Electrochemical Optical Spectroscopy of Metals

A.M.Brodskii, L.I.Daikhin, and M.I.Urbakh

Modern methods of interpreting experimental results obtained by electrochemical optical spectroscopy (EOS) of metal surfaces are discussed. An attempt is made to unify the results so far obtained by this method by searching for correlations between experimental data and the special features of the electronic structure of the metal-electrolyte interface. The comparison is made in the framework of the semi-phenomenological theory.
The bibliography contains 183 references.

I. INTRODUCTION

In a new method of studying the physicochemical properties of the interface between an electrode and an electrolyte, the metal surface is monitored *in situ* by analysing the reflectance spectra in the frequency range from the infrared to the near ultraviolet. We shall call this field of work, which is the object of the present review, electrochemical optical spectroscopy (EOS). The method exploits the advantages of combining electrochemical and optical procedures: these include the possibility of continuously monitoring the surface and of controlling its state (including adsorption) under equilibrium conditions. Another important consideration is the high precision of the measurements by the potential modulation technique.[1]

The successful application of EOS in these systems has stimulated the transfer to other systems (with suitable modifications) of optical methods developed for the study of electrode—electrolyte interfaces. These methods offer attractive prospects for *in situ* study and control of heterogeneous catalytic processes in non-polar as well as in polar media.

Historically, one of the earliest optical methods which we could classify as EOS is the study of photo-electrochemical processes: it has already been reviewed extensively,[2-4] and will not be considered further here. Our principal aim will be to analyse methods of interpreting the results obtained in recent developments of the EOS method: ellipsometry, electro-reflectance, phase modulation of the reflected light, surface-enhanced Raman scattering spectroscopy, and surface plasmon spectroscopy. We have tried to give a unified presentation of all the results so far reported and to bring existing reviews up to date.[5-14] The conclusions which can legitimately be inferred from EOS data are examined in terms of specific experimental information.

II. EXPERIMENTALLY MEASURABLE QUANTITIES AND BASIC FORMULAE

Most of the experimental optical methods of studying metal electrode surfaces rely on measurements of the characteristics of the reflected light. In the case of elastic reflection of light from a planar, uniform interface these characteristics are expressed through the two complex quantities r_s and r_p (the amplitudes of the reflection coefficients of the s- and p-polarised light respectively). The following parameters are often measured directly: the light reflection coefficient $R_{s(p)} = |r_{s(p)}|^2$, the phase $\delta_{s(p)} = (1/2i)\ln(r_{s(p)}/r^*_{s(p)})$, and the ellipsometric parameters ψ and Δ, defined by the expressions $\tan\psi = |r_p/r_s|$ and $\Delta = \delta_p - \delta_s$. Here $i = (-1)^{1/2}$, and the symbol * denotes the complex conjugate. The quantities r_s and r_p depend on the frequency of the light ω, on the angle of incidence and on the orientation of the surface relative to the symmetry elements of the lattice of the monocrystalline electrode, and (most important in electrochemical applications) on the potential step E and other parameters which characterise the state of the surface.

Studies of the metal—electrolyte interface can give information on the changes in $r_{s(p)}$ caused by changes in the properties of the surface. The most accurate results are obtained by using an electrochemical modulation procedure in which the potential applied to the interface has a periodic component:

$$E = E_0 + \delta E \sin \Omega t; \qquad (1)$$

and by applying noise separation techniques to the full reflected signal a harmonic of frequency Ω can be extracted. For small amplitudes of the modulation δE the $r_{s(p)}$ values (like other characteristics of the system) can be expressed as

$$r_{s(p)} = R^{1/2}_{0s(p)}\, e^{i\delta_{0s(p)}} + \frac{d r_{s(p)}}{d E}\bigg|_{E=E_0} \delta E \sin(\Omega t + \delta'). \qquad (2)$$

where $\delta_{0s(p)}$ and $R_{0s(p)}$ are the phase and the reflection coefficient for a fixed value of the potential step $E = E_0$. Eqn.(2) is correct if the function $dr_{s(p)}/dE$ does not have a singularity at $E = E_0$. This stipulation may not apply in some special cases,[15] which therefore require a special treatment (see Section III). The phase shift δ' in Eqn.(2) is finite if the potential-induced changes in the processes which affect the optical properties of the system are slow enough (i.e. if their characteristic time is $\sim\Omega^{-1}$) (see below, p.5).

Modulation methods include electro-reflectance (ER),[1] in which the quantity $(1/R_{s(p)})dR_{s(p)}/dE$ is measured, modulation ellipsometry,[16] in which $d\Delta/dE$ and $d\psi/dE$ are measured, and the electro-modulation of the reflected phase (ERP) method,[17-19] in which $d\delta_{s,p}/dE$ is measured. The ERP method was first applied successfully very recently.[19]

We can distinguish two stages in the interpretation of light reflection data from an electrode surface and in extracting information on the structure of the electrode/electrolyte interface. The first stage consists in establishing a correlation between the optical characteristics of the surface and experimentally observable quantities. In electrochemical systems the contribution of the surface to the optical response is determined by the properties of different parts of the interface region. The most informative (as regards determining the electronic properties of the metal/electrolyte interface) is the contribution from a region of microscopic thickness (~1 Å) near the electrode surface, in which the electron density varies from values characteristic of the metal to values characteristic of the electrolyte. Another contribution to the optical response comes from the dependence of the dielectric constant of the electrolyte on the potential step in the macroscopic diffusion region near the electrode.

It has been shown[20-28] that the following three complex functions of frequency and potential are the main optical characteristics of the microscopic region:

$$\Delta\varepsilon_{2(3)}(\omega, E) = \int dx_1\, dx_1' \delta\varepsilon_{2(3)}(x_1, x_1'; \omega, E)$$

$$\Delta\varepsilon^{-1}_{(1)}(\omega, E) = \int dx_1\, dx_1' [\varepsilon^{-1}_{(1)}(x_1, x_1'; \omega, E) - \varepsilon_0^{-1}(x_1, \omega)\delta(x_1 - x_1')] \quad (3)$$

where

$$\varepsilon_0(x_1, \omega) = \varepsilon_m(\omega)\theta(-x_1) + \varepsilon_{el}\theta(x_1);$$
$$\delta\varepsilon_{2(3)} = \varepsilon_{2(3)}(x_1, x_1', \omega, E) - \varepsilon_0(x_1, \omega)\delta(x_1 - x_1').$$

Here the X_1 axis is normal to the electrode surface, which coincides with the $x_1 = 0$ plane; $\varepsilon_i(x_1, x_1'; \omega, E)$ are the diagonal components of the dielectric permeability tensor averaged over the surface† (i = 1. 2. 3 for the X_1, X_2, X_3 axes respectively), which describes the linear response of the system to an external electromagnetic field; $\varepsilon_m(\omega) = \varepsilon'_m(\omega) + i\varepsilon''_m(\omega)$ is the bulk dielectric constant of the metal; ε_{el} is the bulk dielectric constant of the electrolyte, which is a real quantity at optical frequencies; $\Theta(x)$ is a function of the step [$\Theta(x) = 1$ for $x > 0$ and $\Theta(x) = 0$ for $x < 0$]. The quantity $\varepsilon^{-1}_{(1)}(x_1, x_1'; \omega, E)$ which appears in Eqn.(3) is defined by the expression

$$\int dx_1'' \varepsilon_1(x_1 x_1''; \omega, E)\, \varepsilon^{-1}_{(1)}(x_1'', x_1'; \omega, E) = \delta(x_1 - x_1'). \quad (4)$$

The metal is assumed to be in the half-space $x_1 < 0$, and the electrolyte in the half-space $x_1 > 0$ (Fig.1). The integration with respect to x_1 is carried out over the whole space. The changes in amplitude of the light reflection coefficients $\Delta r_{s,p} = r_{s,p} - r^F_{s,p}$ are expressed in terms of the quantities (3) as follows:#

$$\frac{\Delta r_s(k_\parallel, \omega)}{r^F_s} = i\frac{2[(\omega^2/c^2)\varepsilon_{el} - k_\parallel^2]^{1/2}}{\varepsilon_{el} - \varepsilon_m}\Delta e_3$$

$$\frac{\Delta r_p(k_\parallel, \omega)}{r^F_p} = -i\frac{2\varepsilon_{el}[(\omega^2/c^2)\varepsilon_{el} - k_\parallel^2]^{1/2}\{[(\omega^2/c^2)\varepsilon_m - k_\parallel^2]\Delta\varepsilon_2 + \varepsilon_m^2 k_\parallel^2 \Delta\varepsilon^{-1}_{(1)}\}}{(\varepsilon_{el} - \varepsilon_m)[(\varepsilon_{el} + \varepsilon_m)k_\parallel^2 - (\omega^2/c^2)\varepsilon_m\varepsilon_{el}]}. \quad (5)$$

Here $r^F_{s,p}$ are the unperturbed reflection amplitudes, determined by the classical Fresnel formulae, and $k_\parallel$ is the projection of the wave vector on the plane of the electrode surface§; the (X_1, X_2) plane is assumed to coincide with the plane of incidence of the light.

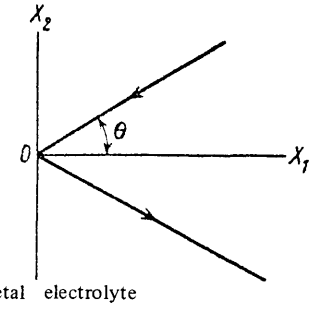

Figure 1. Reflection of light from the metal/electrolyte interface: (X_1, X_2) is the incidence plane of the light, the axis X_3 is normal to the plane of the paper, θ is the angle of incidence.

By using Eqn.(5) for the amplitude $\Delta r_{s,p}$ all the experimentally measured quantities listed above can easily be calculated:

† Throughout this paper the term averaging over the surface will be applied to the process of averaging over a plane parallel to the surface of the electrode and at a distance x_1 from it.

The spatial dispersion of the dielectric constant in the bulk of the metal, which is important only in the silver/electrolyte system at the frequencies used in electrochemistry, is ignored in formulae (5). Formulae which allow for spatial dispersion are given in Refs.20, 21, and 29.

§ Formulae (5) as written are correct if the electrode material has a cubic symmetry (say), and the orientation of the crystal relative to the incidence plane of the light is such that the directions X_1 and X_2 coincide with the crystallographic axes of the crystal. Under these conditions the dielectric permeability tensor $\delta\varepsilon_{ij}(x_1, x_1')$ is diagonalised, $\delta\varepsilon_{ij}(x_1, x_1') = \delta_{ij}\delta\varepsilon_i(x_1, x_1')$. If the surface is isotropic we also have $\delta\varepsilon_2 = \delta\varepsilon_3$. The tensor $\delta\varepsilon_{ij}$ has a diagonal form, and $\delta\varepsilon_2 = \delta\varepsilon_3$, in the frequently encountered case of a polycrystalline electrode. Formulae which apply to this case are given in Refs.20, 21, 28.

$$\frac{1}{R_s}\cdot\frac{dR_s}{dE}=-\frac{4\omega(\varepsilon_{el})^{1/2}\cos\theta}{c}\,\mathrm{Im}\left[\frac{d\Delta\varepsilon_s/dE}{\varepsilon_{el}-\varepsilon_m}\right] \quad (6a)$$

$$\frac{1}{R_p}\frac{dR_p}{dE}=-\frac{4\omega(\varepsilon_{el})^{1/2}\cos\theta}{c}\times$$
$$\times\,\mathrm{Im}\left[\frac{(\varepsilon_m-\varepsilon_{el}\sin^2\theta)\,d\Delta\varepsilon_p/dE+\varepsilon_{el}\varepsilon_m^2\sin^2\theta\,d\,\Delta\varepsilon_{(1)}^{-1}/d\,E]}{(\varepsilon_m-\varepsilon_{el})(\varepsilon_{el}\sin^2\theta-\varepsilon_m\cos^2\theta)}\right] \quad (6b)$$

$$\frac{d\delta_s}{dE}=\frac{2\omega(\varepsilon_{el})^{1/2}\cos\theta}{c}\,\mathrm{Re}\left[\frac{d\Delta\varepsilon_s/d\,E}{\varepsilon_{el}-\varepsilon_m}\right] \quad (6c)$$

$$\frac{d\delta_p}{dE}=\frac{2\omega(\varepsilon_{el})^{1/2}\cos\theta}{c}\,\mathrm{Re}\left[\frac{(\varepsilon_m-\varepsilon_{el}\sin^2\theta)\,d\,\Delta\varepsilon_s/d\,E+\varepsilon_{el}\varepsilon_m^2\sin^2\theta d\Delta\varepsilon_{(1)}^{-1}/d\,E}{(\varepsilon_m-\varepsilon_{el})(\varepsilon_{el}\sin^2\theta-\varepsilon_m\cos^2\theta)}\right] \quad (6d)$$

$$\frac{d\psi}{dE}=-\frac{\tan\psi^F}{1+\tan^2\psi^F}\cdot\frac{4\omega(\varepsilon_{el})^{1/2}\cos\theta}{c}\times$$
$$\times\,\mathrm{Im}\,\frac{\varepsilon_{el}\varepsilon_m^2\sin^2\theta d\Delta\varepsilon_{(1)}^{-1}/dE+\varepsilon_{el}\sin^2\theta\frac{d}{dE}(\Delta\varepsilon_2-\Delta\varepsilon_3)+\varepsilon_m\frac{d}{dE}(\Delta\varepsilon_2-\Delta\varepsilon_3\cos^2\theta)}{(\varepsilon_m-\varepsilon_{el})(\varepsilon_{el}\sin^2\theta-\varepsilon_m\cos^2\theta)} \quad (6e)$$

$$\frac{d\Delta}{dE}=-\frac{2\omega(\varepsilon_{el})^{1/2}\cos\theta}{c}\times$$
$$\times\,\mathrm{Re}\,\frac{\varepsilon_{el}\varepsilon_m^2\sin^2\theta\,d\Delta\varepsilon_{(1)}^{-1}/d\,E+\varepsilon_{el}\sin^2\theta\frac{d}{dE}(\Delta\varepsilon_2-\Delta\varepsilon_3)+\varepsilon_m\frac{d}{dE}(\Delta\varepsilon_2-\Delta\varepsilon_3\cos^2\theta)}{(\varepsilon_m-\varepsilon_{el})(\varepsilon_{el}\sin^2\theta-\varepsilon_m\cos^2\theta)}. \quad (6f)$$

Here $\tan\psi^F=|r_p^F/r_s^F|$. We note that the form of Eqn.(6) is independent of the specific model chosen to describe the optical properties of the surface.

Formulae (6a) and (6b) differ from the expressions obtained from the standard three-layer model,[5] in which two parameters are used to describe the optical properties of a reflecting surface: the thickness d and the dielectric constant ε_l of the transition layer. In the calculation by this model Eqns.(6a) and (6b) are replaced by

$$\frac{1}{R_s}\frac{dR_s}{dE}=-\frac{4d\omega(\varepsilon_{el})^{1/2}\cos\theta}{c}\cdot\frac{d}{dE}\,\mathrm{Im}\,\frac{\varepsilon_l-\varepsilon_m}{\varepsilon_{el}-\varepsilon_m} \quad (7a)$$

$$\frac{1}{R_p}\frac{dR_p}{dE}=\frac{4d\omega(\varepsilon_{el})^{1/2}\cos\theta}{c}\cdot\frac{d}{dE}\cdot\mathrm{Im}\left[\frac{\varepsilon_l-\varepsilon_m}{\varepsilon_m-\varepsilon_{el}}\,\frac{1-\frac{\varepsilon_{el}}{\varepsilon_l\varepsilon_m}(\varepsilon_m+\varepsilon_l)\sin^2\theta}{1-\frac{1}{\varepsilon_m}(\varepsilon_m+\varepsilon_{el})\sin^2\theta}\right] \quad (7b)$$

Whereas the expressions (6a) and (7a) for the reflection of s-polarised light are structurally similar, the expression (6b) for p-polarised light is very different from the corresponding expression (7b) given by the three-layer model. This difference arises partly because in real systems the quantity $\Delta\varepsilon_{(1)}^{-1}$ which appears in (6b) cannot be expressed through the average value of the dielectric constant for the layer (ε_l). However, the most important consideration is that the formal use of the three-layer model (with an anisotropic active layer) complicates the interpretation of experimental data at the microscopic level (see Section III).

Changes in the potential step at the electrode/solution boundary affect not only the electronic properties of the surface but also the distribution of the components in the diffusion layer of the solution, thus affecting the dielectric constant in this region. Hence the measured quantities are determined both by the optical characteristics of the microscopic surface layer and by the characteristics of the macroscopic diffusion layer. In the linear approximation to the interaction of light with the surface region¶ the full ER and ERP signals are described by a sum of terms for the separation effects of these layers. It has been shown[30-32] that under certain conditions the ER and ERP signals are determined by the interaction of the incident light with the macroscopic diffusion layer of the electrolyte. The corresponding expressions for the active components† of the ER and ERP signals are:[32]

$$\left(\frac{1}{R_s}\frac{dR_s}{dE}\right)_a=\sum_i\frac{\partial\varepsilon_{el}}{\partial c_{i,0}}\frac{dc_i(d)}{dE}\cdot\frac{1}{Z_1}\cdot\frac{2l}{(l^4+1)\cos\theta}\times$$
$$\times\{\cos\delta_i[l(1-l^2)-b_1\cos\theta\cdot l^2]+\sin\delta_i\cdot[b_1\cos\theta+l(l^2+1)]\} \quad (8a)$$

$$\left(\frac{d\delta_s}{dE}\right)_a=\frac{1}{2}\sum_i\frac{\partial\varepsilon_{el}}{dc_{i\,0}}\frac{dc_i(d)}{dE}\cdot\frac{l}{(l^4+1)\cos\theta}\times$$
$$\times\left\{\frac{1}{n_{el}^2\cos\theta}[l^2\cos\delta_i-(2+l^4)\sin\delta_i]-\frac{2}{Z_2}[\cos\delta_i(l^2b_2\cos\theta+\right.$$
$$\left.+(1-l^2)l)-\sin\delta_i(b_2\cos\theta-(1+l^2)l)]\right\} \quad (8b)$$

$$\left(\frac{1}{R_p}\frac{dR_p}{dE}\right)_a=\sum_i\frac{\partial\varepsilon_{el}}{\partial c_{i.0}}\frac{dc_i(d)}{dE}\cdot\frac{[4l\cos2\theta]}{l^4+1}\cdot\frac{n_m'n_m''}{f_1(\theta)}\times$$
$$\times\frac{\cos\delta_i[l(1-l^2)-l^2f_1(\theta)]+\sin\delta_i[l(1+l^2)+f_1(\theta)]}{\{[(n_m')^2-(n_m'')^2]\cos^2\theta-n_{el}^2\}^2+4(n_m'n_m'')^2\cos^4\theta} \quad (8c)$$

$$\left(\frac{d\delta_p}{dE}\right)_a=\frac{1}{2}\sum_i\frac{\partial\varepsilon_{el}}{\partial\varepsilon_{i,0}}\cdot\frac{dc_i(d)}{dE}\cdot\frac{l\cos2\theta}{(l^4+1)n_{el}\cos\theta}\left\{\frac{l^2\cos\delta_i-\left(1+\frac{1+l^4}{\cos2\theta}\right)\sin\delta_i}{n_{el}\cos\theta}-\right.$$
$$\left.-\frac{\sqrt{2}\,n_m''\{[(n_m')^2+(n_m'')^2]\cos^2\theta+n_{el}^2\}\{\cos\delta_i[l(1-l^2)+f_2(\theta)l^2]-\sin\delta_i[f_2(\theta)-l(1+l^2)]\}}{[(n_m')^2-(n_m'')^2]^2\cos^2\theta-n_{el}^2]^2+4(n_m'n_m'')^2\cos^4\theta}\right\} \quad (8d)$$

$$l=2\frac{\omega}{c}\xi_0n_{el}\cos\theta;\quad n_{el}=(\varepsilon_{el})^{1/2};$$

$$n_m'+in_m''=(\varepsilon_m)^{1/2};$$

$$b_1=\frac{2\sqrt{2}\,n_m''n_{el}}{(n_m')^2+(n_m'')^2-n_{el}^2};\quad b_2=\frac{\sqrt{2}\,n_{el}[(n_m')^2-(n_m'')^2-n_{el}^2]}{n_m''[(n_m')^2+(n_m'')^2+n_{el}^2]};$$

$$Z_1=\frac{\sqrt{2}\,n_{el}\{[(n_m')^2-(n_m'')^2-n_{el}^2]^2+4(n_m'n_m'')^2\}}{n_m'[(n_m')^2+(n_m'')^2-n_{el}^2]};$$

$$Z_2=\frac{\sqrt{2}\,n_{el}[(n_m')^2-(n_m'')^2-n_{el}^2]^2}{n_m''[(n_m')^2+(n_m'')^2+n_{el}^2]};\quad f_1(\theta)=\frac{2\sqrt{2}\,n_m''n_{el}\cos\theta}{[(n_m')^2+(n_m'')^2]\cos^2\theta-n_{el}^2}$$

$$f_2(\theta)=\frac{\sqrt{2}\,n_{el}\{[(n_m')^2-(n_m'')^2]\cos^2\theta-n_{el}^2\}}{n_m''\{[n_m')^2+(n_m'')^2]\cos^2\theta+n_{el}^2\}}.$$

Here $\xi_0=(2D_i/\Omega)^{1/2}$; D_i and $c_i(d)$ are the diffusion coefficient and the concentration of particles of kind i at the outer boundary of the diffusion layer of thickness d; δ_i is the phase shift between the molecular flow and the potential. In the derivation of these formulae the distribution of concentrations of the various species was expressed by the standard equation[33]

$$c_i(x_1,t)=c_{i,0}+c_i(d)\,e^{-x_1/\xi_0}\sin(\Omega t+\delta_i-x_i/\xi_0-\pi/4), \quad (9)$$

¶ The precision of experimental data does not justify the use of approximations higher than the linear.

† The reactive components $[(1/R_{s(p)}\cdot dR_{s(p)}/dE]_r$ and $(d\delta_{s(p)}/dE)_r$ are obtained from the formulae (8) by replacing the phases δ_i by $\delta_i+(\pi/2)$.

where $c_{i,0}$ is the concentration of particles of kind i in the bulk of the solution. In contrast to Eqn.(6), the quantities in Eqn.(8) show a phase shift with respect to the potential (1). It follows from the formulae (6) and (8) that the angular dependences of $(1/R).(dR/dE)$ and $(d\delta/dE)$, corresponding to the changes in optical properties of the layer of atomic dimensions near the boundary and to the concentration changes in the diffusion layer respectively, are substantially different and can therefore be separated. At low enough frequencies (Ω), when $\xi_0^{-1} > 2\pi c/\omega$, the signal measured at low angles of incidence is determined mainly by the first contribution, and at higher angles of incidence mainly by the second.

III. MICROSCOPIC ELECTRO-MODULATION MECHANISMS

The second main stage in the analysis of light reflectance data is to define the relationship between the parameters $\Delta\varepsilon_{2,3}$ and $\Delta\varepsilon_{(1)}^{-1}$ and the microscopic characteristics of the metal/electrolyte interface, and also to examine the various mechanisms used to modulate the optical properties of the surface. Without these clarifications the information of relevance to chemical studies of the surface phenomena cannot be extracted from the optical data. One possible approach is to use the relationship between the dielectric permeability tensor $\varepsilon_{ij}(\bar{x}, \bar{x}'; \omega)$ and the multi-particle Green function of the system. A simple expression for the non-local dielectric permeability tensor, given by the random phase approximation (RPA),[34,35] is often used at present. This approximation gives a reasonably accurate quantitative relationship between the spectral parameters of the system of electrons in the inhomogeneous medium under study and the behaviour of the reflectance coefficient of the light in the visible and near-u.v. frequency range, without excessively cumbersome formulae.

In the RPA the tensor $\varepsilon_{ij}(\bar{x}, \bar{x}'; \omega)$ is written as

$$\varepsilon_{ij}(\bar{x}, \bar{x}'; \omega) = \varepsilon_p(\bar{x}, \omega)\delta_{ij}\delta(\bar{x} - \bar{x}') + \varepsilon_{ij}^{tr}(\bar{x}, \bar{x}'; \omega) . \qquad (10)$$

The first term in (10) is the plasma component of the dielectric permeability, and the second describes various optical transitions. At the absolute zero of temperature the terms which appear in (10) can be expressed as follows through the Green function:

$$\varepsilon_p(\bar{x}, \omega) = 1 - \frac{4e^2}{m\omega^2}\int d\hat{E}\, 2\Theta(-\hat{E})\,\mathrm{Im}\,G(\bar{x}, \bar{x}'; \hat{E})$$

$$\varepsilon_{ij}^{tr}(\bar{x}, \bar{x}'; \omega) = -\frac{e^2\hbar^2}{m^2\omega^2}\int d\hat{E}\, 2\Theta(-\hat{E})\cdot\left\{\mathrm{Im}\,G(\bar{x}, \bar{x}'; \hat{E})\overleftrightarrow{\frac{\partial}{\partial x_i}}\cdot\right.$$

$$\left.\cdot\overleftrightarrow{\frac{\partial}{\partial x_j'}}G(\bar{x}, \bar{x}'; \hat{E}+\hbar\omega) - \mathrm{Im}\,G(\bar{x}, \bar{x}'; \hat{E})\overleftrightarrow{\frac{\partial}{\partial x_i'}}\overleftrightarrow{\frac{\partial}{\partial x_j}}G^*(\bar{x}, \bar{x}'; \hat{E}-\hbar\omega)\right\}, \qquad (11)$$

where the meaning of the operation $\overleftrightarrow{\partial}/\partial x$ follows from the equality

$$f(\bar{x})\overleftrightarrow{\frac{\partial}{\partial x_i}}g(\bar{x}) = f(\bar{x})\frac{\partial g(\bar{x})}{\partial x_i} - g(\bar{x})\frac{\partial f(\bar{x})}{\partial x_i}$$

Here the symbol $G(\bar{x}, \bar{x}'; \hat{E})$ refers to the one-electron Green function with energy $\hat{E}$, and m and e are the effective mass and the charge of the electron in the metal. Energies are measured from the Fermi level of the metal, and therefore the distribution function at $T = 0$ is of the $2\Theta(-\hat{E})$ type. The integral of the energy which appears in the expression for $\varepsilon_p(\bar{x}, \omega)$ is the distribution of electron density in the system, $\rho(\bar{x})$.

Complete calculations by formulae (11) require extensive information on the electronic structure of the metal/electrolyte system; the procedure is complex and can only be applied in a few special cases, even by using a computer. An alternative approach, less artificial and now widely used, relies on a semi-phenomenological comparison of various properties of the electron spectrum with the behaviour of $\Delta\varepsilon_{2,3}$ and $\Delta\varepsilon_{(1)}^{-1}$ in selected frequency ranges. Approximate expressions for the Green function, which allow a simple physical interpretation, can be used. In the following subsections we shall examine these approximations for different types of spectrum and therefore also for different microscopic mechanisms of the interaction between the light and the surface.

1. Plasma ER

The plasma ER model[36] assumes that the ER effect is due to modulation of the plasma component of the ε_{ij} tensor [first term in (10)] by the change in electron density near the interface caused by the application of the modulation potential, and that the second term in (10) is unaffected by these changes. The latter assumption can be justified only in the range of ω and E values most remote from the photo-emission threshold, and for frequencies far from the optical transition frequencies of the surface layer. The plasma component of the dielectric permeability $\varepsilon_p(x_1, \omega)$, averaged over the surface and allowing also for the collisions between electrons in the bulk of the metal, is often expressed as[10,11]

$$\varepsilon_p(x_1, \omega) = \varepsilon_{el} + (\varepsilon_f(\omega) - \varepsilon_{el})\rho(x_1)/N \qquad (12)$$

$$\varepsilon_f(\omega) = 1 - \frac{\omega_p^2}{\omega(\omega + i/\tau)};\quad \omega_p^2 = 4\pi Ne^2/m;\quad \omega\tau \gg 1 ,$$

where τ is the relaxation time, $\rho(x_1)$ is the electron density (averaged over the surface), and N is the concentration of electrons in the bulk of the metal. For normal incidence of the light on the electrode the model gives the following expression for the relative change in light reflection coefficient and for the phase change:

$$\frac{\Delta R_s}{R_s} = -\frac{4\omega(\varepsilon_{el})^{1/2}}{c}\frac{\Delta Q}{eN}\,\mathrm{Im}\,\frac{\varepsilon_{el} - \varepsilon_f}{\varepsilon_{el} - \varepsilon_m} = -\frac{4\omega(\varepsilon_{el})^{1/2}}{c}\frac{C_{dl}\Delta E}{eN}\,\mathrm{Im}\,\frac{\varepsilon_{el} - \varepsilon_f}{\varepsilon_{el} - \varepsilon_m} \qquad (13a)$$

$$\Delta\delta_s = \frac{2\omega(\varepsilon_{el})^{1/2}\Delta Q}{ceN}\,\mathrm{Re}\,\frac{\varepsilon_{el} - \varepsilon_f}{\varepsilon_{el} - \varepsilon_m} = \frac{2\omega(\varepsilon_{el})^{1/2}C_{dl}\Delta E}{ceN}\,\mathrm{Re}\,\frac{\varepsilon_{el} - \varepsilon_f}{\varepsilon_{el} - \varepsilon_m} \qquad (13b)$$

where

$$\Delta Q = -e\Delta\rho = -e\int dx_1\Delta\rho(x_1);\quad C_{dl} = dQ/dE , \qquad (14)$$

ΔQ is the change in surface charge caused by a change ΔE in the surface potential step, and C_{dl} is the differential double layer capacitance.

According to (13) the intensity of the integral ER signal varies linearly with the density of surface charge, and the differential ER signal is proportional to the differential capacity. These predictions have been confirmed qualitatively for several systems.[37-39] In particular, it was found[38,39] that for $\hbar\omega = 1.3$ eV a lead electrode in 0.1 and 0.25 M solutions of NaF at negative potentials (i.e. in the absence of specific adsorption) gives a linear dependence of $\Delta R/R$ on the charge ΔQ. It follows from (13) that for strongly reflecting metals such as Ag, Au, and Cu, for which $\mathrm{Im}\,\varepsilon_m \ll |\mathrm{Re}\,\varepsilon_m|$, the contribution of the plasma mechanism to $d\delta_s/dE$ is much greater than the contribution to $(1/R_s)dR_s/dE$.

Let us consider the plasma ER in p-polarised light. The quantity $\Delta\varepsilon_{(1)}^{-1}$ in the expression for the ER signal in p-polarised light [unlike $\Delta\varepsilon_{2(3)}$] is strongly dependent not only on the surface charge Q but also on the distribution of electron density $\rho(x_1)$ near the surface. Consider first a simple model for $\rho(x_1)$ [40,41] in which

$$\rho(x_1) = \begin{cases} N - \frac{1}{2}(\beta Q/e + N)\,e^{\beta x_1}, & x_1 < 0 \\ \frac{1}{2}(N - \beta Q/e)\,e^{-\beta x_1}, & x_1 > 0 \end{cases} \qquad (15)$$

Here β is an adjustable parameter, defined by the condition of minimum energy of the ground state of the electron gas in an external field.[41] For metals such as Ag, In, etc. (whose bulk properties are accurately described by the plasma part of the expression for the dielectric constant ε_f) we have, for the condition $|\beta Q| < eN$,

$$\frac{d\,\Delta\varepsilon_{(1)}^{-1}}{dE} \approx \frac{\varepsilon_m - \varepsilon_{el}}{\varepsilon_m\,\varepsilon_{el}}\frac{C_{dl}}{eN} + \frac{1}{\beta^2}\frac{d\beta}{dE}\left[\frac{\varepsilon_m + \varepsilon_{el}}{\varepsilon_m\varepsilon_{el}}\ln\left(-\frac{\varepsilon_m + \varepsilon_{el}}{2}\right) - \right.$$
$$\left. - \frac{1}{\varepsilon_m}\ln(-\varepsilon_m) - \frac{1}{\varepsilon_{el}}\ln\varepsilon_{el} + \frac{i\pi}{\varepsilon_{el}}\right] \qquad (16)$$

This expression shows that the main contribution to $\mathrm{Im}\,(d\,\Delta\varepsilon_{(1)}^{-1}/dE)$ in the case of weak bulk attenuation comes from the region near the point $x_1 = x_1^0$, defined as the solution of the equation $\mathrm{Re}\,\varepsilon_p(x_1) = 0$. This point exists near the surface if the frequency is consistent with $\mathrm{Re}\,\varepsilon_m < 0$, since ε_{el} is always positive. In the frequency range considered the condition $\mathrm{Re}\,\varepsilon_m < 0$ is obeyed by the great majority of metals. When $\mathrm{Re}\,\varepsilon_p(x_1^0)$ vanishes, a positive term proportional to $d\beta/dE$ appears in $(1/R_p)(dR_p/dE)$: this term does not disappear even for the real ε_m values. This effect has been attributed[20,42] to the steep rise of the normal component of the electromagnetic field $\mathscr{E}_1$ at the point $x_1 = x_1^0$, and cannot in principle be described by the three-layer model.

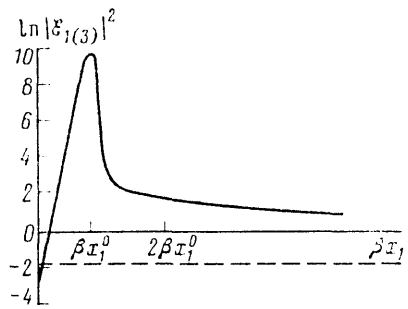

Figure 2. Plots of $\lg|\mathscr{E}_3|^2$ (broken line) and $\ln|\mathscr{E}_1|^2$ (full line) against x_1 for a fixed value of $x_2 = 0$; silver electrode, $\hbar\omega = 2$ eV. The point x_1^0 is found from the condition $\mathrm{Re}\,\varepsilon(x_1^0) = 0$, the parameter β defines the slope of the electron density outside the metal.

The ER spectra in p-polarised light for In and Pb have been calculated[43] by using an expression for $\rho(x_1)$ similar to (15). For $d\beta/dE = 0$ the parameter $(1/R_p)(dR_p/dE)$ for In was found to be negative, becoming positive (in keeping with experimental results[44,45]) for $d\beta^{-1}/dE < -0.02$ Å V^{-1}. For frequencies below the photo-emission threshold (since near the threshold the ER signal is determined by a different effect, see below) the values of $(1/R_p)(dR_p/dE)$ calculated[43] for $d\beta^{-1}/dE = -0.06$ Å V^{-1} agree with the experimental values (see Figs. 3 and 4). It is clear from the experimental results that $d\beta^{-1}/dE$ is very sensitive to the nature of the metal. Thus the study of the plasma ER in p-polarised light can identify the dependence on surface potential of the steepness of the electron density curve outside the metal.

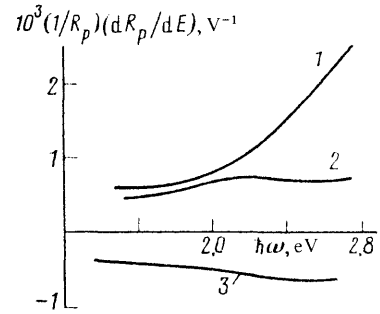

Figure 3. Comparison of the experimental ER spectrum of indium (*1*) in a 0.1 N solution of Na_2SO_4 with theoretical spectra, calculated by the plasma model of ER for $d(1/\beta)/dE$ values of -0.06 Å V^{-1} (curve *2*) and zero (curve *3*), and $E = -1.2$ V (saturated silver chloride electrode);[43] p-polarised light, $\theta = 70°$.

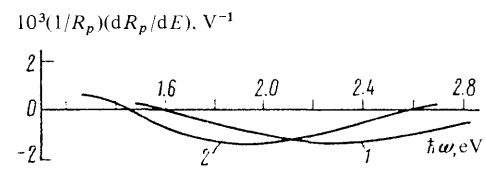

Figure 4. Comparison of the experimental ER spectrum of lead (*1*) in a 0.1 N solution of Na_2SO_4 with the theoretical spectrum (*2*) calculated by the plasma model of ER for $d(1/\beta)/dE = -0.14$ Å V^{-1} and $E = -1.0$ V (saturated silver chloride electrode),[43] p-polarised light, $\theta = 70°$.

Changes in the potential step at the surface can reorient the dipolar solvent molecules near the electrode surface. This effect also leads to a change in the distribution of electron density, and should therefore be observable in electron-reflection in p-polarised light. We have discussed this mechanism[46] using the simplest model of the fixed part of the double layer,[47] i.e. assuming that the solvent dipoles can exist in two states and replacing the discrete distribution of charges from the dipoles by a continuous distribution. The dipole layer is treated as a capacitor in which the density of charge on the plates $q(E)$ is determined by the orientation of the dipoles: $q(E) = ze(N_2 - N_1)/S$, where

N_1 and N_2 are the numbers of dipoles with their positive and their negative pole oriented towards the metal, S is the surface area of the electrode, and ze is the charge on the positive pole of the dipole.[48] The distribution of electron density outside the metal is described by the expression

$$\rho(x_1, E) = \rho_0(E) \exp\left[-2\int_0^{x_1} dx\,((2m/\hbar^2)(W_0 + eU(x, E)))^{1/2}\right], \quad (17)$$

where W_0 is the electronic work function at the zero charge potential (z.c.p.), $U(x, E)$ is the potential distribution in the double layer, and $\rho_0(E)$ is the density of electrons on the electrode surface. By making these assumptions the following expression was obtained[46] for strongly reflecting metals in concentrated electrolytes at potentials close to the z.c.p.:

$$\mathrm{Im}\,\frac{d}{dE}\Delta\varepsilon_{(1)}^{-1} = \frac{\pi^2 e}{\varepsilon_0\varepsilon_{el}(2m/\hbar^2)^{1/2}W_0^{3/2}}\left[C_{dl} + \frac{dq}{dE}\right]x_1^0(0), \quad (18)$$

where

$$x_1^0(0) = \frac{1}{2(2mW_0/\hbar^2)^{1/2}}\ln\frac{(\varepsilon_{el} - \varepsilon_i')\rho_0(0)}{Ne_{el}}, \quad \varepsilon_i' = \mathrm{Re}\,\varepsilon_i.$$

In Eqn.(18) the symbol ε_0 denotes the static dielectric constant of the double layer.

It is clear from (18) that the quantity dq/dE, which defines the rate of reorientation of the dipoles, can be determined in principle by simultaneous treatment of experimental ER and capacitance data. We can show (for example, by model[47] calculations of C_{dl} and q) that in the region of the z.c.p. the reorientation of the dipoles produces a change in sign of the quantity $\mathrm{Im}\,(d\Delta\varepsilon_{(1)}^{-1}/dE)$, and therefore also of $(1/R_p)\cdot(dR_p/dE)$, as compared to a system where reorientation of the adsorbed molecules does not take place. The reason for this effect is that near the double layer, where changes in electric potential have a large effect on the distribution of electron density, the field created by the reorientation of the dipole and the field created by the ions and by the surface charge on the electrode have opposite orientations.

However, not all the effects observed experimentally in the reflection of light by metals can be attributed to modulation of the surface charge. Measurements[49,50] of the electroreflectance and electro-transmittance spectra of s-polarised light for a silver electrode in 1 N Na_2SO_4 solution gave $\mathrm{Re}\Delta\varepsilon$ and $\mathrm{Im}\Delta\varepsilon$ values of similar absolute value but different sign over a wide range of frequency. This result is inconsistent with the prediction from the plasma model that these quantities should have the same sign. The discrepancy was explained[50] by postulating changes in the relaxation time as well as in the concentration of the near-surface electrons in response to changes in the potential step at the surface#. Alternative explanations of the form of the ER signal in s-polarised light at frequencies where the contribution from optical transitions is negligible (and the plasma model should "work") rely on the dependence of the effective mass of the electrons on x_1 near the metal surface. We also note that when conduction is mainly by holes the sign of the ER signal must be the opposite of that given by formula (13a). This may be the reason for the positive sign of the ER signal reported in Ref. 45. Mutually consistent explanations of all these effects would be valuable.

In all the models which allow for the modulation of the surface charge and of the relaxation time the optical characteristics of the surface layer are smooth functions of frequency. Therefore the models cannot explain the experimentally observed maxima and minima in the dependence of $\Delta\varepsilon_{2(3)}$ and $\Delta\varepsilon_{(1)}^{-1}$ on ω. To account for these effects we must allow for the influence of the potential step E on the part of the expression for the dielectric permeability which refers to optical transitions (band-to-band, or within-band, transitions, or transitions involving surface states). The main problem is to identify the physical mechanism of the dependence of $\Delta\varepsilon_{2(3)}$ and $\Delta\varepsilon_{(1)}^{-1}$ on the surface potential step.

2. Effect of Band-to-band and Within-band Optical Transitions

Almost without exception the modulation of band-to-band transitions is described in terms of concepts previously developed to interpret ER in semiconductors. For example, shifts in the Fermi level,[51] bending of the bands,[52] and changes in the relaxation time of band-to-band transitions[53] have been assumed to be produced by the application of an electric field to the sample. That work has already been reviewed in detail.[5,7,9] However, those mechanisms cannot play a major role in metals, because in order to perturb the electronic band structure in the bulk of the metal the external electric field would need to penetrate into the electrode to a depth much greater than atomic dimensions.

A more realistic mechanism of the electro-modulation of band-to-band transitions in metals was suggested in Ref. 54. It applies to the reflection of s-polarised light by polyvalent metals at frequencies close to those of allowed optical transitions between almost parallel bands. It was assumed that at frequencies and potentials far from the photo-emission threshold the dependence of the $\Delta\varepsilon$ tensor on surface potential is determined by the amplitudes of the reflection coefficients of the electron waves incident on the surface from the bulk of the metal. Allowance was made for the dependence on E of the amplitudes of the reflection coefficients of electron waves in the ground and in the excited state. Calculations[54] showed that extrema should appear in the ER spectra at frequencies close to those of allowed band-to-band transitions, due partly to the presence of an interface, which overcomes the requirement of conservation of the normal component of the quasi-momentum in the optical transition, and partly to the possibility of a bulk optical transition in which all the components of the quasi-momentum are conserved. The width of the peak is determined by the mean free path of the electrons in the excited state. A weak dependence of the position of extrema of this type on the surface potential step is typical of bulk optical transitions.

This theory[54] has been used to explain the characteristic features of the ER spectrum of lead in s-polarised light. The band structure of lead[55] contains, near the point W of the Brillouin zone close to the Fermi surface, three almost parallel bands, two of which are partially filled while the third (and uppermost) is empty. Experimental and theoretical frequency dependences of $\hbar\omega\,\mathrm{Im}\,\Delta\varepsilon$ are compared in Fig. 5. The extremum close to $\hbar\omega = 1.2$ eV corresponds to transitions between the highest filled band and the empty band, while the other extremum close to $\hbar\omega = 2.3$ eV corresponds to transitions from the second filled band to the

The possible influence of the modulation of the relaxation time on the ER was first pointed out in Ref. 51. However, allowing for the relaxation time in the dielectric permeability of a thin surface layer poses serious fundamental difficulties.[177]

empty band. Differences between the extrema are ascribed to the special properties of the wave functions of electrons in different bands.

Like the transitions between the electronic bands in the bulk of the metal, transitions involving the surface bands of the metal can affect the dielectric constant of the surface layer. Changes in the surface potential at the metal/electrolyte interface alter the position of the surface band relative to the Fermi level of the metal, thus affecting the contribution from this band to $\Delta\varepsilon_{2(3)}$ and $\Delta\varepsilon^{-1}_{(1)}$. It has been suggested[178] that the maximum at $\hbar\omega = 2.6$ eV observed in the ER spectrum of gold in 1 *N* $HClO_4$ is due to a transition from the surface *d* band to the Fermi level. Increasing the potential shifts the maximum towards lower frequencies, as expected theoretically.[179]

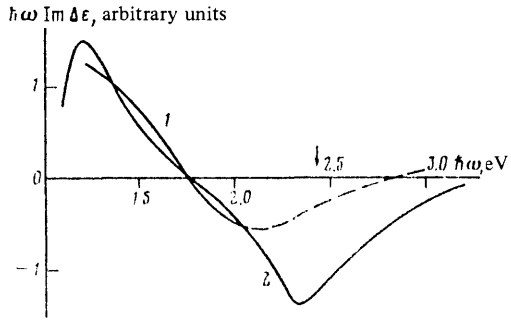

Figure 5. Plots of $\hbar\omega \mathrm{Im}\Delta\varepsilon(\omega)$ against frequency obtained by processing the experimental ER spectrum (*1*) and by calculation (*2*).[54] Lead in a 0.1 M solution of NaF, *s*-polarised light. The broken line is the portion of curve *1* which does not coincide with the calculated relationship because of the photo-emission mechanism of ER; the arrow shows the photo-emission threshold.

The presence of an interface infringes the translational invariance of the system and therefore invalidates the law of conservation of the normal component of the quasi-momentum: optical transitions between states in the same band of the metal therefore become allowed. The contribution of these transitions to the ER should be very sensitive to the structure of the surface: their importance was first pointed out in Ref. 44 and 56. The effect of within-band transitions on the ER signals was later examined in detail,[45, 57–59] using a modulation mechanism based on the effect of the surface potential on the amplitudes of the reflection coefficients of photo-excited electrons at the metal surface. The calculations included the elastic reflection of the electrons from the surface and the possible emission of electrons into the electrolyte.[2] The photo-emission threshold $\hbar\omega_0(E) = \hbar\omega_0 + eE$ (where $\hbar\omega_0$ is the emission threshold at $E = 0$) is a singularity in the electronic spectrum of the metal/electrolyte system. It has been shown[45,57] that this spectral feature is present in the electro-reflectance of the system, and a relationship between the photo-emission current and the ER signal has been obtained.

The existence of a relationship between the photo-emission and the ER offers the possibility of a more rational choice of mechanism for both these phenomena and of extracting more convincing information on the structure of the surface. By combining experimental data on photo-emission and on electro-reflectance we can determine the phases of the matrix elements for the photo-initiated transitions, γ_s and γ_p, which contain information on the surface properties. The phase of γ_p is determined by the properties of the wave functions of the metal electrons in their initial and their final state and by the selection rules of the photo-transition, and depends on the size of the region of the crystal in which the photo-electrons are generated; γ_p is related to the phase of the reflection of the electrons on the Fermi surface from the metal surface.[60] If the photo-excitation is assumed to take place on the surface barrier (surface photo-emission mechanism) the parameter $\tan\gamma_p$ is close to zero.[60] A fairly large value of $\tan\gamma_p$ suggests that the main role in the photo-excitation is played by transitions on the ion cores of the metal near the surface.[61]

For comparison with experiment the most convenient quantities are the second differentials $(1/R)(\mathrm{d}^2R/\mathrm{d}E^2)$ which, like the first differentials $(1/R)(\mathrm{d}R/\mathrm{d}E)$, can be measured directly.[45] The expressions for the second differentials contain fewer parameters, and they identify more precisely the singularity at the threshold. Expressions of the following type have been used[57,60] for $(1/R)(\mathrm{d}^2R/\mathrm{d}E^2)$ in the region of the outer photo-emission threshold:

$$\frac{1}{R}\frac{\mathrm{d}^2R}{\mathrm{d}E^2} = A + B(\hbar\omega - \hbar\omega_0 - eE)^{1/2}\Theta(\hbar\omega - \hbar\omega_0 - eE) + C(\hbar\omega_0 + eE - \hbar\omega)^{1/2}\Theta(\hbar\omega_0 + eE - \hbar\omega). \quad (19)$$

Formula (19) is valid in the vicinity of the photo-emission theshold to with $[(\hbar\omega - \hbar\omega_0 - eE)/\hbar\omega_0]^2$. The parameters *A*, *B*, and *C* in (19) are functions of the frequency and of the angle of incidence: they are independent of *E* and can be expressed in terms of the bulk dielectric constants of the metal and of the electrolyte. The functions are given in an explicit form in Ref. 57.

We should stress that the appearance of the threshold singularity in the expression for $(1/R)(\mathrm{d}^2R/\mathrm{d}E^2)$ is qualitative and unrelated to the details of the calculation. Experimental detection of this singularity is convincing proof of the validity of the chosen physical mechanism of ER.

Formula (19) was obtained by assuming an infinitesimally small amplitude of the modulation δE. However, in experiments the quantity δE is finite, and cannot be too small. Therefore, in view of the singularity in the function $(1/R)\cdot(\mathrm{d}^2R/\mathrm{d}E^2)$, we need to allow more carefully for the non-zero value of δE. An analysis of this problem[15] has shown that a finite value of δE broadens the threshold peaks. In addition to this broadening, however, the fluctuations in the polarisation of the medium near the surface can also affect the dependence of $(1/R)(\mathrm{d}^2R/\mathrm{d}E^2)$ on *E* in the region of the photo-emission threshold. The prospect of characterising these fluctuations is very important in the study of electrode reactions. In order to separate the effect of the polarisation fluctuations we must either design experiments with a smaller modulation amplitude or study systems in which these fluctuations are large.

An analysis of published results[44] shows that the ER of indium, cadmium, lead, and tin includes a substantial contribution from the modulation mechanism considered here. In Fig. 6 the theoretical $(1/R_p)(\mathrm{d}^2R_p/\mathrm{d}E^2)$ curves are compared with experimental curves for indium in a 0.01 *N* solution of Na_2SO_4. In the calculation of the theoretical curves the moduli of the matrix elements were taken from independent photo-emission experiments.[62,63] The phase γ_p of the matrix element of the optical transition excited by a field normal to the surface was treated as an adjustable parameter.

It was found that $\tan\gamma_p = -0.7$, i.e. that the surface mechanism of photo-emission does not play an appreciable part in the case of indium.

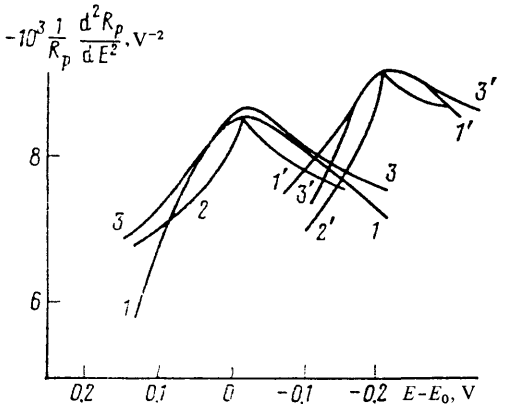

Figure 7. Effect of the modulation amplitude on the potential dependence of $(1/R_p)(d^2R_p/dE^2)$ for indium in a 0.01 *N* solution of Na_2SO_4 with $\theta = 70°$. The experimental curves *1* and *1'* were obtained at frequencies of 2.2 and 2.0 eV respectively, with $\delta E = 0.06$ V.[45] The theoretical curves are for the same frequencies without a correction for broadening (curves *2* and *2'*)[57] and with a correction for broadening (curves *3* and *3'*);[15] $\delta E = 0.06$ V.

Fig. 7, reproduced from Ref. 15, shows the effect of a finite modulation amplitude δE on the threshold behaviour of the ER signal. We note that allowing for instrumental broadening in the theoretical curves brings them into satisfactory agreement with experiment.

IV. ADSORPTION STUDIES

Adsorption on electrodes is one of the basic problems in electrochemistry, and its study is essential to a correct understanding of the mechanism of various electrode reactions. However, the traditional electrochemical methods of determining and studying adsorption, relying exclusively on the measurement of quantities of electricity (i.e. of capacitance), give only limited information. In particular, they cannot distinguish different paths for the transfer of charge between phases. In other words, the quantity of electricity used in the adsorption of the substance is difficult (and sometimes impossible) to separate from the quantity of electricity used in charging the double layer or in the associated Faraday process. The optical methods of studying adsorption discussed in this review usefully complement the traditional methods and offer direct information on the adsorbed species.

1. Determination of Adsorption on an Electrode Surface

Under reversible conditions the adsorption of particles on an electrode surface can be determined strictly by EOS methods.[30-32] Changes in the number of adsorbed particles

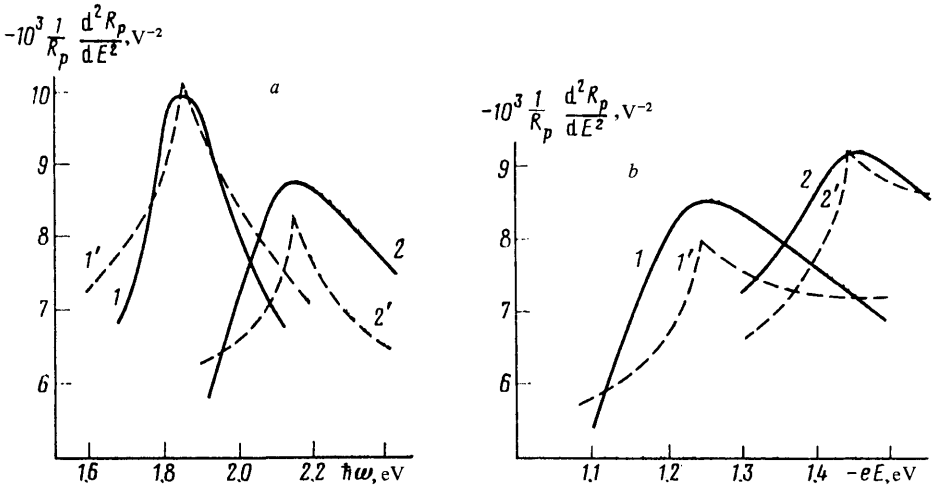

Figure 6. Comparison of experimental and theoretical plots of $(1/R_p)(d^2R_p/dE^2)$ against frequency (*a*) and potential (*b*). The full lines are experimental ER data for indium in a 0.01 *N* solution of Na_2SO_4 for $\theta = 70°$;[45] the broken lines are theoretical;[57] (*a*) curves *1* and *1'* correspond to a potential of −1.6 V, curves *2* and *2'* to −1.3 V (saturated silver chloride electrode); (*b*) curves *1* and *1'* correspond to a frequency of 2.2 eV, curves *2* and *2'* to 2.0 eV.

on the electrode produce changes in the number of particles in the diffusion layer, leading to the experimentally observed effect described by formulae (8). We shall illustrate these effects by considering a 1–1 electrolyte in which neutral molecules of an organic compound are dissolved. Changes in surface potential produce changes in the concentration of particles, both as a result of changes in adsorption and of electro-migration, and the electron-neutrality condition must be obeyed in the region of the diffusion layer. It is easy to show[30,31] that the quantities $dc_i(d)/dE$ and

$$\int_d^\infty dx_1[c_i(x_1)-c_{i0}]$$

which appear in Eqn.(8) can be expressed in terms of the adsorption of particles as follows

$$\frac{d}{dE}c_{org}(d)=\frac{1}{\xi_0}\frac{d\Gamma_{org}}{dE};\quad \frac{dc_A(d)}{dE}=\frac{1}{\xi_0}\left(\frac{\partial\Gamma_A}{dE}+\frac{t^+}{i\Omega F\hat{Z}}\right)$$

$$\frac{dc_B(d)}{dE}=\frac{1}{\xi_0}\left(\frac{d\Gamma_B}{dE}-\frac{t^-}{i\Omega F\hat{Z}}\right)$$

$$\frac{d}{dE}\int_d^\infty dx_1[c_{org}(x_1)-c_{org,0}]=\frac{d\Gamma_{org}}{dE}, \qquad (20)$$

where t^+ and t^- are the transport numbers of the cations (A) and of the anions (B) in the electrolyte; $\hat{Z}$ is the total impedance of the electrode; Γ_{org}, Γ_A, and Γ_B are the surface excesses of the organic compound, the cations, and the anions respectively, equal to the corresponding Gibbs adsorptions under equilibrium conditions; F is the Faraday.

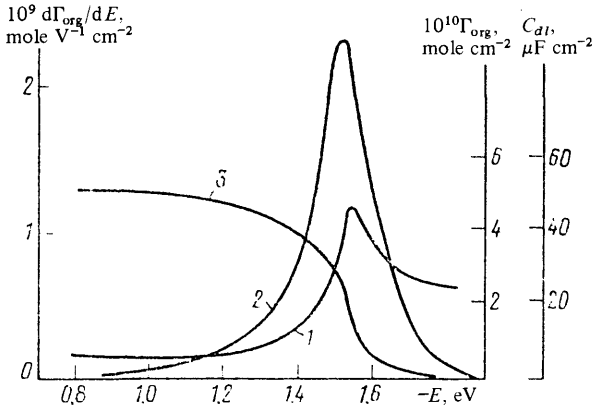

Figure 8. Dependence of the differential capacity (*1*), $d\Gamma_{org}/dE$ (*2*), and Γ_{org} (*3*) on the potential of a lead electrode in a solution of 0.5 *N* Na_2SO_4 + 0.1 M n-C_4H_9OH; modulation frequency Ω = 375 Hz.[30]

By combining formulae (20) and (8b) it has been shown[30] that if the solution is free from organic impurities the differentials $d\Gamma_A/dE$ and $d\Gamma_B/dE$ can be determined as a function of the potential step from the experimental dependence of the impedance $\hat{Z}$ and of $d\delta/dE$ on E. The dependences of $d\Gamma_{A,B}/dE$ on E thus obtained[30] for a lead electrode in a 0.5 *N* solution of Na_2SO_4 are consistent with the result of the Gouy–Chapman theory. If the solution contains an organic substance the above experiments are insufficient to determine $d\Gamma_{org}/dE$, and furthermore the dependence of $d\Gamma_{A,B}/dE$ on E must be calculated theoretically.

The same paper[30] discusses the system consisting of a lead electrode in a 0.5 *N* Na_2SO_4 + 0.1 M n-C_4H_9OH solution. The $d\Gamma_{org}/dE$ curve (curve *2* of Fig.8) was plotted from experimental results by using the dependence of $d\Gamma_{Na^+}/dE$ on E calculated by the Gouy–Chapman theory.

Curve *3* in Fig.8, obtained by integrating curve *2*, is a plot of Γ_{org} against E. The maximum value of Γ_{org} is 5×10^{-10} mole cm^{-2}, which agrees well with the limiting adsorption on mercury.

The contribution of the diffusion layer to ER was first detected[31] in the system indium electrode in a 0.5 *N* Na_2SO_4 + 0.1 M n-C_4H_9OH solution. The most characteristic feature of this ER mechanism is the dependence of the signal on the modulation frequency of the surface potential [see formula (8)].

We should stress that the method gives direct information on adsorption by solid electrodes without an assumed model. Recent work[30-32] should provide a foundation for the development of adequate experimental techniques for determining adsorption by this method.

The method can be used also to study the kinetics of processes taking place near a surface. In particular, by combining it with the photo-emission method of modulating surface concentrations of particles[64] we can, in principle, study fast processes (up to the picosecond range).

2. Determination of the Microscopic Characteristics of Adsorbed Particles

The most important property of optical modulation methods is their ability to provide direct information on the electronic structure of adsorbed particles, on their vibrations, intermolecular interactions, charge transfer, and other microscopic characteristics. This is exactly the information which was lacking in studies of the electrode/solution interface.

Adsorption produces a large change in the electron spectrum of the metal/electrolyte system. As a result of their interaction with the metal the electronic levels of the adsorbed species (atoms and molecules) are both shifted (by an amount Λ) and broadened (by an amount Δ). The parameters Λ and Δ are the basic microscopic characteristics of the adsorbed particles. They depend on the electronic structure of the isolated particles, on the band structure of the metal, and on the potential step at the interface. A knowledge of Λ and Δ is essential for the solution of many problems in the thermodynamics and kinetics of surface phenomena. In particular, the charge q_a on the adsorbed particle[65] can be expressed through Λ and Δ:

$$q_a=Z_a+\frac{2}{\pi}\left[\arctan\frac{\hat{E}_0+\Lambda}{\Delta}-\frac{\pi}{2}\right], \qquad (21)$$

where Z_a is the charge on the ion core of the adsorbed particle, and $\hat{E}_0$ is the position of the energy level of the isolated particle relative to the Fermi level of the metal.

The appearance of new energy levels creates new paths for the adsorption of light, based on electronic transitions from the filled levels of the adsorbed particle to the conduction band of the metal or to the external medium, from the metal to the empty levels of the adsorbed particle, and between the levels of the adsorbed particle. The corresponding changes in the optical properties of the system can in principle be determined by spectroscopic modulation methods.

In order to extract the relevant information from spectroscopic data we need to know the relation between the functions $\Delta\varepsilon_{2(3)}$ and $\Delta\varepsilon^{-1}_{(1)}$ which appear in Eqn.(6) for the experimentally measurable quantities, and also between the parameters Λ and Δ.

Let us consider first the case of small interactions between the adsorbed particles, so that $\Delta\varepsilon_{2(3)}$ can be assumed to be proportional to the number of adsorbed particles N_a. For an adatom with one s level lying below the Fermi level of the metal the imaginary part of $\Delta\varepsilon_{2(3)}$ can be expressed as[66,67]

$$\Delta\varepsilon''_{2(3)}(\omega, E) \sim \frac{N_a}{\omega^4}\rho(0)\left[\arctan\frac{\hat{E}_0+\Lambda+\hbar\omega}{\Delta} - \arctan\frac{\hat{E}_0+\Lambda}{\Delta}\right], \quad (22)$$

where $\rho(0)$ is the density of states having unit orbital momentum on the Fermi surface. In this case the quantity $\Delta\varepsilon''_{2(3)}$ refers to an optical transition from a filled (or partially filled) level of the adatom to the conduction band of the metal. The real part $\Delta\varepsilon'_{2(3)}$ is expressed in terms of $\Delta\varepsilon''_{2(3)}$ by using the Kramers–Kronig relation.

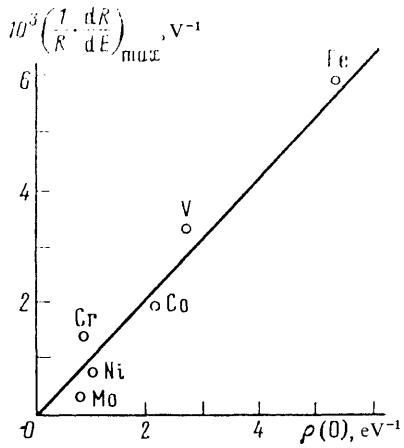

Figure 9. Dependence of the maximum in the ER signal $[(1/R)(dR/dE)]_{max}$ on the density of electronic states at the Fermi level of the metal $\rho(0)$ (calculated per metal atom).[68]

Similar formulae have been obtained[66,67] for transitions from filled states of the metal to empty levels of the adatoms. It follows from (22) that the function $\Delta\varepsilon''_{2(3)}$ has a maximum in the region of the frequency $\hbar\omega_{max} = |\hat{E}_0 + \Lambda|$, and is asymmetric with respect to this frequency. The physical meaning of the formula (22) is relatively simple: the imaginary part of the dielectric permeability tensor is proportional to the product of the number of filled initial states (the term in square brackets) and the number of final states ρ_0 into which the transition can take place. Since $\Delta\varepsilon'_{2(3)}$ is related to $\Delta\varepsilon''_{2(3)}$ by the Kramers–Kronig transformation we can easily show that at $\omega \cong \omega_{max}$ we have $|\Delta\varepsilon'_{2(3)}(\omega)| \ll |\Delta\varepsilon''_{2(3)}(\omega)|$. Therefore it follows from (6a) and (22) that $\Delta R_S/R_S$ goes through a maximum at $\omega \cong \omega_{max}$, so that in the adsorption of the same atoms on different metals $(\Delta R_S/R_S)_{max}$ is proportional to $\rho(0)$. This behaviour of $(\Delta R_S/R_S)_{max}$ has been observed experimentally[68] in a study of the adsorption of water on various transition metals (see Fig.9).

This theory has been applied[69] to the results of experiments on the adsorption of atomic oxygen on platinum immersed in a solution of 0.01 N H_2SO_4 + 1 N Na_2SO_4 at a potential of E = 900 mV relative to the normal hydrogen electrode. The results[69] clearly show a characteristic maximum in the ER signal at frequencies in the range 1.5 eV < $\hbar\omega$ < 3 eV. By comparing these curves[69] with the formulae of Refs.66 and 67 we conclude that in the adsorption of oxygen on platinum (at 0.5 monolayer coverage) the highest initially unoccupied 2p level of the oxygen atom is converted into a resonance level lying 2 eV below the Fermi level of platinum and having a width Δ = 0.3 eV.

At the light frequencies used in ER experiments ($\hbar\omega \cong$ 1.5 to 4.5 eV) electronic transitions to the outer medium are possible for adatom levels lying close to the Fermi surface. We have known[70] that $d\Delta\varepsilon''/dE$ can vary quite sharply near the frequency $\hbar\omega \cong \hbar\omega_e(E) = -\hat{E}_0 - \Lambda + \hbar\omega + eE$, which is the threshold for the transition of the electron from the adatom level of energy $\hat{E}_0 + \Lambda$ to the outer medium. The form of the ER signal is strongly dependent on the symmetry of the wave function of the highest filled state of the adatom.

The expression (6b) for $(1/R_p)(dR_p/dE)$ includes, as well as $d\Delta\varepsilon_{(2,3)}/dE$, the quantity $d\Delta\varepsilon^{-1}_{(1)}/dE$, which can be expressed as

$$\frac{d}{dE}\Delta\varepsilon^{-1}_{(1)} = -\int dx\,dx'\,dx''\,dx'''\varepsilon^{-1}_{(1)}(x, x')\left[\frac{d}{dE}\varepsilon_1(x', x'')\right]\varepsilon^{-1}_{(1)}(x'', x'''). \quad (23)$$

Calculations by this formula are cumbersome in general. However, a useful estimate of $d\Delta\varepsilon^{-1}_{(1)}/dE$ can be obtained by the formula

$$\frac{d}{dE}\Delta\varepsilon^{-1}_{(1)} \simeq -\frac{1}{\varepsilon^2_{eff}}\frac{d\,\Delta\varepsilon_1}{dE}, \quad (24)$$

where ε_{eff} is a parameter independent of E and physically equivalent to the dielectric constant of the medium at the adsorption site of the particle. If the adsorbed particle is sufficiently near the metal the parameter ε_{eff} can be replaced by the dielectric constant of the metal.

The effects so far discussed are associated with optical transitions between the levels of an adsorbed particle and the conduction band of the metal, and are usually observed in ER experiments with s- and p-polarised light, i.e. their polarisation selectivity is not high. This property can be explained by the different symmetries of the electronic states of the metal with energies close to the Fermi level. As a result, whatever the direction of the applied electromagnetic field, we find an allowed optical transition from a level (or to a level) of the adsorbed particle having the prescribed symmetry. However, it has been shown experimentally[71,72] that adsorption can also cause changes in the ER spectra in which the selectivity is marked (the changes in the ER signal caused by adsorption being stronger in p-polarised light than in s-polarised light).

The selectivity of ER is partly due to the bulk optical properties of the metal. The electromagnetic field experienced by the particle is proportional to $1 + r^F_s$ in the case of s-polarised light, and in the case of p-polarised light the normal component of the active field is proportional to $(1 + r^F_p)\sin\theta$. In the optical frequency range for most metals $\varepsilon'_m \ll -1$, and therefore r^F_s is close to -1 and r^F_p is close to 1. Therefore if the angle of incidence is not too small the field acting on the particles is substantially greater for p-polarisation than for s-polarisation of the incident wave. The selectivity of the ER can also be attributed to the increase in the normal component $\mathscr{E}_1$ of

the electromagnetic field near the surface. We note that near the surface the field is $\mathscr{E}_1(x_1) = D_1(0)/\varepsilon(x_1, \omega)$, where $D_1(x_1)$ is the normal component of the electromagnetic induction, which varies only slowly near the surface. Therefore in the neighbourhood of the point $x_1 = x_1^0$, where $\mathrm{Re}\,\varepsilon(x_1^0, \omega) = 0$, the intensity of the field $\mathscr{E}_1(x_1)$ increases (see Fig. 2) if the absorption $\varepsilon''(x_1^0, \omega)$ is small at this point. These effects are not directly related to adsorption, and are typical of any microscopic mechanism of ER and ERP. As a result, signals measured in *p*-polarised light are usually stronger than the corresponding signals in *s*-polarised light.

Adsorption can contribute additional polarisation selectivity, due to the optical transitions between the energy levels of the adsorbed particles. In intramolecular transitions the absorption of light is characteristically related to the orientation of the field relative to the symmetry elements of the molecule. Furthermore, adsorption perturbs the symmetry of the states of the molecule, the changes being most marked in a direction normal to the metal surface. This makes available to the adsorbed particle transitions which are forbidden to the same particles in solution, but these transitions can only take place under the influence of the component of the electric field of the light wave normal to the surface (i.e. for *p*-polarisation). Hence the effect shows a strong polarisation selectivity.

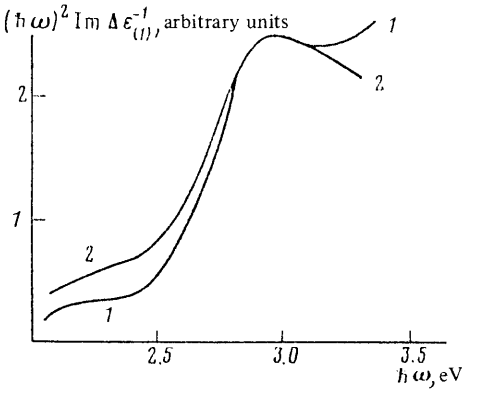

Figure 10. Contribution to the ER of lead from the adsorption of aniline from a solution of 0.1 *N* Na_2SO_4 + 0.0016 M $C_6H_5NH_2$:[73] *1*) experimental plot of the difference between the signals for the above solution and for a solution not containing aniline; *2*) calculated curve.

We have studied[73] the ER of lead in a solution of 0.1 *N* Na_2SO_4 + 1.6×10^{-3} M $C_6H_5NH_2$, allowing for intramolecular optical transitions in the aniline molecules adsorbed on the lead surface. The ER spectra of the lead + aniline system differ from those of pure lead by the appearance of a new minimum in the ER signal at $\hbar\omega = 2.8$ eV in *p*-polarised light, whereas in *s*-polarised light the change in the signal is only slight.[71,72] At this aniline concentration and at a potential $E = -0.7$ V (relative to the silver chloride electrode) the adsorbed aniline molecules are arranged mainly parallel to the lead surface, and furthermore the rate of change in the number of adsorbed molecules oriented normally to the surface is almost zero. This suggests that only adsorbed molecules parallel to the metal surface can affect the ER signal.

Partial charge transfer from the metal to the molecule has been detected electrochemically for the "parallel" adsorption of aniline. Therefore in analysing the experimental results[73] the $^3B_{1u}$ level (which is unoccupied in the molecules in solution) was assumed to be partially filled in adsorption. In this case the observed minimum in the ER signal can be attributed to an optical transition from this level to the $^3B_{2u}$ state. We should stress that this transition is forbidden in the bulk and becomes allowed only under the influence of the normal component of the electric field of the *p*-polarised light, which perturbs the symmetry of the adsorbed molecule in relation to its plane. The symmetry of the initial molecule allows only transitions between these levels in the relevant frequency region.[74]

Theoretical calculations are compared with experimental data in Fig. 10. In the processing of the experiment we found the initial and the final state relative to the Fermi level to be $E_i = 0.4$ eV and $E_f = 2.8$ eV, and their widths to be $\Delta_i = 0.3$ eV and $\Delta_f = 0.4$ eV. From these values of $\hat{E}_{i(f)}$ and $\Delta_{i(f)}$ the charge transfer to the adsorbed molecule can be calculated. By using formula (21) we find $q \approx 0.2$, which is consistent with electrochemical results.

3. Effect of Coverage on the ER Spectra

Experimental results[50,75-83] show that in many cases the ER signal is proportional to the differential with respect to potential of the number of adsorbed particles N_a per unit surface area, dN_a/dE, even at coverages close to a monolayer. For example, in experiments on the dependence of $\Delta R/R$ on the surface coverage of Au and Ag by Pb, Tl, and Cu [82] it was found that in the frequency region where the spectral changes resulting from adsorption do not include structural effects from optical transitions the signal is linearly dependent on N_a at all coverages up to monolayer coverage.

A recent reviewer[84] has explained these results through the effect of the adsorbate on the optical properties of the substrate. One possible mechanism of this effect is a change in the plasma component of the ER due to partial charge transfer between the adsorbed particle and the electrode during adsorption (chemisorption). Electrons injected into the metal influence the density of electrons in the conduction band near the interface and contribute to the plasma component of the ER. In this case the expression for $d\Delta\varepsilon_{2(3)}/dE$ becomes[73]

$$\frac{\mathrm{d}}{\mathrm{d}E}\Delta\varepsilon_{2(3)}(\omega, E) = (\varepsilon_{el} - \varepsilon_f)\left[C_a - \frac{\mathrm{d}}{\mathrm{d}E}(q^{tr}N_a)\right]/eN, \qquad (25)$$

where $C_a(E)$ is the differential capacity of the double layer in the presence of the adsorbed molecules; q^{tr} is the charge of the electrons transferred to the electrode; in the case of charge transfer to the molecule the parameter q^{tr} in Eqn. (25) appears with a minus sign. The ER spectrum produced by this mechanism is similar to the plasma ER spectrum of the pure metal and is determined by the frequency dependence of the dielectric constant of the metal. When q^{tr} is only weakly dependent on N_a the parameter $\Delta R_S/R_S$ is proportional to N_a. It also follows from formula (25) that (in contrast to the plasma ER from a pure surface) in this case the quantity $d\Delta\varepsilon'_{2(3)}/dE$ can be either positive or negative. A change in sign of the plasma component of the ER signal ("inversion" of the plasma ER) has been reported[85] for the adsorption of hydrogen on platinum. Clearly, this observation can be explained by the suggested mechanism.

At frequencies for which the $\Delta R/R$ spectrum is determined by the optical properties of the adsorbate we expect a non-linear dependence of the signal on the coverage of the surface. The effect has been observed in experiments on the adsorption of Cu on Pt and Pb on Pt,[80] and in many other systems.[84]

To explain the experimentally observed non-linearity of the dependence of $\Delta R/R$ on N_a we must allow for the mutual effects between adsorbed particles. In optical experiments these effects may arise mainly for two reasons. On the one hand, because of the effect of adsorbate–adsorbate interactions at higher coverages on the density and other characteristics of the electronic states in the surface layer; the resonance levels of individual adsorbed particles are shifted, their width Γ is changed, and new structures appear, such as a surface band of resonance states.[86] The result is a change in the part of the dielectric permeability tensor (10) corresponding to optical transitions. No detailed discussions of these effects have been published so far: we can only refer to a calculation[87] of $\Delta\varepsilon$ for a metal surface covered with an ordered two-dimensional array of atoms, in which no allowance was made for the interaction with the metal. Starting from the expression for the dielectric permeability tensor (10), (11) in the RPA these workers showed that van Hove singularities in the two-dimensional band structure of the surface layer of atoms can lead to qualitative differences in the reflection coefficients.

On the other hand, at high enough coverages and in the appropriate frequency range the corrections for the local field due to the presence of adsorbed particles may become important. In spite of the many publications already devoted to this topic[83,88–93] the problem is still far from clear. In most of the work so far the surface layer is modelled by a two-dimensional array of dipoles interacting with the light. The results obtained from these models have already been discussed in several reviews.[5,6,83]

A general shortcoming of all the published local field calculations is their reliance on dipole models, which cannot take account of the properties of the adsorbed particles at optical frequencies.[65,94–96] Furthermore, local field effects are important in the same frequency region as the effects caused by changes in the electronic structure of the adsorbed particles as the coverage is increased. This greatly complicates the problems of separating the contributions from different effects. No great reliance can therefore be placed on published comparisons[88–93,97,98] of the local field theory with experiment.

V. ELECTRO-REFLECTION FROM SINGLE CRYSTALS

Until recently ER spectra had been measured mainly on polycrystalline electrodes, with a corresponding loss of information (due to the averaging of the results over all crystallographic directions) and of ease of interpreting the results. Experimental studies of the ER of monocrystals have been reported more recently.[99–109] It was shown that on metals such as Ag, Au, and Cu the ER spectra and their potential dependence depend on the crystallographic face used for the measurement. The effect is not surprising, since the differential capacity, the work function, the matrix elements of the expression for the photo-emission, and the two-dimensional sections of the Brillouin zones are all different on different faces.

Anisotropy of the ER spectra on a clean (110) face of Ag, Cu, and Au crystals was also observed,[99–109] i.e. a dependence of the ER on the orientation of the electric vector of the incident wave with respect to the crystallographic axes of the metal crystal. The anisotropy of the ER is most marked at frequencies close to those of allowed band-to-band transitions.[106] It has been suggested[106] that this effect arises from the anisotropy of bulk band-to-band transitions modulated by the low-frequency field of the double layer.

This phenomenon has been described by using the concepts developed in the theory of ER by semiconductors.[110,111] The double layer field has been assumed[106] to relieve the degeneracy of the bulk states in the region of the critical points lying far from the centre of the Brillouin zone. Under these conditions the matrix elements of the band-to-band transitions become dependent on the angle between the principal symmetry axis at the critical point and the electric vector of the electromagnetic field and of the field of the dipole layer. Furthermore, a model based on the modulation of indirect band-to-band transitions has also been used.[8,99,100] In these studies the azimuthal anisotropy of the ER and the differences in the ER spectra on the (111) and (110) faces of a silver crystal in *s*- and *p*-modulated light were qualitatively accounted for. However, there are serious objections to the application of the suggested mechanism (modulation of the bulk characteristics) to metals.

In contrast to the above approach, based on the anisotropic properties of the bulk states, there have been attempts to relate the azimuthal anisotropy effect to the properties of the surface states of the metal.[109,112] It has been shown theoretically[113] that at the contact between a (110) silver face and an electrolyte a surface band having *s* symmetry is created from the highest level of the bulk band near the Fermi level: this relieves the degeneracy of the *p* states in the bulk band. The bottom of the surface band lies 4 eV above the Fermi level. As a result the matrix element of the transition between states in the bulk band and in the surface *s*-band depends on the direction of the electric component of the electromagnetic field in the plane of the surface: it is zero for $\bar{\mathscr{E}} \parallel \langle 110 \rangle$ and non-zero for $\bar{\mathscr{E}} \perp \langle 110 \rangle$. The quantity dependent on the potential step at the surface is now the bottom of the surface band $\hat{E}_S(E)$. We note that comparison with experiment[109] reveals a strong dependence of $\hat{E}_S$ on E: $(1/e)(dE_S/dE) \cong 3-4$ for the (110) face of a silver crystal. This effect has not been explained satisfactorily so far.

Several papers[80,103,114–117] stress the important role of adsorption factors in the crystallographic and azimuthal anisotropy of ER phenomena. Azimuthal anisotropy in the observed on metal faces which showed no anisotropy in the absence of the adsorbate. A possible explanation is the formation of an anisotropic layer at submonolayer coverages. For example, the adatoms can form regular two-dimensional arrays in which the cell dimensions in two mutually perpendicular directions are very different. At near-monolayer coverages, when the adsorbed lattice is matched to the lattice of the substrate and is therefore isotropic, the ER anisotropy should disappear. This type of dependence of the ER signal on coverage has been observed experimentally.[110] Further theoretical and experimental studies of ER anisotropy are needed to clarify various problems in the structure of adsorbed layers.

VI. I.R. SPECTROSCOPY

Important information on the properties of the metal/electrolyte interface can be obtained by using electrochemical modulation in the i.r. region of the spectrum. By analysing the resulting vibrational spectra we can identify the adsorbed species, determine their mutual arrangement and

their position relative to the atoms of the substrate, and measure their bond lengths and other parameters.[118,119]

However, *in-situ* electrochemical experimentation in the i.r. region of the spectrum is complicated by the absorption of light by the electrolyte under these conditions. As a result, very few attempts to combine i.r. spectroscopy with electrochemistry were reported in recent years, but more recently some significant progress has been made. In a series of investigations[120–123] modulation methods were successfully applied to the study of a platinum electrode in a thin-layer cell. Two different experimental methods were used. In the first the external modulation was supplied through the surface potential step, i.e. this method was essentially the ER technique applied to the i.r. region. The second method, previously used at the metal/vacuum interface, relied on modulation of the polarisation of the incident light. In this case the measured quantity is the difference between the reflection coefficients of *p*- and *s*-polarised light. Unlike the ER method, this technique can be used to determine characteristics of the surface which are not dependent on the potential.

