CHCl + (CH_3)_2CHOH \rightarrow [(CH_3)_2CH]_2O + H_2O,$$
$$(CH_3)_2CHOH \rightarrow C_3H_6 + H_2O.$$

The formation of propene leads in a number of instances to the appearance of adducts of the type of $RCCl_2CH_2CHClCH_3$.[14]

(b) The Reduction of ααα-Trichloroalkanes

The reduction of ααα-trichloroalkanes by different MC in isopropyl alcohol has been investigated for molecules with a chain length ranging from two to ten carbon atoms. Table 2 presents the results of the reduction of 1,1,1-trichloropentane. The choice of this compound is associated with the fact that it contains no other functional groups and the length of the hydrocarbon chain is such that it cannot lead to lateral displacements of hydrogen in the radical.[15] On the other hand, the chain is not so short that the C–Cl bond energy depends on it, since the reactivity of CCl_4 and CCl_3CH_3 is significantly higher than that of ααα-trichloroalkanes with longer chains. According to the data in Table 2, it is possible to set up the following activity series of MC in the reaction investigated:

$$Mo(CO)_6 > Mn_2(CO)_{10} > Fe(CO)_5 \gg W(CO)_6 > Cr(CO)_6 \gg Re_2(CO)_{10}.$$

Thus the MC used have been divided into two groups—the active initiators $Mo(CO)_6$, $Mn_2(CO)_{10}$, $Fe(CO)_5$, and the relatively ineffective $W(CO)_6$, $Cr(CO)_6$, and $Re_2(CO)_{10}$. The reactions involving the active MC have a chain mechanism and the yield of 1,1-dichloropentane under the chosen conditions ranged from 5.6 to 9.2 moles per mole of the MC (Table 2). The Table also shows that the best [$C_4H_9CCl_3$] : [iso-C_3H_7OH] ratio for $Fe(CO)_5$ or $Mn_2(CO)_{10}$ is 1 : 8 (experiments 3 and 5). In the presence of $Mo(CO)_6$ a high yield is obtained at an even lower dilution (experiment 1).

Table 2. The reduction of 1,1,1-trichloropentane (3 mmol) by isopropyl alcohol in the presence of metal carbonyls (0.3 mmol) (3 h).[16]

No.	MC	[iso-C_3H_7OH]/[$C_4H_9CCl_3$]	T, °C	F, %	Yield %	Q*

*The reduction of $C_4H_9CCl_3$ (see Table 2); for other examples of the reduction of ααα-trichloroalkanes, see also Refs. 17, 19, and 21.
**τ = reaction time in hours.

Table 3 presents examples of the reduction of ααα-trichloroalkanes with different chain lengths. The data in this Table demonstrate the wide-scale applicability of the proposed method to the reduction of a wide variety of ααα-trichloroalkanes and confirm the high activity of $Mo(CO)_6$, $Mn_2(CO)_{10}$, and $Fe(CO)_5$ in combination with isopropyl alcohol. The amount of MC can be varied within fairly wide limits depending on its nature. The smallest amount of MC has been used in the case of $Mo(CO)_6$ (Table 3, experiments 3 and 6).

(c) The Reduction of Polychloroalkanes

αααω-Tetrachloroalkanes can be obtained by the telomerisation of ethylene with CCl_4; ααaγ-tetrachloroalkanes are obtained by the addition of CCl_4 to α-olefins. The reduction of tetrachloroalkanes containing from 3 to 11 carbon atoms in the molecule by active MC in combination with alcohols has

Table 4. The reduction of αααω-tetrachloroalkanes $CCl_3(CH_2CH_2)_nCl(RCCl_3)$ by alcohols with initiation by metal carbonyls.

*CCl_2 = CHCl was also obtained in yields of 14% (experiment 1), 42% (experiment 2), and 18% (experiment 3).

been investigated. The results are compiled in Tables 4 and 5. They show that the presence of the chlorine atom in the chain does not have a significant influence on the yields of the corresponding αα*γ*- and ααω-trichloroalkanes compared with the reduction of the unsubstituted ααα-trichloroalkanes. In all cases high yields of the reduced compounds have been obtained under favourable conditions, where the $[CCl_3C_nH_{2n}Cl] : [ROH] : [MC]$ ratios are close to 1 : 8 : 0.1 and the chain reaction proceeds selectively via one chlorine atom of the CCl_3 group.

The formation of the products of the 1,5- and 1,6-shifts of hydrogen in the long-chain radical as side products has been noted in the reduction of ααα-trichloro- and αααγ-tetrachloroalkanes with long chains (with more than 5 carbon atoms) and also of αααω-tetrachloroalkanes starting with $CCl_3(CH_2CH_2)_2Cl$.[19] In the reduction of *gem*-trichloroalkanes with $Fe(CO)_5$ or $Mo(CO)_6$ in combination with isopropyl alcohol such rearrangement proceeds to equal extents, while in the presence of $Mn_2(CO)_{10}$ under the same conditions the rearrangement does not take place.[20]

It is known that the CCl_3 group αααβ-tetrachloroalkanes exhibits a number of characteristic features in chemical reactions. In particular catalytic reduction leads in this instance mainly to dechlorination to 1,1-dichloroalk-1-enes;[9] the reduction of 1,1,2-tetrachloropentane with triethylsilane in the presence of t-butyl peroxide is also accompaned by the formation of $CCl_2 = CHC_3H_7$.[27]

The formation of the dechlorination product has been explained by the fact that the $\dot{C}Cl_2CCl_2H$ radical can be stabilised not only by the abstraction of hydrogen but also by fragmentation with elimination of the chlorine atom in the β-position relative to the radical centre:

$$CCl_3CCl_2H \rightarrow \dot{C}Cl_2CCl_2H \begin{cases} \xrightarrow{HA} CHCl_2CCl_2H, \\ \xrightarrow{-Cl} CCl_2{=}CClH. \end{cases}$$

The fragmentation of radicals with ejection of the β-chlorine atom is a general property of such radicals and has been described in numerous examples of radicals of this type generated by different procedures in various reactions.[29]

As can be seen from Table 5, a dechlorination product, namely trichloroethylene, was obtained in all cases from αααββ-pentachloroethane together with the reduced product. The ratio of the two reaction pathways depends on the nature of the MC. Thus in the presence of $Mn_2(CO)_{10}$ the yields of the reduced product (*sym*-tetrachloroethane) reach 40%, while those of the dechlorinated product (trichloroethylene) are 15–18%. On the other hand, the use of $Mo(CO)_6$ favours the preferential formation of trichloroethylene.

Thus the presence of chlorine in the α-position relative to the CCl_3 group results in the reduction process, which proceeds with a yield of 20–40% and is complicated by the concomitant dechlorination to 1,1-dichloroalk-1-enes.

(d) The Reduction of Trichloromethylcarbinols

The practical importance of the reduction of DDT and trichloromethylcarbinols stimulated the study of its possibility. The results are compiled in Table 6.

ααα-Trichloromethyldimethylmethanol (chlorobutol) and aryl-ααα-trichloromethylmethanols, listed in Table 6, are polyfunctional compounds and are formally capable of a series of side reactions. For example, the reduction of chlorobutol involves also the formation of 1,1-dichloro-2-methylpropene, whose yields depend on the nature of the MC (experiments 1 and 3). Aryltrichloromethylmethanols are secondary alcohols and, by analogy with the reactions of isopropyl alcohol (or cyclohexanol), one may expect the formation of the corresponding ketones.

Table 6 shows, for chlorobutol, that aliphatic α-trichloromethylcarbinols are successfully reduced by isopropyl alcohol in combination with $Fe(CO)_5$, $Mo(CO)_6$, and $Mn_2(CO)_{10}$, the

yields being significantly higher in the presence of the last two MC than in the presence of the first (experiments 1–3).

Aryl-α-trichloromethylmethanols can also be successfully reduced to aryl-α-dichloromethylmethanols by the MC + iso-C_3H_7OH system (Table 6, experiments 4–8). It has been shown that the nature of the substituent in the aromatic ring and the MC employed exert a significant influence on the direction of the process. The reaction proceeds in accordance with the scheme

$$\underset{(I)}{XC_6H_4CH(OH)CCl_3} + \text{iso-}C_3H_7OH \xrightarrow{MC} \underset{(II)}{XC_6H_4CH(OH)CHCl_2} + \underset{(III)}{XC_6H_4CH(CHCl_2)OCH(CH_3)_2};$$

X = H (a), *o*-Cl (b), *n*-CH_3O (c).

The reduction of arylcarbinols (I, a and b) result mainly in the formation of aryl-α-dichloromethylmethanols (II, a and b) (experiments 4 and 5). In the case of the carbinol (Ic) under the same conditions the carbinol (IIc) is hardly formed and the reaction is accompanied by pronounced charring. In order to prevent this, a fiftyfold excess of isopropyl alcohol was employed and $Mo(CO)_6$ or $Mn_2(CO)_{10}$ were used in addition to $Fe(CO)_5$ (experiments 6–8). The product ratio (IIc):(IIIc) then depends on the nature of the MC: in the presence of $Fe(CO)_5$ mainly the ether (IIc) is obtained, while the presence of $Mn_2(CO)_{10}$ the main product is the carbinol (IIc).

*$(CH_3)_2C = CCl_2$ is also formed in yields of 17% (experiment 1) or 3% (experiment 3); $Cr(CO)_6$, $W(CO)_6$, and $Re_2(CO)_{10}$ give rise to low yields of reaction products.

**p-$CH_3OC_6H_4CH(CHCl_2)OCH(CH_3)_2$ (IIIc) is also formed in yields of 35% (experiment 6), 34% (experiment 7) or 10% (experiment 8).

***135 °C, 6 h.

Thus the reduction of α-trichloromethylcarbinols by the MC + iso-C_3H_7OH system can be undoubtedly used to synthesise α-dichloromethylcarbinols.

DDT was successfully reduced to DDD by secondary alcohols in the presence of MC with a yield of 70–90%.

Among the *gem*-trichloromethyl compounds with aromatic substituents, trichloromethylbenzene occupies a special place. The presence of the phenyl group in the α-position relative to the CCl_3 group is responsible for the specific features of its chemical behaviour. Thus it has been found that the reduction of $C_6H_5CCl_3$ by $Fe(CO)_5$ is the presence of isopropyl or ethyl alcohol does not lead to the formation of $C_6H_5CHCl_2$. The products are $(C_6H_5CCl_2)_2$ or $C_6H_5CCl = CClC_6H_5$.[11] The synthesis of $C_6H_5CHCl_2$ from $C_6H_5CCl_3$ in a nearly quantitative yield has been described. The reaction proceeds without a catalyst in ethanol in the presence of $P[N(C_2H_5)_2]_3$ [30] or $(C_2H_5)_3N$ and $HPO(OC_2H_5)_2$.[31]

In conclusion of the discussion of the use of alcohols in combination with various MC for the reduction of trichloromethyl compounds, one may note that isopropyl alcohol is most suitable for preparative purposes. In certain cases cyclohexanol is more convenient, since it is possible to use it at atmospheric pressure. Benzyl alcohol is also active in these reactions. It has been shown in relation to the reaction with 1,1,1,3-tetrachloropropane that alcohols such as CH_3OH and C_2H_5OH combined with $Fe(CO)_5$ are in principle capable of reducing the trichloromethyl group to the dichloromethyl group, but 1,1,3-trichloropropane is formed only in a low yield. In the presence of $Fe(CO)_5$, $(CH_3)_3COH$ does not reduce 1,1,1,3-tetrachloropropane.[14]

2. Silicon Hydrides

Reactions are known where, in the presence of catalysts ($AlCl_3$, $ZnCl_2$, etc), silicon hydrides reduce a series of organic compounds—acid chlorides, amides, nitriles, lactones, carbonyl compounds, and monochloroalkanes.[33] This review deals with the results of the use of silicon hydrides in combination with metal carbonyls to reduce the CCl_3 group to $CHCl_2$. Examples of such reactions are presented in Tables 7–9.

*For the reduction of 1,1,1-trichloro-octane, see Table 8.

**CH_2Cl_2 is also formed in 19% yield.

***$CCl_2 = CHC_3H_7$ was also obtained in 15% yield.

****1,1,5-Trichloropent-1-ene was also obtained in yields of 5% (experiment 12) and 56% (experiment 13).

*****CH_3SiCl_2H was used as the hydrogen donor.

In the absence of metal carbonyls, silicon hydrides do not reduce the trichloromethyl group.[2] The reduction of trichloromethyl compounds by the $Fe(CO)_5$ + silicon hydride system has been studied in greatest detail. The data in Table 7 demonstrate the high effectiveness of this system in the reduction of the trichloromethyl group to the dichloromethyl group in polychloromethanes, ααα-trichloroalkanes, αααγ-tetrachloroalkanes, and αααω-tetrachloroalkanes. The reaction has a chain mechanism in all cases—the yield of

reduced compounds varies from 5 to 12.5 moles per mole of $Fe(CO)_5$. The high effectiveness of this system is illustrated by the ease of the reduction of chloroform (Table 7, experiment 2) [the $Fe(CO)_5$ + iso-C_3H_7OH system is ineffective in this reaction (Table 1, experiment 4)] and also by the fact that CCl_4 is reduced with the formation of a mixture of chloroform and methylene chloride (Table 7, experiment 1). The reduction of all the polychloroalkanes containing the CCl_3 group investigated (except ααaβ-tetrachloroalkanes) by $Fe(CO)_5$ and $(C_2H_5)_3SiH$ (Table 7, experiments 3, 4, and 6–11) or CH_3SiCl_2H (experiment 14) proceeds selectively with a high yield of the reduced products:

$$RCCl_3 + HSiX_3 \xrightarrow{Fe(CO)_5} RCCl_2H + ClSiX_3.$$

In the majority of the examples investigated, it was sufficient to use 1–1.3 moles of silicon hydride per mole of the initial polychloroalkane and 5 mole % of $Fe(CO)_5$ (relative to $RCCl_3$) in order to obtain high yields of products. The use of $HSi(OC_2H_5)_3$ and $HSiCl_3$ gives rise to low yields of the reduction products (Table 7, experiments 12 and 13).

Table 8. The reduction of n-$C_7H_{15}CCl_3$ (3 mmol) by $(C_2H_5)_3SiH$ (4 mmol) in the presence of metal carbonyls (0.15 mmol).[36]

*GKZh-94, a siloxane having the structure $[-Si(C_2H_5)(H)O-]_n$ (32 g), was employed.
**$CCl_2 = CClCH_3$ was obtained in addition in ~1% yield.

The hydrogenolysis of the C–Cl bond by $Fe(CO)_5$, $Mo(CO)_6$, or $Mn_2(CO)_{10}$ in combination with triethylsilane has been investigated for 1,1-trichlorooctane (Table 8).[20] The data in Table 8 show that the most active metal carbonyl is $Mn_2(CO)_{10}$ in combination with triethylsilane. $Mo(CO)_6$ proved to be less effective owing to the occurrence of a dehydrochlorination side reaction. The reactions discussed have a chain mechanism.

It has been shown that, in the reduction of long-chain *gem*-trichloro-alkanes by the MC + $(C_2H_5)_3SiH$ systems a rearrangement with 1,5- and 1,6-migration of hydrogen, noted previously for the reduction of the same compounds by isopropyl alcohol in combination with metal carbonyls, does not occur.[36]

The reduction of trichloromethyl compounds containing a multiple bond proceeds in a more complex manner. It has been shown for 5,5,5-trichloropent-1-ene that the interaction of unsaturated trichloromethyl compounds with various metal carbonyls in combination with isopropyl alcohol or triethylsilane leads to a reduction product in a very low yield at high conversions of the initial polychloroalkene.[36] The reduction of perchloropropene and 1,1,2,3,3-pentachloropropene was more successful;[36] the results are presented in Table 9.

It is noteworthy that the hydrogenation of perchloropropene over PtO_2 (like the hydrogenation of trichloromethylalkanes) leads to a dimeric product—perchlorohexadiene.[37] An analogous result has been obtained also on treatment with CuCl in ethanol.[38]

The reduction of perchloropropene by the $Fe(CO)_5$ + $HSi(C_2H_5)_3$ system takes place non-selectively with formation of a mixture 1,1,2,3,3-pentachloropropene and 1,1,2,3-tetrachloropropene. An increase of temperature and an increase of the $(C_2H_5)_3SiH/C_3Cl_6$ ratio improve the yield of $C_3Cl_4H_2$. Table 9 shows that the reaction can be carried out both with formation of C_3Cl_5H as the main product (experiment 2) and with the preferential formation of $C_3Cl_4H_2$ (experiments 3 and 4). The stepwise course of the process is confirmed by the fact that 1,1,2,3,3-pentachloropropene is capable of being reduced under the same conditions to 1,1,2,3-tetrachloropropene (experiment 5). The attempts to reduce perchloropropene by $Fe(CO)_5$, $Mo(CO)_6$, $Mn_2(CO)_{10}$, and $Mo(N_2)_2 \cdot [(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2]_2$ in isopropyl alcohol were unsuccessful.[36]

3. Mercaptans

Mercaptans are of interest as hydrogen donors becuase of their ready availability, the possible wide variety of their structures, and, in particular, the ease of homolysis of the S–H bond. The interaction of polychloroalkanes with various mercaptants in the presence of $Fe(CO)_5$, $Fe_2(CO)_6(SC_2H_5)_2$, $Mo(CO)_6$, $W(CO)_6$, $Mn_2(CO)_{10}$, and $Re_2(CO)_{10}$ has been investigated in a wide range of examples, namely CCl_4, ααα-trichloroalkanes, ααaω-tetrachloroalkanes, and ααaβω-pentachloropentane.[39–41] The results of the reduction of 1,1,1,7-tetrachloroheptane by n-butanethiol or toluene-α-thiol in the presence of the metal carbonyls enumerated are presented in Table 10. $Re_2(CO)_{10}$ proved to be ineffective in this series too (experiment 8), while the effectiveness of $W(CO)_6$ is low (experiments 4 and 7). A significant difference was discovered between the $Fe(CO)_5$ + R'SH system and the analogous systems with $Mo(CO)_6$ or $Mn_2(CO)_{10}$. In the first instance the reaction has a distinct chain mechanism and the yield of $RCCl_2H$ in moles per mole of the metal carbonyl reaches 16 (experiment 1), while in the other two systems the yield is close to unity. With increase of the molar ratio $[MC]:[Cl(CH_2)_6CCl_3]$ to 0.5, a satisfactory yield of 1,1,7-trichloroheptane is attained (experiments 9 and 10). The increase of the molar ratio $[R'SH]:[RCCl_3]$ from 3:1 to 9:1 (experiments 2 and 5 and also 3 and 6) does not affect the yield of the reduced product. Carbon tetrachloride is smoothly reduced by $Fe(CO)_5$ in combination with butanethiol.[40] The same system does not

reduce chloroform under the same conditions.[40] In all cases the reduction of $RCCl_3$ proceeds selectively to $RCCl_2H$. It has been shown for a series of examples that the process considered obeys the equation

$$RCCl_3 + 2R'SH \xrightarrow{MC} RCCl_2H + R'SSR' + HCl.$$

The following mercaptans have been tested as hydrogen donors: C_4H_9SH,[39-41] $C_6H_5CH_2SH$,[39,41] t-C_4H_9SH[39,41] and C_6H_5SH.[39] The best results were obtained with butanethiol; the use of other mercaptans, in particular of toluene-α-thiol, results in an increase of the yield of side products (cf experiments 1, 9, and 10 with experiments 12–14). The reduction of other αααω-tetrachloroalkanes (containing 3, 5, and 9 carbon atoms in the molecule) and also of 1,1,1-trichloroheptane[41] leads to results similar to those obtained for 1,1,1,7-tetrachloroheptane.

Table 10. The reduction of 1,1,1,7-tetrachloroheptane by mercaptans in the presence of metal carbonyls (140 °C, 3 h).[39,41]

14	$Mo(CO)_6$	1 : 3 : 0.49	60	17*	0.3

*1,1,7-Trichlorohept-1-ene is also formed in yields of 1–3% (experiments 8–10), 16% (experiment 12), 7% (experiment 13), and 26% (experiment 14).

Table 11. The reduction of $CCl_3CHCl(CH_2)_3Cl$ (IV) and $CCl_3CH_2CH(CH_3)CH_2CH_2Cl$ (V) by n-buthanethiol in the presence of metal carbonyls (140 °C, 4 h).[41]

No.	MC	Compound	[$RCCl_3$] : [n-C_4H_9SH] : [MC]	F, %	Yield of $RCHCl_2$, %
1	$Fe(CO)_5$	(IV)	1 : 2.7 : 0.15	100	51*
2	$Fe(CO)_5$	(IV)	1 : 5.6 : 0.18	100	53*
3	$Mn_2(CO)_{10}$	(IV)	1 : 2.7 : 0.48	66	42*
4	$Fe(CO)_5$	(V)	1 : 2.7 : 0.15	100	68**
5	$Mn_2(CO)_{10}$	(V)	1 : 2.8 : 0.50	77	59

*$Cl(CH_2)_3CH = CCl_2$ (VII) was also obtained in yields of 42% (experiment 1), 30% (experiment 2), and 19% (experiment 3) as well as $Cl(CH_2)_3CCl = CCl_2$ (VIII) in yields of 4–5% (experiments 1 and 2).
**$CH_3CHClCH_2CH(CH_3)CH = CCl_2$ (X) was also obtained in 18% yield.

The reactions of 1,1,1,2,5-pentachloropentane (IV) and 1,1,1,5-tetrachloro-3-methylhexane (V) require special consideration (Table 11). As shown above, αααβ-tetrachloro- and αααββ-pentachloro-alkanes undergo two types of reactions with metal carbonyls—reduction and dechlorination. Table 11 shows that, on interaction with both $Fe(CO)_5$ and $Mn_2(CO)_{10}$ in the presence of butanethiol, compound (IV) also gives rise to the reduction product (VI) and the dechlorination product (VII) in comparable yields. The reaction of compound (V), containing in the α-position a methyl side group, with $Fe(CO)_5$ and C_4H_9SH affords, together with the reduction product (IX), also the dehydrochlorination product (X) in a significant yield. Dehydrochlorination does not occur in the presence of $Mn_2(CO)_{10}$.

It is noteworthy that the iron carbonyl complex containing RS ligands, namely $Fe_2(CO)_6(SC_2H_5)_2$, combined with n-butanethiol constitutes a system which is just as effective as the system comprising $Fe(CO)_5$ and n-butanethiol (Table 10, experiments 1 and 11).

4. Tertiary Amines and Amides

Triethylamine, dimethylaniline (DMA), pyridine, and quinoline have been tested as hydrogen donors in the $Fe(CO)_5$ + tertiary amine systems (Table 12). It has been shown for the reaction with 1,1,1-trichloro-octane (Table 12) that dimethylaniline (experiments 1, 2, 6, and 7) and triethylamine (III) are active as hydrogen donors in the reactions investigated, while pyridine (experiment 4) and quinoline (experiment 5) are not, as was to be expected.

Table 12. The reduction of trichloromethyl compounds $RCCl_3$ by tertiary amines in the presence of $Fe(CO)_5$ (130–140 °C).

5**	$CH_3(CH_2)_6$	quinoline	1 : 10.9 : 0.076	18	7	[1]
6	$CH_3COO(CH_2)_4$	DMA	1 : 2 : 0.046	5	66	[35]
7	$C_2H_5O(CH_2)_4$	DMA	1 : 2 : 0.073	10	61	[35]

*The reaction was continued until the complete conversion of the initial $RCCl_3$ (gas–liquid chromatographic analysis).
**The experiments were performed in chloroform.

An advantage of this system is the possibility of reducing trichloromethyl compounds containing substituents which are not inert in an acid medium. Thus 5-acetoxy-1,1,1-trichloropentane was reduced by $Fe(CO)_5$ + dimethylaniline with formation of 5-acetoxy-1,1-dichloropentane in 66% yield (experiment 6). 1,1,1-Trichloro-5-ethoxypentane is also reduced smoothyl (experiment 7).

The chemical reactions of dimethylaniline in the process investigated have been elucidated[35] in the reduction of 1,1,1-trichloropropane by the $Fe(CO)_5$ + DMA system. It was found that the main DMA reaction product is the diamine $(CH_3)_2NC_6H_4CH_2C_6H_4N(CH_3)_2$ (XI). The dimer $(CH_3)_2$. .$NC_6H_4CH_2N(CH_3)C_6H_5$ (XII), the trimer $(CH_3)_2NC_6H_4CH_2$. .$N(CH_3)C_6H_4CH_2N(CH_3)C_6H_5$, and methylaniline are also formed in low yields. It has been suggested that compound (XII) is formed initially and is then converted into compound

(XI) and methylaniline according to data of Braun and Kruber:[42]

$$(CH_3)_2NC_6H_4CH_2N(CH_3)C_6H_5 + C_6H_5N(CH_3)_2 \xrightarrow{H^+} (XI) + C_6H_5NHCH_3.$$
(XII)

Indeed it has been shown in a special experiment that heating of compound (XII) with DMA in the presence of diemthylaniline hydrochloride at 140 °C (i.e. under the conditions of the reduction experiments) leads to the formation of compound (XI).[35] On the basis of the foregoing, it is possible to describe the reduction of a *gem*-trichloromethyl compound by DMA + $Fe(CO)_5$ in terms of Scheme 2:

Scheme 2

$$RCCl_3 + 3C_6H_5N(CH_3)_2 \rightarrow RCCl_2H + (CH_3)_2NC_6H_4CH_2N(CH_3)C_6H_5 + \underset{(XII)}{} + C_6H_5N(CH_3)_2 \cdot HCl;$$

$$(XII) + C_6H_5N(CH_3)_2 \rightarrow (CH_3)_2NC_6H_4CH_2C_6H_4N(CH_3)_2 + C_6H_5NH(CH_3).$$
(XI)

Thus it has been demonstrated experimentally that the hydrogen donors in the processes investigated are indeed tertiary amines containing alkyl substituents. Scheme 2 shows that an equimolar amount of the hydrochloride of the amine employed is formed together with the dichloromethyl compound. The formation of the solid amine hydrochloride, which is difficult to separate from the reaction products, complicates their isolation and is an obstacle to the wide-scale employment of tertiary amines as components of the reduction system.

The $Fe(CO)_5$ + DMF system is active in the initiation of radical reactions, but DMF is a comparatively ineffective hydrogen donor. The above system can therefore be used conveniently in the study of the addition, telomerisation, and rearrangement of radicals in reactions involving trichloromethyl compounds where the reduction of the latter becomes a side process.[43]

Table 13. The reduction of polychloroalkanes $RCCl_3$ by DMF in the presence of $Fe(CO)_5$ (135–145 °C, 3–4 h).

No.	R	$[RCCl_3]:[DMF]:[Fe(CO)_5]$	*F*, %	Yield, %	Refs.
1	$Cl(CH_2)_2$	1 : 3 : 0.1	76	24	[17]
2	$Cl(CH_2)_4$	1 : 1 : 0.08	11	7*	[25]
3	$n\text{-}C_6H_{13}CHClCH_2$	1 : 1 : 0.15	72	28**	[28]

*$CHCl_2(CH_2)_3CHCl_2$ is also formed in 1.7% yield.
**The products of the 1,5-H, 1,6-H, 1,7-H, and 1,8-H rearrangements are also formed in an overall yield of 33%.

Certain data obtained in the study of the reactions of $RCCl_3$ with $Fe(CO)_5$ + DMF are presented in Table 13, which shows that, even in reactions with a high degree of conversion of the initial polychloroalkanes (experiments 1 and 3) and for the molar ratio $[RCCl_3]:[DMF] = 1:3$ (experiment 1) the yields of the reduced compound are 24–28% and the yields of the product formed as a result of the rearrangement of hydrogen in the long-chain tetrachloroalkanes is comparable to the yield of the reduced products.

5. Tetrahydrofuran Combined with Nickel Carbonyl

Nickel carbonyl occupies a special place among the metal carbonyls as a component of the reduction system.[44,45] Reduction of the $CHal_3$ group by an excess of $Ni(CO)_4$ under mild conditions in tetrahydrofuran (T) has been investigated (Table 14). The reduction of trichloro- and tribromo-diarylethanes proceeds in accordance with the following scheme:

$$Ar_2CHCX_3 \xrightarrow[THF]{Ni(CO)_4} Ar_2CHCHX_2;$$
(XIII, a and b) (XIV, a and b)
X=Br, Ar=C_6H_5 (a), X=Cl, Ar=*p*-ClC_6H_4 (b)

Table 14. The reduction of the CX_3 group by $Ni(CO)_4$ and THF {40 °C, $[RCX_3]:[THF] = 1:247$}.[45]

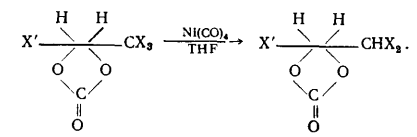
11	(XIX)	—	1:2.2	20	(XX)	60

Together with *gem*-trihalogenodiarylethanes, *gem*-trihalogenodioxilans have been reduced by this method. These labile compounds give rise to *gem*-dihalogenodioxolans under the selected conditions (40 °C), which gives rise to the possibility of a transition to aldehydosugars:



X=Cl: (XV,a–e) (XVI,a–e)
X=Br: (XVII, a and b) (XVIII, a and b)

The $Ni(CO)_4$ + THF system makes it possible to reduce selectively the CBr_3 group to $CHBr_2$ (Table 14, experiment 11). Thus 1,1,1,3-tetrabromo-5-phenylpentane (XIX) is reduced to 1,1,3-tribromo-5-phenylpentane (XX) in 60% yield. The reduction of the CBr_3 group, activated by aryl substituents as in compounds (XIIIa), proceeds under mild conditions with a high yield. When other solvents are used (isopropyl alcohol, dioxan, tetrahydrothiophen, cyclohexane, and benzene), there is virtually no reduction. When the reaction was carried out in DMF, the reduction product was obtained in a low yield and the reaction proceeded in a complex manner. An important difference of the reduction reaction in the presence of $Ni(CO)_4$ involves the use of a (2–5)-fold excess of $Ni(CO)_4$ relative to the trihalogenomethyl compound, which hinders the practical application of this method.

III. SYSTEMS BASED ON OTHER TRANSITION METAL COMPOUNDS

Apart from metal carbonyls, metal chlorides,[46] $H_2PtCl_6 \cdot 6H_2O$,[27,46] and $RuCl_2[(C_6H_5)_3P]$[47] can be used in combination with hydrogen donors (silicon hdyrides and secondary

alcohols). The results obtained are presented in Tables 15 and 16. Table 15 shows that copper, cobalt, and chromium chlorides and $H_2PtCl_6.6H_2O$ combined with triethylsilane reduce CCl_4 to $CHCl_3$ in satisfactory yields but not selectively—1–3% of CH_2Cl_2 is also formed despite the presence of an excess of CCl_4. The reduction of both CCl_4 and ααα-trichloroalkanes by $RuCl_2[(C_6H_5)_3P]_3$ in combination with isopropyl alcohol (Table 16) proceeds selectively and with a quantitative yield.

*The degree of conversion of the initial polychloromethane was 100%.
**The yield was calculated relative to $(C_2H_5)_3SiH$.

Transition metal hydrides are frequently used for the hydrogenolysis of the C–Cl bond in CCl_4, mainly in order to demonstrate the presence of hydride hydrogen in the molecule. For example, $HMn(CO)_4P(C_6H_5)_3$ [48] and $MoH_2(\eta\text{-}C_5H_5)_2$ have been used as reducing agents.[49] It has been shown that $HMn(CO)_4P(C_6H_5)_3$ reduces CCl_4, taken in a large excess, to $CHCl_3$ at room temperature and the latter is reduced quantitatively to CH_2Cl_2 under the same conditions relative to $HMn(CO)_4P(C_6H_5)_3$. Coordination unsaturated $MoH_2(\eta\text{-}C_5H_5)_2$ reduces CCl_4 stepwise: to $CHCl_3$ at −10 °C and to CH_2Cl_2 at 30 °C. However, reactions of this type are of no preparative value, because they require an equimolar amount of the metal hydride.

Thus is has been established that the transition metal carbonyls $Fe(CO)_5$, $M(CO)_6$ (M = Cr, Mo, or W), and $M_2(CO)_{10}$ (M = Mn or Re) generate the $RCCl_3$ radicals on interaction with trichloromethyl compounds. $Fe(CO)_5$, $Mo(CO)_6$, and $Mn_2(CO)_{10}$ combined with hydrogen donors hydrogenate trichloromethyl compounds to dichloromethyl derivatives. It has been found that $Cr(CO)_6$ and $W(CO)_6$ are ineffective in this reaction. A new radical-chain method has been developed for the reduction of a wide variety of trichloromethyl compounds (ααα-tri, αααβ-tetra-, αααγ-tetra, and αααω-tetra-chloroalkanes, DDT and its analogues, and trichloromethyl compounds containing functional groups).

IV. THE MECHANISM OF THE REDUCTION REACTION. STUDY BY THE EPR METHOD

There exists much chemical evidence for the formation of the $R\dot{C}Cl_2$ radicals in accordance with Scheme 3. Thus it has been found that the chain transfer constants in the telomerisation of CCl_4 with propene initiated by $Cr(CO)_6$ [51] and $Mn_2(CO)_{10}$ [52] agree with the values obtained for the same reaction initiated by peroxides.

The formation of the $\dot{C}Cl_3$ radicals on treatment of CCl_4 with $Mo_2(CO)_6(\eta\text{-}C_5H_5)_3$ has been demonstrated.[53] The reaction of CCl_4 with $Fe(CO)_5$ in the absence of hydrogen donors and unsaturated compounds leads to the formation of CCl_3CCl_3,[54] which can be regarded as proof of the intermediate formation of the $\dot{C}Cl_3$ radical. The presence of the $\dot{C}Cl_3$ and $R\dot{C}Cl_2$ radicals obtained by treating trichloromethyl derivatives with metal carbonyls combined with a nucleophile has been frequently revealed by the addition to olefins and other unsaturated compounds.[5,55]

The radical character of the reduction of the CCl_3 group to $CHCl_2$ under consideration has been unambiguously established by EPR in an investigation of a photochemical interaction of polychloroalkanes containing the CCl_3 group with metal carbonyls and also of the reactions of certain hydrogen donors with metal carbonyls.

1. Reactions of Polychlorohydrocarbons with Metal Carbonyls

Certain data obtained using EPR in conjunction with the spin trapping method are presented in Table 17. In all cases it is possible to identify the nitroxy-radicals $RCCl_2N(\dot{O})R'$—the spin-adducts of the $R\dot{C}Cl_2$ radicals and the R'NO spin trapping agent (experiments 1–4, 6, 8–10, and 13–16), whose formation is described by Eqns (1)–(3) of Scheme 3:

Scheme 3

$$M(CO)_n \rightleftharpoons M(CO)_{n-1} + CO, \quad (1)$$

$$M(CO)_{n-1} + RCCl_3 \rightarrow ClM(CO)_{n-1} + R\dot{C}Cl_2, \quad (2)$$

$$R\dot{C}Cl_2 + R'NO \rightarrow RCCl_2N(\dot{O})R', \quad (3)$$

$$ClM(CO)_{n-1} + R'NO \rightarrow ClM(CO)_{n-1}N(\dot{O})R'. \quad (4)$$

In a number of instances it has been possible to identify the spin-adducts of the metal carbonyl metal-centred radicals with the spin trapping agent (experiments 5, 6–8, 11, and 12) [Eqns.(2) and (4) of Scheme 3].

The reliability of the assignment of the signals in the spectrum has been confirmed by the literature data and also by the specific synthesis of the test radicals and of their spin adducts by known methods (Table 17, experiments 3, 4, 10, 14, and 16). Thus the radicals obtained on treatment with mononuclear Fe, Cr, Mo, and W carbonyls as well as the dinuclear Mn and Re carbonyls give rise to nitroxy-radicals on reaction with the spin trapping agents α-phenyl-t-butyl-nitrone (PBN),[56,57,60] nitrosodurene (ND),[57,59,60] and 2-methyl-2-nitrosopropane (MNP)[60] (Table 17) (experiments 1, 2, 6, and 8). The parameters of the spectra of these radicals agreed with the literature data.[58,64] In addition it has been shown that the parameters of the spectra of the nitroxy-radicals obtained by the reaction of metal carbonyls with CCl_4 in the presence of ND agree with the parameters of the radicals obtained by a specific synthesis involving the

photochemical interaction of hexaethyldistannane (experiment 3) or t-butyl peroxide (TBP)[58] (experiment 4) with CCl_4 in the presence of ND.

In conformity with the known rules, $\dot{C}Cl_3$ radicals have been obtained by the reaction of $CHCl_3$ with TBP (experiment 10), while the reaction with $Fe(CO)_5$ yielded $\dot{C}HCl_2$ radicals (experiment 9). Their spin adducts with PBN gave rise to different spectra.[56] The treatment of CCl_4 and $CHCl_3$ with $Fe(CO)_5$ in the presence of MNP gave rise to the same spectrum, namely that of the spin-adducts of the iron-containing radical (XXIII) (experiment 5, 11, and 12).

The radicals $ClCH_2CH_2\dot{C}Cl_2$ have been obtained by two procedures: by treating $ClCH_2CH_2CCl_3$ with $Fe(CO)_5$ and by the reaction of benzoyl peroxide with $ClCH_2CH_2CHCl_2$. The EPR spectroscopic parameters of the spin-adducts of these radicals with PBN are identical (experiments 13 and 14).

The reaction of CCl_3CHCl_2 with $MN_2(CO)_{10}$ in the presence of MNP yielded additional information, namely, in conformity with the general rule,[63-65] the two β-chloroatoms in the nitroxy-radical (XXVIII) are non-equivalent (experiment 15). The same nitroxy-radical has been obtained by a specific synthesis—by abstracting hydrogen from $HCCl_2CCl_2H$ by phenyl radicals in the presence of MNP.[63,65] The hyperfine interaction constants (HIC) for the nitroxy-radicals obtained by the two procedures have the same values (experiments 15 and 16).

Much information has been obtained[59] as a result of the study of the radicals formed on treatment of CCl_4 with $Cr(CO)_6$ in the presence of ND (experiment 6), 2,4,6-tris-(t-butyl)nitrosobenzene (NB) (experiment 7), and MNP (experiment 8). Not only the spin adducts of the $\dot{C}Cl_2$ radicals with the spin trapping agent (experiments 6 and 8) but also the spin-adducts of the chromium-containing radicals (XXIV) and (XXV) (experiments 6 and 7) were identified in these experiments. In addition, the chromium-centred radicals $Cl\dot{C}r(CO)_4(ArNO)$ and $Cl^{53}\dot{C}r(CO)_4(ArNO)$ (experiment 6), $ClCr(CO)_4(ONAr')$ (experiment 7), and the radical (XXVI) (experiment 8) were identified. The richness of the information in this instance arises because in the experiments a sufficient concentration of the chromium-centred radicals had been obtained (experiments 6 and 8), it was possible to identify in the EPR spectrum a quartet of triplets due to ^{53}Cr having $I = 3/2$ (the content of this isotope in natural chromium is 9.5%).[66] It is noteworthy that, when $Cr(CO)_6$ is allowed to react with CCl_4, the resulting $Cl\dot{C}r(CO)_5$ radicals add to ND at the nitrogen atom with formation of the spin-adducts (XXIV) (experiment 6) and to NB via the oxygen atom with formation of the radical (XXV) (experiment 7). The signals in the spectrum were assigned to the radical (XXV) taking into account the data quoted by Terabe and Konaka.[67]

2. Photochemical and Thermal Interactions of Metal Carbonyls with Hydrogen Donors

The interactions of mononuclear and dinuclear metal carbonyls with silicon hydrides, isopropyl alcohol, hexamethylphosphoramide (HMP), and DMF have been investigated. Under certain conditions (ultraviolet irradiation), these hydrogen donors do not constitute an inert medium for metal carbonyls. It has been established by EPR that, under ultraviolet irradiation, the reaction of hydrogen donors with metal carbonyls can proceed via at least two pathways. It has been shown for a series of hydrogen donors that the latter are incorporated in the coordination sphere of the metal carbonyl, substituting a CO group. It has been shown[59] that the reaction of $Cr(CO)_6$ with CCl_4 in the presence of MNP and HMP (Table 18, experiment 1) produces, together with the radicals (XXVII) and (XXVI) identified in the absence of HMP (Table 17, experiment 8), also the radicals (XXIX) obtained as a result of the substitution of the CO groups in the metal carbonyl by HMP and MNP molecules. The spin-adducts of the radicals $OP[N(CH_3)_2]_3\dot{M}n(CO)_4$ were identified in the reaction of $Mn_2(CO)_{10}$ with HMP in the presence of MNP and ND (experiment 12).