In the i.r. spectra region the vibrational degrees of freedom provide the major contribution to the dielectric permeability tensor. The process obeys the "surface selection rule",[123–125] i.e. the reflection coefficients of the light are unaffected by the vibrations of the adsorbed molecules in directions parallel to the metal surface. The need for this selection rule has been explained as follows. Firstly, as was stated above (p.7), the component of the electric field of the light wave normal to the electrode surface, which acts on the adsorbed molecule, is much greater than the components parallel to the surface (see Fig.2). We should stress that this effect is even more marked in the i.r. than in the visible region. Secondly, it has been suggested[124] that far from the metal surface the fields generated by a dipole parallel to the surface and by its image cancel each other out. However, we note that these conclusions[124] apply only to elastic light scattering, and that very different results may be obtained by allowing for spatial dispersion (screening of the charges), which causes qualitative changes in the pattern of charge distributions.[126] Another possible reason for the enhancement of the effect in *p*-polarised light, mentioned above, has so far been ignored in the publications on i.r. spectroscopy: the increase in the amplitude of the normal component of the field acting on an adsorbed particle resulting from the disappearance of the real part of the dielectric permeability of the system in the vicinity of the surface.

The formulae (6), which are applicable to experiments in the i.r. region, are greatly simplified by the surface selection rule, the terms containing $\Delta\varepsilon_{2(3)}$ effectively vanishing. As a result only the reflection coefficient of the *p*-polarised light is affected by adsorption.

VII. SURFACE PLASMON SPECTROSCOPY

A special type of electromagnetic surface wave (surface polaritons) can exist on solid surfaces: in metals these waves are known as surface plasmons. Surface plasmons are localised near the phase boundary and are propagated along the boundary with a wave vector $\mathbf{k}_\parallel = \mathbf{k}_S(\omega)$, related to the frequency ω by the dispersion law $\omega_S = \omega_S(k_\parallel)$. The dispersion law of surface plasmons is very sensitive to the state of the boundary surface. In electrochemical applications it is important to note that this law depends on the surface potential, on the adsorption, and on the degree of non-uniformity of the surface. The dependence of ω_S on the surface potential was first pointed out in Ref.127. A detailed experimental study of the dependence of $\omega_S(k_\parallel)$ on the potential for silver and gold electrodes in a 0.5 M solution of $NaClO_4$ was later reported.[128,129] Measurements were made both on polycrystalline and on monocrystalline electrodes at potentials believed to exclude specific adsorption. The dependence of ω_S on E was found to change sharply (see Fig.11) near the point of zero charge. For silver at potentials more positive than the point of zero charge the quantity $\hbar\omega_S$ decreases at the rate of $d(\hbar\omega_S)/dE \cong -2 \times 10^{-2}$ eV V^{-1}, whereas at potentials more negative than the point of zero charge $\hbar\omega_S$ is practically constant. Similar experiments in electrolytes containing ions having different polarisabilities gave almost the same results. This means that the effect is produced by the changes in the electronic properties of the metal induced by the changes in the potential step. The effect has been explained[21,130] by postulating a plasma model of the dielectric permeability (12), and the electron density near the point of zero charge was expressed as

$$\rho(x_1) = \rho_0(x_1) - \frac{Q}{e} f(x_1); \int dx_1 f(x_1) = 1, \qquad (26)$$

where $\rho_0(x_1)$ is the distribution of electron density at the point of zero charge ($Q = 0$), and $f(x_1)$ is independent of E.

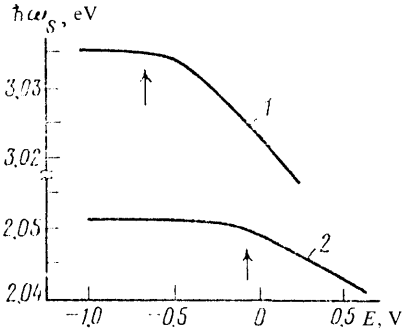

Figure 11. Dependence of the surface plasmon energy on the potential E for polycrystalline Ag (*1*) and Au (*2*) in a 0.5 M solution of $NaClO_4$.[128] E is measured from the potential of the saturated calomel electrode; the arrows denote the points of zero charge.

Explicit forms of the functions $\rho_0(x_1)$ and $f(x_1)$ are given in Ref.131. For the quoted assumptions, the following expression for $d(\hbar\omega_S)/dE$ was obtained:

$$\frac{d(\hbar\omega_s)}{dE} = (\varepsilon_m - \varepsilon_{el}) \frac{C_{dl}(E)}{eN} k_\parallel \hbar B(\omega_s^0) \times \times \left\{1 - \varepsilon_{el}\varepsilon_m \int dx_1 \frac{f(x_1)}{[(\varepsilon_m - \varepsilon_{el})\rho_0(x_1)/N + \varepsilon_{el}]^2}\right\}, \qquad (27)$$

where

$$B(\omega_s^0) = \frac{2(\varepsilon_{el})^{1/2}(-\varepsilon_m)^{3/2}}{(\varepsilon_m - \varepsilon_{el})[\varepsilon_{el}\, d\ln\varepsilon_m/d\omega + 2(\varepsilon_{el} + \varepsilon_m)/\omega]}.$$

Allowing for the steep increase in the differential capacity $C_{dl}(E)$ of this system near the point of zero charge§, Eqn. (27) is qualitatively consistent with experimental results.[128,129]

However, retaining only the first-order terms in Q in the expression for the electron density $\rho(x_1)$ [Eqn.(26)] is justified only at low surface charges (for $Q < 10$ μC cm^{-2}). Therefore Eqn.(27) is valid only in the immediate vicinity of the point of zero charge. To determine the spectrum of surface plasmons over the whole range of potential used in the experiments[128,129] we must allow for the function $f(x_1)$ in (26), and in particular for the dependence of the electron density (β) on E. As was stated above, effects associated with the reorientation of solvent molecules in the double layer may be important in this context. Furthermore, at potentials lying to the right of the point of zero charge oxidation of the electrode is in general possible, and this can substantially affect the $\hbar\omega_s(E)$ dependence. Thus further theoretical and experimental studies are needed to establish unambiguously the electronic structure of the interface between a silver electrode and a solution of an indifferent electrolyte.

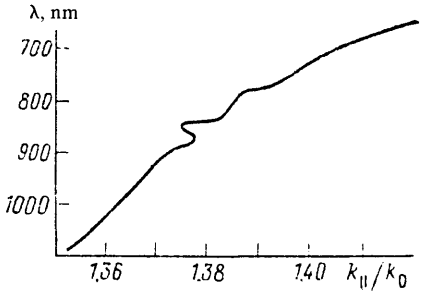

Figure 12. Dispersion curve for the (111) surface of a silver electrode in a 0.1 M solution of NaCl after six activation cycles in the presence of pyridine; $k_0 = \omega/c$.[141]

More than 10 papers have already appeared on the application of surface plasmon spectroscopy to the study of adsorption at metal/air[133–136] and metal/electrolyte interfaces[137–141] (see also the review in Ref.12). The most revealing experiments are the measurements of the frequency dependence of k_s (or of the angle dependence of ω_s) at different potentials. Those measurements were made[141] on a (111) silver face in a solution of 0.1 M NaCl + 10^{-2} M pyridine: they showed that silver–pyridine complexes are formed on the surface, and that they absorb in the region of $\hbar\omega \cong 1.9$ eV. The formation of an absorption region in the surface layer is responsible for some unusual effects in the dispersion curve for the surface plasmons (Fig.12). The double singularity arises from the splitting of the surface plasmon spectrum, which occurs when the resonant frequency for $\Delta\varepsilon_{2(3)}$ or $\Delta\varepsilon_{(1)}^{-1}$ falls into the surface plasmon region. These features in the dispersion curve have been predicted theoretically[142] by using a three-layer model with an absorption region in the surface layer.

Another application of surface plasmon spectroscopy in electrochemical studies should be mentioned. We know from low-energy electron diffraction experiments at the metal/vacuum interface that adsorbates can form superlattices on the surface at sub-monolayer coverages. A similar effect has been observed[143,144] in adsorption at the metal/electrolyte boundary. For example, identical geometrical structures are observed by comparing the adsorptions of Pb on a (111) silver surface in a vacuum and in an electrochemical cell.[145] at low coverages θ_a ($0 < \theta_a < 0.2$) the lead atoms are randomly adsorbed on the surface, but for $0.2 < \theta_a < 0.5$ they form a superstructure of the $(\sqrt{3} \times \sqrt{3})$ type, which disappears at still higher coverages.

The reflection of light from a surface bearing an ordered structure should create surface plasmons with a predetermined value of the wave vector. The effect has been observed[146] in measurements of the differential reflectance ($\Delta R/R$) spectra of a lead-covered (111) silver face. It was shown[146] that at the coverages corresponding to the formation of a superlattice a sharp minimum (denoting the formation of surface plasmons) appears in the $\Delta R/R$ spectrum. The minimum is not observed at low coverages, or at full monolayer coverage. This very important result demonstrates the possibility of obtaining direct information by optical methods on the geometric structure of an adsorbed layer at the metal/electrolyte interface. However, as the authors themselves point out,[146] more experimental results and theoretical studies are needed, and far-reaching conclusions would be premature at present.

VIII. SURFACE-ENHANCED RAMAN SCATTERING

Studies of surface-enhanced Raman scattering occupy a central place in electrochemical optical spectroscopy. The phenomenon, discovered in electrochemical experiments, has stimulated a great deal of interest, both because of its unusual features and through the prospect of new and meaningful ways of studying surfaces. Hundreds of papers, and several reviews, have been written on this topic in the last five years.[162–166,176] The interest shown in this phenomenon is reflected by the original English name ("giant Raman effect") and by the name applied to it in the Soviet literature (anomalously strong Raman scattering, ASRS).

The first report of a Raman scattering (RS) spectrum from pyridine adsorbed on silver was by Fleischmann and coworkers.[147] However, no attempt was made to compare the intensities of the surface and the bulk effect, and the special aspects of the phenomenon were not revealed. Subsequent (though almost simultaneous) publications[148–153] clearly showed that this spectrum is much stronger than the bulk RS spectrum of pyridine. Enhanced Raman effects were soon observed in a large number of systems: aromatic and heterocyclic molecules adsorbed on silver,[148,154] ions adsorbed on silver,[155] and molecules adsorbed on gold and copper electrodes.[156,157] Some very recent papers[158–160] discuss the ASRS from water molecules adsorbed on silver.

The highest enhancement, observed for pyridine adsorbed on a silver electrode, was estimated to be six orders of magnitude. It had been previously assumed that all the adsorbed molecules contribute to the Raman scattering. However, recent work has shown[161] that only a fraction of a monolayer of pyridine is involved in the scattering process. Therefore the enhancement factor could even be 1 or 2 orders

§ A change in Q from −20 to 4 μC cm^{-2} increases the differential capacity from 15 to 130 μF cm^{-2}.[132]

greater. This enhancement effect allows us to study the vibrational characteristics of molecules close to the surface even in the presence of many of the same molecules in the bulk of the electrolyte.

Two explanations have been proposed for the anomalously high intensity of the surface RS. The first relies on the increase in the electromagnetic field near the surface. On an electrode surface, which is rough on a microscopic scale, such an increase can take place through the excitation of surface plasmons.[167,168] This mechanism is controlled mainly by the properties of the metal and of its surface: it is relatively insensitive to the specific characteristics of the adsorbed molecule, and it can therefore be expected to enhance the RS of any molecule which is close enough to the surface. We calculate[169] that the enhancement by this mechanism cannot be greater than two orders of magnitude. A mechanism[171,175] which strengthens the normal component of the electromagnetic field is based on the fact that the real part of the dielectric permittivity of the system vanishes at the point x_1^0 [$\mathrm{Re}\varepsilon(x_1^0, \omega) = 0$]. This mechanism will be effective in RS if the adsorbed molecule is at a distance of approximately x_1^0 from the surface.

The second explanation of the enhanced RS effect depends on the possibility of optical transitions of the electrons from localised surface states (which interact with the vibrations of the adsorbed molecules) into unoccupied states of the conduction band of the metal. It is usually assumed that the localised states are hybridised states of adatoms on the metal electrode and adsorbed molecules.[160,170] Under these conditions resonance Raman scattering (RRS) can take place. However, we should stress that in the case of surface RS the enhancement is due not so much to the fact that the energy of the exciting light is close to the resonance energy (since the state of the adatom–molecule complex is relatively wide) as to the high density of the intermediate states lying near the middle of conduction band of the metal.[171]

Some experimental results can only be explained by the resonance RS hypothesis. For example, on the faces of Ag single crystals no enhancement is observed, and a special pre-treatment of the electrode surface is needed to produce the effect.[170] The treatment consists in alternate formation of a layer of AgCl and reduction to Ag. This produces a large number of Ag adatoms. It has been shown[170,172,173] that the parameters of the absorption band of the adatoms are the same whether they are calculated from the dependence of the ratio of the Stokes and anti-Stokes line intensities on the wavelength of the exciting light or from the ER spectra. This justifies attributing the enhanced RS signal to the presence of adatoms. An irreversible quenching of the enhancement in the Ag + pyridine system has been reported.[174] The effect was produced by applying a cathodic pulse to the surface, causing desorption of the pyridine. At the end of the pulse the RS signal was only 5% of the initial signal, in spite of the readsorption of the pyridine. This observation can be explained by irreversible breakdown of the adatom–adsorbate complexes. Additional evidence in support of the adatom hypothesis is given in Ref.163.

The importance of a knowledge of the angle and polarisation dependence of the Raman scattering cross-section in studies of the mechanism of enhancement has been stressed.[125,171]

Enhanced Raman scattering has already been successfully applied in many laboratories to the study of adsorption. The effect of the surface potential on the orientation of molecules with respect to the electrode surface has been demonstrated by ASRS studies.[152,154] A strong dependence of the shape of the RS line of water on the type of cation and on the pH of the electrolyte has been noted,[160] and it has been suggested[160] that the adsorbed water molecules which contribute to the Raman scattering are not reoriented under the influence of the potential step.

---o0o---

The results considered in this review convincingly show that EOS methods can provide important information on the microscopic structure of the metal/electrolyte interface and on processes taking place near this interface. EOS methods and their interpretation are now being rapidly developed, and it may be useful to list some of the directions of current work. In methods whose microscopic mechanism is relatively well understood (for example, electro-reflectance) we need many more experimental results, and their interpretation, especially for systems including monocrystalline electrodes. EOS studies of phase transitions in near-surface regions are also of great interest.

The possibilities offered by the spectroscopy of surface plasmons and of other surface excited states (polaritons) have been inadequately exploited so far. It would be interesting, for example, to establish the influence of surface plasmons and polaritons on electrochemical reactions.

The search for a comprehensive explanation of the surface enhancement of Raman scattering by adsorbed molecules is currently of interest. We believe that non-linear processes may play an important role in these phenomena. More data not only on the frequency dependence but also on the polarisation and angular dependence of the intensity of the surface Raman scattering of light are needed to solve these problems.

Second harmonic generation at the boundary between two media and its amplification on rough surfaces are currently of interest.[180–183] This phenomenon is closely related to surface Raman scattering, and is potentially very attractive for studying the microscopic structure of surfaces.

Chain Processes and the Non-stationary Nature of the State of the Surface

V.V.Azatyan

The reversible non-stationary nature of the solid surface in branched-chain processes (BCP), which is one of the most important factors determining the regular features of chemical reactions of this class, has been demonstrated. The general regular features of non-thermal BCP which have been observed in the last 10-12 years and which are determined by the change in the condition of the surface and in the contribution of heterogeneous processes to the course of chain combustion have been described and systematised. Kinetic models taking account of the non-stationary nature of the surface and the non-unique nature of the stationary states of the system have been discussed.

INTRODUCTION

One of the most important and general factors in gas-phase chain processes is the reaction of components of the reaction mixture with solid surfaces. These include the surfaces of the reaction vessel, condensed reaction products, and various solid objects or particles introduced into the reaction medium for different purposes (for example, detectors, powdered quenching agents, etc.). The destruction of active intermediates on a solid surface (heterogeneous destruction). leading to termination of the reaction chains, determines to a large extent the regular features of the chain process, including its kinetics and thermal conditions. Heterogeneous termination also determines the magnitude of the concentration gradients of the chain carriers and the rate of the process as a whole. Heterogeneous termination provides a direct channel for the removal of energy from the reacting gas, and hence to a large extent it also determines the temperature gradients in the reaction medium.

A large number of papers have been devoted to the theoretical and experimental study of chain processes under different conditions of heterogeneous chain termination. By taking account of the destruction of the chain carriers on the surface of the reaction vessel, the theory successfully explains such important characteristic features of branched-chain processes (BCP) as the first self-ignition limit, the dependence of the limit on the dimensions of the reaction vessel and the composition of the mixture, and the dependence of the kinetics of the chain process and the first limit on the material of the walls of the reaction vessel.[1-6] The measurement of the first self-ignition limit provides a basis for methods for determining the rate constants of the homogeneous reactions of chain carriers[7-9] and their heterogeneous destruction (see for example Refs.3, 4, 10, and 11).

In a number of cases, chain initiation, that is the formation of active intermediate products involving only the original valence-saturated molecules, also takes place on the surface.[1,3,12-14] The heterogeneous–homogeneous reactions observed over various catalysts have been attributed to heterogeneous initiation.[12,14]

At the same time, up to the present, there has been very little investigation of the role of the surface in chain reactions. Until recently it was considered that chain termination on the surface was the only heterogeneous stage of the process involving the active intermediates. In the examination of the kinetics of chain processes (both in theory and in the treatment of experimental results), the following original propositions relating to the heterogeneous stages were generally accepted.

1. The adsorption of the chain carriers is identical to the reaction involved in their termination. In the quantitative examination of the kinetics of the process, in the solution of the kinetic equations, including their solution by means of a computer, and also in the treatment of experimental data, it was assumed that the sorbed chain carriers rapidly react with identical species to form the original molecules. The properties of the surface were assumed to remain unchanged during the entire process.

2. The heterogeneous destruction of the chain carriers shows first-order kinetics with respect to the concentration of these particles. Thus in the kinetic equations of the chain processes, heterogeneous termination was described by terms which were linearly dependent on the concentrations of the chain carriers.

3. It was generally assumed that if the first self-ignition limit is stable and the kinetic curves giving the concentrations of the components of the reaction mixture are reproducible, then the coefficient of the heterogeneous destruction of the chain carriers (the probability of their destruction on collision with the surface) is constant throughout the entire process. In the study of gas-phase reactions, the surface of the reaction vessel is "conditioned" beforehand by the reaction being studied, to obtain reproducible results. It was assumed that when reproducibility had been achieved, the state of the surface, the efficiency of the heterogeneous termination, and the coefficient of the destruction of the chain carriers on the surface remained unchanged from the beginning to the end of the chain process. The efficiency of the heterogeneous deactivation of the excited species and the accommodation coefficient for the heterogeneous destruction of the atoms and radicals were also assumed to be constant.

The study of BCP and the heterogeneous reactions of free atoms and radicals, however, led the present author to the conclusion that these original propositions are generally inapplicable.[15,16] In constrast to generally accepted ideas, it was found that during and under the influence of a chain reaction, the properties and functions of the surface may undergo extensive reversible changes, and this may not influence the reproducibility of the results. The changes in the state and role of the surface may be brought about by the following factors, not previously taken into account in the theory of chain processes: the chemical reaction of molecules, atoms, and radicals from the gas phase with the surface; the adsorption non-uniformity of the surface; and the reactions of the adsorbate with components of the gas phase.

The possible development of reaction chains involving sorbed atoms and radicals was also noted.[15,16] For example, the works cited gave the following heterogeneous reactions for the oxidation of hydrogen-containing compounds:

$$H_{sorbed} + O_2 \rightarrow HO_2$$
$$H + HO_2 \rightarrow 2OH$$
$$H + HO_2 \rightarrow H_2O + O$$
$$H + HO_2 \rightarrow H_2 + O_2$$

Some of these reactions lead to the transfer of the chain carriers into the volume. Thus the reaction of O_2 with sorbed H atoms and the subsequent stages can lead to the development of chains, which is equivalent to a decrease in the efficiency of the heterogeneous termination.[15,16]

Since the principal regular features of BCP are determined chiefly by the competition between the processes of chain branching and termination, the above heterogeneous processes and the reversible changes in the properties of the surface should play an important role in the process as a whole. Even when the reaction of a sorbed chain carrier with a gas phase species does not lead to the development of chains, but gives the final product, this increases the rate of the chain process, since it provides an additional channel for the consumption of the starting material. The heterogeneous reactions of atoms and radicals, leading to the development of chains, can obviously take place much more rapidly than the decomposition of the molecules on the surface, accompanied by the removal of radicals into the volume. Because of their high rates, the reactions of the type given in Refs.15 and 16 may play an important role even in the fast processes of developing combustion.

It should be noted that until recently, in the study of BCP, most quantitative measurements under static conditions were related to self-ignition limits and to the kinetics of the reaction above the second limit. At the same time, significant changes in the properties of the surface and a contribution from these changes to the process as a whole are to be expected primarily under combustion conditions, in the course of which high concentrations of active intermediate species are produced. It was in the examination of the experimental data under chain combustion conditions that the present author detected significant deviations from the linear theory (see below).

In Ref.15, in the treatment of experimental data from Ref.17, it was found that the observed rates of combustion of H_2 were several times greater than the values calculated by traditional methods which do not allow for the reversible change in the efficiency of the heterogeneous destruction of the chains during combustion. In Refs.15 and 16 it was also shown that the equations used in Ref.17 and in various other studies for the treatment of the experimental data for the most part do not correspond to the actual process: for most experimental conditions (see for example Ref.17), they lead unambiguously to negative values of the concentrations of the starting materials. This is due to the fact that these equations were obtained by the method of quasi-stationary concentrations, without allowance for the homogeneous nonlinear termination of the chains.

Subsequent experiments showed that the change in the properties and the role of the surface during chain combustion, and the significant influence of these changes on the chain process, are important and general properties of a whole class of branched-chain reactions. The principal results of work in which previously unknown general regular features of branched-chain reactions were detected and studied, and the important role of the reversible nonstationary nature of the properties and functions of the surface in these processes was revealed, are described below.

II. GENERAL CHARACTERISTICS OF EXPERIMENTAL PROCEDURE

In most cases the experiments have been carried out under static conditions using vacuum apparatuses, for the most part the standard assemblies for kinetic experiments. A combined procedure was used, involving the simultaneous recording of various kinetic characteristics of the reaction mixture and the process: the pressure of the mixture, the concentrations of the individual components from absorption spectroscopy, the intensity of the chemiluminescence, and, where necessary, temperature.[18-23] The previously prepared reaction mixture was transferred rapidly from an intermediate volume into an evacuated reaction vessel at the required temperature†. An oscillograph was used to record the above characteristics of the reaction system from the start to the end of the experiment. After the experiment with a given portion of gas, the reaction vessel was evacuated. The extent of the evacuation (to ~10^{-4} mmHg) and the evacuation time (3 min after attaining a pressure of ~10^{-4} mmHg) were kept constant in a given series of measurements.

In addition to the vacuum assemblies with lubricated taps, usually employed for kinetic experiments, a high-vacuum assembly in which the taps with lubricant were replaced by metallic vacuum valve taps (without lubricant) was also used. The evacuation system was separated from the rest of the assembly by these valves and by two traps arranged in series and cooled with liquid nitrogen. In the assembly with metal lubricant-free taps, the gas in both traps came into contact only with the cold walls (so-called traps without a hot wall).[23] In the standard assemblies for kinetic experiments, with lubricated taps, high-vacuum Apiezon N (saturated vapour pressure 10^{-9} mmHg) and sometimes Merck (silicone, 10^{-6} mmHg) lubricants were used. In some series of experiments, the vacuum lubricant produced in the Soviet Union (GOST 380183-75) was also used. The experimental procedure has been described in detail.[18-26] When a process was carried out in the same reaction vessel for identical initial conditions, the results of the measurements were the same, irrespective of the grade of lubricant used. Published data[23] show that the results of the study of BCP in this reaction vessel, even in the kinetic range of chain termination and close to the first ignition limit, are independent of whether the reaction vessel is in an ordinary vacuum assembly with lubricated taps or in an assembly in which metal high-vacuum taps without lubricant are used.

---

†In the study of the oxidation of phosphorus vapour, the working mixture was prepared in the reaction vessel.[21]

In most of the studies of this series, the primary aim was to determine whether it is possible to describe chain combustion on the basis of the above generally accepted ideas about the role of the surface, the nature of the heterogeneous reactions of the chain carriers, and the constant efficiency of heterogeneous termination during combustion. In addition to various other kinetic characteristics of BCP, use was also made of one of the most fundamental properties of reactions of this class, namely that chain combustion develops (undergoes self-acceleration) only when the rate of chain branching is greater than the rate of chain termination. For heterogeneous termination, this condition for self-acceleration of the process is determined by the inequality:[1-6]

$$2k_b[B] > k_{het} \quad (1)$$

where k_b is the chain branching rate constant; [B] the concentration of the starting material involved in the branching process; and k_{het} the heterogeneous termination rate "constant".

It can be seen that if the initial concentration of the original molecular substance B is greater than its concentration at the lower limit of self-ignition, for example by 2%, then in the absence of appreciable self-heating of the reaction mixture and positive interaction of the chains, immediately after the combustion of this 2% excess of substance above the limit, the rate of branching will become lower than the rate of termination. As a result, the self-acceleration of the combustion, and then the combustion itself, soon stop. This is the case, however, only if k_{het} is constant during the combustion, as previously assumed. If however in addition to the concentration of the substance B there is also a decrease in the "constant" k_{het}, it is obvious that after the combustion of the excess quantity of the starting material relative to the self-ignition limit, the branching process, for a certain time interval, will remain more rapid than the termination, so that the self-acceleration of the combustion will continue. In this case the self-acceleration of the combustion process will stop only at higher degrees of combustion. Thus if the efficiency of the heterogeneous termination decreases during combustion, the observed degree of combustion at the end of the reaction should be greater than that which would be observed if there were no change in the efficiency of the termination on the surface or in the absence of heterogeneous chain branching.

It can also be seen from Eqn.(1) that if during combustion the value of k_{het}, on the other hand, increases, that is if the efficiency of the termination increases, then the self-acceleration of the chain process will stop before the decreasing concentration of the starting material reaches the value corresponding to the first ignition limit. There is also a decrease in the final degree of combustion.

The final degree of combustion is defined as the fraction of the starting material used up at the end of the combustion:

$$\eta_\infty = \frac{[B]_0 - [B]_\infty}{[B_0]}$$

where $[B]_0$ and $[B]_\infty$ are the concentrations of the starting material at the initial moment and at the end of the combustion respectively.

The first self-ignition limit (P_1) is the average value between two neighbouring initial pressures (P_0), at the lower of which there is no ignition, while at the higher the gas undergoes self-ignition. The ignition was recorded from the chemiluminescence and from the self-accelerating change in the pressure of the mixture, brought about by the change in the number of moles of the gas in the closed volume as a result of the reaction. For the oxidation of silane and phosphorus vapour and the decomposition of NCl_3, the ignition was also recorded from the self-accelerating decrease in the absorption of light of the appropriate wavelength by the starting material. Additional control of the accuracy of the measured ignition limit is made possible by the fact that as the initial pressure approaches the upper limit, the ignition induction period increases sharply, approaching infinity.[19,25]

The degree of combustion can be readily determined from the initial and final pressures and the stoichiometry of the overall process. For example, the equations for the overall processes $2H_2 + O_2 \rightarrow 2H_2O$ and $2CO + O_2 \rightarrow 2CO_2$ show that the decrease in the number of moles of O_2 at the end of the combustion is equal to the decrease in the number of moles of the entire mixture:

$$\Delta[O_2]_\infty = \Delta[M]_\infty \quad (2)$$

where M represents any component of the mixture, and the subscript ∞ refers to the end of the combustion. Thus the degree of transformation of O_2 (degree of combustion) can be determined from the total pressure of the mixture. For a stoichiometric mixture

$$\eta_\infty^{expt} = \frac{(O_2)_0 - (O_2)_\infty}{(O_2)_0} = 3\frac{P_0 - P_\infty}{P_0} \quad (3)$$

The water vapour formed during combustion is absorbed to a large extent by various surfaces.[19,27,28] To determine correctly the final degree of transformation (degree of combustion) in these processes, a procedure has been proposed,[19,25] in which, when combustion has stopped, the water vapour is frozen out, and the residual pressure in the system is then recorded. The experimental value of the degree of combustion is then given by the expression

$$\eta_\infty^{expt} = (P_0 - P_\infty^w)/P_0 \quad (4)$$

where P_∞^w is the pressure after the water vapour has been frozen out.

In the oxidation of silane and phosphorus vapour the decomposition of nitrogen trichloride, the value of η_∞^{expt} was also determined by absorption spectroscopy.[19,20-22,26]

In the region of the first ignition limit and at temperatures appreciably greater than the temperature of the point of the ignition peninsula, heterogeneous termination in fact becomes the only route for the termination of the reaction chains. Moreover, low concentrations of the reagents close to the first ignition limit and relatively long combustion times decrease the self-heating and the role of termolecular reactions in most experiments. In the kinetic range of the chain termination process, however, there is practically no self-heating or termolecular reactions.[19] All this simplifies the interpretation of the results and makes it possible to reach unambiguous conclusions from the experimental data.

III. HETEROGENEOUS SELF-ACCELERATION OF BRANCHED-CHAIN PROCESSES

Fig.1 gives the oscillograms for a series of experiments with detonating gas at different initial pressures in a quartz vessel with a diameter of 5.5 cm, the surface of which was washed with hydrofluoric acid and treated with pulses of the mixture being studied to stabilise the value of the ignition limit and achieve reproducibility of the kinetics of combustion.[19,25] The chemiluminescence oscillograms are not given in Fig.1. The numbering of the curves corresponds to the sequence of the experiments. The quantitative reproducibility is illustrated by the kinetic curves *2* and *6*.

Because of the low pressures and the relatively high temperatures in these experiments, the rate of the heterogeneous disappearance of the H atoms is more than 150 times the rate of the termolecular reaction (VI)#:

$$H+O_2+M\rightarrow HO_2+M \qquad (VI)$$

Thus it is possible, without loss of accuracy, to neglect reaction (VI) and the reactions of those HO_2 radicals which are formed in this termolecular stage. Since the reaction time is much longer than the heat-removal time (by a factor of more than 10^5), there is no self-heating.[19]

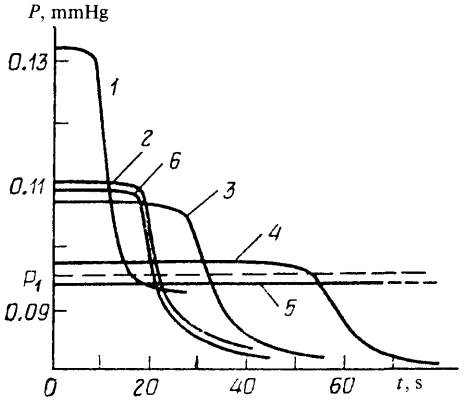

Figure 1. Oscillograms for the change in pressure during the combustion of a $2H_2 + O_2$ mixture at 743 K and different initial pressures (P_1 = 0.095 mmHg).[19,25]

Fig.1 shows that the self-ignition limit P_1 lies between the initial pressures of experiments *4* and *5*, and that, for example, in experiment *4* the magnitude of P_0 and hence the magnitude of $[O_2]_0$ are ~2% greater than the limiting values. If the efficiency of the heterogeneous termination (k_{het}) did not decrease during the combustion, the decrease in pressure accompanying the reaction in experiment *4* would have stopped before the broken line had been reached, that is before P_1. It can be seen from the oscillogram for experiment *4*, however, that the decrease in pressure close to the ignition limit not only does not stop but on the contrary continues to accelerate, even under the limit, reflecting directly the fact that the rate of branching continues to predominate over the rate of chain termination. Since there is no self-heating or purely homogeneous positive interaction of the chains, the predominance of the branching over termination can take place only as a result of a decrease in k_{het} during the combustion. The decrease in the efficiency of the heterogeneous chain termination during the combustion is also indicated by the fact that the combustion stops only after a degree of combustion corresponding to several tens percent O_2, which is greater by an order of magnitude than that expected without allowance for the decrease in the efficiency of the heterogeneous destruction of the chain carriers.

The results of another series of experiments are given in the Table. It can be seen that either ignition does not take place (experiments *3* and *9*), so that there is no combustion, or, if ignition takes place (experiments *1*, *2*, and *4–8*), the reproducible degree of combustion corresponds to tens percent of the mixture, even if the initial concentration is 2% greater than the ignition limit. Thus in this series of experiments at P_0 close to P_1, the degree of combustion is 10 times that expected for a constant efficiency of chain termination.

Final degrees of transformation of a $2H_2 + O_2$ mixture for different initial concentrations (P_1 = 0.097 mmHg, quartz reaction vessel washed with HF, T = 743 K).[19,25]

The theory of BCP[3] gives the following equation relating the concentration of hydrogen atoms in the isothermal flame of a mixture of H_2 and O_2 to the degree of transformation:

$$\frac{[H]}{[O_2]} = \xi = 2\eta + 2\frac{P_1}{P_0}\ln(1-\eta) \qquad (5)$$

This expression was obtained from the generally accepted scheme for the combustion of hydrogen:

$$OH + H_2 \rightarrow H_2O + H \qquad (I)$$

$$H + O_2 \rightarrow OH + O \qquad (II)$$

$$O + H_2 \rightarrow OH + H \qquad (III)$$

$$H + \text{wall} \rightarrow \text{chain termination} \qquad (IV)$$

and does not take account of changes in the reaction mechanism, the properties of the surface, and the efficiency of heterogeneous chain termination during combustion. In Eqn.(5), the ratio P_1/P_0 replaces the ratio $k_4/2k_2[O_2]_0$, where k_2 and k_4 are the rate constants of reactions (II) and (IV). It is assumed that the value of k_4 remains unchanged during combustion, like the value of k_2.

It can be seen from Eqn.(5) that after combustion, that is when $\xi = 0$, the final degree of transformation is given by the expression

$$\eta_\infty = -\frac{P_1}{P_0}\ln(1-\eta_\infty) \qquad (6)$$

This expression relates η_∞ only to the pressures P_0 and P_1, measured in the same series of experiments and relating to the initial moment of the process. It can be seen from Fig.2 that Eqn.(6) does not describe the large degrees of combustion, nor their abrupt increase immediately above the limit,

The following numbering of the elementary stages of the oxidation of hydrogen is used:

$H_2+O_2\rightarrow 2OH$ (0)
$OH+H_2\rightarrow H_2O+H$ (I)
$H+O_2\rightarrow OH+O$ (II)
$O+H_2\rightarrow OH+H$ (III)
H + wall → chain termination (IV)
$H_{sorbed} + O_2 \rightarrow HO_2$ (V)
$H+O_2+M\rightarrow HO_2+M$ (VI)
$H+HO_2\rightarrow 2OH$ (VII)
$H+HO_2\rightarrow H_2+O_2$ (VIII)
$H+HO_2\rightarrow H_2O+O$ (IX)
HO_2 → chain termination (X)

nor the subsequent marked decrease in the dependence of η_∞^{expt} on P_0/P_1 which takes place in spite of the presence of ten percent of the unreacted substance.

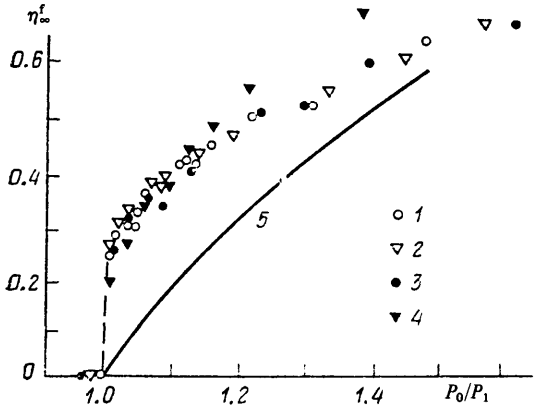

Figure 2. Final degree of transformation at 743 K for a $2H_2 + O_2$ mixture in a quartz vessel with diameter 5 cm, washed with hydrofluoric acid: *1*, *2*) reaction vessel in an assembly with lubricant-free valves, diffusion pump: *1*) oil, *2*) mercury; *3*, *4*) reaction vessel in an ordinary vacuum assembly with lubricated taps, oil diffusion pump; *5*) calculated from Eqn.(6).[23]

The previously accepted ideas about the constancy of the properties and the role of the surface in BCP also do not make it possible to describe the observed development of the chain process with time for all detectable degrees of combustion (Fig.3). It is also possible to compare the observed maximum rate of chain isothermal combustion with the calculated value obtained with the traditional assumption that only chain termination with an unchanged rate "constant" takes place on the surface. It is known that in a system in which combustion has begun, the starting materials are used up practically only in reactions with the chain carrier. Thus in the induction period, that is when the concentration of chain carriers is low, the rate of the process is practically equal to zero (see Fig.1). Thus under combustion conditions, the reaction of H_2 and O_2 molecules with one another can be neglected. The maximum rate of chain combustion is

$$w_{max} = -\left|\frac{d[O_2]}{dt}\right|_{max} = k_2[H]_m[O_2]_m \qquad (7)$$

where t is the time, and $[O_2]_m$ and $[H]_m$ the concentrations of O_2 and atomic hydrogen at the moment corresponding to the maximum rate of the BCP. It is obvious that

$$w_{max} < k_2[H]_{max}[O_2]_0 \qquad (8)$$

where $[H]_{max}$ is the maximum concentration of H atoms, and $[O_2]_0$ the initial O_2 concentration. Eqn.(5) readily gives the following expression for $[H]_{max}$:[19]

$$\frac{[H]_{max}}{[O_2]_0} = \xi_{max} = 2\left(1 - P_1/P_0 + \frac{P_1}{P_0}\ln\frac{P_1}{P_0}\right) \qquad (9)$$

Substituting the value of $[H]_{max}$ from this equation in Eqn.(7) for the conditions of, for example, experiment *3* (Fig.1) ($P_0/P_1 = 1.12$), and using the recommended[30]§ value $k_2 = 2.2 \times 10^{14}_{exp}(-70640/RT)$ $cm^3 mole^{-1} s^{-1}$ gives the calculated value $k_2[H]_{max}[O_2]_0 \cong 10^{13}$ molecule $cm^{-3} s^{-1}$ (that is 7.7×10^{-4} mmHg s^{-1}). From the inequality (8), the discrepancy between experiment and the calculation carried out without allowance for the change in k_{het} during combustion is even greater. There is also a qualitative difference between the dependence of w_{max} on P_0/P_1 observed experimentally and obtained by the traditional calculation.

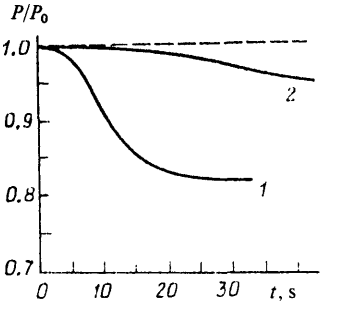

Figure 3. Kinetics of the consumption of O_2 in detonating gas, recorded experimentally (*1*) and calculated using a computer (*2*) according to the reaction scheme (0)–(IV) for a constant k_4 ($P_1 = 0.105$ mmHg). The sections of the curves after the induction periods are given.[29]

An indication that the principal reason for the "anomalies" is to be found in the heterogeneous stages is provided not only by the absence of self-heating and termolecular reactions, but also by the marked dependence of the effect of the anomalies on the material and state of the surface. For example, in reaction vessels from different quartz specimens, differences are observed not only in the ignition limits but also in the final degrees of transformation for a given pressure P_0/P_1.[19,25,31] In a number of other cases, the degrees of combustion are found to be practically identical for appreciably different P_1,[25,31] that is for different initial values of k_{het}. On some surfaces, anomalously high rates and degrees of combustion are not observed, and this does not depend on the value of P_1.

In contrast to the "anomalous" character of the kinetics of the developing combustion and the final degrees of combustion, the behaviour of the system in the induction period is described quantitatively by the familiar[3] expression which does not take account of any change in the value of k_{het} during the process. This also indicates that the factors responsible for the deviation of the kinetics from the linear theory arise during the combustion. Here, as in Refs.19 and 28, the induction period is defined as the time interval from the end of the introduction of the mixture into the reaction vessel to the moment when the greatest curvature is reached on the kinetic pressure curve.

§ Activation energy in J $mole^{-1}$.

Heterogeneous self-acceleration is also observed in the oxidation of CO in the presence of small quantities of H_2.[19,32,33] For example, for a value of $[O_2]_0$ which is 2% greater than $[O_2]_1$, a $2CO + O_2 + 2\%H_2$ mixture under isothermal conditions shows a degree of combustion of 12% (Fig.4), which is several times the value which would be obtained if there were no change in the efficiency of the heterogeneous termination. The anomaly in this case is particularly marked, if account is taken of the fact that in this process there are long chains with infrequent branching,[8,34] and the condition for chain combustion is defined by the inequality

$$2k_2[O_2]\frac{k_3[H_2]}{k_3[H_2]+k_5} \geqslant k_4$$

where k_5 is the rate constant for the heterogeneous disappearance of oxygen atoms. Since the consumption of O_2 and CO is accompanied by the consumption of H_2, which is responsible for the induction, it can be seen from the last expression that if the efficiency of the heterogeneous chain termination remained unchanged, the self-acceleration of the process would not stop until $[O_2]$ became equal to the measured limiting value. As in the case of the examples of the oxidation of H_2 examined above, this process took place isothermally, because of the low pressures and the long combustion times (0.21 mmHg and ~10 s respectively).

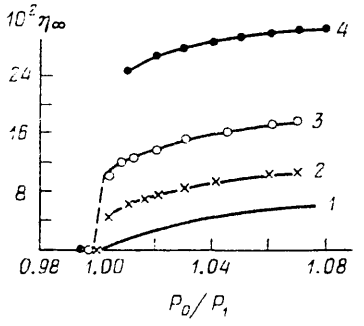

Figure 4. Final degree of combustion of O_2 in a $2CO + O_2 + nH_2$ mixture;[32] *1*) result of the solution of the system of equations for $n = 2\%$; *2*, *3*, *4*) results of the experiment for $n = 1$, 2, and 3% respectively; 723 K.

Heterogeneous self-acceleration is also observed in the branched-chain processes involved in the oxidation of phosphorus vapour[19,21] and silane[22] and the decomposition of nitrogen trichloride.[20,35]

IV. SORPTION OF THE COMPONENTS OF THE REACTION MIXTURE AND ITS ROLE IN COMBUSTION

The adsorption non-uniformity of a solid surface is due to the presence of both defects in the structure of adsorbent and surface compounds of different types. In particular, the surface of quartz under the conditions being considered is hydroxylated to a considerable extent (see for example Refs.36–40), and these hydroxyl groups (isolated or in groups) to a large extent determine the sorption properties of the surface.[36,37] At the temperatures of the experiments on the study of the combustion of H_2, CO, and hydrocarbons, evacuation leads to the partial dehydroxylation of the surface, as shown by the infrared spectra of the surface groups.[36,37] The introduction of water over the surface, however, leads to its rehydroxylation, for example as a result of the opening of siloxane groups.[36,37] The sorption of H_2O does not lead only to the formation of strong hydroxyl bonds "isolated" from one another.[36,37] Under the conditions being considered, water vapour is also extensively chemisorbed on a number of other surfaces used as coatings in kinetic experiments, including B_2O_3;[37] evacuation of the system leads to dehydroxylation of the surface.

Experimental data obtained in recent years show that during chain combustion even at 800–900 K, appreciable adsorption of stable and labile components of the reaction mixture takes place. This obviously influences the properties of the surface. For example, from the stoichiometry of the process

$$2H_2 + O_2 \rightarrow 2H_2O$$

it can be seen that the decrease in the number of moles of the mixture is equal to the number of moles of oxygen reacting.

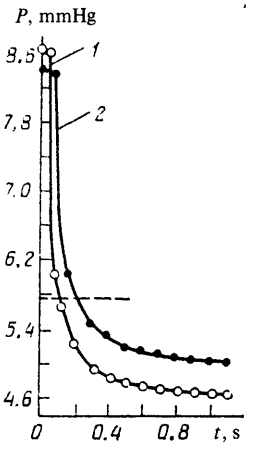

Figure 5. Kinetic curves giving the decrease in pressure during the combustion of a $2H_2 + O_2$ mixture at 923 K over MgO: *1*, *2*) experiments at different initial pressures.[19]

Thus if all the components of the mixture remained in the gas phase, it follows that in a closed volume at the end of the combustion of a stoichiometric mixture, the decrease in pressure should not exceed $^1/_3$ of the initial pressure. It can be seen from Fig.5, however, that, for example, for combustion over MgO the pressure decreases to a much greater extent; the broken line shows the final pressure which would be established for the complete combustion of the mixtures in experiment *1* (Fig.5) if there were no adsorption. Since the pressure of the mixture is lower than the saturated vapour pressure of H_2O, condensation does not take place, and all the additional decrease in pressure is due to adsorption. Special measurements show that during the combustion of H_2 close to the first ignition limit over MgO and over quartz, ~20–30% of the water formed is sorbed.[19,28] This influences the ability of the surface to terminate the reaction chains. The change in the adsorbing power of the surface is obviously accompanied by a change in the conditions of migration of the particles on the surface, that is there is a

change in the specific rate of recombination of the sorbed chain carriers with one another. When a role is played by Hinshelwood's mechanism, this leads to a change in the specific rate of heterogeneous chain termination. Moreover, the decrease in pressure brought about by adsorption leads to an additional change (and in the case being considered, an extensive change) in the coefficients of mass and heat transfer. All this influences the kinetics of BCP.

The adsorption of H_2O vapour on the surface of stainless steel is much weaker. Thus for identical initial conditions and identical values of P_1, the kinetics of combustion are different over MgO and over stainless steel. The extensive adsorption of hydrogen halides formed in the reactions of halogen-containing compounds also influences the efficiency of heterogeneous chain termination.[41]

Special measurements[25] in one of the quartz vessels in which "anomalously" high degrees of combustion were observed showed that the sorption of water vapour beforehand leads not to an increase but to a slight decrease in the extent of combustion.

In a number of processes, rapid sorption of chain carriers, not accompanied by their recombination during the process, also takes place. Thus for example at 400–600 °C, that is at the temperatures of the combustion of H_2, CO, and hydrocarbons, H atoms are rapidly chemisorbed on various surfaces which are often used in kinetic experiments (MgO and various types of technical quartz).[19,25,42] In these experiments, atomic hydrogen was obtained by the dissociation of H_2 on an incandescent tungsten wire and (in some experiments) using a high-frequency discharge. At the heater power used, the rate of chemisorption is limited by the rate of formation of H atoms and is close to the rate of combustion of H_2 with O_2 close to the first ignition limit. In the absence of O_2, some of the atoms remain on the surface for a period of time which is much greater than the time of the combustion of H_2 with O_2. These results are in good agreement with published data on the adsorption of H atoms on the surface of different types of quartz, not accompanied by rapid recombination (see for example Refs.43–47). The adsorption capacity and the rate of adsorption for the MgO surface is tens of times greater than that for the quartz surface.[19,25,42]

It has also been found that molecular oxygen reacts with adsorbed hydrogen atoms.[19,25,42] The characteristic time of this heterogeneous reaction is comparable with the time of combustion of H_2 with O_2 at analogous oxygen concentrations. Since in the experiment with synthetically prepared H atoms the reaction vessel was evacuated before the introduction of O_2, the most strongly chemisorbed H atoms remained on the surface at the start of the reaction. It is obvious that in the experiments on the study of the oxidation of, for example, H_2, some of the atoms adsorbed during the combustion are more weakly attached to the surface and therefore react with O_2 at an even greater rate. Thus some of the chemisorbed hydrogen atoms take part in the chain process, as suggested in Ref.15. The formation of HO_2 radicals in this heterogeneous reaction was observed, for example, in Ref.47. Since, as noted above, under combustion conditions the HO_2 radicals for the most part are involved in reactions in which there is positive interaction of the chains

$$HO_2 + H \rightarrow 2OH$$

it follows that some of the sorbed chain carriers are in fact finally returned to the gas phase, decreasing the efficiency of heterogeneous termination. Thus the mechanism proposed in Refs.15 and 16 has been confirmed experimentally in a number of studies.

The reaction of O_2 with adsorbed H atoms is of course not the only process altering the properties and role of the surface during combustion. At the same time, in addition to heterogeneous self-acceleration, it is the reactions of sorbed atomic hydrogen that led to the after-effect of combustion of H_2 in the oxidation of CO, in spite of the fact that the reaction vessel was evacuated before the introduction of the mixture of CO and O_2.[19,48] Direct experiments proved that the observed strong after-effect is not due to a trace of the molecular component; the introduction of H_2 and even H_2O into the reaction vessel with subsequent evacuation for the same time interval does not influence the combustion of carbon monoxide. On the other hand, treatment of the surface with the flame of a "dry" mixture of CO and O_2, in the course of which mainly oxygen atoms "disappear" on the surface, raises the first ignition limit of hydrogen.[11] Thus the inverse relationship between the state of the surface and the gas-phase process in this case is revealed in the fact that different BCP influence one another as a result of a change in the properties of the surface, which shows a "memory effect".

In a number of BCP taking place at temperatures which are not too high, an important role is also played by the adsorption of the starting materials. One such process is the oxidation of phosphorus vapour (P_4). Studies of this reaction have played an important part in the development of the theory of branched-chain processes. At the same time, the regular features and mechanism of this reaction have not been fully investigated. As in the study of other BCP, until recently no account was taken of possible changes in the state of the surface and change in the efficiency of heterogeneous chain termination. It has been shown experimentally[19,21,49] that under the conditions of the usual experiment with P_4 vapour, extensive adsorption of the vapour on the walls of the reaction vessel and connecting tubes takes place (the saturated vapour pressure is $\sim 2.5 \times 10^{-2}$ mmHg at room temperature). It has also been shown that the destruction of the chain carriers takes place 10^2–10^4 times more intensely on adsorbed phosphorus than on glass and quartz.[11,50] It may be noted that it was because of this previously unrecognised change in the efficiency of heterogeneous chain termination, characteristic of the usual experiment with phosphorus vapour, that the first ignition limit was sufficiently high to be detected and studied in classical experiments.[1,51,52]

EPR has shown[21,53] that during the combustion of P_4 vapour, appreciable quantities of P atoms and phosphorus–oxygen radicals are adsorbed on the walls of the reaction vessel and do not recombine. This to a large extent determines the stoichiometry of the overall gas-phase process. The quantities of these atoms and radicals "condensed" in the matrix of sorbed phosphorus vapour and other components of the mixture change during the combustion. When the combustion process is carried out in a stream, the composition of the sorbed intermediate products changes along the stream.

The influence of sorbed phosphorus on the kinetics of the combustion is shown particularly strongly under conditions when the surface is not completely covered by the adsorbate. Since the adsorbed phosphorus is used up in the reaction with the chain carriers, the efficiency of chain termination decreases during the combustion. Thus under these conditions, anomalously high rates of the process and degrees of combustion are observed.[19,21] The results of one of the experiments are illustrated in Fig.6. P_4 was introduced into an evacuated reaction vessel to give a stationary pressure of 2×10^{-3} mmHg (which is 12 times lower than the saturated vapour pressure over solid white phosphorus). It is obvious that at this low pressure, the surface concentration of adsorbed phosphorus present in equilibrium with the gas phase is also low. When the given P_4 vapour pressure had been established, O_2 was introduced slowly into the

reaction vessel. When the pressure of the mixture reached 4.87×10^{-2} mmHg, the subsequent addition of O_2 was carried out in portions (δ). The pressure of each portion was 2×10^{-4} mmHg. Fig.6 shows that the time intervals between the O_2 supply pulses was 1 min, which is much greater than the ignition induction period. It can be seen from Fig.6 that, for example, in the given series of experiments at 4.98×10^{-2} mmHg, the mixture is under the limit, so that there is no ignition. When the next portion of O_2 is added, the mixture is above the limit, and self-ignition takes place. During combustion under the conditions being considered, there is no homogeneous positive interaction of the chains or self-heating.[19,26] At the same time, Fig.6 shows that the quantity of the mixture which has undergone combustion is ~15 times the quantity of O_2 introduced into the reaction vessel in the last portion, that is the degree of combustion is greater by an order of magnitude than the amount by which O_2 initially exceeds the ignition limit in the given experiment. The maximum rate of the chain combustion is also "anomalously high".

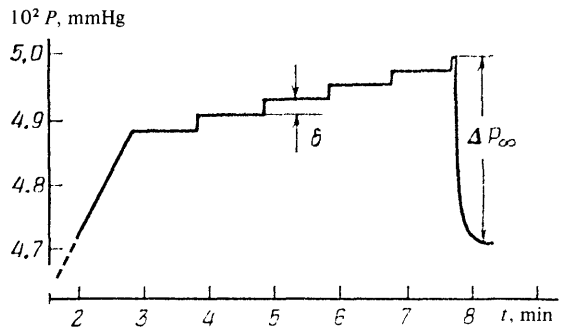

Figure 6. Kinetics of the change in the pressure of P_4 vapour and O_2 for the pulsed introduction of small portions of O_2 into a reaction vessel whose surface was impoverished in phosphorus.[21]

In recent papers,[54-57] the same authors tried to deny that a change in the state of the surface takes place during combustion; these authors state that the "anomalously high" degrees of combustion during the oxidation of H_2 result from the action of some inhibitor liberated from the vacuum lubricant of the taps. The data given in the works cited show, however, that the authors did not evacuate the assembly sufficiently after washing and lubricating the taps, so that the solvent sorbed in the lubricant was desorbed into the reaction vessel; the oscillograms given in Ref.56 show that in the closed reaction vessel in contact with the taps, the pressure increases at a constant temperature, in spite of the fact that in the reaction of H_2 with O_2 the number of moles decreases. This represents a fundamental difference between the experiment in Refs.54–57 and the experiments of all other authors, carried out at the same manometer sensitivity (for example Refs.17, 19, and 25). The introduction of a foreign substance into the reaction vessel in the experiments[54-57] and its inhibiting action are due mainly to the fact that in Ref.56, when the side-arm of the reaction vessel was cooled with liquid nitrogen, the mixture, which was initially under the first self-ignition limit, ignited. These results obviously have no relation to studies by other workers, carried out observing the generally accepted precautions for preventing the introduction of foreign substances into the reaction mixture.

Special experiments[23] showed that with the usual sufficiently thorough evacuation of the assembly, carried out after lubricating the taps, cooling the side-arm of the reaction vessel does not lead to the ignition of a mixture which is directly under the first limit. Moreover, Fig.2 shows that when the familiar requirements of the procedure are fulfilled, the degree of the observed "anomaly" in a given reaction vessel is independent of whether the reaction vessel is in an assembly with metallic lubricant-free valves (open circles and triangles) or in the ordinary apparatus for kinetic experiments with lubricated vacuum taps (black circles and triangles). The same is true of P_1 and the induction period. The results of the measurements coincide, irrespective of whether the connections in front of the intermediate volume are cooled with liquid nitrogen (open circles) or not cooled (open triangles), and also of whether the evacuation is carried out with an oil or a mercury diffusion pump.[23]

In Ref.56, a series of experiments was carried out with continuous cooling of the side-arms of the reaction vessel with liquid nitrogen to prevent the introduction of foreign substances from the insufficiently evacuated lubricant of the taps into the reaction vessel. The oscillograms given show that in all these experiments, the observed maximum rates of the process were appreciably greater (from two to twelve times greater) than the calculated values obtained without allowance for the change in the properties of the surface, that is the reaction rates were "anomalously high" even in those experiments of Ref.56 which the authors called clean. This fact was not noted in Refs.54–56.

It should be specially emphasised that in all the studies, the procedure used in the experiments to detect the "anomalous" kinetics of chain processes, and the vacuum assemblies used, are standard; this procedure and these assemblies have always been used and are still being used to study gas-phase chain processes. In particular, using this procedure and under the same conditions (including the same pressures) as in Refs.19, 23, 25, 29, and 54–57, different authors have determined the principal characteristic features of the first self-ignition limit of mixtures of H_2 with O_2, as a model BCP (see for example Refs.3–5, 10, and 58–60). Thus the assertion in Refs.54–57 that the vacuum lubricant has a distorting influence applies not only to the "anomalies" but also (and particularly) to the generally accepted procedure for studying BCP and to all their familiar regular features, previously established by different workers. As shown above, this assertion by the authors cited,[54-57] which categorises the generally accepted procedure and all the results obtained using it as erroneous, results from the fact that they attribute to the work of other authors the lack of thorough preparation of the assembly for the experiments which was shown in the works cited.

It is obvious that if some impurity had been introduced into the reaction vessel from the vacuum lubricant and had influenced the chain reaction when the usual precautions for ensuring the purity of the reaction mixture had been taken, then a large number of facts would not have been observed—the reliably established characteristic regular features of BCP, familiar from courses of chemical kinetics and from monographs. Examples of these regular features are: the marked dependence of P_1 on the material and the state of the surface of the reaction vessel;[2-6,59] the inverse relationship between the value of P_1 and the diameter of the reaction vessel, including that in the kinetic range of chain termination;[10,58,60] the quantitative agreement between

theory and experiment in the method for controlling ignition by means of metal rods;[4,10] etc.

V. KINETIC MODELS OF THE HETEROGENEOUS SELF-ACCELERATION OF BRANCHED-CHAIN PROCESSES AND A NEW TYPE OF FLAME PROPAGATION

On the basis of data obtained in the study of BCP, including the investigation of the nature of the heterogeneous reactions of the chain carriers and the mechanism of the decrease in the efficiency of termination on the surface, two principal types of kinetic scheme corresponding to the heterogeneous self-acceleration of various processes of chain combustion have been proposed.[19,29] These schemes explain both the ignition limits and the induction periods, and also the kinetics of combustion, including the dependence of the "anomalous" values of w_{max}^{expt} and η_{∞}^{expt} on the initial conditions. Analysis of these schemes shows, in particular, that on a number of surfaces under certain conditions, there is non-uniformity of the stationary states, and this is responsible for the critical phenomena within the ignition range, detected, for example, in Refs.19, 23, 25, 32, and 61.

The first of these reaction schemes takes account of the reactions of the gas-phase components with sorbed atoms and radicals and the subsequent positive interaction of the chains. In the case, for example, of the model BCP of H_2 oxidation, and also the combustion of a number of hydrogen-containing compounds, allowance for the reaction of O_2 with the sorbed H atoms and the reactions of the HO_2 radicals formed, suggested in Refs.15 and 19, leads to the following expression for the effective rate constant of heterogeneous chain termination:

$$k_{het} = k_{het}^0 \left[1 - \beta \frac{k_7 [H]}{(k_7 + k_8 + k_9)[H] + k_{10}} \right] \qquad (10)$$

where k_{het}^0 is the rate of the capture of atomic hydrogen by the surface at unit concentration of these particles in the gas phase (specific rate); β the fraction of sorbed H atoms forming HO_2 radicals with O_2; and k_7, k_8, k_9, and k_{10} the rate constants of the above reactions (VII)–(X) respectively.

Outside the ignition range, and also before the start of the combustion (in the induction period), when the quantity of H atoms is very small, the expression in square brackets in Eqn.(10) is practically equal to unity, so that

$$k_{het} = k_{het}^0$$

Thus in this case the adsorbed H atoms do not influence the efficiency of the heterogeneous termination. During the developed combustion, however, as a consequence of the marked increase in the concentration of atomic hydrogen, the value of k_{het} decreases, as can be seen from Eqn.(10), and tends to its limiting value:

$$k_{het}^c = k_{het}^0 \left(1 - \beta \frac{k_7}{k_7 + k_8 + k_9} \right) \qquad (11)$$

The superscript "c" indicates that the value relates to combustion conditions.

This decrease in the effective rate constant of the heterogeneous chain termination during combustion obviously leads to an additional sharp increase in the rate of the chain process, the concentrations of the chain carriers, and the final degree of transformation, as observed experimentally by the present author in the form of the "anomalies" (for example in Fig.2). Under given conditions, including given concentrations of O_2 and H in the gas phase, the fraction of sorbed hydrogen atoms capable of leading to the formation of HO_2 and to the development of chains depends on the material of the surface. This explains the fact that the extent to which the quantitatively reproducible regular features deviate from those expected on the basis of earlier ideas, that is the magnitude of the "anomalies", depends on the material of the surface¶.

Allowance for the heterogeneous development of the chains also makes it possible to explain the observed sharp decrease in the dependence of the maximum rate and degree of transformation on P_0 when the initial pressure increases above a certain value (see for example Figs.2 and 4). In fact, since the maximum concentrations of the chain carriers usually increase sharply with increase in P_0 and on passing through the first ignition limit, it follows that when the initial pressure is even only slightly greater than P_1, H atoms are formed during combustion in such large quantities that there is an appreciable decrease in k_{het} by the mechanism described above. There is a correspondingly anomalous sharp increase in the values of w_{max}^{expt}, η_{∞}^{expt}, and $[H]_{max}$. At the same time, because of the appreciable concentrations of H atoms even at values of P_0 which are only 1–2% greater than P_1, the constant k_{het} may reach its limiting value defined by Eqn.(11). It is obvious that in this case, with further increase in P_0 in each given experiment, the value of k_{het} will decrease to the above same limiting value, that is by the same amount. As a consequence of the sharp increase in the concentration of chain carriers on ignition, the decrease in k_{het} is complete in the earliest stages of the combustion, and the subsequent chain process proceeds to completion with a new decreased heterogeneous termination rate "constant", equal to k_{het}^c.

There are thus two stable values of k_{het}: one under stationary conditions, equal to k_{het}^0, and another under combustion conditions, given by Eqn.(11). Above a certain initial pressure P_0^* lying in the ignition range, for all values of P_0 the chain combustion takes place with the same stationary value of the heterogeneous termination rate "constant", k_{het}^c, which is much smaller than the initial value k_{het}^0. Since no further decrease in k_{het} takes place with increase in P_0 above P_0^*, the "anomalously" marked increase in η_{∞}^{expt}, w_{max}^{expt}, and $[H]_{max}$ also stops. This means that the dependence of these quantities on P_0 above the initial pressure P_0^* indicated in the absence of other heterogeneous reactions and self-heating should be described, with an accuracy corresponding to the correction for the contribution of the reaction

$$O + OH \rightarrow O_2 + H \qquad (II')$$

by Eqns.(6), (8), and (9), in which, however, the measured value of P_1 is replaced by the value corresponding to the new established value of k_{het}^c.

In fact, it is known that[2-6,59]

$$P_1 = k_{het}/2k_2\gamma_{O_2} \qquad (12)$$

where γ_{O_2} is the mole fraction of O_2. It is therefore obvious that the decrease in k_{het} to k_{het}^c leads to a corresponding lowering of the ignition limit to P_1^c, and the actual abscissae of the measured η_{∞}^{expt} are not P_0/P_1, but P_0/P_1^c. For example, in Fig.7 the experimental dependence of the degree of transformation on P_0/P_1 shows a break at $\eta_{\infty}^{expt} = 0.38$.

¶The reactions of the chains of the type (VII) and (VIII) may involve both desorbed HO_2 radicals and HO_2 radicals situated on the surface. In the general case, therefore, Eqn.(10) contains another negative fraction, analogous to that given, which also increases to its limiting value with increase in the concentration of H atoms during the combustion.

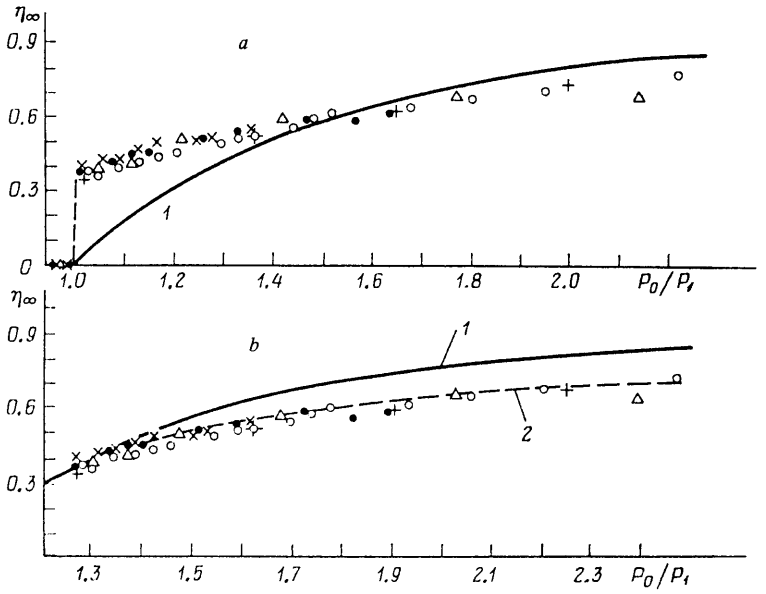

Figure 7. *a*) Change in the degree of transformation of O_2 with change in P_0/P_1 in different series of experiments at 723 K (different point symbols) and the results calculated from Eqn.(6) (curve *1*); *b*) the same data with the values of P_0/P_1 replaced; curve *2*—result of the computer solution of the system of kinetic equations corresponding to reactions (0)–(IV), (II').[19]

According to Eqn.(6), this degree of combustion corresponds to the ratio $P_0/P_1^c = 1.27$ (see curve *1* in Fig.7), which is 25% greater than P_0/P_1 obtained by dividing the initial pressure by the measured value of P_1, that is during the combustion, the values of k^c and P_1 decrease by 25%. Thus by increasing the abscissae of the measured η_∞^{expt} by 25%, it can be shown that all the experimental data lie on the calculated curve obtained by using a computer to solve the system of equations corresponding to the set of stages (0)–(IV) and (II') (broken line and all the experimental points in Fig.7*b*). This calculation was carried out using the published[30] rate constants of the homogeneous stages; the values of k_4 and k_4^c were determined from P_1 and P_1^c using Eqn.(12).

The mechanism of the heterogeneous reactions, examined above, and Eqn.(10), show that k_{het} may decrease even when the specific rate of the capture of these particles by the surface, that is k_{het}^0, does not decrease. The explanation for this may be that the "anomalously" high values of η_∞^{expt} and w_{max}^{expt} are also observed for various surfaces on which the adsorption of the chain carriers takes place in the diffusion range (MgO, stainless steel[19,28,61,62]). Fig.8, in addition to the experimental data of Ref.61, also gives the results of a computer calculation carried out in Ref.63 for the initial conditions of the experiment with allowance for self-heating, termolecular reactions, and homogeneous interaction of the chains, but without allowance for the change in the efficiency of the heterogeneous chain termination. The different calculated curves in Fig.8 correspond to change in the values of the parameters used. The broken calculated curve was obtained using an increased (relative to the recommended value[30]) value of the rate constant of stage (VI). For this value of k_6, the calculated second ignition limit was found to be less than half the measured values. It can be seen that for P_0 only slightly greater than P_1, the observed degrees of combustion are much greater than the calculated values. Moreover, in contrast to the results of the calculation,[63] the experimental curve shows a sharp abrupt increase in η_∞^{expt}, which also stops suddenly with increase in P_0, in spite of the fact that tens percent of the original mixture remain unreacted. Allowance for the reaction of O_2 with adsorbed H atoms makes it possible to explain the observed sharp changes in η_∞ with change in P_0/P_1 (as in the case where the process takes place over a quartz surface). For identical initial conditions and equal values of P_1, the kinetics of the combustion and the degrees of transformation are different over MgO and over stainless steel.[19] The characteristic features of combustion over MgO and over stainless steel, and the role of the non-stationary nature of the surface under these conditions, have been examined in detail.[19,64] In addition to the extensive chemisorption, noted above, of water vapour on the MgO surface during the combustion of hydrogen-containing compounds, which has a marked influence on the properties of the surface, rapid chemisorption of atomic hydrogen also takes place under these conditions. It has been noted[65] that the H atoms obtained by a discharge in H_2 reduce MgO, and in the presence of O_2 the following reactions take place:

$$Mg^{++}O^{2-}Mg^{++} \rightarrow Mg^{++}OH^-Mg^+$$
$$Mg^+ + O_2 \rightarrow Mg^{++}O_2^-$$
$$Mg^{++}O_2^- + H_2 \rightarrow Mg^{++}OH^- + OH$$
$$2Mg^{++}OH^- \rightarrow Mg^{++}O_2^{--}Mg^{++} + H_2O$$

in which the hydroxyl radical is formed.

A number of authors have reported the reduction of quartz by atomic hydrogen (see for example Refs.66 and 40), in agreement with the data of Refs.19 and 42.

The development of the chains and a change in the properties of the surface can obviously be brought about by heterogeneous reactions involving species other than atomic hydrogen. There are examples of oxidation involving oxygen present in a chemical compound in the solid phase (see for example Refs.66–69), including O^- radical-anions. Heterogeneous chain termination in other BCP can also be described by equations analogous to Eqns.(10) and (11).

In many cases, the sorption of a gaseous component leads to structural changes in the layer next to the surface, and to phase transformations;[64,70-72] this in turn influences the kinetics of the heterogeneous stages.

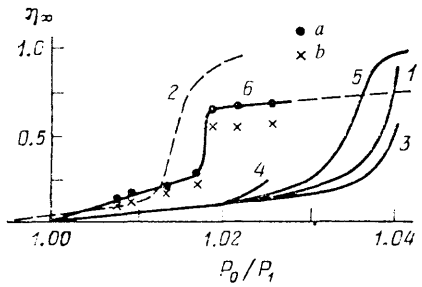

Figure 8. Comparison of the results of the calculation in Ref.63 (curves *1*–*5*) and the experiment in Ref.61 (points and curve *6*); T = 853 K, stainless steel vessel; curves *1*–*5*—calculation for different varying combinations of the rate constants; curve *2* (broken line) was displaced to the left along the abscissa by the authors of Ref.63; the points give the experimental data (*a*—with a correction for the volume of the connecting tubes,[31] *b*—results of the measurements without this correction).

In the theory of chain processes it has been assumed that in the absence of reactions involving interaction of the chains, the change in the concentration of active centres (n) with time (t) is described by the equation

$$\frac{dn}{dt} = w_0 + (f - g)n \qquad (13)$$

where w_0 is the rate of the chain initiation, and f and g the rates of chain branching and termination for unit concentration of the chain carriers (that is the coefficients of linear branching and termination of the chains respectively); f and g have been regarded as being independent of n.

With allowance for Eqn.(11), the equation describing the changes in the concentrations of the carriers with time is obtained in the form

$$\frac{dn}{dt} = w_0 + (f - g_0)n + \frac{an^2}{1 + bn} \qquad (14)$$

where a and b are the combinations of the quantities k_1, k_2, k_3, and β, and $g_0 \equiv k^0_{het}$. Unlike Eqn.(13), Eqn.(14) is non-linear with respect to n; at the same time the presence in eqn.(14) of a positive term in which the power of the quantity n is greater than unity indicates that a sufficiently high concentrations of the chain carriers in the volume or on the surface, the first ignition limit depends not only on the relationship between f and g_0 but also on the concentrations of the chain carriers and on the ratio of the parameters characterising the heterogeneous development of the chains and the reversible changes in the properties of the surface.

From Eqn.(14) it follows, in particular, that it is possible to lower the first ignition limit by artificially increasing the rate of initiation or by the preliminary adsorption of chain carriers. This conclusion has been confirmed experimentally: the preliminary adsorption of H atoms on magnesium oxide and on quartz leads to the quantitatively reproducible lowering of the first ignition limit in the reactions of H_2 with O_2 and of CO with O_2.[11,19,32,73] The quantitative reproducibility of the results shows that in this case also, the change in the properties of the surface under the influence of active intermediate species is reversible. As noted in Refs.19 and 32, in the combustion of CO the heterogeneous development of the chains may involve O atoms in addition to H atoms. The development of chains involving heterogeneous reactions of free atoms and radicals has also been detected in the branched-chain processes involved in the oxidation of silane[22] and phosphorus vapour[19,29] and the decomposition of NCl_3.[19,20]

Heterogeneous reactions of intermediate species, leading finally to chain development, may also play an important role in flame propagation. For example, it can be seen from Eqn.(14) that dn/dt increases with increase in n more rapidly than according to a linear law; this makes possible the non-thermal propagation of the combustion zone.

A number of studies of the decomposition and degenerate-branched oxidation of organic compounds (for example Refs.47 and 74–76) have shown that the adsorbed fragments of the molecules, reacting with O_2, form peroxy radicals which are transferred to the gas phase. In particular, atomic hydrogen, sorbed on the surface of the reaction tube during the decomposition of peroxyformic acid, reacts with O_2 from the gas phase to give HO_2 radicals. These radicals are removed from the reaction zone by the gas stream; they can be condensed by cooling and detected by EPR.[74] The mechanism proposed[76] for the decomposition of peroxyacetic acid includes the reaction of O_2 with adsorbed CH_3 radicals, leading to the partial removal of the methyl peroxy radical into the gas phase. This reaction, which is the analogue of the proposed[15,16] reaction of O_2 with adsorbed hydrogen atoms, also leads to heterogeneous chain initiation. The formation of OH radicals as a result of the reaction of O_2 with sorbed H atoms has been reported.[72,77,78] In these studies, the atomic hydrogen was obtained by an electric discharge in H_2.

The authors of Refs.38 and 79, who detected the reactions of sorbed methyl radicals with gas-phase components during the thermal decomposition of organic compounds over quartz and over MgO, explain the observed regular kinetic features of the chain process on the basis of a reaction scheme which also includes heterogeneous chain development. In a number of studies, the reaction of sorbed hydrogen atoms with deuterium from the gas phase has been observed (see for example Refs.44 and 79). The need to take account of the change in the efficiency of heterogeneous chain termination has also been pointed out in Refs.80 and 81.

The reactions of sorbed chain carriers must apparently be responsible for the observed[22] unique character of the kinetics of the combustion of silane with oxygen in a closed volume close to P_1, shown in Fig.9. It can be seen that the duration of the chemiluminescence after the attainment of the intensity maximum is ten times that before the maximum. It is difficult to attribute this almost constant (and low) rate of combustion to some negative interaction, since it is known[82,83] that in this process, on the contrary, an important role is played by the positive interaction of the chains. An unambiguous indication of this is provided by the observed[82] non-thermal propagation of the flame in a gas mixture outside the self-ignition range. Thus in the kinetics of combustion shown in Fig.9, heterogeneous chain development is probably of considerable importance. This is also indicated by the conditions of double ignition of a mixture of silane with O_2 in a closed volume, which depends on the previous treatment of the surface by the flame.[22,82]

In another type of heterogeneous process leading to "anomalous" self-acceleration of BCP and to non-uniformity of the stationary states, the principal factors are the non-uniformity of the surface and the disappearance of its active

sites during chain combustion. A specific example of a process of this kind is provided by the oxidation of phosphorus vapour.[29] For simplicity it is assumed that the heterogeneous chain termination is determined by only two types of surface: regions occupied by phosphorus, on which termination is very effective,[19,21] and regions free from phosphorus. In this case, the effective rate constant of the termination is given by the expression:

$$k_{het} = k_f + (k_o - k_f)(1 - b_0)\exp\left(-k\int_0^t n\,dt\right) \qquad (15)$$

where k_0 and k_f are the rate "constants" for termination on the active (occupied by phosphorus) and inactive (free) regions of the surface, b_0 the fraction of the inactive part of the surface at the start of ignition, and k the rate constant for the disappearance of the active sites of the surface (in this case the consumption of sorbed phosphorus).[29] It can be seen from Eqn.(15) that there are two stationary values of k_{het}: in the absence of combustion (before the start of the combustion or outside the ignition range), that is for $t = 0$ and $n = 0$, the value is

$$(k_{het})_{t=0} = k_o(1 - b_0) + k_f b_0 \qquad (16)$$

Under conditions where combustion has begun, however, as a result of the rapid increase in n, the value of k_{het} decreases sharply, tending in the limit to $(k_{het})_\infty = kf$. This decrease in the efficiency of heterogeneous chain termination obviously leads to additional self-acceleration of the chain process and to the "anomalously" high degrees of combustion observed experimentally.

If the rate constant k_f in Eqn.(15) is denoted g_0, and the product of the differences in front of the exponent by α, and if account is taken of the fact that k_{het} is represented by g in Eqn.(13), the latter can be written in the form

$$\frac{dn}{dt} = w_0 + \left[f - g_0 - \alpha\exp\left(-k\int_0^t n\,dt\right)\right]n \qquad (17)$$

Unlike Eqn.(13), Eqn.(17) is non-linear with respect to n, and, like Eqn.(14), it shows that the critical conditions for self-ignition depend on the concentration of chain carriers. Correspondingly, BCP may show kinetic features characteristic of processes with homogeneous positive interaction of the chains. Eqn.(17), like Eqn.(14), shows, in particular, that it is possible to have non-thermal propagation of the flame, brought about by a decrease in the efficiency of heterogeneous chain breaking ahead of the combustion front under the influence of the reaction chain carriers. This phenomenon was in fact detected by the present author; in a mixture of P_4 vapour and O_2 present in a long tube at a pressure under the first self-ignition limit, an isothermal flame passes along the tube if a small spark is produced at one end.[84] Special experiments showed that under these conditions there is no homogeneous interaction of the chains, and the regular features of the propagation of the flame depend on the material and state of the surface.[21,26] In these experiments, the quantity of adsorbed phosphorus was small, because of the low partial pressure, lower than the saturated vapour pressure.

The phenomenon of non-thermal "heterogeneous" propagation of a flame may also obviously take place in other BCP. In the more general case, a change in the efficiency of heterogeneous chain termination under the influence of chain combustion may lead to a change in the rate of propagation or to a change in the length of the combustion zone in the stream. In view of what has been said above, the rate "constant" for heterogeneous chain termination, appearing in the equation describing the propagation of the flame, depends not only on temperature but also on the concentration of chain carriers.

The dependence of the rates of branching (*1*) and termination (*2*) on the concentration of active intermediate products in the heterogeneous development of the chains and the passivation of the surface (the cases to which Eqns.(14) and (17) respectively relate) is given in Fig.10. At values of n greater than the abscissa of the second intersection of the curves or the point of tangency of the curves, chain branching predominates over termination, to an extent which is greater, the larger n becomes. This leads to self-ignition of the mixture, non-thermal propagation of the flame, etc. If the termination graph lies below the straight line *2'*, the mixture undergoes self-ignition for all values of n.

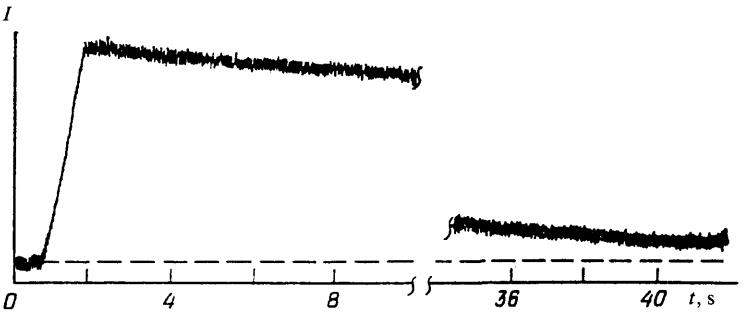

Figure 9. Oscillograms showing the change in the chemiluminescence during the combustion of silane in the mixture: 8% SiH_4 + 76.5% O_2 + 15.5% He; T = 473 K, P_0 = 0.96 mmHg.[22]

A mathematical description has been given[85] for the non-thermal propagation of a flame, brought about by the decrease in the efficiency of heterogeneous chain rupture ahead of the reaction front.