On the other hand, certain hydrogen donors react with metal carbonyls to form metal carbonyl hydrides.[78] The radicals $(C_2H_5)_3\dot{S}i$ [67,68] $(CH_3)_2\dot{C}OH$, and $OP[(N(CH_3)_2]_2\cdot\dot{N}(CH_3)CH_2$,[69] identified in the form of the spin-adducts with the NB, ND, and MNP spin trapping agents, have been obtained by abstracting hydrogen from $(C_2H_5)_3SiH$ (Table 18, experiments 2, 5, and 6),[67,68] iso-C_3H_7OH (experiments 7–9), and HMP (experiments 10 and 11). The formation of radicals with an unpaired electron on the silicon atom in the reactions of $M(CO)_n$ with $(C_2H_5)_3SiH$ has been confirmed by the hyperfine structure (HFS) of the EPR spectra resulting from the splitting by the nuclei of the ^{29}Si isotope, having a magnetic moment $I = 1/2$ (the content of the ^{29}Si isotope in the natural element is 4.7%).[66]

The reaction of DMF with metal carbonyls results in the formation of complex mixtures of radicals (experiments 13–17), including a radical obtained by the abstraction of hydrogen from the methyl group of DMF and identified in the form of a spin-adduct with MNP (XLI) (experiment 15). In addition spin-adducts of radicals to which the structures $(CH_3)_2\dot{N}$ and $(CH_3)_2N(O^-)\dot{C}H$ have been attributed, were identified (experiment 13). The intermediate formation of metal carbonyl hydrides, which were not identified, has been postulated for the reactions of the metal carbonyls with iso-C_3H_7OH, HMP, and DMF; these hydrides apparently ultimately transfer hydrogen to a molecule of the spin trapping agent.[69] Indeed, the spin-adducts of MNP with hydrogen (XXXIII) (experiments 7, 9, 10, 14, and 17) and the spin-adducts of ND with hydrogen (XXXIV) (experiments 8, 11, and 16) have been identified. The formation of transition metal hydrides on interaction of transition metal complexes with alcohols have been described in some communications.[70,71]

The effectiveness of the transition metal hydride complexes as reductants has been demonstrated in a number of reports [see, for example, the reduction of CCl_4 by $HMn(CO)_4\cdot P(C_6H_5)_3$ or $MoH_2(\eta\text{-}C_5H_5)_2$ (in Section III of the present review)]. The authors present evidence in support of the radical character of these reactions.

On the basis of the data presented above, it is possible to consider the mechanism of the reduction reaction as a whole, when the reacting system contains a trichloromethyl derivative, a metal carbonyl, and a hydrogen donor.

The radical-chain mechanism of the above reactions has been unambiguously established. This means that the mechanism involves, as usual, three stages: chain initiation, propagation, and termination.

In broad outline, without considering the reactions of the hydrogen donor, which will be done below, the initiation consists in the dissociation of the mononuclear metal carbonyl with formation of the coordination-unsaturated species $M(CO)_{n-1}$(B) and CO [reaction (1), Schemes 3 and 4]. The species (B) abstract chlorine from $RCCl_3$ with formation of the radical $\dot{R}CCl_2$ [stage (2), Schemes 3 and 4]. In the presence of dinuclear Mn and Re carbonyls the initial initiation stage involves dissociation in accordance with the scheme

$$(CO)_5M—M(CO)_5 \rightleftarrows 2\dot{M}(CO)_5. \quad (C)$$

The radicals (C) abstract chlorine from $RCCl_3$.

[3]*g = 1.9983.

[4]*g = 1.9981.

[5]*Concerning the non-equivalence of the two hydrogen atoms in compound (XXVIII) (see Gasanov and Freidlina[65]).

[6]*g = 1.9993.

[7]*g = 1.9982.

Chain termination can proceed, as usual, via many pathways. One of the possible chain termination pathways has been established experimentally. It has been found that some of the $R\dot{C}Cl_2$ radicals recombine during the reduction process with formation of RCl_2CCl_2R, which is dechlorinated to RCCl = CClR whose formation as a side product has been demonstrated in many instances [stage (5) of Scheme 4]. The most complex component of the scheme is the chain propagation stages in which the principal reaction products are generated. These stages apparently depend on the nature of all the components of the reaction and its conditions. At least three types of chain propagation may be noted:

Scheme 4

$$M(CO)_n \rightleftarrows M(CO)_{n-1} + CO, \quad (1)$$

$$M(CO)_{n-1} + RCCl_3 \rightarrow ClM(CO)_{n-1} + R\dot{C}Cl_2, \quad (2)$$

(1), (2): initiation

$$R\dot{C}Cl_2 + HA \rightarrow RCCl_2H + A^{\cdot}, \quad (3)$$

$$A^{\cdot} + ClM(CO)_{n-1} \rightarrow ACl + M(CO)_{n-1}, \quad (4)$$

$$HA + M(CO)_{n-1} \rightarrow HM(CO)_{n-1} + A^{\cdot}, \quad (3a)$$

$$RCCl_3 + A^{\cdot} \rightarrow R\dot{C}Cl_2 + ACl, \quad (3b)$$

$$R\dot{C}Cl_2 + HM(CO)_{n-1} \rightarrow RCCl_2H + M(CO)_{n-1}, \quad (3c)$$

$$ClM(CO)_{n-1} + HA \rightarrow A^{\cdot} + HCl + M(CO)_{n-1}, \quad (4a)$$

(3), (4), (3a), (3b), (3c), (4a): chain propagation (three variants)

$$2R\dot{C}Cl_2 \rightarrow RCl_2CCl_2R \rightarrow RCCl{=}CClR \quad (5)$$

(5): chain termination.

Firstly, the $R\dot{C}Cl_2$ radicals can abstract hydrogen directly from the hydrogen donor [stage (3)]; the reaction chain is propagated by the $M(CO)_{n-1}$ species [stage (4)]. Secondly, the $R\dot{C}Cl_2$ radicals can abstract hydrogen from the metal carbonyl hydride and not from the hydrogen donor [stage (3c)]; the chain is again propagated by the same $M(CO)_{n-1}$ species. Stage (4a) differs from stages (3), (4), and (3a)–(3c) by the fact that $ClM(CO)_{n-1}$ reacts with the hydrogen donor to form the chain-propagating $M(CO)_{n-1}$ species.

Chemical investigations have established that a hydrogen atom is split off from the hydrogen donor during the reaction with formation of the hydrogen donor oxidation products: acetone, chlorotriethylsilane, the disulphide RSSR, and di- and tri-amides from isopropyl alcohol, silicon hydrides, mercaptans, and dimethylaniline respectively. It has been demonstrated unambiguously by EPR that this splitting off process has a radical mechanism, since the $(CH_3)_2\dot{C}OH$,[69] $(C_2H_5)_3\dot{S}i$,[67,68] $OP[N(CH_3)_2]N(CH_3)\dot{C}H_2$,[69] and $HC(O)N.(CH_3)\dot{C}H_2$ [69] radicals, derived from isopropyl alcohol, triethylsilane, HMP, and DMF respectively, have been identified.

Taking into account the entire information contained in the EPR spectra obtained, the reaction schemes incorporating stages involving reactions of the hydrogen donors are considered below. Schemes 5 and 6, proposed by Gasanov,[69] are presented below in relation to the reactions of $Mn_2(CO)_{10}$ with HMP and the reactions of metal carbonyls with DMF:

Scheme 5

$$Mn_2(CO)_{10} \rightleftarrows 2\dot{M}n(CO)_5,$$

$$\dot{M}n(CO)_5 + OP[N(CH_3)_2]_3 \rightarrow HMn(CO)_5 + OP[N(CH_3)_2]_2N(CH_3)\dot{C}H_2, \quad (XLIV)$$

$$(XLIV) + RNO \rightarrow OP[N(CH_3)_2]_2N(CH_3)CH_2N(\dot{O})R, \quad (XXXV), (XXXVI)$$

$$HMn(CO)_5 \rightarrow HC(O)Mn(CO)_4,$$

$$HC(O)Mn(CO)_4 + OP[N(CH_3)_2]_3 \rightarrow HC(O)Mn(CO)_4\{OP[N(CH_3)_2]_3\},$$

$$HC(O)Mn(CO)_4\{OP[N(CH_3)_2]_3\} \rightarrow H\dot{C}O + OP[N(CH_3)_2]_3\dot{M}n(CO)_4,$$

$$H\dot{C}O + RNO \rightarrow HN(\dot{O})R, \quad (XXXIII), (XXXIV)$$

$$OP[N(CH_3)_2]_3\dot{M}n(CO)_4 + RNO \rightarrow OP[N(CH_3)_2]_3Mn(CO)_4N(\dot{O})R; \quad (XXXVII), (XXXVIII)$$

R=C(CH$_3$)$_3$; 2, 3, 5, 6-(CH$_3$)$_4$C$_6$H.

The radicals (XLIV) have been obtained by an independent procedure involving the treatment of HMP with TBP and have been identified by EPR using the same trapping agents[78] as in Scheme 3. The radicals (XXXIII)–(XXXVIII) have been identified by EPR.

Scheme 6

$$M(CO)_n + HC(O)N(CH_3)_2 \rightarrow [M(CO)_n]^{\ddagger} + H\dot{C}(O^-)N(CH_3)_2,$$

$$(XLV) \rightarrow H\dot{C}O + \bar{N}(CH_3)_2, \quad (XLV)$$

$$\bar{N}(CH_3)_2 + [M(CO)_n]^{\ddagger} \rightarrow \dot{N}(CH_3)_2 + M(CO)_n, \quad (XLVI)$$

$$H\dot{C}O + HC(O)N(CH_3)_2 \rightarrow H_2 + HC(O)N(CH_3)\dot{C}H_2 + CO, \quad (XLVII)$$

$$(XLVI) + HC(O)N(CH_3)_2 \rightarrow HN(CH_3)_2 + (XLVII).$$

In addition, the reaction of DMF with $Mn_2(CO)_{10}$ involves the formation of adducts by $Mn(CO)_5$ via the carbonyl group, namely $(CO)_5MnCH(\dot{O})NMe_2$ (XLVIII) and $(CO)_5MnO\dot{C}HN.(CH_3)_2$ (XVIX).

The radicals (XLV)–(XLIX) have been detected by EPR using MNP and MD as the spin trapping agents (Table 18, experiments 13–17).

It is noteworthy that the hypothesis that the formyl radicals $H\dot{C}O$, unidentified by Gasanov,[69] are formed in Schemes 5 and 6 has analogies in the literature. Thus it has been assumed[71,72] that the exchange of a carbonyl group in $HMn(CO)_5$ for ^{13}CO proceeds via the 1,2-migration of the CO group with its subsequent ejection from the rearranged molecule:

$$HMn(CO)_5 \xrightarrow{1,2\text{-}CO} HC(O)Mn(CO)_4 \xrightarrow{+{}^{13}CO} HC(O)Mn(CO)_4({}^{13}CO) \xrightarrow{-CO} HMn(CO)_4({}^{13}CO).$$

This is analogous to the formation of $HC(O)Mn(CO)_4$ in one of the stages of Scheme 3.

It has been postulated[73] that vinyl polymerisation initiated by $HMn(CO)_5$ can also involve the formation of $H\dot{C}O$ radicals as a result of the 1,2-migration of the CO group with subsequent elimination of the formyl radical.

The data obtained show that the interaction of metal carbonyls with hydrogen donors has a radical character. Its mechanism is extremely complex and depends both on the nature of the metal carbonyl and on the structure of the hydrogen donor. It is natural to suppose that, apart from the reactions indicated in Schemes 5 and 6, the radicals formed as intermediates in the trichloromethyl derivative + metal carbonyl + hydrogen donor system can also enter into other reactions. It has been shown that metal carbonyls in the systems investigated interact not only with the trichloromethyl derivatives but also with the hydrogen donors and thus participate both in the chain initiation stage and in the chain propagation stages. Whereas all the Fe, Cr, Mo, and W monocarbonyls and the dinuclear Mn and Re carbonyls investigated are capable of abstracting Cl from the CCl_3 group, i.e. of participating in the initiation stage, the successful reduction of CCl_3 to the $CHCl_2$ group can be achieved only with the aid of $Fe(CO)_5$, $Mo(CO)_6$, and $Mn_2(CO)_{10}$. Evidently this can be accounted for by the difficulties in other stages of the process. In particular there is a significant difference between the carbonylation capacities of the Mn and Re compounds; carbonylation by the Mn compounds proceeds much more readily[74–77] [cf Stage (4) in Scheme 3].

---o0o---

Thus a fundamentally new radical-chain method for the reduction of trichloromethyl compounds to dichloromethyl derivatives by iron, molybdenum and manganese carbonyls

combined with hydrogen donors has been examined in the present review. The stages involved in a series of radical reactions in the $RCCl_3$ + MC + HA systems have been confirmed experimentally by EPR in conjunction with a spin trapping technique and also by chemical studies. It has been shown that iron, molybdenum, and manganese carbonyls participate not only in the initiation stage (with formation of $R\dot{C}Cl_2$) but also in the subsequent stages involving the formation of dichloromethyl compounds on interaction with trichloromethyl compounds in the presence of hydrogen donors. It has been found that the metal carbonyls interact not only with the trichloromethyl compounds but also with the hydrogen donors (alcohols, silicon hydrides, and DMF) via a radical mechanism.

The process schemes examined are important not only for the understanding and regulation of the reactions involving the reduction of CCl_3 to $CHCl_2$ but also for more complex systems. In particular, chain radical addition and telomerisation reactions in trichloromethyl compound + metal carbonyl + nucleophilic coinitiator + unsaturated compound systems must include a series of stages similar to those characterised in the present review.

Metal-containing Complexes of Lactams, Imidazoles, and Benzimidazoles and Their Biological Activity

S.S.Kukalenko, B.A.Bovykin, S.I.Shestakova, and A.M.Omel'chenko

The results of the latest investigations of the problem of the synthesis of metal-containing complexes of lactams, imidazoles, and benzimidazoles, their structure, and their stability in solutions are surveyed. Some data on their biological activity (pesticide and pharmacological) and the mechanism of their physiological action are presented.
The bibliography includes 190 references.

III. Metal complexes of imidazoles and benzimidazoles 680
IV. Biological activity of complexes of lactams, imidazoles, and benzimidazoles 684

I. INTRODUCTION

One of the aspects of the use of coordination compounds of transition metals is their application as biologically active substances. The involvement of metal ions and their complexes in biological processes has been described in a number of monographs.[1-4] Recently the attention of investigators has been attracted increasingly by biocoordination compounds which can be used as biologically active preparations in medicine and agriculture.[5-11] The employment of complexes of microelements with biologically active substances such as vitamins, hormones, nucleic acids, etc. is of interest in medical practice. Many medicinal drugs behave as ligands which interact specifically with the ions of a particular metal or group of metals. A series of preparations with anticancer, antibacterial, and antiviral activities have been obtained in recent years on the basis of metal complexes; some of these are used in clinical and experimental medicine.

In view of their toxicity and high phytocidal activity inorganic salts of microelements have not found extensive application in agriculture. However, complexes containing microelements and organic compounds are as a rule more active biologically and less toxic. In the assortment of chemical plant protecting agents available throughout the world, metal-containing compounds occupy an important place.[12] Thus, one of the groups of fungicides consists of various copper compounds which are widely employed in the fight against plant diseases; in some of these diseases, the copper compounds cannot be replaced by other preparations.

The complexes proposed for use in agriculture are as a rule more effective even at lower concentrations than metal ions and organic molecules which enter into their composition. They provide the microelements lacking by the plants, are not phytotoxic, have a broad spectrum of activity, are resistant to the action of light and heat, and, what is most important, are not toxic to warm blooded animals or their toxicity is low. The complexes make it possible to combine in one molecule several biometals or several different molecules with biological activity and acting synergistically, which results in an appreciable enhancement of the overall effect. The complexes act more slowly than salts, but their activity is more prolonged and involves no risk for agricultural crops.

Preparations based on complexes greatly improve the pesticidal qualities of polymeric materials and compositions based on them. The use of complexes and salts mixed with other pesticides to prepare biocidal paints for the coating of the bottoms of ships and other underwater constructions is effective.[13]

The rapid development of biocoordination chemistry is directly related also to the study of the role of metal complexes in processes important in living organisms. One of such problems involves the study of the mechanism of the action of physiologically active substances on biological membranes, enzymes, etc. Here membrane-active compounds, promoting the selective transfer of metal ions through biological and artificial membranes, which is basically related to the complex formation process, are of considerable importance.

Among the various classes of biologically active coordination compounds, complexes with nitrogen-containing heterocycles as ligands have attracted attention.[14] The metal-containing complexes of lactams and azoles, which play an important role in biological processes and have also found applications in pharmocological preparations and as effective plant protecting agents, are promising in this sense.

The present review is devoted to the latest advances in the field of complexes of transition metal salts with certain nitrogen-containing heterocyles—lactams, imidazoles, and benzimidazoles. It describes the current data on the synthesis, structure, and biological activity of these complexes.

II. COMPLEXES OF LACTAMS

The complexes of lactams with heavy metal salts (I) were first obtained in the 1950's.[15]

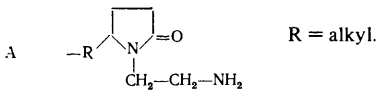
$$MX_m \cdot nA \quad \text{(I)}$$

M = Fe, Co, Ni, Cu;
X = halogen;
$m = 2$;
$n = 3.8$;
A = amide, lactam.

Compounds (I) are readily formed from the initial reactants on heating to 40–160 °C in the presence of a solvent [tetrahydrofuran (THF), methanol, and ethanol] or in the presence of an excess of the initial amide.[15-17] As a rule, between 3 and 10 moles of the amide are used per mole of the metal salt.

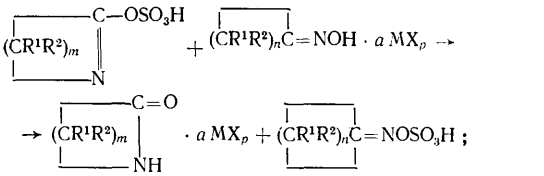
Madan and co-workers[18-20] proposed a method of synthesis of copper-containing complexes of lactams by the interaction of the latter with copper(I) chloride subjected to preliminary dehydration by boiling in 2,2-dimethoxypropane for 2 h. A series of metal complexes of butyrolactam and ε-caprolactam were synthesised in this way. The complexes of 8-caprolactam with cobalt salts have been described.[21] They are obtained in solution in orthoformic ester (tri-isopropoxymethane).

The complexes of 5-alkyl-1-(β-aminoethyl)-2-pyrrolidinones with platinum and palladium salts[22] having the formula (I) with M = Pt or Pd, X = Cl or Br, and $m = n = 2$ have also been synthesised:



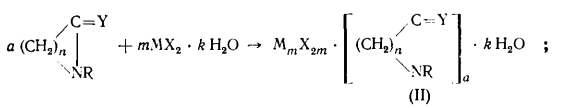
R = alkyl.

Another method of synthesis of metal complexes of lactams[23,24] consists in the reaction between lactam *O*-sulphates and complexes of alicyclic ketoximes with metal halides (Lewis acids):



$m, n = 3—11$, R^1, $R^2 = H$, alkyl, alkenyl;
M = Cu (II), Zn, Al, Sn (II), Sb (III), B, Zr (IV), Fe (III), Ni (II).