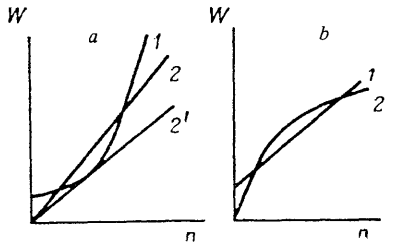

Figure 10. Rates of branching (*1*) and termination (*2*) in the cases corresponding to Eqns.(14) (*a*) and (17) (*b*).[29]

VI. PULSED CHAIN COMBUSTION AND THE NON-STATIONARY NATURE OF THE STATE OF THE SURFACE

A characteristic manifestation of the inverse relationship between the kinetics and mechanism of the heterogeneous reactions of chain carriers and gas-phase BCP is the condition of repeated self-ignition in a closed volume close to the first limit, which has been detected and studied for the decomposition of NCl_3 [19,20] and the oxidation of carbon monoxide,[18,19,48] silane,[22,82] and phosphorus vapour.[19,21,26,49] In most experiments, the concentrations of the reagents were very low, and ignition was not accompanied by self-heating.

The pulsed combustion of, for example, hydrocarbons and CO was also observed earlier.[86] The pressure of the mixture was several hundred mmHg, however, and the process was accompanied by considerable self-heating of the mixture. On this basis, the periodic ignition in the closed volume was related to the self-heating.[86-88] It is not excluded that under certain conditions, self-heating is in fact one of the necessary conditions for repeated ignition.[89,90] It cannot be assumed, however, that self-heating is necessary for pulsed conditions in all cases. Close to the first ignition limit, the regular features of the pulsations are determined to a large extent by the dependence of the reactions of the sorbed chain carriers, the desorption of the molecular reagents, and the change in the efficiency of the heterogeneous termination on the nature of the surface and on the type of BCP. In the oxidation of CO and P_4 vapour and the decomposition of NCl_3, the number of ignitions for a single introduction of gas into the reaction vessel may be greater than 50, depending on the initial conditions, including the quantity of sorbed chain carriers.

The decisive role of chemisorbed chain carriers in, for example, the pulsed combustion of CO over an MgO surface was shown by the following experiment.[48] It was established that when the ignition of a "dry" mixture of CO and O_2 was carried out repeatedly, the number of pulsations decreased from one experiment to another. Since the concentration of the original reagents and the other conditions remained unchanged in all the experiments, the marked decrease in the number of pulsations was due to the change in the properties of the surface. The introduction into this reaction vessel of H_2, water vapour (the original promoters), CO_2 (the combustion product), or a mixture of H_2 and O_2 at a pressure below its first ignition limit, with subsequent evacuation, led to practically no increase in the number of ignitions of the $2CO + O_2$ mixture introduced into the reaction vessel after the evacuation. If however two or three ignitions of H_2 with O_2 were carried out in this "exhausted" reaction vessel, then after evacuation the picture of repeated ignition of CO was restored. This shows that intermediate combustion products, that is hydrogen atoms, are chemisorbed on the surface, remain partly on the surface after evacuation, and subsequently lead to the repeated ignition of the mixture of CO and O_2 when it is introduced into the reaction vessel.

The pulsed combustion of CO over, for example, MgO is explained as follows.[19] As shown by EPR spectroscopy,[11,91] in the combustion of CO in the presence of hydrogen or water vapour under the given conditions, tens percent of H_2 (H_2O) are present as atoms and radicals. An appreciable proportion of the latter disappear on the surface. As noted above, there is considerable chemisorption of H atoms during combustion. As a result, there is a decrease in the concentration in the reaction mixture of hydrogen (or water), which acts as the initiator of the given chain reaction; as a result, the combustion stops. After some time, the initiator is returned from the wall into the volume (as H_2 or H_2O molecules), and when its concentration exceeds the critical value, the mixture ignites again. Since some of the O_2 and CO are used up in each ignition, the pulsations are gradually quenched.

Under certain oscillation conditions, the intensity of the ignitions passes through a maximum with increase in their sequence number.[19,20,21,92] The explanation given in Ref.19 for this regular feature was based on allowance for the changes in the ignition period, the quantity of desorbed reagent (starting material, inductor, etc.), and the properties of the surface. The conclusions reached[18,19] about the important role of the reversible non-stationary nature of the properties of the surface under pulsating CO combustion conditions agrees with the fundamental ideas in later papers.[80,81,93,94]

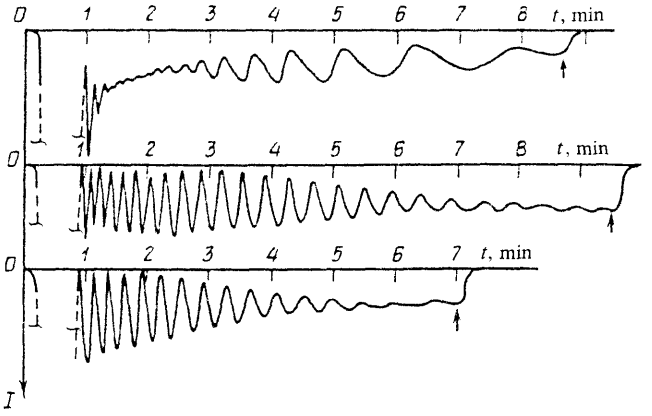

Figure 11. Repeated ignition of NCl_3 in a mixture with helium over different surfaces; the arrow indicates the moment of evacuation.

The active role of the non-stationary state of the surface (primarily as a result of the change in the concentration of chain carriers sorbed on it) under pulsating conditions is also indicated directly by data on the oxidation of silane.[22,83]

This chain reaction shows reversible changes in the properties of the surface, which have a marked influence on the course of the BCP, the "memory effect" of the surface, and hysteresis.

Fig.11 gives oscillograms showing the change in the intensity of the absorption of light (at a wavelength of 248 nm) by nitrogen trichloride under conditions of repeated ignition in a closed volume over NaCl. The increase in the concentration of NCl_3 between ignitions was due to its desorption. The difference in the pulsation conditions in different experiments was due to the fact that the preliminary treatment of the surface, including its treatment by the reactions of the chain carriers, was carried out in different ways.[20] The observed change in the period of the fluctuations and the extent of the combustion on the first oscillogram shows that the efficiency of the heterogeneous chain termination decreases during ignition.

In the study of BCP pulsed conditions, an extremely fruitful approach is to analyse mathematical models of the reactions using, in particular, the methods of stability theory, if account is taken of the reactions of the sorbed chain carriers in the analysis of the phase trajectories;[19] for this purpose, at least one of the axes of the phase space must be assigned to these sorbed species.

VII. HETEROGENEOUS SELF-RETARDATION OF BRANCHED-CHAIN PROCESSES

On a number of surfaces, as a result of heterogeneous reactions of the components of the reacting mixture, the efficiency of chain termination may increase (in contrast to the decrease described above).[29,96] In this case, the values of the rates and the final degrees of combustion reproduced quantitatively in the experiment are lower than the values calculated from the linear theory, that is they are "anomalously" low. This heterogeneous self-retardation has been detected[25,95] for the combustion of detonating gas over NaCl and over alkaline $K_2B_4O_7$.

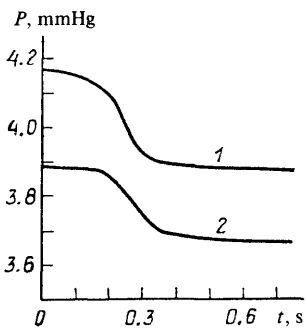

Figure 12. Oscillograms showing the change in the pressure of a $2H_2 + O_2$ mixture over NaCl in two experiments with different initial partial pressures of oxygen $P_0(O_2)$ equal to 1.39 mmHg (curve *1*) and 1.29 mmHg (curve *2*); P_1 = 3.19 mmHg.

Fig.12 gives as examples oscillograms showing the change in the pressure of the mixture with time in two experiments of one of the series at 787 K (quartz vessel with diameter 5.2 cm, covered with sodium chloride). The O_2 pressure at the limit ($P_1(O_2)$) was 1.06 mmHg. Thus for example in the first experiment the initial oxygen pressure $P_0(O_2)$ was greater than $P_1(O_2)$ by 0.3 mmHg. This means that if the efficiency of the heterogeneous chain termination did not increase during the combustion, the self-acceleration of the process would stop after the combustion of this quantity of O_2 in excess over the limit. Since according to the stoichiometry of the process the decrease in the O_2 pressure, within an accuracy corresponding to the concentrations of the active intermediate chain-carrier species, is equal to the decrease in the pressure of the mixture as a whole ($\Delta P(O_2) = \Delta P$), then for a constant value of k_{het}^c the self-acceleration would stop (that is the kinetic curve would show an inflection) only at $\Delta P \cong 0.33$ mmHg. Fig.12 shows, however, that the self-acceleration stops well before this quantity of O_2 has undergone combustion. The inflection (see for example curve *1*) is observed at a value of ΔP equal to only 0.14 mmHg, that is at an O_2 pressure which is 18% greater than $P_1(O_2)$, measured in the same series of experiments. Fig.12 also shows that the combustion stops at $\Delta P = 0.29$ mmHg, that is at an O_2 pressure which is even slightly greater than $P_1(O_2)$. At the same time, if the efficiency of the heterogeneous chain termination were constant, then when this value of $P(O_2)$ had been reached, the reaction should have taken place at maximum rate. The same "premature" stoppage of the chain combustion also takes place in the second experiment.

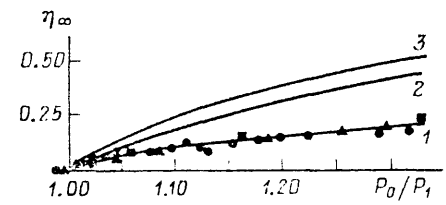

Figure 13. Dependence of the final degree of transformation of H_2 with O_2 on P_0/P_1: *1*) experiment over NaCl (the different point symbols correspond to the data from different series of experiments at 787 K); *2*, *3*) calculated from Eqn.(6) and from the analogous equation for the diffusion range.[95]

Fig.13 gives the dependence of the degree of transformation on P_0/P_1, obtained experimentally and calculated from Eqn.(6), and also using the analogous equation for the diffusion range of termination.[95] The results of the measurements are reproduced quantitatively in different series of experiments. The values of P_1 measured in different series also coincide. At the same time, the data show that the observed values of η_∞^{expt} are ~2.5 times lower than the results of the calculation which does not take account of the change in k_{het}^c during the combustion. The experimental values of the maximum rates are also several times smaller than the calculated values. Thus the results obtained show that self-retardation of the combustion of a $2H_2 + O_2$ mixture takes place over NaCl. This self-retardation is revealed primarily by the fact that the concentrations of the starting materials remaining after combustion are higher than the quantitatively reproducible limiting concentrations measured in the same experiments.

A noteworthy feature is that the first ignition limit of detonating gas in a quartz vessel with a non-continuous coating of MgO, for example, at 869 K is 3.88 mmHg, that is it is close to the value of P_1 over NaCl at 787 K. At the same time, in contrast to the combustion over NaCl, in the

case of MgO the values of w_{max}^{expt} and η_{∞}^{expt}, observed in the absence of self-heating, are appreciably greater than the calculated values obtained without allowance for the change in the properties of the surface during combustion.[19,62] The dependence on P_0/P_1 over MgO differs qualitatively from that observed over NaCl. The sorption of H_2O on NaCl is slight,[95] and, which is more important, does not lead to any significant increase in the specific rate of chain termination. Resonance fluorescence and emission spectroscopy have shown directly[97] that atomic hydrogen, formed in a flame of H_2 and O_2, with NaCl and KCl surfaces leads to the appearance of sodium and potassium atoms respectively in the gas phase. A change takes place in the chemical composition of the surface, which becomes darker. The reaction of the H atoms with the Cl^- ions of the crystal lattice apparently leads to the reduction of metal cations, some of which volatilise (metal atoms were detected in the gas phase), and some are oxidised. The heterogeneous destruction of atoms on the surfaces of metals and their oxides is extremely efficient.[6,50]

Reaction in the volume according to the scheme:

$$Na_2 + H \rightarrow Na + NaH$$

is also not excluded. In this case, the reproducibility of the kinetic data is ensured by the fact that the layer of NaCl above the quartz surface is sufficiently thick.

Analysis has shown[29] that self-retardation of the combustion of detonating gas also takes place in the experiments corresponding to the kinetic curves given in Ref.98; after combustion has stopped, the O_2 concentration remains higher than the concentration corresponding to the first ignition limit and measured in the same experiments. At the same time, if the rates of branching and termination are linearly dependent on the concentration of chain carriers, then it is known that the chain combustion undergoes self-acceleration until the concentration of the starting material is higher than the first ignition limit.[1-5] Thus if in Ref.98 the results of the measurements were reproduced, this means that in these experiments there was self-retardation of the combustion of H_2, which was not noted in the work cited. On the contrary, the authors cited,[98] pointing out the slight discrepancy between the experimental data and one of the approximate equations, and attributing this influence merely to the ballast volume, consequently point out the quantitative agreement between the experimental data on the dependence of the maximum rate on the decrease in pressure and the results of the calculation carried out using an equation which does not take account of the change in the state of the surface. This agreement was illustrated[98] using diagrams. The quantitative agreement between the calculation and the experimental data of Ref.98 was also mentioned in Refs.1 and 4. Since at the same time the kinetic curves giving the change in pressure in Ref.98, as already noted, show marked self-retardation of the combustion, good reproducibility apparently was not obtained. In Ref.99, in the section giving the data on the detection, above $K_2B_4O_7$, of "anomalously" high degrees of combustion of H_2, that is degrees of combustion greater than the calculated values, it is pointed out that in a vessel insufficiently pretreated by ignitions, the observed degrees of combustion are lower than the calculated values in the initial series of experiments.

Analysis of the regular features of the pulsed combustion of NCl_3 in various series of experiments in Ref.35 also reveal heterogeneous self-retardation of BCP over various surfaces.

In view of the non-uniformity of surfaces and the variety of heterogeneous processes, it is possible that in addition to reactions leading to the self-retardation of BCP, other process take place simultaneously on other centres, leading to a decrease in the efficiency of heterogeneous termination.

---o0o---

In most experiments to reveal the heterogeneous factors and carry out the most complete investigation of their role in the mechanism of chain reactions (for example in Refs.2–4, 19–23, 25–29, and 32), the processes were carried out under isothermal conditions. At the same time it is obvious that the characteristic features of the chemical mechanism of BCP, including the change in the efficiency of heterogeneous chain termination, and also the reversible non-stationary nature of the properties of the surface, play an important part in the non-isothermal process (see Figs.5 and 8 and also Refs.19, 31, 61, and 64). Since heterogeneous termination is one of the principal routes for the removal of energy from the reaction system, the change in the rate "constant" of this termination influences the thermal conditions of BCP not only through the change in the kinetics of the combustion, but also directly.

It should be noted that the nature, rate, and role in the chain process of the reactions of sorbed chain carriers with molecular components differ fundamentally from the familiar heterogeneous decomposition of valence-saturated molecules, which is also sometimes accompanied by the removal of atoms and radicals into the reaction volume (see for example Refs. 12–14 and 100–107). The decomposition of the original molecules with the transfer of active fragments from the surface to the volume in the chain process is only heterogeneous chain initiation. A variation of this initiation is the decomposition of intermediate molecular products on the surface in many processes involved in the slow oxidation of organic compounds in the liquid and gas phases†.[47,75,101-103] Chain initiation by the reactions of molecular intermediate products (degenerate branching) increases the rate of the process. In the absence of appreciable self-heating, however, it cannot lead to the high rates characteristic of chain combustion or to "anomalous" features analogous to those described above.

The branching of the chains was not degenerate in any of the processes studied in a series of investigations to detect and study the non-stationary nature of the surface in chain combustion processes (see for example Refs.15, 19, 21, 22, and 32); in these processes, branching is brought about by active centres, that is free atoms and radicals, which undergo reactions differing qualitatively from decomposition. The lifetimes of these particles in the reaction mixture are much shorter than the time of the development of one chain. Thus the reaction chain during its development becomes branched, in contrast to the case of degenerate branching. The heterogeneous processes responsible for the observed regular features (for example in Refs.16, 19–23, 25–29, 32, 48, and 84) are also not due to the decomposition of intermediate species formed in the homogeneous stages. Moreover, the rates of the heterogeneous stages involving the chain carriers in the processes studied in the works cited are 10 times the rates of the reactions which play a role in degenerate-branched processes.

As noted in Ref.29, the reversible changes in the properties of the surface and the reactions of sorbed species should also have a significant influence in the combustion of hydrocarbons, including "cold flame" conditions and the

†In some liquid-phase oxidation processes, isomerisation of a peroxide radical takes place on the surface, with subsequent decomposition to a valence-saturated molecule and another radical.[102]

negative temperature dependence of the rate. Regular features indicating this type of heterogeneous process were observed in Refs.108–110, where it was shown that in the oxidation of hydrocarbons taking place only in the presence of a heterogeneous catalyst, the self-heating of the mixture in the centre of the reaction vessel is greater than that directly over the catalyst. The authors cited[108–110] also detected "hysteresis" phenomena, fluctuating hydrocarbon combustion conditions above the catalyst.

The emission of excited molecules from the surface into the gas phase, observed in some studies (see for example Ref.111) may also influence the kinetics of the chain reaction, if these molecules are involved in the stage limiting the rate of the process.

It was also pointed out in Ref.29 that the non-stationary nature of the properties of the surface should lead to a change with time in the rate "constant" of heterogeneous deactivation; in this process also, an inverse relationship to the state of the surface should be expected. This must be taken into account in processes taking place with the participation of excited species, including those in fluorination processes. Appreciable non-stationary character may also be shown by the value of the energy accommodation coefficient in heterogeneous recombination, both in chain processes and in plasma-chemical processes.

Thus a large number of new regular kinetic features have been detected for different types of BCP over different surfaces. The principal factors determining these regular features have been revealed. It has been shown that the development of chain combustion with time, and also the dependence of the main characteristics of the process on the initial conditions, differ qualitatively and quantitatively from those expected on the basis of earlier ideas which did not take account of the heterogeneous development of the chains and the reversible change in the efficiency of heterogeneous termination during combustion.

The above examples of the theoretical interpretation of the observed phenomena show that for the description of the regular kinetic features of BCP, the theory should take account of both those reactions whose rates are directly proportional to the concentrations of the chain carriers and those reactions whose rates show a non-linear dependence on these concentrations, while appreciable non-linearity appears in the course of the heterogeneous chain termination. Thus even in the initial stages of chain combustion, when the consumption of the starting materials can still be neglected, the process corresponds to non-linear differential equations.

The reversible changes detected and studied in the last twelve or thirteen years in the state, role, and composition of the solid surface during gas-phase branched-chain reactions, and also the marked influence of these changes on the process as a whole, are opening up new perspectives for the solution of various applied problems. Since heterogeneous recombination is accompanied by fairly strong chemisorption of chain carriers and their reaction with the solid surface, it is possible to bring about a directed change in the composition and properties of surfaces using appropriate chain processes (see for example Refs.22, 83, and 97). By selecting the solid material, it is possible to achieve the removal, from the surface into the gas reaction medium, of active intermediate species with the required chemical character, including species containing atoms from the solid phase.[97] By carrying out appropriate preliminary chemical modification of the surface using a gas-phase process, it is possible to bring about the chain reaction between the given starting materials for given initial conditions and ignition limits at different rates to give different final compositions (see for example Refs.19, 22, and 48).

The subsequent development of the theory of branched-chain processes and the solution of applied problems related to combustion or the existence of heterogeneous chain termination require allowance for the above regular features and factors.

Radical Processes in the Adsorption of Olefins on Zeolites

A.A.Slinkin and A.V.Kucherov

The formation and reactions of radical species in the interaction of olefins with zeolites of different types are examined and the nature of the oxidation-reduction centres, the mechanism of the thermal reactions of radicals, and the possible role of radical structures in catalytic processes on zeolites are discussed.
The bibliography includes 37 references.

I. INTRODUCTION

The catalytic reactions and mechanisms of the adsorption of olefins on zeolites of different types have been the subject of numerous studies and their results have been surveyed in a number of monographs.[1-3] In the vast majority of the publications the catalytic and adsorption processes involving olefins are discussed taking into account the formation as intermediate species of carbonium ions or carbanions on Lewis or Brønsted centres.

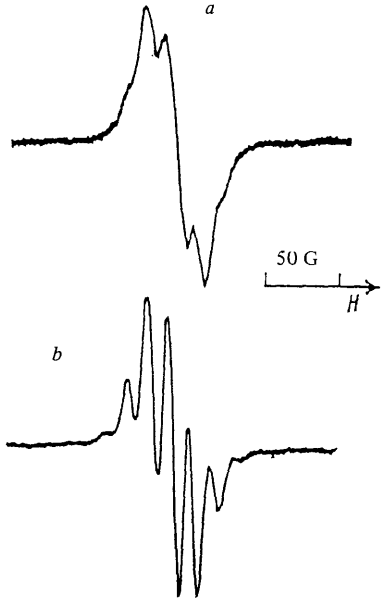

Figure 1. The EPR spectra arising in the adsorption of oct-1-ene (*a*) and pent-2-ene (*b*) from solution in CCl_4 on the lanthanide-form of the zeolite Y.[6]

Many fewer studies have been devoted to the radical species arising in the interaction of olefins with zeolites of different structure and to the nature of the centres initiating the formation of radicals, the mechanism of the thermal reactions of radicals, and their possible role in catalytic processes. This problem has acquired particular interest in recent years in connection with the discovery of the unique ability of high-silica zeolites to convert olefins into aromatic compounds.[4,5] The aim of the present review was to survey the available data concerning the mechanisms of the formation and reactions of radicals in the adsorption of olefins on zeolites and also to discuss the nature of the centres responsible for the one-electron charge transfer process.

II. THE FORMATION OF RADICALS IN THE ADSORPTION OF OLEFINS ON ZEOLITES OF THE FAUJASITE TYPE

The EPR spectra arising in the adsorption of olefins (2-methylbut-2-ene, 4-methylpent-2-ene, pent-2-ene, and oct-1-ene) on zeolites were apparently first published by Hirschler et al[6] (Fig.1): the adsorption was carried out from solutions in CCl_4 on the lanthanide-, Ca-, and Ce-forms of a type Y zeolite after their preliminary heat treatment at 500 °C in a stream of dry air. The same spectra, albeit slightly broadened owing to the high concentration of radicals, were observed in the adsorption of the pure olefins. The removal of the sorbed gases from CCl_4 (by evacuation) does not alter the EPR spectra, i.e. the oxygen contained in solution does not influence their characteristics.

The ratios of the intensities of the components of the spectrum (1 : 6 : 15 : 20 : 15 : 6 : 1) (Fig.1*b*) agree well with the EPR spectrum for the case of six equivalent protons with a hyperfine structure (HFS) constant a_H = 13.5 G. The EPR spectrum of oct-1-ene with the component intensity ratios 1 : 4 : 6 : 4 : 1 and a_H = 12.0 G corresponds to a species with four equivalent protons. The EPR spectra observed in the adsorption of 2-methylbut-2-ene and 4-methylpent-2-ene contain respectively 7 and 5 poorly resolved components with approximately binomial intensity ratios. The above values of a_H, which are approximately equal to half the corresponding values for the protons of the CH_3 group in the ethyl radicals (26.87 G), show, according to Hirschler et al,[6] that the unpaired electron in the radicals formed can be delocalised over two carbon atoms. It is fairly difficult to understand how radicals with five or six equivalent protons are formed from the adsorbed olefins mentioned above. It is believed[6] that the EPR signal produced can be associated with the olefin isomerisation or polymerisation products. At any rate, the polymer extracted from the zeolite, formed after the adsorption of pent-2-ene, gave rise to the

same EPR spectrum as that observed in the adsorption of pent-2-ene. Hirschler et al[6] do not express any views about either the nature of the centres on which the radical species are formed or the structure of the radicals formed.

Suzaki et al[7] continued the investigation of the properties of radicals arising in the adsorption of the olefin (but-1-ene) from the gas phase on the cation-substituted (Ce, Mg, Ca, Sr, Zn) zeolites Y and compared the rate of formation of the radicals with the rate of isomerisation of but-1-ene. The adsorption of but-1-ene on the CaY zeolite (degree of exchange 91.8%) at 25 °C leads to the appearance of a spectrum which is completely identical with that illustrated in Fig.1*b* with $a_H = 14.7$ G and $g = 2.002$. At temperatures from −16° to 25 °C and a but-1-ene pressure p ranging from 0.065 to 160 mmHg the steady-state concentration N of the radicals formed is expressed by the equation

$$N = N_s \frac{Kp}{1 + Kp}, \qquad (1)$$

where $N_S = 2 \times 10^{11}$ spins cm^{-2} and $K = K_0 \exp(\Delta H/RT) = 0.9$ (mmHg)$^{-1}$ (at $T = 25$ °C and for $\Delta H = 4.1$ kcal mole^{-1}); N_S amounts to 10^{-3} of the number of adsorbed but-1-ene molecules, i.e. 0.1% of the adsorbed olefin molecules are converted into radicals. A characteristic feature of the behaviour of the radicals formed is that they are stable if the gas phase contains but-1-ene molecules but recombine on evacuation (the EPR signal gradually disappears), the kinetics of this process being described by a second-order equation. If thermal desorption is carried out after the disappearance of the EPR signal, then it is possible to observe the presence of octane, octene, butane, butene, propene, and propane.

The experiments carried out by Suzaki et al[7] to investigate the influence of the zeolite dehydration temperature on the intensity of the EPR spectrum enabled them to put forward certain considerations about the mechanism of the formation of the radicals. Thus the possibility of the formation of a radical as a result of the transition of an H atom from the OH group of the zeolite to a but-1-ene molecule with formation of a 2-butyl radical is postulated†, because the intensity of the EPR spectrum increases by a factor of 15 on reducing the dehydration temperature from 600° to 250 °C. According to the authors,[7] the increase of the signal intensity after the addition of H_2O confirms the proposed mechanism and the formation of octane at temperatures above 100 °C and the decrease of the EPR signal intensity on evacuation are due to the recombination of the 2-butyl radicals. The seven equally spaced lines in the EPR spectrum have been explained by the interaction of the unpaired electron with the six equivalent hydrogen atoms of the radical formed. If this is true, then, as stated correctly by the above investigators,[7] the HFS constant should be the same as for the α- and β-protons in the butyl radical in the liquid phase, i.e. approximately twice as great as the measured value (14.7 G). The authors suggest that this contradiction cannot be eliminated by assuming the formation of the allyl radical as a result of the abstraction of a hydrogen atom from the but-1-ene molecule, because in this case it would be difficult to account for the influence of the dehydration temperature and the addition of H_2O on the EPR signal intensity.

Thus the authors[7] postulate the formation of the 2-butyl radical and suggest that the low HFS constant can be due either to the perturbation of the wave function of the unpaired electron under the influence of the electrostatic field of the zeolite lattice or to the decrease of the unpaired electron density of the carbon atom of the radical owing to the partial transfer of the electron to the zeolite, i.e. the formation of a partly charged 2-butyl radical.

Another important feature of the investigation of Suzaki et al[7] is the attempt to compare the concentration of radicals with the degree of isomerisation of but-1-ene and to show that the 2-butyl radical can behave as an intermediate in the isomerisation process. This idea is seemingly confirmed by four observations:

1. the number of radicals in different cation-substituted forms of the zeolite Y is correlated with the degree of conversion of but-1-ene (Table 1);
2. the dependence of the rate of isomerisation on the hydrocarbon pressure is of the same type as the corresponding dependence of the intensity of the EPR signal of the radical formed, which is described by Eqn.(1);
3. at a constant pressure the degree of isomerisation of but-1-ene changes following the addition of H_2O in proportion to the change in the EPR signal intensity; we may note that, when the EPR signal intensity changes by a factor of approximately 4, the degree of isomerisation is only slightly altered;
4. following the addition of O_2, the isomerisation reaction is suppressed and 2-butyl radicals are converted into peroxy-radicals.

Table 1. Dependence of the degree of conversion α of but-1-ene and the concentration of radicals N_S on the type of zeolite employed (β is the degree of exchange).[7]

Catalyst	β, %	$10^{-15} N_S$, spins/100 mg	α, %	Catalyst	β, %	$10^{-15} N_S$, spins/100 mg	α, %
CeY	91.8	200	88	ZnY	91.8	2	20
MgY	72.5	80	80	CuX	—	*	13
CeY	67.5	60	68	CoX	83.3	nil	5
CaY	93.2	10	58	MgX	96.8	nil	traces
CeX	—	10	37	ZnX	100	nil	traces
NH_4Y	90.5	9	72	TlX	100	nil	traces
SrY	97.6	4	65	NaY	100	nil	traces

*It may be that the EPR signal of the radical is not observed owing to its overlap by the signal due to the Cu^{2+} cation.

However, having measured the rate of isomerisation and the rate of formation of radicals using a mixture of deuteriated and non-deuteriated but-1-enes, the authors showed that the rate of isomerisation is higher, i.e. the 2-butyl radical is not an intermediate and is not in equilibrium with the intermediate of the isomerisation reaction. It is also assumed that a small proportion of 2-butyl radicals on the outer surface of the zeolite may be an intermediate product of the isomerisation process.

Although the authors[7] seemingly demonstrated that the radicals formed in the adsorption of but-1-ene on cation-substituted zeolites Y are not intermediates in the isomerisation reaction, this idea was again discussed by Otsuka et al.[8] They investigated the isomerisation of *cis*-but-2-ene at 25 °C on the zeolite HY (degree of exchange 86%) subjected to vacuum heat treatment in the range 400–650 °C. They studied the influence of promoting agents (CCl_4, $SiCl_4$, $GeCl_4$, $SnCl_4$, and HCl) on the rate of reaction and compared the latter with the concentration of the radicals formed on the initial and promoted zeolites. It was found that the rate of isomerisation on the zeolite evacuated at 650 °C increases sharply in the presence of preadsorbed CCl_4.

†Here and henceforth the radical $CH_3CH_2\dot{C}HCH_3$.

The promoting effect of CCl_4 is manifested only for zeolites heat-treated above 500 °C. An infrared spectroscopic study of the interaction of CCl_4 with the acid OH groups of the zeolite heat-treated at 650 °C showed that this interaction is weak and reversible: the entire adsorbed CCl_4 is removed by evacuation at room temperature.

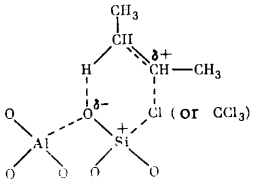
On the other hand, the data presented in Table 2 show that CCl_4 preadsorbed on the zeolite evacuated at 650 °C induces a sharp increase of the EPR signal intensity during the subsequent adsorption of *cis*-but-2-ene. The adsorption of the olefin on the clean specimen is accompanied by the appearance of only a weak EPR signal. It is noteworthy that this signal consists of a seven-component spectrum with $g = 2.003$ and $a_H = 14.5$ G and is almost identical with the signals observed by other workers;[6,7] among all the chloro-compounds investigated, only CCl_4 induces a sharp increase of the EPR signal intensity. The specimen evacuated at 400 °C is not subjected to the promoting effect of CCl_4 as regards the intensity of the EPR signal due to the adsorbed olefin and also the catalytic activity.

Table 2. The relative intensities I of the EPR signals of the radicals formed in the *cis*-but-2-ene + chloro-compound + zeolite HY system at 25 °C.[8]

Adsorbate	I, rel. units
CCl_4 + butene	17*
CCl_4 + butene	280
$SnCl_4$ + butene	21
$GeCl_4$ + butene	5
$SiCl_4$ + butene	13
HCl + butene	5
Butene	7
Butene	23**

*The temperature of the preliminary heat treatment of the zeolite was 400 °C; in the remaining cases it was 650 °C.
**After 24 h; in the remaining cases—after 1 h.

In conformity with the hypothesis put forward by Suzaki,[7] Otsuka et al. believe that the EPR spectrum observed during the adsorption of *cis*-but-2-ene is due to the formation of a partly charged 2-butyl radical, which is an intermediate in the isomerisation reaction, and the increase of the rate of the isomerisation reaction under the influence of CCl_4 is related to precisely this factor. The observed[8] increase of the rate of isomerisation under the influence of other chlorine-containing additives, which do not induce an increase of the EPR signal, has been explained by the modification of the Brønsted acid centres. The unique ability of precisely CCl_4 to promote the formation of radicals in the adsorption of the olefin is associated, according to Otsuka et al,[8] with the possibility of the dissociation of CCl_4 into the radical species CCl_3 and Cl (not detected by EPR) on centres arising in the high-temperature dehydroxylation. The CCl_3 or Cl radical species stabilised on the electron-accepting centre promote the formation of a partly charged 2-butyl radical on interaction of the olefin with the acid OH group. The proposed mechanism of the interaction is shown below:



The results of detailed studies of the interaction of various olefins with cation-substituted zeolites of the faujasite type have been described.[9–12] It is emphasised[9] that the adsorption of olefins on zeolites leads to the appearance of EPR spectra with an odd number of components, which cannot be explained, according to the author,[9] by the addition (or abstraction) of hydrogen atoms to (from) the olefin molecule, since the signal of such a radical would have had an even number of components (if all the hydrogen atoms in the molecule participate in the formation of the HFS). It is therefore suggested that the radical species arises as a result of electron transfer from the zeolite lattice to the olefin molecule. Data for the formation of the radical in the adsorption of but-1-ene on the zeolite CeX (68% exchange) are presented as an example. The EPR spectrum produced contains seven components ($g = 2.0037$, $a_H = 14$ G); the signal intensity is much greater in this case when the adsorption is carried out on a specimen activated *in vacuo* and then treated with O_2. It is suggested that an electron is transferred to the olefin molecule from the Ce^{3+} cation or from the reduction centre.

A further development of the study quoted above involved the investigation[10] of the formation of radicals in the adsorption of various olefins (propene, isobutene, *cis*- and *trans*-but-2-enes, but-1-ene, and *cis*- and *trans*-pent-2-enes). After the adsorption of the above olefins, EPR spectra containing seven and nine components and having a binomial distribution of intensity appear ($g = 2.0023 \pm 0.0005$, $a_H = 14$ G). The author[10] suggests that the radical species do not have the allyl structure, because 3,3,dimethyl-but-1-ene, which does not produce such a structure, gives rise to an identical EPR spectrum. Cyclic olefins (cyclopentene and cyclohexene) give rise to intense EPR signals with a poorly resolved HFS.

The following properties of the radical species may be noted in relation to the radicals formed in the adsorption of isobutene:

1. the radicals are stable at room temperature;
2. an increase of temperature to 50 °C entails an increase of signal intensity, which falls on further increase of temperature;
3. cooling to room temperature again results in the appearance of a signal with an HFS but with a lower intensity;
4. the radicals are stable when acted upon by O_2, CO_2, and H_2O: exposure of the specimens to air for several days does not result in the destruction of radicals;
5. the adsorption of H_2O, before the adsorption of the olefin or simultaneously with the latter, inhibits the formation of radicals.

The influence of various substituting cations in zeolites X and Y and also of the heat treatment conditions has been studied in greater detail by Krzyzanowski.[11] The appearance of a seven-component spectrum of the type described above in the adsorption of propene on zeolites X and Y containing the cerium, lanthanum, and praeseodymium cations proceeds, according to the author,[11] as a result of electron transfer from the lanthanide cation (particulary Ce^{3+}) to the propene molecule. The same mechanism of the formation of the radical has been put forward for the zeolite FeY containing Fe^{2+} cations capable of being converted into Fe^{3+}. However, zeolites containing Co^{2+} do not generate radicals following the adsorption of an olefin, like the zeolite CaX. The adsorption on the zeolite CaY results in the observation of a low-intensity EPR signal. The behaviour of zeolites AgY and AgX proved to be interesting.[11] In this case the EPR signal (an intense singlet with $g = 2.0025$ and a width $\Delta H = 7.2–7.4$ G) appeared also in the adsorption of ethylene, which had not been observed in studies involving other zeolites.

It is essential to note that for the zeolites CeX and CeY there exists a threshold degree of exchange which depends on the activation temperature and the type of zeolite and below which radicals are not formed in the adsorption of an olefin. Table 3 presents the corresponding data for the formation of radicals in the adsorption of but-1-ene. It is striking that the threshold concentration for the zeolite CeY is lower than for the zeolite CeX (particularly at low activation temperatures). This fact has been explained[11] by the lower degree of migration of cerium cations in the zeolite Y towards centres which are not readily accessible for interaction with olefinic centres (S_I in hexagonal prisms and $S_{I'}$ and $S_{II'}$ in sodalite cells).

Table 3. The influence of the degree of exchange β and the activation temperature T_a of the zeolites on their ability to form radicals.[11]

Type of zeolite	T_a, °C	β, %	n
CeX	300	40	11.3
CeX	450	45	12.7
CeX	550	56	15.8
CeY	300	15	2.8
CeY	450	20	3.7
CeY	550	55	10.3

Notation: n is the number of Ce^{3+} cations per unit cell.

The conditions of heat treatment and the atmosphere in which it is carried out exert a significant influence on the concentration of the radicals formed. For decationated zeolites and the zeolites CaY and CeY with degrees of exchange guaranteeing the localisation of the cations in the large cavities, an increase of the activation temperature from 200° to 600 °C is accompanied by an increase of the EPR signal intensity possibly as a result of the increase of the number of defects on dehydration. On the other hand, in the case of the zeolites CeX with large degrees of exchange, the activation temperature can promote the migration of the cations to inaccessible centres and can decrease the concentration of the radicals formed.

The activation of the zeolite in an O_2 atmosphere increases sharply the concentration of the radicals formed in the adsorption of an olefin[11] and the higher the activation temperature the greater the EPR signal intensity. The effect of activation increases both with increase in the degree of exchange and with increasing O_2 pressure at the given temperature. When the zeolites activated in O_2 are treated with hydrogen, the intensity of the EPR signal due to the radicals formed in the subsequent adsorption of olefins diminishes to a greater extent the higher the temperature of the treatment in H_2. For the cerium-containing zeolites, the activating influence of O_2 can be explained by the appearance of cerium cations in the highest valence states (for example, Ce^{4+}), which are involved in the one-electron transfer.

The influence of O_2 on the formation of radicals in the adsorption of butene on the zeolite CaNaX has been studied in greater detail by Krzyzanowski.[12] He was able to show that, when the treatment of the zeolite in O_2 at 200 °C is accompanied by the appearance of the O_2^- radical-anion, then the concentration of the latter diminishes in the adsorption of butene. It has been suggested that the butene molecule is converted into a radical by abstracting an electron from the oxygen radical-anion. Krzyzanowski[12] also observed the following extremely interesting effect: in the adsorption of butene on CeNaX the concentration of the O^- radical-anions initially rises sharply and then falls (Fig.2). This phenomenon was explained by the conversion of the diamagnetic forms of the oxygen anions (O^{2-} or O_2^{2-}) into the paramagnetic form O^- on interaction with butene molecule and by the subsequent decrease of the O^- concentration accompanied by the simultaneous increase of the concentration of organic radicals. Thus in the first instant of adsorption the olefin molecules behave as electron acceptors (the appearance of the paramagnetic form O^-) and are converted into radical-anions, after which the concentration of the O^- radical-anions diminishes either owing to the formation of the neutral form O and the subsequent increase of the concentration of the organic radical-anions or owing to the conversion of O^- into O^{2-}; in the latter case the olefin molecules behave as electron donors. Krzyzanowski[12] did not discuss the question which of these processes leads to a decrease of the O^- concentration.

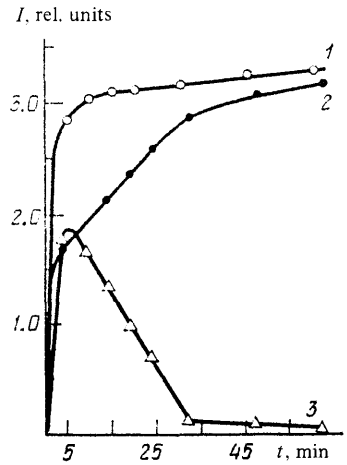


Figure 2. Variation of the intensity I of the EPR signals of radicals with the time t for the CeNaX-68 zeolite treated in N_2O at 500 °C (curves *1* and *3*) and 200 °C (curve *2*): *1*) and *2*) radicals formed in the adsorption of butene; *3*) O^- radical-ions.

Thus we have considered studies in which the formation of organic radicals was observed in the adsorption of olefins on decationated and various cationic forms of zeolites of the type of faujasite. Analysis of the results shows that at present there is not any single point of view both on the nature of the radicals formed and on the centres responsible for their appearance as well as their role in catalytic processes. We can only note the most important questions which have not yet been solved or which have received contradictory answers in studies by different investigators.

1. It has been shown that the adsorption of various olefins both from solution[6] and from the gas phase[7-12] on cationic and decationated forms of faujasites leads to the appearance of EPR signals which have virtually identical parameters. However, it is not clear whether this spectrum refers to a primary radical or an oligomeric radical or whether

it is characteristic of polymeric products which can be extracted from the zeolite surface.[6] It has been established that the heat treatment of the zeolite in O_2 increases significantly the intensity of the EPR signal during the subsequent adsorption of the olefin,[9,11,12] but data concerning the influence of O_2 and H_2O on the formation of radicals are contradictory. Thus it has been shown[6,10] that the presence of O_2 does not influence either the parameters of the EPR signal or its stability, while the adsorption of H_2O simultaneous with that of the olefin or its preliminary adsorption inhibits the formation of radicals. It has been established[7] that H_2O promotes the formation of radicals and that the form of the signal changes under the influence of O_2; this has been attributed to the formation of peroxy-radicals.

2. According to Suzaki et al.[7] and Otsuka et al.,[8] in the adsorption of olefins on faujasites alkyl radicals are formed as a result of the transfer of a hydrogen atom from the zeolite OH group to the olefin molecule and are stabilised by the partial transfer of electron density to the zeolite lattice. It is not clear whether this mechanism is sufficient for the stabilisation of the highly reactive alkyl radicals and, furthermore, on this assumption it is difficult to account for the strong activating influence of the treatment in O_2 and the appreciable increase of the EPR signal intensity on the cationic forms of zeolites (particularly the Ce-forms) compared with the H-form. The Ce^{3+} and Fe^{2+} cations cannot behave as radical-forming donor centres either,[9,11] because they are absent from the oxidised forms of zeolites. The Ce^{4+} cation functioning as an acceptor centre also cannot be regarded as responsible for the formation of radicals in the general case, because the latter are produced also on the decationated forms and on zeolites containing the Mg^{2+}, Ca^{2+}, and La^{3+} cations,[7] which do not behave as acceptor centres. The oxygen radical-anions formed under extremely specific conditions on the surfaces of faujasites[13] likewise cannot be regarded as the cause of the appearance of radicals in the adsorption of olefins, because in most cases they have not been detected either after the oxidative treatment of the zeolite or in the course of the adsorption of the olefin.

3. In our view, there is at present no convincing evidence that the above organic radicals are intermediates on faujasites, for example, in the isomerisation of olefins.[7,8] This hypothesis has been in essence rejected by Suzaki et al.,[7] although Otsuka et al.[8] later returned to it. Since the fraction of the radicals formed relative to the total number of adsorbed olefin molecules is 0.1%, it is evident that the amount of isomerisation products determined experimentally is due to the conversion of molecules which do not form radicals.

Next we shall consider the mechanisms of the formation and reactions of the radicals arising in the adsorption of olefins on high-silica zeolites, because in this case the available data permit a more detailed analysis of the nature of the radical-forming centres and of the structure of the radical species.

III. THE NATURE OF THE RADICALS FORMED IN THE ADSORPTION OF OLEFINS ON MORDENITE

The few studies devoted to the formation of radicals in the adsorption of olefins on mordenites dealt mainly with the character of the conformation and of the rotation of the radical species in the zeolite channels. Shih[14] obtained EPR spectra in the adsorption of *cis*- and *trans*-but-2-enes on the zeolite HM at low temperatures. It consists of a sextet of triplets arising owing to the interaction with the α- and β-hydrogen atoms, accompanied by the splittings a_{H_α} and a_{H_β} presented below:

Olefin	a_{H_β}, G	a_{H_α}, G	T, °C
cis-But-2-ene	16.2±0.4	8.2±0.4	−30
trans-But-2-ene	16.2±0.4	8.2±0.4	−50

Shih[14] assumes that the 16.2 G splitting is caused by the two identical CH_3 groups, while the 8.2 G splitting is due to the hydrogen atoms in the α-position, the small splitting by the α-hydrogen atoms being caused by the non-planar conformation of the alkene radical-cation.

The adsorption of tetramethylethylene on the zeolite HM at 25 °C is accompanied by the appearance of an EPR spectrum consisting of 13 equidistant components with a splitting of 17.5 G, corresponding to the interaction of the unpaired electron with the 12 equivalent protons.[15] The character of the spectrum changes little in the temperature range from −196° to 25 °C, which is due to the free rotation of the radical.

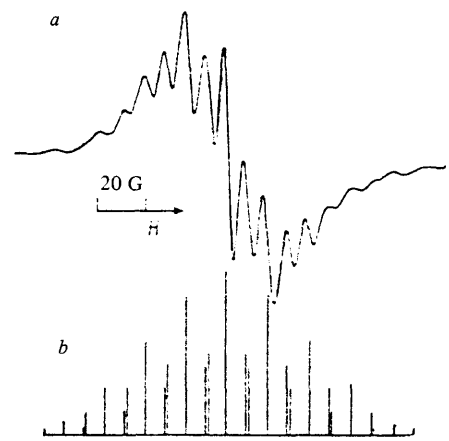

Figure 3. EPR spectrum arising in the adsorption of propene on the zeolite HM: *a*) experiment; *b*) calculation.

The EPR spectrum arising in the adsorption of a cyclic olefin (cyclopentene) on the zeolite HM was obtained in the same study.[15] A spectrum arises at −125 °C which can be accounted for by the splitting caused by the interaction with the four equivalent β-hydrogen atoms (a_{H_β} = 37 G) and two equivalent α-hydrogen atoms (a_{H_α} = 14.5 G). It is striking that in this case the splitting by the α-atoms is greater than in the case of the but-2-enes,[14] which is associated with the rigid planar conformation of cyclopentene. The observed EPR spectrum arising from the cyclopentene radical-cation[15] was accounted for on the hypothesis that the molecule rotates about an axis perpendicular to the five-membered ring. Calculation by the Hückel method showed that the unpaired electron is in a bonding π orbital and that its density is distributed equally between the two carbon atoms. Thus the splitting a_{H_α} = 14.5 G observed for cyclopentene is close to the value calculated from the McConnell relation $a_H = Q_{CH}\rho_C$ (Q_{CH} is a proportionality constant and ρ_C the π-electron spin density at the carbon atom), provided that Q_{CH} = 29.9 G (ρ_C = 0.5).

The adsorption of propene, but-1-ene, and pent-1-ene at 20 °C on the zeolite HM has been investigated by Leith.[16] All three hydrocarbons give rise to an EPR spectrum consisting of 19 lines with a_H = 8.1 G (Fig.3). The spectrum was described on the assumption that a radical of the type $CH_3-\overset{\beta}{C}H_2\overset{\alpha}{C}H=\overset{\alpha}{C}H=CHCH_3$ is formed from C_3H_6 and that the following interactions take place: (1) the interaction of one β-proton with one proton of the fixed CH_3 group (triplet with a_H = 33.6 G); (2) the interaction of one β-proton with two α-protons and with one proton of the CH_3 group (quintet with a_H = 16.8 G); (3) the interaction of the central proton with the last proton of the CH_3 group (triplet with a_H = 8.1 G). Heating to 100 °C reduces the splitting to 4.3 G and at 200 °C a broadened singlet with $\Delta H \cong 15$ G is observed. In our view Leith's description of the spectrum,[16] based on the concept of the formation of a linear dimer and of the presence of the three non-equivalent hydrogen atoms in one of the CH groups, is to some extent arbitrary. One should note that the observed spectrum is not sufficiently well resolved. However, Leith's observation[16] that the EPR spectra appearing in the adsorption of different linear olefins at 20 °C are identical is an important result.

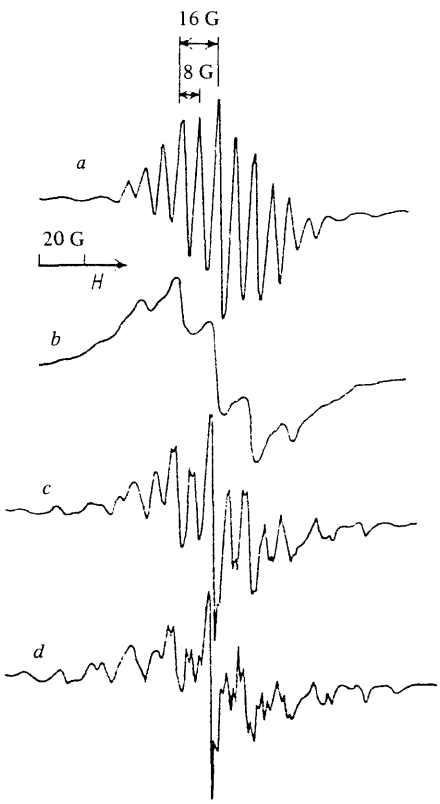

Figure 4. EPR spectra obtained 3 min (*a*), 1.5 h (*c*), and 8 h (*d*) after the adsorption of propene on the zeolite HM at 20 °C; *b*) spectrum of the specimen cooled to −196 °C after adsorption.

Unfortunately the studies of the formation of radicals in the sorption of olefins on zeolites HM examined above disregarded many important questions. (a) The nature of the primary radicals formed in the sorption of different olefins, the character of their thermal transformations, and the influence of various compounds on these processes were not analysed; (b) the structure of the centres responsible for the formation and reactions of the radical species was not discussed.

These problems were examined in greater detail in other investigations.[17-19] A study was made of the formation of radicals in the interaction of ethylene, propene, but-1-ene, isobutene, pent-1-ene, pent-2-ene, oct-1-ene, 2-methylhept-2-ene, cyclopentene, and cyclohexene with the zeolite HM. Fig.4 presents the EPR spectra observed in the adsorption of propene at 20 °C. Immediately after the adsorption of propene, an isotropic spectrum appears (Fig.4*a*); cooling the specimen to −196 °C is accompanied by the reversible conversion of this spectrum into that shown in Fig.4*b*. At 20 °C the spectrum in Fig.4*a* is slowly converted into that in Fig.4*c* (over a period of approximately 1.5 h) and further into the spectrum in Fig.4*d* (over a period of approximately 8 h). It is striking that the maximum intensity of the spectrum in Fig.4*a* is attained 5 min after adsorption, after which the signal intensity remains unaltered for approximately 6 h and corresponds to a spin concentration of 8×10^{17} spins g^{-1} (or one radical species per approximately 250 unit cells of the zeolite HM). Experiments involving the adsorption of propene on the deuteriated surface of the zeolite HM[17] showed that the hydrogen atoms of the radical species rapidly exchange with the OD groups of the zeolite HM even at −78 °C.

EPR spectra analogous to those illustrated in Fig.4 are observed in the adsorption of all the olefins investigated, except the cyclic olefins, at 20 °C. There are only some differences in the signal intensities and in the case of ethylene a spectrum with an HFS is observed against the background of a broader line.[20] These results confirm the data published earlier.[16]

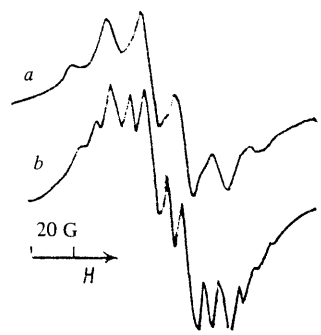

Figure 5. EPR spectra arising in the adsorption of propene on the zeolite HM at −78 °C: *a*) 2 h after adsorption; *b*) after brief warming of the specimen and recooling to −78 °C.

The identity of the EPR spectra obtained in the adsorption of various olefins shows that even at 20 °C rapid chemical reactions occur and the spectrum in Fig.4*a* is that of a radical with a secondary structure identical for different initial olefins. The data obtained in the study of the adsorption of olefins at a low temperature, where one can expect the formation of radicals from the unaltered molecules of the initial olefin, are therefore significant. For this purpose, a study was made[17] of the formation of radicals in the adsorption of ethylene, propene, but-1-ene, isobutene, pent-1-ene, and cyclopentene at −78 °C. It was noted that,

after the adsorption of ethylene on the zeolite HM at −78 °C, the EPR signal is not manifested for at least 3 h. The EPR spectrum arising in the adsorption of propene is illustrated in Fig.5*a*. Its intensity is appreciably lower than in the adsorption at 20 °C and its character remains unaltered for 5 h at −78 °C. A decrease of temperature to −196 °C is accompanied by an increase of the intensity of the broad line and the identical broadening of all the HFS components. A slow increase of temperature from −78 °C leads to an irreversible change in the EPR spectrum (Fig.5*b*), which is transformed at 20 °C into one of the type shown in Fig.4*a* and further into that in Fig.4*d*.

The adsorption of isobutene at −78 °C gives rise to the EPR spectrum shown in Fig.6*a*; cooling of the specimen to −196 °C results in the irreversible transition to the spectrum in Fig.6*b*. In this case too a gradual increase of the temperature of the specimen is accompanied by irreversible changes in the spectrum (Fig.6*c*). Fig.6*d* illustrates the spectrum obtained in the adsorption of but-1-ene at −78 °C; it coincides with that for the same olefin published by Shih.[14] The adsorption of pent-1-ene at −78 °C gives rise to the EPR spectrum of the type shown in Fig.4*a*, which is characteristic of the adsorption of propene at 20 °C. The changes in the spectrum on raising the temperature are identical with those shown in Figs.4*a*–4*d*.

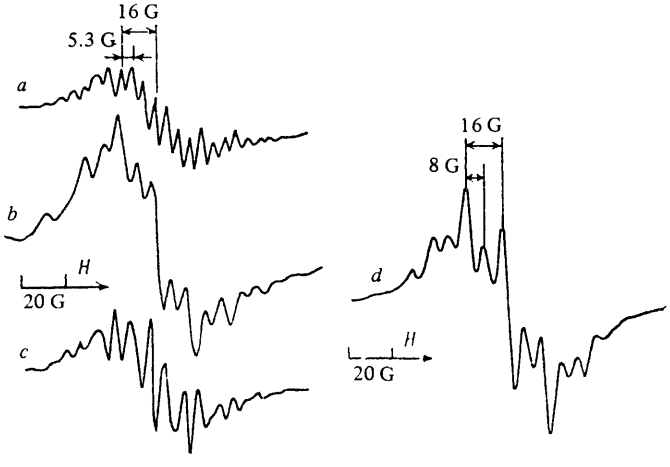

Figure 6. EPR spectra arising in the adsorption of isobutene (*a*–*c*) and but-1-ene (*d*) on the zeolite HM at −78 °C: *a*) 1 h after adsorption; *b*) after cooling to −196 °C; *c*) after brief reheating from −78 °C to 20 °C and recooling to −78 °C.

It is essential to note that the EPR spectra arising as a result of the interaction of all the olefins investigated with the zeolite HM[17] are stable only in the absence of oxygen; the introduction of O_2 at 20 °C leads to the instantaneous irreversible disappearance of the spectrum.

We shall analyse in greater detail the results of a study[17] of the first stage in the adsorption of olefins at 20 °C. The isotropic spectrum (Fig.4*a*), consisting of 11 equally spaced components with a splitting of approximately 8 G between them and non-binomial ratios of their intensities, is converted at −196 °C into the spectrum in Fig.4*b*, containing five equally spaced components with a splitting of 16 G and nearly binomial intensity ratios. Presumably, the radical species formed on adsorption contains two groups of protons: (1) a group of four equivalent protons (the interaction with these protons corresponds to a_H = 16 G), whose signal broadens slightly at −196 °C; (2) a group of two equivalent protons (giving a splitting of 8 G), whose signal broadens markedly at −196 °C. The EPR spectrum comprising eleven equidistant components, calculated on the basis of these postulates, has intensity ratios similar to those observed.

The fact that at 20 °C identical EPR spectra arise (Fig.4*a*) following the adsorption of different olefins, in which the number of substituents at the double bond varies from zero (ethylene) to three (2-methylhept-2-ene), can be explained by the formation of the same hydrocarbon radical fragment, which determines the structure of the EPR spectrum.

The set of data obtained for the adsorption of olefins at −78 °C confirm the hypothesis concerning the secondary nature of the radical giving rise to the spectrum of the type illustrated in Fig.4*a* and makes it possible to postulate the following reaction scheme and the following structure of the radical species. Evidently the EPR spectra arising in the course of the adsorption of olefins at −78 °C are due to the formation of primary radicals. The absence of the EPR signal in the adsorption of ethylene at this temperature shows that the radical-forming centre in the zeolite HM does not possess sufficient electron affinity to ionise the ethylene molecule, in view of its high ionisation potential compared with substituted olefins, and the appearance of an EPR spectrum of the type shown in Fig.4*a* when ethylene is adsorbed demonstrates ambiguously the occurrence of the oligomerisation reaction.

The EPR spectrum corresponding to the adsorption of propene at −78 °C (Fig.5*a*) indicates the formation under these conditions of a radical containing five equivalent protons. This radical, formed as a result of the abstraction of one hydrogen atom from the propene molecule, probably has an allyl structure in which all the hydrogen atoms are equivalent as a consequence of the delocalisation of the π-bond and rapid exchange. Although the hydrogen atoms in the free allyl radical are not equivalent,[21] the situation may be different for the species stabilised in the structure of the zeolite HM. As already stated above, heating of the specimen with propene adsorbed at −78 °C is accompanied by the disappearance of the spectrum shown in Fig.5*a* and the appearance of the spectrum of the type illustrated in Fig.4*a*. Formally these exchanges in the spectrum can be accounted for by the disappearance of one of the five equivalent hydrogen atoms, to which corresponds a_H = 16 G, and the appearance instead of a group of two hydrogen atoms (a_H = 8 G). From the standpoint of chemical reactions, such a change in the spectrum is probably associated with the alkylation of the allyl structure and the formation of a species in the spectrum for which a_H = 16 G is associated with the four α-protons of the allyl system and a_H = 8 G is associated with the two β-protons. The fact that the EPR spectrum of the radical formed in the adsorption of pent-1-ene at −78 °C is identical with that in Fig.4*a* apparently confirms the structure of the secondary radical species put forward above.

However, a different version of the structure cannot be ruled out either for the species giving rise to a spectrum of the type shown in Fig.4*a*, namely it can consist of an alkene radical arising without the elimination of a hydrogen atom, in the spectrum of which a_H = 8 G is due to the interaction with the two α-protons, while a_H = 16 G is due to the interaction with the four β-protons. The EPR spectra of the alkene radicals containing from four to six β-protons

differ little from one another and the distributions of the intensities of the eleven central components are similar in these three cases, while the components at the edges of the spectrum are weak.

We shall now consider the possible structure of the radicals formed in the adsorption of isobutene and but-1-ene at −78 °C. The EPR spectrum comprising 21 equidistant lines with a_H = 5.3 G (Fig.6*a*) can be interpreted if it is assumed that the adsorption of isobutene entails the formation of an alkene radical-cation in which six equivalent β-protons give rise to a septet with a_H = 16 G, while two α-protons give rise to a triplet with a_H = 5.3 G. The reduction of the temperature of the specimen to −196 °C inhibits the rotation of the radical, a_H for the α-protons increases to 8 G, and the spectrum of the type shown in Fig.6*a* degenerates into one of the type in Fig.6*b* (15 equidistant lines with a_H = 8 G). It should be noted that the spectrum of the type in Fig.6*a* cannot be accounted for by the formation of a radical species having the structure of an allyl type, i.e., in contrast to the adsorption of propene, the adsorption of isobutene involves the formation of an alkene radical-cation.

As stated above, the EPR spectrum arising in the adsorption of but-1-ene is identical with the spectra of sorbed *cis*- and *trans*-but-2-enes[14] and its HFS is due to a septet generated by the six β-protons and the triplet due to the two α-protons with a_H = 16.3 and 8.2 G respectively. It is of interest to note that the spectrum for but-1-ene (Fig.6*d*) is identical with that obtained in the adsorption of isobutene at −196 °C (Fig.6*b*), which indicates the presence in both radicals of six equivalent protons in two CH_3 groups and confirms the identical character of the radicals in these two cases.

In our view, the radical with the allyl structure is formed only in the adsorption of propene at −78 °C, while in the case of the remaining olefins the formation of radicals of the alkene type without the elimination of the hydrogen atom is probably preferred.

The set of data examined permits the conclusion that even at 20 °C, as a result of rapid reactions involving the isomerisation of the double bond, skeletal isomerisation, and oligomerisation, the primary radicals formed from different adsorbed olefins at −78 °C can give rise to oligomers of different structure and molecular weight containing a radical fragment having the same chemical structure and responsible for the appearance of identical EPR spectra. These structurally identical radical fragments are localised in sections of the mordenite lattice with a specific geometry and this constitutes the manifestation of the unusual "matrix" effect of the zeolite.

We shall attempt to carry out an analysis in order to discover the process with which the slow changes in the structure of the EPR spectra at 20 °C can be associated (Figs.4*a*, 4*c*, and 4*d*). Data for the adsorption of C_3D_6 at 20 °C show that the integral intensity of the EPR signal does not change over several hours, i.e. the changes in the HFS if the spectrum are not associated with the change in the concentration of the radical species. Analysis of the HFS of the spectra in Figs.4*c* and 4*d* suggests that they are anisotropic, i.e. the changes in them are not related to a change in the structure of the radical fragments formed. In this case the gradual transition from the isotropic (Fig.4*a*) spectrum to the anisotropic (Figs.4*c* and 4*d*) spectra can be caused by the transition from the initial disordered disposition of the radical species to an ordered arrangement of the latter in space in the geometrically regular mordenite structure. The ordering process is accompanied by the inhibition of the rotation of the radical species, which is demonstrated by the fact that, on cooling to −196 °C, the isotropic spectrum (Fig.4*a*) changes its shape markedly (Fig.4*b*), while the spectrum in Fig.4*d* hardly changes on cooling in this way. Thus presumably at 20 °C there is rapid initial formation of radical fragments, which are gradually accommodated in lattice elements with a specific geometry, distributed regularly in the mordenite structure, and produce a "sublattice" of ordered radicals.

For the adsorption of C_3H_6 on the zeolite HM at 20 °C, Leith[16] recorded an EPR spectrum identical with that shown in Fig.4*c* but less well resolved, i.e. it can be regarded as an intermediate form of a slowly changing signal.

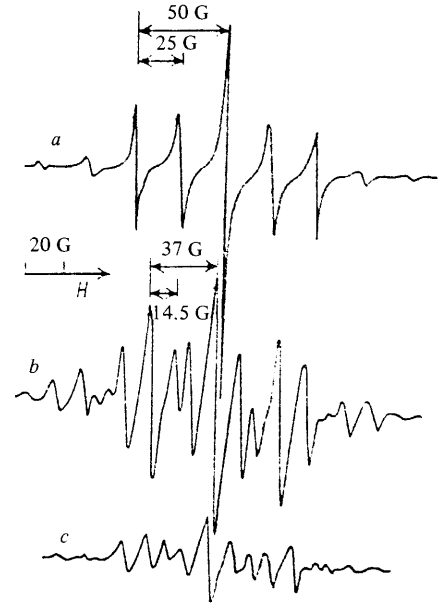

Figure 7. EPR spectra observed in the adsorption of cyclopentene on the zeolite HM: *a*) 3 min after adsorption at −78 °C; *b*) after cooling to −196 °C; *c*) at 20 °C.

Kucherov and Slinkin[17] also described unusual changes in the structure of the EPR spectra of cyclic olefins (cyclopentene and cyclohexene) as the temperature is altered. Fig.7 presents the EPR spectra arising in the adsorption of cyclopentene on the zeolite HM. Its adsorption at −78 °C is accompanied by the rapid appearance of the spectrum in Fig.7*a*, which does not vary with time. Cooling of the specimen to −196 °C leads to the reversible conversion of the signal into the spectrum shown in Fig.7*b*. An increase of the specimen temperature to 20 °C is accompanied by the irreversible transition from the spectrum in Fig.7*a* to that in Fig.7*c*, which then remains unaltered at 20 °C for at least 18 h. It is significant that the disappearance of the signal due to the adsorbed cyclopentene radical-cation on treatment with O_2 is reversible; in contrast to the radical-cations of olefins, the spectrum in Fig.7*c* is fully restored on evacuation of the system for 2–4 h at 20 °C.

The results were accounted for by Kucherov and Slinkin[17] in the following way. The nine line spectrum (Fig.7*a*) with non-binomial intensity ratios, arising in the adsorption of cyclopentene at −78 °C, is due to the formation of an alkene radical species in which there are two groups of protons: two equivalent α-protons (to which corresponds a_H = 50 G) and four equivalent β-protons (a_H = 5 G). The spectrum

in Fig.7*b* agrees well with that obtained earlier[15] for the adsorption of cyclopentene on the zeolite HM at −125 °C. This spectrum is due to an alkene radical and consists of 15 HFS components; it is possible to identify in this spectrum a quintet (a_H = 37 G) due to four β-protons and a triplet (a_H = 14.5 G) due to two α-protons. The spectrum in Fig.7*c* arising at 20 °C has an HFS which differs little from that of the spectrum in Fig.7*b*; consequently, at temperatures ranging from −196 °C to 20 °C, the chemical structure of the cyclic alkene radical-cation remains unaltered and only the degree of freedom of its rotation changes.

In order to understand the mechanism of the reactions of olefins on high-silica zeolites, it is extremely important to examine the character of the thermal transformations of the radical species formed following the adsorption of various olefins on the zeolite HM; the existing information about these reactions is discussed in the next Section.

IV. THE REACTIONS OF RADICAL SPECIES AT ELEVATED TEMPERATURES ON THE HM ZEOLITE AND OTHER ZEOLITES

The reactions of C_2–C_8 olefins, cyclopentene, cyclohexene, and also a series of compounds having a significantly different chemical structure, namely acetylene, butadiene, allyl chloride, allyl alcohol, n-hexane, cyclohexane, and methyl alcohol, have been investigated[18] on the H-forms of zeolites whose characteristics are given below:

Zeolite	SiO_2/Al_2O_3	Degree of decationation, %
HM	10	92
HM-26	26	99
HY	4.3	70
HKL	5.2	82
H-Cesite	5.2	95

The EPR spectra observed on heating an HM zeolite specimen with propene adsorbed at 20 °C are illustrated in Fig.8. The changes in the HFS shown in Fig.8 are typical for all C_2–C_8 olefins. We may note that the introduction of O_2 leads to the immediate disappearance of the spectra in Figs. 8*a*–8*c*, while the spectrum in Fig.8*d* not only does not disappear in the presence of oxygen but its intensity actually increases markedly with retention of the HFS. In the adsorption of olefins on the HM zeolite specimen heated to 300 °C the spectrum shown in Fig.8*d* appears immediately. The adsorption of olefins in air is not accompanied by the appearance of an EPR signal, but the subsequent heat treatment of the system in the presence of O_2 at 250–300 °C leads to the appearance of an intense signal of the type illustrated in Fig.8*d*. The same EPR signal appears on heating the zeolite HM with adsorbed cyclopentene and cyclohexene at 300 °C.

The adsorption of acetylene and allyl chloride on the zeolite HM at 20 °C with subsequent heat treatment at 300 °C likewise leads to the appearance of the spectrum shown in Fig.8*d*. An analogous process proceeds also when butadiene and allyl alcohol are adsorbed on the zeolite HM with subsequent heat treatment at 300 °C. It is remarkable that the EPR spectrum of the type in Fig.8*d* arises also on heating the HM zeolite specimen at 250–300 °C with saturated compounds such an n-hexane, cyclohexane, and methanol.

Thus, for all the compounds enumerated above adsorbed on the zeolite HM, heat treatment at 250–300 °C leads to the appearance of the same EPR spectrum of the type shown in Fig.8*d*: the HFS of the EPR spectra arising in the reactions of different compounds are identical and there are only insignificant differences in the resolution of the individual components.[18]

In order to understand the nature of the signal generated, a study was made of the interaction of benzene and toluene with the zeolite HM at 300 °C. In both cases intense symmetrical singlets with ΔH = 3.7 and 7 G respectively arise at this temperature.

Apart from the zeolite HM, the EPR spectra generated in the high-temperature (up to 450 °C) interaction of benzene, n-hexane, and methanol with the zeolites HY, HKL, and H-cesite have been investigated.[18] In contrast to the zeolite HM, heating of all the zeolites investigated up to high temperature produces singlet EPR spectra without any HFS. Only on mordenite with a higher modulus (the zeolite HM-26 was obtained by direct synthesis) do n-hexane and methanol give rise on heat treatment to 350 °C to the EPR spectrum of the type shown in Fig.8*d* having a somewhat poor resolution of the HFS components compared with the zeolite HM.

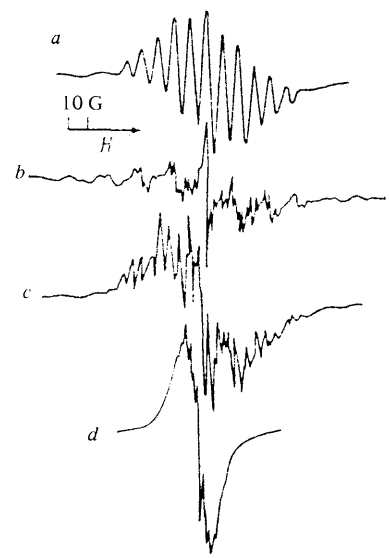

Figure 8. EPR spectra arising on heating the zeolite HM specimen containing propene adsorbed at 20 °C: *a*) at 20 °C, 5 min; *b*) at 90 °C, 50 min; *c*) at 200 °C, 15 min; *d*) at 300 °C, 20 min.

Thus only the zeolite HM possesses the unique ability to generate selectively, after the adsorption of compounds of different classes (unsaturated and saturated) at 250–300 °C, a structure giving rise to a characteristic EPR spectrum. We shall consider the nature of the radical generating this type of EPR spectrum.

It has been shown[17] that, when olefins of different types are adsorbed on the zeolite HM at 20 °C, the same radical fragment is formed rapidly and then undergoes further transformations on raising the temperature. The disappearance of the EPR signal produced on heating the specimen to 200 °C, after the addition of O_2, is probably associated with the retention by the radical formed of an alkene (or allyl) structure. However, the appearance at 250–300 °C of radical species resistant to the action of O_2 (the spectrum in Fig.8*d*) suggests that their chemical nature has changed fundamentally. It is known that radicals formed in the adsorption of aromatic compounds on zeolites are resistant

to the action of O_2.[22] In an earlier study[16] it was already suggested that the high-temperature treatment of propene adsorbed on the zeolite HM is accompanied by the formation of radicals of this kind. It has been shown[18] that, after adsorption with subsequent high-temperature treatment of all the zeolites investigated, benzene and toluene produce a singlet EPR spectrum. The EPR spectra obtained in the adsorption of isomeric xylenes on the zeolite HM at 20 °C have also been published;[18] the fact that the EPR spectrum appearing after the adsorption of *o*-xylene is identical with the spectrum Fig.8*d* arising on heat treatment of zeolite HM specimens with various compounds adsorbed on them is noteworthy. It is striking that the EPR spectrum arising following the adsorption of *o*-xylene is extremely stable at temperatures up to 300 °C in an oxidising atmosphere and fully retains its HFS. The EPR spectra for *m*- and *p*-xylenes adsorbed on the zeolite HM are converted into a spectrum of the type shown in Fig.8*d* on heating to 200 °C.

Thus it can be seen that the adsorption of compounds of different classes on the zeolite HM at 250–300 °C produces selectively adsorbed 1,2-dialkylphenylene radicals. We use by convention the term 1,2-dialkylphenylene radicals for the radicals giving a spectrum of the type in Fig.8*d*, because they are spectroscopically identical with the radicals formed in the adsorption of *o*-xylene, whose EPR spectrum does not change on raising the temperature from 20° to 300 °C. It is noteworthy that the EPR spectrum in Fig.8*d* with equally spaced components and $a_H = 1.8$ G cannot be described using the known HFS constants for the protons of the benzene ring and the CH_3 groups of the *o*-xylene radical-anions.[23] This may be caused by a change in the chemical composition of the adsorbed radical compared with the *o*-xylene molecule or by a change in the HFS constants of the hydrogen atoms for the adsorbed radical compared with the radical in the liquid phase.

The following questions arise in the analysis of the results:

1. what can be the general chemical mechanism of the reactions leading to the formation of aromatic molecules from compounds of different classes on the zeolite HM;
2. what can be the causes of the selective formation of adsorbed radicals with a specific structure on the zeolite HM at high temperatures.

The mechanism of the chemical reactions leading to the formation of aromatic compounds on the H-forms of high-silica zeolites from unsaturated and saturated hydrocarbons is still not known. It is only clear that it must be complex because hydrogenation–dehydrogenation reactions do not take place on these zeolites. Presumably the process proceeds via the complex disproportionation of the initial molecules with formation, on the one hand, of light saturated compounds and, on the other, of unsaturated compounds. As a result, a non-cyclic hydrocarbon fragment with a high degree of unsaturation, for example, tetraene, whose cyclisation leads to the formation of an alkylated aromatic compound, may be formed on the active centre on the zeolite surface. Aromatic molecules may be formed in this way not only from unsaturated but also from a series of saturated compounds, which are initially converted into olefins by the abstraction (in the form of CH_4) of the terminal group.

This idea about the character of the process agrees with the conclusions of a study[24] of the synthesis of compounds on the zeolite HM from labelled [2-^{13}C]isobutene and it has been suggested that aromatic molecules are formed via intermediate dimerisation and triene formation stages. Analysis of the reactions of n-hexane, cyclohexane, and cyclohexene when these are adsorbed on the zeolite HM also shows that the cracking and oligomerisation reactions play a decisive role in high-temperature transformations. The formation of benzene, whose heat treatment would yield products characterised by a narrow singlet ($\Delta H = 3.7$ G) in the EPR spectrum, might have been expected for the above compounds, particularly cyclohexene. However, experiments showed that these compounds form 1,2-dialkylphenylene radicals, which indicates a complex mechanism for the formation of the aromatic ring. For example, the process involving cyclohexane should proceed via ring opening with formation of an olefin and its oligomerisation followed by cracking with formation of polyenes and their ring closure to give the aromatic system.

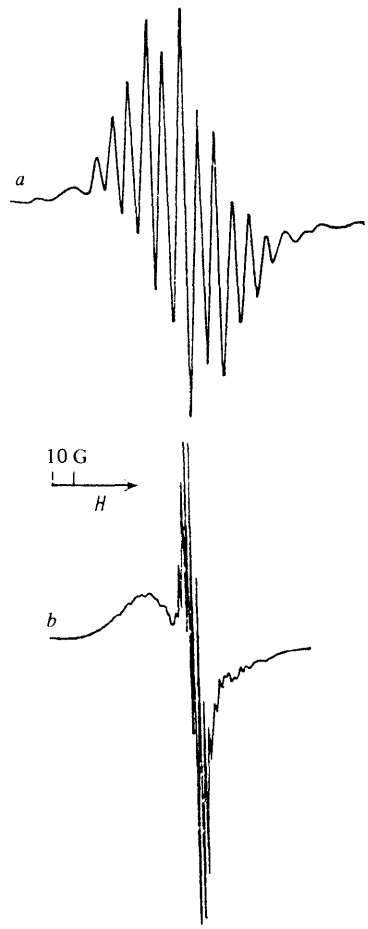

Figure 9. EPR spectra observed in the successive interaction of propene, benzene, and oxygen with the zeolite HM at 20 °C: *a*) zeolite HM + C_3H_6; *b*) (zeolite HM + C_3H_6) + C_6H_6 + O_2.

The data available do not yet permit the final conclusion that the formation of aromatic compounds from various starting materials on high-silica zeolites is a radical process, but one cannot rule out that the intermediate radical species are important participants in this process.

The understanding of the nature of the centres propagating the formation of aromatic compounds on high-silica zeolites is extremely important for the elucidation of its mechanism. An attempt to solve this problem has been undertaken.[19]

V. THE INFLUENCE OF ADDITIVES ON THE FORMATION OF RADICAL SPECIES AND THEIR HIGH-TEMPERATURE REACTIONS ON THE ZEOLITE HM

Initially we shall consider the experimental results obtained in a study[19] of the influence of added O_2, NH_3, H_2O, and SO_2 on the adsorption of an olefin (C_3H_6) and an aromatic compound (C_6H_6) on the zeolite HM.

Fig.9 presents the EPR spectra arising on consecutive interaction of C_3H_6, C_6H_6, and O_2 with the zeolite HM at 20 °C. The adsorption of C_3H_6 leads to the appearance of the 11-component signal described above. After the evacuation of the gas phase and the adsorption of C_6H_6, a signal due to the benzene-radical cation is not observed. Subsequent admission of O_2 leads to the immediate disappearance of the signal shown in Fig.9*a* and the appearance of the characteristic intense seven-component signal (Fig.9*b*) due to the benzene-radical cation.

Data[19] concerning the influence of the preliminary adsorption of NH_3 and H_2O on the concentration of the radical species formed in the interaction of C_3H_6 and C_6H_6 with the zeolite HM at 20 °C are presented in Fig.10. Evidently the adsorption of NH_3 and H_2O induces only a decrease of the intensity of the EPR signals but does not affect the HFS of the spectra arising following the adsorption of C_3H_6 and C_6H_6, i.e. it affects the amount but not the structure of the radical species; both NH_3 and H_2O inhibit the formation of radical-cations from C_6H_6 molecules at 20 °C to a much greater extent than the formation of radical species from C_3H_6.

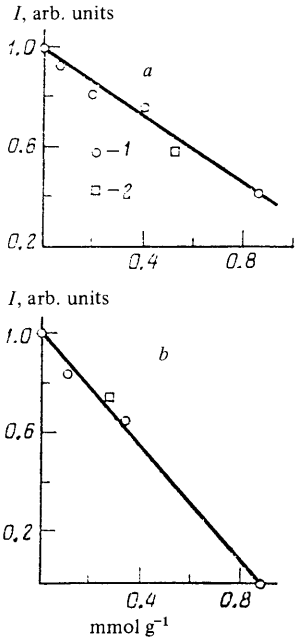

Figure 10. Dependence of the intensity I of the EPR signals in the adsorption of C_3H_6 (*a*) and C_6H_6 (*b*) at 20 °C on the amounts of NH_3 (1) and H_2O (*2*) preadsorbed on the zeolite HM

It is essential to note that at 20 °C the inhibiting effect of H_2O molecules described above is analogous to the effect of NH_3, while in the high-temperature (300 °C) heat treatment of the zeolite HM containing the chemisorbed C_3H_6 the adsorbed H_2O molecules do not prevent the formation of 1,2-dialkylphenylene radicals, while NH_3 molecules exert a powerful inhibiting effect on the process: the adsorption of 0.86 mmole of NH_3 per gramme of the zeolite HM fully suppresses the formation of 1,2-dialkylphenylene radicals.

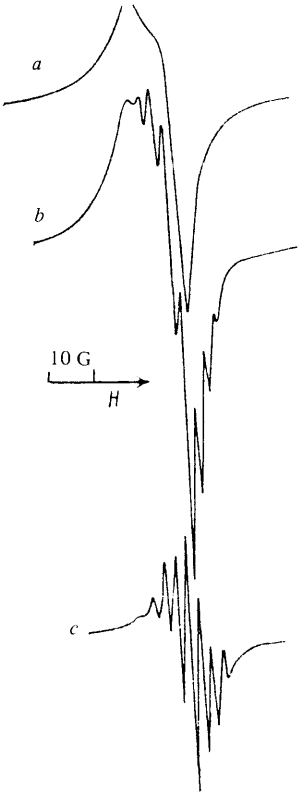

Figure 11. EPR spectra observed on interaction of the zeolite HM with SO_2 and C_6H_6 at 20 °C: *a*) zeolite HM + SO_2; *b*) (zeolite HM + SO_2) + C_6H_6; *c*) after the admission of air.