The complexes of unsubstituted and *N*-substituted lactams and thiolactams with heavy metal salts having the general formula (II) have been described.[35-38] They are obtained by the reaction of the corresponding lactams with heavy metal salts in absolute ethanol at room temperature or on boiling:



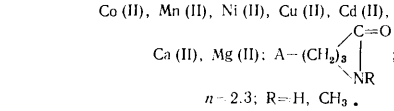
(II)

$a = 1—4$; $n = 3,5$; $m = 1,2$; $k = 0—2$;
M = Cu (II), Zn, Mn (II), Hg (II), Ni (II), Y = O, S;
X = Cl, Br, NO_3; R = H, Ph, CH_3, —CHCCl₃ (OH).

Complexes of a similar type, where the complex-formation reaction proceeds without the elimination of a mobile hydrogen atom, are usually crystalline compounds which contain water of crystallisation derived from the solvent or from the surrounding medium. They can be converted into anhydrous complexes by recrystallisation from an anhydrous solvent such as THF. The complexes (I) are as a rule soluble in water and many organic solvents. The solutions produced are usually stable, but sometimes the complex decomposes on heating into the initial amides and heavy metal salts. Heating of the complexes above the melting point can also lead to decomposition into the initial components. Compounds (I) can be employed as catalysts of the carbonylation reaction and in many instances their catalytic activity is higher than that of the simple salts.[15] The complexes described[18-20] are stable under normal conditions and do not undergo photochemical decomposition and decomposition on heating to 120 °C. All the caprolactam complexes investigated behave as powerful electrolytes.

Recently numerous studies devoted to the determination of the structure and stability of the lactam complexes have appeared in the literature.[39-44] As a rule, infrared and ultraviolet spectroscopy, NMR, EPR, X-ray diffraction, and X-ray spectroscopy are used for the determination of the structures. The infrared spectroscopic and NMR methods make it possible to determine reliably the type of coordination in the complexes of lactams. Coordination to the complex-forming agent takes place as a rule via the oxygen atom, which is demonstrated by the bathochromic shift of the carbonyl group frequency by 30—40 cm^{-1} compared with the free lactam. The small changes in the NH stretching vibration frequencies in the infrared spectra indicate merely a general rearrangement of the ligand molecule in the course of the complex formation process. Lactams behave as monodentate ligands. The stability constants of the complexes are determined as a rule polarographically and by potentiometric titration. Certain physicochemical properties of the metal complexes of lactams have been investigated.[42-44] The number of molecules of water of crystallisation has been determined by the derivatographic method and the molar conductance of the melts and solutions of these complexes has been investigated.

The physicochemical properties of the lactam complexes have been studied in greatest detail by Madan and co-workers.[18-20] It has been shown that the coordination of the ligand to the transition metal is via the carbonyl oxygen atom of the ligand. The perchlorates of these complexes have the general formula



$n = 2.3$; R = H, CH_3.

However, the halogen-containing complexes of Co^{2+}, Cu^{2+}, Mn^{2+}, and Fe^{3+} exhibit appreciable structural differences in relation to the perchlorate complexes. An octahedral structure of the cation and a tetrahedral structure of the anion are characteristic of the cobalt complexes $[CoA_6]^{2+}[CoX_4]^{2-}$, where X = Cl, Br, I, or NCS. The copper and manganese complexes incorporate one or two molecules of the ligand A: MA_2Cl_2 and $MACl_2$. The iron chloride complex has the formula $[FeA_4Cl_2][FeCl_4]$. All these complexes have been characterised by the infrared and electronic spectra and their electrical conductivities and magnetic susceptibilities have been studied.

The coordination compounds of zinc complexes of lactams have been investigated.[45] The compounds obtained were identified by infrared spectroscopy and some of their properties were studied: molar conductance and thermal stability, which is important in connection with the use of such compounds as lactam polymerisation activators. It has been shown that the bond between the zinc atom and the lactam is formed via the oxygen atom. All these complexes contain neither water nor a solvent. The enlargement of the lactam ring on passing from caprolactam to caprylolactam in the case of chloride and bromide complexes does not affect the molecular structure. In the iodide- and thiocyanate-containing complexes the enlargement of the lactam ring entails the coordination of a smaller number of molecules. The complex cation $[ZnA_6]^{2+}$ is not formed in the presence of these anions. The greatest thermal stability is shown by bromides and then by the chlorides.

Complexes of tervalent chromium salts with pyrrolidinone and caprolactam have been described.[48] Their structure has been demonstrated with the aid of infrared spectra. The composition and structure of complexes of 5-alkyl-1-(β-aminoethyl)-2-pyrrolidinones with platinum and palladium salts have been established.[22] Comparison of the infrared spectra of the complexes and the initial ligands reveals an appreciable bathochromic shift of the $\nu(NH_2)$ bands, which indicates the involvement of the amino-nitrogen atom in coordination to the metal. The presence in the spectra of the initial ligands of a broad band associated with the stretching vibrations of the NH_2 group at 3400—3300 cm^{-1} and the fairly low stretching vibration frequency of the carbonyl group (1705—1709 cm^{-1}) indicate the presence of an intramolecular hydrogen bond in the ligands. Complex formation involves the rupture of the

hydrogen bond, which is demonstrated by the increase of $\nu(C{=}O)$ to 1722 cm^{-1}. The latter finding is also confirmed by the fact that the C=O group of the ligand does not participate in coordination (otherwise its frequency in the spectrum of the complex would have been lower than that of the free ligand). The nitrogen atom of the heterocycle is also not involved in complex formation, which can be accounted for by the presence of the mesomeric effect, which reduces the electron density at the ring nitrogen atom.

Thus analysis of the physicochemical data of various workers (mainly infrared spectroscopic data) permits the conclusion that in the complexes of unsubstituted and *N*-alkyl-substituted lactams the ligand is coordinated to the metal via the oxygen atom, while in the complexes of 1-(β-aminoethyl)-substituted lactams coordination is via the amino-nitrogen. The nitrogen atom of the heterocycle is not involved in complex formation.

The structure of compound (II), described in a number of patents,[35-38] has been demonstrated with the aid of infrared spectra; the presence of molecules of water of crystallisation has been confirmed by the derivatographic method and the molar conductances of the complexes have also been investigated.

Compounds (II), namely dipyrrolidinocopper(II) dichloride and tricaprolactamocopper(II) dichloride monohydrate, have been investigated by X-ray diffraction and X-ray spectroscopy.[51-52] The structure of the single crystal of $Cu(P)_2Cl_2$, where P = pyrrolidinone, has been described and is illustrated in Fig. 1. The molecules in the crystal are combined into dimers with highly asymmetric Cu...Cl...Cu bridges. The

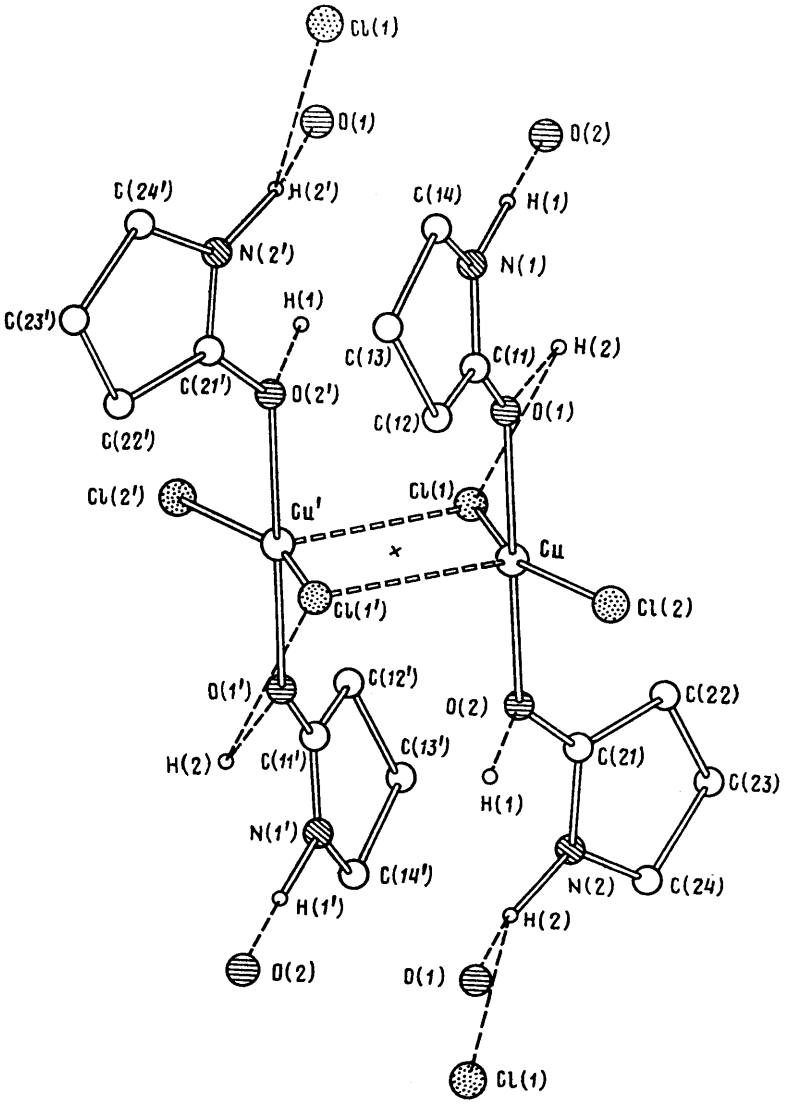


Figure 1. The structure of the dimer in the crystal structure of the $CuCl_2$ complex of 2-pyrrolidinone; the H atoms of the CH_2 groups are not shown.[51]

coordination of the copper atom is intermediate between square and trigonal-bipyramidal (with the ligand atoms in the axial positions). The free coordination site in the *trans*-position relative to the chlorine atom is not completely shielded (<159°).

A different picture obtains for the complex with caprolactam. The structure of tricaprolactamocopper(II) dichloride monohydrate is ionic (Fig.2). The complex is made up of the $[Cu(CL)_6]^{2+}$ cations (CL = caprolactam), which possess crystallographic symmetry with the Cu^{2+} ion at the centre of symmetry, and the anions $[CuCl_3(CL)]^-$, whose number is twice as great. Thus the complex has the formula $[Cu(CL)_6]^{2+}[CuCl_3(CL)]_2^-$. The molecule of water of crystallisation is evidently split off at the instant of the growing of the single crystal. Like pyrrolidinone, caprolactam is a monodentate ligand and is coordinated to the copper atom via the oxygen atom.

The copper atom in the anion has a coordination number of 4 (three Cu–Cl bonds and one Cu...O bond). On the other hand, in the cation copper has a coordination of 4 + 2, i.e. four normal coordinate bonds and two weakened Cu–O(4) and Cu–O(4′) bonds. They correspond to extremely weak metal–oxygen interactions. The caprolactam has in all cases the chair configuration, which is also characteristic of free caprolactam. The cations and anions are combined via hydrogen bonds into an infinite puckered layer.

Analysis of the infrared spectra of compounds (II) has shown that the vibration frequencies of the carbonyl group are reduced by 40–45 cm^{-1} compared with the free ligands. The involvement of the oxygen atom in complex formation cannot fail to alter the lactam system and displacements are therefore observed in the region of the ν(NH) stretching vibration frequencies, but the M – N bond is not formed. It follows from the foregoing that the lactam complexes have

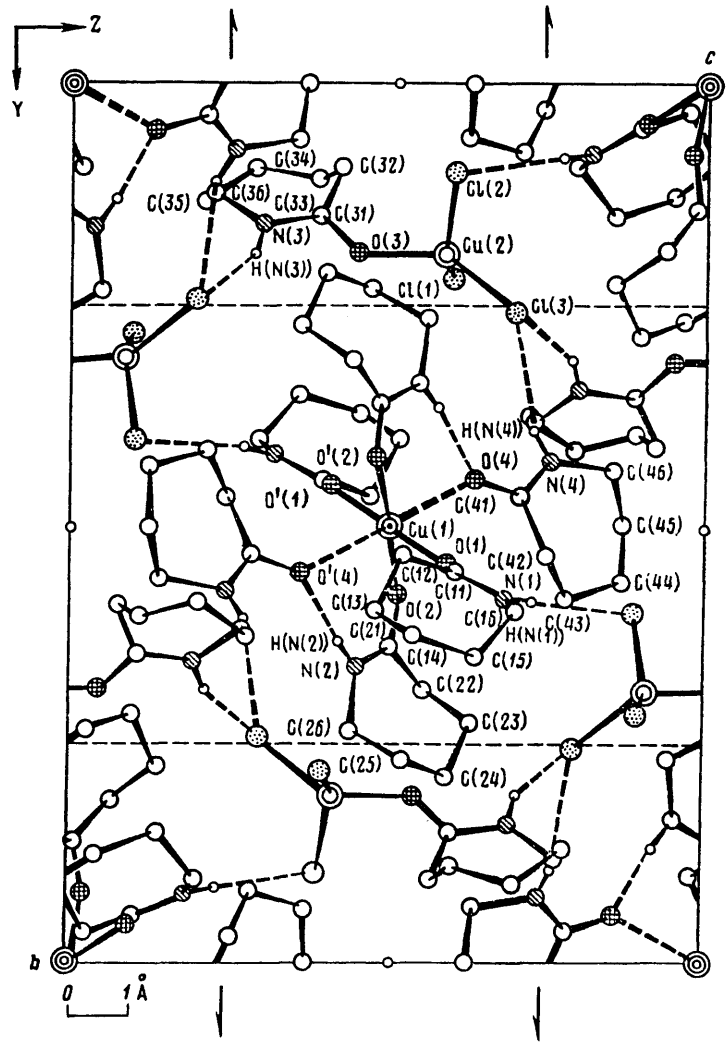

Figure 2. The structure of the $CuCl_2$ complex of caprolactam projected along the a axis (the H atoms of the CH_2 groups are not shown); the dashed lines represent the hydrogen bonds and the additional coordination interactions.[52]

completely different structures depending on the size of the lactam ring. The pyrrolidinone complex has a covalent structure and is dimeric in the crystalline state, while the caprolactam complex has an ionic structure and consists of a polymer.

Analysis of the literature quoted in this Section shows that all the lactam complexes with heavy metal salts are readily soluble in water and polar organic solvents and sparingly soluble in non-polar solvents; they are stable under normal conditions and behave like strong electrolytes.[18-20]

The complexes may or may not contain molecules of water of crystallisation. The most convenient methods of their synthesis are based on the direct interaction of the ligand with heavy metal salts in a polar solvent.

Modern physicochemical methods are used to establish their structures: infrared and ultraviolet spectroscopy, NMR, EPR, and determinations of electronic conductivity and magnetic susceptibility. However, the most reliable methods, which unambiguously establish the structure of the complex and the spatial disposition of the atoms in the molecule, are X-ray diffraction and X-ray spectroscopy.

Unfortunately these methods cannot be used to determine the structures of all complexes, as X-ray diffraction involves the growing of a single crystal and this cannot be achieved in all cases.

III. METAL COMPLEXES OF IMIDAZOLES AND BENZIMIDAZOLES

The early studies on the chemistry of coordination compounds of imidazoles and benzimidazoles were described in the review of Garnovskii et al.[61] A paper on the synthesis and structure of complexes of azoles with metal halides was published later.[62]

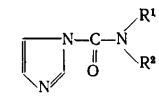
The complexes of azoles are usually obtained by the interaction of the components on heating in organic solvents or by fusing azoles together with metal halides.[63-72] These methods of synthesis frequently lead to compounds containing a large number of solvent molecules. In order to obtain complexes with low coordination numbers, the decomposition of their solvates *in vacuo* at 80–150 °C is therefore employed. In certain cases the presence of solvents leads to the formation of solvolysis and substitution products.

In the case of sparingly soluble metal salts, the ligand exchange method is used. For this purpose, one obtains initially relatively unstable and readily soluble complexes of the salts MX_n (X = halogen), for example, with ethers or acetonitrile, and they are then used in reactions with solutions in imidazole or benzimidazoles. In particular, such a method has been used to synthesise copper(I) complexes. The ligand exchange reaction is carried out in an inert atmosphere.[73-76]

The complexes synthesised can contain between one and six ligand molecules. The number of coordinated groups depends little on the basicity of the imidazole derivatives, but basicity is important in the synthesis of compounds with benzimidazole and its usbstituted derivatives. Thus, imidazole (pK_a = 7) complexes containing from one to six azole molecules have been isolated,[65-70] while only compounds having the composition $MX_2.4HA$ are readily obtained from benzimidazole (pK_a = 5.53).[74,75]

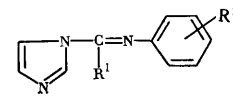
It is important to note that the introduction of bulky substituents into the ligand molecule frequently diminishes the number of coordinated groups. However, when the substituents are remote from the coordination centre, the composition of the complexes is the same as for the unsubstituted molecule. Thus *N*-alkylimidazoles form complexes having the composition MX_2A_6 even in the presence of the butyl substituent, while compounds containing not more than four ligand molecules can be isolated for 2-methyl- and 1,2-dimethyl-imidazoles.[66-69]

The same phenomenon occurs in the synthesis of imidazole complexes with pesticidal activity. Thus the complexes of Cu^{2+}, Mn^{2+}, Fe^{2+}, Ni^{2+}, Ca^{2+}, and Mg^{2+} chlorides with carbamoyl imidazoles contain between two and four ligand molecules:



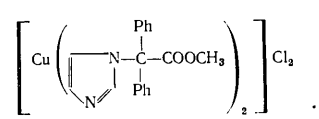
R^1 = alkyl; R^2 = phenoxyalkyl.

On the other hand, the interaction in an inert organic solvent of imidazole derivatives of the type

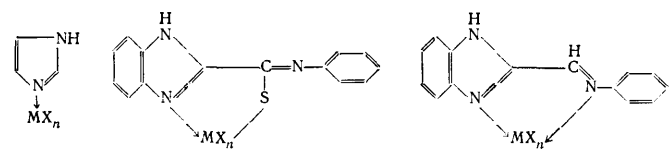


(R^1 = alkyl, alkoxy-group, or $PhCH_2$; R^2 = Cl or CF_3) with Cu^{2+}, Zn^{2+}, Mn^{2+}, Co^{2+}, Fe^{2+}, and Al^{2+} sulphates, chlorides, acetates, and nitrates leads to the formation of complexes containing only two or three ligand molecules.[160-166]

The nature of the metal has little influence on the composition of the complexes. Only copper salts, for which it is not always possible to isolate complexes containing six molecules of azole ligands, are an exception. Thus, the copper complex of methyl diphenylimidazole-1-acetate, which is obtained by the reaction of the ligand and $CuCl_2$ in an alcoholic medium, contains only two molecules of the imidazole derivative:[167]



The question of the location of the coordinate bond is important for imidazoles, benzimidazoles, and their substituted derivatives. Depending on the type of molecule, the metal, and the conditions of synthesis, the coordinate bond can be located at the "pyridine" N(3) atom, or at another heteroatom (O or S) present in the substituted molecule, or in the π-electron system:



According to the literature data discussed by Garnovskii and co-workers,[61,62] coordination takes place predominantly via the nitrogen atom of the "pyridine" type. In this case the molecules of imidazoles and benzimidazoles play the role of monodentate ligands.

The same conculsion concerning the location of the bond in imidazole *N*-ethylimidazole, and *N*-propylimidazole biologically active complexes of Mn^{2+}, Pt^{2+}, and Pd^{2+} was arrived at by other investigators.[77-82]

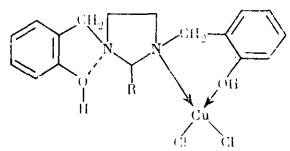
A number of studied have been devoted to metal complexes with 1-vinylimidazoles (A), including those exhibiting biological activity.[83-85] It has been shown by ^{13}C NMR that the coordination of the ligand in the complexes of vinylimidazoles with tin halides $R_{4-n}SnX_n.nA$ (R = alkyl; *n* and *m* = 1 and 2) takes place via the "pyridine" nitrogen atom, which

can entail a change in the mutual orientation of the vinyl group and the heterocycle. The same mode of addition of the ligand obtains in the complexes $MX_n.2A$ and $MX_n.4A$, where MX_n represents Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, and Al^{3+} halides. However, Shchelokov et al,[86] who investigated the Pt^{2+} and Pd^{2+} complexes with 1-vinylimidazole, reached the conclusion, on the basis of infrared spectra, that the vinyl group can be involved in the formation of a bond with the central atom.

2-Hydroxymethyl-1-vinylimidazole, 1-vinyl-2-vinyloxymethylimidazole, 1-ethyl-2-vinyloxymethylimidazole, as well as their benzimidazole analogues have been used as ligands.[87,88] Complexes with the halides, sulphates, and acetates of a series of transition metals have been isolated. Their composition ranges form 1:1 to 1:4 (M:A). The chlorides and acetates show respectively the highest and lowest coordinating capacities. The presence of a substituent in the 2-position in the imidazole ring leads to the formation of complexes in which the metal is coordinated to a smaller number of ligands than in the case of unsubstituted 1-vinylimidazole.

Spectroscopic data have shown that the hydroxymethylimidazoles are coordinated via the nitrogen atom in the 3-position in the imidazole ring. The coordination interaction involves also the π-electron system of the heterocylce and the vinyl group.

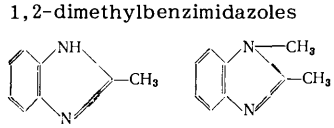
Metal complexes with imidazolidine derivatives have been described.[89,90] Compounds containing not more than two ligand molecules, whose bonds with the central atom are formed via a nitrogen atom as well as the atoms of other functional groups present in the molecule, are produced, for example:



R = Ph, $C_6H_4OCH_3$, CH_3.

In surveying the studies of recent years on the synthesis and properties of complexes of benzimidazole and its substituted derivatives,[91-96] one may note the rarely encountered case where the bond between the benzimidazole ligands and the complex-forming agent in the mixed copper(II) carboxylate complexes with benzimidazole $CuZ.HA.H_2O$ (HA = Benzimidazole and Z = residues of malonic, succinic, malic, or maleic acid) is believed[91] to be formed via the nitrogen atom of the NH group, whose stretching vibration frequency undergoes a bathochromic shift on coordination.

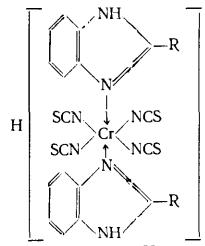
On the basis of the bathochromic shift of the ν(CN) stretching vibration frequency of the imidazole ring on coordination, it has been concluded that the molecules of benzimidazole derivatives in the complexes of bivalent zinc and manganese with 2-methyl- or 1,2-dimethylbenzimidazoles



(HA) (A')

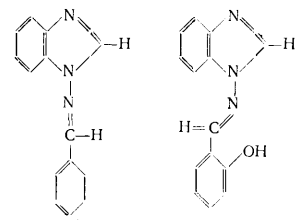
having the compositions $MX_2.HA$ and $MX_2.2A'$ (X = Cl, Br, I, NO_3, CH_3COO, or $1/2SO_4$) add to the zinc(II) and manganese(II) ions via the nitrogen atom in the 3-position in the imidazole ring. The spectra of the complexes can also contain bands characteristic of the acid residues present in the inner sphere.

In the chromium(III) complexes of 2-ethyl and 2-propylbenzimidazoles which have been isolated, the *N*-coordination of the thiocyanate groups has also been indicated:



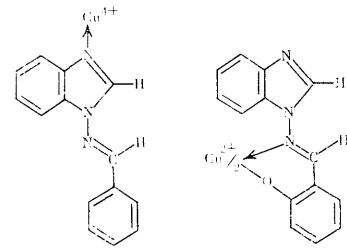
R = C_2H_5, C_3H_7

After the interaction of copper(I) halides and acetates with benzylidene-1-aminobenzimidazole (A') and salicylidene-1-amino-benzimidazole (A"),



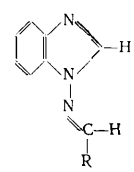
(A') (A")

complexes of two types were isolated: the molecular adducts CuX.A', $2CuAc_2.3A'$, CuX.A", and CuX.3A", as well as the inner complex $Cu(A'' - H)_2$, where X = Br or I. It has been shown by infrared spectroscopy that the azomethines are coordinated to the copper(I) atom via the nitrogen atom of the "pyridine" type in the benzimidazole ring in the molecular adducts and via the azomethine group in the inner complex, for example:



A study of the EPR spectra of the complexes obtained has shown that the interaction of the azomethines (A') and (A") with copper(I) halides is not accompanied by a change in the valence state of copper in the case where complexes of the type of adducts are formed. The interaction involving the formation of the inner complex leads to the formation of bivalent copper complexes and CuBr is oxidised more readily than CuI.[97]

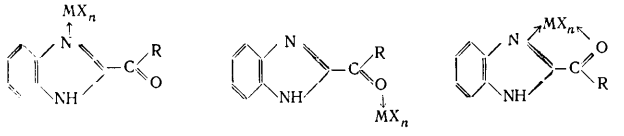
The complex-forming properties of the azomethines of 1-aminobenzimidazoles are determined by the specific features of the steric and electronic structures of the ligand. It has been established that the coordination interaction of the azomethines of 1-aminobenzimidazoles with metal salts proceeds in the first place via the N-donor centre of the hetero-fragment and not via the azomethine bond $-N = C\lesssim$:[98]



R = Ph, $C_{10}H_7$, 3-IC_6H_4, 3-$NO_2C_6H_4$, 4-$NO_2C_6H_4$, 2-HOC_6H_4, 3-BrC_6H_4, 5-BrC_6H_4, 4-HOC_6H_4.

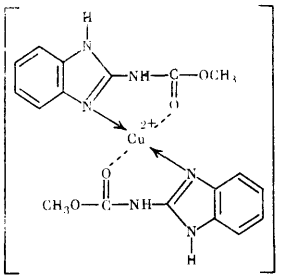
Transition metal complexes with 2-(2-hydroxyphenyl)- and 2-(2-aminophenyl)benzimidazoles contain one or two ligand molecules. It has been shown by infrared spectroscopy that the aminophenyl derivative of benzimidazole is coordinated via the amino-group of the aniline residue and the tertiary N(3) atom of the imidazole ring. In the complexes of 2-pyridylbenzimidazoles with lanthanides and molybdenum(III) coordination is achieved via the nitrogen atom of the pyridine ring and the N(3) atom of the imidazole ring.[99-106]

In the complexes with carbonylbenzimidazoles the coordinate bond is located predominantly at the nitrogen atom of the heterocycle and complex formation proceeds via the oxygen atoms only in the case of the "hardest" Lewis acids:[61]



R = H, alkyl .

Copper(II) complexes with methyl benzimidazole-2-carbamate (HA) have been described.[107] A product having the composition $CuX_2.2HA$ (X = Cl or Br) was obtained. The infrared spectrum of the ligand contains in the region of the stretching vibrations of the NH group a single band at 3300 cm^{-1}. The stretching vibration band of the carbonyl group is at 1710 cm^{-1} and $\nu(C=N)$ is at 1630 cm^{-1}. There is hardly any change in the position of the 3300 cm^{-1} NH vibration band in the spectrum of the complex, although its intensity is appreciably reduced. The vibration bands of the carbonyl and C = N groups are at 1735 and 1645 cm^{-1}. On this basis, it has been suggested that the bond with the metal ion in the complex is formed via the tertiary nitrogen atom and the carbonyl oxygen atom:



As stated in previously published reviews,[61,62] the type of polyhedra formed in the complexes with azoles depends on a series of factors: the coordination number and the electronic configuration of the complex-forming agent, the character of the anion, the nature of the ligand, and in some cases also the state of aggregation of the system. The configuration of the complexes with imidazoles and benzimidazoles was usually determined from magnetic susceptibility and spectroscopic data. Studies on the X-ray diffraction of such compounds are more rarely encountered.

It has been shown on the basis of the observed effective magnetic moments at different temperatures, spectroscopic data, and electrical conductivity in methanol that the complexes with 4-methylimidazole (HA) having the composition $[M(HA)_6]X_2$ [M = Co(II) or Ni(II)] and also $[Ni(HA)_6].[HgCl_4]$, $[Ni(HA)_2(NCS)_4]^{2-}$ and $[Ni(HA)_4(NCS)_2]$ have an octahedral or distroted octahedral configuration, while the complexes $[Ni(HA)_2Cl_2]$ and $[Ni(HA)_4X_2]$ have a tetrahedral configuration. The thiocyanate group in the inner sphere is present in the form of an ion coordinated to the nitrogen atom, which plays the role of a bridge.[108] An X-ray diffraction study of the compound CoA_2Q_2, where A = 1-methylimidazole and Q = 2,4,6-trichlorophenol, showed that Co^{2+} is located in a distorted tetrahedral environment made up of the nitrogen atoms of the two A ligands and the oxygen atoms of the two Q ligands. In view of the bond between the metal ion and one of the chlorine atoms of the Q ligand, the environment of the metal becomes of the distorted square-pyramidal type with one of the nitrogen atoms at the apex of the pyramid. The structure is stabilised by two intramolecular hydrogen bonds C–H...Cl between a carbon atom of A and a chlorine atom of Q. For the same ligands in the Co^{2+}, Zn^{2+}, and Ni^{2+} complexes, it has been found by spectrophotometric and EPR methods that the Q anion in MQ_2A_n is linked to the central atom and the complexes have the configuration of a distorted tetrahedron or a distorted octahedron.[109,110]

The structure of $[CuA_4(AcO)_4].6H_2O$ consists of centrosymmetric dimers linked by acetate bridges. The copper atom is involved in a tetragonal-pyramidal coordination with one bridging acetate ligand at the apex of the pyramid and with the nitrogen atoms in the two methylimidazole ligands and the oxygen atoms of the acetate ions at the base of the pyramid. Water molecules form a system of hydrogen bonds.[111]

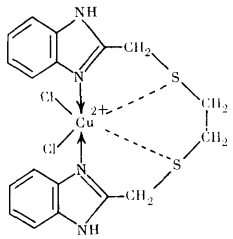
On the basis of X-ray diffraction data and the results obtained by other physical research techniques, it has been established that the copper complexes of 1-methylimidazole and substituted iminoacids have a square-planar structure. The copper atom is located at the centre of symmetry and is surrounded by the two oxygen atoms of the carbonyl groups and two nitrogen atoms of the substituted imidazole. On coordination of two water molecules, the complex has a distorted octahedral configuration.[112,113]

Rhodium complexes containing imidazole (HA^1), benzimidazole (HA^2), and 2-methylbenzimidazole (HA^3) with the compositions $[Rh(HA^1)_4Cl_2]Cl$, $[Rh(HA^2)_4Cl_2]Cl$, $[Rh(A^2)_3].3H_2O$, and $[Rh(HA^3)_4(H_2O)_2]Cl_3$, as well as the iridium compounds $[Ir(HA^2)X_3(H_2O)_2]I$ (X = Cl, Br, or I) and $[Ir(HA^2)_4X]X$ (X = Br, I, NO_2, or NCS), have a polymeric octahedral structure with bridging groups. On the other hand, the complexes $[Pt(HA^3)_4]Cl_2$, $[Pt(HA^1)_2Cl_2]$, $[Pt(HA^2)_2Cl_2]$, and $[Pt(HA^3)_2Cl_2]$, as well as compounds in which the chloride ion has been replaced by the Br^-, I^-, and NO_3^- ions are monomeric and have a planar *trans*- or *cis*-configuration.[114]

The complexes coordinating between four and six 2-methylbenzimidazole molecules have a distorted tetrahedral configuration for Cu^{2+}, a tetrahedral configuration for Co^{2+}, and an octahedral or tetrahedral configuration for Ni^{2+} and Fe^{3+}.[115] The nickel compounds $[Ni(HA)_4]X_2$ (X = Cl, Br, or NO_3 and HA = benzimidazole and its derivatives) have a square-planar structure. On heating, the chloride, bromide, and nitrate complexes are converted into $[Ni(HA)_4]X_2$ and the values of μ_{eff} indicate the formation of a distorted octahedral configuration. The replacement of the benzimidazole derivative by the unsubstituted ligand makes it possible to achieve such a transition also for the iodide compounds.[116]

X-Ray diffraction and electronic spectroscopic data as well as measurements of the magnetic susceptibility have shown that the Co^{2+}, Ni^{2+}, and Cu^{2+} complexes of 5-nitrobenzimidazole have pseudotetrahedral and distorted octahedral structures. The cobalt and halogen-containing nickel compounds with 3,4-dihydro-1-phenyl-1*H*-1,4-oxazino[4,3*a*]benzimidazole have a tetrahedral configuration. On the other hand, the nickel(II) thiocyanate complex is square planar. In all the compounds indicated the ligand is coordinated via the N(3) atom of the benzimidazole ring. In the copper complexes of

tris(2-benzylimidazolymethylamine) there is a trigonalbipyramidal or distorted octahedral configuration. The study of the structure of the complex



showed that the copper atoms are located in a distorted trigonal-bipyramidal environment with the N(3) atom of the ligand in the axial position and also with two S atoms and Cl^- ions in the equatorial plane.[117-120]

The stability of the complexes of azoles had not been the subject of systematic study previously. There were only isolated investigations of the stability of imidazole compounds. The stability of the complexes is directly related to their biological activity. It follows from Azizov's study[5] that complexes with an average stability constant $\lg \beta \cong 8-9$ exhibits the highest bioactivity. Numerous publications devoted to the investigation of the thermodynamic and kinetic stabilities of coordination compounds with imidazole, benzimidazole, and their substituted derivatives have appeared recently. Thus the relative basicities of imidazole and its substituted derivatives have been estimated[121-125] and studies have been made of the complex formation reactions of cobalt(II), copper(II), and nickel(II) salts with the above ligands. It follows from the values of pK_B found for the ligands in benzyl and n-butyl alcohols that the electron-accepting properties of the imidazoles become more pronounced with enhancement of the acid properties of the alcohols. In DMSO, acetonitrile, and acetone the differences between the proton-accepting properties of the ligands in each solvent depend mainly on the inductive effect of the substituent, on which steric effects associated with the number, size, and degree of branching of the substituents in the imidazole molecule may be superimposed. When electron-donating substituents are introduced into the ligand molecule, an increase of the stability of the Co^{2+} and Cu^{2+} complexes is observed, while the introduction of the electron-accepting substituents entails some decrease of the stability of the complexes. The study of the complex formation reaction between Ni^{2+} and imidazoles demonstrated a decrease of the rate of formation of the complex in the presence of small amounts of added acetone, which can be accounted for by the specific solvation of the ligand and by a change in the dielectric constant of the medium.

The presence of the hydroxide ion influences the formation of complexes by the Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, and Hg^{2+} salts with imidazole (HA). At low ligand concentrations the complex $M(OH)_2.HA$ is formed, while at high concentrations the complex $M(HA)_n$ ($n = 1-4$) is formed stepwise.[126-130]

The study of the formation of mixed complexes with imidazole and aminoacids showed that Zn^{2+} reacts with imidazole, histamine (H_2R), and histidine (H_3Q) to form the complexes $[Zn(HA)_n]^{2+}$ ($n = 1-4$) and also $[Zn(HA)_nR]$ ($n = 1$ or 2) and $[Zn(HR)Q]^{2-}$ and $[Zn(H_2R)Q]^-$. The composition of the complexes shows that imidazole is coordinated as a monodentate ligand without the elimination of a proton while histamine and histidine are coordinated as bi- and tri-dentate ligands with abstraction of one, two, or three protons.[131-134]

The dissociation constants of the ligands and the stepwise stability constants of the Cu^{2+}, Co^{2+}, Ni^{2+}, and Zn^{2+} complexes with 4-methylimidazole (HA) have been determined. In the case of Co^{2+} in aqueous solution there is an equilibrium between the octahedral complexes $[Co(H_2O)_{6-n}(HA)_n]^{2+}$ and the tetrahedral compounds $[Co(H_2O)_{4-n}(HA)_n]^{2+}$. The dependence of the formation constants K_n on the number of coordinated ethylimidazole molecules n for Cu^{2+} and Zn^{2+} is anomalous in the case of K_3 and K_4. In this case the logarithms of the constants are equal to the sums of the corresponding quantities for the complexes $[M(HA)_4]^{2+}$, $[M(H_2O)_2(HA)_2]^{2+}$, and $[M(H_2O)(HA)_3]^{2+}$ formed simultaneously in solution.

The stability constants ($\lg \beta_n$) show that the stability of the complexes of methylimidazole is somewhat lower than that of the corresponding compounds of the butyl derivative as a consequence of the lower basicity of methylimidazole. The stability of the complexes of Co^{2+}, Ni^{2+}, and other transition metals with 1-methyl-, 2,2-dimethyl-, 2-ethyl-, 1-methyl-, 2-ethyl-, 1,2,4-trimethyl-, 1-propyl-, and 1-butyl-imidazoles diminishes with increase in the size of the substituent in the imidazole molecule. In the complex formation reaction of the transition metals with imidazole derivatives having involved substituents, 1:1 complexes are formed as a rule. Thus 2-[(2-carboxyphenyl)azo]-4,5-diphenylimidazole reacts with Th^{4+}, UO_2^{2+}, and Ce^{3+} ions in ethanol to form compounds with the composition indicated and stability constants, $\lg \beta$, 7.17, 6.91, and 6.68 respectively for these ions.[135-143]

A number of studies have been devoted to the complex formation reactions of transition metals with benzimidazole and its substituted derivatives. It has been noted[144-146] that the formation of complexes by copper(II) and cobalt(II) chlorides and nitrates in non-aqueous solutions is influenced by the nature of the solvent and to a lesser extent by the size and character of the substituent in the benzimidazole molecule. In the case of cadmium(II) carboxylates the stability of the complex with benzimidazole depends on the charge of the complex species. The addition of the first benzimidazole molecule to the complex cation is less favourable than the interaction with the uncharged species. This is associated with the change in the strength of the dative $d-\pi^*$ bond between the metal carboxylate and benzimidazole. A π-dative interaction has been noted in the formation of complexes by substituted benzimidazoles with Co^{2+}, Zr^{2+}, Ni^{2+}, and Mn^{2+}. Benzimidazole and 4-azobenzimidazole form the complexes $[M(H_2O)_{6-n}(HA)_n]^{2+}$, while 2-hydroxymethylbenzimidazole forms the complexes $[M(HA)_4]^{2+}$.[147-149]

Summarising the literature data presented for the metal complexes of imidazoles and benzimidazoles, one may conclude that the azole complexes isolated from solutions or melts contain between one and six ligand molecules. The coordinate bond is as a rule located at the "pyridine" nitrogen atom and other heteroatoms in the substituted azole molecule and is involved in complex formation only in the case of "hard" Lewis acids.

The type of polyhedra of the transition metal complexes of imidazole, benzimidazole, and their derivatives depends on a number of factors. The data presented lead to the conclusion that the geometrical configuration of the complexes with azoles varies from distorted octahedral to square planar. The nature of the complex-forming agent and the ligand as well as the character of the anion of the metal salt are very important in this instance.

In considering the stability of the complexes of azoles in solution, one may note its decrease with increase in the size of the substituent in the ligand molecule. The stability is influenced by the inductive and steric effects of the substituents in the azole molecule and also by the nature of the organic solvent (the majority of studies on the formation of complexes by imidazoles and benzimidazoles have been performed in a non-aqueous medium). In the series of benzimidazole complexes the stability is influenced also by the π-dative

interaction involving the *d* electrons of the metal and the antibonding π* orbitals of the ligand molecule.

IV. BIOLOGICAL ACTIVITY OF COMPLEXES OF LACTAMS, IMIDAZOLES, AND BENZIMIDAZOLES

The study of the biological activity of complexes is important for medicine and agriculture. Investigation of the properties of these substances in biological cycles of toxic elements and in the first place in their interaction with various organisms in the environment (bacteria, fungi, higher plants, and animals) plays an important role.

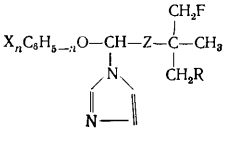
The use of biocoordination compounds in medicine is based on the fact that the concentration of biometals in various tissues for the normally functioning organism must be maintained at vigorously specified levels by regulating them with the aid of the system of appropriate proteins and hormones. In some cases it is necessary to resort to special preparations containing the particular bioelement in a form assimilable by the organism.[2]

Biocoordination compounds as chemical plant protecting agents have been attracting increasing attention in the agricultural industry. This is because the metal-containing organic compounds exhibit a high activity against a broad spectrum of pathogens and are as a rule safe for the environment.