Fig.11 presents the EPR spectra[19] arising on successive interaction of SO_2 and C_6H_6 with the zeolite HM at 20 °C. The adsorption of SO_2 on the evacuated zeolite HM specimen is accompanied by the appearance of a signal (Fig.11*a*) analogous to that described by Ono and co-workers[25,26] and interpreted by them as a signal of the SO_2^- radical-anion. The adsorption of C_6H_6 on the zeolite HM specimen containing preadsorbed SO_2 is accompanied by a very rapid transition from the spectrum shown in Fig.11*a* to that in Fig.11*b*, which consists of a superposition of the spectrum in Fig.11*a* due to the SO_2^- radical-anion with unaltered intensity and the seven-component signal of the benzene radical-cation. The subsequent adsorption of O_2 leads to a transformation of the spectrum in Fig.11*b* into that in Fig.11*c*, i.e. to a marked decrease of the intensity of the signal of SO_2^- for a constant intensity of the spectrum of $C_6H_6^+$.

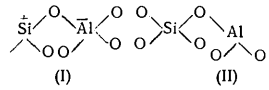
A completely different pattern arises in the successive interaction of the zeolite HM with SO_2 and C_3H_6 at 20 °C. In this case the adsorption of C_3H_6 induces a sharp increase of the intensity of the signal of the SO_2^- radical-anion (by a

factor of approximately 5) and the intensity of the 11-component spectrum is much smaller than in the interaction of the zeolite HM with C_3H_6 in the absence of SO_2.

Finally, in contrast to NH_3, the adsorption of SO_2 does not influence the formation of 1,2-dialkylphenylene radicals in the high-temperature reaction of adsorbed hydrocarbons.[19]

In order to understand the chemical nature of the centres on which the olefin and aromatic radicals are formed, it is necessary to concentrate attention in the first place on the characteristic features of the influence of O_2 on the formation of radicals from olefins and aromatic compounds. The following facts should be noted: (1) for the formation of radical-cations, it is essential that the oxidative centre in the zeolite HM should be activated by the chemisorbed O_2;[22] the presence of O_2 in the gas phase does not interfere with the formation of aromatic radical-cations and does not influence the HFS of the EPR spectra; (2) the formation of radicals from olefins hardly requires the activation of the oxidative centres on the zeolite HM surface by oxygen and the presence of O_2 in the gas phase leads to the irreversible destruction of these radicals.

It might have been supposed that radicals are formed from olefins and aromatic compounds during adsorption on two different types of oxidative centres, some of which are not activated, while others are activated by O_2, i.e. these centres can have different chemical structures. In a study of zeolites of the type of faujasite[27] it was observed that their dehydroxylation can produce Lewis centres of two types#:



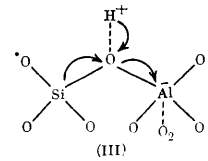
(I) (II)

We shall assume that the centres (I) and (II) are equally accessible to olefin (C_3H_6) molecules and the molecules of the aromatic hydrocarbons (C_6H_6), the aromatic molecule being adsorbed more strongly on the activated centre than the olefin molecule. Aromatic and olefin molecules are then formed respectively on the centres (I) and (II). If this were so, then, under the conditions of the experiment (Fig.9) on the successive interaction of C_3H_6, C_6H_6, and O_2 with the zeolite HM, the adsorption of C_3H_6 on the zeolite would have led to the formation of olefin radicals both on the centres (I) and (II), while in the successive adsorption of C_6H_6 its molecules would have displaced the olefin radicals from the centres (I). As a result the intensity of the EPR signal should diminish, but this effect has not been observed. It is difficult to suppose that the preservation of the intensity of the EPR signal due to the olefin radicals after the adsorption of C_6H_6 is due to the inaccessibility of the centres (I) to benzene molecules. It is more logical to assume that the olefin and aromatic radicals are formed on oxidative centres of the same type.

Before considering the nature of this centre, we shall note that it must differ from the structure of the centres (I) and (II) postulated for faujasites, because radical-cations are not formed on the zeolite HY after the adsorption of C_6H_6, while the adsorption of C_3H_6 results in the formation of a radical resistant to the action of O_2 and giving rise to a very weak five-component spectrum and a binomial distribution of intensities.[6-8] In addition it is significant that heating of the zeolite HM specimen to 450 °C is not accompanied at all by the formation of Lewis centres of types (I) and (II).[28]

The centre (II) is more characteristic of mordenite rather than zeolites of the type of faujasite.

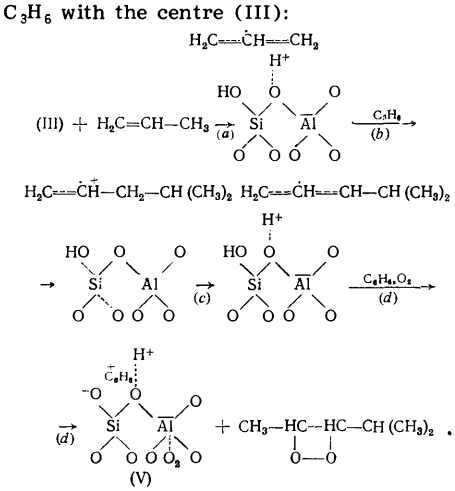
Thus it is necessary to assume the existence in the zeolite HM of active centres of a fundamentally different kind, arising at low heat-treatment temperatures (200–450 °C). In analysing the nature of the oxidative centre in the zeolite HM, the authors[19] considered the following structure:



(III)

It has a Brønsted centre, a radical acceptor centre, and an O_2 molecule chemisorbed on Al, which plays the role of an activator in the formation of aromatic radical-cations.

The possibility of the existence in SiO_2 of Si–O· and Si· centres and their reactivity has been investigated.[30-32] It is possible to imagine the following mechanism of the interaction of C_3H_6 with the centre (III):



An allyl radical is formed in stage (*a*) with transfer of a hydrogen atom to the radical centre, while in stages (*b*) and (*c*) dimerisation with participation of the bridging proton takes place. After the adsorption of benzene and the subsequent adsorption of O_2, the allyl radical is oxidised and destroyed [in stage (*d*)] and the benzene radical-cation is formed. It should be noted that dimerisation can precede the formation of the radical and in the case of C_2H_4 the process should proceed precisely in this sequence. It is significant that the interaction of the centre (III) with C_3H_6 is accompanied not only by the formation of an allyl radical but also probably by the removal of the activating oxygen, because otherwise the adsorption of C_6H_6 in stage (4, *d*) might have led to the formation of benzene radical-cations without the additional introduction of O_2 into the system. In the adsorption of C_6H_6 on the zeolite HM specimen containing adsorbed olefin radicals the C_6H_6 molecules are apparently localised within the zeolite channels near the centre (IV) and after the introduction of O_2 into the system are rapidly converted into radical-cations with formation of the centre (V).

The data for the inhibiting effect of NH_3 and H_2O on the formation of radicals from C_3H_6 and C_6H_6 (Fig.10) indicate a complex structure of the oxidative centre and can be readily understood if it is supposed that the centre has the structure (III). The adsorbed NH_3 molecule interacts with the bridging H^+ ion of the centre (III), which prevents the formation of an oligomeric radical [stage (*b*)]. Comparison of the data obtained with the results described by the present authors[17,18] permits a somewhat more detailed specification of the scheme presented above. Monomeric allyl

radicals [stage (*a*)] are formed in a small amount in the adsorption of C_3H_6 on the centres (III) at −78 °C. Heating of the system to 20 °C is accompanied by a sharp increase of the intensity of the EPR spectrum and a change of its HFS owing to the formation of oligomeric radicals.[17] An increase of the concentration of the radical species as a result of oligomerisation and a decrease of the ionisation potential (for example, from 9.94 eV for C_3H_6 to 8.9 eV for 3-methylbut-2-ene) makes it necessary to postulate the inhomogeneity of the centres (III) of the zeolite HM in terms of their oxidising power.

We may note that the oligomerisation process need not necessarily be associated with participation of the most acid protons. When only the strongest Brønsted centres are involved in oligomerisation, the EPR spectrum would cease to be observed after the adsorption of only approximately 0.35 mmole of NH_3 per gramme of the zeolite HM (centres for which the heat of adsorption of NH_3 is 140 kJ mol^{-1}).[33] Thus the combination of the strongest oxidising and acid properties is not obligatory for the centre (III).

The adsorption of NH_3 prevents not only the formation of radicals from the adsorbed olefin at 20 °C but also the high-temperature aromatisation of various compounds with formation of 1,2-dialkylphenylene radicals,[18] which is due to the strong interaction of the NH_3 molecules with centres of type (III) on the zeolite HM.

The mechanism of the decrease of the intensity of the EPR signal of the benzene radical-cation on adsorption of NH_3 (Fig.10*b*) is less clear, because in this case the H^+ ion is not involved directly in the formation of the radical although it can interact with the aromatic ring, causing its partial polarisation. It is significant that the decrease in the concentration of the benzene radical-cations under the influence of the adsorption of NH_3 is accompanied also by a decrease in the intensity of the singlet EPR signal arising on heating the specimens to 150–300 °C.

The adsorption of H_2O, like that of NH_3, inhibits the formation of radicals both in the adsorption of C_3H_6 and in that of C_6H_6, apparently as a result of the analogous blocking of the centre (III). It is striking that, in contrast to NH_3, H_2O is desorbed on raising the temperature and does not prevent the conversion of the adsorbed C_3H_6 into 1,2-dialkylphenylene radicals.

We shall now discuss the influence of the addition of SO_2 on the formation of radicals in the adsorption of an olefin and the aromatic compound. There are significant differences in the influence of adsorbed SO_2 on the concentrations of these radicals. On the one hand, the intensity of the EPR signal of the SO_2^- radical-anion does not change following the adsorption of C_6H_6 and the concentration of the $C_6H_6^+$ radical-cation is independent of the presence of adsorbed SO_2 molecules on the zeolite HM specimen. On the other hand, the adsorption of C_3H_6 on such a specimen containing adsorbed SO_2 molecules, some of which, as in the previous case, are in the form of SO_2^-, is accompanied by a sharp (by a factor of 5) increase of the concentration of SO_2^- and an appreciable decrease of the concentration of olefin radicals compared with their concentration on the clean zeolite HM.[19]

The results can be explained by the following processes occurring in the adsorption of C_3H_6 and C_6H_6:

$$RH + (III) \rightarrow \dot{R} + HO{-}Si\!\!\begin{array}{l}/\\ \backslash\end{array} \qquad (2)$$

$$\dot{R} + SO_2 \rightarrow R^+ + SO_2^- \ . \qquad (3)$$

Reaction (2) proceeds in the adsorption of both C_3H_6 and C_6H_6, but reaction (3) does not occur in the case of the $C_6H_6^+$ radical-cation, because its ionisation potential (9.90 eV) is higher than that of the C_6H_6 molecule (9.24 eV);[34] the concentration of SO_2^- ions does not therefore change on adsorption of C_6H_6. On the other hand, the ionisation potential of the olefin radical is lower than that of the initial molecule and reaction (3) is in this case accompanied by an increase in the concentration of the SO_2^- radical-anions. It is significant that an electron is definitely transferred to the SO_2 molecule from the olefin radical and not from the solid, because in the latter case an increase of the intensity of the signal of SO_2^- would have been observed as a result of the adsorption of C_6H_6.

The electron transfer from the olefin radical to the acceptor molecule described above is very similar to the formation of the SO_2^- radical-ion on the MgO surface in the adsorption of C_3H_6.[35] The following reactions probably occur in this system:

$$RH \rightarrow R^- + H^+ \ , \qquad (4)$$

$$R^- + O_2 \rightarrow \dot{R} + O_2^- \ , \qquad (5)$$

$$2\dot{R} + O_2 \rightarrow R{-}O{-}O{-}R \ . \qquad (6)$$

The difference between this reaction sequence and the previous one consists in the fact that the adsorption of C_3H_6 on the zeolite HM leads immediately to the formation of a radical and not a carbanion, but at the same time the introduction of O_2 is accompanied by the destruction of $\dot{R}$ via reaction (6) and the signal of the O_2^- radical-ion cannot therefore be detected in the EPR spectrum.

The influence of the introduction of various cations into the zeolite HM on the formation of radical species from different compounds, including olefins, has been examined.[36] It has been shown that the introduction of Be^{2+} and Ce^{4+} hardly influences the oxidation–reduction properties of the HM zeolite centres. It has been found that, despite their localisation in the large channel and their dipole–dipole interaction with the chemisorbed radicals, the introduction of Cu^{2+} cations lowers only slightly the concentration of the radical species formed at 20 °C from both aromatic compounds and from C_3H_6. The introduction into the zeolite HM of the ions Na^+, Mg^{2+}, Ba^{2+}, and Ni^{2+}, which are localised at sites which are not readily accessible to adsorbed molecules, leads to a considerable (by a factor of 10–30) decrease of the concentration of radicals. It has been suggested[36] that the formation of the oxidation–reduction centres in the zeolite HM is associated with the rupture of highly strained Si–O–Si(Al) bonds and the cations can have a stabilising effect on the mordenite skeleton.

VI. THE FORMATION AND REACTIONS OF RADICALS ON ZEOLITES OF THE ZSM TYPE

So far only one study devoted to the formation and reactions of radicals in the adsorption of unsaturated hydrocarbons on the zeolite H-ZSM-5 has been published.[37] The zeolite specimen was subjected to a preliminary heat treatment in an atmosphere of O_2 at 500 °C for 1 h; the reaction volume was then evacuated at the same temperature for 2 h, cooled to room temperature, and the specimen was transferred *in vacuo* into the cell of the EPR spectrometer, where the alkene and alkyne vapours were adsorbed at a low temperature.

Fig.12 presents the EPR spectra obtained at a reduced temperature for the initial zeolite ZSM-5 specimen and the specimen after the adsorption of but-2-yne and 3,3-dimethylbut-1-ene. The latter spectrum is isotropic (g = 2.0028 and a_H = 17.5 G) and has been assigned to the radical of

2,3-dimethylbut-2-ene arising as a result of the intramolecular rearrangement of 3,3-dimethylbut-1-ene. The EPR signal appearing as a result of the adsorption of but-2-yne on the zeolite ZSM-5 at −123 °C consists of seven components with a_H = 10.0 G, which is due to the presence in the molecule of two equivalent CH_3 groups, which rotate almost freely within the zeolite channel. On raising the temperature above 27 °C, the spectrum in Fig.12*c* is transformed into a nine-component spectrum (g = 2.009 and a_H = 6.60 G) and does not change further on raising the temperature to 200 °C.

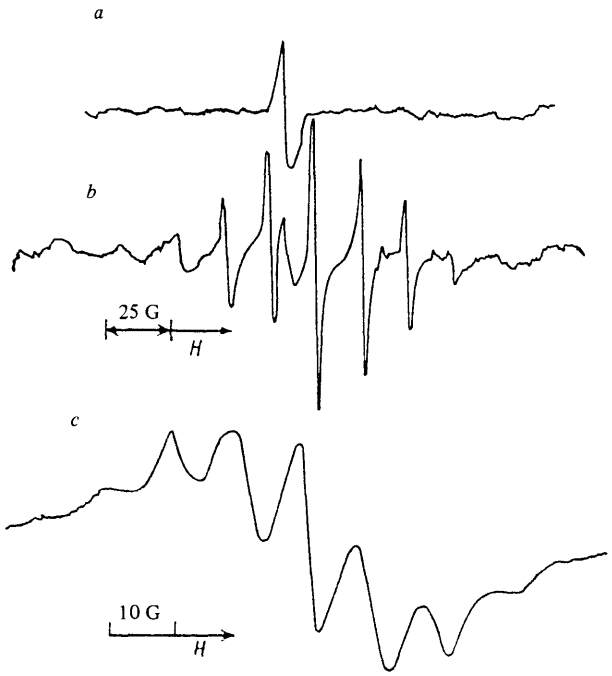


Figure 12. EPR spectrum of the lattice defects in the zeolite ZSM-5 at −150 °C (*a*) and the EPR spectra arising in the adsorption of 3,3-dimethylbut-1-ene at −150 °C (*b*) and but-2-yne at −123 °C (*c*) on the zeolite ZSM-5.

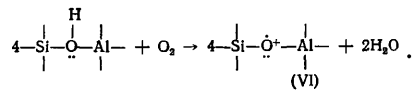
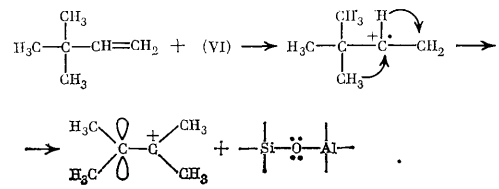
It has been suggested[37] that the spectrum in Fig.12*a* for the initial zeolite specimen is due to the appearance during the heat treatment of the zeolite in air at 500 °C of defect centres (VI) having a radical structure:



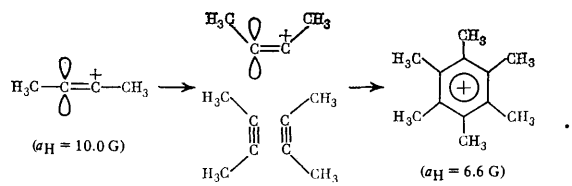
The centre (VI) obtained in this way is a hole in the oxygen atom of the zeolite lattice. According to the author,[37] the unpaired electron occupies a non-bonding molecular orbital of the oxygen atom, because at −196 °C a signal with an HFS characteristic of the reaction of the unpaired electron with the nuclear spin of the Al atom is not observed. Furthermore, the g-factor of the signal in Fig.12*a*, which is 2.0092, is equal to the g-factor of the signals due to the isoelectronic holes formed on X-irradiation of silicate and borate glasses. It has been suggested that the energy required for the appearance of such a radical centre is close to that necessary for the removal of an electron from the non-bonding orbital of the oxygen atom in the H_2O molecule, which is 12.61 eV according to photoelectron spectroscopic data. If this is true, then the positive radical centre is a powerful acceptor trap, in which the adsorbed molecule forms a radical-cation via a charge transfer mechanism:

Unfortunately it is not stated in the above study[37] what is the concentration of such defect centres in the zeolite ZSM-5 and whether this concentration corresponds to the number of radical-cations formed. It is necessary to note that the nature of the centre (VI) and the character of the processes occurring on it are in essence identical to those for the centre (V) in the zeolite HM and the mechanism of the formation of radical-cations in the adsorption of olefins is the same as that discussed above.

The following mechanism has been proposed[37] for the formation of the radical and its isomerisation in the adsorption of 3,3-dimethylbut-1-ene on the centre (VI):



The change in the structure of the EPR spectrum of the adsorbed but-2-yne radical-cation on raising the temperature has been explained[37] by trimerisation accompanied by the formation of hexamethylbenzene radical-cations localised in the cylindrical channels of the zeolite ZSM-5:



Thus, in this case, as for the examples of the reactions of olefins on the zeolite HM discussed above, the final structure is an aromatic radical-cation. However, the author's hypothesis[37] that the hexamethylbenzene radical-cation is localised within the channel in the zeolite ZSM-5 is in our view erroneous, because in this zeolite the channel diameter, and not the channel radius as stated by Shih[37] is 5.8–6.0 Å; hexamethylbenzene molecules cannot be localised in such channels.

---o0o---

The results of a few studies of the formation and reactions of the radicals arising in the adsorption of olefins on zeolites of types Y, HM, and ZSM-5 were examined above. Analysis of the available data shows that the adsorption of olefins of different types at room temperature on cationic and decationated forms of zeolites of the faujasite type is accompanied by the appearance of EPR spectra with virtually identical parameters. EPR spectra of identical structure also arise in the adsorption of various olefins at 20 °C on cationic, decationated, and dealuminated forms of mordenite,

but their parameters differ significantly from those observed in the adsorption of the same olefins on faujasites.

In the discussion of the results it was shown that the radicals formed in the adsorption of olefins on mordenites at 20 °C are secondary radical species arising due to oligomerisation processes and that both oxidative and Brønsted centres participate in the formation of these species. The adsorption of olefins on mordenites at low temperatures is accompanied by the formation of primary radicals characterised by individual EPR spectra. An important feature of mordenites is their ability to form selectively aromatic structures, giving rise to EPR spectra with the characteristic HFS, from compounds of different classes on zeolite lattice elements with a specific geometry.

Despite the considerable advances made, many problems still remain unsolved. The chemical nature of the radicals formed on faujasites has not been elucidated and in particular it is not known whether these radicals are primary adsorbed species or whether they are formed later as a result of subsequent chemical reactions. The mechanism of the activating influence of oxygen has not been established and its role in the formation of radicals has not been elucidated. Furthermore, the fundamental question of the nature of the oxidative centres involved in the formation of radicals still remains open, particularly for faujasites.

The solution of these problems is important not only in itself but it is also essential for the understanding of the mechanisms of the catalytic processes involving olefins and in particular on high-silica zeolites, for which one cannot rule out the possibility of an important role of reactions involving radical species.

It is noteworthy that the application of the EPR method to the elucidation of the mechanisms of the thermal transformations of compounds of different classes, including olefins, adsorbed on zeolites is important also for the analysis of the nature of the "coke" deposits formed under these conditions, which play a decisive role in the deactivation of zeolite catalysts.

The Structure and Valence Isomerisation of Antiaromatic Compounds

M.N.Glukhovtsev, B.Ya.Simkin, and V.I.Minkin

Various criteria of aromaticity and their relation with molecular structure are discussed. The characteristics of the quantum-chemical calculations of the electronic structure and geometry of antiaromatic molecules, determined by the specific structure of their potential energy surfaces corresponding to the ground and lowest excited states, are analysed.
The bibliography includes 264 references.

I. INTRODUCTION

Among the theoretical ideas of organic chemistry, it is difficult to find another concept like aromaticity which is as general and plays as important a role in systematic treatment of structural characteristics, stability, physical properties, and reactivity and is at the same time so vaguely but physically unambiguously defined. Indeed, the brief survey below of the unceasing attempts to canonise the concept of aromaticity demonstrates the possibility of enclosing it within a rigorously fixed framework whatever the theoretical and experimental approaches employed.

This factor is the cause of the unceasing controversy whether or not the term "aromaticity" is legitimate. Binsch[1] expressed an extreme point of view. In his paper "Aromaticity—an Exercise in Chemical Gibberish" he defines the main purpose of the concept of aromaticity simply as an "alibi for a certain aura of intellectual respectibility necessary to the investigator when the conclusions arising from his work are on the edge of banality". In fact, it is impossible to isolate a single physically defined structural or energetic parameter which would characterise the degree of aromaticity of a molecule or ion. However, many other concepts of theoretical organic chemistry, whose fruitfulness arouses no doubts, would not withstand such a rigorous criterion. It is sufficient to recall concepts such as isomerism,[2,3] tautomerism,[3,4] conformation, and configuration.[5] The very concept of molecular structure is far from unambiguous when subjected to a rigorous analysis.[5,6]

Numerous reviews[7-11] and monographs[12-16] have been devoted to the analysis of the development of the concept of aromaticity. The energetic aspect, the relative stability of the structure, is nowadays associated primarily with aromaticity or aromatic character. Although individual attempts have been made to extend the concept of aromaticity to acyclic compounds (for example, the concept of Y-aromaticity has been introduced[17]) and saturated compounds (σ-aromaticity[18]), in general it is used to describe the enhanced stability of a particular type of cyclic structures relative to acyclic structures.[9,19,20] Finally, a tendency has become increasingly clear to relate the enhanced stability of aromatic structure to the closed nature of its electron shell.[17]

The synthesis and theoretical studes of various types of cyclic structures, for which the above conditions are realised and which therefore possess an increased relative stability, have led to the formation of a whole series of new structural concepts refining the concept of aromaticity and demonstrating its fruitfulness. The scheme illustrated in Fig.1 provides a by no means complete representation of various structural types of aromaticity.

The task of the present review is to examine the problem of antiaromaticity, mainly from the standpoint of its structural aspect. Since the concept of antiaromaticity is set against that of aromaticity, it is evident that the main feature of antiaromaticity is cyclic destabilisation, i.e. the energetically unfavourable nature of a planar cyclic structure of a conjugated molecule or ion with declocalisation of π-bonds.

As will be shown below, the main cause of the antiaromatic character of a structure is specific features of the structure of the electron shells of the corresponding cyclic conjugated compounds. A detailed understanding of these features involves a fairly profound theoretical study of the problem, requiring the application of the most refined methods of modern quantum chemistry. Because of the instability of antiaromatic compounds and the consequent difficulty of their experimental study, the quantum-chemical approach assumes a particular importance in this instance.

The data obtained with the aid of quantum-chemical calculations can be used to identify the most promising trends in preparative research and to investigate the details of the mechanisms of reactions of antiaromatic compounds. In view of this, in the present review attention is concentrated on the theoretical study of the structures of antiaromatic compounds and it is endeavoured to demonstrate to what extent the combination of the theoretical and experimental methods of organic chemistry has been fruitful in this instance.

The review deals with the principal types of antiaromatic compounds—monocyclic polymethines $(CH)_m$ with $4n\pi$-electrons, annulenoannulenes, and their heterosubstituted derivatives. Various compounds classified as antiaromatic contain fragments corresponding to these structures. In view of this, the observed characteristic features of the electronic and geometrical structures and of valence isomerisations of antiaromatic compounds are fairly general.

The instability of antiaromatic compounds is responsible for their tendency to undergo valence isomerisation reactions and rearrangements, as a result of which the energetically unfavourable planar conjugated bond system breaks down. Quantum-chemical data made it possible to interpret the instability of antiaromatic compounds from the standpoint of the properties of the corresponding potential energy surfaces (PES), which determine the wide variety of types of valence isomerisations; the PES of antiaromatic compounds are characterised by relatively low barriers to isomerisation—the proximity of the surfaces corresponding to excited states which as a rule gives rise to electronic lability of the molecule.[29-32] These features of the PES of antiaromatic compounds hinder the application of traditional computational schemes, which do not always yield equivalent results.

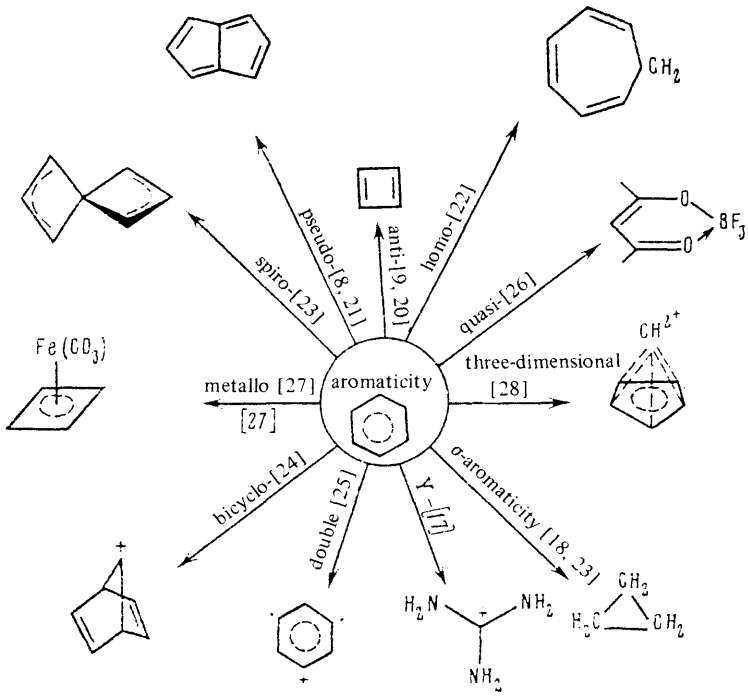

Figure 1. Illustration of the wide variety of aspects of the concept of aromaticity. Structures corresponding to a particular type of aromaticity are presented.

Note. Numbers in square brackets denote references (Ed. of Translation).

Because of this, the class of antiaromatic compounds constitutes a kind of "touchstone" for the estimation of the limited applicability of a particular theoretical method and makes it possible to elucidate its limitations and scope for further improvement.

1. Criteria of Aromaticity and Antiaromaticity

An unambiguous criterion which could be used to classify particular compounds—aromatic or antiaromatic—does not exist. The criteria based on reactivity data characterise the kinetic stability and are determined by the properties not only of the ground state of the molecule but also those of the transition state in the reaction considered. The capacity to undergo electrophilic substitution reactions, which is frequently regarded as the most characteristic feature of aromatic compounds,[13] cannot always be used as a sufficiently reliable sign of aromaticity.[33] In their monograph "Facts and Theories of Aromaticity", Lewis and Peters[16] concluded on the basis of a detailed discussion of various interpretations of the term "aromaticity" that the most general definition reduces to the following: "an aromatic molecule is a molecule which resembles benzene". Even in this definition, it is necessary to establish which feature of similarity is the most important. In the present reivew the structural-energetic criterion has been adopted for this purpose: a conjugated compound is aromatic if the delocalisation of π-electrons stabilises its cyclic structure relative to the corresponding acyclic polyene structure (for example, benzene and hexa-1,3,5-triene). On the other hand, in the case of a greater stability of the acyclic reference structure (cyclobutadiene and buta-1,3-diene) the given system is classified as antiaromatic.

Quantitative estimates of the degree of aromaticity or antiaromaticity are based on the concept of resonance energy.

(a) Energetic criteria of aromaticity and antiaromaticity. The resonance energy. Hückel[34] showed that the molecule or ion with a monocyclic structure is stabilised when the bonding π-orbitals are completely filled with electrons and the non-bonding and antibonding molecular orbitals (MO) are unoccupied. The fulfilment of these conditions leads to the familiar $(4n + 2)$ rule for the number of π-electrons in an aromatic monocyclic compound. On the other hand, annulenes with $4n$ π-electrons in the ring have an open π-electron shell. The cyclic delocalisation of π-electrons in these systems leads to the destabilisation of the structure. Consequently, $[4n]$-annulenes must be classified as antiaromatic systems.

The general concept—the requirement that all the bonding MO are completely filled and the remaining MO are unoccupied—proved to be fruitful also for three-dimensional systems [polyhedral carbaboranes,[35] pyramidal structures $(CH)^{n+}_{n+4}$,[36] and organometallic clusters,[37] for the determination of the stability of which specific electron count rules have been proposed[38,39]]. This concept has been extrapolated also to acyclic conjugated molecules. For example, the stable guanidinium cation, which contains six π-electrons, has been assigned to the class of so-called molecules with a centre of aromaticity (Y-aromaticity[17]), while trimethylenemethane (four π-electrons) can be regarded as an antiaromatic system in this sense.[31]

The contribution of conjugation to the energy of the molecules is characterised by the Hückel resonance energy (HRE), which is defined in terms of the Hückel approximation[40] as the difference between the total π-electron energies of the conjugated molecule and a system consisting of m

isolated double bonds present in the classical (Kekulé) structure of the conjugated molecule:

$$\mathrm{HRE} = E_\pi^m - mE_\pi(\mathrm{C{=}C}), \qquad (1)$$

where E_π^m is the π-electron energy of the conjugated molecule.

However, estimates of aromaticity with the aid of the HRE did not prove to be entirely satisfactory. Thus, in conformity with Eqn.(1), the degree of aromaticity should increase with increasing size of the π-electron system, which conflicts with certain experimental data. For example, the kinetic stability of polyacenes diminishes on successive linear annelation (pentacene and hexacene readily interact with atmospheric oxygen[43]). In a number of instances unduly high HRE correspond to antiaromatic molecules,[44] for example, the HRE of pentalene (2.46β) is higher than for benzene (2β).

Dewar[45,46] developed a more rigorous scheme for the estimation of the resonance energies of cyclic conjugated structures. He adopted as the reference structure a polyene in which the numbers of the σ- and π-bonds are equivalent to those in the cyclic compound and not the system of isolated π-bonds adopted when Eqn.(1) is used. Using the approximation assuming the additivity of the bond energies in acyclic polyenes,[47] it is possible to calculate the total energy of any acyclic or cyclic polyene with localised double bonds by adding together the energies of all the bonds. The Dewar resonance energy (DRE) is defined as the difference between the heat of formation of a given conjugated molecule and the heat of formation calculated for the classical (Kekulé) reference structure:

$$\mathrm{DRE} = -(\Delta H^m - \Delta H_{\mathrm{add}}), \qquad (2)$$

where ΔH_{add} is the heat of formation calculated for the model reference structure (the minus sign is included because the values of DRE for aromatic systems are assumed to be positive (see Dewar,[45] p.480). For example, for benzene we have $\Delta H_{\mathrm{add}} = 3E_1 + 3E_2 + 6E_{\mathrm{C-H}}$, where E_1 and E_2 are parameters representing the energies of the "polyene" single and double bonds. Thus DRE can be expressed in a form more convenient for comparison with the HRE:

$$\mathrm{DRE} = -(E_\pi^m - (n_1E_{1\pi} + n_2E_{2\pi})) \qquad (3)$$

where n_1 and n_2 are the numbers of single and double bonds in the Kekulé structure of the π-electron system considered and $E_{1\pi}$ and $E_{2\pi}$ are the π-electron energies of the "polyene" single and double bonds.

The method for the calculation of the resonance energies described above makes it possible to take into account more accurately the contribution of cyclic conjugation to E_π. Furthermore, since the calculation of the DRE is based on the scheme of the Pariser–Parr–Pople (PPP) method modified by Dewar and de Llano,[42] which makes it possible to take into account the contribution of σ-bonds, the values of DRE in Eqn.(2) contain a correction for the energy of the contraction (extension) of the σ-bonds in the cyclic conjugated compound relative to the model structure. The values of DRE are satisfactorily correlated with experimental stability data[44] (furthermore in the case of annulenes, for example, a series of correlations have been observed between the physicochemical properties and the resonance energy, in particular between the $\Delta G^{\neq}$ for the Diels–Alder reaction with maleic anhydride and the difference between the corresponding resonance energies).

On the basis of the Hückel method, Hess and Schaad developed a scheme for the calculation of the resonance energy (HSRE) in which account was taken of the differences between the immediate environments of the bonds (C–C and C=C).[45,46]

The sharp increase of the number of empirical parameters for heteroatomic molecules must be included among the disadvantages of the DRE and HSRE definitions. Furthermore, the values of DRE and HSRE can be found only for molecules for which it is possible to construct Kekulé structures and hence the above definitions are inapplicable to radicals, ions, and non-classical structures (see, however, Hess and Schaad[47]).

The definition of the topological resonance energy (TRE),[48–50] based on the employment of the Hückel theory and the methods of the theory of graphs,[51] is free from these disadvantages. The concept of the TRE is applicable to any conjugated system, including ions, radicals, and radical-ions.[52,53]

The TRE, defined by the formula

$$\mathrm{TRE} = \sum_j (g_jx_j - g_j^{\mathrm{acycl}}x_j^{\mathrm{acycl}}) \qquad (4)$$

(g_j are the filling numbers for the filling of π-orbitals by electrons in the ground state, x_j the roots of the characteristic polynomial for the conjugated system, and x_j^{acycl} and g_j^{acycl} refer to the acyclic polynomial[48–50] corresponding to the given molecular graph), characterises the cyclic conjugation energy in the given molecule or ion.

We emphasise that, in estimating the degree of aromaticity with the aid of the TRE, there is no need to select a suitable reference structure. Furthermore, the acyclic polynomial used in the definition of the TRE need not correspond to any real structure which can be represented in the traditional way. This is both an advantage and a disadvantage of the TRE as a criterion of aromaticity, since the concept of the TRE is not linked directly to the concepts of structural chemistry familiar to chemists. In a number of instances, the estimates of the TRE are nevertheless unsatisfactory.[54–56] Thus the TRE for cyclobutadiene (−1.226β) has been obtained on the assumption that $g_1 = g_2 = 2$. However, according to Hund's rule, it must be assumed that $g_1 = 2$ and $g_2 = g_3 = 1$; the TRE then obtained is +0.304β, i.e. cyclobutadiene then appears to be actually more aromatic than benzene.

Table 1. The values of HRE, DRE, HSRE, and TRE for certain annulenes, annulenoannulenes and monocyclic conjugated ions (all the resonance energies have been normalised per π-electron in the calculation).

Compound	HRE, β units (Refs.34, 41)	DRE, eV (Refs.42, 44)	HSRE, β units (Refs.45–47)	TRE, β units (Refs. 48–50, 52, 53)
Cyclobutadiene	0.000	−0.1335	−0.268	−0.3065
Benzene	0.333	0.1450	0.065	0.046

The values of DRE, HSRE, and TRE for benzene and certain antiaromatic compounds are listed in Table 1 (to facilitate comparison, the RE for different systems have been calculated per π-electron). The values of TRE normalised in this way are linked to the HSRE by the relation[57]

$$\mathrm{TRE} \cong \mathrm{HSRE} + (0.69/N)\ln K, \qquad (5)$$

where N is the number of π electrons, K the number of Kekulé structures; the values of TRE and HSRE are calculated per π electron.

The heats of isodesmic[58] reactions, characterising the stability of the given cyclic systems relative to the corresponding acyclic compounds with the same types of single and double bonds, have also been used to determine the resonance energy. Thus the heats of the given reactions can be used to estimate the energy of cyclic conjugation in the given system, reflecting thereby its aromatic or antiaromatic character,[60] for example (the values of ΔH are given in kJ mol^{-1}):

$$+ 4CH_4 \rightarrow 2CH_3{-}CH_3 + 2CH_2{=}CH_2 \qquad (6)$$

ΔH = —294.5 [MINDO/3 (Ref.59)]; —217.1 (MNDO); —268.6 [STO-3G (Ref.60)]; —278.2 [4-31G (Ref.60)]; —284.1 [6-31G//3-21G (Ref.61)]†;

$$+ 6CH_4 \rightarrow 3CH_3{-}CH_3 + 3CH_2{=}CH_2 ; \qquad (7)$$

ΔH = 30.4 (MINDO/3); 154.8 (MNDO).

(b) Magnetic criteria of aromaticity and antiaromaticity. It has been suggested that a compound be defined as aromatic if induced diamagnetic π-electron ring currents are maintained in its molecule (diatropic system). The ring current influences the chemical shifts in the ^{1}H NMR spectra and the current itself is used as a quantitative measure of the aromaticity of the compound. On the other hand, paramagnetic ring currents (paratropic systems) are characteristic of antiaromatic compounds, for example [4n]annulenes (see the relevant reviews[62,63]).

In the case of [4n + 2]annulenes there is a simple relation between the resonance energy per π-electron (RE/π-E in β units) and the system of π-electron ring currents I [64–66]:

$$RE/\pi\text{-}E = \frac{\pi^2 I}{kS}, \qquad (8)$$

where S is the area of the ring; for benzene, it has been assumed that $S = 1$, $k = 3$;[64] $k = 4$.[65]

In addition a linear correlation has been observed between the difference between the chemical shifts of the signals due to the external and internal protons for $\tau_{ext} - \tau_{int}$ in the ^{1}H NMR spectra of [n]annulenes and the value of RE/π-E:[67]

$$\frac{(\tau_{ext} - \tau_{int})}{S} = m(RE/\pi\text{-}E), \qquad (9)$$

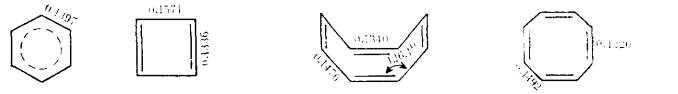
where m is a constant.

However, for non-alternate hydrocarbons and for heterocyclic systems, the relation between the resonance energy and the magnetic criteria is not sufficiently defined.[64] Furthermore, the results of calculations of ring currents for antiaromatic systems depend greatly on the method employed (see, for example, Mallion[62]).

The use of magnetic parameters as exhaustive criteria has been subjected to serious criticism.[16,62] We may point out, for example, that the manifestation of diatropism does not necessarily indicate a tendency towards electrophilic substitution reactions or even the stabilisation of the cyclic conjugated system.[66] In many cases the system may be diatropic and antiaromatic, for example, bicyclo[6.2.0]-decapentane.[68]

†Here and henceforth the abbreviations proposed by Pople are used; the numerals in brackets indicate that a non-empirical calculation has been carried out in terms of, for example, the 6-31G basis set, for the geometry optimised in terms of the 3-21G basis set.

(c) Structural criteria of aromaticity and antiaromaticity. The most distinctive structural characteristics of the benzene molecule are its planarity and complete equalisation of the C–C bond lengths. In conformity with the structural criterion, analogous properties are to be expected for aromatic molecules. On the other hand, for antiaromatic molecules, in which the cyclic conjugation destabilises the structure, one may expect a tendency towards the localisation of double bonds, i.e. towards the breakdown of the equalisation of the C–C bond lengths.



[according to results of *ab initio* calculations (Ref.69)] [according to electron diffraction data (Ref.70)] [according to results of *ab initio* calculations (Ref.71)]

It has been suggested that the molecule be regarded as aromatic when the lengths of the carbon–carbon bonds are in the range 0.136–0.143 nm, i.e. are close to the value of 0.1397 nm in benzene, and should be regarded as a polyene when the C=C bond length is in the range 0.134–0.135 nm, while the C–C bond length is 0.144–0.1475 nm.[16] A quantitative character has been given to this criterion. The degree of aromaticity has been estimated from the means square deviation of the carbon–carbon bond lengths:[72]

$$\delta = \frac{\sum_{rs} (d_{rs} - \bar{d})^2 / \bar{d}^2}{n}, \qquad (10)$$

where d_{rs} is the length of the bond between the atoms r and s and $\bar{d}$ is the average length of n bonds (Å).

The aromaticity index A was then determined[72] from the formula

$$A = 1 - 225\delta . \qquad (11)$$

Subsequently the expression for A was modified in order to take into account the requirement for the equalisation of the distribution of electron density along the ring bonds of the aromatic molecule.[73] However, difficulties then arise in the case of molecules such as those of azulene owing to the considerable length of the transannular bond and in the case of heterocyclic conjugated molecules. Developing the criterion of bond length equalisation for the definition of aromaticity, Kruszewski and Krygowski[74] suggested that two aromaticity indices, based on the harmonic oscillator model (HOMA), be introduced. The value of HOMA$_d$ is determined by the length d(Å) of the carbon–carbon bonds:

$$HOMA_d = 1 - \frac{a}{n}\sum_{r=1}^{n} (X_r - 1.397)^2 \qquad (12)$$

where $a = 98.89$, X_r is the length of the rth bond, and n is the number of bonds. HOMA$_d$ = 1 has been obtained for the structure of benzene with D_{6h} symmetry and HOMA$_d$ = 0 has been found for the molecule with D_{3h} symmetry. Thus HOMA$_d$ reflects the increase of the energy of the π-electron system when the bond lengths deviate from the value in benzene (1.397 Å).

The index HOMA$_p$ is determined by the bond orders:

$$HOMA_p = 1 - \frac{3.66}{n}\sum_{rs}^{n} \left(\frac{2}{3} - P_{rs}\right)^2 , \qquad (13)$$

where P_{rs} is the order of the bond between the atoms r and s.

The planarity of the molecule is usually regarded as a characteristic feature of aromatic systems.[13] However, the non-planar character of the structures of [4n]annulenes can

hardly be interpreted solely as a consequence of antiaromaticity,[75,76] because the strains in the σ-electron system can play a decisive role in the breakdown of planarity. Cyclooctatetraene has a non-planar structure with D_{2d} symmetry but its π-electron energy is a minimum for a planar configuration and the non-coplanar distortion leads to an increase of this energy.[75] The non-planar character of the carbon skeleton for cyclo-octatetraene and of its derivatives is due to angular strains which arise in the planar σ-electron system (their contribution to the enthalpy of the transition to the D_{2d} configuration is ~85%).[77,78]

Thus one should not completely identify antiaromaticity with the tendency towards the breakdown of the planar structure of the molecule. A molecule which can be classified as antiaromatic can deviate only slightly from a planar conformation, as, for example, for 1,5-bisdehydro[12]annulene,[76] and at the same time the properties of the σ-electron system can determine the non-planar structure also in the case of aromatic compounds. For example, non-empirical calculations for the cyclobutadiene dication (two π electrons) point to a non-planar structure with D_{2d} symmetry.[79,80] On the other hand, calculations by the MINDO/3 method have shown[81] that a saddle point and not a minimum on the potential energy surface of cyclobutadiene (C_4H_4) corresponds to the non-planar structure of its molecules, which have the same symmetry.

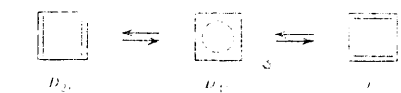
Thus the structural criterion of antiaromaticity is apparently most correctly treated as the energetic preference for a planar structure with alternating bond lengths as compared with a planar highly symmetrical structure with equalised carbon–carbon bond lengths. The generality of this structureal criterion is confirmed by the results of Nakajima and Binsch et al., who developed the theory of lattice instability in a series of studies (see the relevant reviews[82,83]).

In order to determine the stability of a highly symmetrical planar configuration of the molecule relative to distortions leading to planar structures of lower symmetry, it is necessary to estimate the force constant of the corresponding normal vibration Q_i which causes the deformation of the highly symmetrical configuration. A conjugated cyclic system is aromatic if the "fixation of double bonds" of the first or second order is not observed (in the first-order bond fixation, the symmetry of the σ-skeleton does not change in contrast to the second-order bond fixation).[83] The second-order double bond fixation is characterised by a minimum eigenvalue λ of the bond–bond polarisability matrix and the corresponding eigenvector determines the symmetry of the distortion. If λ_{max} (in units of β) is less than a critical value $\lambda_{cr} = 1.22$, then the system is stable in relation to distortions leading to the breakdown of the equalisation of bond lengths. For example, the minimum force constant for the in-plane vibrations of benzene corresponds to a distortion b_{2u} to give the D_{3h} structure, but $\lambda_{max} = 0.791 < \lambda_{cr}$ and a distortion of this kind is not realised. On the other hand, for pentalene and heptalene the calculated λ_{max} exceed λ_{cr} and a dynamic alternation of bond lengths,[83] analogous to the topomerisation of the D_{2h} structure of cyclobutadiene,[84,85] should obtain for such compounds, which makes it possible to classify pentalene and heptalene as antiaromatic systems.

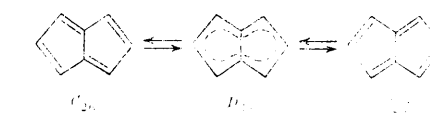
The criterion of the lattice instability is consistent with the criteria based on the resonance energies and magnetic properties.[64]

The degree of instability of the molecular configuration and the possibility of a reduction of symmetry are caused by the second-order Jahn–Teller effect, which depends on the difference $\Delta E = E_1 - E_0$ between the energies of the ground and first excited singlet states.[82] The following criterion of the instability of the geometrical configuration of the molecule has been formulated: if the quantity ΔE calculated for a given structure with equalised bond lengths is less than the empirically selected quantity 1.2 eV, then the force constant of the in-plane skeletal vibration will assume a negative value, giving rise thereby to a tendency towards a distortion resulting in a less symmetrical structure with alternating carbon–carbon bond lengths.[82,86,87] Thus $\Delta E = 0.35$ eV has been obtained for the pentalene structure with D_{2h} symmetry and this structure is unstable in relation to distortions giving rise to a structure with C_{2h} symmetry.

Thus a minimum on the potential energy surface does not correspond to a highly symmetrical configuration of the singlet state of antiaromatic molecules. On the other hand, there are minima on the potential energy surface corresponding to structures with reduced symmetries involving alternating bond lengths, which are interconverted via a multiplicity of valence isomerisation modes. The topomerisation of structures with alternating bond lengths is then the main process:



(14)



(15)

For benzene, the structure with D_{6h} symmetry corresponds to a minimum on the potential energy surface for the C_6H_6 system. For example, the structure of the singlet state of cyclobutadiene with D_{4h} symmetry is the transition state in the topomerisation reaction of the D_{2h} configuration (Fig. 2).[88–90]

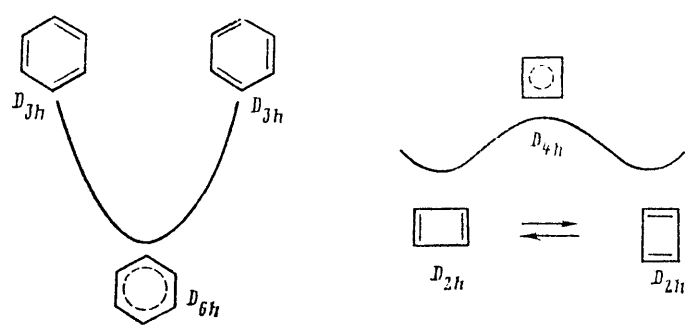


Figure 2. Potential curves for benzene and cyclobutadiene molecules along the coordinate corresponding to the shift of the double bonds.[3] In the case of benzene a skeletal vibration is observed in the Raman spectrum at 1585 cm^{-1}. For cyclobutadiene, the topomerisation of the D_{2h} structure takes place.

The multiplicity of other proposed aromaticity–antiaromaticity criteria,[12–16,91–96] and their interrelations[97] cannot be discussed within the framework of the present review. Furthermore, almost all the remaining definitions are to some extent derived from the fundamental criteria of aromaticity–antiaromaticity considered above.

We may note that the application of the concept of resonance energy and magnetic criteria to antiaromatic molecules does not in fact always lead to definite conclusions.[55,62]

2. Characteristic Features of the Calculation of the Electronic Structure of Antiaromatic Molecules

The complex relief of the potential energy surfaces of antiaromatic molecules and the closeness of the energy surfaces for the ground and lowest excited states, which in many instances leads to their touching and even intersecting, are all factors which impose more stringent requirements on the rigour of the quantum-chemical calculations of the electronic structures of antiaromatic molecules. When the SCF MO method is used, one encounters the problem of the stability and multiplicity of the Hartree–Fock (HF) solutions.[98–114]

In this connection it is necessary to note two aspects of the problem. The first involves the methodology of the correct selection of the computational scheme which can yield specific results for antiaromatic molecules. The second involves the interrelation between the so-called singlet instability of the HF solutions for antiaromatic molecules and the lattice instability, which we mentioned in the previous section as one of the structural criteria of aromaticity–antiaromaticity. The schemes for the calculation of the stabilities of solutions have been examined in a number of studies.[99,107–109] They reduce to the evaluation of the eigenvalues of the instability matrices, whose elements are determined from the familiar formulae for the matrix elements of the HF Hamiltonian between singly excited states and between the ground and doubly excited states.[99]

It is possible to discover a series of instability levels[108–111] which determine the concrete form of the instability matrix. In the case of a closed shell the singlet and triplet (non-singlet) instabilities are treated within the framework of the restricted Hartree–Fock method (RHF), which presupposes identical spatial wave functions for electrons with different spins. The singlet instability is the instability in the variations of the overall wavefunction with retention of the twofold occupation of the orbitals. The triplet instability is one corresponding to the abandonment of the restriction in the RHF method imposed by the requirement for the twofold occupation of the orbitals and to variations characteristic of the unrestricted Hartree–Fock method (UHF).

The triplet instability of the solutions obtained in the calculation by the RHF method is a sufficient (but not necessary) condition for the existence in the calculation by the UHF method of a solution with a lower energy.[99,108] This type of instability is much more common than the singlet instability. The instability of the relative occupation of the MO [the so-called filling up (FU) instability[107]] where the filling of the highest orbitals can lead to solutions with a lower total energy, to the breakdown of the Aufbau-principle of the filling of energy levels,[100] is of special interest.

If the solution by the RHF method is unstable, it is necessary to take into account correlations effects.[115] For a correct description of the electronic structures of antiaromatic molecules, there exist in this instance two alternative procedures.[116] Firstly, remaining within the framework of the one-determinant approach, one can employ MO of lower symmetry than that of the nuclear skeleton, while in the presence of triplet instability one can employ the UHF method. This procedure makes it possible to obtain results which agree well with experimental data, in contrast to those based on the use of fully symmetrical solutions (see, for example, Karpfen and Petkov[117] and Canuto et al.[118]). In the presence of triplet instability, the transition to the UHF approximation makes it possible to describe the multiplicity of the electronic state of the highly symmetrical configurations of antiaromatic molecules.[119–122] For example, analysis of the stability of the solution for cyclobutadiene obtained by the UHF method indicates a singlet ground state having a D_{4h} structure.[119,122] On the other hand, the cyclopropenyl anion (D_{3h}) and the cyclopentadienyl cation (D_{5h}) have a triplet ground state.[119] Thus the study of the character of the stability of the HF solution permits qualitative conclusions about the nature of the electronic ground states of the given molecules which are fully confirmed by non-empirical calculations taking into account the electronic correlation energy.[88–90]

Another procedure for taking into account correlation effects is also possible, involving the superposition of configurations made up of MO with corresponding symmetries or involving the use of multiconfiguration self-consistent field methods (MC SCF). Although this approach requires the allowance for a large number of configurations and involves a considerable consumption of computer time, nevertheless it is perhaps the most preferable. In relation to the cyclopropenyl anion, cyclobutadiene, the cyclopentadienyl cation, and other antiaromatic molecules, the multiconfiguration approximation was developed further by Borden and Davidson (see the relevant reviews[29,31] and the literature quoted therein).

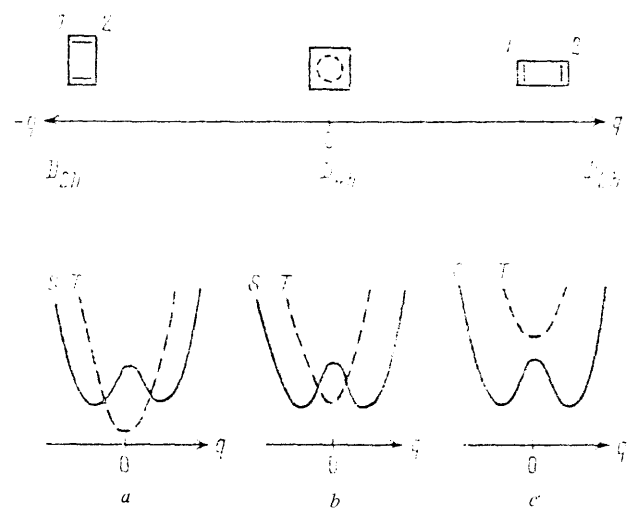

Figure 3. The forms of cross-sections through the potential energy surface for C_4H_4 along the locus of the minimum energy of the reaction (LMER) involving the topomerisation of the cyclobutadiene structure with D_{2h} symmetry (q is the reaction coordinate).

The second structural aspect of the problem of the instability of the HF solutions is determined by the relation between the singlet instability of solutions by the RHF method and lattice instability. The singlet instability has been revealed by the results of calculations by semiempirical methods of the PPP type for aromatic hydrocarbons only when unrealistic values of the resonance integral β were used.[123] However, for antiaromatic molecules the singlet instability of the RHF

solutions has been found even for values of the resonance integral β close to the standard values.[124,125] The singlet instability entails the existence of a solution with an electron distribution corresponding to a reduced symmetry, which gives rise to a tendency towards the distortion of the highly symmetrical geometrical configuration (lattice instability)[126-129] and determines the symmetry of this distortion.[129] The relation between the matrix of the singlet instability and the expression for the force constant when the molecular configuration is distorted as a consequence of the second-order Jahn–Teller effect has been demonstrated.[130]

Thus the singlet instability in the solutions by the RHF method for antiaromatic molecules is responsible for the possibility of the lattice instability, which is one of the structural criteria of aromaticity-antiaromaticity and makes it possible to predict a number of characteristics of the potential energy surface. The presence of the single instability should be regarded as an indication of the necessity to correct the initial hypothesis concerning the form of the nuclear configuration.[131] The possibility of a dynamic process involving the isomerisation of antiaromatic molecules is generally speaking an essential consequence under these conditions of the singlet instability and must be investigated in each specific case. The quantum-chemical calculation of the potential energy surfaces of antiaromatic compounds, to the results of which the next Section of this review is devoted, assumes particular importance in this connection.

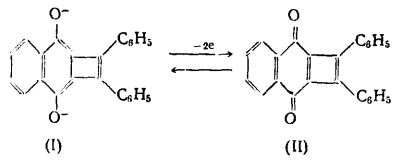
II. THE STRUCTURE AND VALENCE ISOMERISATION OF ANTIAROMATIC $(CH)_n$ POLYMETHINES AND THEIR HETERO-SUBSTITUTED DERIVATIVES

1. Cyclobutadiene

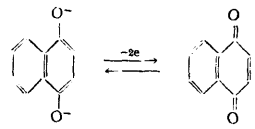
Cyclobutadiene (CBD) is the key structure in the theory of antiaromatic systems. Just as the benzene molecule is a prototype of an aromatic system, CBD is regarded as an example of a system which is antiaromatic not only on a relative scale (compared with the corresponding model system), but also on the absolute scale,[132] bearing in mind the degree of localisation of the molecular π orbitals. This implies that the electronic-structural properties of CBD are directly opposed to those of benzene. The bond conjugation in the four-membered ring of CBD causes a sharp destabilisation of the structure which is expressed in negative resonance energies for CBD (Table 1), the localisation of the double bonds in the ring, a tendency towards reactions involving addition to the double bonds, and the stereochemical non-rigidity of the CBD molecule associated with the fluctuations of the positions of the π bonds in the molecule.

Monographs and reviews have been devoted to CBD.[29,31,133-135] Here we shall briefly consider the principal manifestations of the antiaromaticity of CBD by comparing the thermodynamic stabilities of CBD and its derivatives, the tendencies towards isomerisation, and the structural characteristics.

The resonance energies of CBD calculated by different procedures (Table 1) may be compared with the experimental data. The latter are based on a comparision of the energy relations of isotypical reactions, some of which lead to the formation of the [4]annulene fragment, with other reactions in which this fragment does not arise. For example, a study has been made[9,136] of the reversible electrochemical oxidation-reduction of the quinones (II) and (IV):



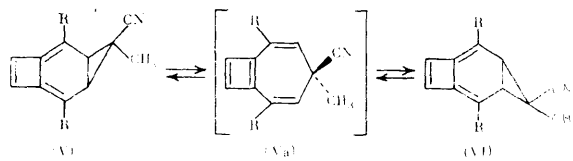
(I) (II) (16)



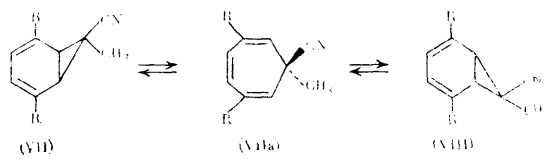
(III) (IV) (17)

The much higher oxidation potential of compound (I) compared with that of compound (III) has been interpreted[9,136] as the manifestation of the characteristic features of the antiaromaticity of compound (I), which contains an annelated cyclobutadiene fragment. The energy of the antiaromatic destabilisation of CBD after taking into account the influence of steric effects in the system of compound (I) (see also Herr[137]) has been estimated as 60–80 kJ mol^{-1}.

Another approach[138] is based on a comparison of the activation barriers to the topomerisation reactions (V) ⇌ (VI) and (VII) (VIII) determined by dynamic NMR.



(18)



(19)

The differences between these barriers are attributed to the formation in the first case of the destabilised structure (Va) containing the antiaromatic CBD ring. The resonance energy of the unsubstituted CBD has been estimated as approximately 88 kJ mol^{-1}.

As mentioned above in Section (I), calculations of the heat of the isodesmic reaction (6) also indicate the antiaromaticity of CBD.

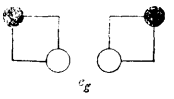
Paramagnetic ring currents have been observed[135] in an NMR study of tri-t-butylcyclobutadiene, which makes it possible to classify CBD as a paratropic system and, in conformity with the magnetic criteria, as an antiaromatic system.

(a) The geometrical structure of the type of the electronic ground state of CBD. The problems of the geometry and the multiplicity of the electronic ground state of CBD have found a reliable theoretical and experimental solution only recently (see the detailed review of Bally and Masamune[135]). Here we shall note only the most significant features.

Numerous calculations for CBD have led to three possible types of cross-sections through the potential energy surface for the C_4H_4 system corresponding to the locus of the minimum energy of the reaction involving the topomerisation of the CBD structure with D_{2h} symmetry via a structure having the D_{4h} symmetry (Fig.3).

The results of the majority of the calculations show that in the singlet ground state CBD has an equilibrium configuration with D_{2h} symmetry. The scheme in Fig. 3*a* corresponds to the results of Allinger et al.[139] (PPP method, the σ-skeleton is treated by the method of molecular mechanics). On the other hand, the conclusions concerning the energy of the lowest singlet and triplet states having a structure with D_{4h} symmetry have been contradictory. For the CBD structure having this symmetry, two electrons in the e_g orbitals can be accommodated in different ways, which leads to six degenerate configurations within the framework of the one-determinant approximation.

By considering their interactions and using the symmetry properties, it can be shown that in the given instance there is a possibility of the electronic states $^1A_{1g}$, $^1B_{1g}$, $^1B_{2g}$ and $^3A_{2g}$ (whose energies relative to that of the $^3A_{2g}$ state are 280, 251, and 29 kJ mol^{-1} according to the results of non-empirical calculations in terms of the 6-31G basis set[89]), differing in the ways the electrons are accommodated in the orbitals. Orbitals of the e_g type are localised at different carbon atoms:



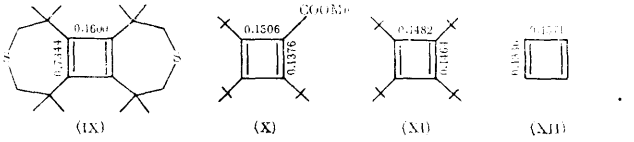
The corresponding exchange integral should be very small (it should be approximately zero in terms of the NDO approximation), which has two consequences. Firstly the energies of the $^3A_{2g}$ and $^1B_{1g}$ states are similar, because the electrons in the e_g orbitals are separated in space and the energy of the interelectron interaction depends less on whether the spins are parallel of not.[90] Secondly, as a result of the dynamic spin polarisation#, which is much more effective in the case of the singlet state, the energy of the $^1B_{1g}$ state is lower than that of the $^3A_{2g}$ state (see the scheme in Fig. 3*c*). Since this type of effect cannot be described in terms of the approximation of the RHF method without taking into account the configuration interaction, the energy of the $^1B_{1g}$ state is significantly too high.

The electronic structure of CBD with a nuclear configuration having the D_{4h} symmetry cannot be described satisfactorily in terms of the one-determinant approximation and, for example, non-empirical calculations in terms of the 4-31G basis set lead to the conclusion that the triple state of the CBD molecule with D_{4h} symmetry has an energy lower by 22.6 kJ mol^{-1} than that of the singlet state with a nuclear configuration with D_{2h} symmetry (Scheme *a* in Fig. 3).[141]

Non-empirical calculations with allowance for configuration interaction lead to differences between the energies of the $^3A_{2g}$ and $^1B_{1g}$ states of 30.5–58.2 kJ mol^{-1} depending on the basis set,[68–90] which confirms the results of the earlier study[142] (1968) which lead to the scheme in Fig. 3*c*. Analogous results have been obtained by the MC SCF calculations for CBD in the π-electron approximation,[143] and also by calculations based on the MNDOC method[144] (the corresponding energy differences are 29.7 and 39.3 kJ mol^{-1}).

The results of the calculations have been confirmed recently by experimental data. Using the technique of flash photolysis, it has been established that the T_1 state of the peralkylated CBD has an energy higher by 50 kJ mol^{-1} than that of the singlet ground state.[145]

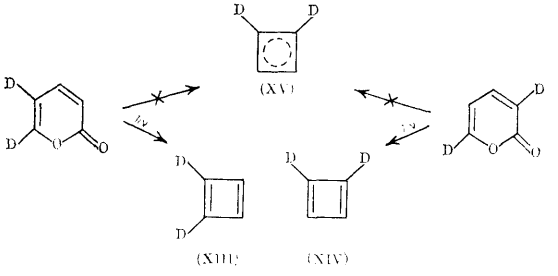
The most accurate calculated data for the geometry of CBD have been obtained by a non-empirical method in a study[67] employing an extended basis set including polarisation functions taking into account the electron correlation (see also, Clark and Harrison[146]). In the singlet ground state of CBD, the carbon σ-skeleton has the form of a rectangle with localised double bonds. It is striking that the C–C bond lengths actually exceed the usual values (the C–C bond length in ethane is 0.1537 nm) which can be accounted for by a tendency towards the decrease of the destabilising effect of conjugation [the results of *ab initio* calculations are quoted for structure (XII) [69]]:



(IX) (X) (XI) (XII)

The considerable differences in the C–C bond lengths are confirmed by the results of X-ray diffraction studies on CBD derivatives of the type of (IX)–(XI).[145,147–149] The equalisation of bond lengths in structure (XI) can be explained by steric causes.[150]

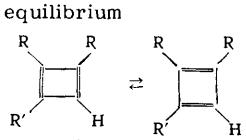
Although the results of earlier investigations[151,152] of the infrared spectra of CBD (isolated in matrices) were interpreted as evidence for a square configuration of the carbon skeleton of the molecule, it was shown subsequently that the presence in the IR spectrum of CBD of four bands due to the skeletal vibrations of the four-membered ring with frequencies below 2000 cm^{-1} [153] can be compatible only with a rectangular molecular structure. This conclusion was recently confirmed by experiments on the matrix isolation of two dideutero-substituted CBD derivatives (XIII) and (XIV) obtained by the photolysis of [5,6-D_2]- and [3,6-D_2]-α-pyrones respectively:[154]



(XV) (XIII) (XIV)

Earlier, it has been assumed erroneously that the reactions indicated lead to the formation of the same product having the square structure (XV). Calculation of the IR spectra of 1,2-dideuteriocyclobutadienes confirmed structures (XIII) and (XIV).[155]

The study of the equilibrium



(20)

R = t-C_4H_9, R′ = 1) t-C_4H_9, 2) t-C_4D_9

#Its essential feature is as follows.[140] The e_g orbitals are localised at different carbon atoms and the electrons present in them, which have opposed spins in the case of a singlet state, determine the disposition in space of the remaining electrons in the preceding, in terms of energy, CBD orbitals, since the repulsion between an electron in one of the e_g orbitals (for example with a spin α) and the electron in the preceding MO with the same spin is smaller, as a consequence of the exchange interaction, than the repulsion between the electrons with the opposite spins. Since the two electrons in the e_g orbital and their spin states are interchangeable, the spin polarisation is dynamic, in contrast to the similar statistical spin polarisation in radicals.

by dynamic ^{13}C NMR provided direct evidence for the existence of the valence isomers of CBD with alternating carbon–carbon bond lengths (in the ring), in contrast to the description of CBD in terms of resonance structures (cf. Fig.2).

Thus, whereas in the case of aromatic compounds, for example, benzene, structures with alternating bond lengths (the structures with $D_{3}h$ symmetry in Fig.2) cannot be observed experimentally, because the transition via the fully symmetrical $D_{6}h$ form does not involve the overcoming of an energy barrier and takes place at an electron oscillation frequency of approximately 10^{15} s^{-1},[152] in the case of CBD reaction (14) does in fact require the movement of nuclei. Thus in the ground state the geometry of CBD belongs to the $D_{2}h$ symmetry group with localised double bonds in the ring. Consequently both the structural criteria of aromaticity–antiaromaticity and the energetic (resonance energies, heats of isodesmic reactions) and magnetic criteria show that CBD is antiaromatic.

(b) Valence isomerisations of CBD. The closeness of the potential energy surfaces for the ground and lowest excited states of antiaromatic compounds leads to the possibility of low-barrier valence isomerisation reactions, in contrast to benzene and other aromatic molecules. Fig.4 illustrates schematically the valence isomerisation reactions of CBD based on calculations by the MINDO/3 method.[157–160]

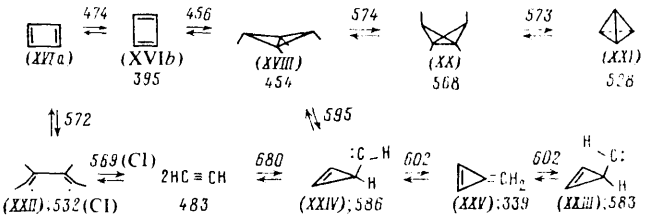


Figure 4. Schemes illustrating the principal valence isomerisations of CBD according to calculations by the MINDO/3 method.[157–160] The numerals under the numbers designating the structures represent the calculated heats of formation (in kJ mol^{-1}) and the numbers along the arrows represent the heats of formation of the structures of the transition state (in kJ mol^{-1}). The calculations for the cyclodimerisation of acetylene to CBD have been made taking into account the configuration interaction (CI).[159] The concerted cyclisation mechanism cannot be described satisfactorily within the framework of the one-determinant approximation because of the triplet instability of the RHF solutions.[160]

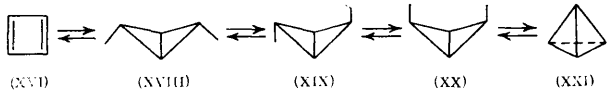
Two types of reactions are possible theoretically in principle: topomerisation occurring as a fluctuation of π-bonds in the ring [the bond shift process—see Eqn.(14)],

and the interconversion of CBD and the only theoretically permissible isomeric form—tetrahedrane:



(21)

The isomerisation reaction (14) can be regarded as the manifestation of a second-order Jahn–Teller effect. The lowest singlet $^{1}B_{1g}$ state of the structure with $D_{4}h$ symmetry can be mixed with the $^{1}A_{1g}$ state, which has a similar energy, as a result of vibrations with $b_{1}g$ symmetry corresponding to deformations which convert the CBD structure with $D_{4}h$ symmetry into the rectangular form.[89] The triplet $^{3}A_{2}g$ state of the $D_{4}h$ structure of CBD might be mixed, as a consequence of the $b_{1}g$ vibration, with the $^{3}B_{2}g$ state, but the triplet state with a suitable symmetry has an unduly high energy. This in fact explains why the geometry with $D_{4}h$ symmetry corresponds to the $^{1}A_{2}g$ state of CBD.

It has been suggested[161] that the interconversion of the rectangular $D_{2}h$ topomers of CBD of the type of compounds (XVIa) and (XVIb) (Fig.4) can proceed via a rhombic and not quadratic transition state with $D_{2}d$ symmetry. However, in the case of the CBD structure having the $D_{4}h$ symmetry there are no excited singlet states whose interactions with the $^{1}B_{1}g$ state would lead to the rhombic distortion of the structure.[88,89]

It follows from the results of non-empirical calculations that the $^{1}B_{1}g$ state with a $D_{2}h$ structure of CBD has only one negative force constant corresponding to the $b_{1}g$ distortion, while the $^{1}A_{2}g$ state has no negative force constants. Thus the $D_{2}h$ structure of CBD in the $^{1}B_{1}g$ electronic state does indeed correspond to the transition state in the topomerisation of the $D_{2}h$ structure and the activation barrier has been estimated as 34.7–56.1 kJ mol^{-1} (*ab initio* calculations[88–90]).

We may note that Dewar and Kollmer[157] quote an energy difference between the lowest singlet and triplet states of the CBD structure with $D_{2}h$ symmetry amounting to 54.8 kJ mol^{-1} (MINDO/3 method). Correspondingly, the activation barrier to the topomerisation of $D_{2}h$ structures is 79.5 kJ mol^{-1}, but, in terms of the NDO approximation, the above energy difference between the lowest singlet and triplet states should be zero. Indeed the calculations for the CBD molecule by the MINDO/3 method, which we repeated, confirmed this. The activation barrier to the topomerisation of the $D_{2}h$ structures of CBD proved to be 24.7 kJ mol^{-1}, which agrees well with the results of non-empirical calculations,[88–90] in contrast to the results of Dewar and Kollmar.[157] The use by the latter workers of an initial density matrix corresponding to the double filling of one of the CBD molecular π-orbitals with e_{g} symmetry led to an artefact solution.[125] This is yet another example demonstrating the complexity of the calculation of the electronic structure of antiaromatic molecules discussed above (Section I).

The experimental barrier to the topomerisation of tri-t-butylcyclobutadiene found by dynamic NMR is 10.5 kJ mol^{-1}.[162]

The direct thermal cyclisation of CBD to tetrahedrane [reaction (21): ($\pi 2a + \pi 2a$ – cycloaddition)] and the reverse reaction are forbidden by the Woodward–Hoffman rules,[163] which is the reason for the kinetic stability of tetrahedrane, whose energy is higher than that of CBD.[69,146,164–169] Indeed, the valence isomerisation of tetra-t-butyltetrahedrane to tetra-t-butylcyclobutadiene takes place only at 135 °C and above.[170,171] The reversibility of the isomerisation has been confirmed by low-temperature NMR data. In view of the prohibition of the concerted mechanism of the thermal isomerisation CBD ⇌ tetrahedrane, reaction (21) has been shown by calculations[69,166–168] to proceed in several stages involving the formation of the diradicaloid intermediates (XVIII) and (XX) (Fig.5).

The following values have been obtained for the total activation energy for the isomerisation reaction CBD → tetrahedrane: 179.5 kJ mol^{-1} (MINDO/3 [159]), 255.6 kJ mol^{-1} (MNDO – CI 2 × 2 [168]), and 143.4 kJ mol^{-1} (*ab initio*, DZ + P basis, with allowance for electronic correlation[69]). The diyl (XIX) is the transition state in the reaction (XVIII) → (XX),

which constitutes the rate-limiting stage. The activation barrier for this reaction has been estimated as 142 kJ mol^{-1} (*ab initio*, DZ + P basis, with allowance for correlation energy[69]), 120.9 kJ mol^{-1} (MINDO/3), or 125.1 kJ mol^{-1} (MINDO/3, with allowance for CI 3 × 3 [153]).

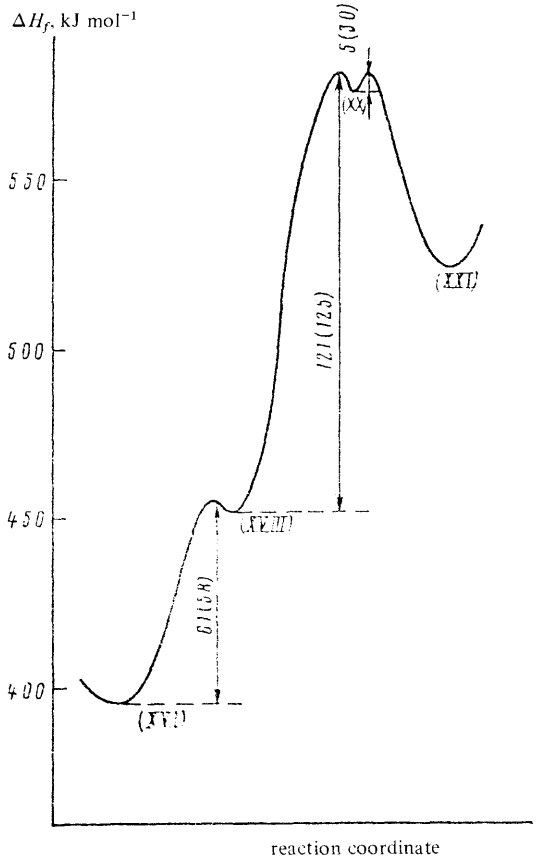


Figure 5. Cross-sections through the potential energy surface for the C_4H_4 structure along the locus of the minimum energy of the reaction involving the CBD → tetrahedrane isomerisation (calculation by the MINDO/3 method[153]). The activation barriers (in kJ mol^{-1}), calculated taking into account the 3 × 3 configuration interaction, are indicated in brackets.

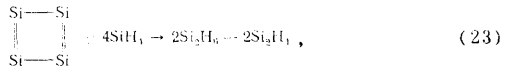
2. Hetero-substituted Cyclobutadienes

The analogues of cyclobutadiene have been studied to an incomparably lesser extent than cyclobutadiene itself. Calculations and individual experimental data are available only for sila- and aza-substituted derivatives.

Silacyclobutadiene. The results of the calculation of the heat of the isodesmic reaction (22) (*ab initio*, 6-31G/3-21G basis[61])

(22)

(ΔH = −223 kJ mol^{-1}), which is a characteristic of the stability of the conjugated cyclic system, indicate the antiaromaticity of silacyclobutadiene. On this scale, the degree of antiaromaticity of cyclobutadiene exceeds by 61.1 kJ mol^{-1} that of silacyclobutadiene [see reaction (6)]. This is caused mainly by the fact that the introduction of the silicon atom with its diffuse atomic orbitals into the ring decreases the destabilising effect of the conjugation in the four-membered ring. Indeed the degree of antiaromaticity of tetrasilacyclobutadiene, estimated from the heat of reaction (23) by the MINDO/3 method, is significantly lower than in the case of cyclobutadiene:[172]

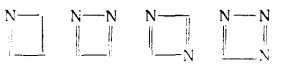


(23)

for which ΔH = −68.6 kJ mol^{-1}.

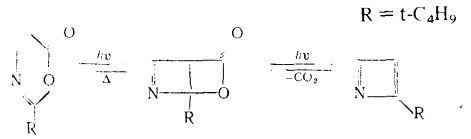
According to the results of non-empirical calculations (6-31G/3-21G basis),[61] silatetrahedrane has a total energy higher by 139.3 kJ mol^{-1} than silacyclobutadiene.

Azacyclobutadienes. The unsubstituted azacyclobutadiene (azet) (XXVI) has not so far been obtained, but there exist data demonstrating the experimental detection of a number of its derivatives.[173,174]



(XXVI) (XXVII) (XXVIII) (XXIX)

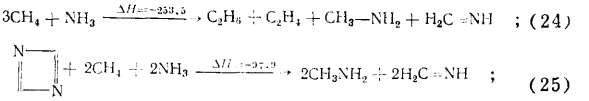
For example, when oxazinone was irradiated, t-butylazacyclobutadiene was obtained:



In order to compare the properties of cyclobutadiene and its aza-derivatives, we shall discuss the influence of aza-substitution on the e_g π orbitals of CBD with D_{4h} symmetry (Fig. 6).

Monoaza-substitution leads to the removal of degeneracy from the e_g π orbital in the D_{4h} structure of CBD, stabilising the a_1 π orbital (the C_{2v} structure of azet)[54] (the change in the energies of the π orbitals of conjugated cyclic systems on aza substitution has been considered;[176] see also the aza-substitution of trimethylenemethane in the case of Y-antiaromaticity[177]). 1,3-Diaza-substitution leads to an even greater change in the relative energies of the e_g π orbitals, stabilising the b_{2g} orbital. This results in an increase of the energy difference between the ground ^1A_g and the first excited singlet $^1B_{1g}$ states of the structure of 1,3-diazet with D_{2h} symmetry, which promotes an increase of both the antiaromatic character and the lattice instability of the structure in conformity with the aromaticity-antiaromaticity criteria.[16,81] 1,2-Diaza-substitution should not lead to an appreciable stabilisation of any one of the e_g π orbitals of the D_{4h} structure of CBD relative to another.

Calculations by the MINDO/3 method of the heats of the isodesmic reactions (24)–(26) indicate a higher stability of 1,3-diazet compared with 1,2-diazet and of azet compared with cyclobutadiene[59] (the values of ΔH for the reaction are indicated in kJ mol^{-1}):



(24)

(25)

(26)

The results of non-empirical calculations (STO-3G basis) of the heats of reaction (25) also indicate a greater stability of 1,3-diazet ($\Delta H = -201.4$ kJ mol^{-1}) compared with CBD ($\Delta H = -268.6$ kJ mol^{-1}).[60]

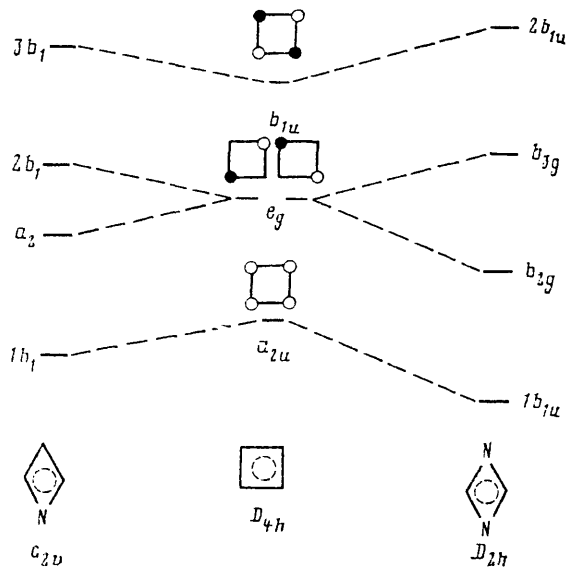


Figure 6. Correlation of the π MO for the cyclobutadiene structure, the azet structure with D_{2h} symmetry, and the 1,3-diazet structure with D_{2h} symmetry.