The question of the physiological activity of coordination compounds of lactams and azoles has been inadequately investigated. The metal complexes of azoles play an important role in biological objects and processes.[150-152] The imidazole group enters into the composition of the most important enzymes: creatine kinase, chymotrypsin, carboxypeptidase A, carboanhydrase B, and others. The imidazole group is very important in phosphorylation systems. Haemoproteins fulfil an important biological role. The involvement of the imidazole group of histidine in the binding of oxygen by haemoglobin and myoglobin has been postulated.

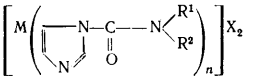
Metal complexes with imidazole, benzimidazole, and their derivatives possess pharmacological activity. Stimulators of antitumour protection, preparations with antimicrobial activity, etc. have been found among them.[81,85]

Such compounds include platinum(II) and palladium(II) complexes of 1-ethyl- and 1-propyl-imidazoles having the composition MX_2A_2 and MX_2A_4 (X = Cl, Br, or I). The complexes of many transition metals with imidazole derivatives having the general formula

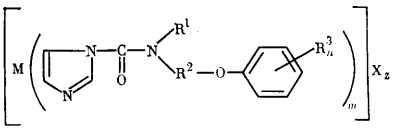


where Z = CO or CH(OH), R = H or F, X = halogen, alkyl, NO_2, CN, alkoxycarbonyl, substituted phenyl, or unsubstituted phenyl, and n = 0–3 can be used in medicine and veterinary practice for the treatment of dermatomycoses and systemic mycoses. The cobalt(II) and nickel(II) complexes containing two or four molecules of 3,4-dihydro-1-phenyl-1*H*-oxazino[4,3*a*]benzimidazole possess antiviral properties.[153-156] There are some data concerning the pharmacological activity of the metal complexes of lactams.[157-160] Thus, certain 1,5-disubstituted pyrrolidinones and their salts exhibit vasodilating, antiulcer, and hypotensive activities. Lactam derivatives, in particular silylated lactams, have attracted attention as valuable physiologically active substances. They function as mediators in the inhibition of the nervous system and posses anticonvulsant, [illegible]

Many metal complexes with imidazole, benzimidazole, and lactams exhibit a pesticidal activity. Thus carbamoylimidazoles and their complexes with copper(II), manganese(II), iron(II), calcium(II), nickel(II), and magnesium(II) salts are active fungicides:

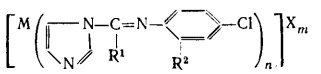


(R^1 = alkyl, R^2 = phenoxyalkyl, X = univalent anion, and n = 2–4) and



(R^1 = alkyl, R^2 = branched alkylene, R^3 = alkyl or halogen, n = 0–5, m = 2 or 4, and X = univalent anion). At a concentration of 1 g litre^{-1} the preparations inhibit the development of *Botrytis cinerea* and *Erysiphe graminis*.[160-162]

The copper(II), zinc(II), manganese(II), cobalt(II), iron(III), and aluminium(III) compounds

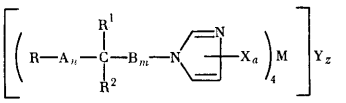


(R^1 = alkyl, alkoxyalkyl, or $PhCH_2$, R^2 = Cl or CF_3, n = 2 or 3, X = univalent anion, and m = 2 or 3) exhibit a broad spectrum fungicidal activity.

The complexes and the ligands entering into their composition can also possess plant growth stimulating properties, apart from their fungicidal activity. At a concentration of 4 g litre^{-1}, they influence the growth of soya, tomatoes, the cottonplant, etc., they intensify the green colour of leaves and bushing out, and inhibit apical tissues.[163-166]

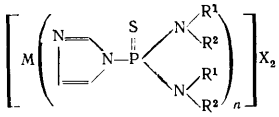
The copper complex of methyl diphenylimidazole-1-acetate (A) $[Cu(A)_2]Cl_2$ is a fungicidal preparation (especially active against powdery mildew fungi). At a concentration of 1.2×10^{-4}–1×10^{-9}% the preparation greatly reduces the infection of barley by the fungus *Erysiphe graminis*, the infection of the apple tree by *Podosphaera lencotricha*, and of cucumbers by *Erysiphe cichoreaclarum*.[167]

The calcium(II), magnesium(II), manganese(II), copper(II), zinc(II), nickel(II), cobalt(II), tin(II), cadmium(II), chromium(III), and iron(III) complexes of 1-arylalkylimidazoles possess fungicidal activity:[168-171]



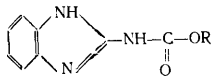
(R = aryl or substituted aryl, R^1 and R^2 = alkyl, alkenyl arylakyl, substituted arylakyl, phenyl, substituted phenyl, etc., A and B = alkylene, X = alkyl, halogen, or NO_2, a = 0–3, n and m = 0 or 1, and Y = anion). In contrast to the free imidazoles, the complexes are not phytotoxic, can be used to treat green plants, and also can serve as seed pickling agents. They suppress the development of phytopathogenic fungi and are effective against barley *helminthosporiosis*, the grey mould and mildew of the leguminous plants, tomatoes, and the grape vines, phytophtorosis of tomatoes, piriculariosis of rice, and the stem and grey rust in wheat.

The cobalt(II), cadmium(II), iron(II), nickel(II), manganese(II), and zinc(II) complexes of imidazolylphosphonothioic diamide, i.e.

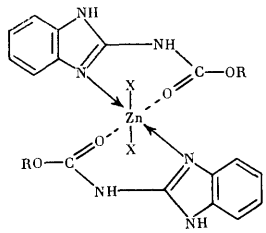


where R^1 and R^2 = alkyl, Ph, CH_2CHCH_2, CH_2Ph, or furfuryl, X = non-phytotoxic anion, and n = 1–4, possess fungicidal activity. The compounds can be used as bactericides for the protection of plants and also various materials (polymers, fabrics, and paper).[172–174] At a concentration of 24–100 mg litre^{-1}, the complexes induce 75–100% destruction of *Phytophtora infestans*, *Venturia inaequalis*, and other fungi.

Transition metal complexes of benzimidazole derivatives have been investigated as effective fungicides. The zinc(II) and copper(II) complexes of urethanes

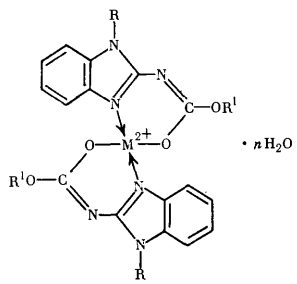


where R = lower alkyl, have been described in patents,[175–178] for example:



The complexes exhibit protective and eradicating fungicidal activities. At a concentration of 16–80 mg litre^{-1} they are active against apple scab and powdery mildew. A number of transition metal complexes of methyl benzimidazole-2-carbamate exhibit a broad spectrum of fungicidal activities, are non-toxic to man, and their fungicidal activity persists for a long time. The preparation can be used for the protection of plastics and leather.

Fungicidal and acaricidal activities are shown by the cadmium(II), zinc(II), copper(II), nickel(II), manganese(II), and cobalt(II) complexes having the general formula



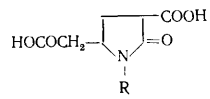
where R = $-\overset{O}{\overset{\|}{C}}-NHR^2$; $-\overset{O}{\overset{\|}{C}}-R^3$, $-\overset{S}{\overset{\|}{C}}-CCl_3$ (R^1 = alkyl, R^2 = alkyl or substituted alkyl, etc. R^3 = H, alkyl, alkenyl, cycloalkyl, phenyl, etc., n = 0–3[179,180]). Dehydration of the compounds leads to an increase of their fungicidal activity and also to an appreciable improvement of stability on storage.

Mixtures exhibiting a synergistic effect are also employed as fungicidal preparations. They contain zinc salts and methyl 1-butylcarbamoylbenzimidazole-2-carbamate. They readily penetrate plants and exhibit a prolonged protective activity. Fungicidal preparations containing a mixture of methyl benzimidazole-2-carbamate and the manganese or zinc salt of ethylenebisdithiocarbamic acid in proportions ranging from 1:1 to 1:20 (1:10 are the preferred proportions).[181]

Less information is available in the literature about the pesticidal activity of lactam complexes. The use of coordination compounds of lactams agains plant pathogens has been reported.[182–186] The substances proved to be effective inhibitors of the growth of certain phytopathogenic bacteria inducing diseases of the grapevine and certain melon crops. In particular, they inhibit the growth of *Bacterium tumefaciens*, *Pactobacterium aroideae*, and *Xanthomonas campestris*.

Complexes based on 5-alkyl-1-(β-aminoethyl)-2-pyrrolidinones, described by Sedavkina and Shebaldova,[22] exhibit antimicrobial and antiphage activities. The parmacological and pesticida' activities of pyrrolidinonecarboxylic acids have been mentioned.[53–60] The zinc(II), copper(II), and calcium(II) complexes

show an antifungal effect. The zinc salt shows a greater inhibiting activity against dermatophytes than the copper salt. On the other hand, the calcium salt influences protein metabolism in bony and skin tissues. Fungicidal preparations containing only the copper salt of the amidodicarboxylic acid



(R = H, alkyl, or cycloalkyl) are especially effective against phytophtorosis and the genuine powdery mildew of cucumbers.[58]

Among the lactam complexes of transition metal salts, the preparation "Kartotsid" [Cartocide?] the copper(II) complex of ε-caprolactam exhibiting a broad spectrum of fungicidal acitivity and safe for the environment, is promising.[187] It can replace the familiar fungicidal preparations, namely copper oxide chloride and Khomezin—in sugar beet and potato plantations, vineyards, and orchards, and also makes it possible to reduce appreciably the consumption of copper.[188] Furthermore, the preparation has a low toxicity (LD_{50} = 1200 mg kg^{-1}) for warm blooded animals.

When biologically active metal complexes are used, it is very important to investigate the mechanism of their action on living cells. The character of the action of biocoordination compounds is at present by no means always clear. There exist at least three possible mechanisms of their action: (1) the activity is manifested by the ligand and the role of the metal reduces to creating a suitable transport form; (2) the metal ion itself exhibits an activity and the complex is necessary for the transport of the metal ion across the cell membrane; (3) the active species, namely the complex ions, can interact with cell centres important for vital activity.[2]

The majority of the theories of the mechanism of the action of copper-containing preparations are based on the adsorption capacity of the fungal cell protoplasm. It is known that a deposit of the copper-containing fungicides on the plant is not absolutely insoluble in water—a certain microamount of copper is present in solution. According to the cumulative theory, the copper present in solution is absorbed by the spores, which disturbs the equilibrium and fresh portions of copper dissolve. The process continues until the sport accumulates a toxic dose of copper.[189]

In certain cases the fungicidal properties of copper complexes can be explained by their structure. Thus the free coordination site in the *trans*-position relative to the chlorine atom is not fully shielded in the compound having formula(II) and described in patents[35-38] (see above), where the ligand is caprolactam and the inorganic salt is $CuCl_2$. Precisely this fact can explain the high biological activity of the compound. Probably owing to the imperfection of the coordination environment of the copper atom, the latter interacts with the sulphhydryl groups of enzymes and coenzymes, since the latter are especially sensitive to the action of heavy metals. This leads to the precipitation of the protein substance, as a result of which the fungus is destroyed. However, the available data about the behaviour of complexes in bio-objects are as yet inadequate for an unambiguous solution of the problem of the mechanism of the action of these complexes.

In order to determine the mechanism of the action of the fungicidal preparation "Kartotsid", a study has been made of its interaction with two-layer phospholipid membranes,[190] since transfer across a two-layer membrane is decisive in the action of any physiologically active susbstance. It is known that two-layer lipid membranes are effective models of cell membranes. Measurements of the membrane potential, electrical resistance, and electrical capacitance of lipid two-layer membranes as a function of the "Kartotsid" concentration suggested that the primary mechanism of its fungicidal action is associated with the increase of conductivity and with the breakdown of the structural organisation of the cell membrane. The increase of the membrane conductivity is caused by the lipophilic properties of the membrane-active form of "Kartotsid". The molecules of the preparation in living organisms apparently act not only on the surface regions of the cell membranes but also penetrate into the interior of the cell.

As a result of their penetration into the cell, the copper ions inactivate enzymes, forming chelate complexes. The activity of many enzymes is known to diminish following the substitution of the active metal of the enzyme complex (for example, magnesium) by heavy metals such as copper or mercury. Thus the role of the lactam molecules in the complex with the copper ion probably reduces to facilitating the transmembrane transfer of Cu^{2+} ions into the interior of the cell.

Summarising the data presented concerning the physiological activity of imidazole, benzimidazole, and lactam complexes, one may conclude that at present they have not as yet found a wide-scale application in the national economy, although much work is already being done along these lines. Evidently many transition metal complexes of the above ligands possess pesticidal and pharmacological activities. In most instances the activity of the complexes is higher than that of their constituent organic molecules. Furthermore, the complexes are always less toxic for warm blooded animals than the coordinated physiologically active ligands. It has been shown in relation to the preparation "Kartotsid" that bio-coordination compounds contain less toxic copper than the preparations based on simple copper salts used at present which is extremely important from the ecological standpoint. All these factors make one confident that physiologically active metal complexes will find more extensive applications in agriculture in the immediate future.

The Synthesis and Luminescence-spectroscopic Properties of Fluorescent Condensation Polymers

N.N. Barashkov

The results of studies on the synthesis of polycondensation phosphor-containing aliphatic and aromatic polymers as well as the products of polymer-analogue transformations with phosphor-groups in the side chain are examined. The light absorption and luminescent properties of the polymers obtained and of model compounds having an analogous structure are discussed. The bibliography includes 108 references.

IV. Aromatic fluorescent polymers 699

I. INTRODUCTION

Numerous studies on the synthesis and spectroscopic properties of fluorescent polymers have been published in recent years. However, the available results have not so far been the subject of a suitable survey in the Soviet literature. Foreign reviews deal only with data on the synthesis and spectroscopic properties of polymerisation phosphor-containing polymers.[1-3] Nevertheless the knowledge of the luminescence-spectroscopic properties of such polymers, obtained both by polymerisation and polycondensation, is of great theoretical importance in view of the possibility of investigating intramolecular and intermolecular electronic energy transfer and migration processes in a polymeric medium and is of definite practical interest, because the fluorescent properties of polymers are closely related to their photoconducting characteristics and resistance to the action of light.

In recent years a number of trends have arisen in technology which utilise the capacity of certain polymers for intense fluorescence. These include in the first place the preparation of daylight fluorescent pigments on a polymeric base and of plastic scintillators[4] as well as polymeric active elements for laser technology.[5]

In the present review an attempt is made to survey the available literature data on the synthesis and spectroscopic characteristics of aliphatic and aromatic phosphor-containing condensation polymers.

II. ALIPHATIC POLYCONDENSATION POLYMERS

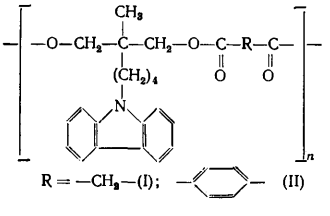
It is known[6-8] that many of the natural polycondensation polymers (proteins) glow in the range 280–360 nm as a result of the emission of light by aromatic aminoacid residues—those of tryptophan, tyrosine, and phenylalanine. Synthetic polycondensation polymers [of the type of polycaprolactam and poly(ethylene terephthalate) containing chromophoric groups in the chain], which have a bright colour and apparently fluoresce, were first obtained by Bykov and co-workers at the beginning of the 1960's.[9-12] Data obtained in these and similar investigations have been surveyed in a review.[13]

Concentrating on later investigations, we may note that the ability of polycondensation polymers to fluoresce has been usually imparted by introducing into the composition phosphor fragments related to carbazole, anthracene, pyrene, or other condensed aromatic or heteroaromatic nuclei. We shall consider polymers of each of these types.

1. Carbazole-Containing Polymers

Carbazole-containing polymers, obtained by polarisation methods, in particular polyvinylcarbazole, are promising materials for electrophotography, which is based on the phenomenon of the photoeffect in electrically charged high-resistance films.[14] Cheap electrophotographic layers, whose sensitivity is close to those made from inorganic photoconductors, can be obtained on the basis of such polymers.[15] According to Voishchev et al,[16] certain polycondensation carbazole-containing polymers, which have been described in fair detail in the literature,[17] also exhibit a high photoconductivity. However, the luminescence-spectroscopic properties of such materials have been investigated less fully than those of polyvinylcarbazole and related compounds.[1] Thus the synthesis of fluorescent polyesters[18-20] and polyurethanes[21] with ω-9-carbazolylbutyl groups, as well as polyamides based on 3,6-diamino-9-ethylcarbazole[22] has been described in a series of reports by Tazuke and co-workers.

The polyesters (I) and (II) have been obtained by the polycondensation of 6-carbazolyl-2,2-dihydroxymethylhexane with the diethyl esters of dicarboxylic acids at 150–160 °C for 3 h in a nitrogen atmosphere and then *in vacuo* for 10 h:[18,19]



The light absorption and fluorescent properties of the polymers (I) and (II) have been investigated simultaneously with the properties of the model compound (III) (Fig.1), which is a product of the condensation of 6-carbazolyl-2,2-dihydroxymethylhexane with ethyl acetate. Fig.1*a* shows that the absorption properties of the polymers (I) and (II) are similar in the range $\lambda > 270$ nm, where the only

light absorbing group is the carbazolyl group. The differences in the range $\lambda < 270$ nm are associated with absorption by the terephthalate unit. The fluorescence spectra of the polyester (I) and of the model compound (III) are identical and contain only the monomer fluorescence band with $\lambda_{max} = 368$ nm. On the other hand, an additional broad structureless exciplex band with $\lambda_{max} = 490$ nm appears in the fluorescence spectrum of the polyester (II). The intensity ratio of the exciplex and monomer fluorescence bands† I_e/I_m depends on the degree of polycondensation n[19] and diminishes when the solution is diluted. The latter finding indicates the operation of an intermolecular mechanism of the formation of the exciplex even at a concentration of 10^{-4} M.[18]

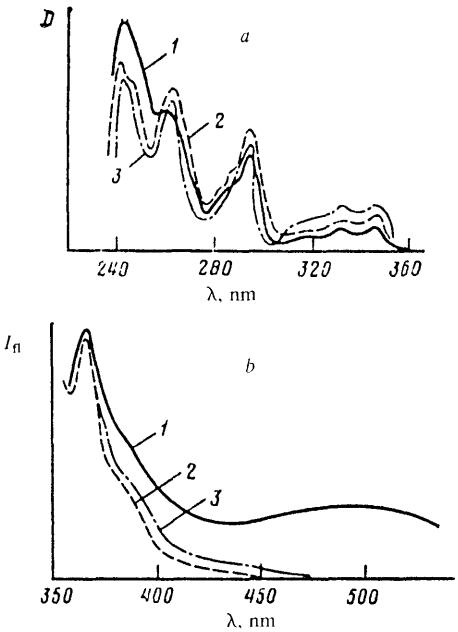


Figure 1. Absorption (*a*) and fluorescence (*b*) spectra of dioxan solutions of the polymers (II) (curve *1*) and (I) (curve *2*) and the model compound (III) (curve *3*).[18]

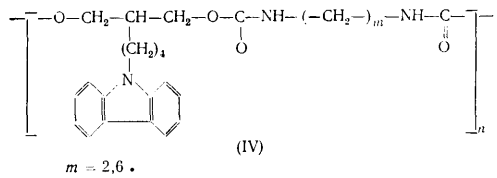
It follows from the fluorescence quantum yields for the polyester (I) and the model (III) (~0.3) and for the polyester (II) (less than 0.1) that the probability of the fluorescence of the exciplex formed as a result of the interaction of the excited carbazolyl group of the model (III) with a terephthalate group is lower than for the carbazolyl group. Comparison of the fluorescence lifetimes of compounds (I), (II), and (III) justifies the hypothesis that the reduced fluorescence intensity of the carbazolyl groups of the polyester (II) is due to the dynamic quenching of the fluorescence by terephthalate groups.