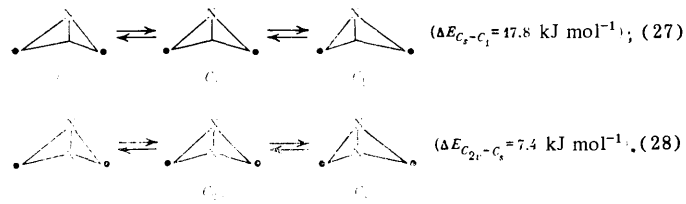
A decrease of the antiaromatic character of azet compared with CBD follows from the calculations of the Dewar resonance energy: −71.1 kJ mol^{-1} [44] and −64.8 kJ mol^{-1} [178] have been obtained for CBD and azet respectively. Despite the variation of the initial density matrix, calculations by the Pariser–Parr–Pople (PPP) method for 1,2-diazet cannot yield a solution corresponding to a structure with equalised bond lengths.[179,180]

The substitution of three carbon atoms must be treated as a special case because in this instance both e_g π orbitals of the CBD structure with D_{4h} symmetry are stabilised. The structure with alternating bond lengths having the C_S symmetry corresponds to a minimum on the potential energy surface for CN_3H and not the structure of triazet with C_{2v} symmetry (calculations by the MINDO/3 method[59]). Consequently, in contrast to the tendencies characteristic of mono- and 1,3-di-aza-substitution, 1,2-diaza-substitution and triaza-substitution do not stabilise the highly symmetrical configuration, which, by virtue of the small energy difference between the ground and first excited singlet states, involves lattice instability.[179,180]

Thus analysis of the transformations of the molecular orbitals of the CBD molecule with D_{4h} symmetry for different types of aza-substitution justifies the expectation of three different types of potential energy surface corresponding to reactions (14) and (21) for azacyclobutadienes. (The results of the calculations and of the valence isomerisations of azacyclobutadienes are presented in Fig.7).

Isomerisation to structures of lower symmetry is characteristic of the C_S structure of 1-azabicyclo[1.1.0]butane-2,4-diyl (XXXI) and the C_{2v} structure of 1,3-diazabicyclo[1.1.0]-butane-2,4-diyl (XXXVII) [59] (the energy differences calculated by the MINDO/3 method are indicated in brackets):



($\Delta E_{C_2-C_1} = 17.8$ kJ mol^{-1}); (27)

($\Delta E_{C_{2v}-C_s} = 7.4$ kJ mol^{-1}). (28)

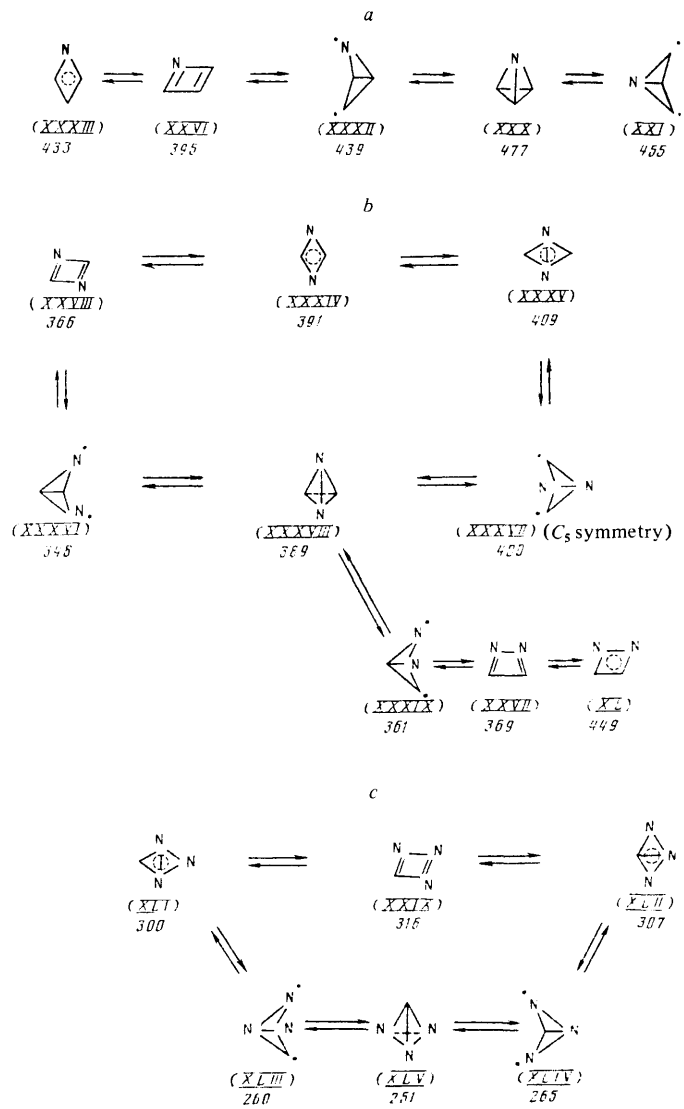


Figure 7. Schemes illustrating the valence isomerisations of azet (*a*), 1, 2- and 1,3-diazets (*b*), and triazet (*c*). The numerals under the numbers designating the structures represent the heats of formation (in kJ mol^{-1}) calculated by the MINDO/3 method.[59,179,181] Minima on the potential energy surface correspond to all the structures with the exception of structures (XXXIII), (XXXIV), and (XL), to which maxima correspond.

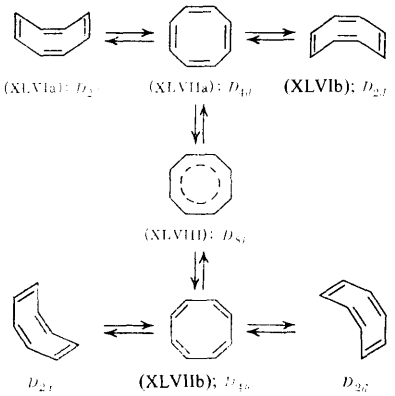
The reactions involving the cyclisation of azabicyclo[1.1.0]-butanediyls to the corresponding azatetrahedranes are prohibited by bond symmetry conservation rules[182] (see Glukhovtsev et al.[59] for the given reactions) and are characterised by high activation barriers, which is the reason for the kinetic stability of the corresponding azatetrahedranes.

3. Cyclo-octatetraene

The structure of cyclo-octatetraene (COT), which is the second member of the series of [4*n*]annulenes with $n = 2$, has been studied in extremely great detail.[183–185] This compound and some of its derivatives are stable substances and there exist fairly reliable experimental data for their geometry, the type of the electronic ground state, and the most characteristic chemical properties.

The boat configuration (XLVI) with D_{2d} symmetry corresponds to the COT molecule in the ground state. According to calculated data,[186–188] its energy is lower by 63–75 kJ mol^{-1} than that of the planar structure (XLVII) with D_{4h} symmetry. Only one compound with a planar cyclo-octatetraene fragment is known, namely the cyclic perfluorotetracyclobutane derivative, in which there is a slight alternation of the bond lengths in the COT ring (0.1425 nm) according to X-ray diffraction data.[189]

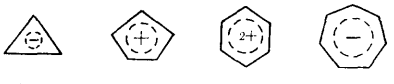
The planar forms of COT with D_{4h} and D_{8h} symmetries are the transition states for the most important COT isomerisation reactions—the enantiomerisation (XLVIa) ⇌ (XLVIb) and the structural topomerisation (XLVIIa) ⇌ (XLVIIb) respectively. The latter process is isotypical with the topomerisation of the D_{2h} structure of CBD.



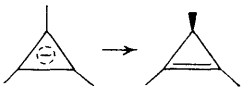
In the case of certain tri- and tetra-methyl-substituted COT the isomerisation, involving the formation of structure (XLVIII) with D_{8h} symmetry (fluctuation of π-bonds), can compete with the ring inversion which proceeds via the D_{4h} structure, although the barrier to ring inversion in COT is lower by 8.4–12.5 kJ mol^{-1} (see the relevant reviews[78–84]). Comparison of the activation energies for ring inversion and for the fluctuation of π-bonds makes it possible to estimate the COT delocalisation energy. The difference between these energies was found to be 14.2 kJ mol^{-1} in the case of 1,3-di-t-butylcyclo-octatetraene.[78] The antiaromatic character of COT is thus fairly weak.[77]

4. Antiaromatic Monocyclic Ions

The cyclic ions (XLIX)–(LII) containing $4n$ π-electrons and having a ring symmetry D_{mh} ($m = 3$, 5, 6, and 7 respectively) have an unclosed electron shell. In the singlet state in such systems a second-order Jahn–Teller effect is observed, being manifested, as in the case of CBD and COT, by a transition to a geometrical structure with a reduced symmetry and involving alternating bond lengths.

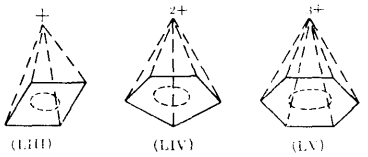


There is also a possibility of the formation of non-planar systems, which leads to the breakdown of cyclic conjugation as a result of the exclusion of one of the p_z orbitals from the conjugation system and to a decrease of the degree of antiaromaticity of the molecule, for example, in the case of the cyclopropenyl anion (CPA):

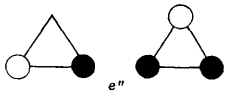


(29)

In addition the ions (L)–(LII) can have isomers in the form of non-classical polyhedral structures with $C_{(m-1)}$ symmetry provided that the latter satisfy the essential electronic requirements for three-dimensional aromaticity,[28] for example:



The cyclopropenyl anion. The unsubstituted CPA has not so far been obtained, but is triphenyl derivative is known. It has a strongly antiaromatic character, which is confirmed by the unusually high pK_a of its conjugate acid—triphenylcyclopropene (p$K_a \geq 51$).[9,20] Calculations[190–194] show that CPA has a triplet ground state and the D_{3h} geometry. Since the π orbitals with e'' symmetry cannot be localised in such a way that they have no common carbon atom, the corresponding exchange integral is fairly high.



As a result, the dynamic spin polarisation is not any way significant, in contrast to CBD and Hund's rule holds.[140]

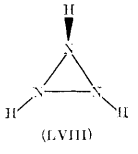
The degenerate character of the highest incompletely occupied e'' orbitals in the CPA structure with D_{3h} symmetry [the π-electron configuration of the state is $(a_2'')^2(e'')^2$] leads, as for CBD, to a second-order Jahn–Teller effect and to a decrease of the energy of the singlet $^1A_1$ state§ by 48.9 kJ mol^{-1} as a result of the decrease of the symmetry of the nuclear configuration to C_{2v} [194] [structures (LVIIa) and (LVIIb) with unequal C–C bond lengths]:

§ The designations for the electronic states of CPA and the cyclopentadienyl cation (CPC) correspond to the C_{2v} symmetry group (for further details, see the relevant literature[29,194–196].

The energies of the C_{2v} structures (LVIIa) and (LVIIb) (in kJ mol^{-1}) are indicated in brackets relative to the energy of the $^3A'_2$ state of the D_{3h} structure (LVI), found by a non-empirical method (STO-3G, CI basis);[194] the numerals opposite the bonds represent their lengths in nm.

However, in contrast to CBD, the singlet $^1A_1$ state is not the electronic ground state of CPA. This important conclusion must nevertheless be regarded as preliminary, because sufficiently reliable results can be obtained only by calculations where account is taken of the interaction of the configurations constructed not only on the basis of π orbitals but also σ orbitals.[195,196] Indeed, calculations carried out taking into account the configurations constructed on the basis of π orbitals describe incorrectly the form of the potential energy surface for the $^1A_1$ state.[196]

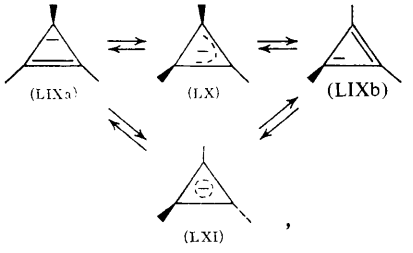
Non-empirical calculations[190] and calculations performed by the MINDO/3 and NDDO [193] methods have shown that additional stabilisation of the singlet state of CPA is achieved as a result of the displacement of the C–H bond in structures (LVIIa) and (LVIIb) from the plane of the three-membered ring. According to the results of non-empirical calculations (taking into account CI) for the $(NH)_3^{2+}$ system,[195] which is isoelectronic with respect to CPA, the electronic triplet state of the planar structure having the D_{3h} symmetry has a lower energy than the singlet state. However, the ground state of the ion $(NH)_3^{2+}$ is of the singlet type and a structure with displacement of the N–H bond from the plane of the ring in (LVIII) corresponds to it:



(LVIII)

The energy of the triplet state is also reduced in a structure of this type but to a lesser extent than that of the singlet state.

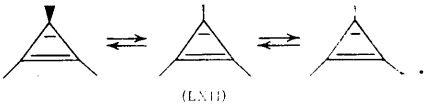
The valence isomerisations of CPA. The high symmetry (D_{3h}) of the CPA structures subjected to the Jahn–Teller effect is responsible for the formation of a multiplicity of local minima on the potential surface in the vicinity of the point corresponding to the given structure. According to the Murrell–Laidler theorem,[197] the singlet state of the structure with D_{3h} symmetry cannot be the transition state for the isomerisations of configurations having a lower symmetry, which has been confirmed by calculations.[192,194] Two types of isomerisations are possible, namely fluctuations in the position of the double bond [structures (LX) and (LXI) are the transition states]:



(LIXa) (LX) (LIXb) (30a)

(LXI) (30b)

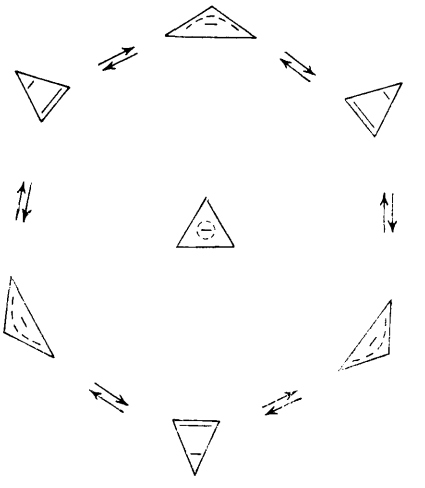
and the inversion of the carbanionic carbon [structure (LXII) is the transition state]:



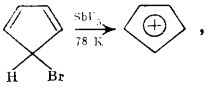
(LXII) (31)

The activation energies for reactions (30a) and (31) calculated by the CNDO/2 method[92] are 90 and 107 kJ mol^{-1}. An activation energy of 88.7 kJ mol^{-1} corresponds to the isomerisation reaction (30b), which proceeds via the transition state (LXI).[192]

The fluctuation of the double bond in planar structures (singlet state) of CPA of the type (LVIIa) and (LVIIb) can be represented by the following scheme, which shows that the reaction pathway runs in the "valley" encircling the "top of the hill" on the potential energy surface corresponding to the configuration with the D_{3h} symmetry:

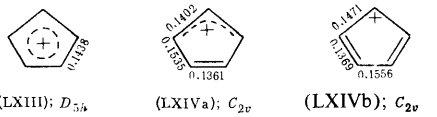


The cyclopentadienyl cation (CPC). Experimental studies, especially the EPR spectrum of CPC obtained by treating 5-bromocyclopentadiene with antimony pentafluoride at 78 K,[198]



(32)

confirmed the results of quantum-chemical calculations[199–204] showing that the electronic ground state of CPC (LXIII) is of a triplet type and has a geometry with D_{5h} symmetry. The energy of the singlet state corresponding to structure (LXIV) with C_{2v} symmetry is higher by only 30.5 kJ mol^{-1} (*ab initio* calculation, STO-3G, CI basis[204]).

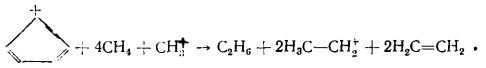


(LXIII); D_{5h} (LXIVa); C_{2v} (LXIVb); C_{2v}

The comparatively small difference between the energies of the singlet and ground states makes it possible to stabilise the former by introducing substituents into the ring.[205] In the case of the $^1A_1$ state of the structure with D_{5h} symmetry a second-order Jahn–Teller effect is observed.[29,204] The stabilisation energy on transition to the structure with C_{2v} symmetry is 56.1 kJ mol^{-1},[201] which is approximately three times greater than the analogous quantity calculated on the basis of the same scheme for CBD.[29] This can be accounted for by the greater similarity of the energies of the states, which can become mixed on distortion of the geometry of the nuclear skeleton of the CPC.

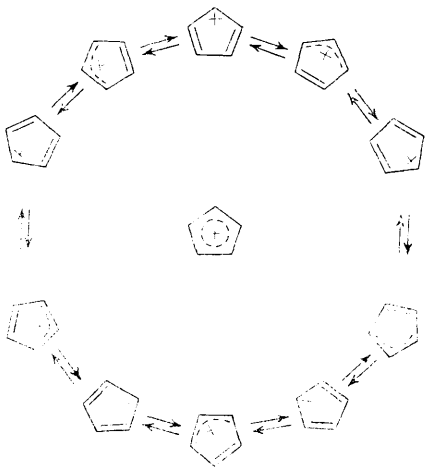
The antiaromaticity of CPC is confirmed both by the alternation of the bond lengths in structures of the singlet state and by the resonance energies (Table 1) and the heat of the

isodesmic reaction (33), which amounts to −12.6 kJ mol^{-1} (*ab initio* calculation, 4-31G basis).[202]

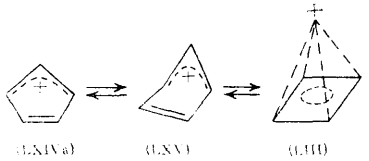


(33)

The valence isomerisations of CPC. Two main types of valence isomerisation are possible for CPC—the shift of the π-bonds in the planar structure described as pseudorotation of structures with C_{2v} symmetry:



and isomerisation to the classical square pyramidal structure (LIII), the possibility of the existence of which has been demonstrated by calculations using the extended Hückel method (EHM):[206]



(LXIVa) (LXV) (LIII) (34)

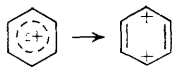
The pathway of the reaction involving bond shifts does not intersect the region corresponding to the D_{5h} configuration, which cannot be the transition state in the given reaction according to the Murrell–Laidler theorem.[197] Indeed, calculations have shown[204] that the symmetry-prohibited concerted isomerisation reaction $C_{2v} \rightarrow D_{5h} \rightarrow C_{2v}$ has a considerable activation barrier. The minimum energies for structures (LXIVa) and (LXIVb) differ by not more than 4.18 kJ mol^{-1}.[204]

The activation barrier of reaction (34) involving isomerisation to the square pyramidal structure (LIII), having an energy higher by 58.6 kJ mol^{-1} than structure (LXV), is 238.6 kJ mol^{-1} (MINDO/3 method[200]). According to revised data,[203,207] structure (LXV) is in its turn more stable by only 2.9 kJ mol^{-1} than structure (LXIVa). An interconversion reaction, whose transition state is structure (LXVI), is possible for structure (LIII), the activation barrier amounting to 77.8 kJ mol^{-1} (calculation by the MINDO/3 method).[39]

(LXVI)

The existence of structure (LIII) has been confirmed experimentally (the dimethyl derivatives[208] and also the trimethyl derivative[209] have been obtained; see also the relevant reviews[210,211]).

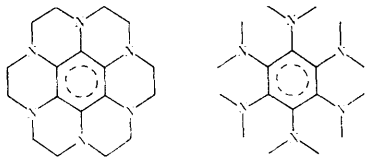
The benzene dication. The studies on the benzene dication and its fragmentation pathways have been the subject of numerous investigations.[212–214] Calculations by the MINDO/3 method have shown that the triplet state of the structure with D_{6h} symmetry is more stable by 40 kJ mol^{-1} than the singlet state,[214] which agrees with experimental data indicating a triplet ground state of the hexachlorobenzene dication.[215] When the limitations due to the D_{6h} symmetry were removed in the course of calculations on the structure of the singlet state of the benzene dication (LI), a distortion of the geometry was observed (without an activation barrier), resulting in the conversion into the less symmetrical structure (LXVII) with D_{2h} symmetry, whose energy is lower by ~320 kJ mol^{-1}.[214]



(LI: D_{6h}) (LXVII: D_{2h})

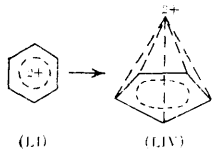
At the same time, structure (LXVII), which has four π electrons, is insufficiently well favoured by energy factors, which leads to the possibility of its fragmentation into acyclic structures.

A number of procedures have been proposed for stabilising the benzene dication by introducing substituents,[216,217] for example, as in systems (LXVIII)–(LXIX).



(LXVIII) (LXIX)

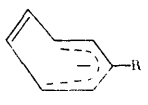
As in the case of CPC, one can assume that the antiaromatic character of the benzene dication promotes its isomerisation to the more stable non-classical pyramidal structure (LIV).



(LI) (LIV)

The hexamethyl derivative of the dication (LIV) is stable under the usual conditions.[218]

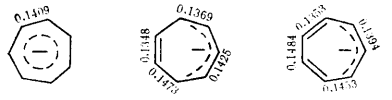
The cycloheptatrienyl anion. It has been suggested that the cycloheptatrienyl anion (CHA) is an intermediate in many reactions,[219,220] including the cycloheptatriene dimerisation reaction under the influence of bases.[221] Certain monosubstituted CHA, investigated by NMR which indicates a non-coplanar structure (LXX), are known.[222]



(LXX)

Here R = CO_2R^1, $CONR^2R^3$, or SO_2R^1, where R^1, R^2, and R^3 are aryl or alkyl. The planar structure of CHA with D_{7h} symmetry (eight π electrons) has a pair of e' orbitals (π4 and π5 orbitals), which are degenerate with respect to energy. In this case there is a possibility of the following electronic states: a triplet ($^3A'_2$) and two singlet ($^1A'_1$ and $^1E'_3$) states. As a consequence of a second-order Jahn–Teller effect, the state E'_3 is mixed with the low-lying singlet state $^1A_1$, which distorts structure (LII) to give structures (LXXI) and (LXXII) with C_{2v} symmetry. Calculations by the MINDO/3

and MNDO methods have shown that minima on the potential energy surface of the $(CH)_7^-$ ion correspond to the planar structures (LXXI) and (LXXII) having similar energies [the numerals under the numbers of the structures represent the energies relative to structure (LXXI) in kJ mol^{-1} found by the MINDO/3 method; the numerals in brackets have been found by the MNDO method;[222] the numbers opposite the bonds represent their length in nm calculated by the MINDO/3 method]:

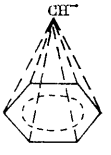


(LII); D_{7h} 30.6 (27.2) (LXXI); C_{2v} 0 (0) (LXXII): C_{2v} 0.04 (0.17) .

These results can be regarded as preliminary in view of the known tendency of the MINDO/3 and MNDO methods to "flatten" cyclic hydrocarbon structures.[223]

The energy of the triplet state of the structure with D_{7h} symmetry is higher by 9.8 kJ mol^{-1} than that of the singlet state of structure (LXXI) with C_{2v} symmetry (the MINDO/3 method).[222]

Isomerisation involving bond shifts may be expected for CHA, i.e. (LXXI) → (LXXII), which is analogous to that examined above for the cyclopentadienyl cation. The isomerisation to the pyramidal structure (LXXIII)



(LXXIII): C_{6v}

does not occur in this case because the electron count rules[39] do not hold for structure (LXXIII) and such a system must be unstable.

5. 4π-Electron Three-membered Heterocycles

Oxiren (LXXIV), 1H azirine (LXXV), and thi-iren (LXXVI) are known as extremely unstable compounds, which can be isolated only using the matrix isolation technique (see the review of Tores et al.[224]).

(LXXIV) (LXXV) (LXXVI)

Oxiren and its substituted derivatives have been proposed as intermediates in many reactions, in particular in the Wolff rearrangement of α-diazoketones. However, the experimental attempt to identify oxiren as an intermediate in this reaction were unsuccessful.[225] Indeed quantum-chemical calculations, including non-empirical calculations with allowance for electron correlation, have shown that a very shallow minimum on the potential energy surface of the C_2H_2O system corresponds to oxiren. Furthermore, oxiren has a much higher energy than isomers such as, for example, keten and hydroxyacetylene.[193, 226–233] The kientic stability of oxiren is extremely low. Thus the activation barrier to the isomerisation to formylmethylene has been estimated as only 3.3 kJ mol^{-1} (*ab initio* calculation, DZ + P basis, allowance for electron correlation),[230] while that for isomerisation to keten is about 32 kJ mol^{-1}.[231] Such instability of oxiren can be accounted for by the fact that in the series of systems (LXXIV)–(LXXVI) the mechanism of the reverse $p \rightarrow \pi^*$ donation, which stabilises the three-membered ring, is least evident for oxiren by virtue of the greater electronegativity of oxygen.[39]

III. NON-ALTERNANT[*n*]ANNULENO[*n*]ANNULENES CONTAINING INTERNAL OR PERIMETRIC 4*m*π-ELECTRON RINGS

The question of the aromatic or antiaromatic character of compounds of this series, namely propalene (LXXVII), pentalene (LXXVIII), and heptalene (LXXIX), has aroused a prolonged controversy.

(LXXVII) (LXXVIII) (LXXIX)

The Hückel rule has been derived in the study of monocylic systems and its direct application to annulenoannulenes is incorrect (see also Section IV). Calculations by the HMO method yielded similar delocalisation energies for azulene and heptalene.[41,234] However, the conclusion that heptalene is aromatic, based on this finding, conflicts with experimental data indicating the absence of any manifestations of aromatic character by heptalene.[7]

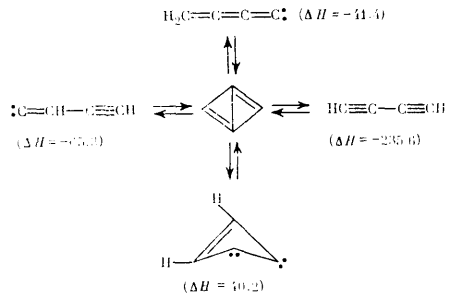
Higher delocalisation energies have also been obtained for pentalene,[7,41] which serve as a basis for the conclusion concerning its stability.[235] At the same time, the unsuccessful attempts to synthesise pentalene (see the relevant reviews[236, 237]) contradict to this conclusion. All these factors stimulated much interest in detailed calculations of the electronic structures of non-alternant [*n*]annuleno-[*n*]annulenes.

1. Propane

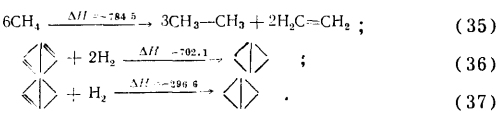
Propalene [bicyclobutadiene (LXXVII)] is stable, according to MINDO/1 calculations, relative to its valence isomer diacetylene, whose photochemical cyclisation is believed to be capable of resulting in the formation of propalene.[238] Calculations by the MINDO/1,[238] MINDO/3,[239] MNDO,[240] and *ab initio* [240] methods indicate a C_2h structure of the ground state, which is more stable than the orthorhombic D_{2h} structure with equalised lengths of the peripheral carbon–carbon bonds in the ring (Table 2). However, according to the results of calculations by the MNDO method,[240] diacetylene has a lower energy than propalene and the activation barrier to the isomerisation of propalene to the carbene (LXXX) has been estimated as only 3.8 kJ mol^{-1}:

(LXXVII); C_{2h} (LXXX) .

Non-empirical calculations in terms of the 4-31G basis altogether failed to demonstrate the existence of a barrier, which, in combination with the data in Table 2, permitted the authors[240] to conclude that propalene is thermodynamically and kinetically unstable in contrast to the optimistic predictions of Baird and Dewar.[238] The relative stability of propalene can be estimated from the calculated heats (the ΔH are indicated in kJ mol^{-1}) of the isomerisation reactions (the MINDO/3 method):[239]



The propalene ring strain energy has been estimated [using the isodesmic reaction (35)] as 784.5 kJ mol^{-1} (the MNDO method).[240] Calculation of the resonance energies by the method of Hess and Schaad indicates the antiaromaticity of propalene,[241] which is greater than that of pentalene (Table 1). At the same time the energy of the antiaromatic destabilisation, determined from the heats of the hydrogenation reactions of propalene [reaction (35)] and 1-bicyclobutene [reaction (36)] has been estimated as only 108.9 kJ mol^{-1}, which is much less than the strain energy (the ΔH for the reactions are indicated in kJ mol^{-1}):



(35)

(36)

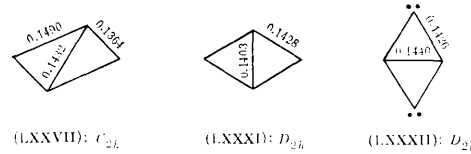
[a] An estimate of the electron correlation energy in terms of the Meller–Plesset perturbation theory taking into account second-order terms.

The minimum on the potential energy surface for the C_4H_2 system does not correspond to the propalene structure with D_{2h} symmetry and the latter is converted via a barrier-free process into a structure with C_{2h} symmetry and alternation of bond lengths.[239,240]

Calculations in terms of the π-electron approximation have led to the conclusion that propalene with the D_{2h} configuration is subject to lattice instability.[242] The employment of the UHF approximation does not result in a qualitative change in the conclusions.[243]

Calculations for propalene by the PPP method revealed a multiplicity of solutions of the Hartree–Fock equations with the initial density matrix varied,[125] which is a characteristic feature of calculations for conjugated systems containing internal or perimetric $4n\pi$-electron rings. Indeed, with the exception of instances of an anomolously distorted geometry,[244] calculation by the PPP method leads to the same solution regardless of the initial density matrix or the initial geometry.[245] For example, for an initial benzene geometry with D_{3h} symmetry, calculation by the PPP method in terms of the Dewar σ,π parametrisation[42] (optimisation of bond lengths) leads to a D_{6h} structure (cf. Fig.2). However, depending on the initial density matrix, three different solutions have been obtained for propalene corresponding to a structure with C_2h symmetry and different bond lengths [structure (LXXVII)], structure (LXXXI) with D_{2h} symmetry [the $(b_{1u})^2(b_{2g})^2$ π-electron configuration], and the D_{2h} structure (LXXXII) of the dicarbene type [the $(b_{1u})^2(b_{3g})^2$ π-electron configuration], i.e. the structural data differ in the order of the frontier MO (Fig.8).



(LXXVII): C_{2h} (LXXXI): D_{2h} (LXXXII): D_{2h}

(The numerals along the bonds represent their lengths in nm.)

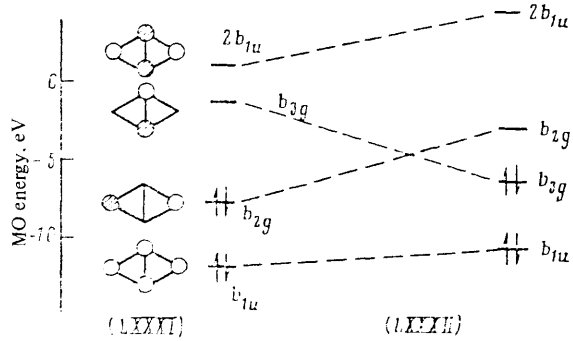


Figure 8. Correlation of the π MO of structures (LXXXI) and (LXXXII) with D_{2h} symmetry (PPP method).[239]

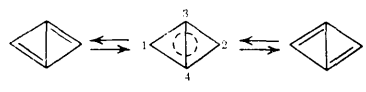
The solution of the Hartree–Fock equations corresponding to structure (XXXII) is unstable with respect to the filling of the MO in order of their increasing energies[107,125,264] (see Section I).

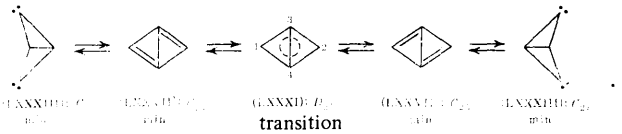
We shall consider the valence isomerisations of propalene. Together with the topomerisation [reaction (38)] of the propalene structure with C_{2h} symmetry, there is a possibility of another non-coplanar mode of isomerisation.



C_{2h} D_{2h} C_{2h} (38)

Indeed, when the length of the transannular bond is altered, the b_{2g} orbital is destabilised, and the b_{3g} orbital is stabilised (Fig.8), there is a possibility of the formation of structure (LXXXII) of the dicarbene type. The instability of the wave function of this structure with respect to the filling of the MO justifies the expectation that propalene can isomerise via the extension of the transannular bond (isomerism involving bond extension[206]). Calculations by the MINDO/3 method confirmed the above hypothesis, as can be seen from the schematic illustration of the valence isomerisation of

propalene (the type of stationary point on the potential energy surface for the C_4H_2 system is indicated under the numbers designating the structures):[239]

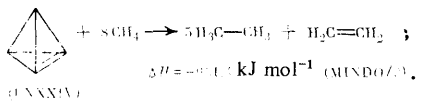


However, the planar structure of the dicarbene type having D_{2h} symmetry, analogous to that obtained in PPP calculations, was converted by a barrier-free process into the non-planar dicarbene structure (LXXXIII) with C_{2v} symmetry.

The relative energies of the valence isomers of C_4H_2, found by semiempirical[239] and non-empirical[240] methods, are presented in Table 2. Evidently, the results obtained in terms of the MINDO/3 approximation are in fact satisfactorily correlated with the results of non-empirical calculations, in which account was taken of the correlation energy by the Meller–Plesset method.

The activation barrier in the isomerisation of propalene (LXXVII) to the non-planar dicarbene C_{2v} structure (LXXXIII) is 72.4 kJ mol^{-1} (MINDO/3) [239] (Fig.9). In contrast to butalene (six π electrons), whose isomerisation on bond extension leads to the formation of *p*-benzyne,[247] the propalene (four π electrons) isomer analogous to 1,3-dehydrocyclobutadiene is not formed. The structure with C_{2v} symmetry, corresponding to the dicarbene structure (LXXXII) found in calculations by the PPP method, is energetically more favourable.

Structures (LXXXIII) can isomerise to dehydrotetrahedrane (LXXXIV), but this compound must be extremely strained:

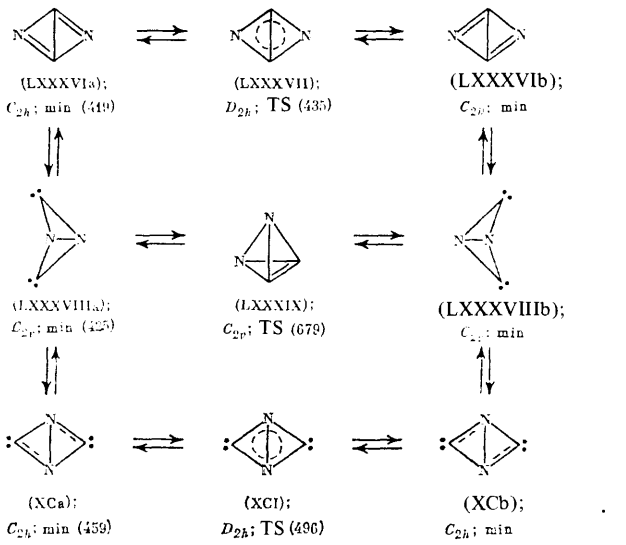


(39)

Analogous data for tetrahedrane (XXI) are presented in the following scheme:

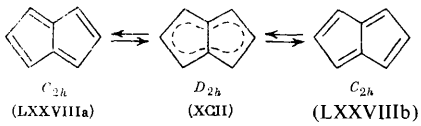
(40)

Diaza-substitution, which stabilises tetrahedrane,[59] does not lead in this instance to the stabilisation of dehydrotetrahedrane, which follows from the results of calculations of the structure of 1,2-diazapropalene and calculations for its valence isomers. Together with the type of symmetry of the structures, the scheme below indicates the character of the stationary point (TS denotes the transition state) on the potential energy surface of the C_2N_2 system, the heats of formation calculated by the MINDO/3 method (in kJ mol^{-1}) being indicated in brackets [we may note that structure (LXXXIX) corresponds, as in the case of dehydrotetrahedrane (LXXXIV), to a transition state; however, the latter is not that of the isomerisation reaction (LXXXVIIIa) ⇌ (LXXXVIIIb) but of another reaction[239]].



2. Pentalene

Unsubstituted pentalene has not so far been obtained, but many of its substituted derivatives are known (see the relevant reviews[236,237]). In particular, 2-methylpentalene, which is extremely unstable and shows a very great tendency towards dimerisation, has been obtained at −195 °C under the conditions of matrix isolation.[248] Comparison of the electronic spectra of methylpentalene,[248,249] 1,3-dimethylpentalene,[250] as well as the electronic and photoelectron spectra of 1,3,5-tri-t-butylpentalene[251–255] with the results of quantum-chemical calculations[252–255] supports the formation of a structure of type (LXXVIII) with unequal bond lengths. X-Ray diffraction study of 1,3,5-tri-t-butylpentalene led to the same conclusion.[256] The pentalene structure (XCII) with D_{2h} symmetry is subject to lattice instability[129] and has a higher energy than the C_{2h} structure by 25.9 kJ mol^{-1} (NDDO method[252]), by 14.6 kJ mol^{-1} (PPP method[255]), by 46.0 kJ mol^{-1} (CNDO/2 method[86]), but 56.1 kJ mol^{-1} (MINDO/3 method[255]), but 46.4 kJ mol^{-1} (MNDO method[240]), and by 56.9 kJ mol^{-1} (non-empirical calculation, 4-31G//STO-3G basis[254]) and is the transition state in the topomerisation of the latter:



(41)

The experimental barrier to the topomerisation of 1,3,5-tri-t-butylpentalene is 21 kJ mol^{-1} (dynamic NMR [254]). 2,5-Diaza-substitution decreases the barrier to 14.6 kJ mol^{-1} (MINDO/3 method[255]). We may not that the activation energy for the topomerisation of the heptalene structure with C_{2h} symmetry is 108.3 kJ mol^{-1} (MNDO method[240]), which is twice as high as the corresponding value for pentalene.

In the calculations for pentalene by the PPP method, solutions corresponding to structures with C_{2h} and D_{2h} symmetry as well as one with D_{2h} symmetry but with a very long transannular bond (HOMO) having a_u symmetry have been obtained depending on the initial density matrix.[125] The inversion of the frontier π MO is characteristic of solutions corresponding to structures with D_{2h} symmetry. According

to the results of non-empirical calculations in terms of the 4-31G basis (the UHF approximation),[254] the energy of the T_1 state of the pentalene structure with D_{2h} symmetry is lower by 7.1 kJ mol^{-1} than the energy of the electronic singlet state. Here one must bear in mind that an unduly low energy of states with higher multiplicity is usually obtained in terms of the UHF approximation.

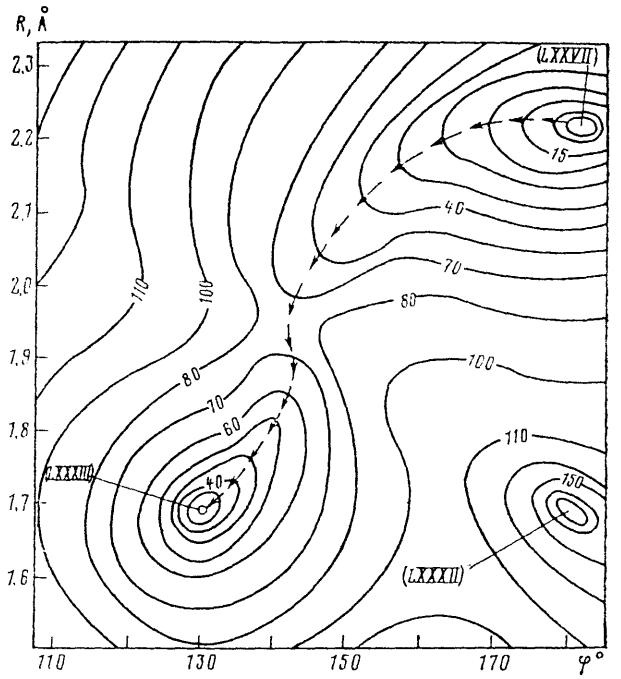


Figure 9. Potential energy surface for the isomerisation reaction of propalene with C_{2h} symmetry [(LXXVII) → (LXXXIII)]; the pathway corresponding to the minimum energy of the reaction is indicated by arrows. The numbers in the gaps in the lines represent the energies (in kJ mol^{-1}) relative to that of the propalene C_{2h} structure; ϕ is the dihedral angle between the C(1)C(2)C(4) and C(1)C(2)C(3) planes [for the significance of the numbering, see reaction (38)]; R is the distance between the C(1) and C(2) atoms.[239]

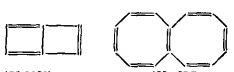
IV. ALTERNANT [n]ANNULENO-[n]ANNULENES CONTAINING INTERNAL OR PERIMETRIC $4k\pi$-ELECTRON RINGS

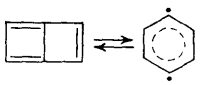
Naphthalene can be regarded as a bridged (transannular bond) analogue of [10]annulene [a$(4n + 2)\pi$-electron system]. We shall consider the cause of the lability of butalene (XCIII) and octalene (XCIV), whose analogues are also $(4n + 2)\pi$-electron systems, namely benzene and [14]-annulene, but they contain internal $4k\pi$-electron rings.



(XCIII) (XCIV)

The study of these cyclic compounds is of interest because it makes it possible to discover the rules governing the influence of the internal rings on the properties of the system as a whole.

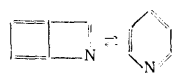
Despite the presence of six π electrons, butalene is nevertheless extremely unstable and its formation only as an intermediate is postulated.[257,258] Calculation of the resonance energy indicates the antiaromaticity of butalene, which contains two cyclobutadiene fragments (Table 1), although its extent is smaller than for cyclobutadiene. Consequently, in this instance the influence of the individual rings prevails over the cyclic conjugation effect along the periphery of the system (six π electrons). At the same time, the contribution of the six-membered $(4n + 2)\pi$-electron butalene ring to the overall exaltation of the diamagnetic susceptibility determines the diatronic character of the antiaromatic system under consideration.[66] Calculations by the MINDO/3 method have shown that the butalene structure corresponds to a minimum on the potential energy surface for the C_6H_4 system.[247] The isomerisation of butalene to p-benzyne (XCV) (isomerism involving bond extension) is allowed by the orbital symmetry conservation rules:[259]



(XCIII) (XCV) (42)

The activation barrier in the given reaction has been estimated as 19.2 kJ mol^{-1}.[247] The difference between the energies of butalene and p-benzyne is 150.2 kJ mol^{-1} according to the results of calculation by the MINDO/3 method. It also follows from the results of non-empirical calculations in terms of the 4-31G basis that butalene corresponds to a minimum on the potential energy surface, but the above energy difference between structures (XCIII) and (XCV) amounted to 323 kJ mol^{-1}.[260]

Monoaza-substitution of butalene does not result in a significant stabilisation of the molecule. The energy difference between 2-azabicyclo[2.2.0]hexa-1,3,5-triene (XCVI) and 2,5-bisdehydropyridine (XCVII) has been estimated as 172 kJ mol^{-1} (by the MNDO method).[261] The activation barrier in the extremely exothermic isomerisation reaction (43) (ΔH = −172 kJ mol^{-1}) is 15.9 kJ mol^{-1}.



(XCVI) (XCVII) (43)

Detailed calculations for octalene (XCIV), which has a nonplanar structure,[262] have not been made.

---o0o---

The advances achieved in the theory of the chemical structure of antiaromatic systems have promoted further progress in the experimental and theoretical methods for the investigation of molecules. As a result, antiaromatic compounds which had not existed earlier, such as, for example, cyclobutadiene, have become entirely real objects for experimental study.

Bearing in mind the position occupied by the theory of aromaticity–antiaromaticity in the conceptual system of organic chemistry and the multiplicity of ways in which the essential feature of this concept is reflected in various theoretical ideas, it is to be expected that further study of antiaromatic molecules will deepen our understanding of the structure of conjugated organic molecules and will help in the solution of the key problem of the relation between the structures and properties of compounds.

During the preparation of the review for the press, two studies which in our view are of significant interest were published. On the basis of a model calculation of the tunnelling rate constant, Carpenter[263] showed that the contribution of the tunnel mechanism to the automerisation of cyclobutadiene ($D_{2h} \rightleftharpoons D_{4h} \rightleftharpoons D_{2h}$) at temperatures below 0 °C may be more than 97%, determining the low activation entropy, in agreement with experimental data.

Jug[264] proposed a method for the estimation of aromaticity based on the calculation of the total ($\pi + \sigma$) bond order as a weighted sum of the eigenvalues of the two-centre components of the density matrix and demonstrated its relation with π-electron ring currents, which constitute a magnetic criterion. This approach makes it possible, in principle, to consider any compounds, avoiding the limitations of the schemes considered above (DRE, HSRE, TRE). At the same time, the necessity for the preliminary calculation of the optimised molecular geometry undoubtedly significantly complicates the application of this criterion of aromaticity–antiaromaticity.

New Chemical Agents for Protection against Ionising Radiation

V.G.Yashunskii and V.Yu.Kovtun

Data obtained in the search for radioprotectants among organic monomeric compounds during the period from 1974 to 1983 are surveyed.
The bibliography includes 332 references.

I. INTRODUCTION

Despite the extremely modest advances achieved as a result of many years of studies undertaken to find new chemical means for protection against ionising radiation, the interest in this problem has not weakened. Interesting monographs[1,2] and reviews,[3-7] devoted to the search for, synthesis, and applications of chemical radioprotectants, have been published in recent years but they cover data obtained over a long period or deal with only individual aspects of this question. Since the need for the search for chemical prophylactic radioprotective agents has increased every year, it is of interest to follow the development and characteristics of the research in this field during recent years.

A review published in 1975[8] summarised the results of the search for chemical radioprotectants during the period between 1968 and 1973. This review surveys and gives a systematic account of the literature data obtained in the search for prophylactic antiradiation agents among new organic monomeric compounds published during the last ten years (from 1974 to 1983 inclusive).

So far as possible, the entire data have been arranged systematically in a manner analogous to that employed in an earlier review.[8]

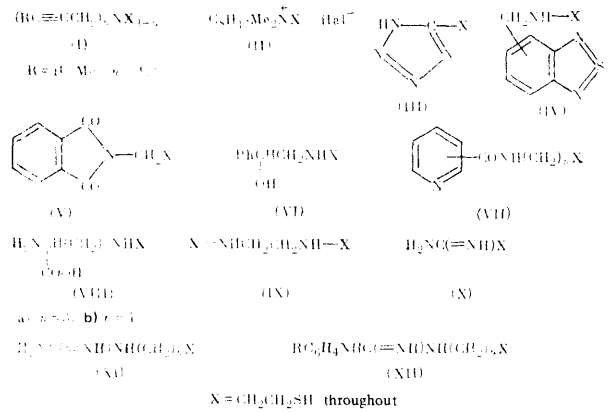
II. SULPHUR-CONTAINING COMPOUNDS—DERIVATIVES OF β-MERCAPTOETHYLAMINE

Recently, new structural analogues and various derivatives of one of the oldest and most widely known radioprotectant—β-mercaptoethylamine (MEA) have appeared. The simple fragment $\rangle N-\overset{|}{C}-\overset{|}{C}-S-$ constitutes the basis of the *N*- and *S*-substituted derivatives synthesised: thiols, disulphides, thiosulphates, phosphorothioates, isothiuronium salts, thiazolidines, etc. The available data will be considered in this sequence.

1. Aminoalkanethiols

The syntheses of a series of MEA derivatives with an unsubstituted thiol group containing various substituents at the nitrogen atom have been described. It has been observed that, among compounds with unsaturated hydrocarbon groups, the alkyl derivatives, for example compound (I), have proved to be the most active and least toxic.[9] It has been shown that the radioprotective effect (RPE) is reduced on quaternisation of the amino-group as in compound (II)[10] and after the introduction of heterocyclic residues—the tetrazolyl [compound (III)[11]], benzo-2,1,3-thiadiazolylmethyl [compound (IV)[12]], phthalimide [compound (V)[13,14]], and 2-hydroxy-2-phenylethyl [compound (VI)[15]] residues.

N-Pyridinoyl derivatives (VII) have been proposed as radioprotectants.[15]



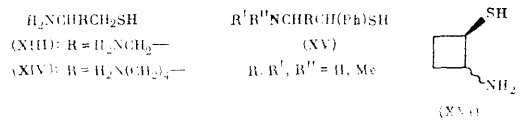
X = CH_2CH_2SH throughout

The MEA derivatives obtained as a result of multistage synthesis, namely the ornithine derivative (VIIIa) and the lysine derivative (VIIIb), have different protecting effects on irradiated mice:[16] compound (VIIIa) administered intraabdominally (i/a) in a dose of 150–300 mg kg^{-1} ensures a 50–100% survival rate, whilst compound (VIIIb) is inactive. Neither compound is effective when administered perorally (p/o).

Compound (IX),[17] which exhibits an antioxidant activity, has been proposed as a radioprotectant.

The replacement of the amino-group in MEA by the amidine group as in compound (X) leads to an appreciable increase of the radioprotective effect and to a decrease of toxicity.[18] In order to investigate antiradiation properties, a series of mercaptoalkylguanidines have been synthesised—unsubstituted [compound (XI)[13]] and aryl-substituted [compound (XII)[19]]. Among them, compounds (XI, $n = 0$) and (XII, R = H, $n = 1$) proved to be the most active.

MEA analogues with various substituents in the hydrocarbon chain have been described. The introduction of the aminomethyl residue at the carbon atom nearest to the nitrogen atom in MEA [compound (XIII)] entails a sharp decrease of activity, while the aminobutyl analogue (XIV) is highly effective in small doses administered intra-abdominally and perorally, although its toxicity is much higher.[20]



It has been shown in experiments on mice[21] that in the series of *C*-phenyl-substituted MEA derivatives (XV), substitution of the hydrogen atoms at the C and N atoms by methyl groups results in a decrease of the radioprotective activity. The introduction of the mercaptomethyl group at one of the carbon atoms in the MEA molecule does not enhance the protecting effect.[22]

The relation between the RPE and structure has been investigated[23] for a series of cyclic MEA analogues—derivatives of *cis*- and *trans*-2-amino-1-mercaptocyclobutane (XVI) and their analogues. The greatest RPE was exhibited by the *cis*-isomers of compound (XVI) when they were administered intra-abdominally or enterally. Analogous cyclopropyl derivatives have also been studied.[24] A series of MEA derivatives having substituents at the sulphur atoms have been synthesised and it has been shown that the introduction of an unsaturated substituent, as in compound (XVII), results in the disappearance of the protecting effect.[9] Compounds having an amidinoethyl substituent, as in compound (XVIII), exhibit a moderate RPE.[25] It is of interest that the introduction of an acetyl substituent into compound (II) to give compound (XIX) decreases the toxicity but the radioprotective properties are preserved.[10]

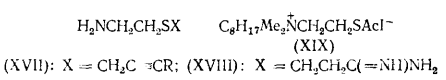


Table 1. Comparative effectiveness of MEA and compound (XIV).[24]

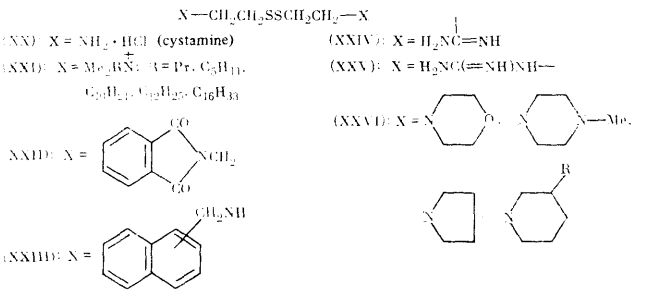
$H_2NCHRCH_2SH$		LD_{50}, mg kg^{-1}	ED, mg kg^{-1}	% protection	*I*
MEA.HCl	i/p	250	150	87	3.1
(R = H)	p/o	615	300	73	3.6
(XIV).2HCl	i/p	88	25	90	6.5
[R = $H_2N(CH_2)_4$]	p/o	450	75	70	10

Notation. LD_{50} is the dose of the test substance which results in the death of 50% of animals and ED is the effective dose. *I* = protectant index.

The number of closest MEA analogues (mercaptoalkylamines) investigated in recent years is small—approximately 50 (during the previous period 1968–1970, about 130 of these were described); among these compounds, one merits attention, namely 2,6-diaminohexane-1-thiol (XIV). Its advantage over MEA is clearly seen from the data in Table 1.

2. Aminoalkyl Disulphides

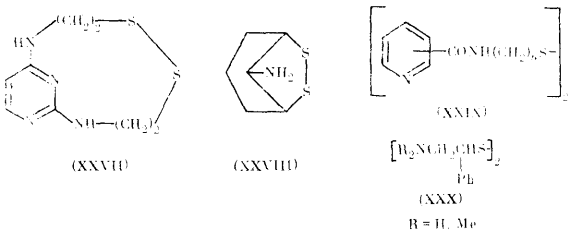
The interest in the search for more effective cystamine (XX) analogues has not weakened. It has been confirmed[10] that the replacement of the free amino-groups in the molecule of compound (XX) by quaternary ammonium groups, including those incorporating higher alkyl groups, as in compound (XXI), results in a decrease of the RPE. The same result has been obtained[13] when the amino-groups were substituted by phthalimidomethyl residues (XXII). The 1- and 2-naphthylmethyl derivatives of cystamine (XXIII) proved to be inactive:[12]



The bisamidine analogue (XXIV)[18] and the bisguanidine analogue (XXV)[13] of cystamine are not inferior to the latter as regards activity.

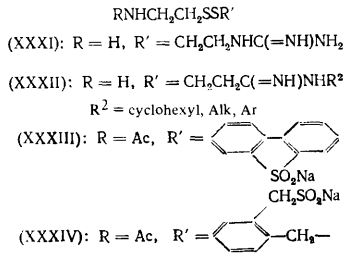
A pronounced radioprotective activity has not been observed in a whole series of bis(aminoethyl) disulphides containing at the nitrogen atoms heterocyclic substituents such as the 2-quinoxalinyl,[27] benzo-2,1,3-thiadiazol-4-ylmethyl and the corresponding 5-methyl,[12] 2-pyridylmethyl,[27] 2-pyrimidinyl,[27,28] and phenyltetrazolyl[27] groups. On the other hand, it has been observed that compounds of the type of (XXVI) with the morpholine and 4-methylpiperazine groups exhibit an RPE which is not inferior to that of unsubstituted cystamine.[27,28]

The macrobicyclic disulphide (XXVII),[29] the bicyclic disulphide (XXVIII),[30] and the disulphides containing pyridinecarboxylic acid residues (XXIX)[15] have been described as radioprotective agents.



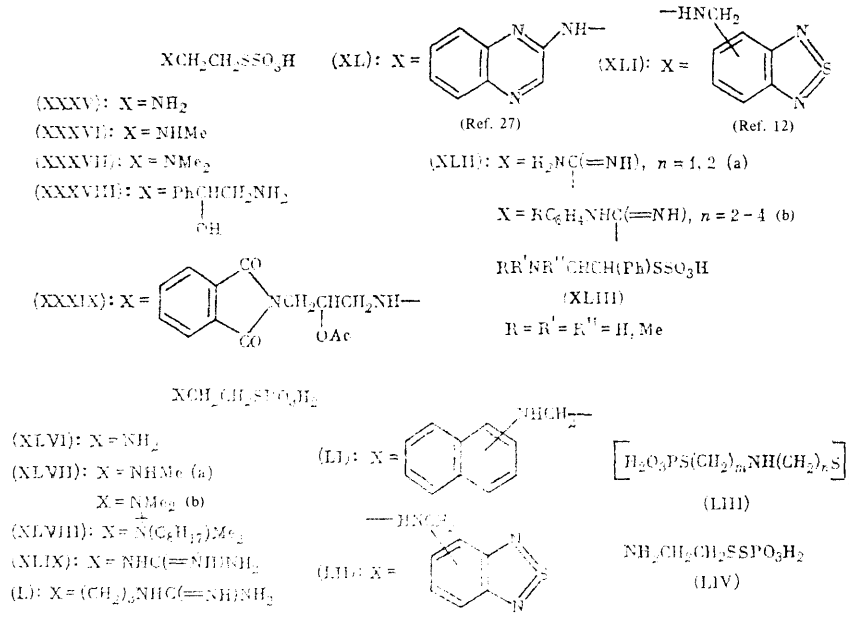
A fairly distinct antiradiation effect has been exhibited by certain *C*-phenyl-substituted cystamines (XXX).[21,31]

Interesting results have been obtained in a study of the asymmetric disulphides (XXXI),[13] (XXXII),[32,33] (XXXIII), and (XXIV),[34] containing the aminoethyl fragment. Thus the last compound is superior in its activity to the disulphide (XX) and all the analogues quoted above; its LD_{50} (for i/a and p/o administration) is greater than 900 mg kg^{-1} and ensures 100% protection of mice against the absolutely lethal radiation dose when administered intra-peritoneally in a dose of 75 mg kg^{-1}; when taken orally the dose is 600 mg kg^{-1}



3. Aminoalkyl Thiosulphates

Much less attention than in previous years has been devoted to derivatives of *S*-aminoethylthiosulphuric acid (XXXV) (Bunte salts). It has been found that methylation of the nitrogen atom, as in compounds (XXXVI) and (XXXVII), results in an appreciable enhancement of the protecting activity:[35,36]



As for other MEA derivatives, the introduction of the naphthylmethyl residue at the nitrogen atom eliminates the protecting effect almost completely.[12] Compounds (XXXVIII) and (XXXIX) also showed a low activity.[14] Like the disulphides, the majority of Bunte salts with heterocyclic substituents at the nitrogen atom proved to be inactive and only compounds (XL) and (XLI) led to 60–70% survival rate of mice and only after administration in near-toxic doses.

The amidine [compound (XLIIa)[18]] and arylguanidine [compounds (XLIIb)[19]] derivatives have been investigated. Compound (XLIIa, $n = 2$) is somewhat superior to compound (XXXV) as regards activity.

C-Phenyl derivatives (XLIII) showed a pronounced protecting effect.[21,31]

It is noteworthy that a much greater number of compounds with a similar structure were investigated in the previous period and among them highly effective radioprotectors were discovered.[8]

4. Aminoalkyl Phosphorothioates

The main trend in studies in this field involves the discovery of radioprotectants most promising for practical use in cancer X-radiotherapy and not the synthesis of new compounds.[37–39] Among a series of other compounds, *S*-[*N*-(3-aminopropyl)-2-aminoethyl]phosphorothioic acid (gammaphos, WR-2721), which is at present undergoing clinical tests in the USA and Japan, has attracted special attention.[40,41]

Several studies have been devoted to the synthesis and investigation of the RPE of derivatives of polyaminopolyalkyl phosphorothioates widely represented in the previous period. It has been shown that the introduction of the hydroxy-group into the hydrocarbon chain (see Table 2) does not as a rule reduce the RPE after intra-peritoneal administration to mice, but these substances do not protect when administered orally.[14,37,39]

Table 2. The radioprotective activity of $RSPO_3H_2$ administered intra-peritoneally to mice.[14]

R	LD_{50}, mg kg^{-1}	ED, mg kg^{-1}	% protection
$H_2N(CH_2)_3NHCH_2CH(OH)CH_2$—	875	200	100
$H_2NCH_2CH(OH)CH_2NH(CH_2)_2$—	825	300	93
$H_2NCH_2CH(OCOMe)CH_2N(CH_2)_2$—	>1250	500	100
$H_2NCH_2CH(OH)CH_2NH(CH_2)_3$—	>700	600	100
$HO(CH_2)_2NH(CH_2)_2NH(CH_2)_2$—	200	100	60
$H_2NC(CH_2OH)_2CH_2$—	>1250	250	100
$H_2N(CH_2)_2NH(CH_2)_2$— (XLIV)	1020	300	100

The introduction of an additional aminoalkyl group increases the toxicity and decreases somewhat the RPE of compounds (XLV) compared with compounds (XLIV); the greatest dose reduction factor (DRF), amounting to 1.8, is

shown by compounds with $l = m = n = 2$ and $l = n = 2$, $m = 3$.[42]

$H_2NCH_2CH_2CH_2NHCH_2CH_2SPO_3H_2$
(XLIV)
$H_2N(CH_2)_l NH\,(CH_2)_m\,NH(CH_2)_nSPO_3H_2$
(XLV)

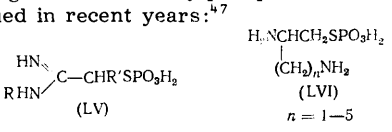
It has been found that the replacement of the hydrogen atoms by the methyl group, as in compound (XLVIIa), at the nitrogen atom of aminoethylphosphorothioic acid (XLVI) does not decrease the RPE; the presence of two methyl groups results in the loss of radioprotective properties by compound (XLVIIb),[35] but the introduction of an additional octyl substituent, as in compound (XLVIII), enhances the RPE with a slight increase of toxicity.[10]

It has been reported[43] that the guanidine derivatives (XLIX) and (L) exhibit a radioprotective activity. As for the aminoalkanethiols and disulphides, the naphthylmethyl derivatives (XLI) proved to be inactive.[12] *N*-Benzo-2,1,3-thiadiazolylmethylaminoethylphosphorothioic acids (XLII) showed the highest RPE.[12]

It was found[44] that the nature of the cation linked to compound (XLVI) has different effects on the toxicity and radioprotective activity; the piperidine and morpholine salts proved to be comparable to sodium salts in terms of their specific activity, while adamantylammonium salts proved to be inactive.

It has been shown recently[45] that derivatives of aminoethylphosphorothioic acid, containing the alkyl disulphide group at the nitrogen atom, as in compound (LIII), exhibit radioprotective activity in doses of 12.5–200 mg kg^{-1}. A new type of phosphorothioic acid derivatives has been discovered and investigated by Sverdlov and co-workers,[46] who showed that the disulphide (LIV) protects up to 55% of mice against radiation over a period of 15–60 min when introduced intra-peritoneally. An approximately the same effect has been obtained also in the case of gamma-neutron irradiation. The substance is inactive when introduced enterally.

Studies designed to search for radioprotectants among amidine analogues of aminoethylphosphorothioic acid (LV) have continued in recent years:[47]



(LV)

(LVI)
$n = 1$—5

R = H, R′ = Alk
R′ = H, R = 1-adamantyl (Ad),
3-Me=Ad, 3, 5, 7-Me_3=Ad

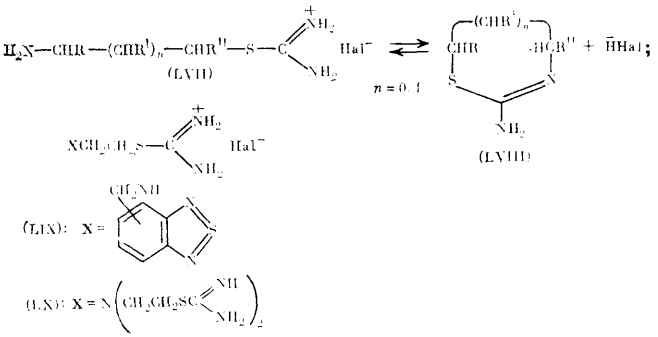
It has been shown that the replacement of the hydrogen atom at the carbon atom by the methyl group, as in compound (LV, R′ = Me), hardly affects the toxicity of the protecting effect when introduced intra-peritoneally but in the enteral administration the toxicity is reduced by a factor of ~1.5, while the effective protective dose increases by approximately the same factor. With increase of the bulk of the group R′, the toxicity of the compounds increased with a simultaneous reduction and even loss of radioprotective activity. Unexpectedly, it was found that the introduction of methyl groups into the adamantyl group results in only a sharp increase of toxicity in the complete absence of a protecting effect (possibly owing to the sharp reduction of solubility in water).

The antiradiation activity of *C*-aminoalkyl derivatives (LVI) has been investigated[20] and it has been shown that they are not inferior in this respect to compound (XLVI) when introduced intra-peritoneally, but, with the exception of compound (LVI, $n = 4$), they are all inactive when introduced enterally. It is of interest that the *L*-isomers of compounds (LVI, $n = 3$ or 4) showed no differences as regards the RPE compared with the corresponding racemates. Table 3 presents data for compounds of this series.

5. Aminoalkylisothiuronium Salts

A number of studies have been devoted to the synthesis and radioprotective properties of derivatives of 2-aminoethylisothiuronium (AET) (LVII, R = R′ = R″ = H, $n = 0$), including cyclic compounds.

The toxicity and radioprotective activity of various *N*- and *C*-substituted AET (LVII, $n = 0$ or 1) and the corresponding cyclic forms, namely 2-aminothiazolines and 2-aminothiazines (LVIII, $n = 0$ or 1), have been investigated.[48–51] It has been shown that the cyclic forms, which are the products of the metabolism of AET derivatives in the organism, are less active as radioprotectants; all new compounds are inferior to AET in their antiradiation activity but they exhibit a broader spectrum of therapeutic activity and the duration of their RPE is longer.



(LVII)

(LVIII)

(LIX)

(LX)

Table 3. The radioprotective activity of compound (LVI) in mice.[20]

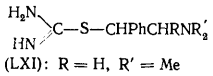
n	Method of administration	LD_{50}, mg kg^{-1}	ED, mg kg^{-1}	% protection	*I*
1	i/p	>900	400	80	>4
2	i/p	>1250	250	100	>10
3	i/p	>1000	250	100	>8
4	i/p	325	62.5	80	9.4
	p/o	750	500	80	2.7
5	i/p	500	200	100	5
	p/o	>1000	400	30	>3
(XLIV)	i/p	1020	300	100	6.8
	p/o	1500	600	100	5

It has been found in relation to *S*-(2-aminopentyl)isothiuronium salts (LVII, R = Pr, R′ = R″ = H, $n = 0$) that[52] both the optical isomers of this compound and the racemic form exhibit a pronounced RPE in experiments on cells but hardly protect irradiated mice. The *N*-benzo-2,1,3-thiadiazolinyl-3-methyl derivative of AET (LIX)[12] as well as the unusual tri-isothiuronium derivative (LX)[53] showed a weak RPE.

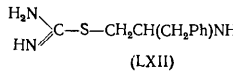
It has been shown[54–56] that the adenosine triphosphate salt of AET (adeturon) exhibits a high radioprotective activity under the conditons of acute irradiation and also in prolonged and fractionated irradiation. In experiments on monkeys 50% protection was achieved after intravenous

administration in a dose of 150 mg kg^{-1} 6–15 min before irradiation.

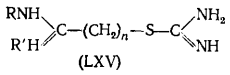
Interesting results have been obtained by modifying the carbon chain of AET with aryl substituents. Compounds (LXI)[21,31] and (LXII)[31] exhibit a high RPE, but the replacement of a hydrogen atom in compound (LXI) by the methyl group, as in compound (LXIII), or the replacement of the dimethylamino-group by the piperidino-group, as in compound (LXIV), fully abolishes the radioprotective properties of the molecule.[21]



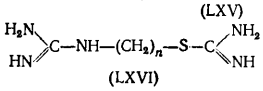
(LXI): R = H, R′ = Me
(LXIII): R = R′ = Me
(LXIV): R = H, R′ = $(CH_2)_5$



(LXII)



(LXV)



(LXVI)

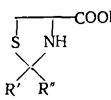
A series of AET derivatives in which the amino-group has been replaced by the amidino-group, as in compound (LXV),[18,57,58] or the guanidino-group, as in compound (LXVI),[19] have been synthesised. The synthesis and the radioprotective activity of compounds in the (LXV) series with different substituents at the nitrogen atom of the amidino-group and also with different lengths of the carbon chain have been studied in detail[57,58] and it has been shown that, when R = R′ = H, compounds with n = 1 or 3 are effective, while those with an even number of methylene groups are completely inactive. Among derivatives (LXV) substituted at both nitrogen atoms, the compound with the 2-methoxyphenyl residues showed the highest activity.[58]

Compounds in which the isothiuronium group is included in a ring will be considered together with other heterocyclic compounds.

6. Thiazolidines

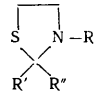
In contrast to other derivatives of mercaptoethylamine, more studies have been devoted to its cyclic analogues, namely thiazolidines, than in the previous period. These compounds have attracted attention because some of them are capable of protecting animals when administered several hours before irradiation,[4,59] showing at the same time a broad spectrum of therapeutic activity.[60]

It has been shown[59,61,62] that, among derivatives of 2,2-dialkylthiazolidine-4-carboxylic acid (LXVII), the methyl esters (LXVII, a and b) are greatly inferior to the corresponding ethyl esters (LXVII, c and d) as regards the RPE. The ester (LXVIId) proved to be an effective radioprotectant; its hydrochloride (LD_{50} = 1750 mg kg^{-1}) ensured 90% protection of mice when administered intra-peritoneally in a dose of 813 mg kg^{-1} 15–30 min before irradiation:[59,61]



(LXVII)

a) R = R″ = Me, R′ = Et; b) R = R′ = R″ = Me; c) R = R′ = Et, R″ = Me; d) R = Et, R′ = R″ = Me; e) R = R″ = Me, R′ = CH_2COOEt; f) R = Et, R′ = COOEt, R″ = Me; g) R = H, R′R″ = $(CH_2)_n$ (n = 5–7); h) R = Et, R′ = H, R″ = CHPhCOOEt



(LXVIII)

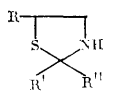
R = H, COOEt; R′ = Me, Pr, Ph
R″ = CH_2COOEt, $CH(CH_2Ph)COOEt$

The introduction of the ethylcarbonylmethyl [compound (LXVIIe)], ethoxycarbonyl [compound (LXVIIf)], or ethoxycarbonylphenylmethyl [compound (LXVIIh)] residues in the 2-position in place of the alkyl group full abolishes activity.[53,61] The absence of protection has been observed[63] also for the products of the condensation of cysteine with cyclic ketones (LXVIIg).

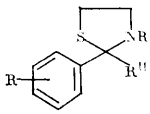
Comparison of the toxicities and radioprotective activities of the alkyl esters of 2,2-dimethylthiazolidine-4-carboxylic acid (LXVIII, R = alkyl, R′ = R″ = Me) and the corresponding cysteine esters showed[62] that the latter are less toxic and their radioprotective activity is higher. The esters of lower alcohols (ethyl and propyl) proved to be less toxic in both series.

A series of compounds containing the ethoxycarbonylmethyl group in the 2-position in the thiazolidine ring [compounds (LXVIII)] have been synthesised and investigated.[64] Among them, compound (LXVIII, R = H, R′ = Pr, R″ = CH_2COOEt) proved to be the most active. After the introduction of the ethoxycarbonyl group at the nitrogen atom, which increases the stability of the heterocycle, a fairly pronounced effect is maintained in the methyl derivative (LXVIII, R = COOEt, R′ = Me, R″ = CH_2COOEt).

Interesting results have been obtained in the study of thiazolidines without carboxy-groups. The high effectiveness of 2,2,5-trimethylthiazolidine (LXIX), whose hydrochloride protects 90% of mice irradiated with an absolutely lethal dose after intra-peritoneal administration in a dose of 500 mg kg^{-1} (LD_{50} = 1150 mg kg^{-1}) during periods from 2 to 60 min before irradiation.[59]



(LXIX): R = R′ = R″ = Me;
(LXX): R = H, R′ = Me, R″ = Et;
(LXXI): R = H, R′ = H, Me, R″ = Alk, alkenyl, alkynyl



(LXXII)
R = H, Hal, OH, Me, MeO;
R′, R″ = H, Me

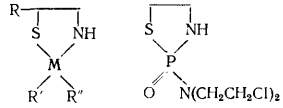
(LXXIII)
R = H, Alk, Ar

Its isomer (LXX) has a somewhat lower activity and is more toxic (LD_{50} = 845 mg kg^{-1} for the hydrochloride).[59] It has been found that the RPE increases with increase of the degree of unsaturation of the substituent R″, as in compound (LXXI).[9]

Among 2-arylthiazolidines (LXXII) (more than 30 compounds), substances have been found, namely compounds [LXXII, R′ = R″ = H, R = 3-F, 3,4-$(OMe)_2$ or R = 4-OMe, R′ = Me, R″ = H], which exhibit a pronounced antiradiation activity,[60,65,66] The authors were unable to establish a relation between the rate of hydrolysis of these compounds, leading to the liberation of free MEA, and the radioprotective activity.[65,67] 2-(4- and 5-Benzo-2,1,3-thiadiazolinyl) derivatives exhibited a low level of protection.[12] A series of monosaccharide derivatives of thiazolidine have been described.[68]

Six-membered homologues of thiazolidines, namely perhydro-1,3-thiazines (LXXIII), containing alkyl and aryl substituents in the 2-position,[69] are of undoubted interest: among the 16 compounds of this series which have been synthesised, several highly effective radioprotectants (LXXIII, R = H, Ph, 4-FC_6H_4, 3-BrC_6H_4, or 2-MeC_6H_4) have been discovered. It has been observed that the RPE of the bases and the hydrochlorides are very different; thus, for R = Me, Pr, or 2-MeC_6H_4, the free bases show a much higher activity than the hydrochlorides, but, when R = 4-FC_6H_4 or 3-BrC_6H_4, the hydrochlorides are more effective.[69]

The RPE of several thiazolidines in which the carbon atom in the 2-position has been substituted by heteroatoms have been studied. In experiments on cell cultures[67] and on mice[70] it has been shown that germanium derivatives (LXXIV)[67,70] have higher RPE than all the thiazolidine derivatives investigated previously but are more toxic. Silathiazolidines exhibit a high RPE.[70]



(LXXIV)
R = H, Me; R′ = R″ = Alk
M = Ge, Si

(LXXV)

It has been shown that the anticancer preparation cyclophosphamide (LXXV) is inactive when introduced intraperitoneally 1–24 h before irradiation, but, when it is administered 2–4 days ahead, it protects 50% of the lethally irradiated animals.[71]

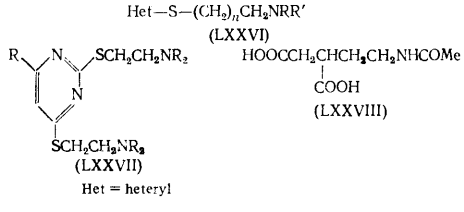
An unusual outcome of the search for radioprotectants in the thiazolidine series carried out in the previous period has been the establishment of correlations between the radioprotective activity and the calculated electron density at the sulphur and nitrogen atoms[72] and also structural factors (calculation by the Free–Wilson method).[73]

Thus, several substances with a high radioprotective activity have been found among fairly large numbers of thiazolidine derivatives synthesised and investigated.

7. Other Derivatives of Mercaptoalkylamines

This Section deals with compounds synthesised and investigated as potential radioprotectants whose structure is more remote from that of MEA and which were not included in the previous Sections. These are derivatives of mercaptoalkylamines with non-functional substituents at the sulphur atom and also with a modified hydrocarbon chain, including those where the chain is incorporated in a cyclic system or contains a carbonyl group.

Among the large group of *S*-heteryl-substituted mercaptoalkylamines (LXXVI),[74–79] the highest activity (up to 70–90% survival rate) was shown by compounds with hydroxypyrimidine[74] and quinazoline[74,78] rings as well as di-substituted pyrimidines (LXXVII).[74] The succinic acid derivatives (LXXVIII)[80] have a similar activity.

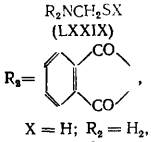


Het—S—$(CH_2)_nCH_2NRR'$
(LXXVI)

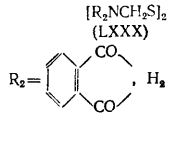
(LXXVII)
Het = heteryl

(LXXVIII)

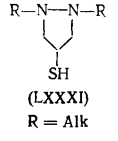
Derivatives of mercaptomethylamine (LXXIX) and (LXXX)[81] are of interest, but the results of biological studies are not presented in the relevant communication.



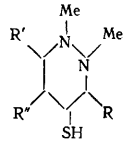
R_2NCH_2SX
(LXXIX)
X = H; R_2 = H_2,
X = SO_3H



$[R_2NCH_2S]_2$
(LXXX)



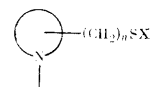
(LXXXI)
R = Alk



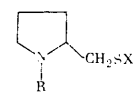
(LXXXII)

Another unusual group of mercaptoalkylamine derivatives are compounds in which the nitrogen atom is incorporated in a heterocyclic ring. Among compounds of the type of (LXXXI) and (LXXXII),[82,83] none have been found with radioprotective activity.

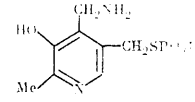
At the same time highly effective radioprotectants have been discovered among nitrogen-containing heterocycles in which the *S*-functional group is in the side chain, as in compound (LXXXIII):



(LXXXIII)



(LXXXIV)
X = SO_3H, PO_3H_2, C(=NH)NH_2
a) R = H, X = PO_3H_2;
b) R = Me, X = PO_3H_2



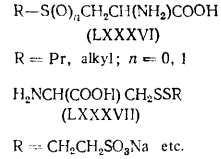
(LXXXV)

The heterocyclic system in these compounds is represented by the pyrrolidine [compound (LXXXIII)[35,36]], imidazole,[84] tetrazole,[11] pyridine,[85,86] pyrimidine,[87,88] and benzimidazole[87] rings.

Perhaps the most interesting result has been obtained in the study of the phosphorothioic derivatives (LXXXIV). It was shown[35] that compound (LXXXIVa) has a high RPE, while the replacement of the hydrogen atom by the methyl group, as in compound (LXXXIVb), entails the loss of activity.

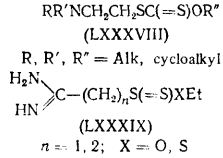
Comparison of the rates of hydrolysis of the phosphorothioate to the thiol and of the RPE for different time intervals between the administration of compound (LXXXIVa) and irradiation of mice led to the conclusion that there is no relation between these quantities. Pyridoxamine phosphorothioate (LXXXV) also gives rise to a high RPE.[86]

Derivatives of cysteine, namely esters,[62] sulphides and sulphoxides (LXXXVI),[89] and di- and poly-sulphides (LXXXVII)[90] have been synthesised as potential radioprotectors.



R—$S(O)_nCH_2CH(NH_2)COOH$
(LXXXVI)
R = Pr, alkyl; n = 0, 1

$H_2NCH(COOH)CH_2SSR$
(LXXXVII)
R = $CH_2CH_2SO_3Na$ etc.

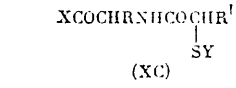


$RR'NCH_2CH_2SC(=S)OR''$
(LXXXVIII)
R, R′, R″ = Alk, cycloalkyl

(LXXXIX)
n = 1, 2; X = O, S

Among xanthates of the type of (LXXXVIII),[91] substances have been discovered which are superior to AET in terms of their RPE; it has been noted that some of them increase the survival rate of mice under the conditions of gamma-neutron irradiation; the amidino-derivatives (LXXXIX) are less active.

The summarising communication by Japanese investigators[92] quotes data concerning a large number of mercaptoalkanoylaminoacids (XC) investigated, which are analogues of mercaptopropionylglycine (XCa) (thiol, meprin, MPG) studied previously. Among them, only the amide (XCb) showed a pronounced radioprotective activity close to that of compound (XCa). Derivatives of MPG, namely compounds (XC, c and d),[93,94] the disulphide (XCe),[95,96] the thiosulphate (XCf),[97] and the phosphorothioate (XCg)[97,98] have been described as radioprotectants.



(XC)

a) X = OH, Y = R = H, R' = Me;
b) X = H_2N, Y = R = H, R' = Me;

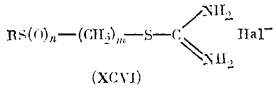
III. OTHER SULPHUR-CONTAINING COMPOUNDS

Apart from the compounds in which the aminoalkanethiol structure is repeated, sulphur-containing substances of different structure with or without nitrogen atoms in their composition have been synthesised and investigated in recent years as potential antiradiation agents.