A method has been proposed[21] for the synthesis of carbazole-containing polyurethanes involving the polycondensation of 9-(6-hydroxy-5-hydroxymethylhexyl)-carbazole with aliphatic di-isocyanates in boiling anisole:

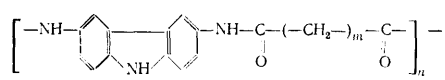


(IV)

$m = 2,6$.

The spectroscopic properties of the polymers (IV) and (I) are similar, i.e. are determined mainly by the carbazole chromophore without an admixture of exciplex states.

The polyamides (V), containing carbazole groups in the main chain and not in the side chain, have been obtained by the polycondensation of 3,6-diamino-9-ethylcarbazole with aliphatic dicarboxylic acid dichlorides in 9-ethylcarbazole using triethylamine as the catalyst:[22]



V

$m = 2, 6, 8$.

The fluorescent properties of the polymers (V) and of the model compound 9-ethyl-3,6-bis(propionylamino)carbazole have been investigated in solutions in hexane and *m*-cresol. It is shown that solutions of both compounds are characterised by the same monomeric fluorescence without a contribution due to the glow of excimers. The significant bathochromic shift of the fluorescence band, observed for the solution in *m*-cresol ($\lambda_{max} = 410$ nm) is explained by the authors by the formation of a hydrogen bond between the OH group of the solvent and the amide bond in the test substances.

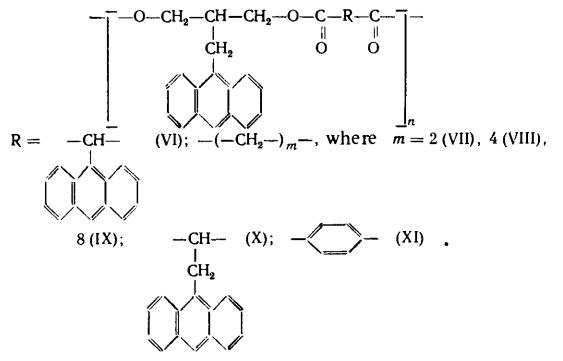
2. Anthracene-Containing Polymers

It is known[23] that anthracene-containing polymerisation systems of the type of poly-9-vinylanthracene belong to the class of photosemiconductors, which are promising for the preparation of electrophotographic layers. Presumably polycondensation polymers with anthracene fragments in the side chain will also be of interest as photoconducting materials. However, all the available literature data on such polymers deal primarily with questions of electronic energy transfer in these systems and with the observation of excimer glow and not with their photoconducting characteristics.

Among anthracene-containing polycondensation polymers, one should distinguish polyesters,[24-28] polyurethanes,[26-28] and polymeric quaternary ammonium salts (polyionenes).[29-31]

In order to obtain the polyesters (VI)–(XI), 2-(9-anthryl)-methylpropane-1,3-diol was subjected to polycondensation with dicarboxylic acid esters at 150–160 °C in the presence of catalytic amounts of calcium acetate and antimony trioxide:[24]

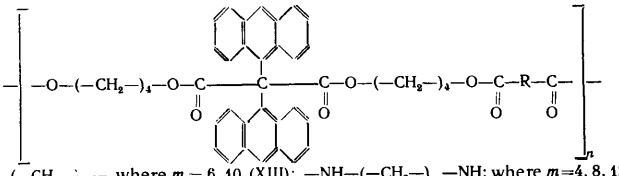
†Here and henceforth monomer fluorescence should be understood as the emission associated exclusively with the nature of the individual chromophoric polymer fragments, while the excimer and exciplex fluorescence should be understood as the emission by complexes consisting respectively of two identical or different molecules, one of which is in the ground state, while the other is in an excited state.



The polymers synthesised are soluble in tetrahydrofuran (THF) and, according to gel-permeation chromatographic data, have a low molecular weight (n = 2–7). The polyesters (VII), (IX), and (XI) were also synthesised by the reaction of the initial propanediol with the dithiol esters of the corresponding dicarboxylic acid at 150–160 °C for 2–3 h in an atmosphere of nitrogen and then *in vacuo* for 13–18 h in order to remove the thiophenol.[25] This method made it possible to obtain polyesters with higher molecular weights (n = 4–25).

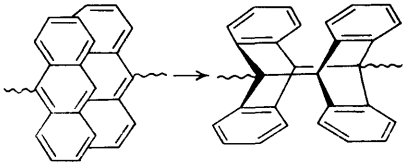
A study of the luminescence-spectroscopic properties of solutions and films of polymers as well as solutions of the model 1,3-diacetoxy-2-(9-anthryl)methylpropane (XII) showed that the light absorption properties of all the substances investigated are similar. The fluorescence spectra of solutions of the polymers contain both monomer bands with λ_{max} = 392, 415, and 440 mn as well as bands due to excimer glow with λ_{max} = 460 nm (Fig.2). It was found that the ratio I_e/I_m for the polymer solutions falls from 0.431 to 0.024 in the series of compounds (VI) > (X) > (VII) > (VIII) > (IX) > (XI). In the polymer films the excimer fluorescence predominates over the monomer fluorescence (Fig.2*b*). The fact that the polyester (VI) has the most intense excimer fluorescence is apparently associated with the high efficiency of the energy transfer in this polymer. A study of the dependence of I_e/I_m on the content of the polymer (VI) in solution showed that the interaction between the anthryl units predominates at a concentration $\leqslant 10^{-3}$ M (I_e/I_m = const.), while at higher concentrations the contribution of intermolecular interactions increases (I_e/I_m increases with increasing concentration). The occurrence of energy transfer process between various phosphor units has been demonstrated in relation to the polyester (X): on excitation of fluorescence with light having λ = 280 nm, which is absorbed by naphthyl groups, emission from the anthryl units alone was observed (Fig.2*b*).

A method has been proposed[26,27] for the synthesis of the polyester (XIII) and the polyesterurethanes (XIV) by the polycondensation of 9,10-bis-4-(hydroxybutylenoxycarbonyl)dianthracene with acid dichlorides or di-isocyanates:



The polymers obtained are readily soluble in chloroform and methylene chloride and have comparatively high molecular weights.

It has been shown[27] that, when the polymers (XIII) and (XIV) are irradiated with light at a wavelength of 300 nm at 196 K, a small fraction (up to 5%) of the dianthracene units are photolysed to anthroate groups:



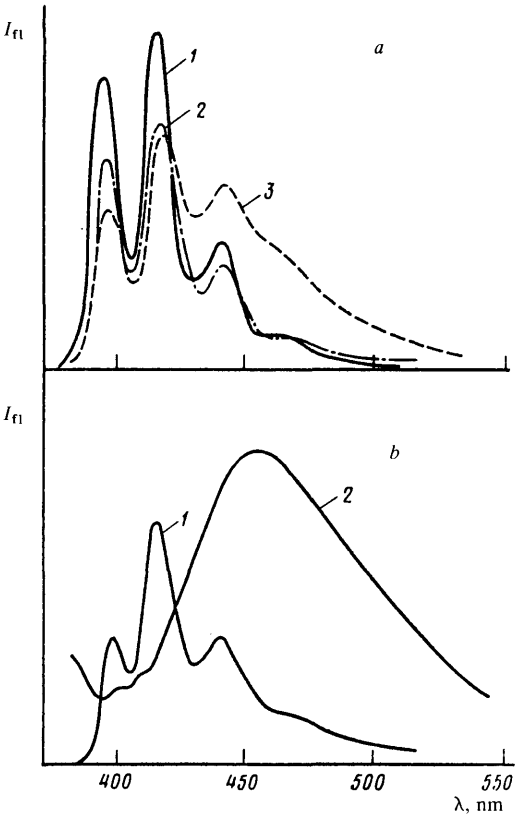


Figure 2. Fluorescence spectra: *a*) of solutions in THF of the model compound (XII) (curve *1*), the polyester (X) (curve *2*), and the polyester (VI) (curve *3*); *b*) of a solution of the polyester (VIII) in THF (curve *1*) and of a film of the polyester (VII) (curve *2*).[24]

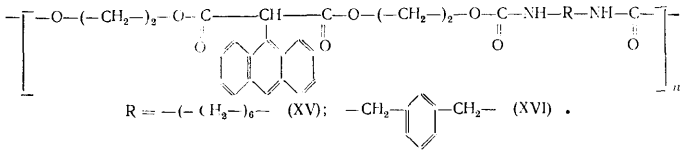
The anthroate end groups are formed as sandwich dimers, which gradually decompose to the monomeric state on heating.[27] The formation of dimers is indicated by a broad structureless band with a maximum at 500 nm in the fluorescence spectra of the polymers after photolysis at 196 K. In the specimens of polyesterurethanes (XIV) the structure of the sandwich dimers is retained at 20 °C, while in the polyesters (XIII) these complexes are stable only at low temperatures. The fluorescence spectra of the isolated anthroate end groups show that the rotational mobility of

the phosphor units in the polymer (XIV) is lower than in (XIII). The restricted mobility of these groups influences the formation of new dianthracene units on irradiation with light at the wavelength corresponding to the ^1L_a absorption band of the anthroate group.

The anthracene-containing polyurethanes (XV) and (XVI) were obtained[28] by the interaction of bis(2-hydroxyethyl)-9-anthrylmethyl malonate and the corresponding di-isocyanates in anisole for 6 h:



The polymers (XV) and (XVI) are soluble in THF and have molecular weights ranging from 4100 to 11000 according to gel-permeation chromatographic data.

Fig.3 presents the absorption and emission spectra of polyurethane (XV) films. The broad absorption bands at 360 and 380 nm are apparently associated with the presence of sandwich dimers, which are formed as a result of the close spacing of the anthryl groups parallel to one another. The fluorescence spectra of solutions of the polymers (XV) and (XVI) in THF correspond to transitions involving the emission from both monomeric units and excimers. The fluorescence excitation spectra of the polymer films are broader than the analogous spectra of the solutions, which indicates an appreciable role of the interaction between the macromolecules in the solid specimen.

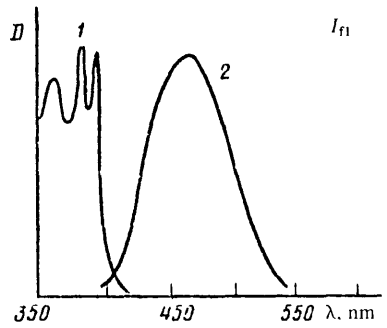


Figure 3. Absorption (curve *1*) and emission (curve *2*) spectra of a film of the polyurethane (XV).[28]

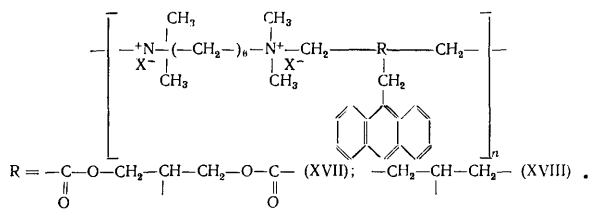
The light absorption and fluorescence properties of the polyionenes obtained by the Menshutkin reaction involving the interaction of 1,3-bis[halogenoacetoxy-2(9-anthryl)-methylpropane] or 2-[(9-anthryl)methyl]trimethylene halides with tertiary diamines have been described in a series of communications:[29-31]



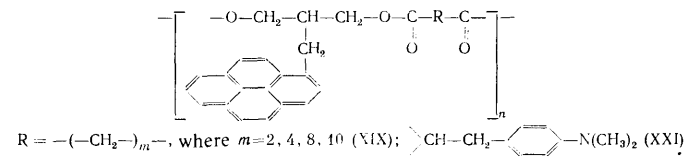
The polymers (XVII) and (XVIII) were synthesised in dimethylformamide, dimethylacetamide, dimethyl sulphoxide, or sulpholan at 40–60 °C over periods of 20–126 h.

Like other polymers with a similar structure,[15] the polyionenes obtained are apparently capable of forming conducting radical-ion salts with powerful electron acceptors (of the type of tetracyanoquinodimethane). The presence of the electron-donating anthryl groups in the polymers should have a favourable effect on the electrophysical characteristics of these systems.

The study of the fluorescent properties of the polyionenes (XVII) and (XVIII) showed that the formation of hydrophobic domains in aqueous solutions due to the anthrylmethyl groups, which are responsible for the appearance of a broad structureless excimer emission band with a maximum at 500 nm, is characteristic of these substances. The addition of methanol to solutions of the polymers promotes the decomposition of the hydrophobic domains and diminishes the intensity of the excimer fluorescence. On the other hand, the addition of electrolytes intensifies the excimer glow and this effect is greater the higher the ionic strength of the solution.

3. Pyrene-Containing and Other Polycondensation Polymers

Tazuke and co-workers considered the synthesis of a series of pyrene-containing polyesters based on monomers of the type of 3-pyrenylpropane-1,3-diol.[25,32-35] The use for this purpose of the reaction of the diol with dithiol esters of dicarboxylic acids at 150–170 °C initially in an inert atmosphere and then *in vacuo* made it possible to obtain the polymers (XIX) with molecular weights higher by a factor of 2–5 than in the traditional polycondensation of diols with acid dichlorides:[25,35]



The light absorption properties of the polyesters (XIX) are independent of the nature of the acid residue and are similar to the properties of the model compound (XX)—the product of the acylation of 3-pyrenylpropane-1,3-diol (λ_{max} = 344 nm). On the other hand, in the fluorescent properties of these systems there are differences (Fig.4) associated with the appearance of the exciplex glow (λ_{max} = 480–490 nm) in the case of the polymer.

The emission spectra of the polymers (XIX) are close to those of other pyrene-containing polyesters (XXI) with dimethylaniline side groups.[32-34] The latter were synthesised by the bulk polycondensation of the corresponding propanediol with diethyl 4-(*NN*-dimethylamino)benzyl malonate in the presence of calcium acetate as the catalyst at 160–210 °C *in vacuo*.

Polymers similar to the polyester (XXI) and containing electron-donating (*NN*-dimethylaniline) and electron-accepting (pyrenyl) groups are of interest from the standpoint of the formation of charge-transfer complexes, which as a rule exhibit an enhanced photosensitivity over a wide spectral range.[15,23]

The absorption and fluorescence spectra of solutions of the model compound (XX) and of the polyester (XXI) are compared in Fig.4*b*. Comparison of the absorption spectra of the polymer and the model indicates a weak interaction between the chromophores in the ground state. It was

found[32] that the ratio of the intensities of the exciplex fluorescence with λ_{max} = 498 nm and of the monomer fluorescence with λ_{max} = 377 nm increases with increasing concentration of the polymer solution and the character of the relation is determined by the nature of the solvent. Whereas in an effective solvent (dichloroethane) the relation $I_e/I_m = f(c)$ is linear, in a poor solvent (mesitylene) it tends to saturation. The authors concluded[32] that in mesitylene the intermolecular formation of the exciplexes reaches saturation at an early stage, while in dichloroethane their formation is facilitated by "allosteric" association in which the macromolecules are arranged relative to one another in such a way that the electron-accepting fragments of one of them adjoin the electron-donating fragments of another without disturbing the conformation of the polymer as a whole. Association of this kind is particularly favourable for macromolecules with a moderate molecular weight. Indeed the $I_e/I_m = f(n)$ relation for the polyesters (XXI), in which the degree of polycondensation n is controlled and varies from 1 to 18, passes through a maximum at n = 14 (in dichloroethane) and n = 7 (in mesitylene).[33]

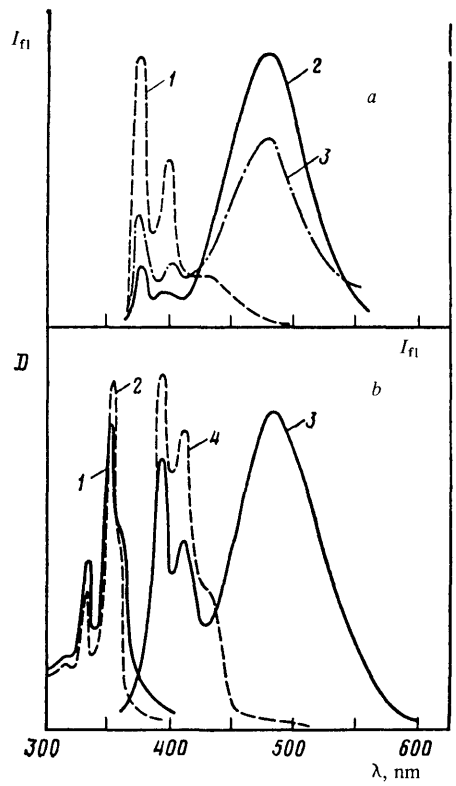


Figure 4. *a*) Emission spectra of solutions in THF of the model compound (XX) (curve *1*) and the polymer (XIX) with R = $-(CH_2)_2-$ (curve *2*) and $-(CH_2)_{10}-$ (curve *3*); *b*) absorption spectra (curves *1* and *2*) of solutions in 1,2-dichloroethane and emission spectra (curves *3* and *4*) of solutions in dioxan of the model compound (XX) (curves *2* and *4*) and the polymer (XXI) (curves *1* and *3*).[32]

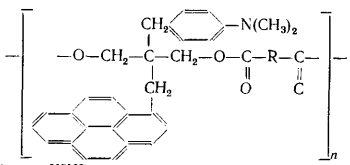
Together with intermolecular complex formation, intramolecular association also makes some contribution to the formation of exciplexes. This has been confirmed by the observation[33] that the model compound containing both the dimethylaniline and pyrenyl fragments exhibits an appreciable exciplex fluorescence regardless of the concentration of the solution. On the other hand, a solution of a mixture of two model compounds, each of which contains one of the above groups, does not exhibit an exciplex glow.

It has been shown[34] that the role of the intramolecular interactions in the polyesters (XXI) becomes dominant when the temperature is reduced to 77 K. In this case the band with λ_{max} = 498 nm disappears from the fluorescence spectra of the polymers and a new band appears with λ_{max} = 440 nm, which has been attributed to the emission of an electron donor–electron acceptor complex. Its formation is confirmed by the broadening of the band in the absorption spectra of solutions of the polymer (XXI) relative to the spectra of the model compounds. In contrast to the glow of the exciplexes, the intensity of the fluorescence of the donor–acceptor complexes increases with increasing molecular weight of the polymer and with decrease of temperature and is almost independent of the polymer concentration in solution.

The polyesters (XXII), which also contain the pyrene and dimethylaniline groups, but, in contrast to the polymers (XXI), these are attached to a single carbon atom, have been investigated:[35]



R = $-(-CH_2-)_m-$ (XXII); $-NH-(-CH_2-)_m-NH-$ (XXIV), where m=2–10.

Measurement of the fluorescence spectra of the polyesters (XXII) and of the model compound (XXIII)—the acylated 2-(4-*NN*-dimethylaminobenzyl)-2-(1-pyrenylmethyl)propane-1,3-diol—in solution in THF demonstrated the presence of a weak band with λ_{max} = 380 nm in the region corresponding to emission from the monomeric pyrene units and of intense exciplex fluorescence with λ_{max} = 520 nm.

Comparison of the emission spectroscopic data for the polymers (XXI) and (XXII) shows that the mutual approach of the electron-donating and electron-accepting fragments entails a bathochromic shift of the exciplex fluorescence. The authors emphasise[35] that the exciplex bands in the fluorescence spectra of solutions of the polyesters (XXII) and the model compound (XXIII) have different forms. The difference is apparently caused by the fact that only the intramolecular interaction of the donor with the acceptor occurs in solutions of the model compound at a concentration less than 10^{-5} M, while in the case of polymers both intramolecular and intermolecular interactions take place.

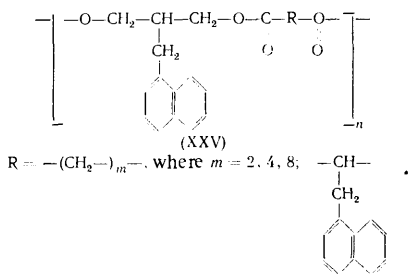
Other polymers with pyrenyl and dimethylaniline groups, namely the polyurethanes (XXIV), have been described.[36] They were synthesised by the interaction of 2-(4-*NN*-dimethylaminobenzyl)-2-(1-pyrenylmethyl)propane-1,3-diol with di-isocyanates in anisole at 150–160 °C in the presence of triethylamine as the catalyst.