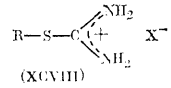
The synthesis of radioprotectants having the isothiuronium structure is traditional. Thus Japanese investigators achieved the synthesis of a series of isothiuronium derivatives (XCVI),[102] one of which has been obtained independently by Soviet workers.[103] A series of di-isothiuronium compounds (XCVII) have also been obtained independently by Japanese and Soviet investigators.[53,104,105] A satisfactory correlation between their physical properties and the RPE has been established.[104]

A study has been made of 34 compounds having the isothiuronium structure and containing an organophosphorus anion [compounds (XCVIII) and (XCIX)].[106-111] *S*-Ethylisothiuronium diethyl phosphate and metaphosphate as well as *S*-isopropylisothiuronium metaphosphate showed the highest RPE.[110]



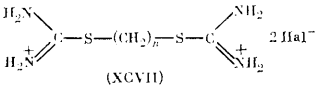
(XCVI)

R = H, Alk; m = 1, 2; n = 0, 2



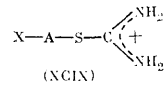
(XCVIII)

R = Alk;
X⁻ = anion of phosphorus-containing acid



(XCVII)

n = 2, 6



(XCIX)

A = alkylene or hydroxy-alkylene;
X = residue of phosphorus-containing acid

Arylisothiuronium derivatives (C) and (CI),[53,87,105] thiosulphuric acid derivatives (C),[87,99] and the disulphides (CII)[90] have been proposed as potential radioprotectants.

Substances with a distinct antiradiation activity have been discovered among derivatives of dithiocarboxylic acids (CIIIa), (CIV),[112,113] (CIIIb),[103] and (CV).[53,105]

Derivatives of 2-*N*-alkoxyiminoalkanethiols (CVI)[114] have been studied as radioprotectants, but they proved to be almost inactive.

RC(=NOR")CHR'SX
(CVI)

(CVII)

1-(3,3-Dimercapto-2-cyanoacryloyl)pyrrolidine (CVII)[27] afforded 80% protection to irradiated mice when administered enterally in a near-toxic dose, but its activity is low when it is administered orally.

Compounds (CVIII) containing the amidine fragment[115-117] exhibit a weak radioprotective activity.

As already stated, the search for prophylactic antiradiation agents has also been conducted among sulphur compounds not containing nitrogen, for example, among the alkyl derivatives (CIX), (CX),[103] and (CXI)[118] as well as aromatic and heterocyclic derivatives (CXII)[81,99] and (CXIII).[119]

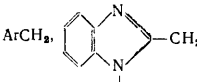
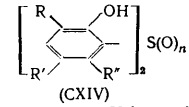
(CXIII)

R = $ArCH_2$,





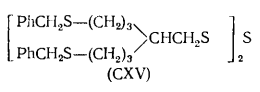
(CXIV)

R, R', R" = H, NO_2, Hal; n = 0—2

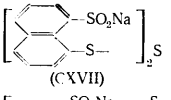
The sulphur-containing bisphenols (CXIV) exhibit a pronounced radioprotective activity[120] (when administered intra-abdominally 1 and 5 h before irradiation), but these data require additional checks, since the substances were introduced in the form of a solution in dimethyl sulphoxide, which is itself known to have a protecting activity.

2,3-Dimercaptopropanesulphonic and dimercaptosuccinic acids or their potassium and sodium salts have been proposed as radioprotectants.[121]

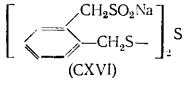
5-Thio-D-glucose has been subjected in recent years to extensive studies as a radioprotectant for normal and tumour tissues.[39,122-124]



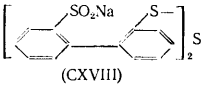
(CXV)



(CXVII)



(CXVI)



(CXVIII)

The continuation of studies initiated previously on the synthesis and radioprotective activity of a series of trisulphides yielded compounds (CXV)–(CXVII) having an aromatic structure;[34,125] compound (CXVIII) with LD_{50} of 430 mg kg^{-1} when administered intra-peritoneally almost fully protects mice in a dose starting from 4.6 mg kg^{-1}, while all the animals in the control group died.

This substance is less effective when administered orally. The introduction of chlorine atoms into the *meta*-positions relative to the sulphur atoms lowers the activity significantly. The phenyl and particularly the naphthyl analogues (CXVI) and (CXVII) are greatly inferior to the biphenyl compound (CXVIII) as regards activity.

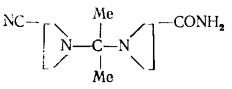
The attempt to find effective radioprotectants among selenium compounds were unsuccessful.[126-130]

Thus, among sulphur compounds which do not belong to the series of mercaptoethyl derivatives, trisulphides containing residues of sulphinic acid, phosphorus-containing isothiuronium derivatives, and 5-thio-D-glucose are of greatest interest as potential radioprotectants.

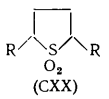
IV. HETEROCYCLIC COMPOUNDS

Compared with previous years, there has been a marked growth of interest recently in heterocycles as potential radioprotectants. The main trends in the search for radioprotectants in this extensive branch of organic chemistry have been described in a review.[3]

2-(2-Cyanoaziridino)-2-(2-carbamoylaziridino)propane (CXIX), which ensures a 50% survival rate of mice when administered intra-peritoneally in a dose of 50 mg kg^{-1} two days before irradiation has been proposed for the prophylaxis and treatment of radiation damage.[131-133]



(CXIX)

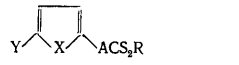


(CXX)

a) R=H; b) R=CH(OH)$CH_2CH_2CONR'_2$, R'=H, Me

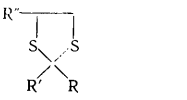
It has been observed[134] that sulpholan (CXXa) and its bisbutyramide derivatives (CXXb) exhibit a pronounced radioprotective activity; they are actually superior to MEA (DCF = 1.6). A relation between the electron-donating properties of substances in this series and their radioprotective activity has been found with the aid of quantum-mechanical calculations.

A series of dithiocarbamate derivatives of furan and thiophen [compounds (CXXI)] have been investigated. Among them, only compound (CXXIa) showed a weak RPE, while the remaining compounds are inactive[135]



(CXXI)

A=SO_2NH, R=Me, X=S, Y=H (a)
A=$C(CN)_2$, SONH; R=Alk, K; X=O, S; Y=H, Cl



(CXXII)

R=Alk, Ph, H; R'=Alk, Ar, Ac; R, R'=alkylene; R''=H, Alk

Continuation of earlier studies on the synthesis and the RPE of dithiolans by French investigators alone yielded 92 new derivatives of this class of heterocycles [compounds (CXXII)],[65] among which 32 afforded more than 50% protection to irradiated mice. It was impossible to establish general structure–activity relations, but certain partial conclusions can apparently be made. Thus the introduction of polar substituents into the 4-position (R'') and of aryl substituents into the 2-position (R) weakens the protecting activity; the presence of cycloalkyl substituents in the 2-position (R') promotes a decrease of activity.[136,137] Among 1,2-dithiolans (CXXIII),[138] effective radioprotectants have not been discovered.

Whereas 1,3-dithiolen (CXXIV)[27] does not exhibit radioprotective activity, there are data for the 1,2-dithio-derivative (CXXV)[139,140] showing that it has been used to protect the central nervous system of human beings against radiation in X-ray therapy.

R=H, Me, SH; R'=H, Me; R, R'=alkylene; R'=H, CH_2Cl

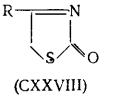
(CXXVII)

R=H, R'=Alk, Ar; R, R''=alkylene; R''=H, Me

Among 19 1,3-oxathiolan derivatives (CXXVI),[66] 5-chloromethyl-1,3-oxathiolan-2-thiol showed the highest activity; the introduction of an aryl substituent in the 2-position results in a loss of protecting activity. In contrast to this, 1,3-oxazolidines (CXXVII)[65,141,142] exhibit an RPE only in the presence of an aryl substituent in the 2-position; the *m*-chlorophenyl derivative showed the highest activity.

Thiazolidine and 2-aminothiozoline derivatives were examined above.

Among 4-hydrazinothiazolin-2-one derivatives (CXXVIII),[143] 5-alkyl-2-aminothiazolin-4-ones[144] and 5-alkyl-2-hydrazinothiazolin-4-ones (CXXIX),[143] compounds affording 30–60% protection to irradiated mice, were found.



(CXXVIII)

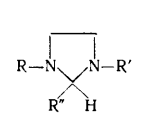
(CXXX)

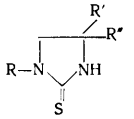
a) R=2,4-$(HO)_2C_6H_3$, Ph; R'=NH_2,
b) R=*m*-ClC_6H_4, R'=NH_2

A fairly high RPE has been discovered for 2-amino-4-arylthiazoles, in particular the phenyl and 2,4-dihydroxyphenyl derivatives (CXXX);[145-147] the replacement of the amino-group by the hydrazino-group entails the loss of activity,[145] while incorporation of the hydrazino-group in the pyrazole ring sometimes almost fully restores the initial level of protection.[148,149] Comparison of the antioxidant properties of the dihydroxyphenyl derivatives (CXXXa) in relation to a model fat and the RPE enabled the authors to conclude that there is no relation between the ability of these compounds to inhibit free-radical processes and their radioprotective activity.[146]

Among 36 imidazolidines, the highest RPE has been found for the 2-(*p*-tolyl) derivative monomethylated at the nitrogen atom [compound (CXXXI)]; alkylation of the second nitrogen atom has an ambiguous effect.[66] Ethylenethiourea has no radioprotective activity, but, after the introduction of methyl groups both into the hydrocarbon chain and at the nitrogen atom, compounds with an appreciable RPE are produced (30–40% protection) [compounds (CXXXII)].[66]

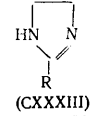


(CXXXI)
R, R′=H, Me; R″=Ar

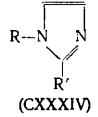


(CXXXII)
R=H, Me; R′, R″=H, Alk, Ar, R′, R″=alkylene

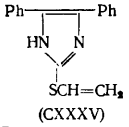
A deeper investigation of the RPE of imidazole and Naphthysin has been continued[113,115] together with the search for new radioprotectants among imidazoline and imidazole derivatives. In contrast to imidazolidine derivatives, 2-phenylimidazoline and its benzyl analogue (CXXXIIIa) proved to be inactive, while 2-imidazolidinethione (CXXXIIIb) protected 70–80% of the irradiated animals.[150] On passing to imidazoles, the 2-phenyl derivative (CXXXIV) again proved to be active.[150] Mono- and di-alkylimidazoles (CXXXIV) had a high RPE in experiments on mice,[150] while 4,5-diarylimidazolyl vinyl sulphides (CXXXV) proved to be relatively ineffective.[151]



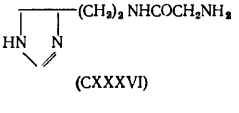
(CXXXIII)
a) R=Ph, $PhCH_2$;
b) R=OH, SH



(CXXXIV)
R=Alk, H; R′=H, Me, Ph



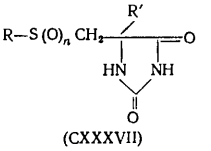
(CXXXV)
R=H, $CH=CH_2$



(CXXXVI)

A high radioprotective activity is observed after the subcutaneous administration of glycylhistamine (CXXXVI) to mice 24 h before irradiation and after intra-peritoneal administration 30 min before irradiation.[152] The substance administered intra-peritoneally becomes inactive after 24 h.

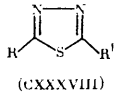
Interesting results have been obtained in the study of thiomethyl derivatives of hydantoins (CXXXVII); thus 5-propyl- and 5-allylthiomethyl-5-methylhydantoins (CXXXVIIa) are four times superior to cystine in terms of the test based on the survival of irradiated mice and by a factor of 2 in terms of the duration of their activity.[89,153] The replacement of the methyl group by hydrogen or the oxidation of sulphide sulphur to sulphoxide sulphur fully abolish the protecting activity of compounds (CXXXVII, b and c).[89,153]



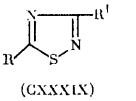
(CXXXVII)
a) R=H, Pr, $CH_2CH=CH$; R′=Me, $n=0$,
b) R=$CH_2CH=CH$; R′=Me; $n=1$,
c) R=$CH_2CH=CH$; R′=H; $n=0$.

Familiar medicinal preparations derived from pyrazolone (antipyrine, amidopyrine, and analgin[154,155]) as well as 1-heterylpyrazolones and 1-heterylpyrazoles,[148,149] possess weak protecting properties.

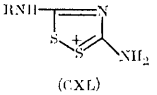
It has been shown[75] that, in the presence of the amino- and mercapto-groups in the molecules of 1,3,4-thiadiazole (CXXXVIII) and 1,2,4-thiadiazole (CXXXIX), the level of protection in mice does not exceed 30%. It has been found[156] that the 5-amino-3-arylamino-1,2,4-dithiazolium salts (CXL) exhibit a moderate protecting activity, the presence of the methoxy-group in the benzene ring tending to increase the activity.



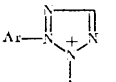
(CXXXVIII)
R = NR''_2; R′ = H, Me, SH, SMe



(CXXXIX)



(CXL)
R = H, Ar



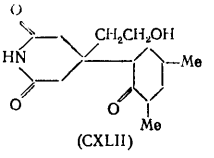
(CXLI)

The protecting effects of 5-mercaptomethyl-1,2,4-triazolin-3-one and 5-mercaptomethyl-1,2,4-triazoline-3-thione as well as the 2,5-diphenyl-1-phenylamino-1,3,4-triazolium salt are weak.[143]

Substances with a pronounced radioprotective activity have not been found among 5-substituted tetrazoles;[11] the water-soluble di- and tri-aryltetrazolium quaternary salts (CXLI), some of which, for example, compound (CXLI, R = Ar = Ph, X = Cl), protect up to 60% of mice irradiated with a lethal dose, are more promising in this respect.[157,158]

Thus highly effective radioprotectants belonging to the series of aryl derivatives of oxazolidines, thiazolidines, imidazolines, and thiomethylhydantoins have been found among five-membered heterocyclic compounds.

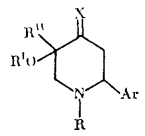
The search for radioprotectants among six-membered aromatic and non-aromatic heterocycles was less successful. Thus 3-hydroxy-2-methyl-4-pyrone (maketol)[159] does not protect irradiated mice.



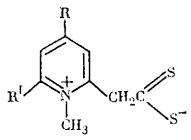
(CXLII)

Cycloheximide (CXLII) is of interest.[160] In experiments on rats it did not show a radioprotective activity when administered intra-abdominally directly before irradiation, but, when introduced in a dose of 2 mg kg^{-1} 6 and 12 h before irradiation, it effectively protected the skin and radiosensitive tissue. This compound is particularly attractive because it protects selectively normal tissues but not tumours.

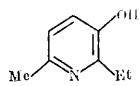
The structures of the piperidines and pyridines which have been investigated as potential radioprotectants but showed a low protecting activity or none at all are presented below:



R = Me, $PhCH_2$;
R^I = H, Ac; R^{II} = H, Me;
X = O, HOH (Ref.161)



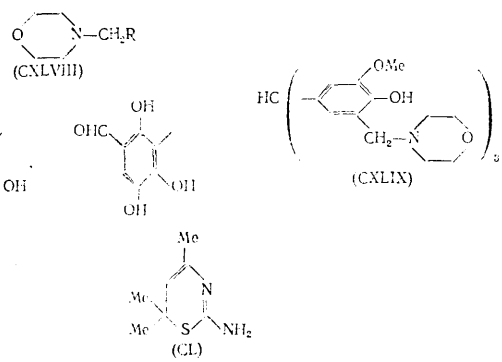
R = H, Me;
R^I = H, CH_2CSSNa (Ref.162)



(Ref.163)

Pyridinecarboxylic acids and their derivatives have been proposed as radioprotectants.[15] Nicotine bitartrate increases the lifespan of both young and old irradiated rats;[164] the possibility of using it in X-ray therapy is being considered.

Among six-membered heterocyclic compounds containing two heteroatoms, the Mannich bases (CXLVIII)[165] and (CXLIX),[166] which contain morpholine in their composition, exhibit a pronounced RPE. Thiomorpholine derivatives have been proposed as radioprotectants.[167,168]



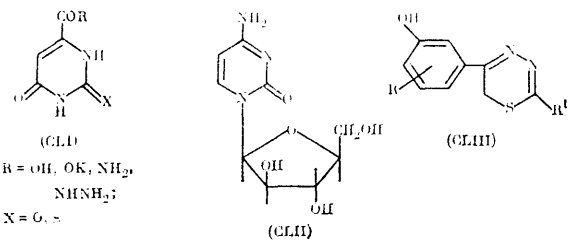
(CXLVIII)

(CXLIX)

(CL)

In the series of six-membered heterocyclic compounds with two heteroatoms, a pronounced antiradiation activity has been discovered only for 2-amino-4,6,6-trimethyl-1,3-thiazine (CL).[169]

A low level of protection against radiation or its total absence have been noted in a series of tetrahydro-derivatives of 2-amino- and 2-mercapto-1,3-oxazines[170] and the corresponding 1,3-thiazine[170,171] and pyrimidine[171] derivatives, the 2-thiones of hexa- and tetra-hydropyrimidines,[53,172] and also certain sulphur-containing derivatives of pyrimidine[135,162,173] and 2-amino-5-bromo-4-hydroxy-6-phenylpyrimidine.[39]



(CLI)

R = OH, OK, NH_2, $NHNH_2$;
X = O, S

(CLII)

(CLIII)

Two groups of investigators observed independently the high RPE of orotic acid and some of its derivatives (CLI).[174,177]

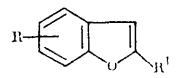
The familiar cytostatic compound cytosine arabinoside (CLII) does not protect mice when administered intra-abdominally 15–60 min before irradiation, but, when it is administered 48–72 h prior to radiation, the survival rate of mice irradiated with a lethal dose is 90%.[178]

A pronounced radioprotective effect has been observed for certain derivatives of 2-methylmercapto-1,3,4-thiadiazine (CLIII).[146] *sym*-Diphenyltetrazine and its 1,2-dihydro-analogue proved to be inactive.[143]

Thus, among six-membered heterocyclic compounds, derivatives of orotic acid and cytosine arabinoside are of greatest interest.

Among heterocyclic compounds investigated as potential radioprotectants, condensed systems and in the first place benzoheterocycles occupy a notable place.

2-Acetyl-6-methoxybenzofuran exhibits the highest RPE (70% survival rate) among the 14 benzofurans (CLIV) synthesised.[179]



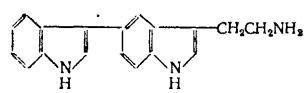
(CLIV)

R = H, OMe; R^I = H, CHO, Ac, CN, COOEt

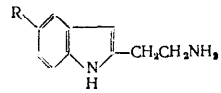
Indole derivatives are important among condensed heterocycles. The search for radioprotective agents in this series of compounds has been conducted mainly in two directions, i.e. via the modification of the tryptamine molecule (in the side chain or in the benzene ring) and via the synthesis of compounds with a non-tryptamine structure.

It has been shown[180] that tryptamine containing the indole substituent in the 5-position, as in compound (CLV), is superior in its radioprotective activity to the initial tryptamine but is inferior to mexamine.

5-Substituted isotryptamines (CLVI) proved to be weakly active.[181]

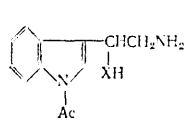


(CLV)

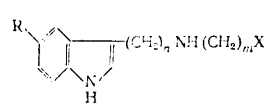


(CLVI)
R=H, Me,Cl, OH

Much attention has been devoted to the synthesis and investigation as possible radioprotectants of sulphur-containing derivatives of tryptamine and serotonin.[182–187] They are considered here and not in the previous Sections, since their indole structure in all probability plays the main role in their radioprotective activity. The synthesis of β-mercaptoethylamine and its *S*-functional derivatives (the sulphide, disulphide, sulphonate, and thiosulphate) with the indole substituent at the carbon atom [compound (CLVII)] did not lead to compounds with an appreciable radioprotective activity with the exception of compound (CLVII, R = H), which exhibits an RPE somewhat superior to that of tryptamine. A series of compounds in which the hydrogen atom in the amino-group of tryptamine or mexamine has been substituted by mercaptoalkyl groups [compounds (CLVIII)] have been synthesised.[183,184]



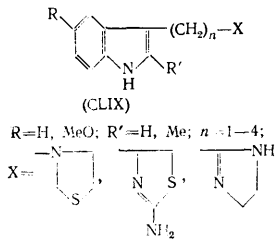
(CLVII)
X = SH, SO_3H, SSO_3H



(CLVIII)
R = H, MeO; n = 1, 4; m = 2, 3;
X = SH, SSO_3H, SPO_2H_2, $NHCH_2CH_2SH$

However, none of them has advantages as a radioprotectant relative to the initial unsubstituted amines. Analogous results have been obtained for 3-heterylalkyl-indoles and their 5-methoxy-derivatives (CLIX).[184,186]

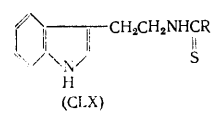
Thioamides containing the tryptamine residue (CLX) exhibt a high RPE.[185]



(CLIX)

R=H, MeO; R′=H, Me; n = 1—4;

X =

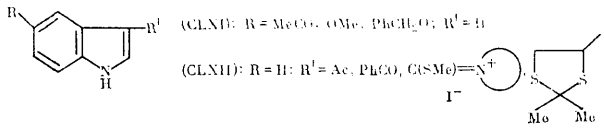


(CLX)

R=Me, Ph, $PhCH_2$

It has been shown[188] that the RPE of a series of 3-indolylalkylamines is correlated with the electron-donating activity calculated by quantum-mechanical methods.

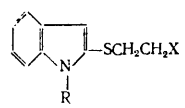
Attention has been given to indole derivatives without the aminoethyl group in the 3-position. Among a large number of 5-alkoxy- and 5-acetyl-substituted compounds (CLXI) as well as 3-carbonyl derivatives of indole (CLXII), substances with a moderate protecting activity have been discovered.[189] The absence of a pronounced radioprotective activity has been demonstrated for a series of 2-amino- and 4-, 5-, and 6-aminoethyl-indoles.[185,190]



(CLXI): R = MeO, OMe, $PhCH_2O$; R′ = H

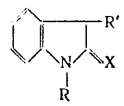
(CLXII): R = H; R′ = Ac, PhCO, C(SMe)=N⁺ I⁻

Indoles containing the mercaptoethyl functional group in the 2-position of the ring, as in compound (CLXIII),[185] exhibit a moderate RPE. Among indolinones, only the thio-derivative (CLXIV) shows a moderate radioprotective activity.[185]



(CLXIII)

X = NH_2, 

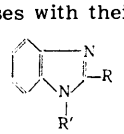


(CLXIV)

R=H, Me; R′=CH_2CN, CH(CN)COOH, $CH_2CH_2NH_2$; X=O, S

The search for radioprotective substances among derivatives of 2-aminobenzothiazole did not lead to compounds with an appreciable radioprotective activity.[147,169,191]

Certain other bicyclic heterocycles have been shown to exhibit an antiradiation activity. It has been stated[150,192] that a series of 2-alkyl- and 2-arylalkylbenzimidazoles (CLXV) exhibit a fairly high protecting activity in mice, which depends on the degree of lipophilicity of the molecule. The ethyl and *p*-chloro-α-hydroxybenzyl substituents [compounds (CLXV, a and b)] proved to be optimal; it is of interest that the toxic *o*-chloro-analogue shows no radioprotective activity.[150] It has been found that the toxicity of the compounds increases with their activity.



(CLXV)

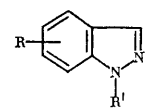
R=Alk, Ar, aryl alkyl;

R′=H

a) R=Et, b) R=

On the other hand, no appreciable protective activity has been observed for a whole series of benzimidazole derivatives with unsaturated and sulphur-containing substituents[151] and also *NN′*-dimethylbenzimidazolines and benzimidazolium salts.[79]

Interesting results have been obtained by a group of French investigators in a study of 23 compounds of the indazole series [compounds (CLXVI)].[193] They discovered that 6-nitroindazole (CLXVIa), administered in a dose corresponding to one half of LD_{50}, protects up to 90% of mice when administered intra-peritoneally 10 min before irradiation, while the 7-nitro- and 1-(*p*-chlorobenzoyl)-5-nitro-derivatives (CLXVI, b and c) ensured 70—80% protection of the animals when administered in a dose corresponding to one quarter of LD_{50}.

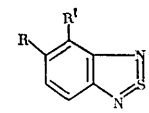


(CLXVI)

a) R = 6-NO_2, R′ = H

b) R = 7-NO_2, R′ = H

c) R = 5-NO_2; R′ = *n*-ClC_6H_4CO



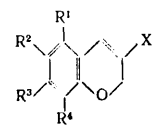
(CLXVII)

R=H; R′ = OH, NH_2, MeNH, Me_2N;

R = R′ = NH_2

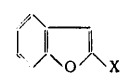
Extensive studies designed to find radioprotectants among benzo-2,1,3-thiadiazoles (CLXVII)—synthetic substitutes for a group of vitamins K [12,194–199]—made it possible to discover compounds with a pronounced antiradiation activity. These are in the first place the 4-hydroxy-, 4-amino-, 4-methylamino-, 4-dimethylamino-, and 4,5-diamino-derivatives.

Among the large group of 2*H*-chromenes (CLXVIII), substances have been found with a high radioprotective activity; the results for some of these are listed in Table 4.[179–200] The study of the comparative RPE of 2*H*-chromenes (CLXVIII) and benzofurans (CLXIX) containing identical substituents showed that the former have a more pronounced protective activity.



(CLXVIII)

X = CHO, Ac, CN, COOEt



(CLXIX)

Table 4. The radioprotective activity of compound (CLXVIII)[179] (intra-peritoneal administration to mice, 900 R γ-irradiation).

R¹	R²	R³	R⁴	X	LD_{50}, mg kg⁻¹	% protection		I
						for MTD*	for 1/4 LD_{50} dose	
H	H	OMe	H	CHO	600	60	50	6
H	H	H	H	MeCO	1000	40	80	7.2
H	H	OMe	H	MeCO	1000	80	60	6.4
H	H	H	OMe	MeCO	1000	100	50	6
OMe	H	H	H	MeCO	1000	30	70	6.8

*MTD = maximum transferable dose.

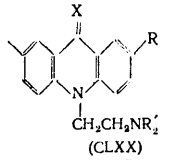
It has been reported[159,201–206] that many flavanoid compounds exhibit a pronounced radioprotective activity, but highly effective radioprotectants have not been discovered among them.

The vinyl derivatives of quinoline and its *N*-oxide,[207] derivatives of *N*-methylquinolinium and isoquinolinium containing the dithioacetic acid residue,[162] and *N*-acylaminoisoquinolinium salts[143] showed a low protecting effect in experiments on mice. Studies designed to find radioprotectants have been carried out among sulphenylamides and sulphides derived from quinoline and its *N*-oxide,[87,172,208-210] quinoxaline,[211] and 1,2-dihydrophthalazine,[212] but data on their activities are not quoted.

Apressin, which is a familiar medicinal preparation consisting of 1-hydrazinophthalazine,[155] protects 26.6% of the irradiated mice, while diazepam (7-chloro-1,3-dihydro-1-methyl-5-phenyl-1*H*-1,4-benzodiazepin-2-one) not only increases somewhat the survival rate of mice but also diminishes the toxicity of MEA.[213]

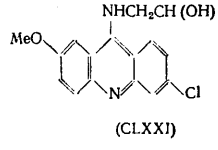
More complex benzoheterocyclic compounds have been subjected to radiobiological investigations to a much lesser extent.

Substances protecting more than 50% of the animals could not be found among *N*-substituted acridones (CLXX).[241] Acranil (CLXXI), an inductor of interferon, inhibits approximately the same effectiveness.[215]



(CLXX)

R=H, Cl, Br; R'=Me, Et; X=O, S



(CLXXI)

Thus certain indazole and chromene derivatives showed the highest radioprotective activity among benzoheterocyclic compounds.

In the series of condensed heterocyclic compounds, much attention has been devoted, as in the preceding period, to derivatives of purine and particularly adenosine. Substances with a moderate RPE have been discovered among sulphur-containing purine derivatives (CLXXII)[76] and (CLXXIII).[216] 2,6-Dimercaptonebularine has been described as a radioprotectant.[217] The absence of radioprotective activity has been noted for purine-8-thione and pyrido[2,3-*d*]imid-2-azolinethione.[135]

It has been found[218,219] that inosine (CLXXIV) exhibits a low protective activity, which is shown more distinctly when administered to small laboratory animals several days before irradiation. An increase in the survival rate of the irradiated mice has been observed after the prophylactic administration of certain 6-substituted adenosines.[220-222] The *p*-hydroxyphenylethyl and the indol-3-ylethyl derivatives (CLXXV) proved to be the most effective. It has been suggested[221] that the RPE of substances of this series is achieved via two pathways—via direct action at the cellular level and indirectly by virtue of the cardiovascular hypoxia induced by them. It has been shown[219,223] that the monophosphates of purine nucleosides exhibit a radioprotective activity and that their combination with ATP and sulphur-containing radioprotectors has a DRF = 2.[223] A review devoted to the mechanisms of the radioprotective activity of adenine compounds constitutes a kind of summary of studies on these lines.[224]

A clinical application of *S*-adenosylmethionine (CLXXVI) in X-ray therapy has been reported.[225]

The alkaloid emetin, which is an inhibitor of protein synthesis, exhibits a pronounced protecting activity when administered intra-peritoneally in a dose of 6.5 mg kg^{-1} 6–12 h before irradiation but not directly before irradiation.[160] The medicinal drug methotrexate also affords no protection when administered directly before irradiation, but provides 80% protection in mice when administered 24–48 h prior to irradiation.[178]

Derivatives of α-carboline proved to be ineffective.[197] The radioprotective properties of nalidixic acid (CLXXVII) have been reported.[226]

Detailed study of various types of synthetic porphyrins and their metal complexes showed[227-231] that among them there are compounds with a moderate RPE. This applies primarily to the *meso*-derivatives of aetioporphyrin-1 (CLXXVIII) and the tetra-alkyl ether-esters of haematoporphyrin (CLXXIX).

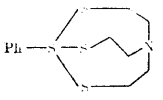
It has been observed[242] that the acetylbenzoyl derivatives of the polycyclic alkaloid aconine is somewhat inferior in its radioprotective activity to MEA and AET. The silicon-containing heterocycle (CLXXX) has been proposed as a radioprotectant.[243]



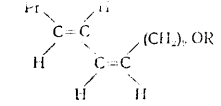
(CLXXX)

It follows from the data presented that substances with a high radioprotective activity have been discovered among heterocyclic compounds of different structure, which shows that further search for radioprotectants among them is promising.

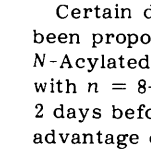
V. COMPOUNDS OF DIVERSE STRUCTURE

In this Section we shall consider aliphatic, aromatic, aliphatic-aromatic, and also certain phosphorus-containing compounds.

Isobombykol and its esters (CLXXXI) exhibit a high radioprotective activity.[244] Tests on a large number of patients showed that the prophylactic administration of *O*-alkylglycerols (CLXXXII)[245] diminishes the number of patients contracting radiation sickness in X-ray therapy.

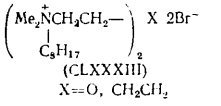


(CLXXXI)



(CLXXXII)

R = C_nH_{2n-1}; n = 7–16



(CLXXXIII)

X = O, CH_2CH_2

R"NHCHR'CHRCN

(CLXXXIV)

R, R', R" = H, Alk

Among other glycerol derivatives, 16 lipids and phospholipids of different structure have been studied, but effective protectors have not been found among them.[236] Nor have satisfactory antiradiation agents been found among different derivatives of amines, hydroxyamines, and diamines;[21] ethylenediamine[21] and quaternary salts of the type of (CLXXXIII),[10] which exhibit a pronounced RPE, are exceptions.

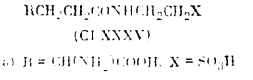
When administered in a dose of 30 mg kg^{-1} to mice, acetyl-β-methylcholine has a DRF = 1.27.[237]

The radioprotecting activity of β-aminonitriles (CLXXXIV) has been reported.[238,239]

Aminoacid derivatives continued to attract the attention of investigators. In particular, it has been shown[240] that potassium and magnesium aspartates administered to mice with food increase their survival rate and stimulate cell proliferation and differentiation in the thymus, spleen, and bone marrow.

Among the series of aminoacid protease inhibitors, only antipain increases somewhat the survival rate of mice.[24]

In recent years careful studies have been made of γ-*L*-glutamyltaurine (litoralon) (CLXXXVa), which was isolated from natural sources and subsequently synthesised and which exhibits a vitamin A-like activity.[246–250] This virtually non-toxic compound ensures a 50% survival rate of animals when introduced intra-peritoneally into mice in a dose of 100 mg kg^{-1} 4 days before irradiation. γ-Aminobutyryltaurine and its phosphorus analogue (CLXXXV, b and c) exhibit an analogous activity.[246–248]

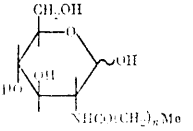


(CLXXXV)

a) R = $CH(NH_2)COOH$, X = SO_3H

b) R = CH_2NH_2, X = SO_3H

c) R = CH_2NH_2, X = $PO(OH)_2$



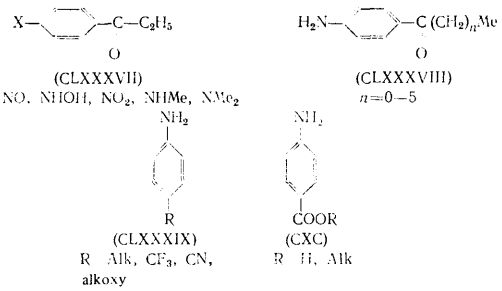
(CLXXXVI)

Certain disacharride derivatives with a low toxicity have been proposed as radioprotectants, but their RPE is low.[251,252] *N*-Acylated D-glucosamines (CLXXXVI), particularly those with *n* = 8–12, administered to mice in a dose of 0.05 mg kg^{-1} 2 days before irradiation, exhibit a high RPE.[253,254] A disadvantage of these substances is that they are virtually insoluble in water.

Thus aminoacid derivatives and, in particular litoralon, proved to be the most interesting among aliphatic compounds.

Since the 1950's, attempts have been made to employ antioxidants to protect the organism against the effects of radiation. During this period, studies have also been made of phenolic antioxidants used in the food industry, in particular of 2,6-di(t-butyl)-4-methylphenol,[255,256] but the degree of protection proved to be low.

Studies have continued on the radioprotective properties of derivatives and analogues of *p*-aminopropiophenone (CLXXXVII).[257] The influence of substituents on the RPE of compounds (CLXXXVII)–(CXC) has been investigated and it has been found that the aniline derivatives (CLXXXVIII, *n* = 3 and 4), (CLXXXIX, R = CF_3 or CN), and (CXC, R = Me or Et) have a somewhat higher activity than the parent *p*-aminopropiophenone.



(CLXXXVII)

(CLXXXVIII)
n=0–5

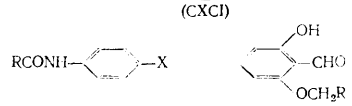
(CLXXXIX)
R = Alk, CF_3, CN, alkoxy

(CXC)
R = H, Alk

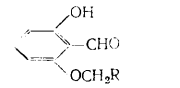
When administered in a dose of 12 mg kg^{-1} 72 h before irradiation, chlorambucil (CXCI) ensures a 65% survival rate of mice.[178]

The anilides (CXCII) investigated proved to be relatively ineffective.[258,259]

(CXCI)



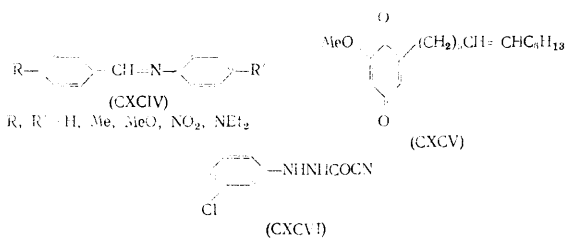
(CXCII)
R = Me, X = OH;
R = 2-OH-3-$NO_2C_6H_3$, X = Cl



(CXCIII)
R = Ar, CH_2CH_2R'
R' = H, Alk, CH_2COOH

The ethers of 2,6-dihydroxybenzaldehyde (CXCIII) have been proposed as radioprotectants.[260]

The radioprotective activity of a series of azomethines (CXCIV) has been investigated.[261] They exhibited only a weak antiradiation activity; a semiempirical calculation by the Hückel LCAO-MO method yielded a satisfactory correlation between the electron-donating properties of the compounds and the RPE.[261] The azomethines based on trihydroxybenzaldehydes proved to be more effective:



(CXCIV)
R, R' = H, Me, MeO, NO_2, NEt_2

(CXCV)

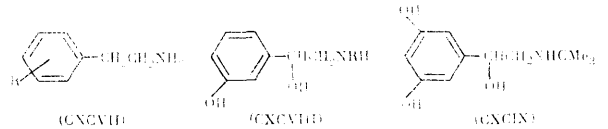
(CXCVI)

Among quinone derivatives, irisquinone (CXCV) has been proposed as a radioprotectant.[263]

The studies on organic derivatives of hydrazines have been continued: the data for the RPE of (3-chlorophenyl)hydrazino-oxoacetonitrile (CXCVI), which is an energy metabolism inhibitor, are contradictory,[264,265] while the medicinal preparation phelazine(2-phenylethylhydrazine) has a low activity.[155]

Considerable attention has been devoted during the period under consideration to phenylethylamine derivatives (CXCVIIa). Among compounds unsubstituted in the benzene ring, 2-amino-1-phenylethanol is the most active.[21,31]

More than 30 *o*-, *m*-, and *p*-hydroxy and *o*-, *m*-, and *p*-alkoxy-phenylethylamines (CXCVII) have been investigated, but no substances have been discovered among them which would increase the survival rate of the irradiated mice by more than 40%.[266] The replacement of the amino-group by the amido-, carbamido- and hydantoin groups decreased the toxicity but did not increase the RPE.[267]



(CXCVII)
R = H (a), OH, OAlk

(CXCVIII)
a) R = Me
b) R = Et

(CXCIX)

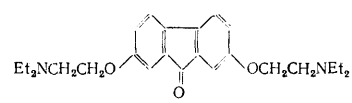
The introduction of the hydroxy-group in the β-position of *m*-hydroxyphenylethylalkylamine increases sharply the radioprotecting activity.[21,268–272] The *N*-methyl derivative (mezaton) and also the *N*-ethyl derivative (phetanol) [compounds (CXCVIII, a and b)] (25–50 mmol kg^{-1}) exhibit a stable RPE combined with a low toxicity (LD_{50} = 4.8 mmol kg^{-1}) when administered to mice subcutaneously (s/c) and intra-peritoneally. It has been shown[268,269] that the ED_{50} for the laevorotatory *S*-isomer of mezaton (CXCVIIIa) is lower almost by a factor of 2 than for the racemate (8.3 and 13 mol kg^{-1} respectively). It has been found that the *ortho*- and specially the *para*-hydroxy analogues of compound (CXCVIIIa) are less active.[269,272] The level of protection is reduced after the introduction of an additional hydroxy-group into the molecule of compound (CXCVIIIa) in the 4- or 6-position of the benzene ring.[269,270] The replacement of hydrogen in the amino-group by more bulky substituents, for example the adamantyl[269] or carbamido-groups,[267] leads to the loss of the RPE.

At the same time, the use of the β-sympathomimetic compound terbutaline (CXCIX) as a radioprotectant in the X-radiotherapy of tumours has been mentioned.[273]

Esterification of the phenolic hydroxyl or its substitution by the toluene-*p*-sulphonamide residue in compound (CXVIIIb) lowers the RPE.[269] 2-Amino-1-β-naphthylethanol proved to be inactive.[182]

Thus derivatives of arylalkanolamines are not inferior to aminothiols and indolylalkylamines as regards their RPE, being actually superior to them in terms of the width of their activity spectrum and the low optimum effective dose required,[268] but they suffer from the disadvantage that they give rise to a sharp and prolonged increase in blood pressure.[270]

The mechanism of the protection afforded by these compounds has not been ultimately elucidated. There exist convincing data showing that their action is associated with induced circulatory hypoxia,[31,270,271] but experimental data such as the lack of a decrease of the partial O_2 pressure in the liver and spleen when radioprotective doses of mezaton are used,[269] the presence of a protecting effect at the cellular level,[274,275] and the concentration-dependent influence of adrenolytic compounds on RPE[276,277] show that protection by these compounds can be achieved by their direct action on the cells. The radioprotective activity of sympathomimetic compounds is apparently realised via both a pharmacological pathway (indirectly) and at the cellular level; depending on the structure of the radioprotectant, the relative contributions by these pathways can vary.



(CC)

Tilorone (CC), which is a familiar interferon inductor, gives rise to a cyclic type of enhancement of the resistance of animals to radiation; thus, when administered to mice intra-peritoneally 15–30 min before irradiation, it gives rise to a pronounced RPE, after 3 h it is completely ineffective, and after 6 h its protection again reaches the initial

level. Satisfactory results have been obtained when compound (CC) was administered 2–3 days before irradiation.[215,273]

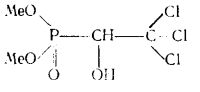
Steroids with a wide variety of structures have been used to increase the resistance of animals to radiation (see, for example, Refs.178, 279–285), but effective radioprotectants have not been discovered among them and furthermore these compounds were frequently administered to animals repeatedly over a fairly long period.

Various vitamins continue to attract the attention of radiobiologists but their protecting effect does not as a rule exceed an amount corresponding to a 30–40% survival rate.[286–292]

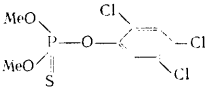
The results of studies of the radioprotective effect of vitamin K (ubiquinones) on mice merit attention. They proved effective when administered intra-peritoneally 10 h before irradiation.[292]

The demonstration of a high DRF in experiments on rabbit erythrocytes on treatment with riboflavin (DRF = 4.0), vitamin B_{12} (DRF = 3.6), and cytochrome *c* (DRF = 4.7) is also noteworthy.[291]

It has been found that penicillin exhibits a low radioprotective effect.[293]



(CCI)



(CCII)

The radioprotective activity of the organophosphorus compounds chlorophos (CCI) and trichlorometaphos (CCII) has been investigated in detail. When administered intra-peritoneally 3 h before irradiation, they afford protection to rats (DRF = 1.18 and 1.42 respectivcly).[294–299] These substances show a higher RPE when combined with dianabol and MEA.[297]

Thus, among aromatic and other compounds examined above, derivatives of phenylalkanolamines, which exhibit a high RPE and a broad therapeutic spectrum, have attracted attention.

Summarising, certain conclusions can be drawn. The number of publications devoted to the search for prophylactic radioprotective agents has increased somewhat, but the number of substances investigated (per annum) diminished somewhat, which applies in the first place to compounds with the aminothiol structure. A new class of highly effective radioprotectants, namely derivatives of arylalkanolamines, has been discovered. The relative contribution of heterocyclic compounds as potential radioprotective agents has greatly increased. It has been shown that thiazolidine derivatives are not unique among heterocyclic compounds as appeared to be the case previously; dithiolans and oxazolidines possess approximately the same activity. Other highly effective compounds, for example, chromenes and orotic acid derivatives, have been discovered.

For the first time, it has become possible to speak with confidence of the possibility of the practical application of radioprotectants. This has been confirmed by clinical studies on several preparations simultaneously, namely gammaphos, meprin, 5-thio-D-glucose, and terbutaline, in the prophylactic treatment designed to afford protection against radiation damage in cancer X-ray therapy.

A particularly vigorous search for new radioprotectants is to be expected in the next few years among heterocyclic compounds, arylalkanolamines, and aminothiol derivatives containing functional groups. This will be assisted by the data obtained in recent years demonstrating high RPE values for certain substances and data concerning the relation between structure and activity in various series of organic compounds.

---o0o---

During the preparation of the manuscript for the press, several communications concerned with the search for radioprotective substances were published. The salts of adenosine 5'-monophosphate with MEA and cystamine have been investigated as radioprotectors;[300–303] *N*-adamantoylmercaptoethylamine proved to be relatively inactive.[304] Among the *S*-2-thiazoline[305] and *S*-2-furfuryl[306] derivatives of MEA, the latter showed a high RPE; the replacement of the amino-group by the amidino- or guanidino-group does not increase the activity.[306] Effective substances in the series of *N*-adamantyl derivatives of gammaphos and its analogues have not been discovered.[304] It has been found that, among derivatives of compounds (XXXV) and (XLVI) substituted at the nitrogen atom by aryloxyalkyl and arylalkyl groups, the highest activity is shown by *S*-2-[4-(5-methoxy-3-methylphenoxy)butylamino] ethylthiosulphuric acid.[307]

The preparation adeturon described above has been recommended for clinical tests in X-radiotherapy.[301,303,308] The adamantyl and adamantoyl derivatives of AET proved to be relatively inactive.[304] In contrast to the data recorded above concerning the relation between structure and activity, a correlation has been reported between the period of the radioprotective activity of 2-phenyl- and 2-*m*-bromophenyl-thiazolidines and their metabolism.[309] It has been shown that halogenoalkylisothiuronium salts exhibit a moderate RPE.[310]

The results of studies of the radioprotecting activity of sodium diethyldithiocarbamate have attracted attention: following its intra-peritoneal administration to mice 30 and 120 min before irradiation in a dose of 1000 mg kg^{-1}, the DRF = 1.5–1.6 was attained (for a dose of 335 mg kg^{-1} of the same substance, Bacg et al.[311] achieved 40% protection); sodium diethyldithiocarbamate has been recommended for clinical tests in X-ray therapy.[312–314]

Highly effective radioprotectors have been found among nitrogen-containing aromatic heterocyclic compounds with the mercapto-group in the side chain. The highest activity is shown by 2-mercaptomethylpyridine and the corresponding phosphorothioate (the *N*-oxides and 2-pyrazinylmethylphosphorothioic acid are somewhat inferior to them) as well as all the mercaptopyridine isomers.[315]

The radioprotective properties of alkyl 2-furyl and alkyl 2-pyranyl sulphides have been investigated.[316] Effective radioprotectants have not been discovered among pyridazine and pyridazine-3,6-dione derivatives.[317] Salts of mexamine with adenosine 5'-phosphates, which are more active than mexamine itself, have been obtained and investigated.[318] It has been shown that 1-β-hydroxyethyl-5-nitro-2-phenacylthiobenzimidazole[319] and certain xanthine, adenine, 8-aza-adenine, and 2-thio-8-aza-adenine derivatives which have been investigated[320] exhibit a weak protecting activity.

Among other bicyclic and tricyclic nitrogen-containing heterocycles of the quinoline[321] and azepine[322] series, derivatives of tetrahydro-1*H*-pyrido[3,2-*b*]azepine and tetrahydro-1*H*-pyrido[2,3-*b*]azepinone showed a high RPE.[322] The results of the primary selection from a series of synthetic porphyrins, namely derivatives of deuterioporphyrin (IX), mesoporphyrins IX and II, aetioporphyrins I and II, and coproporphyrin I (77 compounds in all), have been published.[323]

Interesting results have been obtained in the study of sulphur-containing sugars as radioprotectants.[324] Thus 6-thio-D-fructose (LD_{50} = 17.5 g kg^{-1}) administered intra-abdominally to rats in a dose of 500 mg kg^{-1} 30 or 120 min before irradiation ensured a 100% survival rate of the animals, whereas all the control animals died. The protective effect persists also if the compound is administered 6 h before irradiation.[324]

Among other substances of natural origin, radioprotecting activity has been observed for the tetrapeptide taftsin,[325] the polypeptide melittin,[326] and also the natural prostaglandin E_2 and its synthetic analogue 1,6-dimethylprostaglandin E_2.[327]

In the series of aromatic amines (*o*-toluidine derivatives), substances with radioprotective activity were not found.[322] A pronounced radioprotective activity of certain antihelminthic preparations has been reported,[328] namely 3,5-dibromo-*N*-[4-chloro-3-(4-chlorobenzoyl)phenyl]-2-hydroxybenzamide (tetalid [sic]) and 3,5-di-iodo-*N*-[4-chloro-3-(2,5-dimethylbenzoyl)phenyl]-2-hydroxybenzamide, but these data require confirmation, since the compounds were administered to the animals in solution in dimethyl sulphoxide, which itself exhibits a radioprotective activity.

As a supplement to the data discussed in the review, references may be made to studies devoted to the radioprotective effect of ubiquinones,[329] vitamin B_{12} and folic acid,[330] *N*-substituted 2-amino-1-*m*-hydroxyphenylethanols,[331] and the nitriles of cinnamic and hydrocinnamic acids.[332]

Phosphorohalidites and Phosphoropseudohalidites in the Arbuzov Reaction with Halogen-containing Compounds

V.A.Shokol and B.N.Kozhushko

The literature data on the reactions of phosphorohalidites and phosphoropseudohalidites with various halogen-containing compounds are surveyed and described systematically.
The bibliography includes 133 references.

I. INTRODUCTION

In his studies of the structure of phosphorous acid and its esters as long ago as the beginning of the present century, Arbuzov established that fully esterified phosphorous acids readily rearrange to esters of alkylphosphonic acids under the influence of alkyl halides.[1,2] Subsequently the reaction was extended to fully esterified phosphonous and phosphinous acids:

$$RR^1POR^2 + R^3X \rightarrow R^3P(O)RR^1 + R^2X\ .$$

In contrast to the full esters, phosphorohalidites and phosphonohalidites are less reactive and in most cases do not interact with alkyl halides under the usual conditions of the Arbuzov reaction. It appears that phosphorohalidites and phosphonohalidites because of their weak nucleophilic properties were made to undergo the Arbuzov rearrangement only after more than 50 years elapsed. Apart from its theoretical importance, this reaction is also of considerable practical interest, since with its aid it is possible to obtain extremely reactive derivatives of tetracoordinate quinquevalent phosphorus which may serve as the starting compounds in the synthesis of a wide variety of derivatives of phosphoric, phosphonic, and phosphinic acids. Several extensive reviews and review reports have been published[2-23] on reactions of the full esters, thioesters, and amidoesters of tervalent phosphorus acids with organic compounds both containing and not containing a halogen. In these publications there are only individual examples of reactions of phosphorohalidites and phosphoropseudohalidites. Certain aspects of the reactions of these phosphorus derivatives with halogen-containing compounds were described in somewhat greater detail in monographs,[24,25] in a report,[26] and in a review.[27] There are no complete reviews on the Arbuzov reaction involving phosphorohalidites and phosphoropseudohalidites.

We felt it of interest and timely to survey the available literature data on the reactions of these phosphorus derivatives with halogen-containing compounds.

II. REACTIONS OF PHOSPHOROMONOHALIDITES AND PHOSPHONOMONOHALIDITES WITH ALKYL HALIDES

It has been found during the last decades that the most reactive phosphorohalidites and phosphonohalidites are the monofluoro-derivatives: di-isopropyl phosphorofluoridite, alkyl methylphosphonofluoridites, and alkyl *NN*-dimethylphosphoramidofluoridites react with methyl iodide to form the products of the Arbuzov reaction:[28-30]

$$AlkOP(X)F + MeI \rightarrow MeP(O)(X)F + AlkI\ ;$$
$$X = AlkO,\ Me,\ Me_2N\ .$$

Dialkyl phosphorofluorofluoridites react analogously with carboxylic acid chlorides:[31]

$$(AlkO)_2PF + RCOCl \rightarrow RCOP(O)(OAlk)F + AlkCl\ .$$

It was established subsequently that compounds containing an activated carbon–halogen bond enter into the reaction with dialkyl phosphorohalidites under fairly mild conditions:

$$-\ddot{O}-\overset{|}{\underset{|}{C}}-Cl(Br, I),\quad -\ddot{S}-CH_2Cl\ =\ddot{N}-\overset{|}{\underset{|}{C}}-Cl(Br)$$

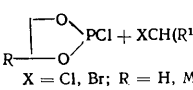
Alkyl α-chloroethyl ethers readily react with dialkyl phosphorochloridites to form alkyl α-alkoxyethylphosphonochloridates,[32,33] while alkyl -chloromethyl and alkyl αα-dichloromethyl ethers enter into the Arbuzov reaction only in the presence of a catalyst ($FeCl_3$):[34]

$$(RO)_2PX + R^1OCH(R^2)Cl \xrightarrow{(FeCl_3)} R^1OCH(R^2)P(O)(OR)X + RCl\ ;$$
$$X = Cl;\ R = Et,\ Bu,\ Am;\ R^1 = Et,\ Bu;\ R^2 = Me\ ;$$
$$X = Cl,\ F;\ R = Et;\ R^1 = Me,\ Et;\ R^2 = H,\ Cl\ .$$

The esters of chloro- and dichloro-acetic acids do not react with dialkyl phosphorohalidites. In contrast to them, the esters of alkoxychloroacetic acids do interact with dialkyl phosphorochloridites and phosphorofluoridites in the presence of catalysts (Lewis acids) and in their absence, while the esters of alkoxydichloroacetic acids react only in the presence of a catalyst:[34-37]

$$(EtO)_2PX + ClC(R^2)(COOR)OR^1 \xrightarrow{(FeCl_3)} R^1O(ROCO)C(R^2)P(O)(OEt)X + EtCl\ ;$$
$$X = Cl,\ F;\ R \text{ and } R^1 = Me,\ Et;\ R^2 = H,\ Cl\ .$$

When cyclic alkyl phosphorochloridites react with alkyl chloromethyl, alkyl bromomethyl, and alkyl dichloromethyl ethers, the Arbuzov reaction always proceeds with the rupture of the C–O bond at the unsubstituted carbon atom:[38-42]

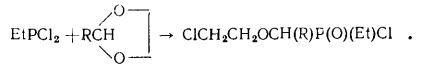


$$PCl + XCH(R^1)OR^2 \rightarrow R^2OCH(R^1)P(O)(Cl)OCH(R)CH_2Cl\ ;$$
$$X = Cl,\ Br;\ R = H,\ Me;\ R^1 = H,\ Cl;\ R^2 = Alk(C_1 - C_4)\ .$$

It has been shown[43-49] that the following are formed initially when phosphorus trichloride, alkyl phosphorodichloridites, and dichloroethyl- and dichlorophenylphosphines react with acetals, α-chloroethers and also dialkyl phosphorochloridites and alkyl ethyl(phenyl)phosphonochloridites among other tervalent phosphorous acid esters which enter into the Arbuzov reaction:

$$R^1CH(OR)_2 + R^2PCl_2 \rightarrow R^2(RO)PCl + R^1CHClOR \rightarrow ROCH(R^1)P(O)(R^2)Cl\ ;$$
$$PCl_3 + 2R^1CH(OR)_2 \rightarrow (RO)_2PCl + 2R^1CHClOR\ ;$$
$$(RO)_2PCl + R^1CHClOR \rightarrow ROCH(R^1)P(O)(OR)Cl\ ;$$
$$R = Alk;\ R^1 = H,\ Me;\ R^2 = AlkO,\ Et,\ Ph\ .$$

Dichloroethylphosphine reacts similarly with 2-alkyl-1,3-dioxolanes:[50]



$$EtPCl_2 + RCH(OCH_2CH_2O) \rightarrow ClCH_2CH_2OCH(R)P(O)(Et)Cl\ .$$

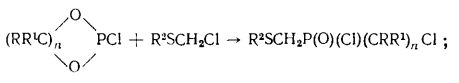
The reactions of dialkyl phosphorochloridites with acylals lead to the formation of α-chloroethers, which interact with the initial dialkyl phosphorochloridites:[51]

$$(RO)_2PCl + MeCH(OR^1)OCOMe \rightarrow (RO)_2POCOMe + MeCHClOR^1\ ;$$
$$(RO)_2PCl + MeCHClOR^1 \rightarrow R^1OCH(Me)P(O)(OR)Cl\ .$$

Alkylacetyl phosphorochloridites and acetyl phosphonochloridites, formed when phosphorodichloridites or dichlorophosphines are treated with acetic anhydride or an acetic acid acylal, react with α-chloroethers analogously to dialkyl phosphorochloridites and alkyl phosphonochloridites.[52-57] A reaction of the same type occurs between phosphorus trichloride and a mixture of acetic anhydride and its acetal:[58]

$$RPCl_2 + (MeCO)_2O \rightarrow RP(Cl)OCOMe \xrightarrow{MeCH(Cl)OR^1} R^1OCH(Me)P(O)(R)Cl\ ;$$
$$R = AlkO,\ Et,\ Ph\ .$$

The reaction of cyclic phosphorochloridites with alkyl chloromethyl sulphides has been patented:[59]



$$(RR^1C)_n(O_2)PCl + R^2SCH_2Cl \rightarrow R^2SCH_2P(O)(Cl)(CRR^1)_nCl\ ;$$
$$n = 2,\ 3;\ R \text{ and } R^1 = H,\ Me\ .$$

III. REACTIONS OF PHOSPHORODIHALIDITES WITH ALKYL HALIDES

Arbuzov showed that neither methyl iodide nor benzyl chloride act upon the "Menshutkin acid chloride" ($MeOPCl_2$) even on heating at 200 °C for 12 h.[3] However, according to patent data,[60,61] the products of the Arbuzov rearrangement are formed on heating (in a sealed tube at 260–325 °C) methyl phosphorodichloridite with MeI, MeCl, or CCl_4 in the presence of catalysts ($FeCl_3$, ZnI_2, NiI_2, etc). Under milder conditions in the absence of a catalyst, methyl phosphorodichloridite reacts with allyl iodide[62] and ethyl phosphorodichloridite reacts with 4,5-methylenedioxy-2-propylbenzyl iodide.[63]

Methyl and ethyl phosphorodichloridites[64-70] and also butyl phosphorodifluoridite[69-71] enter into the Arbuzov reaction much more readily (than into the reaction with methyl iodide) on treatment with α-chloroalkyl ethers containing[69,70] or not containing[66-68,71] an electronegative alkoxycarbonyl group or three methyl groups at the α-carbon atom.

When alkyl phosphorodichloridites[71-73] and butyl phosphorodifluoridite[71,73] react with dichloromethyl methyl and di(chloromethyl) ethers[72] or with the alkyl esters of alkoxydichloroacetic acids,[71,73] only one chlorine atom is involved in the reaction even in the presence of a large excess of the phosphorodihalidite, while in the reaction of methyl phosphorodichloridite with di(α-chloroethyl) ether or αα-diiodoethyl methyl ether both halogen atoms are substituted:[27]

$$ROCR^1R^2Cl + R^3OPX_2 \rightarrow ROCR^1R^2P(O)X_2 + R^3Cl\ ;$$
$$X = Cl,\ F;\ R = Alk(C_1 - C_4),\ ClCH_2;$$

$$R^1 = H,\ CCl_3,\ COOMe,\ COOEt;\ R^2 = H,\ Cl;$$
$$R^3 = Me,\ Et,\ Bu\ ;$$

$$2MeOPCl_2 \xrightarrow{MeOCl_2Me} MeOCMe[P(O)Cl_2]_2\ ;$$

$$2MeOPCl_2 \xrightarrow{O(CHClMe)_2} O[CH(Me)P(O)Cl_2]_2\ .$$

The reaction of dialkyl formals with an excess of phosphorus trichloride in the presence of $ZnCl_2$ results in the formation of α-chloroethers and alkyl phosphorodichloridites, which react with one another via the mechanism of the Arbuzov reaction:[47,48,74]

$$PCl_3 + (RO)_2CH_2 \rightarrow ROPCl_2 + ROCH_2Cl \rightarrow ROCH_2P(O)Cl_2\ .$$

Alkyl chloromethyl and aryl chloromethyl sulphides react with alkyl phosphorodichloridites analogously to α-chloroethers:[75,76]

$$RSCH_2Cl + R^1OPCl_2 \xrightarrow{-R^1Cl} RSCH_2P(O)Cl_2\ ;$$
$$R = Et,\ Pr,\ iso\text{-}Pr,\ Bu,\ Ph\ .$$

IV. PHOSPHOROHALIDITES IN REACTIONS WITH α-CHLORO- AND α-BROMO-ALKYL ISOCYANATES

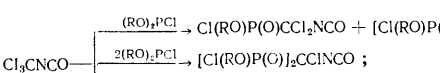
Dialkyl phosphorochloridites and dialkyl phosphorofluoridites undergo the Arbuzov rearrangement very readily on reaction with α-chloro- and α-bromo-alkyl isocyanates, forming α-alkoxychlorophosphonylalkyl and α-alkoxyfluorophosphonylalkyl isocyanates:[24,26,77-85]

$$(RO)_2PX + YCH(R^1)NCO \rightarrow X(RO)P(O)CH(R^1)NCO + RY\ ;$$
$$X = Cl,\ F;\ Y = Cl,\ Br;\ R = Et,\ iso\text{-}Pr;\ R^1 = H,\ Cl,\ Ph,\ BrCH_2,\ CCl_3\ .$$

The reaction of dichloromethyl isocyanate with two moles of dialkyl phosphorofluoridite produces bis(alkoxyfluorophosphonyl)methyl isocyanate:[26,80,81]

$$2(RO)_2PF + Cl_2CHNCO \rightarrow [F(RO)P(O)]_2CHNCO\ .$$

The reaction of trichloromethyl isocyanate with one mole of dialkyl phosphorochloridite affords a mixture of alkoxychlorophosphonyldichloromethyl and bis(alkoxychlorophosphonyl)chloromethyl isocyanates, while the reaction with two moles of the reagent gives rise to the bisphosphorylated isocyanate only. Whatever the proportions of trichloromethyl isocyanate and dialkyl phosphorofluoridite, it is possible to isolate only bis(alkoxyfluorophosphonyl)chloromethyl isocyanate:[26,86]



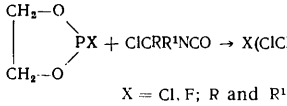
$$Cl_3CNCO \xrightarrow{(RO)_2PCl} Cl(RO)P(O)CCl_2NCO + [Cl(RO)P(O)]_2CClNCO\ ;$$
$$Cl_3CNCO \xrightarrow{2(RO)_2PCl} [Cl(RO)P(O)]_2CClNCO\ ;$$
$$Cl_3CNCO \xrightarrow[n=1,\ 2,\ 3]{n(RO)_2PF} [F(RO)P(O)]_2CClNCO\ .$$

Dialkyl phosphorochloridites react also with dichlorophosphonyl dichloromethyl isocyanate to form a mixed bisphosphorylated chloromethyl isocyanate:[26,86]

$$(RO)_2PCl + Cl_2P(O)CCl_2NCO \rightarrow Cl(RO)P(O)[Cl_2P(O)]CClNCO\ .$$

Cyclic phosphites (2-chloro- and 2-fluoro-phospholans) react with chloro-, dichloro-, and trichloro-methyl isocyanates via the mechanism of the Arbuzov rearrangement

involving ring opening and the formation of the corresponding β-chloroethoxychloro- and β-chloroethoxyfluorophosphonylalkyl isocyanates:[26,87]



$$X = Cl, F;\ R \text{ and } R^1 = H, Cl\ .$$

When alkyl phosphorodichloridites and phosphorodifluoridites react with α-chloro- or α-bromo-alkyl isocyanates, dichlorophosphonyl- and difluorophosphonyl-alkyl isocyanates are formed. The reaction proceeds only in the presence of Lewis acids as catalysts:[24,26,77-79,81-84,86,88-90]

$$R^2OPX_2 + YCRR^1NCO \rightarrow X_2P(O)CRR^1NCO\ ;$$
$$X = Cl, F;\ Y = Cl, Br;\ R = H;\ R^1 = H, Cl, CCl_3, CH_2Cl,;$$
$$CH_2Br, Ph \text{ or } R = R^1 = Cl\ .$$

α-Bromobenzyl isothiocyanate reacts with alkyl phosphorodichloridites and phosphorodifluoridites analogously to α-halogenoalkyl isocyanates:[91]

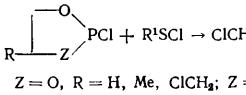
$$ROPX_2 + PhCHBrNCS \rightarrow X_2P(O)CH(Ph)NCS\ ;$$
$$X = Cl, F\ .$$

V. PHOSPHOROHALIDITES IN REACTIONS WITH SULPHENYL CHLORIDES

Dialkyl phosphorochloridites and phosphorofluoridites react very readily with alkane- and arene-sulphenyl chlorides via the mechanism of the Arbuzov rearrangement to form the alkyl and aryl esters of phosphorohalidothiolates:[25,92-95]

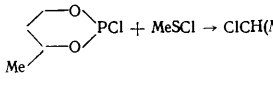
$$(RO)_2PX + R^1SCl \rightarrow R^1S(RO)P(O)X\ .$$

Five-membered cyclic phosphorochloridites, namely 2-chloro-1,3,2-dioxaphospholans, 2-chloro-1,2,3-oxathiaphospholans, and 2-chloro-1,3,2-oxazaphospholans, react with alkane- and arene-sulphenyl chlorides with ring opening at the C–O bond (at the unsubstituted carbon atom in 1,3,2-dioxaphospholans:[96-98]



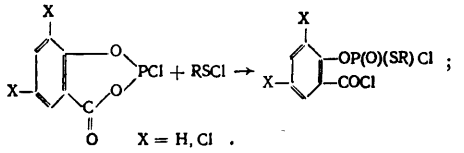
$$Z = O,\ R = H, Me, ClCH_2;\ Z = S, NAlk,\ R = H\ .$$

The C–O bond at the substituted carbon atom is ruptured in six-membered cyclic phosphorochloridites:[98]



When a mixture of an alkyl phosphorodichloridite and acetic anhydride or acetic acid is treated with alkane- and arene-sulphenyl chlorides, acetyl alkyl phosphorochloridites are apparently formed initially and undergo the Arbuzov rearrangement with formation of acetyl chloride.[99,100] The cyclic "salicyl phosphorochloridite" reacts similarly:[101]

$$ROPCl_2 + (MeCO)_2O \rightarrow RO(MeCOO)PCl \xrightarrow{R^1SCl} R^1S(RO)P(O)Cl\ ;$$



$$X = H, Cl\ .$$

Alkane- and arene-sulphenyl chlorides are more reactive than alkyl halides; they enter into the Arbuzov reaction with alkyl phosphorodichloridites and phosphorodifluoridites in the absence of catalysts:[93,94,102-108]

$$ROPX_2 + R^1SCl \rightarrow R^1SP(O)X_2\ .$$

The Arbuzov reaction probably proceeds also when a mixture of phosphorus trichloride and acetic anhydride is treated with alkane- and arene-sulphenyl chlorides:[100]

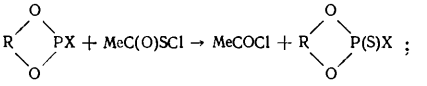
$$PCl_3 + (MeCO)_2O \rightarrow MeCOCl + MeCOOPCl_2 \xrightarrow{RSCl} RSP(O)Cl_2\ .$$

Selenyl chlorides react with alkyl phosphorodichloridites analogously to sulphenyl chlorides, but the reaction proceeds only in the presence of catalysts ($SbCl_5$, BCl_3):[108,109]

$$ROPCl_2 + CF_3SeCl \rightarrow CF_3SeP(O)Cl_2\ .$$

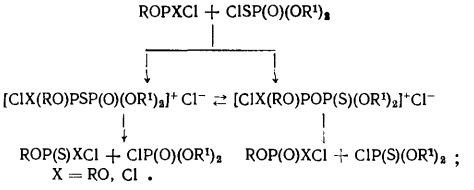
Acetyl-, dialkylphosphono-, and dialkylamino- or *N*-alkyl-*N*-(dialkyl phosphonoamino)-sulphenyl chlorides also react readily with dialkyl phosphorohalidites and alkyl phosphorodihalidites, but the products of the Arbuzov rearrangement are not formed.

Thus cyclic phosphorochloridites, phosphorobromidites, and phosphorofluoridites react with acetylsulphenyl chloride to form acetyl chloride and phosphorohalidothionates:[110-112]



$$R = -(CH_2)_2-,\ -CH_2CH_2CH(Me)-;\ X = Cl, Br, F\ .$$

When dialkyl phosphonosulphenyl chlorides are treated with dialkyl phosphorochloridites and alkyl phosphorodichloridites, either sulphur or oxygen is split off:[25,113]



$$X = RO, Cl\ .$$

Dialkyl phosphorochloridites and alkyl phosphorodichloridites react with dialkylamino- and *N*-methyl-*N*-dialkoxyphosphonylamino-sulphenyl chlorides in proportions of 2 : 1 to form an alkyl chloride, an alkyl phosphorodichloridate, or phosphoryl chloride and amides of phosphorothionic acids, while dialkyl phosphorofluoridites and alkyl phosphorodifluoridites are converted into mixtures of phosphorofluoridothionates and phosphoramidofluoridates. It has been suggested that the products of the Arbuzov rearrangement, namely alkoxyhalogenophosphonyl- or dihalogenophosphonyl-sulphenyl amides, are formed initially and then react in different ways with a second molecule of the corresponding phosphorohalidite:[25,114-118]

$$ROPXY + R^1R^2NSCl \rightarrow [XY(RO)PSNR^1R^2]^+Cl^- \rightarrow RCl + [XYP(O)SNR^1R^2]\ ;$$
$$X = Cl, F, OR;\ Y = Cl, F;\ R^1 = Me,\ R^2 = P(O)(OEt)_2 \text{ or } R^1 \text{ and } R^2 = Alk\ ;$$
$$[XClP(O)SNR^1R^2] + ROPXCl \rightarrow [XClP(O)SP(NR^1R^2)(OR)XI^+Cl^- \rightarrow$$
$$\rightarrow XP(O)Cl_2 + R^1R^2NP(S)(OR)X\ ;$$
$$X = Cl, OR\ ;$$
$$[XFP(O)SNR^1R^2] + ROPXF \rightarrow [XFP(O)S(NR^1R^2)P(OR)FX] \rightarrow XFP(O)NR^1R^2 + ROP(S)FX;$$
$$X = F, OR\ .$$

Dichloromethyleneiminosulphenyl chloride reacts with alkyl phosphorodichloridites analogously to dialkylaminosulphenyl chlorides:[119,120]

$$2ROPCl_2 + Cl_2C{=}NSCl \rightarrow Cl_2C{=}NP(S)(OR)Cl + POCl_3 + RCl\ .$$

VI. REACTIONS OF PHOSPHOROHALIDITES WITH *N*-CHLORO-COMPOUNDS

Dialkyl phosphorochloridites and phosphorofluoridites as well as alkyl phosphorodichloridites and phosphorodifluoridites react very readily with esters of *N*-chloroamidocarboxylic acids [*N*-chloroimidic acids? (Ed.of Translation)] via the mechanism of the Arbuzov reaction:[121]

$$ROPXY + R^1(R^2O)C{=}NCl \rightarrow R^1(R^2O)C{=}NP(O)XY ;$$
$$X = RO, Cl, F;\ Y = Cl, F;\ R^1 = Me, R^2O;\ R^2 = Me, Et .$$

The reactions of dialkyl phosphorochloridites with the esters of *N*-alkyl-*N*-chlorocarbamic acids also yield the products of the Arbuzov rearrangement:[122]

$$(RO)_2PCl + R^1OCON(R^2)Cl \rightarrow R^1OCON(R^2)P(O)(OR)Cl .$$

When phosphorus trichloride reacts with glycols and esters of *N*-alkyl-*N*-chlorocarbamic acids, the initial products are apparently cyclic phosphorochloridites, which then react with the *N*-chloro-compounds:[123]

$$PCl_3 + HOROH \rightarrow \text{cyclic } R(O)_2PCl \xrightarrow{R^1OCON(R^2)Cl} R^1OCON(R^2)P(O)(ORCl)Cl ;$$
$$R = (CH_2)_2,\ (CH_2)_3,\ CH(Me)CH(Me) .$$

Alkyl phosphorodichloridites react with the alkyl esters of *N*-alkyl-*N*-chlorocarbamic acids in the presence of the catalyst ($FeCl_3$):[124]

$$ROPCl_2 + R^1OCON(R^2)Cl \xrightarrow{FeCl_3} R^1OCON(R^2)P(O)Cl_2 .$$

When butyl phosphorodifluoridite is heated with *N*-chloro-*NN'*-dimethylbenzamidine, *N*-difluorophosphonyl-*NN'*-dimethylbenzamidine is obtained.[125]

VII. REACTIONS OF PHOSPHOROPSEUDOHALIDITES WITH ALKYL HALIDES AND *N*-CHLORO-COMPOUNDS

Dialkyl phosphorocyanidites enter into the Arbuzov reaction with alkyl iodides on prolonged heating in a sealed tube at 160 °C:[126]

$$(RO)_2PCN + R^1I \rightarrow R^1P(O)(OR)CN ;$$
$$R = Et, Pr;\ R^1 = Me, Et, Pr .$$

The esters of *N*-chlorimidocarboxylic acids [*N*-chloroimidic acids? (Ed.of Translation)] react with dialkyl phosphorocyanidites and alkyl phosphorodicyanidites in benzene:[121]

$$ROP(X)CN + R^1(R^2O)C{=}NCl \rightarrow R^1(R^2O)C{=}NP(O)(X)CN ;$$
$$X = RO, CN;\ R^1 = Me, R^2O;\ R^2 = Me, Et .$$

On prolonged refluxing, diethyl phosphoroisocyanatidite reacts with alkyl iodides via the mechanism of the Arbuzov rearrangement to form *O*-ethylalkylphosphonyl isocyanates:[127,128]

$$(EtO)_2PNCO + RI \rightarrow RP(O)(OEt)NCO ;$$
$$R = Me, Et, Bu, C_8H_{17} .$$

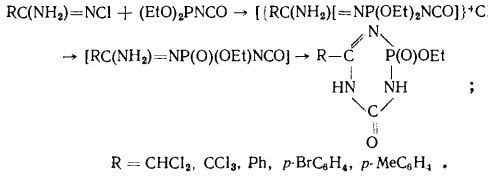
α-Chloroalkyl ethers react with diethyl phosphoroisocyanatidite much more readily than alkyl iodides, whilst αα-dichloroalkyl ethers react only in the presence of the catalyst ($FeCl_3$):[24,129]

$$(EtO)_2PNCO + ROCR^1R^2Cl \rightarrow ROCR^1R^2P(O)(OEt)NCO ;$$
$$R = Me, Et;\ R^1 = H, Cl;\ R^2 = H, COOMe, COOEt .$$

Ethyl phosphorodi-isocyanatidite reacts with α-chloro- and αα-dichloroalkyl ethers only in the presence of the catalyst:[129,130]

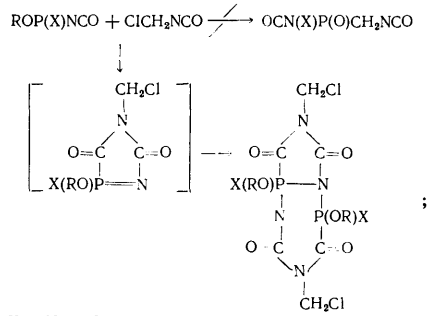
$$EtOP(NCO)_2 + ROCR^1R^2Cl \xrightarrow{FeCl_3} ROCR^1R^2P(O)(NCO)_2 ;$$
$$R = Me, Et;\ R^1 = H, Cl;\ R^2 = H, CCl_3, COOMe, COOEt .$$

The reactions of diethyl phosphoroisocyanatidite with *N*-chloroamidines yield the corresponding phosphonium salts, which readily split off ethyl chloride and are converted into *N*-(*O*-ethylisocyanatophosphonyl)amidines. The latter cyclise to 2-ethoxy-2,4-dioxo-6-R-2,3,4,5-tetrahydro-1,3,5,2-triazaphosphorinanes:[127,131]



$$RC(NH_2){=}NCl + (EtO)_2PNCO \rightarrow [\{RC(NH_2)[{=}NP(OEt)_2NCO]\}^+Cl^-] \rightarrow$$
$$\rightarrow [RC(NH_2){=}NP(O)(OEt)NCO] \rightarrow \text{cyclic } R(NH)_2C{=}NP(O)(OEt) ;$$
$$R = CHCl_2,\ CCl_3,\ Ph,\ p\text{-}BrC_6H_4,\ p\text{-}MeC_6H_4 .$$

When diethyl phosphoroisocyanatidite and alkyl phosphorodi-isocyanatidites are treated with chloromethyl and *p*-chloromethylphenyl isocyanates, it is not possible to obtain the products of the rearrangement—the reaction proceeds via a different pathway. The [3 + 2] -cycloaddition initially results in formation of a substituted 3,5-dioxo-Δ^1-1,4,2-diazaphospholine, which dimerises very readily to the tricyclic 1,3,2λ^5,4λ^5-diazadiphosphetidine:[24,132,133]



$$ROP(X)NCO + ClCH_2NCO \rightarrow OCN(X)P(O)CH_2NCO \rightarrow \text{cyclic } [X(RO)P{=}N]_2 ;$$
$$X = NCO,\ R = Me, Et, Pr, Bu \text{ or } X = RO = EtO .$$

It follows from the data presented in this review that a new development has arisen in recent years in the Arbuzov reaction, whose 80th anniversary occurs in 1985, consisting in the fact that phosphorohalidites, phosphoropseudohalidites, phosphonohalidites and phosphonopseudohalidites, which exhibit reduced nucleophilic properties, are also capable of undergoing the rearrangement on reaction with various halogen-containing electrophiles. The extension of the Arbuzov reaction to phosphorohalidites, phosphoropseudohalidites, phosphonohalidites, and phosphonopseudohalidites made it possible to obtain directly the mono- and di-halides and the mono- and di-isocyanates of tetracoordinate phosphorus acids, as well as their other highly reactive derivatives, which have found extensive applications in the synthesis of a wide variety of organophosphorus compounds possessing useful properties.

The Mechanism of the Reaction of Hydrogen with the Metals of the Iron Sub-group

L.V.Babenkova, N.M.Popova, and I.N.Blagoveshchenskaya

The results of quantum-chemical studies of the mechanism of formation of the metal-hydrogen adsorption bond and the solution of hydrogen in group VIII metals, and the results of experimental studies of the chemisorption properties of metals of the iron sub-group with respect to hydrogen, have been reviewed. The experimentally observed regular features of the change in the bond strength and the concentration of different forms of chemisorbed hydrogen agree with the results of the quantum-chemical calculations.
The bibliography contains 111 references.

I. INTRODUCTION

Extensive experimental and theoretical material has now been accumulated in the study of the adsorption of hydrogen on transition metals.[1-8] A number of problems related to the nature of the adsorption bond, the structure of the surface centres, etc. have not yet been resolved, however. The application of modern physical methods of study (low-energy electron diffraction (LEED), ultraviolet spectroscopy, energy-loss spectroscopy (ELS), etc.) and quantum-chemical methods to the study of the reaction of hydrogen with transition metals has made it possible to approach an understanding of the mechanism of the chemisorption of hydrogen and the relationship between the adsorbing power of metals and their electronic structure.

Recent studies illuminating the role of *d* and *sp* electrons in the adsorption of hydrogen, the influence of the structure of the active centre on the chemisorption of hydrogen, and various models of the dissociative chemisorption of hydrogen on 3*d* transition metals will be reviewed.

II. THE NATURE OF THE METAL HYDROGEN ADSORPTION BOND

1. The Role of *d* and *sp* Electrons in the Adsorption of Hydrogen on 3*d* Metals

In the first papers proposing models of the surface active centres in the chemisorption of hydrogen on transition metals,[6,9,10] it was assumed that the adsorption of hydrogen involves only *d* electrons, and that the directions in space and the splitting of the *d* orbitals with respect to energies are preserved for the surface atoms of the metal (Goodenough's model of the electronic structure of transition

metals[11] was used). It was shown that several types of chemisorption active centres may be formed on the (111), (110), and (100) crystallographic faces of single crystals of nickel and platinum as a result of the emergence of the corresponding e_g or t_{2g} orbitals on to the surface.

Modelling adsorption complexes in accordance with Goodenough's theory of the electronic structure of transition metals gives satisfactory correlations between the experimental and calculated values of the kinetic and thermodynamic parameters of adsorption. A large amount of data on the change in the electronic state of metal and hydrogen atoms during chemisorption, obtained in the last ten years using modern physical and quantum-chemical methods of study, however, indicate that not only the *d* orbitals, but also the *sp* orbitals, of transition metals are involved in the formation of the H–M bond.[12–28]

The principal results of the study of the adsorption of hydrogen on transition metals, obtained using cluster models of adsorption[12,13] and semi-empirical methods of calculation, taking account of the contribution of both the *d* and the *sp* orbitals of the metal to the formation of the H–M bond can be considered.

Calculations by the extended Hückel method (EHM) of the energy of adsorption of a hydrogen molecule on the cluster formed by two neighbouring atoms in a metal lattice (M = Cu, Ni) have shown that the interaction of the 1*s* orbitals of the hydrogen molecule with the $3d_{z^2}$ orbitals of Ni_2 leads to the activationless dissociation of the hydrogen molecule with the subsequent localisation of the H atoms on the $3d_{z^2}$ centres of of nickel; the 4*s* orbitals of nickel and copper can form bonds only with hydrogen atoms.[14]

The simultaneous participation of the 3*d*, 4*s*, and 4*p* electrons of the nickel atom in the chemisorption of atomic hydrogen with allowance for the influence of the nearest neighbouring metal atoms in the lattice has been examined by the EHM in Ref.15 (3*d* and 4*s* electrons) and in Refs.16 and 17 (3*d*, 4*s*, and 4*p* electrons). The adsorption was calculated for surface clusters consisting of 8, 9, or 10 nickel atoms, arranged in such a way that the metal atom interacting with hydrogen had the complete immediate environment corresponding to its position on the (100), (110), or (111) faces of a face-centred cubic (f.c.c.) lattice. The most satisfactory agreement between the calculated and experimentally determined values of the H–M bond energies (290 kJ $mole^{-1}$ [29]) was observed when the simultaneous contributions of both the 3*d* and the 4*s* surface states of the nickel atom were taken into account in the calculation.[15] The population of the $3d_{z^2}$ orbital of the nickel atom interacting directly with the hydrogen atom changed during adsorption from 1.904 to 0.972, and that of the 4*s* orbital from 0.468 to 0.368. The changes in the populations of the $3d_{x^2-y^2}$, $3d_{xy}$, $3d_{xz}$, and $3d_{yz}$ orbitals, and also the 4*p* orbitals of the given atom, and the 3*d* and 4*sp* orbitals of the metal atoms surrounding the active centre, were found to be slight for all types of cluster examined.[15–17]

The preferred participation of the 4*s* orbitals of Ni in bond formation with molecular forms of hydrogen has been demonstrated.[18] A semi-empirical MO LCAO calculation of the adsorption of a hydrogen molecule on a centre formed by two neighbouring nickel atoms (Ni–Ni bond length 2.49 Å), with allowance for the contribution to the bond of the 1*s* orbital of hydrogen and the $3d_{z^2}$ and 4*s* orbitals of the metal, on the energy surface of the dissociative chemisorption revealed three states corresponding to two molecular[18,30] and one atomic[18] form of chemisorption. When only the 3*d* orbitals of nickel were involved in the H_2–M_2 interaction, one state, corresponding to the adsorption of atomic hydrogen, was detected.[18]

The complete neglect of differential overlap (CNDO) showed that, irrespective of the structure of the crystallographic face, the extent of the participation of the 4*s* orbitals in bond formation is much greater than that of the 3*d* orbitals.[20]

Calculations of the change in the density of the surface *d* and *sp* states of transition metals (M = Ni, Pd, W) in an M_9 cluster with the (100) structure of an f.c.c. lattice during the chemisorption of atomic hydrogen, carried out by the X_α discrete variation method, made it possible to reach various conclusions about the mechanism of the interaction of a hydrogen atom with a metal surface.[19] As a hydrogen atom approaches an Ni_9 cluster, as a result of Coulombic interaction with the cluster, the energy of the 1*s* level of the hydrogen atom is lowered considerably, and approaches the energies of the 4*sp* levels of nickel. Thus the interaction of the 1*s* orbital of the hydrogen atom takes place primarily with the molecular orbital of the Ni_9 cluster situated at the bottom of the valence zone and including mainly the 4*s* and 4*p* orbitals of the nickel atom (Fig.1). This leads to the formation of two new levels: a bonding $1a_1$ and a hypothetical antibonding $2a_1'$; the latter interacts with the 3*d* orbitals of nickel, leading to the production, in the valence zone of the cluster, of a $2a_1$ level (with an energy ~4 eV lower than the Fermi level), characteristic of the H–M bond.[19] The formation of a new level situated 5.9 eV (Ni [31]) or ~5.6 eV (Fe [32]) below the Fermi level has been detected in an ultraviolet spectroscopic study of the adsorption of hydrogen.

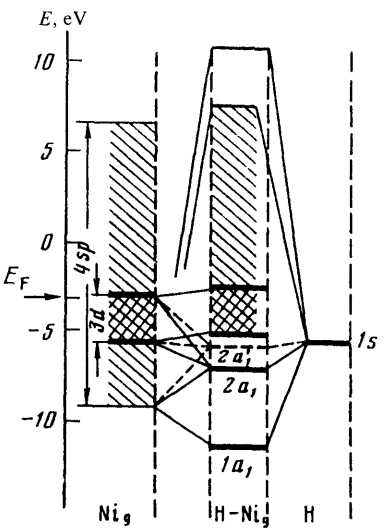

Figure 1. Schematic diagram of the interaction of the 1*s* orbital of a hydrogen atom with the 4*sp* and 3*d* orbitals of an Ni_9 cluster[19] (E_F is the Fermi level).

As a result of the formation, in the valence zone of the metal, of the antibonding $2a_1'$ level, produced as a result of the interaction of the 1*s*(H) and 4*s*(Ni) states[19] (see Fig.1), the population of the Ni–Ni bond becomes negative, leading to repulsion of neighbouring nickel atoms and to a decrease in the strength of the M–M bond in the lattice. It should be noted that in calculations of the adsorption of hydrogen on Pd and W [19] in the valence zone of the cluster H–M_9 only the

formation of the bonding level was observed; this is due to the differences in the electronic structures of Ni (the lowest occupied energy levels of the 3*d* zone are appreciably higher than the bottom of the 4*sp* zone) and Pd (the positions of the bottoms of the 4*d* and 5*sp* zones coincide). These data are in good agreement with the fact that nickel hydride, unlike palladium hydride, is unstable.[19]

The participation of both the *d* and *sp* surface states of transition metals in H–M bond formation was also detected experimentally in a study of the state of the surface of a solid during the adsorption of hydrogen.[33–36] The use of NMR [33] to study the adsorption of hydrogen on polycrystalline Cu, Pt, and W made it possible to reveal two adsorption states on the surface of Pt and W specimens, characterised by differences in the magnitude and direction of the resonance shift, and one adsorption state for Cu; the latter is a consequence of the participation of only the 4s orbitals of the metal in H–M bond formation.

Comparison of the directions of the resonance shifts in the adsorption of hydrogen on Pt and W with that obtained for Cu [33] shows that both the 5*d* and the 6*s* electrons take part in H–M bond formation. For Pt, the contribution of the 5*d* states to the production of both types of adsorption is much greater than that of the 6*s* states, whereas for W, predominant participation of the 5*d* orbitals is observed only for one less mobile (that is more firmly bound) adsorption state.

The predominant role of the 4*sp* states of the metal in H–M bond formation was detected in a study of the adsorption of hydrogen on the (111) face of a single crystal of nickel by photoelectron spectroscopy.[34] Comparison of the photoemission spectra obtained with gradual decrease in the degree of covering of a nickel surface with hydrogen (Fig.2) shows that the surface states of the metal are displaced to higher energies and gradually quenched in the range of energies corresponding to the 4*sp* zone of Ni (~0.25–0.50 eV below the Fermi level, see Fig.2). At the same time, the surface 3*d* states of nickel undergo practically no changes with increase in the time of exposure of the specimen in hydrogen.[34]

The predominant participation of the *sp* orbitals for Ni [34,36] and of the *d* orbitals for Pt and Pd [33] in H–M bond formation has been related to the differences in the electronic structures of these metals.[33,34]

According to quantum-chemical data, the H–M bond energy is determined by the extent of the participation of the surface *d* and *sp* states of the metal in the interaction with hydrogen, which in turn is determined by the structure of the chemisorption active centre.[15–17,20,22] Calculated data obtained by the extended Hückel method on the extent of the participation of the valence 3*d* and 4*s* electrons in the adsorption of atomic hydrogen on different crystal faces of nickel show that the role of the 4*s* orbitals of the metal increases with increase in the strength of the H–M bond, whereas the contribution of the 3*d* orbitals is greater for weak interactions with hydrogen; thus the population of the overlap of the 1*s* orbital of the hydrogen atom with the $3d_{z^2}$ and 4*s* orbitals of nickel changes as follows in the series of faces (110), (100), (111) (with decrease in the strength of the bond): 0.0452, 0.0526, and 0.0600 for the $3d_{z^2}$ orbital, and 0.1589, 0.1479, and 0.1399 for the 4*s* orbitals.[15]

The same regular features are observed for the chemisorption of molecular hydrogen.[21] For weak chemisorption of a hydrogen molecule (long H–Ni bond and short H–H bond) for the periodic model of the surface [an ideal crystal lattice, containing 250 atoms, with the f.c.c. structure, (100) face], the greatest contribution to bond formation is made by the 3*d* orbitals of nickel (Table 1), whereas with increase in the strength of the H–Ni bond, the participation of the 4*sp* states of the metal in adsorption predominates. For the cluster model of chemisorption, irrespective of the size of the particle, the 3*d* states of the metal make a smaller contribution to bond formation than the 4*sp* states (Table 1). The contribution of the *d* or *sp* orbitals of the metal to the interaction with hydrogen is determined by the structure of the chemisorption active centre.[15–17,22,25,37]

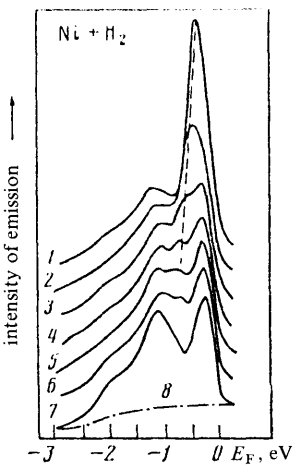

Figure 2. Photoelectron spectra of the (111) face of a single crystal of nickel for different degrees of covering of the surface by hydrogen:[34] *1*) original specimen; *2*) specimen kept in H_2 at 0.2 Langmuir; *3*) at 0.4; *4*) 0.6; *5*) 0.8; *6*) 1.0; *7*) 1.2; and *8*) (spectrum corresponding to complete saturation of the surface with hydrogen) 10.0 Langmuir (1 Langmuir = 10^6 mmHg). The broken line shows the displacement of the surface states with increase in the degree of covering of the surface.

Table 1. Contribution of the surface 3*d* and 4*sp* states of nickel to the formation of the H_2–M bond.[21]*

*The calculations were carried out by the extended Hückel method.

The EHM has been used to calculate the values of the energy of adsorption of atomic hydrogen and the population of the overlap of the 1*s* orbital of hydrogen with the 3*d* and 4*sp* orbitals of nickel for 11 different types of adsorption complex ("surface molecules").[16,17] Comparison of the energies of adsorption ΔE_{ads} obtained for the restricted periodic model of the surface and for the cluster model shows that on all crystallographic faces, the bond between the

hydrogen atom and one nickel atom (position *A*) is preferred (ΔE_{ads} has values from −2.80 eV to −2.46 eV) to the formation of multicentre bonds with the hydrogen atom situated between two (position *B*, ΔE_{ads} between −2.60 eV and −2.23 eV), three, or four (position *C*, ΔE_{ads} between −2.38 eV and −2.24 eV) nickel atoms. Irrespective of the number of bonds formed by the hydrogen atom with the metal atoms, the 4*sp* states of nickel play the greatest part in the interaction. The adsorption of hydrogen on all types of centre is accompanied by the formation of a negatively charged form of hydrogen;[15–17] the magnitude of the charge is determined by the structure of the active centre, and amounts to −0.35 e for centres of type *A*, −0.30 e for centres of type *B*, and −0.25 e for centres of type *C*.

Analogous data on the strength of the bond formed by a hydrogen atom adsorbed on a nickel surface in positions *A*, *B*, or *C* were obtained in Ref. 22, again by the EHM; the maximum displacement of charge from the metal to the hydrogen atom (−0.725, −0.605, and −0.536 e), the greatest population of the bond between the hydrogen atom and the nearest nickel atom (0.428, 0.317, and 0.237), and the maximum decrease in the total energy of the H–M system (−1118.445, −1118.080, and −1117.599 eV for adsorption on the centres *A*, *B*, and *C* respectively) correspond to the adsorption of the hydrogen atom on the centre of type *A*.

On the other hand, calculations of the stability of the multicentre bond of the chemisorbed hydrogen atom on nickel, carried out by the CNDO [20,38] and Wolfsberg–Helmholtz MO [6] methods for the adsorption of atomic hydrogen on the *A*, *B*, and *C* centres of the (100), (110), and (111) faces of a single crystal of nickel showed that an increase in the number of metal atoms taking part in bond formation with the hydrogen atom is accompanied by a significant increase in the bond energy: −1.6, 2.8, 3.2, and 3.0 eV for an H atom combined with one, two, three, and four nickel atoms.[38] Irrespective of the type of adsorption centre and crystallographic face, however (as in Refs. 15 and 17), negative charge is displaced from the metal to hydrogen (0.2 e); the magnitude of the charge changes little with change in the structure of the active centre.

Evidence of the preferential adsorption of hydrogen on centres formed by three, four, or five metal atoms (centres of type *C*) is also provided by the results of an experimental study of the chemisorption of hydrogen by low-energy electron diffraction,[39–46] energy-loss spectroscopy,[40] and inelastic neutron spectroscopy,[46,47] which showed that best agreement between the experimental and calculated data on the change in the structure and electronic state of the metals during the chemisorption of hydrogen is observed when multicentre models of chemisorption ($H–M_n$) are used.

2. Model of the Dissociative Chemisorption of Hydrogen

Quantum-chemical calculations of the energy of interaction in an $H_2–M_n$ system (where M = Ni, Pt, Pd) make it possible to reach various conclusions about the mechanism of the dissociative chemisorption of hydrogen and to determine the reasons for the production and to predict the relative height of the energy barrier to rupture of the H–H bond.[12,14,18,22,48]

The interaction of the molecular orbitals of hydrogen with the molecular orbitals of an Ni_{13} cluster (adsorption at the centre of the crystallographic (111) face of an icosahedron) leads to an appreciable change in the electronic structure of the metal (Fig. 3). At the bottom of the 3*d* zone, a new band ϕ^* (−9.571 eV) appears, formed mainly by the contribution of the antibonding $1s\sigma_u$ state of hydrogen and the valence level of the metal, including an appreciable proportion of the *d* state. The production, in the valence zone of the cluster, of a level containing antibonding states of hydrogen, and the appreciable transfer of electrons to this level from the *d* zone of the metal (−0.19 e) leads to a significant decrease in the strength of the H–H bond and is responsible for the dissociation of the hydrogen molecule.[22]

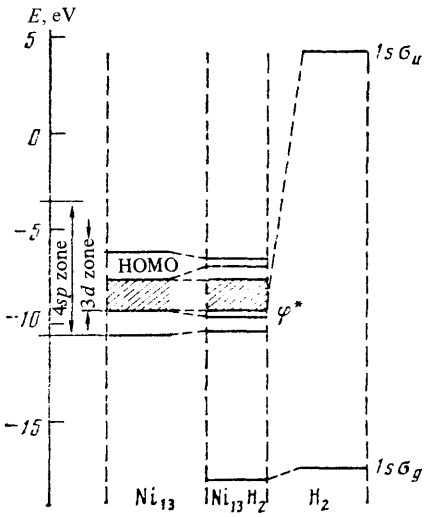

Figure 3. Schematic diagram of the interaction of the electron levels of the hydrogen molecule and an Ni_{13} cluster.[22]

A similar mechanism for the dissociation of molecular hydrogen in its adsorption on transition metals of the fourth period (Ti–Ni) was proposed[12] on the basis of MO LCAO calculations of the adsorption of a hydrogen molecule on a cluster formed by two metal atoms (M–M distance 2.5 Å). Since the hydrogen molecule does not have electron levels situated close to the 3*d* zone of the metal† (the magnitude of the 1*s*(H)–3*d*(Ni) overlap integral is ~0.1, whereas for 1*s*(H)–4*s*(Ni) it is ~0.5), the adsorption of molecular hydrogen takes place as a result of the donor–acceptor interaction of the occupied 1*s* orbital of hydrogen with the unoccupied bonding 4*s* orbitals of the metal.[12] The hydrogen molecule is positively charged.[12,27] The subsequent movement of the hydrogen molecule along the reaction coordinate (that is decrease in the H–M distance) is accompanied by the interaction of the antibonding 1*s* and 4*s* orbitals of the hydrogen molecule and the metal atom, leading to the formation of a new level in the valence zone of the $H_2–Ni_2$ cluster and the transfer of the 3*d* electrons of nickel to this level.[12]

The height of the energy barrier to the dissociation of molecular hydrogen is determined by the position of the 4*s* antibonding and 3*d* levels of the metal;[12] the higher these

†According to Ref. 22, the 3*d* zone of nickel in the Ni_{13} cluster lies in the energy range from −9.232 eV to −7.652 eV, and the *sp* zone in the range from −10.624 eV to −4.488 eV, whereas the bonding and antibonding levels of the hydrogen molecule have energies of −17.56 eV and 4.17 eV respectively.

levels on the energy scale, the more closely they approach the antibonding 1*s* levels of the hydrogen molecule, and hence the more readily the antibonding 1s(H) and 4s(M) states interact and the more readily the 3*d* electrons of the metal are transferred to the newly formed molecular orbital.

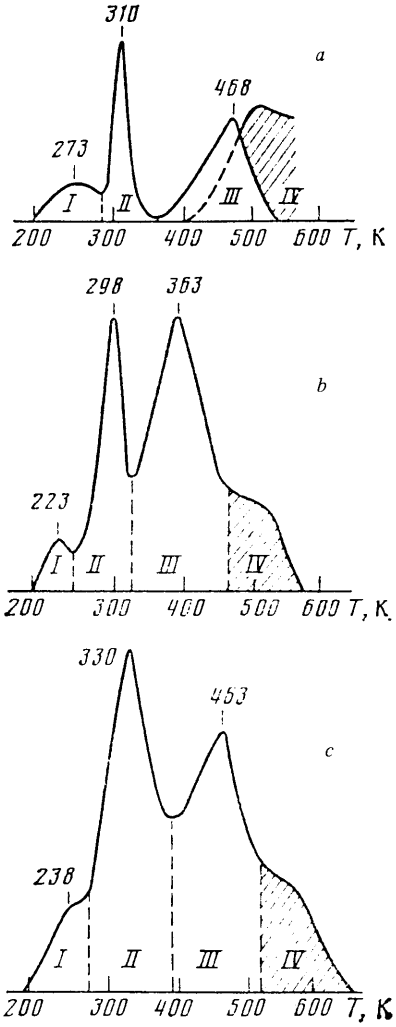

Figure 4. Spectra of the desorption of hydrogen from α-Fe (*a*), α-Co (*b*), and Ni (*c*) blacks (T_{ads} = 573 K);[50,52,54] *I,II,III*) forms of adsorbed hydrogen; *IV*) (hatched region) dissolved hydrogen.

Thus an analysis of theoretical and experimental studies of the mechanism of the chemisorption of hydrogen on transition metals of period IV shows that the adsorption of hydrogen takes place as a result of the interaction of the 1*s* states of the hydrogen molecule with the surface 4*sp* and 3*d* states of the metal atoms, with the preferential participation of the *sp* states. This interaction leads to the formation, in the valence zone of the metal, of a new level containing an appreciable proportion of the antibonding states of hydrogen and the 4*s* states of the metal, and to the transfer of the 3*d* electrons of the metal to this level, and hence to the dissociative chemisorption of hydrogen on the surface of the transition metals. The nature and strength of the H–M bond formed is determined by the extent of the participation of the 4*sp* and 3*d* states of the metal in the interaction; the greater the contribution of the *sp* states, the stronger the resulting H–M bond. The contribution of the *d* or *sp* states of the metals to the interaction in turn is determined by the electronic structure of the metal and the structure of the adsorbed complex.

The above data on the mechanism of the chemisorption of hydrogen on transition metals can be compared with the results of the study of the state of hydrogen in metal blacks of the iron sub-group (Fe, Co, Ni), obtained by temperature-programmed desorption.[49–54]# The reaction of hydrogen with these metals leads to the production of four forms of hydrogen, due to the existence of different types of adsorption complexes on the surface of the blacks studied (Fig.4). From the kinetics of the desorption, forms I and II were classified as molecular, and form III as an atomic form of chemisorption. The energetic uniformity of the most strongly bonded hydrogen of form IV, detected for Fe, Co, and Ni (the complete removal of the hydrogen of form IV under isothermal conditions at the temperature of the start of the desorption of the hydrogen of this form), together with published data on the solution of hydrogen in metals of the iron sub-group, made it possible to classify the hydrogen of form IV as hydrogen dissolved in the bulk of the metals studied;[50,53,54] the regular features of the solution of hydrogen will be examined in the next section.

A study of the distribution with respect to the activation energy of desorption of the hydrogen adsorbed in forms I, II, and III showed that part of the atomic hydrogen of form III (~40–50%) is characterised by similar values of the activation energy of desorption. The energetic uniformity of this fraction of the atomic hydrogen of form III on the surface of non-noble metals is due to the adsorption of hydrogen on centres of a single type (possibly one-centre adsorption), whereas the firmly bound and energetically less uniform fraction of the hydrogen of form III corresponds to the adsorption of hydrogen atoms on centres of different types (a multicentre bond of the form $H–M_n$, where n = 2, 3, 4, 5). Thus data on the state of hydrogen on the surface of non-noble metals (Fe, Co, Ni), obtained by thermal desorption, provide evidence of the greater strength of the multicentre $H–M_n$ bonds.

Comparison of the thermal desorption characteristics of hydrogen for the series Fe, Co, Ni (Table 2) shows that the strength of the bond produced by molecular forms of hydrogen tends to increase along the period; there is an increase in the temperature at which desorption is complete and in the proportion of molecular adsorption. The observed increase in the strength of the bond and increase in the proportion of molecular adsorption on going from Fe to Ni correlates with the change in the radius of the metal atoms along the period, leading to a downward displacement, on the energy scale, of the unoccupied bonding 4*s* levels of the metal, and to their maximum approach to the bonding 1*s* level of the hydrogen molecule. This last feature leads to a lowering of the energy barrier to the formation of the

#The Ni and Co black specimens studied were obtained by the reductive decomposition of the formates in a stream of H_2 at 573 K and 623 K. Fe black was prepared by decomposing iron nitrate and then reducing the oxides in H_2 at 773 K (30 h).

adsorbed complex H_2–M_n(Table 2).[12,18,26,27] The relative concentration and bond strength of the atomic adsorbed hydrogen on Fe, Co, and Ni blacks, on the other hand, decreases slightly from Fe to Ni (Fig.4 and Table 2). According to calculated data,[12,26,27] this may be due to an increase in the energy difference between the antibonding 1*s* level of hydrogen and the 4*s* antibonding and 3*d* levels of the metals involved in H–M bond formation, leading to an increase in the energy barrier to the dissociation of the hydrogen molecules (Table 2).

Notes: *r* is the atomic radius; $T_{end\ des.}$ the temperature of the end of the desorption of molecular hydrogen; [H_2] the fraction of molecular hydrogen; $E(H_2\text{–}M)$ the energy of the complex H_2–M; *l* the equilibrium length of the H_2–M bond; $E_{des.\ at}$ the activation energy of the desorption of the atomic hydrogen of form III; [H] the fraction of atomic hydrogen; and $E_{diss}(H_2\text{–}M)$ the dissociation energy of the complex H_2–M.

*Calculated data.

Thus the experimental data on the variety of forms and the change in the quantity and bond strength of molecular and atomic hydrogen in the series Fe, Co, Ni [49–57] agree with the results of quantum-chemical calculations on the chemisorption of hydrogen, taking account of the electronic structure of both hydrogen and the metals.[12,13,15–22,27,30,58]

III. SOLUTION OF HYDROGEN IN METALS

1. Dependence of the Solubility of Hydrogen on the Electronic Structure of Transition Metals

The study of the solubility of hydrogen in the metals of the iron sub-group (Fe, Co, Ni) is of considerable practical importance. A number of monographs and reviews have been devoted to the problem of the solution of hydrogen in massive specimens (films, membranes, wires, etc.),[59–65] but published data on the solubility of hydrogen in dispersed metals are few and contradictory.[66–70] Since Fe, Co, and Ni are used as catalysts mainly in the dispersed state, it is of interest to determine the quantitative characteristics of the solubility of hydrogen in these metal blacks.

The main regular features of the solution of hydrogen in transition metals can be examined first. In recent years, increasing attention has been paid to the search for correlations between the ability of transition metals to dissolve hydrogen and their electronic structure.[67–72] Attempts are being made to establish the relationship between the solubility of hydrogen and the difference in the electron densities of the metal and hydrogen,[73] the concentration of valence electrons,[73,74] the density of states on the Fermi surface of the metal,[74,75] etc.

The main regular features of the change in the structure of the valence zone of the 3*d* and 4*d* transition metals with increase in the number of hydrogen atoms introduced into the lattice are qualitatively similar, as shown by calculations of the electronic structures of the hydrides of these metals with the stoichiometric composition, containing hydrogen as the proton.[71,76] On going from the pure metal to the compound containing 5 at.% hydrogen in the bulk of the metal ($MH_{0.05}$), a new metal–hydrogen level is produced, which lies below the conductivity zone and which is formed by the *s* states of hydrogen and hybridised *s*–*d* states of the metal;[71,76] further increase in the hydrogen concentration in the bulk of the metal is accompanied by broadening of the metal–hydrogen level.[71] Comparison of the electronic structures of pure palladium and the palladium–hydrogen system[75] indicates that the Fermi level is displaced to higher energies; the density of states on the Fermi surface decreases considerably.

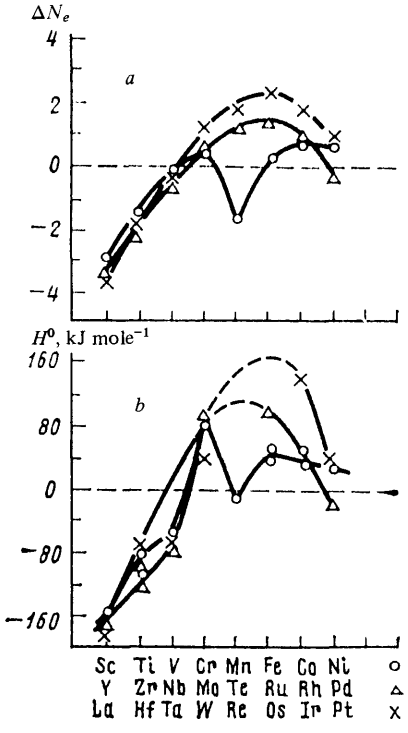

Figure 5. Change in the difference in the electron density ΔN_e on the metal and hydrogen atoms (*a*) and the heat of solution H^0 of hydrogen (*b*) along the 3*d*, 4*d*, and 5*d* periods[73] (the unit of density is ~6 × 10^{22} electron cm^{-1}).

Data obtained in calculations of the change in the electronic structure of transition metals during their saturation with hydrogen[71] have made it possible to estimate the heat of formation of the hydrides of 3*d* and 4*d* transition metals ΔE as the difference between the total energies of the zones of the

pure metal and compounds with different stoichiometric compositions. The stable hydrides of elements from the left-hand side of the fourth period (Sc, Ti, V) are formed with the liberation of considerable quantities of heat (from −40 kJ mole^{-1} to −200 kJ mole^{-1}). The formation of the products of the interaction of hydrogen with metals from the right-hand side of the period (Fe, Co, Ni, Cu; Fig.5*b*) is accompanied by the absorption of heat (from +40 kJ mole^{-1} to +90 kJ mole^{-1}).[71]

According to Ref.73, the transition metals which lie at the start of the 3*d* and 5*d* periods and which have a lower electron density than that on the hydrogen atom are also capable of dissolving hydrogen exothermally to give stable hydrides (Figs.5*a* and 5*b*). Metals with a higher electron density than that on the hydrogen atom dissolve only small quantities of hydrogen, with the absorption of heat (Figs.5*a* and 5*b*).[73]

According to Ref.74, depending on their position in the periodic system, the transition metals can be divided into two groups differing in the influence of dissolved hydrogen on the strength of the bonds formed by the atoms in the metal lattice: 1) metals whose *d* level is less than half filled; and 2) metals containing more than six valence electrons.

The introduction of the 1*s* electron of the hydrogen atom into the electron zone of metals of the first type increases the strength of the bond formed by the atoms in the lattice, leading to the formation of stable hydrides [60,71,73] (the metals of sub-groups III–V of the periodic system); the strength of the bond between the atoms in the lattice of metals of the second type (the transition metals of sub-groups VI–VIII) decreases when the 1*s* electron of the hydrogen atom is introduced (hydrogen brittleness). According to the Engel–Brewer theory,[77,78] this influence of dissolved hydrogen on the strength of the bond formed by the metal atoms in the crystal lattice is due to a change in the number of unpaired *d* electrons in the transition metals. The additional 1*s* electron of the hydrogen atom increases the number of unpaired electrons in metals whose valence zone is less than half filled, leading to an increase in the strength of the bond between the atoms in the lattice. For metals of the second type, whose outer level contains more than six electrons, the 1*s* electron of the hydrogen atom lowers the total number of unpaired electrons, leading to a decrease in the strength of the M–M bond in the crystal.

The dependence of the quantity of dissolved hydrogen on the number of unpaired *d* electrons in the outer level of the metal atom is clearly observed for transition metals with a small number of *d* electrons (d^2–d^4; Ti, Zr, V, La, Hf, etc.); the element with the smallest number of *d* electrons corresponds to the highest solubility of hydrogen and the greatest increase in the strength of the M–M bond.[74]

For metals with a valence level which is more than half filled (Fe, Co, Ni, Ru, Rh, Pd, etc.), best agreement between the calculated and experimental data on the extent of the solution of hydrogen is obtained using a model which relates the ability to dissolve hydrogen to the density of states on the Fermi surface of the given metal;[74] a higher density of states (Fig.6*a*) corresponds to a greater ability to dissolve hydrogen. These models have been used[74] to calculate the magnitude of the change in the strength of the M–M bond when the 1*s* electron of the hydrogen atom is introduced into the valence zone of the metal. The introduction of the additional electron increases the strength of the Ti lattice (ground state $3d^24s^2$) by 7.1%, whereas the bond between the atoms in the Ni lattice (ground state $3d^84s^2$) is weakened by 8.57%.

Comparison of calculated data on the extent of the disordering of metal lattices when hydrogen is absorbed[74] (Fig.6*b*) with the heats of solution of hydrogen[73] (Fig.5*b*) shows a distinct correlation between these quantities: the greater the decrease in the strength of the interaction between the metal atoms when the 1*s* electron of hydrogen is introduced (Fig.6*b*), the greater the endothermic effect of solution (Fig.5*b*).

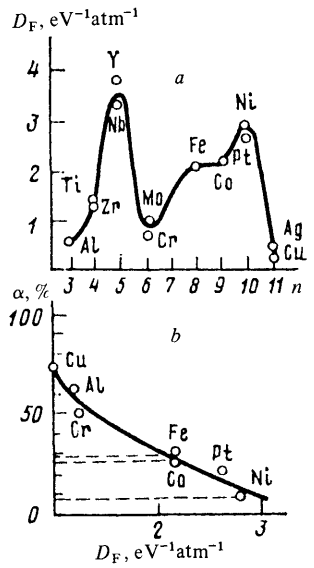

Figure 6. Density of states D_F on the Fermi surface (*a*) and extent of the disordering of the lattice α for 3*d* transition metals when hydrogen is dissolved in them (*b*) [74] (*n* is the number of electrons in the outer levels).

2. Influence of the State of the Surface on the Extent of the Penetration of Hydrogen into Metal Lattices

A significant unsatisfactory feature of theoretical methods for studying the solution of hydrogen by transition metals is the fact that no account is taken of the contribution of processes taking place on the metal surface during the solution of hydrogen. The absorption of hydrogen by the bulk of the metal is a complex multistage process, involving the adsorption and dissociation of the hydrogen molecule, the penetration of hydrogen atoms into the bulk, and diffusion in the volume of the metal.[59,61,63] Calculations[79] have shown that for metals characterised by an exothermic effect for the solution of hydrogen, the heat liberated during adsorption is sufficient for the penetration of the hydrogen atom into the bulk of the metal.

When hydrogen dissolves in metals for which this process is endothermic (Fe, Co, Ni), the heat liberated during the adsorption of hydrogen is insufficient for the penetration of the hydrogen atom into the bulk of the metal; penetration can take place only at high temperatures, when the adsorbed hydrogen atom acquires sufficient energy to overcome the energy barrier to penetration into the bulk of the metal.[79]

Analysis of the influence of various factors on the rates of the processes taking place on the surface of iron, nickel, and other transition metals during the solution of hydrogen in them[61] shows that change in the extent of the defect character (disperse nature) of the surface (plastic deformation,

the application of strokes, scratches, polishing, sintering at high temperatures[80-83]), its chemical composition (surface coatings[81,84,85]), or temperature[62,80,86-90] leads to a considerable change in the rate of penetration of H atoms into the bulk.

The rate of the penetration of hydrogen atoms into the bulk (ν) at high temperatures (>670 K) obeys the law $\nu \sim p^{1/2}$ (where p is the hydrogen pressure), indicating that solution is preceded by dissociation of the hydrogen molecule.[59,63,64] At temperatures <670 K, deviation from the $\nu \sim p^{1/2}$ relationship is observed, and the kinetic curves show inflections in the temperature range ~470–670 K [61,62,80,86-90] (Figs.7 and 8). According to Ref.61, the existence of the inflection is due to a change in the mechanism of solution; at temperatures <670 K (before the inflection), the surface reactions involving the dissociation of molecular (or the recombination of atomic) hydrogen take place at slow rates, that is they determine the rate of penetration; the activation energy of the penetration of hydrogen in this temperature range is high (107.0 kJ mole^{-1} for Fe). At temperatures >670 K (after the inflection), when the surface reactions take place readily and do not limit the rate of penetration of hydrogen, the activation energy of this process is only 37.6 kJ mole^{-1} (Fe) and practically coincides with the activation energy of diffusion.[87]

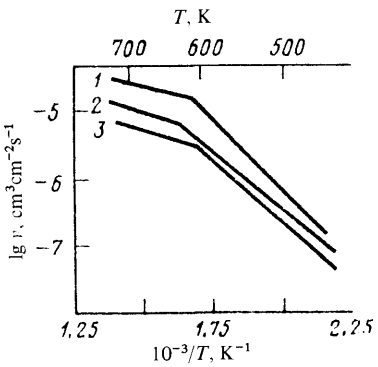

Figure 7. Temperature dependence of the rate of penetration of hydrogen V through iron membranes of different thickness l:[87] 1) l = 0.25 mm, 2) l = 0.5 mm, 3) l = 1.0 mm.

The role of the atomisation of molecular hydrogen in the process of solution in metals has been clearly demonstrated in a study of the permeability of a nickel membrane for deuterium previously ionised under gas-discharge conditions and for deuterium from the molecular state.[88] For the ionised deuterium, the temperature dependence of the rate of penetration (Fig.8) does not show an inflection (curve *1* in Fig.8), whereas for the non-ionised deuterium, at temperatures >630 K, as in Ref.87, a change in the rate of penetration of deuterium atoms into the bulk of the metals takes place (an inflection is observed; curve *2* in Fig.8). The activation energy of the penetration of deuterium is 61 kJ mole^{-1} at T < 630 K, and 10.5 kJ mole^{-1} at T > 630 K.[88]

The position of the point of inflection on the curve giving the temperature dependence of the rate of penetration of hydrogen depends markedly on the extent of the defect character (disperse nature) of the metal surface;[61,80-83,91] with change in the surface structure of the specimen, for example as a result of plastic deformation,[80] the inflection (~660 K) is displaced to higher temperatures (~790 K).

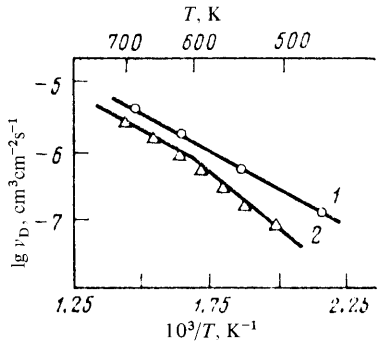

Figure 8. Temperature dependence of the rate of penetration of deuterium ν_D through a nickel membrane under gas-discharge conditions (*1*) and from the molecular phase (*2*).[88]

Change in the chemical composition of the surface layer of the specimen is also reflected in the rate of penetration of hydrogen into the bulk of the metal.[81,84,85] Covering an iron membrane with a thin layer of palladium[81] or other materials highly active in the atomisation of hydrogen (Ni and Pd blacks) leads to a marked increase in the rate of the penetration of hydrogen, whereas layers of Cu or Ag on an iron membrane surface decrease the magnitude of the hydrogen flux.[84] The application of thin coatings changes the electronic structure of metal surfaces, leading to an increase or a decrease in the rate of the dissociation or recombination of hydrogen;[61] for example, a gold membrane, which is practically impermeable to hydrogen, begins to allow it to pass freely if its inner surface is covered with a thin layer of nickel (thickness ~1 × 10^{-5} cm).[85]

Thus the dissolution of hydrogen in metals at temperatures <670 K is limited by surface reactions (adsorption, dissociation; recombination, desorption). The deviation of the values of the rate of penetration from the $\nu \sim p^{1/2}$ law at T < 670 K has been related[61] to a decrease in the number of active centres on the surface with decrease in the degree of dispersion of the metal, to the shielding action of surface impurities inactive with respect to the dissociation of hydrogen, and to the presence on the surface of chemisorbed hydrogen which does not have a sufficient reserve of energy for penetration into the metal lattice.[61]

The decrease in the rate of the stage involving the recombination of atomic hydrogen (or the dissociation of molecular hydrogen on the surface of nickel films, accompanied by an increase in the activation energy of the process at low temperatures, has been attributed[62,92] to the formation of a nickel hydride β-phase, whose catalytic activity in the recombination of atomic hydrogen is ~3 times lower than that of pure nickel.[92,93] Calculation of the standard free energy (G^0) of the H–M system for the reaction

$$4M + H_2 \rightarrow 2M_2H$$
$$M = Ni, Pd$$

has shown, however, that the formation of nickel hydrides at atmospheric pressure and relatively low temperatures is thermodynamically unlikely, since under these conditions the

value of G^0 for the NiH system is +23.6 kJ mole^{-1}, whereas for the formation of stable hydrides PdH, $G^0 = -11.8$ kJ mole^{-1}.

The preparation of stable hydrides of iron, cobalt, and nickel by the direct reaction of the metal with hydrogen is possible only under extremely severe conditions, at hydrogen pressures >10–20 thousand atm and temperatures >500 K.[62, 65,94] A study of the solubility of hydrogen in palladium and nickel, carried out using calculation methods,[95] showed that the formation of stoichiometric nickel hydrides (H/Ni = 1) is possible at hydrogen pressures not less than 28 thousand atm.

The study by various modern methods (X-ray diffraction, NMR, magnetic methods, etc.) of the state of hydrogen in the volume of metals which absorb it endothermally has indicated that the hydrogen atom transfers the 1*s* electron to the unfilled *d* zone of the metal, and is present in the lattice as a proton.[59,60,63,79,97] According to calculations,[96] the effective charge of the hydrogen atom is +0.45 e in the Pd lattice, +0.53 e for Ni, and +0.26 e for Fe.

There are at present two widely encountered views on the equilibrium position of a hydrogen atom introduced into a metal lattice. The authors of Refs.63 and 98, who used the precision method of secondary X-ray spectra to study the state of iron saturated with hydrogen, concluded that the hydrogen endothermally absorbed by the metal is present as a proton, inserted into the electron cloud of the metal atoms ("proton gas"). On the other hand, the theoretical calculation of the equilibrium positions of hydrogen atoms in metals which crystallise with a face-centred cubic lattice shows that in a structure of this type, the particles introduced occupy octahedral vacancies.[99,100] Experimental neutron diffraction studies of the structure of the products of the reaction of palladium and nickel with hydrogen also indicate that the protons occupy octahedral positions in the f.c.c. lattice.[101,102]

Calculation of the positions of hydrogen atoms introduced into the body-centred cubic lattice of α-Fe, Ta, V, and Nb [103] showed that in α-Fe the hydrogen atoms occupy only octahedral positions, in Ta and Nb the hydrogen can occupy octahedral and tetrahedral positions, and in V it occupies only tetrahedral lattice positions.

It is of considerable interest to identify the surface active centres by means of which the hydrogen atoms penetrate into the metal lattice. Kinetic and thermodynamic calculations[104,105] have shown that for metals which dissolve hydrogen exothermally (for example Pd), the heat of the adsorption of hydrogen on the centres responsible for its solution should not exceed ~68 kJ g-atom^{-1}, so that more firmly bound forms of chemisorption cannot be in equilibrium with absorbed hydrogen.[104] Experimental confirmation of the suggestion that hydrogen penetrates into the bulk of palladium via centres which chemisorb hydrogen with a relatively low bond energy is provided by data obtained by thermal desorption.[79, 106,107] The first portions of hydrogen are adsorbed on a Pd wire (104–306 K) on centres with a high M–H bond energy (heat of adsorption 60–120 kJ g-atom^{-1}); solution of hydrogen does not take place. Dissolved hydrogen appears in the desorption spectrum only when hydrogen covers the regions of the surface with a low heat of chemisorption (30–60 kJ g-atom^{-1}) (this is the low-temperature range of hydrogen desorption, characterised by a high energetic uniformity).

The authors of Ref.106, who used a micro-gravimetric method to study the kinetics of the sorption and desorption of hydrogen, concluded that the penetration of hydrogen into the palladium lattice takes place via regions which adsorb weakly bound forms of hydrogen (heat of adsorption 7 kJ g-atom^{-1}). Calculation of the thermal effects of all stages of the sorption of hydrogen showed that the movement of hydrogen from the state preceding the penetration of hydrogen into the bulk of palladium is energetically more favourable (activation energy of absorption 15 kJ g-atom^{-1}) than its migration along the surface to centres with a high heat of adsorption (activation energy of migration 55 kJ g-atom^{-1}).[106]

The conclusion that the desorption of absorbed hydrogen takes place via adsorption centres with a low hydrogen–metal bond energy was also previously reached for dispersed Pd,[107] Ta, and W.[108]

The solution of hydrogen in dispersed Fe, Co, and Ni was studied by temperature-programmed desorption[49,50,53,54] to determine the temperatures of the start of the solution and the removal of dissolved hydrogen from the bulk of metals; to differentiate adsorbed and dissolved forms of hydrogen according to the temperature ranges and activation energies of desorption; to estimate quantitatively their concentrations in the metals; and to study the influence of the surface adsorbed forms on the removal of hydrogen from the lattices of these metals.

Dissolved hydrogen appears in α-Fe black at $473 < T \lesssim 573$ K, in α-Co black at 373–423 K, and in Ni black at 298 to 373 K, that is on going from one metal to another along this triad, the temperature of the start of the solution (curve *3* in Fig.9) and the activation barrier to this process decrease; E_{abs} for α-Co black is 18 kJ mole^{-1},[52] whereas for Ni black this energy is 2.5 kJ mole^{-1}.[50] In accordance with the model relating the solubility of hydrogen in transition metals to their electronic structure,[74] the minimum heats of the endothermic solution are observed for metals which have the maximum density of states on the Fermi surface. For nickel, which has the highest density of states on the Fermi surface (curve *1* in Fig.9) and the lowest heat of solution (curve *2* in Fig.9), the absorption of hydrogen requires the minimum expenditure of energy compared with Fe and Co (curve *3* in Fig.9).

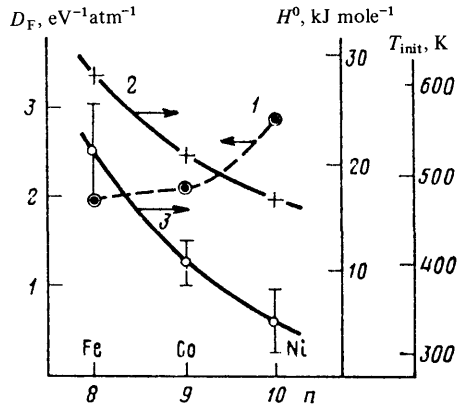

Figure 9. Correlation between the heat of solution H^0 (*2*),[73] the temperature of the start of the solution of hydrogen T_{init} (*3*),[53,54] and the density of states on the Fermi surface D_F (*1*)[74] for the metals of the first triad of Group VIII of the periodic system (n is the number of outer electrons).

Comparison of the solubility of hydrogen in α-Fe, α-Co, and Ni blacks shows that the absorption capacity of α-Fe black with respect to hydrogen is 10^3 times greater than that

for α-Co and Ni blacks; the ratio of the number of hydrogen atoms absorbed by the metal to the total number of metal atoms in the specimen is ~1 for α-Fe black, 1.7×10^{-3} for α-Co black, and 1.4×10^{-3} for Ni black. The sharp decrease in the quantity of dissolved hydrogen in the order Fe > Co > Ni is evidently also due to differences in the electronic structures of the metals. The solubility of hydrogen is higher, and the solution takes place with an exothermic effect, in those transition metals on whose atoms the electron density is lower than that on hydrogen atoms.[73] In metals which dissolve hydrogen with an endothermic effect, the electron density on the metal atoms is generally higher than that on hydrogen atoms.[73] For iron, however, the difference in the electron density on the Fe and hydrogen atoms is much lower than that for Co and Ni (see Fig.6a), and this is apparently responsible for the higher solubility of hydrogen in iron. The high absorption capacity of α-Fe with respect to hydrogen (specimen saturation temperature 773 K) is quantitatively comparable with that of Pd [1,2,8,107,109,110] (saturation temperature ~298 K), in good agreement with the similarity in the values of the electron density on the α-Fe and Pd atoms.[73]

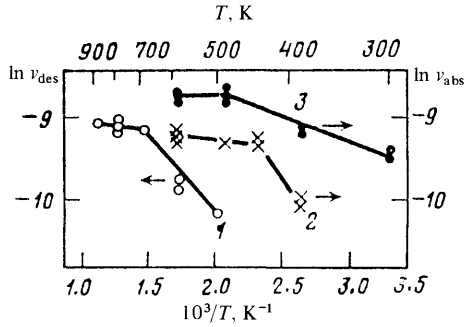

Figure 10. Temperature dependence of the rate of desorption of dissolved hydrogen from α-Fe black (*1*) and the rate of adsorption of hydrogen by α-Co (*2*) and Ni (*3*) blacks.[52,54]

In the determination of the activation energy of the desorption or absorption of dissolved hydrogen, the curves giving the temperature dependence of the rate of desorption (α-Fe black, Fig.10) [53,54] or absorption of hydrogen (α-Co and Ni blacks, Fig.10, see Ref.111 for the method of calculation) showed inflections at temperatures of 673 K for α-Fe, 423 K for α-Co, and 473 K for Ni. At low temperatures (before the inflection), the activation energy for the desorption of hydrogen from α-Fe black is 14.6 kJ $mole^{-1}$; E_{abs} for hydrogen for α-Co and Ni blacks is 18.0 kJ $mole^{-1}$ and 2.5 kJ $mole^{-1}$ respectively. At high temperatures (after the inflection), the slope of the straight lines decreases, and the values of E_{des} and E_{abs} indicate that the processes take place with practically no activation barrier; E_{des} for α-Fe black is 2.5 kJ $mole^{-1}$, and E_{abs} has the values ~0.4 kJ $mole^{-1}$ and <0.1 kJ $mole^{-1}$ for α-Co and Ni blacks respectively. Comparison of the temperatures of the liberation of adsorbed (Fig.4) and dissolved (Fig.4 and curve *3* in Fig.9) forms of hydrogen from α-Fe, α-Co, and Ni blacks indicates that the absorption or desorption of dissolved hydrogen with low activation energies takes place at a temperature above that corresponding to the complete removal of adsorbed forms of hydrogen from the surface.[49-54]

Data on the temperature boundaries of the liberation of adsorbed and dissolved forms of hydrogen and the start of the desorption and solution of hydrogen in the bulk of Fe, Co, and Ni blacks, which dissolve hydrogen endothermally (Figs.4 and 9), indicate that, in contrast to metals which dissolve hydrogen exothermally (Pd, Ta, W),[105-108] the removal of hydrogen dissolved in Fe, Co, and Ni takes place on the sections of the surface which chemisorb firmly bound forms of hydrogen.

Thus the systematic study of the processes involved in the chemisorption of hydrogen for metal blacks of the iron subgroup has revealed the regular features of the change in the strength of the bonds formed by atomic and molecular hydrogen, and also the absorption power of the blacks, and has made it possible to relate these characteristics to the positions of the metals in the periodic system. The data obtained on the concentration, forms, and bond energies (E_{des}) of hydrogen, which is one of the components of catalytic processes, can be used to develop active catalytic systems and to determine their mechanism of action.

Moreover, the quantitative characteristics obtained for the desorption of dissolved hydrogen from dispersed Fe, Co, and Ni may be useful in the development of processes preventing the corrosion breakdown of these metals.

Complexes of Molecular Oxygen with Organic Molecules

A.L.Buchachenko

Molecular oxygen forms complexes with organic molecules. Evidence for such complex formation and its manifestations are described and criteria are formulated whereby one can distinguish the usual equilibrium complexes from impact (collision) complexes. The principal types of complexes and the electron orbitals with the aid of which the species combined in the complex come into contact are examined.
The bibliography includes 30 references.

I. INTRODUCTION

Molecular oxygen is a participant in an enormous number of physical and chemical processes. The question whether it reacts as a free molecule or whether its reactions are preceded by some kind of interaction, physical or "semichemical", with the other reactants or with other molecules is important for the chemistry of oxidation processes (where the involvement of oxygen in the initiation of thermal and photochemical oxidation is important), for the photonics of molecules (where oxygen participates in the quenching of electronically excited states, energy transfer, and sensitisation), and for the optical properties and the chemistry of the atmosphere (photochemical reactions of oxygen, the change in the transparency of the atmosphere as a result of the optical absorption by the possible oxygen complexes, etc.)

This review discusses the following question: in what state is molecular oxygen present in organic liquids and does it interact with organic molecules and how does such interaction take place—via the formation of "normal", equilibrium complexes or in contact pairs where the overlap of the electron shells of the reacting species takes place only at the instant of contact between them on collision (this state of the pair is sometimes referred to as an impact or collision complex). The spectroscopic manifestations (in electronic and magnetic resonance spectroscopy), which permit conclusions concerning the nature of the oxygen complexes and about the electron orbitals involved in complex formation, are examined: the chemical manifestations and chemical consequences of the complex formation reactions of oxygen and of its solvation by organic molecules are discussed.

II. ELECTRONIC SPECTROSCOPY AND NMR OF THE OXYGEN COMPLEXES

The manifestations of the formation of complexes between molecular oxygen and organic molecules were first observed by electronic spectroscopy. Evans[1,2] was the first to observe a marked increase of the intensity of the bands corresponding to the forbidden S_0-T_1 transition in the absorption spectra of aromatic hydrocarbons under the influence of dissolved oxygen. It was shown that the vibrational structures of these bands and of the phosphorescence spectra of the hydrocarbons are identical: even the positions of the 0–0 transitions coincide. Both these findings demonstrate reliably that oxygen induces the removal of the spin prohibition of the electronic transitions in many aromatic molecules:[3] it is also clear that the removal of the spin prohibition requires contact between the molecules and the merging of the electron clouds of the molecules of O_2 and the other reactant.

Another manifestation of the complex formation is the appearance of a new structureless absorption band at $\lambda \geq 300$ nm, which is attributed to the complex of O_2 with an aromatic molecule and is believed to be a charge-transfer band. For benzene, $\varepsilon_{max} \cong 900$ at the maximum of this band, while $\varepsilon_{max} \cong 0.4$ for the S_0-T_1 band.[3] Such bands have also been observed for many other compounds—alcohols, ethers, and saturated hydrocarbons. A band at 340 nm has been observed for the O_2 + naphthalene system and has been interpreted as one corresponding to the simultaneous electronic transition of the O_2 molecule to an excited singlet state and of the naphthalene molecule to a triplet state with retention of the overall spin and energy.[3] All these features indicate the occurrence of an interaction of the O_2–organic molecule pair which entails the merging of the electron clouds of the reacting species. The state of the pair in which this interaction takes place is short-lived and the interaction itself is apparently weak.

The nature of the complexes remains obscure. It has been suggested that the species combined in the complex are linked by van der Waals forces, but this conflicts with the spectroscopic characteristics of the complex formation. It is also not confirmed by measurements of the nuclear paramagnetic relaxation of ethylene and ethane in the gas phase in the presence of O_2:[4] the marked difference between the polarisabilities of these molecules is in no way manifested in the nuclear relaxation, which rules out any serious contribution by the van der Waals interaction.

Razuvaev and co-workers used the phenomenon of the quenching of the luminescence of excited molecules by oxygen to investigate the interaction of the latter with organoelemental compounds.[5–8]. It is known that oxygen quenches excited states in both gaseous and liquid phases with a high efficiency and this fact also indicates the occurrence of an interaction between the electron clouds of the oxygen and

excited molecules†. It is most probable that the complexes formed under these conditions are of the donor–acceptor type in which the reacting species are combined via specific orbitals with formation of "semichemical" bonds between them. A partial charge transfer between the species apparently takes place in such a complex but the question whether this state is a collision complex or a normal, equilibrium complex cannot be resolved unambiguously solely from electronic spectroscopic evidence.

Razuvaev and co-workers measured the luminescence intensity of solutions of organoelemental molecules in hexane frozen at 77 K and compared such intensities with solutions containing oxygen and deoxygenated solutions. In the presence of oxygen the intensity of the luminescence of the molecules falls markedly. If it is assumed that the O_2 complexes do exist and that they do not luminesce, it is easy to derive a relation between the luminescence intensity in the presence of oxygen (I) and in its absence (I_0) and the concentration (or pressure) of oxygen:

$$I_0/I = 1 + K[O_2]; \; I_0/I = 1 + K\gamma p_{O_2} \quad , \qquad (1)$$

where γ is the Henry constant for the solubility of oxygen (the authors adopted $\gamma = 1.5 \times 10^{-2}$ mol litre^{-1} atm^{-1} for hexane) and K is the complex formation equilibrium constant for the organic molecule M:

$$M + O_2 \overset{K}{\rightleftarrows} M \cdot O_2 \quad .$$

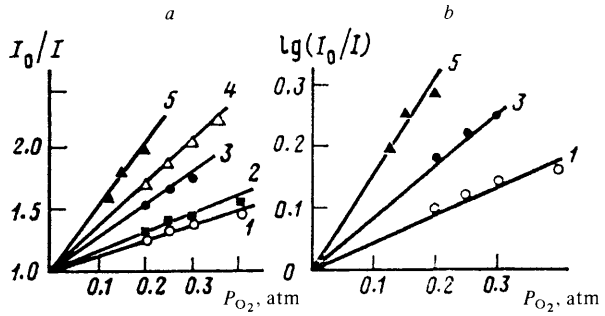

Figure 1. Dependence of the intensity of the fluorescence of organoelemental molecules on the oxygen pressure in terms of the variables of Eqns.(1) (*a*) and (2) (*b*): 1) Ph_4Si; 2) Ph_4Ge; 3) Ph_4Sn; 4) Ph_3SiH; 5) Ph_4Pb.[6]

†In order to avoid the quenching effect of oxygen in liquid solutions, prolonged evacuation of the latter (up to several days) is required. This fact is frequently accounted for by the existence of stable long-lived oxygen complexes. As will be shown below, this view is in all probability erroneous; the long duration of the quenching effect of oxygen is apparently associated with the presence of other quenching agents—comparatively stable intermediate oxidation products, which gradually decompose in the absence of oxygen (on evacuation). These products are sometimes stable and it is then altogether impossible to eliminate fully the quenching effect by evacuation.

Eqns.(1) resemble in their form the familiar Stern–Volmer equation and are indeed valid (Fig.1). The equilibrium constants K have been obtained from them. For the compounds Ph_3E (E = P, As, Sb, or Bi), Ph_4E (E = C, Si, Ge, Pb, or Sn), Ph_3SiH, Ph_3GeH, $(CH_3)_4Sn$, etc., the measured constants K are in the range 90–400 litre mol^{-1}; they are higher for Ph_3N (650 litre mol^{-1}) and for the compound $PhGeH_3$, we have K = 2000 litre mol^{-1}.[6] For organomercury compounds of the type Ph_2Hg, $(C_6F_5)_2Hg$, PhHgCl, $PhHgCCl_3$, etc., the constants K are in the range 250–500 litre mol^{-1};[6] the constants for organoelemental phenols are listed in Table 1.

The experimental technique used to measure the complex formation constants on the basis of the quenching of the luminescence is simple and convenient, but one must be sure that the equilibrium $M + O_2 \rightleftharpoons M.O_2$ is attained at 77 K. On freezing, the diffusion of oxygen is greatly retarded (particularly in a solid solution) and at 77 K there is therefore a possibility that the equilibrium corresponding to a higher temperature becomes "frozen". In other words, at 77 K the $M + O_2$ system may not be at equilibrium. Furthermore, the method presupposes a homogeneous distribution of both oxygen and the luminescing molecules in the solid solution, which necessitates certain precautions when this method is employed.

Table 1. The equilibrium constant for the oxygen complexes of phenols (77 K).[6]

Phenol	K, litre mol^{-1}	Phenol	K, litre mol^{-1}
	300		270
	350		280
	280		380
	300	—	—

Another feature of the luminescence method for the measurement of the equilibrium constant is that one must rule out the possibility of the static quenching of the luminescence of the molecules by oxygen via the Perren mechanism. The static quenching presupposes that there is a sphere with a radius r around the O_2 molecule within which the luminescence of the molecules is quenched, while outside it no quenching takes place. This quenching mechanism is referred to as the inductive-resonance mechanism; it gives rise to the following relation between the luminescence intensity and the

oxygen concentration c:

$$I_0/I = \exp(\alpha c), \quad (2)$$

where $c = \gamma p_{O_2}$ (mol litre^{-1}) and $\alpha = {}^4/_3\pi r^3 N_A$ (litre mol^{-1}) the overall volume of the quenching spheres (here r is expressed in dm and N_A is the Avogadro number). In terms of the variables of Eqn.(2), the dependence of $\lg(I_0/I)$ on c should be represented by a straight line, from the slope of which it is possible to determine the radius of the quenching sphere r. Fig.1*b* illustrates such relations for certain data taken from Fig.1*a*. Evidently Eqn.(2) sometimes holds just as satisfactorily as Eqn.(1) and in order to distinguish them it is necessary to make measurements over a wider range of concentrations of the quenching agent (oxygen). Only then is it possible to establish whether the decrease in the luminescence intensity is caused by complex formation or by the static oxygen quenching.

It has been shown[9] that oxygen in the presence of benzene does not influence the intensity of the luminescence of organoelemental compounds, i.e. O_2 does not behave as a quenching agent under these conditions. This is an important fact, which implies, firstly, that benzene molecules also form complexes with O_2, competing with the molecules of the organoelemental compounds for oxygen, and, secondly, that the oxygen attached to the benzene molecule is incapable of combining with the molecules of the organoelemental compounds and of quenching their luminescence. These results also demonstrate that the luminescence quenching method used[5-9] to analyse the complex formation by molecular oxygen is apparently not complicated by static quenching processes and that the quenching itself is of the exchange-resonance type, determined by the contact between the electron clouds of the reacting species (as in the analogous processes involving quenching by oxygen in gases and liquids).

Thus electronic spectroscopy reveals a number of features indicating a definite interaction of oxygen with organic molecules: the change in the intensity of the electronic transitions, the removal of spin prohibitions, the appearance of new bands in the electronic absorption spectrum, and the quenching of excited states by oxygen. There exist also arguments in support of the view that this interaction cannot be reduced solely to the universal van der Waals interaction and that it has a specific donor–acceptor character. However, electronic spectroscopy cannot yield more definite information about the nature and dynamics of this interaction; more unambiguous results are provided by NMR spectroscopy.

The oxygen molecule has two π-electron systems in two perpendicular planes passing through its D_{∞},h axis. Each of the π-electron systems incorporates three electrons, two of which form an unshared pair, while the third is a single, unpaired electron.[10] The O_2 molecule has a triplet ground state, i.e. the spins of the two single electrons are added together to give an overall spin $S = 1$. The energy of the magnetic dipole interaction of the single electrons is 33000 G and the spin–lattice relaxation time of the electrons is very short, amounting to approximately 50 μs at 1.5 K and $\lesssim 10^{-12}$ s at 300 K.

If the oxygen in the liquid is not in the free state and is partly linked to other molecules, forming complexes with the latter (so far it is immaterial whether these are the usual or collision complexes), then such interaction is inevitably accompanied by the merging of the electron clouds of the reacting species and the partial transfer of the unpaired electrons of the oxygen to the other species—the ligand. The appearance of an unpaired electron in the organic molecule (in both the usual and collision complexes) creates a local magnetic field at the nuclei and induces a line shift in the NMR spectrum of this molecule (it is referred to as the paramagnetic shift). The local magnetic field of the unpaired electron at the ligand nucleus periodically appears and vanishes because the complex is periodically formed and decomposes; each time the orientation of the unpaired electron and hence the direction of the local magnetic field which it generates at the ligand nucleus is random. This leads to the partial averaging of the local magnetic field. Furthermore, such averaging occurs also in the complex itself if the electron relaxation (the reorientation of the electron spin) is rapid. For oxygen complexes, the averaging of the local field of the electron at the ligand nucleus takes place via both mechanisms—via both the formation and decomposition of the complexes and as a result of the short electron relaxation time ($\lesssim 10^{-12}$ s). As a result of the averaging process, the paramagnetic shift of the NMR signal of the ligand in the complex is given by[11]

$$\Delta_0 = \delta_L - \delta_0 = -a\left(\frac{\gamma_e}{\gamma_n}\right)\frac{\gamma_e S(S+1)H_0}{3kT} = -a\alpha, \quad (3)$$

where δ_0 is the position of the NMR peak of the free molecule [in parts per million (p.p.m.)], δ_L is the position of the same peak in the spectrum of the complex, i.e. when the molecule becomes a ligand, γ_e and γ_n are the gyromagnetic ratios for the electron and the nucleus, H_0 is the external magnetic field strength, S the spin of the paramagnetic species (for oxygen, $S = 1$), and a the electron–nucleus (hyperfine) interaction (HFI) constant characterising the local magnetic field of the electron at the ligand nucleus. The parameter α is defined by Eqn.(3), is temperature dependent, and can be readily calculated; in particular $\alpha = 200$ p.p.m. G^{-1} for protons at 26 °C, for the ^{19}F nuclei at the same temperature, we have $\alpha = 211$ p.p.m. G^{-1}, while at 40 °C $\alpha = 202$ p.p.m. G^{-1}.

The paramagnetic peak shifts in the NMR spectra of organic molecules in the presence of oxygen are an unambiguous and reliable manifestation of complex formation by oxygen—a manifestation of the combination of the electron clouds of the oxygen and organic molecules. The magnitude and direction of the paramagnetic shift depend on the sign of the HFI constant involving the ligand nucleus in the complex. The sign of the HFI constant demonstrates the mechanism whereby the unpaired electron is transferred in the complex from oxygen to the ligand and in which orbitals it is located, while the magnitude of the constant determines the density of the unpaired electron transferred from oxygen to the s shell of the ligand atoms. It is linked to the spin density $\rho(0)$ in the s shell of the atom by the familiar Fermi relation:

$$a = ({}^8/_3)\pi\gamma_e\gamma_n\rho(0). \quad (4)$$

The NMR method makes it possible to solve also another important problem—namely that of the complexes (of the usual or collision types) in which the paramagnetic shifts arise. If the usual complexes are formed and the complex formation equilibrium

$$M + O_2 \overset{K}{\rightleftarrows} M \cdot O_2 \quad (I)$$

is established, as a result of which the organic molecule M is periodically either in a free state, or in the complex $M.O_2$ then the paramagnetic shift Δ of the NMR peak observed experimentally is defined by the equation[11]

$$\Delta = \delta - \delta_0 = \Delta_0 p_L, \quad (5)$$

where p_L is the mole fraction of the complex $M.O_2$. Here δ_0 is, as before, the position of the NMR peak in the spectrum of the free molecule and δ is its position in the presence of

oxygen:

$$\delta = \delta_0 p_0 + \delta_L p_L \ . \qquad (6)$$

Condition (6) describes the averaging of the position of the NMR peak due to the rapid exchange of the molecule between the two states (the free molecule and the ligand in the complex with oxygen), whose mole fractions are p_0 and p_L respectively. Eqn.(5) is obtained taking into account Eqn.(6) and the self-evident normalisation condition $p_0 + p_L = 1$.

After determining p_L on the basis of equilibrium (I), i.e.

$$p_L = \frac{K[O_2]_0}{1 + K[M]_0} \qquad (7)$$

and substituting it in Eqn.(5), we obtain

$$\Delta = \frac{\Delta_0 K[O_2]_0}{1 + K[M]_0} \ , \qquad (8)$$

where $[O_2]_0$ and $[M]_0$ are the concentrations in solution of oxygen and of the other molecules involved in the complex formation. The magnitude of this shift, referred to the concentration $[O_2]_0 = 1$ M (the reduced paramagnetic shift), will be designated by Δ^*:

$$\Delta^* = \frac{\Delta_0 K}{1 + K[M]_0} \ . \qquad (9)$$

Eqns.(8) and (9) can be expressed in a linear form:

$$\frac{[O_2]}{\Delta} = \frac{1}{\Delta_0}(K^{-1} + [M]) \ , \qquad (10)$$

$$\frac{1}{\Delta^*} = \frac{1}{\Delta}(K^{-1} + [M]) \ , \qquad (11)$$

where the subscripts to $[O_2]_0$ and $[M]_0$ have been omitted.

If the paramagnetic shifts arise in collision complexes which exist only when the two species are in contact during the period of their "settled" life, then the mole fraction p_L of such complexes can be easily calculated, provided that one knows the coordination number of the complex n (i.e. the number of nearest neighbours) and the probability that the test molecule M enters the first (contact) coordination sphere of the oxygen molecule:

$$p_L = \frac{[M \cdot O_2]}{[M]} = \frac{n[O_2][M]}{[M] + [N]} \cdot \frac{1}{[M]} = \frac{n[O_2]}{[M] + [N]} \ , \qquad (12)$$

where [N] is the concentration of other molecules in the mixture.

Evidently the concentration dependences of p_L and of the paramagnetic shifts for complexes of these two types differ appreciably. In order to distinguish such complexes, it is sufficient to investigate the concentration dependence of the paramagnetic shift and to test whether Eqns.(10) and (11) or (12) hold.

Finally the third advantage of NMR in the study of the oxygen complexes is the possibility of the direct measurement of the concentration of dissolved oxygen. For this purpose, the paramagnetic shifts are measured in solutions at different concentrations placed in two sealed tubes arranged coaxially one inside the other, the inner tube containing oxygen (under a pressure of 0.1–5 MPa depending on the oxygen concentration which it is desired to ensure in the solution). The concentration of the dissolved oxygen in the inner tube is determined from the distance between the NMR peaks in the spectrum of an inert solvent present in the inner and outer bulbs. The shift δ_χ of the peaks due to the inner tube relative to those of the outer tube is due to the magnetic volume susceptibility of the dissolved oxygen and is related to its concentration $[O_2]$ by the expression[12]

$$\delta\chi = (2\pi/3) \cdot 10^{-3} \chi_m [O_2] \qquad (13)$$

where χ_m is the molar magnetic susceptibility of oxygen:

$$\chi_m = \frac{4N_A\beta^2 S(S+1)}{3kT} = \frac{0.496 S(S+1)}{T} \ . \qquad (14)$$

Here N_A is the Avogadro number, β the Bohr magneton, and S the electron spin of the oxygen molecule; in particular at 26 °C we have

$$\delta_\chi \text{ (p.p.m.)} = 6.94\,[O_2], \qquad (15)$$

where the O_2 concentration is expressed on a molar scale.

Having measured the concentration dependence of the paramagnetic shifts (i.e. their dependence on the mixture composition) and the oxygen concentration, it is possible to test the validity of Eqns.(10)–(12) and to determine the type of complexes formed by oxygen and their quantitative characteristics (the equilibrium constants K and the HFI constants a).

III. OXYGEN COMPLEXES OF ORGANIC AND ORGANOELEMENTAL MOLECULES

The paramagnetic shifts of the NMR peaks induced by molecular oxygen have been observed in many investigations[11, 13–15] for a large number of various organic molecules. They were first observed by Polak and Navon,[13] but, owing to their low magnitude (the authors worked at low pressures up to 0.3–0.4 MPa), it was impossible to reach definite conclusions about the origin of these shifts. The concentration dependences of the paramagnetic shifts at high oxygen pressures were investigated only quite recently and reliable evidence has been obtained for the existence of the oxygen complexes.[11]

Buchachenko and Pokrovskaya[11] were interested primarily in the interaction of aromatic molecules, particularly benzene, with molecular oxygen. Their initial idea was that the interaction of oxygen with benzene would induce paramagnetic shifts of the benzene NMR peaks, which could be reckoned relative to the position of the NMR peaks of cyclohexane—the solvent which is traditionally regarded as inert and which the authors assumed would not interact with oxygen, i.e. its NMR peak would not undergo paramagnetic shifts.

An example of the recording of the NMR spectrum of a benzene–cyclohexane mixture (for the volume ratio $C_6H_6 : C_6H_{12} = 14 : 1$) is illustrated in Fig.2. The narrow peaks are due to benzene and cyclohexane in the bulb without oxygen and the broadened peaks are due to benzene and cyclohexane in the bulb containing oxygen. The oxygen-induced shift of the benzene peak is 172.9 Hz and the shift of the cyclohexane peak is 160.9 Hz. The difference between the shifts is 12.0 Hz and exceeds by two orders of magnitude the error of the measurement. Consequently, apart from the shifts caused by the magnetic susceptibility of the dissolved oxygen (which should be the same for benzene and cyclohexane), there exists also the paramagnetic shift $\Delta = 12.0$ Hz, which, as suggested in the beginning, is caused by the interaction of benzene with oxygen.

However, it is impossible to claim *a priori* which mixture component (benzene or cyclohexane) is inert in relation to oxygen. The paramagnetic shifts of the NMR peaks were therefore determined in the spectra of mixtures of benzene and cyclohexane of different composition and were analysed by two methods: it was initially assumed that cyclohexane is inert and the paramagnetic shifts of the benzene peaks

were reckoned relative to the cyclohexane peak (for example, the shift of 12.0 Hz for the $C_6H_6 : C_6H_{12} = 14 : 1$ mixture is due to benzene in this version). In the second method it was assumed that the paramagnetic shift is undergone by the cyclohexane peak and benzene is the inert solvent and that the ^1H NMR peaks of benzene do not undergo a paramagnetic shift; in this method the shift $\Delta = 12.0$ Hz for the above mixture was attributed to cyclohexane. The paramagnetic shifts Δ were converted into the reduced shifts Δ^*; the oxygen concentrations necessary for this recalculation were determined from total shifts of the NMR peaks of benzene.

The reduced shifts Δ^* are plotted in Fig.3 as a function of mixture composition; its analysis permits the conclusion which component (benzene or cyclohexane) is the one with which oxygen interacts. If it is assumed that the cyclohexane is inert in relation to oxygen, then the shifts of the benzene peaks reckoned relative to the cyclohexane peaks (curve 2) increase with increasing benzene concentration. This relation has no physical significance, since at a constant oxygen concentration the mole fraction of the benzene–oxygen complexes should diminish with increasing benzene concentration because the complexes are diluted by the free benzene molecules. As a result, the paramagnetic shift of the benzene peaks should diminish with the increasing benzene concentration; this prediction is completely in conflict with experiment.[11]

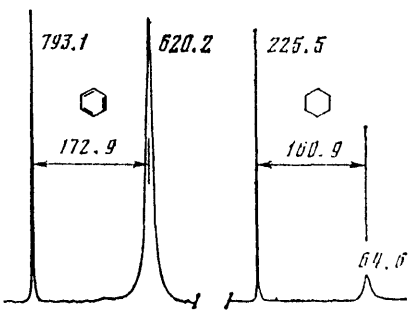

Figure 2. NMR spectrum of the benzene–cyclohexene mixture measured at a frequency of 100 MHz. The numerals opposite the NMR peaks indicate their frequencies (in herz) relative to hexamethyldisiloxane.[11]

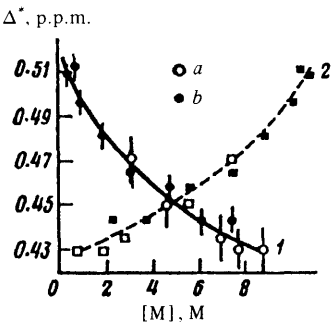

Figure 3. Concentration dependence of the reduced paramagnetic shifts Δ^*: 1) the shifts of cyclohexane peaks relative to benzene lines; 2) the shifts of benzene peaks relative to cyclohexane lines; temperature (°C): *a*) 20; *b*) 10.[11]

On the other hand, if it is assumed that the benzene molecules are inert with respect to oxygen, then the concentration dependence of the shifts of the cyclohexane peaks reckoned relative to the positions of the benzene peaks has the correct form: the mole fraction of the cyclohexane complexes and hence the shifts of the cyclohexane peaks diminish with increasing cyclohexane concentration. (Fig.3, curve 1). Furthermore, the concentration dependence of the paramagnetic shifts of the cyclohexane peaks obeys Eqn.(11) (Fig.4); the equilibrium constant for the complex formation reaction between cyclohexane and oxygen, calculated by Eqn.(11), is 1.6×10^{-2} litre mol^{-1}, while the HFI constant for the complex, averaged over all the ligand (cyclohexane molecules) protons is positive (the peaks shift in a weak field) and amounts to +0.15 G. If it is assumed that the transfer of the unpaired electron from oxygen in the complex takes place to only one of the twelve ligand hydrogen atoms (the bond between oxygen and the ligand is formed via this atom), then the HFI constant for this atom amounts to $0.15 \times 12 = 1.8$ G, which corresponds to the unpaired electron density in the 1s orbital of the hydrogen atom (approximately 0.36×10^{-2}). We may note that this density is positive, i.e. the unpaired electrons are transferred from oxygen to the ligand hydrogen atom via a delocalisation mechanism.

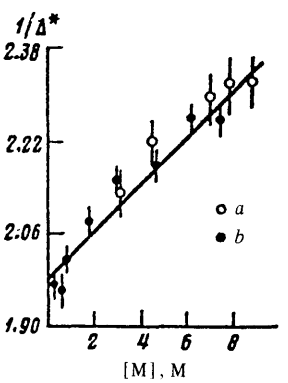

Figure 4. Dependence of the reciprocal of the reduced paramagnetic shift of the NMR peak of cyclohexane on its concentration in terms of the variables of Eqn.(11); temperature (°C): *a*) 20; *b*) 10.[16]

Thus it follows unambiguously and reliably from the analysis of the concentration dependence of the paramagnetic shifts that the cyclohexane NMR peaks shift to a greater extent under the influence of oxygen than do the benzene peaks. Since the paramagnetic shifts of the cyclohexane peaks are small, those for benzene are smaller still and in principle can be neglected and one can assume that the benzene peak does not undergo a paramagnetic shift at all. In terms of this approximation, benzene can be regarded as an inert solvent in the sense that its peak in the ^1H NMR spectrum hardly shifts and can be used as the reference signal for the measurement of the paramagnetic shifts of the peaks of all other molecules. Furthermore, it follows from this that the shift of the benzene peak is caused almost wholly by the magnetic volume susceptibility of the dissolved oxygen (Buchachenko and Pokrovskaya[11] gave direct experimental evidence for this fact) and can be used to measure its concentration.

Another important result consists in the fact that the interaction of oxygen with cyclohexane (and, as will be shown below, also with other molecules) takes place in the usual complexes and not in collision complexes, which is indicated by the validity of Eqns.(10) and (11) for the concentration dependence of the paramagnetic shifts. The same dependences hold for the paramagnetic shifts of the NMR peaks of the protons of *p*-difluorobenzene in benzene. The complex formation equilibrium constant is 0.25 litre mol^{-1} and the HFI constant for the protons is −0.01 G.

The absence (or more precisely the negligible magnitude) of the paramagnetic shifts of the proton NMR peaks for benzene does not strictly speaking imply that benzene is inert in relation to oxygen and is not involved in complex formation reactions with the latter. The absence of a shift can be a consequence of the fact that benzene forms with oxygen complexes of different types (for example via the C−H bond and the π-electron system) and the paramagnetic shifts of the proton signals induced in these complexes have different signs so that on average they fairly effectively cancel out. In order to test this hypothesis, the paramagnetic shift of the ^{13}C NMR peak of benzene was measured. In the benzene spectrum at 24 °C the shift $\Delta(^{13}C)$ was 0.49 p.p.m. at an O_2 concentration (determined from the shift of the proton resonance peak) of 0.123 M. Hence it follows that the reduced paramagnetic shift $\Delta(^{13}C) \cong 4$ p.p.m., i.e. its value is large, exceeding by an order of magnitude the paramagnetic shifts of the signals of the protons in cyclohexane. The presence of such a shift is direct evidence for the formation of a complex between benzene and oxygen. The shift is directed downfield, which implies that in the complex the positive spin density of the unpaired electron is transferred from oxygen to the π-electron system of the benzene molecule and the mechanism of this transfer involves direct delocalisation.

The most complete and reliable results have been obtained by Karmilov and co-workers,[14,15] but the paramagnetic shifts were measured in these investigations relative to the position of the NMR peak of cyclohexane, which was assumed to be inert with respect to oxygen. Bearing in mind the results of Buchachenko and Pokrovskaya[11] and introducing corrections for the paramagnetic shift of the cyclohexane peaks, it is now possible to find the true paramagnetic shifts for these molecules relative to benzene; the negative shifts correspond to an upfield displacement of the NMR lines, while the positive shifts correspond to a downfield displacement (Table 2). The difference between the signs and magnitudes of the paramagnetic shifts is striking. This fact constitutes the strongest evidence that the paramagnetic shifts are induced in the usual complexes of the molecules with oxygen and not in collision complexes, where the paramagnetic shifts are induced by the van der Waals interaction and should have the same sign for all the nuclei regardless of the chemical species to which they belong.

It is seen from the data in Table 2 that the signs and magnitudes of the paramagnetic shifts depend on the chemical structure of the ligand and obey definite rules. The NMR peaks of the protons in the OH and NH groups (in water, alcohols, and aniline, and pyrrolidine) as well as the CH groups in chloroform and CH_2Cl_2 undergo an upfield paramagnetic shift, i.e. in the complexes with oxygen the negative spin density of the unpaired electron appears on these protons. The signals of the protons of the aliphatic CH_2 and CH_3 groups (in alcohols, cyclohexane, hexamethylbenzene, dimethylaniline, *o*- and *p*-xylenes, tetramethyl-*p*-phenylenediamine, and cyclohexene) undergo downfield paramagnetic shifts, i.e. the positive spin density of the unpaired electron is transferred to these protons in the complex with oxygen.

Finally, the signals of the protons of aromatic rings (in toluene, *o*- and *p*-xylenes, *p*-difluorobenzene, naphthalene, and tetramethyl-*p*-phenylenediamine) undergo upfield paramagnetic shifts, which indicates the appearance of a negative spin density on these protons in the oxygen complex.

Table 2. The paramagnetic shifts Δ* of the NMR peaks of the molecules induced by the formation of their complexes with oxygen.