The study of the fluorescence characteristic of solutions of the polymers (XXIV) showed that the position of the exciplex fluorescence maximum is in the range from 485 to 505 nm and depends significantly on the molecular weight of the polymer and its concentration in solution. The ratio I_e/I_m increases with increasing concentration in the intermediate range of molecular weights, which indicates the association of the macromolecules in solution. Comparison of the spectra of polymers in which the number of methylene

groups in the di-isocyanate residue is 6 and 8 demonstrated convincingly that even small changes in the structure of the polymers (XXIV) and hence in the rigidity of the polymer chain have an appreciable influence on the intermolecular and intramolecular formation of exciplexes and the fluorescence properties of the polymer.

Apart from the polymeric system with pyrenyl fragments examined above, polycondensation polymers with phosphor units of the naphthalene,[37-40] *p*-phenylenediacrylic,[41,42] 3-methoxybenzanthrone,[43] and naphthalimide[44] types are known.

Polyesters with the naphthylmethyl side groups (XXV) have been synthesised by the polycondensation of 2-[(1-naphthyl)-methyl]propane-1,3-diol with the diethyl esters of dicarboxylic acids at 150–160 °C for 3 h in an inert atmosphere and then *in vacuo* for 10 h:[37]



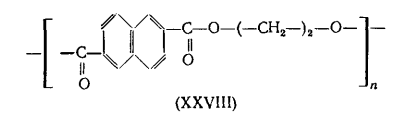
(XXV)

R = $-(CH_2-)_m-$, where $m = 2, 4, 8$; $-CH-$ with CH_2 and a naphthyl group

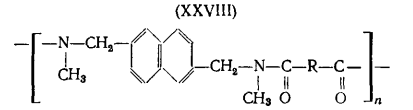
According to gel-permeation chromatographic data, the polymers have a low molecular weight (n = 3–10).

The study of the fluorescence properties of the polymers (XXV) was preceded by the investigation of model compounds—1,3-bisacetoxy-2-(1-naphthyl)methylpropane (XXVI) and di[3-(1-naphthyl)propyl]adipate (XXVII). It was found that, in contrast to the emission spectra of the model compound (XXVI), those of solutions of the polymers (XXV) contain, together with the monomeric fluorescence band having λ_{max} = 324 nm, also a broad excimer band with λ_{max} = 400 nm. The intramolecular formation of excimers takes place even in those cases where the naphthyl groups are separated by 16 carbon atoms and two oxygen atoms. The ratio I_e/I_m for the polymeric system (XXV) is higher that for the corresponding dimeric system (XXVII). The authors[37] explain this by the fact that the local concentration of the naphthyl units in the ground state in the vicinity of the excited group, considered in isolation, is higher in the polymer macromolecule than in the dimeric system.

The fluorescence properties of naphthalene-containing polymers of another type, namely the polyesters (XXVIII) and polyamides (XXIX) with naphthalene nuclei bound directly in the main polymer chain, have been described:[38,39]



(XXVIII)



(XXIX)

R = $-(-CH_2-)_m-$, where $m = 2, 4, 6, 8$.

Comparison of the fluorescence properties of the polyesters (XXV) and (XXVIII) shows that the introduction of the naphthalene fragments into the main polymer chain induces a bathochromic shift of the monomer and excimer glow. The ratio of the intensities of the excimer (λ_{max} = 420 nm) and monomer (λ_{max} = 370 and 385 nm) fluorescence of solutions of the polymer (XXVIII) in chloroform increases by a factor of 3 when its concentration rises from 0.024 to 43 dl g^{-1} and, on passing to solid films, the increase is by a factor greater than 6 (compared with the minimum concentration in solution). The same type of dependence of I_e/I_m on the polymer concentration in solution has been observed also for the phenyl-containing polyester.[39] However, in the case of the polyester (XXVIII) one observed the formation of intramolecular excimers, which fluoresce even in very dilute solutions, and this is apparently associated with the longer lifetime of the excited states of the naphthyl chromophores. This is valid also for other types of naphthalene-containing polymers.[1]

We shall consider the formation of fluorescent intermolecular charge-transfer complexes in relation to the polyamide (XXIX).[38] We may note that the only complete review of studies on such complexes has been published recently.[40]

Fig.5 presents the fluorescence spectra of dilute solutions of the polyamide (XXIX) (m = 4) in methylene chloride in the presence and absence of a low-molecular weight electron donor (triethylamine). Evidently, when triethylamine is added to the polyamide, the intensity of the intrinsic fluorescence of the polymer, with a maximum at 360 nm, diminishes and a broad exciplex fluorescence band appears with a maximum at 500 nm. A linear relation has been found between the concentration of triethylamine and the ratio I_e/I_m. It has been shown that tendency towards the formation of exciplexes diminishes in the series of polyamides with decrease of m in the acid residue, i.e. in parallel with increasing steric restriction of the mobility of the naphthyl groups.

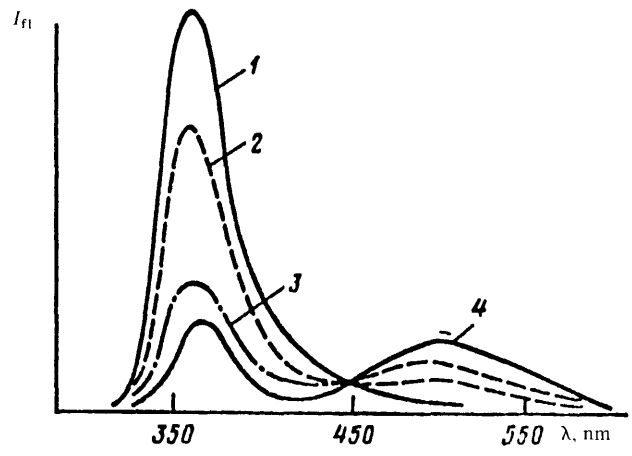


Figure 5. Fluorescence spectra of solutions of the polyamide (XXIX) (m = 4) in methylene chloride in the absence of triethylamine (curve *1*) and in the presence of various concentrations of triethylamine (M): *2*) 0.01; *3*) 0.06; *4*) 0.19.[38]

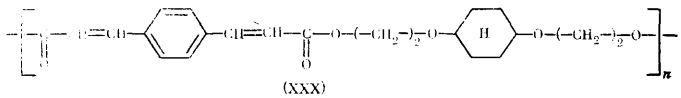
An industrial photoconducting polymer (XXX), used for the preparation of printing plates and obtained from *p*-phenylenediacrylic acid and 1,4-bis(2-hydroxyethoxy)-cyclohexane, has been investigated from the standpoint of its fluorescence properties:[41,42]



(XXX)

At the same time a study was made of the fluorescence characteristics of the model compound (XXXI), namely the diethyl ester of *p*-phenylenediacrylic acid. Fig.6, which presents the emission spectra of these two systems, shows that those of solutions of the model compound and the polymer (XXX) contain short-wavelength monomer fluorescence bands with a maximum at 370 nm and a longer-wavelength broad band due to the excimer glow, the intensity ratio of these bands depending on the concentration of the solution. The spectrum of a film of the polymer shows only the excimer fluorescence with a maximum at 470 nm.

It has been shown[41] that the kinetics of the decay of the glow in the region of 470 nm can be fitted by the sum of two exponential functions; the short-lived fluorescence is due to the monomer, but the long-lived fluorescence is due to the excimers. The lifetime of the long-lived fluorescence diminishes with increasing concentration of the phenylene diacrylate groups, which indicates a bimolecular character of the decay of the excimer glow. It has been found that the excimers are formed on excitation of pairs of chromophores already present in solution before excitation.

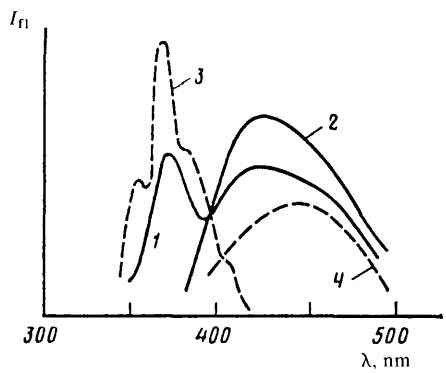


Figure 6. Emission spectra of dilute solutions of the polymer (XXX) (curve *1*) and the model compound (XXXI) (curve 3) in 1,2-dichloroethane, of a film of the polymer (XXX) (curve *2*), and of a concentrated solution of the polymer (XXXI) (curve *4*).[41]

The melaminotoluene-*p*-sulphonamideformaldehyde (MTSF) resins, which are frequently used as the polymer base for the preparation of daylight fluorescent pigments,[4] can be classified as an aliphatic polycondensation polymer. The phosphor containing a reactive group is added in the synthesis stage of the MTSF resins, which consists in heating a mixture of toluene-*p*-sulphonamide, melamine, and formaldehyde; the resulting polymer is chemically bound to the phosphor molecule. The chloromethyl, hydroxymethyl, carboxy, anhydride, or amino-groups can be used as the reactive groups of this kind, while 3-methoxybenzanthrone residues[43] and derivatives of 1,8-naphthalic acid[4,44] can serve as the phosphor fragments.

Analysis of the available data on the synthesis and spectroscopic properties of fluorescent polycondensation polymers permits the conclusion that those whose phosphor fragments were introduced into the macromolecule via the diamine (diol) component and not via the acid component have been most thoroughly investigated. The phosphor groups are mainly responsible for the long-wavelength absorption and fluorescence characteristics of the polymers and the emission spectra can show both the monomer bands and the excimer (exciplex) fluorescent bands. The tendency towards the formation of exciplexes increases appreciably when the macromolecule contains fragments capable of intramolecular and intermolecular donor–acceptor interaction.

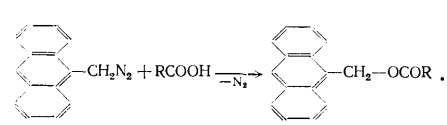
III. PRODUCTS OF POLYMER-ANALOGUE TRANSFORMATIONS

The first fluorescent polymers obtained by the method of polymer-analogue transformations have been proteins coloured by active luminescent dyes. A condition for the covalent binding of these dyes to proteins having SH, OH, and H_2N side groups is the presence in them of reactive groups of the type of SO_2Cl, N=C=O, and N=C=S. Derivatives of naphthalene, anthracene, fluorescein, rhodamine, and a number of others are used to dye proteins.[45]

The study of protein macromolecules labelled with luminescent dyes makes it possible to investigate the properties of electronically excited states and the specific features of the electronic transitions in such systems and enables one to follow the kinetics of the structural and physicochemical transformations of proteins.[46] Furthermore, the purely analytical use of the luminescence for the determination of the protein in biological preparations is of considerable interest.[4]

Some of the early investigations of macromolecules with phosphor side groups were those of Wahl,[47,48] who described the interaction of polymers containing amino-groups (of the type of polyvinylamine, poly-*p*-aminostyrene, and polyethyleneimine) with 1-dimethylaminonaphthalenesulphonyl chloride. The reaction was carried out by mixing an aqueous solution of the polymer with a solution of the sulphonyl chloride in acetone. Depending on the reactant ratio, fluorescent polymers with different numbers of naphthalene groups in the side chain are formed.

Later the luminescent units were introduced into the side chains of polymers by the reaction of their carboxy-groups[49–53,55] (see also Metaga and Kubota[54]), the acid chloride groups,[56] hydroxy-groups,[57–61] or benzene rings.[51,62] The interaction of polymeric acids of the type of polyacrylic and polymethacrylic acids or their copolymers with phosphors such as 9-anthryldiazomethane, 9-methyl-10-anthryldiazomethane, or diazomethyl α-naphthyl ketone has been investigated.[49–51] The reaction was carried out both in a homogeneous medium (methanol) and in immiscible solvents (water–hexane) at 20–55 °C:

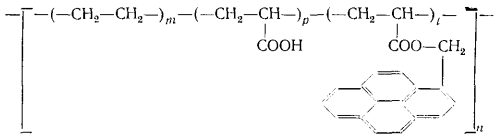


The concentration of the fluorescent groups introduced can be varied within wide limits by altering the polymer : diazomethane ratio. The fluorescence properties of the resulting polymers were similar to those of the model 9-anthrylacetoxymethane. Monomer fluorescence without an admixture

of the glow due to excimers is characteristic of both types of compounds. The study of polymers labelled with anthracene fragments made it possible to employ the method of polarised luminescence[63,64] for the investigation of the relaxation phenomena in solutions of macromolecules (intramolecular and intermolecular interactions, structure formation, gel formation, etc.).

The interaction between 9-anthryldiazomethane and the copolymers of styrene with acrylic, methacrylic, and vinylbenzoic acids followed by spectrophotometric measurements on the reaction product in the range 390–410 nm has been suggested for the analytical determination of the content of carboxy-groups in these polymers.[50]

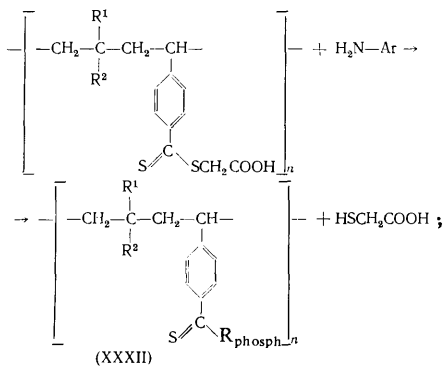
Polymeric styrene-containing sensitisers (XXXI), which are of interest for the preparation of photosensitive layers, have been obtained[53] from a radiation-modified polyethylene containing 45–47% of grafted COOH groups. Compound (XXXI) was synthesised by the reaction of the modified polyethylene with 1-hydroxymethylpyrene in THF or acetonitrile at 60 °C in the presence of dicyclohexylcarbodiimide as the catalyst.



(XXXI)

The study of the fluorescence properties of films of the polymers (XXXI) with different degrees of esterification showed that the intensity of the excimer fluorescence with λ_{max} = 465 nm increases as the concentration of the pyrene groups rises.

A number of interesting coloured polymers exhibiting a weak fluorescence have been described.[52] They were obtained by the reaction of polyethylene-4-thiobenzoylthio-2-acetic acid or the copolymers of the initial thioester with styrene, methyl methacrylate, or methacrylic acid and diamines of the type of Acridine Yellow, 1-aminoanthraquinone, and Cresol Blue:



(XXXII)

$R^1 = C_6H_5$, $R^2 = H$; $R^1 = CH_3$, $R^2 = COOH$ or $COOCH_3$; R_{phosph} = phosphor residue.

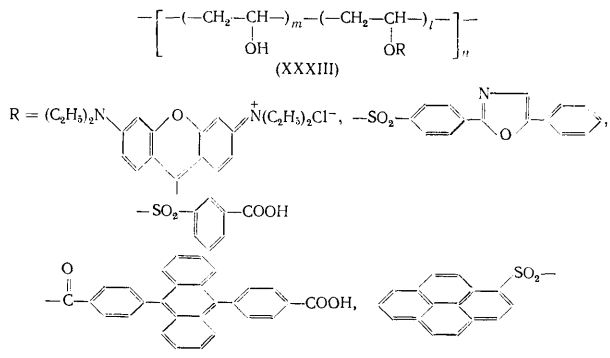
The reaction is carried out in a 1 : 1 dimethylformamide–benzene mixture with a polymer : amine ratio of 2 : 1 for 24 h at room temperature. The fluorescence properties of the copolymers (XXXII) were not investigated in detail. It was only noted that the intensity of the glow of the initial dyes, for example, of Acridine Yellow, diminishes appreciably after binding to the polymer. The authors[52] do not give any explanation of the observed phenomenon. In our view its possible cause is the formation of hydrogen bonds between the diaminoacridine fragment and the hydrogen donor present in the system, namely thioglycolic acid, which promotes the quenching of the fluorescence according to Mataga and Kubota.[54]

Whereas the carboxy-groups of the polymers have been used in a number of studies[49–53] to form strong covalent bonds with the fluorescent molecule, in the systems described by Fenyo[55] the bond linking polyacrylic and polymethacrylic acids to the phosphor amine is salt like. Fenyo's aim[55] was to investigate the conformational behaviour of the macromolecule in solution. Compounds which the authors chose as the amines were auramine, which does not dimerise and exhibits a weak fluorescence, and 9-aminoacridine hydrochloride, which is capable of forming dimers and exhibits an intense fluorescence. It has been shown that the binding of the dye is determined by three factors: the nature and conformational state of the polyions (the degree of ionisation α), the polymer : dye molar ratio, and the ionic strength of the solution. The intensity of the emission by auramine increases by a factor of 100 in the presence of poly(methacrylic acids). An increase of the fluorescence quantum yield and of the relative content of the bound dye with increasing polymer : dye ratio has been observed for this compound.

An increase in the degree of ionisation of the polymeric acid diminishes the efficiency of the binding of the dye to the polymer in the case of auramine and, conversely, leads to its increase in the case of 9-aminoacridine hydrochloride. Furthermore, it has been observed that, for low values of α, the addition of poly(methacrylic acids) to the last phosphor diminishes the intensity of its fluorescence. Fenyo[55] put forward an explanation of the observed differences in the behaviour of the phosphors on the basis of a comparison of the rigidities of the skeletons of their molecules and the presence of side groups in the latter.

We shall now proceed to the polymer-analogue transformations of hydroxylated polymers. Fluorescein isothiocyanate has been used[57] as reagent with the OH groups of a constituent of starch, namely amylose having a molecular weight of 1700. The fluorescence lifetimes of the resulting polymer were measured at different concentrations and pH of the solutions.

The luminescence-spectroscopic properties of films and solutions of poly(vinyl alcohol) (XXXIII), containing four types of phosphors as side groups, namely diphenyloxadiazole, diphenylanthracene, rhodamine B, and pyrene, have been investigated:[58–60]



(XXXIII)

The polymers (XXXIII) were synthesised by treating poly(vinyl alcohol) with the corresponding sulphonyl chloride or acid chloride in *N*-methylpyrrolidinone, initially at room temperature and then at 60–70 °C. Depending on the ratio of the initial reactants, polymers containing from 5 to 10 phosphor fragments per 1000 elementary units were obtained.

The polymers (XXXIII) exhibit an intense fluorescence and are highly soluble in water, which permits their use as luminescent probes in the study of biological membranes.[63] The polymeric structure of these probes determines their enhanced selectivity in relation to individual cell components as compared with low-molecular-weight phosphors.

Fig.7 presents the absorption and emission spectra of specimens of the first three types of polymers (XXXIII) in the form of thin films. Their comparison with the spectra of the initial phosphor monomers[4] demonstrates their similarity. The similarity of the fluorescence characteristics of the polymers to those of the corresponding low-molecular-weight compounds confirms the monomer character of the emission without an appreciable contribution by excimer states. The same conclusion can be reached on the basis of a comparison of the emission spectra of solutions of these systems.

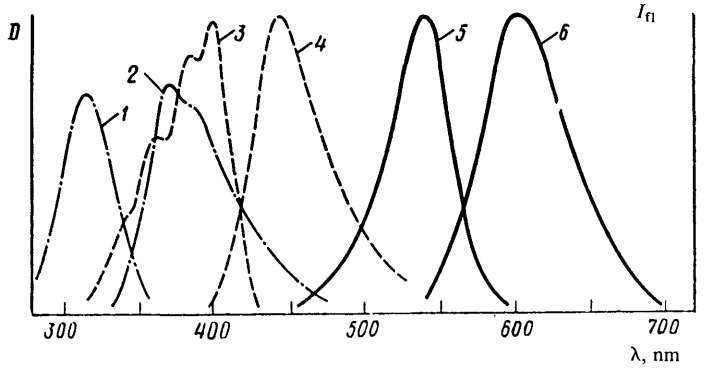


Figure 7. Absorption (curves *1*, *3*, and *5*) and fluorescence (curves *2*, *4*, and *6*) spectra of films of the polymers (XXXIII) containing diphenyloxazole (curves *1* and *2*) diphenylanthracene (curves *3* and *4*), and rhodamine B (curves *5* and *6*) units in the side chain.[60]