Molecule (ligand)	Group	Δ*, p.p.m.	Molecule (ligand)	Group	Δ*, p.p.m.
Water (in acetone)	OH	−0.52	*o*-Xylene	CH_3	+0.33
Methanol	OH	−0.32		⩾CH	−0.03
"	CH_3	+0.33	*p*-Xylene	CH_3	+0.34
Ethanol	OH	−0.52		⩾CH	−0.18
"	CH_2	+0.49	*p*-Difluorobenzene	⩾CH	−0.14
"	CH_3	+0.33	$(CH_3)_2N-C_6H_4-N(CH_3)_2$	CH_3	+0.35
Chloroform	CH	−0.42	"	⩾CH	−0.20
CH_2Cl_2	CH_2	−0.32	Cyclohexene	α-CH_2	+0.55
Phenylacetylene	≡CH	−0.52	"	β-CH_2	+0.40
$PhNH_2$	NH_2	−0.62	"	⩾CH	+0.10
Pyrrolidine	NH	−0.17	Cyclo-octadiene	CH_2	+0.37
Acetone	CH_3	+0.05		⩾CH	+0.20
$(CH_3)_3SiOSi(CH_3)_3$	CH_3	+0.02	Cyclo-octatetraene	⩾CH	+0.07
Cyclohexane	CH_3	+0.42	Naphthalene	α-CH	−0.43
Hexamethylbenzene	CH_3	+0.18	"	β-CH	−0.10
$PhN(CH_3)_2$	CH_3	+0.23			

These findings permit definite conclusions about the structure of the oxygen complexes and the nature of the orbitals involved in the "joining together" of the species in the complex. Molecules containing the OH and NH groups as well as those of $CHCl_3$ and CH_2Cl_2 add to the unshared electron pair of oxygen via their O−H, N−H, or C−H bonds (Fig.5*a*). These are complexes of the *n*−σ type (or hydrogen bonded complexes), in which oxygen provides the *n* orbital and the ligand the σ orbitals of the O−H, N−H, or C−H bonds. The negative spin density on the hydrogen atom of the bond involved in complex formation (O−H, N−H, or C−H) appears in this complex as a result of the spin polarisation of the hydrogen bond by the unpaired π electron of the oxygen molecule. The structure and the electronic interactions of these oxygen complexes resemble those of the anlogous complexes with participation of organic radicals.[16,17]

The aliphatic CH_2 and CH_3 groups add via the C−H σ-bonds to the π orbital of oxygen, forming π−σ complexes (Fig.5*b*); as a result of delocalisation, a positive spin density appears on the hydrogen atom of the ligand (as in the radical complexes of the same type[17]) and there is a downfield paramagnetic shift (in cyclohexane, the methyl groups of alcohols, amines, xylenes, toluene, etc.).[16]

Aromatic molecules apparently add via the π-electron system to the π orbital of oxygen, forming a π−π complex (Fig.5c); the unpaired π electron is then partly transferred to the π-electron system of the ligand from oxygen and induces, via the spin polarisation of the C−H bonds, a negative spin density in the 1*s* orbitals of the hydrogen atoms of the aromatic ring. The negative paramagnetic shifts for the aromatic protons in substituted benzenes and in naphthalene can be explained in precisely this way. This is also supported by the positive paramagnetic shift (downfield) of the signals of the ^{13}C nuclei of benzene (see above), indicating the appearance of a positive π-electron spin in the π-electron system of benzene.

However, we may note that the paramagnetic shifts of the peaks due to aromatic protons are small in absolute magnitude and those for benzene are altogether negligible, which implies that benzene (and apparently other aromatic molecules) form

complexes of two types: $\pi-\pi$, in which a negative spin density appears on the protons, and $\pi-\sigma$ (as for cyclohexane), in which a positive spin density appears on the protons via direct delocalisation. The almost complete and mutual cancellation of these two contributions for benzene ensures that the overall paramagnetic shift of the benzene protons is zero. In other paramagnetic molecules this cancellation is incomplete with the contribution by the $\pi-\pi$ complex predominating and an upfield paramagnetic shift.

The mutual cancellation of the paramagnetic shifts due to various complexes apparently takes place also for the acetone and hexamethyldisiloxane protons, for which the paramagnetic shifts are very small. In this case the positive shift due to the $\pi-\sigma$ complexes is compensated by the negative shift due to other complexes (for example, $n-\sigma$).

Special mention should be made of the paramagnetic shift of the signals due to the protons of double bonds (cyclohexene, cyclohexadiene, and cyclo-octatetraene). These shifts are directed downfield, are small in absolute magnitude, and depend on the chemical structure of the ligand. In these instances, too, two contributions are added together: the positive contribution due to the $\pi-\sigma$ complexes (via the direct delocalisation of the spin from the π orbital of oxygen to the C–H σ-bond (Fig.5*b*) and the negative contribution due to the $\pi-\pi$ complexes (delocalisation of the π-electron density from oxygen to the π-electron system of the double bond with subsequent spin polarisation of the C–H bonds attached to the double bond). The same mutual cancellation takes place in this instance as for aromatic protons; the only difference is that the $\pi-\sigma$ interaction makes the dominant contribution. The involvement of the double bonds in $\pi-\pi$ interaction and the presence of the positive spin density of the unpaired π-electron in the π-electron system of the double bonds are indicated by the considerable positive shift of the protons in the α-CH_2 group in cyclohexene, which exceeds that due to the protons of the β-CH_2 group. This additional positive shift of the signal of the α-CH_2 protons arises owing to the direct delocalisation of the unpaired π electron from the double bond to the α-CH_2 group via the hyperconjugation mechanism.

The π-electron spin density is also transferred from oxygen to the π-electron system of phenylacetylene (Table 2) as a result of $\pi-\pi$ interaction. It then induces, via spin polarisation, a negative spin density on the acetylene proton, which is accompanied by an upfield paramagnetic shift of the peak due to the latter.

The concentration dependence of the paramagnetic shifts has been investigated in mixtures of benzene with cyclohexane, *p*-xylene, cyclo-octadiene, hexamethyldisiloxane, *p*-difluorobenzene, and acetone. In most cases the dependence proved to be very weak and difficult to measure; this implies that the complexes with oxygen are weak and their stability constants at 20 °C are small and satisfied the condition $K[M] \ll 1$, i.e. $K \lesssim 10^{-2}$ litre mol^{-1}; for these complexes, $\Delta^* = \Delta_0 K$ (Table 2). The concentration dependence of the paramagnetic shift could be measured and the equilibrium constant and the constant for the hyperfine interaction in the complex could be determined only for cyclohexane and *p*-difluorobenzene.[11,16]

The paramagnetic shifts of the nuclei belonging to different fragments of the same molecule are different (Table 2). Thus in toluene the shifts for the aromatic and methyl protons are different not only in magnitude but also in sign. The same is characteristic of methanol, ethanol, xylene, and naphthalene, which implies that different structural elements of the same molecule interact with oxygen in different ways. Furthermore, the temperature dependences of the shifts for different groups of the same molecule are likewise different. Thus the shifts for the methanol methyl protons depend only slightly on temperature, while for the hydroxyl proton the temperature coefficient of the shift is 0.5 kcal mol^{-1}; in toluene the shifts for aromatic protons are almost independent of temperature, while for the methyl protons their dependence is pronounced with a temperature coefficient of 1.7 kcal mol^{-1}.[15]

The different temperature dependences of the shifts for different functional groups in the same molecule imply that the molecules interact with oxygen via individual fragments and not as a single whole, i.e. the interaction has a specific localised character. Furthermore, both these facts, namely

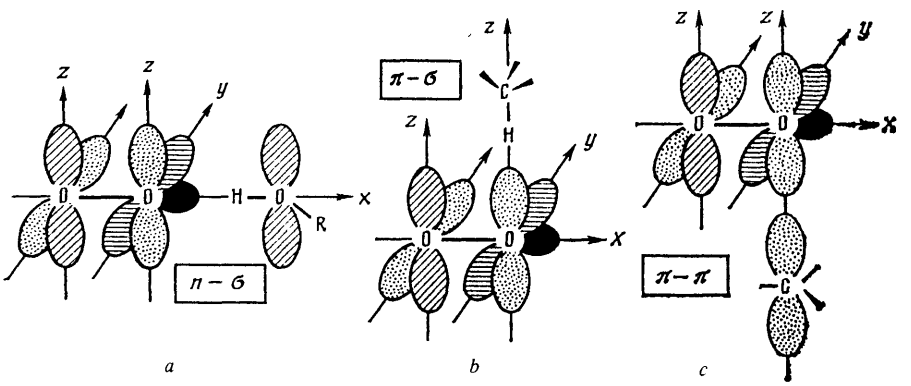

Figure 5. Molecular models of the oxygen complexes: *a*) the $n-\sigma$ complex in which oxygen provides the *n* orbital and the ligand the σ orbital of the O–H, N–H, or C–H bond; *b*) the $\pi-\sigma$ complex in which oxygen provides the π orbital and the ligand the σ orbital of the bond; c) the $\pi-\pi$ complex in which both oxygen and the ligand provide the π orbitals for the complex formation reaction.[16]

the different shifts and their different temperature dependences, demonstrate convincingly that the dominant type of interaction in the oxygen–organic molecule pair is equilibrium complex formation. As already stated previously, the paramagnetic shifts induced in collision complexes should be the same both in magnitude and in sign for all nuclei and in addition should be independent of temperature.

An important criterion used in the "recognition" of the complexes and the identification of the orbitals involved in complex formation is the competition between two or more ligands for the oxygen orbitals. This criterion was formulated in the analysis of the structures of radical complexes.[18] The idea is that the concentration dependences of the paramagnetic shifts of the solvated molecules depend on whether two different ligands add to the same oxygen orbital or to different orbitals. In the former case the ligands compete for their "site" in the given oxygen orbital, while in the latter they do not compete and add independently and autonomously to different orbitals. Clearly in the case of non-competing ligands the addition of one ligand should not influence the paramagnetic shifts of the signal due to the other ligand. On the other hand, such an influence should occur for the competing ligands, tending to "sit" on the same electronic orbital of oxygen. Thus it follows from the concentration dependence of the cyclohexane shifts in the presence of acetone, water, and tetramethylsilane that cyclohexane is a stronger ligand than water.[14] The molecules of methanol (hydroxy-group) and CCl_4 are not competing ligands, i.e. they add to different oxygen orbitals: the OH group of methanol adds to the *n* orbital and CCl_4 adds to the π orbital. Dimethylaniline (the CH_3 group) and CCl_4 are competing ligands, both molecules adding via their C–H and C–Cl bonds to the oxygen π orbital.[14]

The experimental results for the paramagnetic shifts of competing ligands are as yet insufficient to reach final conclusions about the detailed structure of the oxygen complexes. However, one can already reach the general preliminary conclusion that the oxygen π orbital is more active in complex formation than the *n* orbital. This property differentiates the oxygen complexes from those of organic radicals: in the latter case the *n* orbitals give rise to more stable complexes with organic molecules than the π orbitals.[17] This feature is apparently associated with the electronic structure of the oxygen molecule, in which the *n* orbitals in the π-electron system have not been formed distinctly and are strongly coupled with the π orbitals of single electrons, while the *n* orbitals of the 2*s* electrons are too "weak" for complex formation.

We may note that, for a number of molecules (acetone, chloroform, and phenylacetylene), considerable paramagnetic shifts of the NMR peaks due to the ^{13}C nuclei have also been observed;[14] this indicates a fairly pronounced overlap of the electron clouds of the interacting species in the oxygen complex and a far-reaching delocalis at ion of the spin density from the oxygen to the ligand. Thus for acetone (^{13}C in the CO group) the paramagnetic shift Δ^* at acetone concentrations of 1.5–4.5 M in benzene amounted to 0.2–0.5 p.p.m.[16] The ^{13}C peaks shifted downfield, indicating that a partly unpaired π electron is transferred to the π-electron system of acetone from oxygen. This transfer apparently proceeds via the π–π interaction (as in the complex with benzene).

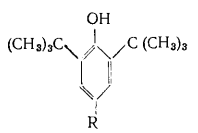
The paramagnetic shifts of the NMR peaks of the protons in diphenyl- and dibenzyl-mercury in the presence of oxygen have been measured[19] relative to cyclohexane. After introducing a correction for the cyclohexane shift, we obtain the true paramagnetic shifts for these organomercury molecules (Table 3).

Since both toluene and xylene form complexes with oxygen, it is evident that the phenyl and benzyl groups in the organomercury molecules should also add to oxygen. However, the marked difference between the paramagnetic shifts of these two groups of molecules (Table 3) shows that the complex formation with the mercury atom is the dominant process and makes the maximum contribution to the paramagnetic shifts for the organomercury molecules. The temperature dependence of the shift has also been measured for dibenzylmercury; the temperature coefficient is approximately 1 kcal mol^{-1}.[19]

Table 3. The paramagnetic shifts Δ^* (in p.p.m.) for the protons (CCl_4, 25 °C).[19]

Molecule	⩾CH	CH_3 (or CH_2)	Molecule	⩾CH	CH_3 (or CH_2)
Ph_2Hg	−0.47	—	Toluene	−0.07	+0.38
$(PhCH_2)_2Hg$	−0.22	−0.12	*o*-Xylene	−0.03	+0.33

The paramagnetic shifts for the protons of a number of phenols (including organoelemental phenols) of the type



have been measured;[20,21] their values, corrected for the paramagnetic shift of cyclohexane, are listed in Table 4.

Table 4. The paramagnetic shifts Δ^* (in p.p.m.) for the protons of phenols (CCl_4, 25 °C).

R	OH	Ring *meta*-protons	R	OH	Ring *meta*-protons
$C(CH_3)_3$	−0.20	+0.13	$Si(CH_3)_3$	−0.38	+0.05
CH_3	−0.12	+0.20	$Ge(CH_3)_3$	−0.64	+0.07
H	−0.14	+0.26	$SiPh_3$	−0.67	—
Cl	−0.25	+0.10	$GePh_3$	−0.97	—
NO_2	−0.57	−0.32			

A common property of the oxygen complexes of these phenols is an upfield paramagnetic shift of the peaks of the hydroxyl protons; this implies that the negative spin density of the unpaired electron appears on the hydroxyl proton in the complex. Evidently oxygen adds to the hydroxy-group of phenol via the unshared electron pair (hydrogen-bonded complex). Furthermore, the positive π-electron density is transferred to the π-electron system of the benzene ring in the complex and is distributed in the π-electron system of the ring in the same way as in aromatic alternant radicals: it is positive in the *o*- and *p*-positions and negative in the *m*-position. A positive spin density should then appear on the *m*-protons as a result of spin polarisation and their NMR signal should undergo a downfield paramagnetic shift (in agreement with experiment, see Table 4).

Another piece of evidence for the appearance of the unpaired π electron in the benzene ring of the ligand is the downfield paramagnetic shift of the signal due to the methyl group in the *p*-position in the spectrum of a phenol with

R = CH_3 (Δ^* = +0.61 p.p.m.); it arises as a result of the delocalisation of the π electron from the *p*-position of the benzene ring via the hyperconjugation mechanism.[20]

It is not clear whether the unpaired electron is transferred from oxygen to the hydroxy-group and to the π-electron system of the benzene ring in the same complex or different complexes (i.e. to the hydroxy-group in complexes of one type and to the π-electron system in those of another). It is incontrovertible that the paramagnetic shifts of the peaks in the spectra of element-containing phenols exhibit anomalies (Table 4), which implies that, apart from the interaction of oxygen with the hydroxy-group and the benzene ring, there is also a direct and significant (in magnitude) interaction of oxygen with the atoms of the elements. This conclusion is likewise valid for other organoelemental phenols investigated by Razuvaev et al.[21]

IV. OXYGEN COMPLEXES OF ORGANOFLUORINE MOLECULES

It is known that organofluorine hydrocarbons and their derivatives dissolve molecular oxygen effectively and are therefore used to transport the latter in blood substitutes and in liquid-phase respiration.[22,23] The state of oxygen in these solutions and the causes of its anomalously high solubility are unknown. The hypothesis has been put forward that organofluorine liquids have a "porous" structure with a large free volume which is accessible to oxygen, but it lacks any kind of foundation.

It is most likely that oxygen in organofluorine liquids exists in a state where it is partly bound in complexes. In order to test this hypothesis, a study was made of the paramagnetic shifts of the ^{19}F NMR peaks in the spectra of organofluorine molecules in the presence of dissolved oxygen.[24] Very large paramagnetic shifts were observed and their concentration dependence was found to obey Eqn.(11) (Fig.6), whence the complex formation equilibrium constants and the HFI constants for the ^{19}F nuclei were obtained (Table 5). Compared with the paramagnetic shifts of the ^{19}F NMR peaks, the proton resonance shifts of the molecules of compounds 2, 3, and 4 (Table 5) are negligible, i.e. the CH_2 and CH_3 groups and the double bonds are hardly involved in complex formation with oxygen, which implies that the interaction of oxygen with the molecules is localised exclusively at the fluorine atoms. The positive spin density is then transferred to the electronic orbitals of the fluorine atom (there is a downfield shift of the ^{19}F lines and the constant *a* is positive). The positive sign of the constant *a* implies that an interaction of the π–*n* type takes place in the complex, i.e. the π orbital of oxygen adds to the unshared electron pair of the fluorine atom. Approximately 0.1% of the unpaired electron is then transferred to the inner 2*s* shell of the fluorine atom.

Table 5. The equilibrium constants *K* and the HFI constants *a* for the complexes of O_2 with organofluorine molecules (40 °C).

No.	Molecule	*K*, litre mol^{-1}	*a*, G
1	C_6F_6	0.13±0.01	+0.49
2	$(CF_3)_3CCH{=}CH_2$	0.12±0.01	+0.36
3	$(CF_3)_2CCH{=}CHCH_3$	0.11±0.01	+0.28
4	$CF_3CF_2CF_2COO(CH_2)_3CH_3$	0.12±0.02	+0.37

It follows from the concentration dependence of the shifts that the transfer of the unpaired electron from oxygen to the organofluorine ligand and the paramagnetic shifts of the ^{19}F NMR peaks take place in equilibrium complexes and not in collision complexes; single-ligand complexes with a 1:1 stoichiometry of the interacting species, i.e. complexes of the type $M.O_2$, predominate under these conditions.

The equilibrium constants *K* for different molecules are fairly large and differ little from one another; in particular, they are almost identical (Fig.6) for the CF_3 and CF_2 groups of the molecules of compound 4 (Table 5). This constancy also indicates the localisation of the interaction of oxygen via the fluorine atom, in which the structure of the remainder of the molecule does not play an especially important role. Thus organofluorine molecules do indeed form fairly stable complexes with molecular oxygen in which the electron clouds of the interacting species overlap and there is a partial transfer of the unpaired electrons from oxygen to the ligand (the organofluorine molecule).

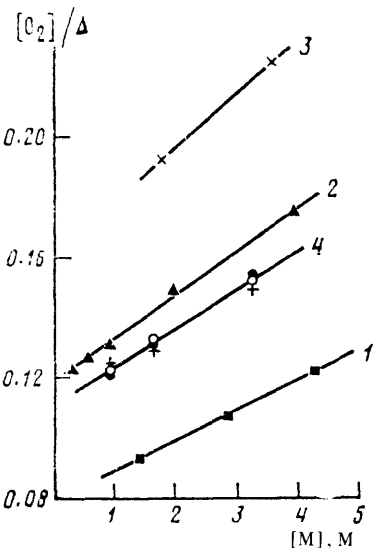


Figure 6. Concentration dependence of the paramagnetic shifts of the ^{19}F NMR peaks in terms of the variables of Eqn.(11); the numbers of the straight lines correspond to those of the compounds in Table 5.[24]

$K = 2.4 \times 10^{-2}$ litre mol^{-1} has been found reliably for *p*-difluorobenzene in benzene from the parameters of the ^{19}F NMR spectrum on the basis of the dependence of $\Delta^*(^{19}F)$ on the concentration of *p*-difluorobenzene (Eqn.11); $a(^{19}F)$ = +2.3 G. The ^{19}F peak shifts downfield, the shift being caused by the direct interaction of the π orbital of oxygen with the *n* orbital of the fluorine atom of the ligand.[16]

Signs of complex formation, namely the paramagnetic shifts of the peaks due to the ^{19}F and ^{13}C nuclei, have also been observed for a number of other organofluorine molecules.[25,26] We may note that no studies have been made of the concentration dependence of the shifts in the above investigations and the HFI constants calculated from the paramagnetic shifts in the pure, undiluted organofluorine liquids were therefore determined incorrectly. For this reason the correlations established by Hamza et al.[26] between the ^{19}F HFI constants

and the solubility of oxygen are erroneous and the conclusions based on these correlations concerning the causes of the high solubility of oxygen are unfounded.

Knowing the equilibrium constants, it is possible to calculate the fraction of oxygen bound in complexes in the solution.[24] Thus 52% of the entire dissolved oxygen is present in complexes in pure C_6F_6 at 40 °C, while in pure compound 2 (Table 5) 41% is bound under the same conditions; in compound 3 the proportion of oxygen bound in the complex with the CF_3 group is 37% and, when account is taken of all the fluorine-containing groups (CF_3 and CF_2), the proportion is 65%. We may note that the solubility of oxygen in organofluorine liquids exceeds on average its solubility in proton-containing analogues by a factor of 1.5–2. This "excess" oxygen content in organofluorine compounds is approximately consistent with the amount of oxygen incorporated in the complex, i.e. the cause of the anomalous solubility of oxygen in organofluorine compounds is its complex formation reaction.

V. OXYGEN COMPLEXES IN CHEMICAL REACTIONS

The question of the role of complexes in chemical reactions has no unambiguous solution; complex formation by no means always ensures the molecular organisation of the chemical reaction and frequently inactivates the reactants and inhibits the reactions.

Molecular oxygen is active in radical-chain reactions and its activity masks the chemical behaviour of its complexes. The contribution of chemical processes in which the complexes are detected or manifested can therefore be isolated only on rare occasions.

The photochemical oxidation of specially purified ethanol by molecular oxygen has been studied.[27] Solutions of oxygen in ethanol were irradiated with light corresponding to the absorption band, which appeared only in the presence of oxygen. It was found from the difference between the electronic absorption spectra of ethanol saturated with nitrogen and oxygen and was attributed to the oxygen complexes. This band lies in the range 2170–2700 Å and the intrinsic absorption of alcohol begins only at $\lambda < 2200$ Å. On irradiation with light at $\lambda > 2400$ Å, which is absorbed only by the complexes, oxygen was absorbed and oxidation products were formed. Both the kinetics of the consumption of oxygen and the composition of the products were typical for autocatalytic oxidation: the acceleration of the consumption of O_2 in time was observed and the yields of hydrogen peroxide and acetaldehyde (in comparable amounts) pass through a maximum, which is typical for intermediate products, while the yield of acetic acid (the final product) increased monotonically and reached a limit.

The oxidation was apparently initiated by the absorption of light by the oxygen complex (possibly with formation of the radicals $CH_3CH_2\dot{O}$ and $H\dot{O}_2$ or $CH_3\dot{C}HOH$ and $H\dot{O}_2$ as a result of the primary electron transfer in the excited complex and subsequent proton transfer). The disproportionation of the radicals in the primary pair can ensure comparable yields of CH_3CHO and H_2O_2 (as has been observed experimentally[27]). The subsequent consumption of these products cannot be accounted for unambiguously. It can be associated either with the fact that the oxidation is a chain process (possibly even with short chains) or the fact that oxygen also forms complexes with CH_3CHO and H_2O_2, which are involved in further photoinduced reactions. Experimental data do not so far permit unambiguous answers, but the conclusion that the complexes of O_2 with organic molecules initiate the photoinduced oxidation is entirely reliable.

The rules governing the autoxidation of organoelemental compounds also make it necessary to adopt the hypothesis of the formation of an oxygen complex as the first stage in the oxidation process. The presence of this stage has been justified experimentally in the oxidation of diethylcadmium;[28] the oxygen complex is transformed further into organoelemental peroxide compounds.

The behaviour of the O_2 + trimethylboron system has been subjected to a quantum-chemical analysis.[29] The geometrical parameters of the system and the orientation of the interacting species are illustrated in Fig.7. As the species approach one another to a distance $r \leq 3.5$ Å, their energetically favourable orientations are grouped near the C_3 symmetry axis of the trimethylboron molecule, i.e. oxygen tends to "stick" to the boron atom. As the O_2 molecule moves along the z axis on the potential energy surface, there is a local minimum corresponding to an intermediate complex in a triplet state (complex A), whose coordinates are $r = 2.25$ Å, $\gamma = 100°$, and $\alpha = 0$. It is subsequently transformed into another complex with the coordinates $r = 1.65$ Å, $\gamma = 102°$, and $\alpha = 90°$ in a triplet state (complex B).

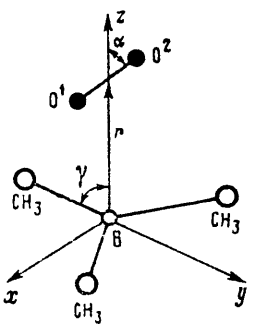

Figure 7. The geometrical parameters of the O_2 + trimethylboron system.[29]

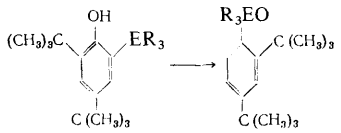
For the singlet state of the system, there is one minimum on the potential energy surface (whose coordinates are $r = 1.60$ Å, $\gamma = 102°$, and $\alpha = 90°$) and the transfer of complex B to this minimum hardly requires a change in energy and is accompanied by a redistribution of electron density.

On moving along the reaction coordinate, electron density is transferred from the O_2 molecule to the other species involved, the strength of the O–O bond in the O_2 molecule diminishes (mainly as a result of the loosening of the π-bond), and the B...O_2 bond formed has σ character. One of the B–CH_3 bonds is weakened and oxygen is inserted with formation of $(CH_3)_2BOOCH_3$. It has been suggested that the primary peroxides, whose subsequent decomposition initiates the chain oxidation of the organometallic compound, are formed via this pathway.

A minimum on the potential energy surface has also been predicted theoretically for the complexes of O_2 with benzene, pyrrole, and aniline, where O_2 is located above the plane of the molecules, the depth of the minimum being independent of the mutual orientations of the interacting species and the equilibrium distance at the minimum is approximately 3 Å, while the charge is transferred from the aromatic molecule to O_2.[30] It is difficult to say anything definite about the reliability of these results.

Finally one should note the influence of oxygen on the isomerisation of organoelemental phenols.[8] In the absence

of oxygen, shielded phenols (Table 1) are stable, but in the presence of O_2 they rearrange to ethers, for example:



;

E = Si, Ge .

Oxidation products are not then observed, which makes it necessary to assume that the rearrangement takes place in the complex of molecular O_2 with phenol. A correlation has actually been found between the stability of phenols with respect to the rearrangement and the complex formation constants K determined from the quenching of the luminescence (Table 1): the higher the value of K, the easier the rearrangement of the phenol.

The complex formation reaction with oxygen is probably important in the initiation of oxidation processes, especially in the atmosphere (in particular in the decomposition of Freons). Nor can one rule out the involvement of the complexes in steps where oxygen adds to radicals in kinetic chain propagation reactions.

---o0o---

Many spectroscopic features (the removal of spin prohibitions, the appearance of new absorption bands, and the quenching of excited states) indicate the formation of complexes between molecular oxygen and organic molecules. However, the most reliable criteria and evidence for complex formation are the paramagnetic shifts of the NMR peaks and their temperature and concentration dependences. They demonstrate unambiguously that the formation of normal, equilibrium complexes constitutes the main and "strongest" intermolecular interaction in the oxygen–organic molecule pair. This is accompanied by the combination of the electron clouds of the interacting species and the partial transfer of unpaired electrons from oxygen to the ligand. The equilibrium constants and the fraction of spin density transferred have been determined for a number of organic molecules and even the energy has been estimated for some of them.

The n orbitals of oxygen (they give rise to complexes of the $n-\sigma$ type) and the π orbitals (giving rise to complexes of the $\pi-\sigma$, $\pi-n$, and $\pi-\pi$ types) participate in complex formation, the π-complexes predominating.

A number of examples indicating the involvement of the oxygen complexes in chemical reactions were examined above. However, one can assume that their importance in chemistry is much wider. The oxidation of polyconjugated aromatic molecules to endoperoxides and the oxidation of polyene hydrocarbons (β-carotene, retinal, and vitamin A) and polymers (polyacetylene) apparently proceeds via $\pi-\pi$ complexes. The oxygen $\pi-\sigma$ complexes lie on the coordinate of the RH + O_2 → $\dot{R}$ + $H\dot{O}_2$ reaction, which ensures the initial chain initiation in chain oxidation processes. Their role is also important in the photoinitiation of oxidation processes, because the complexes exhibit an intrinsic optical absorption. These processes are particularly significant in the chemistry of the atmosphere in connection with the danger of the breakdown of the ozone layer by Freons. The formation of complexes between Freons and oxygen and their photodissociation can prove to be important elements of the mechanism of the decomposition of Freons in the atmosphere and they must be taken into account in modelling chemical-ecological phenomena.

There is little doubt that elementary photophysical processes involving the oxygen-induced quenching of the excited states and sensitisation (deactivation, energy transfer, the removal of spin prohibitions, and the change in spin multiplicity) are induced precisely in the complexes and that the exchange-resonance mechanisms of these processes operate in the latter.

Finally, the formation of complexes by molecular oxygen has so far been only slightly investigated; there is little information about the structure and dynamics of the complexes, about their reactivity, and about their role in chemical reactions of oxygen. This applies particularly to the complexes of oxygen with organoelemental molecules, among which a special place belongs to the oxygen complexes of organofluorine derivatives. Much remains obscure and contradictory concerning the formation of complexes between oxygen and aromatic molecules and concerning the way in which the interacting species are "joined together" in the complex.

However, the considerable progress achieved in this field during the last three–five years must be noted: until then, nothing definite whatsoever was known about the oxygen complexes (apart from certain assumptions and guesses). This progress is due to the development of new ideas and approaches (in particular the application of nuclear magnetic resonance) for the solution of complex formation problems. It is evident that the ideas and approaches developed can be used also to investigate the complexes of oxygen with inorganic molecules, for the solution of the problems of the activation of oxygen, in the search for and synthesis of molecular oxygen transporting agents, etc.

The Orientation of Nematic Liquid Crystals

E.F.Luk'yanchenko, V.A.Kozunov, and V.I.Grigos

The methods for the homeotropic, filted, and homogeneous alignment of nematic liquid crystals on solid supports are examined. A systematic account is given of the literature on chemical orientation agents and methods for the formation of anisotropic orienting surfaces. The physicochemical and anisotropic-elastic mechanisms of the alignment of liquid crystals on solid supports are discussed.
The bibliography includes 225 references.

I. INTRODUCTION

The studies of Frederiks and Tsbetkov,[1,2] carried out in our country during the 1930's, attracted the attention of investigators to the liquid crystal state of matter and recent advances in microelectronics have made it possible to employ the unique properties of liquid crystals in practice. Fields associated with the investigation and development of information-reproducing devices employing electro-optical effects in nematic liquid crystals (NLC) are developing particularly vigorously.

The study of the alignment (orientation) of the NLC on solid surfaces is of great interest for both theoretical research into the physical chemistry of surfaces and for the application of electro-optical effects in the technology of the preparation of liquid crystal displays. The orientation methods depended for a long time on the experimenter's art and skill and only recently have become available for industrial use as a consequence of intense investigations, which have been described in a number of reviews.[3-7]

In recent years the number of studies devoted to this problem has continued to grow. Research is being prosecuted in the following main fields: the development of new technological procedures and chemical agents for the alignment of NLC; the study of the mechanism of the orienting effect of the surface; the optimisation of the orientation parameters in liquid crystal devices. An attempt has therefore been made in the present review to give an up-to-date description of the methods and mechanisms of orientation with allowance for the influence of the latter on the electro-optical characteristics of NLC.

II. CHARACTERISTICS OF THE ALIGNMENT OF NEMATIC LIQUID CRYSTALS

(a) The NLC Director

The macroscopic state of NLC is characterised by the direction of the preferential orientation of the long molecular "axis" which is called the director. The intermolecular interaction of the liquid crystal material with the solid surface can lead to different positions of the director relative to the support. Depending on the angle ϕ between the director and the normal to the surface (Fig.1), the following types of alignment are distinguished: homeotropic ($\phi = 0$), tilted ($0 < \phi < \pi/2$), and planar ($\phi = \pi/2$). The homogeneous (planar or tilted) alignment, where the NLC molecules are arranged almost parallel to a specific direction, i.e. have a constant azimuthal angle α,† is a special case of the alignment of NLC most frequently used in indicator devices.

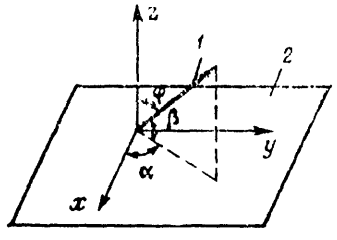

Figure 1. Alignment of the NLC director (line *1*) relative to the plane of the support (line *2*).

(b) The Energy of the Anchoring of NLC to the Support

An important characteristic of the interaction of NLC molecules with the surface is the energy of anchoring to the surface, defined as the energy which must be consumed to rotate the director from the equilibrium position by a certain angle. Two quantities are distinguished, one of which (W_1), corresponds to the rotation of the director by an angle $\Delta\phi$ in a plane perpendicular to that of the support and the other (W_2) corresponds to the rotation by an angle $\Delta\alpha$ in the azimuthal plane xy. The dependence of the anchoring energy on the angle of rotation of the director is represented by the phenomenological formulae[6] $W_1 = W_\phi \sin^2 \Delta\phi$ and

† Henceforth we shall assume throughout that this direction coincides with that of the x axis, i.e. $\alpha = 0$.

$W_2 = W_\alpha \sin^2 \Delta\alpha$, where W_ϕ and W_α are the polar and azimuthal anchoring energies corresponding to the rotation of the director from the initial position by angles $\phi = \pi/2$ and $\alpha = \pi/2$ respectively.

In the terminology of physical chemistry of surfaces, the anchoring energy W_ϕ can be represented as the difference between the energies of the interfacial NLC–solid support interaction γ_{LS} for the planar and homeotropic alignments: $W_\phi = \gamma_{LS}(\pi/2) - \gamma_{LS}(0)$. The interfacial energy can be expressed in its turn in terms of the surface energies of both phases at the interface with a vacuum (γ_L and γ_S):[8]

$$\gamma_{LS} = \gamma_S + \gamma_L - W_a, \quad (1)$$

where W_a is the energy of adhesion of the NLC to the support.

If the energy of the interaction of the NLC molecule with the surface of the support is sufficiently large and determines a particular direction of the director relative to the surface which does not change under the influence of external fields (i.e. the energies W_ϕ, $W_\alpha \to \infty$), then such a case is referred to as strong anchoring. On the other hand, if an electric or magnetic field can break down the order on the surface (W_ϕ and W_α are finite), then the anchoring is regarded as weak.[9]

III. CHEMICAL ORIENTING AGENTS

In the formation of homogeneously aligned NLC specimens, it is necessary to take into account the chemical nature of both the liquid crystal material and of the solid surface. In research and technological developments NLC belonging to the classes of Schiff bases, azobenzenes, azoxybenzenes, phenyl benzoates, cyanobiphenyls, phenylcyclohexanes, and their derivatives are used most frequently.[10] The surface of the supports used in liquid crystal devices is as a rule inhomogeneous and contains sections consisting of glass and a conducting film (usually indium or tin oxide). The chemical structure of the support can be modified in various ways in order to impart to it the required surface properties: as a result of the influence of external factors (temperature, chemical medium); by the adsorption of a monolayer of a surfactant; by depositing a special orienting layer with the required surface structure.

1. The Alignment of NLC on Glass and Oxide Films

The majority of clean oxide surfaces promote the planar alignment of NLC.[7,11–14] The homeotropic alignment observed on freshly sputtered In_2O_3, SnO_2, ZrO_2, Al_2O_3, and MgO films[13–18] for Schiff base and cyanobiphenyl NLC can be accounted for by the effect of amphiphilic impurities present in them as a result of the partial degradation of the NLC.[13]

The influence of external factors on the chemical structure and orienting properties of the surface can be traced in relation to a glass support. The glass surface contains mainly the siloxane $\geqslant$Si–O–Si$\leqslant$ and silanol $\geqslant$Si–OH groups, whose number is determined by the previous history of the glass. The cleaning of supports by etching in acid and peroxide solutions converts the siloxane groups into silanol group and promotes the homeotropic alignment of the NLC molecules with polar end groups.[18–21] On the other hand, etching of the supports in alkalis or annealing at an elevated temperature, particularly *in vacuo*, entails the conversion of the silanol groups into siloxane groups and homeotropic alignment is not observed even for NLC with polar groups at either end of the molecule.[21]

Chemical cleaning of the surface proved to be one of the first methods for the preparation of homogeneously aligned specimens,[17–21] but, as a result of the marked dependence of the type of alignment on the nature of the NLC[13,14] and poor reproducibility, it is hardly used nowadays.

2. The Orienting Effect of Surfactants

(a) Surfactant Additives in a Liquid Crystal Material

After the observation of the homeotropic alignment of *p*-methoxybenzylidene-*p'*-n-butylaniline (MBBA—one of the classical objects in studies on NLC) following the addition to the latter of small amounts (0.5 wt.%) of a polyamide resin,[22,23] a large number of additives with an analogous effect also on other types of NLC were proposed (Table 1). Many fewer additives have been proposed for the attainment of the planar alignment of NLC; these include dicarboxylic acids,[37] diazopolyoxycycloalkanes, diazopolyoxydicycloalkanes,[57] and aromatic ethers with an NLC structure.[58]

Table 1. The surfactants used for the homeotropic alignment of NLC.

**The anisotropy of the dielectric constant of the NLC.

The mechanism of this type of alignment is based on the fact that the surfactant molecules present in the liquid crystal material as additives are adsorbed on the surface of the support after coming into contact with it and alter the energy of the interface, promoting a specific type of alignment of the NLC.

The concentration of the additive selected is usually in the range 0.1–2 wt.%. A smaller amount may not have a sufficient orienting effect, a larger amount reduces the temperature range for the existance of the mesophase, while ionic surfactants cause in addition an appreciable increase of the conductivity of the NLC, which is undesirable for NLC indicators based on field effects. A disadvantage of this method of aligning NLC is a decrease of the concentration of the adsorbed surfactant molecules going from the filling orifice of the indicator to its periphery, which leads to a non-uniformity of the alignment of the NLC. Account must be taken of the fact that the surfactants entering the NLC from adhesives and substances used to make a hermetic seal[59] or the impurities in the NLC and its decomposition products[13,14] may exert an undesirable orienting influence in the preparation of liquid crystal indicators.

(b) Deposition of a Surfactant Film on the Support

The majority of the surfactants described above can be deposited directly on the support by adsorption from solutions or by the Langmuir–Blodgett method. The structure of the surfactant monolayers and the alignment of the NLC on the latter depend on the density of the molecules adsorbed on the surface.[7,27] Thus, when hexadecyltrimethylammonium bromide is used, an increase of its molecular density on glass results in the replacement of the planar alignment of MBBA by its homeotropic alignment;[44,45] the homeotropic alignment of cyanobiphenyls and azoxybenzenes is achieved only at a specific concentration of stearatochromium chloride, used to treat the support;[60] on the other hand, the orienting influence of lecithin is impaired by increased packing density of its molecules on the surface.[27,28]

Surfactants containing long alkyl groups, for example, barium stearate,[42] the aliphatic monoamines $C_nH_{2n+1}NH_2$ (n = 12 to 16),[31–33] and fluoro-derivatives of various types with a C_nF_{2n+1} (n = 5–10) end group[55,66] are used as a rule to achieve the homeotropic alignment of NLC. The length of the hydrocarbon group affects the surface energy of the surfactant film and hence the alignment of the NLC. Thus, when the number of carbon atoms is changed from 10 to 6 in aliphatic monoamines, the angle of tilt of the MBBA director to the surface β (see Fig. 1) diminishes from 78° to 30°.[33] The molecules of surfactants proposed for the attainment of a planar alignment frequently contain not less than two polar end groups capable of being adsorbed on the surface.[37,61,62]

Orienting surfactants are usually deposited on the support from organic or aqueous solutions, but other methods can also be employed. For example, on films deposited from a gas discharge in metal alkoxide vapours, a homeotropic alignment of NLC has been observed for quadrivalent metals and a planar alignment for tervalent metals.[63]

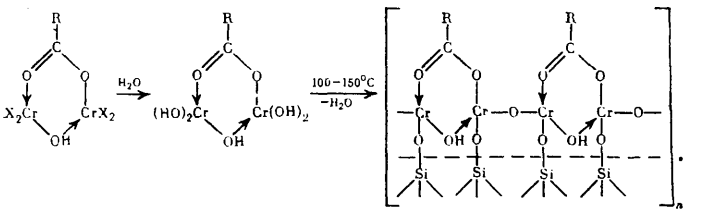
The structure of the NLC molecules themselves also plays a major role. In contrast to the majority of other classes of compounds, azoxybenzenes are not aligned homeotropically on surfaces covered by lecithin,[28] while cyanobiphenyls are not aligned in a planar manner on films of dicarboxylatochromium complexes.[64]

The surfactant monolayers physically adsorbed on the surface are unstable with time: the interaction of the polar groups of the NLC or impurities with surfactant molecules can alter the structure of the orienting layer and lead to breakdown of orientation.

(c) The C emisorption of Surfactants by the Surface of the Support

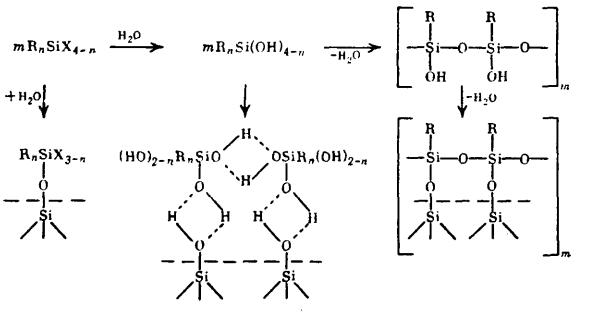
In order to improve the stability of the alignment of NLC, it has been suggested that one use surfactants which bind chemically to the support as a result of the interaction with the surface hydroxy-groups. It has been reported that the replacement of the silanol groups on the surface of silica by alkoxy-groups at elevated temperatures when amines are used as catalysts makes it possible to obtain a stable homeotropic alignment of many NLC.[36,37] However, this method is apparently very sensitive to the number of silanol groups, because it was impossible to reproduce these results in another study.[7]

A stable homeotropic alignment of not only nematic but also cholesteric and smectic liquid crystals is achieved on supports treated with carboxylatochromium complexes, which form hydrogen and siloxane bonds with the atoms in the surface layer of the support:



Here R is an aliphatic[50,51] or *o*-phenyl group[52] and X is an anion. On the other hand, organochromium complexes with dicarboxylate ligands are used to achieve a planar alignment.[64]

Alkoxy- and chloro-silanes have been widely investigated and used as orienting surfactants.[3,7,65–67] The increased interest in these substances is due to the effective adhesion and stability of organosilicon films on hydrophilic supports as a result of chemical interaction with the silanol surface groups. The hydrolytic and polycondensation processes occurring both in the solution of R_nSiX_{4-n} and on the surface of the support lead to the formation of a polysiloxane layer:[68]



Silanes can therefore be regarded as both surfactants and as the starting compounds for the deposition of polymer films (see Table 2 below). The supports are usually treated with silanes by immersion, centrifugation, and boiling in aqueous or organic solutions (1–5 wt.%) or in the vapour phase (in the case of volatile silanes).

Table 2. Polymeric materials of the orienting films.

Material of orienting film	Method of deposition	Starting materials	References
	Homeotropic alignment of NLC		
Polysiloxanes	Polymerisation in glow discharge	Hexamethyldisiloxane, trimethylvinylsilane	75, 76
"	Cathodic sputtering	Tetraethoxysilane	63

Poly (vinylpyridinium bromides)	From aqueous solution	Poly(2-methyl-5-vinylpyridylbutyl bromide)	46
Poly-γ-methyl-*L*-glutamate	—	—	122

In order to achieve a homeotropic alignment, alkoxy- and chloro-silanes with long alkyl or fluoroalkyl chains are used, for example $[C_nH_{2n+1}(CH_3)_2N(CH_2)_3Si(OCH_3)_3]^+Cl$ with n = 12–18,[3,31,32,65] $C_{18}H_{37}SiCl_3$,[7,42] and $C_nF_{2n+1}Si(OR)_3$ with n = 4–8.[56] Organosilicon compounds which promote a planar alignment of NLC contain as a rule a group with a ring structure (phenyl, biphenyl, or cyclohexyl groups)[7,66,69] or a hydrocarbon chain capable of binding via several groups to the support, for example, $CH_3OOCCH_2NHNH(CH_2)_nNH.(CH_2)_mSi(OC_2H_5)_3$ with n = 2, 3 and m = 2–5[70] or $CH_3NH.(CH_2)_3Si(OCH_3)_3$.[3,65]

One must note that, owing to the marked dependence of the quality of the orienting surfactant film on the preparation of the surface, an inhomogeneity in the orientation of the NLC may be observed on plates with an electrode pattern. This disadvantage is eliminated by introducing surfactants into film-forming solutions based on hydrolysable compounds, such as, for example, $Si(OC_2H_5)_4$, $Ti(OC_4H_9)_4$, or $AlCl_3$.[71–74] The polymer coatings formed adhere strongly to both the glass and to the electrode film, playing at the same time the role of a protective dielectric layer.

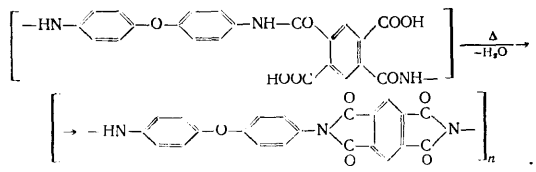
Orienting surfactants forming chemical bonds with the support are nowadays widely used in the technology of the manufacture of liquid crystal devices, particularly with an initial homeotropic alignment. However, their use is not always compatible with the formation of a hermetic seal for the indicators by means of a glass frit because the thermal stability of surfactant films is comparatively low (usually up to not more than 200 °C).

3. Orienting Polymer Coatings

In order to create surfaces with specific physicochemical properties, polymer films obtained by a wide variety of methods are frequently used. With the exception of certain polymers, proposed to achieve a homeotropic alignment of NLC, most of them orient NLC homogeneously after mechanical rubbing (Table 2). The conditions in the deposition of the polymer have a considerable influence on its orienting properties. For example, the homeotropic and planar alignments of MBBA on polytetrafluoroethylene films, deposited respectively by cathodic sputtering[76] and by means of a sliding contact,[42] have been reported. The method involving deposition from solutions of compounds which undergo hydrolysis and polycondensation has interesting possibilities in this connection. The wide-scale application of this procedure (see, for example, the relevant patents[71–74,112–120]) can be explained by the fact that, by selecting the heat treatment temperature and by mixing in various proportions silicon, titanium, aluminium, tin, cerium, zinc, etc. compounds, it is possible to alter the chemical structure of the surface, achieving thereby a homeotropic or planar alignment of the NLC and at the same time one can regulate the optical and dielectric properties of the orienting films.

Among the multiplicity of materials listed in Table 2, poly(vinyl alcohol) (PVA) layers and polyimide films are most widely employed. The ready availability of PVA films, the simplicity of their deposition, and their effective adhesion to glass and oxide surfaces have led to their extensive application in laboratory practice. However, their unsatisfactory dielectric characteristics, low thermal stability (up to not above 180 °C), and the loss of their orienting capacity under the influence of moisture frequently prevent their application in industrial technology.

Polyimide films have a high breakdown potential and a very high thermal stability (up to 450 °C), which makes it possible, in particular, to achieve a hermetic seal for indicators with the aid of readily fusible glass. Polyimide films are obtained by the thermal dehydrocyclisation of polyamidoacids, which are deposited on the support by centrifugation or by immersion in an organic solution; a 5–10 wt.% solution of polypyromellitamido-acid in dimethylformamide (DMF) is used as a rule.[103] The heat treatment of the films must be carried out in at least two stages: at 80–100 °C the solvent is removed from the layer and at 300° to 400 °C the imidisation process proper takes place:



The main disadvantage of polyimide films is the reduction of the effectiveness of adhesion under the influence of moisture. In order to improve the adhesion of the orienting coating to glass, it has been suggested that the surface of the support be modified with organosilicon compounds having the formula R_nSix_{4-n} [104] or that a sublayer of an inorganic material[123,124] or an epoxide resin[125] be deposited. An increased resistance of polyimides to moisture can also be attained by copolymerising them with organosilicon[107,111] and epoxide compounds.[108,109]

A new promising trend in the formation of liquid crystal devices, involving the employment of plastic supports instead of glass supports, has been established in recent years.[126,127] In this connection publications devoted to the selection of chemical orientation agents for such surfaces have appeared. Thus it has been suggested that an orienting PVA film[127] or mixed alkylalkoxy-derivatives of titanium and aluminium[128,129] be deposited on a poly(ethylene terephthalate) support.

4. The Polar Energy of the Achoring of the NLC to the Support

The structure of the surface determines not only the direction of alignment of NLC molecules but also the energy of their anchoring to the support. This quantity has a significant influence on the behaviour of the NLC layer in electric and magnetic fields[9] and information about its estimation and about the possibility of its regulation is therefore important. It has been suggested that the bonding energy with the surface in the case of weak anchoring be determined qualitatively from the dimensions of different alignment defects,[33] from the critical field in the deformation of the NLC layer by magnetic[31,32] or electric[29,132,133] fields, or from the extent of double refraction.[134,135] It must be emphasised that reliable methods for the measurement of the anchoring energy are so far lacking and the values quoted in the literature are merely estimates.

The influence of chemical orienting agents on the polar energy of the anchoring of the NLC to a solid surface W_ϕ is illustrated in Table 3, which lists the few experimental and theoretical estimates available in the literature. The dependence of W_ϕ on the length of the hydrocarbon group, the type of the polar group in the surfactant molecules, and the nature of the support has been investigated.[31,32] It has been shown that, with increase of the length of the alkyl group of the orienting surfactant, the anchoring energy initially increases and then falls; in the homologous series $[C_nH_{2n+1}(CH_3)_2N(CH_2)_3Si(OCH_3)_3]^+Cl^-$ the maximum value of W_ϕ is attained for n = 14–16. It has also been noted that the use of cationic surfactants leads to a higher value of W_ϕ than in the case of non-ionic alkylamines and amphoteric lecithin, the energy of anchoring the NLC to glass being almost a factor of two smaller for the same surfactant than the energy of anchoring to indium oxide. Thus the polar energy of anchoring the NLC to a solid surface is evidently determined by steric, dispersion, and polar factors.

IV. ANISOTROPIC ORIENTING COATINGS

In order to produce liquid crystal specimens with a homogeneous (planar or tilted) alignment, it is insufficient to ensure the distribution of NLC molecules at a specific angle relative to the surface of the support; it is also necessary to impart anisotropic properties to the surface, so that, on interaction with the latter, the NLC molecules are "built in" along one specified direction. For this purpose, one usually employs supports with a definite surface relief (as a rule in the form of grooves and humps) and also films with an ordered molecular structure.

The methods used to impart anisotropy to the surface properties of the support in order to achieve various angles of tilt of the director relative to the surface (the angle β, see Fig.1) are given in Table 4. A homogeneous alignment of the NLC parallel to the surface ($\beta = 0$) is observed on inorganic films obtained by "oblique" sputtering at angles ψ between the direction of the stream of particles and the support in the range $15° < \psi < 45$ °C, on surfactant films with an ordered molecular structure, and on photolithographic gratings. Low tilt angles of the director ($0° < \beta < 5$ °) are realised on rubbing the surface, on double oblique sputtering, and on ionic etching of the support; intermediate values of β are achieved on oblique sputtering of silicon or germanium oxide at low angles relative to the surface of the support. Finally, angles β close to 90° are obtained when films which have been rubbed or sputtered on are treated with surfactants used for homeotropic alignment and also as a result of oblique sputtering of Al_2O_3 or CaF_2 on fluorocarbon films polymerised in a plasma and on surfaces treated with surfactants having short alkyl chains.

1. Surfaces with an Orienting Microrelief

One of the commonest methods for the achievement of a homogeneous orientation of NLC involves rubbing the support with a soft fabric, paper, and brushes.[176,177] This method has been modified in a study[178] whose authors suggest that the support be lapped in one direction with diamond paste. The study of the surface by electron microscopy showed that this results in the formation of a system of parallel humps and grooves ~1 μm wide. However, rubbing a chemically inhomogeneous surface can lead to the inhomogeneity of the orientation on different sections of the support with an electrode pattern and to low thermal stability and moisture resistance of the orienting coating. Lapping the protective SiO_2 layer deposited on top of the electrodes makes it possible to obtain a more homogeneous alignment of the NLC with a tilt angle of the director $\beta \approx 0.05°$.[149]

A highly ordered homogeneous alignment on large areas can be achieved by rubbing organic coatings whose surface properties promote a planar alignment of the NLC (see Table 2). The tilt angle of the director achieved on rubbed surfaces depends on the type of NLC, the material of the orienting layer, and the pressure of the rubbing device, varying from 0.2–0.3°[149] to 3–4°.[151]

A multiplicity of other methods have also been proposed recently for the creation of an orienting surface microrelief, for example ionic etching of a dielectric film,[154] scanning with an electron or laser beam,[179] and the use of lithographic procedures.[180–182] However, all these methods are fairly complex for industrial use and, by virtue of its simplicity high productivity and low cost, the rubbing of polymer films therefore remains the most suitable technological method for the attainment of a homogeneous alignment of NLC.

2. Sputtered Inorganic Films

The vacuum sputtering of metals and their oxides and fluorides at low angles relative to the surface of the support results in the formation of a thin film with an anisotropic structure. The suggestion that such films be used for the homogeneous alignment of NLC[183] gave rise to a large number of studies of their orienting capacity.[139–145,155–164,184–190] For example, Au, SiO, GeO, Al_2O_3, MgF_2, CaF_2, as well as other metals, oxides, and fluorides have been tested as materials for the formation of sputtered films; the majority of these orient the NLC molecules in a planar manner with an arbitrary azimuth under the conditions of normal sputtering (sputtering at right angles to the surface?).

The dependence of the surface structure of the sputtered films and of their orienting properties on the angle between the beam and the support during sputtering has been examined in detail in a number of studies.[140,187–190] When the sputtered particles are incident at angles in the range $15° < \psi < 45°$ relative to the support, its surface consists of a system of islands which are extended in the direction at right angles to the plane containing the normal to the surface and the direction of sputtering.[140] Such a surface orients NLC homogeneously, so that $\beta = 0$ and the director coincides with the direction of the long axis of the islands. For $\psi < 15$ °C, the surface relief of the orienting film consists of closely adjacent small asymmetric columns, whose shape and dimensions depend on the material of the film and its thickness; on supports of this kind, NLC molecules are aligned at an angle $\beta = 20–30°$ relative to the plane of incidence of the sputtered particles.[163,187,188]

In order to achieve low tilt angles of the NLC director relative to the surface, it has been suggested that the sputtering process be carried out in two stages: initially at an angle $\psi = 30°$ and then at a very low angle (≲5°) at right angles to the direction of the first sputtering (or in the reverse order).[155–159] Under these conditions, β depends on the thickness of the second layer, which should be very small (~4 Å), since it has been suggested that, in order to

introduce asymmetry along the grooves formed in the first sputtering, it is necessary to deposit individual asymmetric islands and not a continuous film.[156]

It is noteworthy that, in contrast to other fluoride and oxide films, the sputtered CaF_2 [173] and Al_2O_3 [172] films align NLC almost homeotropically with different deviations from $\phi = 0$, depending on the angle of sputtering.

High-frequency plasma reactors can also be used to deposit thin anisotropic films.[79,80,146,147] The homogeneous alignment of NLC with $\beta = 0$ is observed on supports treated at an angle of 50–70° with a stream of plasma containing argon, oxygen, and organosilicon free-radical species.

The principal disadvantage of the vacuum method is the inhomogeneity of the alignment of NLC on supports of comparatively large size owing to the differences between the angles of sputtering for different sections of the plate. In view of the difficulty of achieving low tilt angles of the director, the method of oblique sputtering is used most frequently only in the preparation of indicator devices of small size working under static conditions in those cases where a high thermal stability and moisture resistance of the orienting layers is required.

3. Surfactant Films with an Ordered Molecular Structure

The surfactant films formed on withdrawing the supports from solutions by the Langmuir–Blodgett method can have anisotropic surface properties as a result of an ordered molecular structure and can align NLC homogeneously with the angle of tilt of the director $\beta = 0$. Polymer molecules of extended shape, capable of binding chemically to the support, have been reported to be surfactants of this type: PVA,[191] polymethylsiloxane,[84] and poly(2-methyl-5-vinylpyridiniabutyl) bromide.[46]

In the presence of a dichroic dye, the layers of organic polymers with molecules arranged in such a way that their long axes are almost parallel to one another, possess not only orienting but also polarising properties and can be used as internal polaroids in liquid crystal indicators. Thus the anisotropy of the surface and optical properties of PVA layers with a dye is achieved by directional withdrawal from solution or by shear deformation with the aid of a scraper.[192,193] An orienting polarising film is also formed when a gel of a dichroic dye is deposited with subsequent centrifugation or mechanical deformation of the layer parallel to the surface of the support with the aid of an auxillary plate.[194] The use of internal polaroids does not as yet allow the attainment of a high degree of polarisation of light and a homogeneous alignment of the NLC on supports of a large area but nevertheless it leads to the possibility of simplifying the design of the display and the protection of the polaroids against the unfavourable effect of the external medium.

Thus all the methods described for the formation of anisotropic coatings permit the achievement of any homogeneous tilted alignment of NLC.

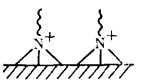
V. THE MECHANISMS OF THE ORIENTING EFFECT OF THE SURFACE

In the first studies undertaken to produce homogeneously aligned specimens it was already suggested that physicochemical forces play a decisive role in the mechanism of the alignment of NLC on a solid surface. On the basis of experimental observations, Friedel[20] concluded as early as 1922 that the NLC is aligned homeotropically on the support, provided that its molecules do not interact with the solid surface and in a planar manner in the presence of any kind of physicochemical interaction. The homogeneous alignment of NLC on supports rubbed with leather, paper, or fabric has been explained[177] by the dipole interaction of the liquid crystal molecules with the organic impurities transferred on to the surface during rubbing. The subsequent studies made it possible to refine these conclusions, but a complete understanding of the orienting effect of the support has not as yet been achieved. This is associated both with the inadequate theoretical development of the physical chemistry of surfaces and with the experimental difficulties due to the indefinite structure of the support and the lack of reliable methods for the measurement of the surface energy and the energy of the anchoring of the NLC to the support, the contamination of the liquid crystal material by decomposition products, and other causes.

Nematic liquid crystals usually consist of extended molecules ~20 Å long containing alkyl chains and alkoxy-, cyano-, azoxy-, and other polar groups and for this reason the intermolecular interaction with a solid surface can take place via both dispersion and polar forces (interactions of the dipole–dipole and dipole–induced dipole types) and hydrogen and other bonds. Account must also be taken of steric factors and, when a specific relief is created on the surface of the support, the anisotropic-elastic forces also play a significant role.

1. The Steric Model

Investigations of the intermolecular interaction of NLC with a solid surface have been stimulated by reports of the orienting influence of surfactants adsorbed on the support.[22–25] One of the first models[27,43] considered only steric factors on the assumption that surfactant molecules with long alkyl chains are arranged at right angles to the surface owing to the electrostatic interaction with the polar surface of the support, as happens for example, in the case of hexadecyltrimethylammonium bromide $C_{16}H_{33}N^+(CH_3)_3Br^-$ (HMAB):



Steric factors then favour the incorporation of the long NLC molecules parallel to the alkyl chains, i.e. the homeotropic alignment. Evidently this approach is important only in special cases.

2. The Criterion of Creagh and Kmetz

The first attempt at a thermodynamic explanation of the alignment of NLC on a solid surface was undertaken by Creagh and Kmetz,[15] who proposed that the difference between the surface energies of the support and the liquid crystal ($\gamma_S - \gamma_L$) be used as a measure of the free energy which determines the relative probability of the homeotropic alignment relative to the planar orientation. When $\gamma_S < \gamma_L$, the intermolecular forces within the NLC prove to be greater than the surface interaction forces, the liquid crystal does not wet the support and is aligned homeotropically. When $\gamma_S > \gamma_L$, the forces governing the anchoring to the surface predominate, the NLC wets the support, and is aligned in a planar manner.

The theoretical principles of this approach have been formulated by Porte.[33] If only dispersion forces operate between the NLC and the support, then the adhesion energy

W_a can be described by the Fowkes relation:[195]

$$W_a = 2(\gamma_L\gamma_S)^{1/2} \quad (2)$$

The equilibrium angle ϕ between the director and the normal to the surface corresponds to the condition for a minimum in the interfacial tension expressed in the form $\gamma_{SL}(\phi) = \phi_S + \gamma_L(\phi) - 2[\gamma_L(\phi)\gamma_S]^{1/2}$. The simplest calculation shows that the homeotropic alignment obtains when $\gamma_S < \gamma_L(0)$, the tilted alignment obtains when $\gamma_L(0) < \gamma_S < \gamma_L(\pi/2)$, and the planar alignment obtains when $\gamma_S > \gamma_L(\pi/2)$, which is consistent with the criterion of Creagh and Kmetz.

In view of the difficulty of the experimental determination of the surface energy of the support γ_S, it has been suggested that the critical surface energy γ_{cr} be used as the characteristic of the energy state of the orienting surface.[3]. The quantity γ_{cr} is found by extrapolating the results of measurement of the wetting angles θ for non-polar liquids with known values of $\gamma_L > \gamma_{cr}$ to $\theta = 0°$.[196] This empirical criterion has come to be widely used and was subsequently repeatedly tested.[28,42–45,76,197] However, the quantity γ_{cr} is not a fundamental property of the solid and depends on the nature of the liquids and the presence of adsorbed layers on the surface and the relative humidity. It has been shown that the critical surface energy is determined by the dispersion contribution to the surface energy of the support ($\gamma_{cr} = \gamma_S^d$) and can be used to characterise only non-polar surfaces.[198] The experimentally observed types of alignment are therefore by no means always consistent with the rule of Creagh and Kmetz.[7,28,42–45] Subsequent studies showed that this model constitutes only a special case of a more general mechanism of alignment.

3. The NLC–Support Polar Interaction

The polar interaction of NLC molecules with a charged solid surface is more difficult to describe theoretically than the dispersion interaction but it must be taken into account in considering the alignment mechanisms. The importance of allowing for polar forces has been demonstrated in a number of studies,[43–45] whose authors investigated systematically the alignment of MBBA on surfaces with different surface densities of adsorbed HMAB molecules. On a clean glass support, MBBA molecules are arranged parallel to the surface as a result of a dipole interaction. With increase in the density of the molecules of the orienting agent adsorbed on the glass the electrostatic field of the support is shielded. Finally, for the maximum density of HMAB molecules, only the dispersion component of the adhesion energy of MBBA remains and its molecules are oriented at right angles to the surface.

Thus, in describing the surface interaction of two phases with the aid of Eqn.(1), one must bear in mind that all the terms of this equation consist of dispersion and polar components: $W_a = W_a^d + W_a^p$; $\gamma_i = \gamma_i^d + \gamma_i^p$; $d_i + p_i = 1$, where $d_i = \gamma_i^d/\gamma_i$ and $p_i = \gamma_i^p/\gamma_i$ are the relative contributions of the dispersion and polar component of the surface energy, while i = L or S. The quantity γ_i^p can be made up in its turn of the following principal components: $\gamma_i^p = \gamma_i^{pp} + \gamma_i^{pi} + \gamma_i^h$, where γ_i^{pp} takes into account the dipole–dipole interaction, γ_i^{pi} the interaction of the dipole–induced dipole type, and γ_i^h the hydrogen and other bonds on the surface.

The total adhesion energy can be formulated as the sum of the dispersion component of the type defined by Eqn.(2) [$W_a^d = 2(\gamma_L^d\gamma_S^d)^{1/2}$] and the polar component, for which different expressions have been proposed. Thus Perez et al.[46] use an expression for W^p in terms of the electrostatic field of the support E: $W_a^p = E\delta\mu$, where δ is the number of NLC molecules per unit surface and μ the effective dipole moment of the NLC molecules, which depends on their alignment. Another expression for the total adhesion energy with allowance for polar factors has been proposed by Girifalco and Good:[199] $W_a = 2\Phi(\gamma_S\gamma_L)^{1/2}$, where Φ is the interaction parameter. When there are no polar forces, $\Phi = 1$ and this expression becomes identical with the Fowkes equation [Eqn.(2)] and the criterion of Creagh and Kmetz can be used to estimate the degree of alignment of the NLC on a solid surface. If the dipole–dipole interaction predominates among all types of polar interaction between the NLC molecules and the support, then the parameter Φ can be expressed in terms of the geometrical mean of the corresponding components of the surface energy:[200]

$$\Phi = (p_S p_L)^{1/2} + (d_S d_L)^{1/2}, \quad (3)$$

whereupon $W_a^p = 2(\gamma_S^p\gamma_L^p)^{1/2}$. It has been shown empirically that in many cases the harmonic approximation[46,200] can also be used to calculate W^p, which leads to the expression $W_a^p = 4\gamma_S^p\gamma_L^p/(\gamma_S^p + \gamma_L^p)$.

4. The Models of Alignment Based on the Girifalco–Good–Fowkes Equation

A whole series of studies[60,137,138,201–203] have considered models of the alignment of NLC on a solid surface employing the Girifalco–Good–Fowkes equation:[199] $\gamma_{SL} = \gamma_S + \gamma_L - 2\Phi(\gamma_L\gamma_S)^{1/2}$ or, after substituting Eqn.(3) for the parameter Φ:

$$\gamma_{SL}(\varphi) = \{[\gamma_L^d(\varphi)]^{1/2} - (\gamma_S^d)^{1/2}\}^2 + \{[\gamma_L^p(\varphi)]^{1/2} - (\gamma_S^p)^{1/2}\}^2. \quad (4)$$

Here the dependence of γ_L on the angle of alignment of the NLC ϕ is written in the form proposed by Parson:[204]

$$\gamma_L^d(\varphi) = \gamma_L^d(0) + \Delta\gamma_L^d \sin^2\varphi \ ;$$
$$\gamma_L^p(\varphi) = \gamma_L^p(0) + \Delta\gamma_L^p \sin^2(\varphi + \theta_p) \ . \quad (5)$$

The analogous relations for $\gamma_L(\phi)$ and $p_L(\phi)$ are also used.[201] Here $\Delta\gamma_L^{d,p} = \gamma_L^{d,p}(\pi/2) - \gamma_L^{d,p}(0)$ are the anisotropies of the dispersion and polar contributions to the surface energy of the NLC at the interface with a vacuum and the parameter θ_p takes into account the possible discrepancy between the directions of the dipole moment of the NLC molecules and the director.

The polar anchoring energy $W_\phi = \gamma_{SL}(\pi/2) - \gamma_{SL}(0)$, calculated by Eqns.(4) and (5) for MBBA [$\gamma_L^d(0) = 29$ mJ m^{-2}, $\gamma_L^p(0) = 9$ mJ m^{-2},[205] and $\Delta\gamma_L^d = \Delta\gamma_L^p = 4.5 \times 10^{-2}$ mJ m^{-2} [32]] on surfaces treated with organosilicon surfactants, is 20–54 mJ m^{-2},[138] which agrees with the measured values (Table 4). The experimental determination of the azimuthal anchoring energy $W_\alpha = \gamma_{SL}(\pi/2) - \gamma_{SL}(0)$ in terms of Eqn.(4) for heptylcyanobiphenyl on rubbed surfaces leads to values in the range 4×10^{-3}–5×10^{-2} mJ m^{-2}, while on SiO_x films sputtered at an angle $\psi = 30$ °C it leads to 8.8×10^{-2} mJ m^{-2} [206] (see Table 5 above).

The equilibrium angle ϕ can be calculated from the condition for a minimum in the interfacial energy: $\partial\gamma_{SL}/\partial\phi = 0$.

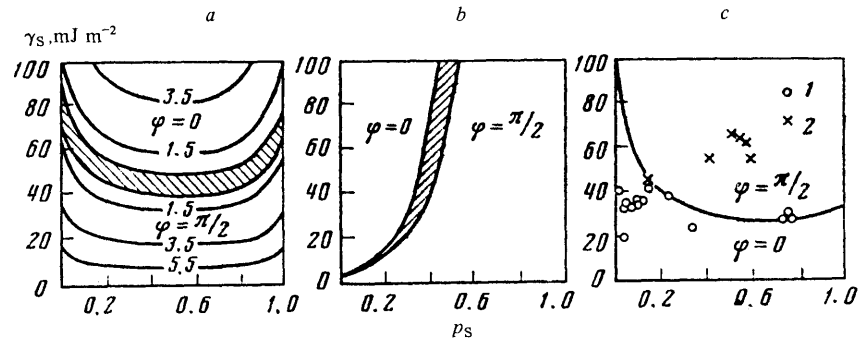


Figure 2. Alignment diagrams for the angle ϕ: *a*) for model NLC with the parameters $\gamma_L(\pi/2) = 40$ mJ m^{-2}, $\gamma_L(0) = 50$ mJ m^{-2}, $p_L(0) = p_L(\pi/2) = 0.5$; *b*) for MBBA according to Köhler's data:[201] $\gamma_L(\pi/2) = 29.1$ mJ m^{-2}. $\gamma_L(0) = 28.1$ mJ m^{-2}, $p_L(\pi/2) = 0.29$, $p_L(0) = 0.34$; c) for MBBA according to Naemura's data:[138] $\gamma_L^d(0) =$ 29 mJ m^{-2}, $\gamma_L^p(0) = 9$ mJ m^{-2}, $\Delta\gamma_L^d = \Delta\gamma_L^p = 0.045$ mJ m^{-2} [$\gamma_L(0) = \gamma_L(\pi/2) = 38$ mJ m^{-2}, $p_L(\pi/2) = p_L(0) = 0.24$]. The numerals opposite the curves indicate the values of W_ϕ (mJ m^{-2}); the transition region with $0 < \phi < \pi/2$ is shaded. Experimental points according to Naemura's data:[138] 1) for $\phi = 0$; 2) for $\phi = \pi/2$.

It has been suggested that the results of the calculation be represented in terms of the so-called alignment diagrams. where each point corresponds to a support with specific values of γ_S and p_S.[201] The alignment of the NLC molecules on such a surface is characterised by the position of this point relative to the boundary lines calculated by Eqns.(4) and (5) for $\phi = 0$ and $\phi = \pi/2$ (Fig.2*a*).

Table 5. Azimuthal energies of anchoring of NLC to various anisotropic surfaces.

*Calculation by Eqn.6.

The form of the alignment diagram depends on the parameters of the NLC: $\gamma_L^p(0)$, $\gamma_L^d(0)$, $\Delta\gamma_L^p$, and $\Delta\gamma_L^d$. Thus Figs.2*b* and 2*c* present the alignment diagrams for MBBA calculated from Köhler's results[201] and Naemura's results.[137] The significant difference between the accuracies of the predictions of the type of alignment can be accounted for by the difference between the accuracies of the estimates of the molecular parameters of MBBA and primarily the sign of $\Delta\gamma_L^p$. The experimental observations of the alignment of MBBA on various supports carried out by Naemura[137,138] agree best with the alignment diagram shown in Fig.2c.

The example described clearly demonstrates the difficulty of using alignment diagrams associated with the lack of reliable methods for the measurement of the components of the surface energies for both the NLC and the solid surface. Even the measurement of the surface energy of the NLC by familiar procedures, such as the Wilhemy plate, sessile drop, and capillary rise methods, leads to a scatter of the values of γ_L for the same material up to 30%. This can be caused both by the non-equilibrium conditions in the measurements and by the presence of impurities in the NLC. The values of γ_L for different NLC range from 25 to 40 mJ m^{-2}.[7,207–211]

The experimental determinations of the anisotropy of the surface tension $\Delta\gamma_L$ are available in the literature for only two NLC: 4.5×10^{-2} mJ m^{-2} for MBBA [32] and 5×10^{-3} mJ m^{-2} for cyanopentylbiphenyl.[134] It is noteworthy that such a low value of $\Delta\gamma_L$ corresponds to the virtual absence of a transitional region with $0 < \phi < \pi/2$ from the alignment diagram.

The determination of the surface energy of the solid surface presents even greater difficulties, since it cannot be measured directly. Furthermore, the structure of the surface of the support is as a rule undetermined and depends on the conditions of preparation, heat treatment, and purification of the supports. For example, the undetermined adsorption of the vapour of the liquid diminishes the interfacial free energy at the solid surface–vacuum interface by an amount $\gamma_{SG} = \gamma_S - \pi_0$. Owing to the lack of experimental data, the value of π_0 is usually neglected, by assuming it to be small compared with γ_S and γ_L. At the same time according to Adamson's data,[8] the ratio $\pi_0/\gamma_L = 0.1$–0.3 for polar liquids, so that the above assumption is not always correct.

Thus for a correct representation of the physicochemical interaction of NLC with solid surfaces, further experimental studies in this field are essential, because only they can demonstrate the practical value of the models described above.

5. The Alignment of NLC on Cleavage Surfaces of Single Crystals

This aspect of the interaction of NLC with a solid surface has so far been little investigated, although the first experiments on the alignment of *p*-azoxyanisole on fresh cleavage surfaces of NaCl crystals were carried out as early as the beginning of this century. It has been shown that the layer of NLC on the cleavage surface of a single crystal can be divided into separate regions, within which the director is aligned in certain cases along simple crystallographic directions: for example, this is the [110] or [1$\bar{1}$0] direction for the (001) face of the NaCl crystal.[9] In the general case the alignment of the director in the cleavage plane depends on the symmetry of the single crystal[212] and for ferroelectric materials it also depends on the direction of the spontaneous polarisation vector and on the dielectric anisotropy of the NLC.[213]

The study of the characteristics of the alignment of liquid crystals on the cleavage surfaces of single crystals of different structure should make an additional contribution to the understanding of the mechanism of the physicochemical interaction of NLC with a solid surface.

6. The Elastic Interaction of NLC with a Textured Surface

In order to account more fully for the orienting effect of the support, it is necessary to consider, apart from physicochemical forces, also anisotropic-elastic forces in the NLC layer. A simple explanation of the homogeneous alignment of NLC on surfaces having a relief in the form of parallel grooves has been proposed.[178,214] It is based on the calculation of the additional elastic energy ΔW which the NLC molecules would have had as a consequence of deformation near the textured surface if they had been oriented at right angles and not parallel to the grooves. In the absence of other orienting factors, ΔW is the azimuthal anchoring energy W_α. If the surface relief is described by a sinusoidal function with an amplitude A and a wavelength λ, then the above energy is defined by the following expression on the assumption of strong anchoring of the NLC to the support:

$$\Delta W = 2\pi^3 k A^2/\lambda^3 \qquad (6)$$

where k is the elastic constant of the NLC.

The anchoring energies W_α, calculated by Eqn.(6) for different anisotropic surfaces, are listed in Table 5. Evidently there is a satisfactory agreement between the calculated and experimental W_α and, owing to their finer texture, the films sputtered at an angle make it possible to obtain an anchoring energy higher by an order of magnitude than for rubbed surfaces.

The low tilt angle of NLC molecules on rubbed supports can apparently be accounted for by the asymmetric form of the grooves arising under the conditions of a non-uniform mechanical action.[151] The minimisation of the energy of elastic deformation on sputtered films leads to different tilt angles of the director as a function of the parameters of the surface relief of the films.[139,188]

According to the elastic mechanism of orientation, the azimuthal energy of the anchoring of the NLC to the support can be regulated by altering the amplitude and wavelength of the surface relief. However, competition between the anisotropic physicochemical forces and the anisotropic-elastic forces can prevent the alignment of the NLC molecules along the grooves. Thus when during the coating of the working cell the stream of the liquid crystal material is directed at right angles to the grooves, the direction of the director deviates from that of the grooves by an angle which increases with the width of the grooves and gives a smaller value of ΔW. The energy W_α of the anchoring of NLC to the surfaces of surfactant films having an ordered molecular structure is of the same order of magnitude as ΔW for rubbed surfaces (Table 5). In particular, as a result of this agreement, the rubbing of extended polymer films in a direction which does not coincide with that of the long molecular axis of the polymer leads to the breakdown of the orientation of the NLC.[93] The anisotropy of the surface energy of sputtered films[206,219] and films which have been rubbed on[206] also indicates the need to allow for the physicochemical properties of the support together with the geometry of its surface.

Thus the interfacial interaction of NLC with a solid surface determines characteristics such as the polar angle ϕ and the polar anchoring energy W_ϕ, while the direction of the director α and the azimuthal anchoring energy W_α are specified both by anisotropic-elastic forces, related to the geometry of the surface of the support, and by anisotropic physicochemical forces.

VI. EXAMPLES OF THE PREPARATION AND APPLICATIONS OF ALIGNED NEMATIC LIQUID CRYSTALS

In the technology of the preparation of liquid crystal displays, the selection of the method for orienting the NLC whereby the required tilt angle of the director can be achieved necessitates the allowance for factors such as the chemical structure of the NLC, the composition of the glass employed for the support, the technological intermediate layers, the dimensions of the support, and the temperature regime of the subsequent operations. The correct choice of the method of cleaning the surface plays a very important role. In order to eliminate the influence of alkali metal ions diffusing from the glass, it is desirable to employ a sublayer of an oxide or polymeric material. Certain examples of technological processes for the creation of various types of orientation are given below.

1. Homogeneous Alignment of NLC

Deposition of PVA Films with an Ordered Molecular Structure (by the Langmuir–Blodgett Method)

Glass plates with an electrode pattern are coated with silicon oxide, washed in an ultrasonic bath with a peroxide–ammonia mixture, washed with deionised water, and dried by centrifugation. A bath with a mobile barrier is filled with an aqueous PVA solution (0.03 wt.%) and cassettes with the plates are immersed in it. With the aid of the mobile barrier, an oriented monolayer of PVA molecules is established on the surface of water and the cassette is withdrawn from the solution, after which the plates are heat-treated at 150 °C for 20 min. The angle of tilt achieved is $\beta = 0° \pm 0.5°$ and the director is aligned at right angles to the direction of withdrawal. The orienting capacity of the films persists up to 160 °C.[191]

The Rubbing on of Polyimide Films

Glass plates with an electrode pattern are washed in hot chromic acid mixture and water and then treated with an aqueous solution of γ-aminopropyltriethoxysilane (0.1 wt.%) and dried by centrifugation. A solution of polypyromellitamidoacid in dimethyl formamide (5 wt.%) is deposited on the

plates by immersion with subsequent centrifugation at 3000 rev min^{-1}. The plates are maintained successively at 80°, 130°, and 300 °C, 30 min at each temperature. The polyimide film formed is rubbed with Kapron brushes; the tilt angle of the director achieved is $\beta \cong 1-3°$ and the director is aligned along the direction of rubbing. The orienting capacity of the film persists up to 450 °C.[95,103]

The Oblique Sputtering of Germanium Monoxide

A film of germanium monoxide 200–250 Å thick is sputtered onto glass plates by one of the technological procedures described with a temperature of the source of 800–850 °C, at a pressure of 5×10^{-3} Pa and at an angle $\psi = 30-50°$ relative to the surface of the support. The angle of tilt of the director achieved is $\beta = 0°$ and the director is perpendicular to the direction of the beam of the sputtered substance. The film retains its orienting capacity up to 450 °C.[145]

2. The Tilted Alignment

The Sputtering of Germa ium Mo oxide

The sputtering of GeO under the conditions described in the previous example at an angle of 5–8° relative to the surface of the support makes it possible to achieve a tilt angle of the director $\beta = 25-35°$.[145]

Double Oblique Sputtering of Silico Oxide

A second film ~10 Å thick is sputtered at an angle $\psi = 30°$, after rotating the support by 90° relative to the normal to the surface, on top of a film of silicon oxide 200–300 Å thick which had been sputtered at an angle of 5° relative to the surface of the support; the temperature of the source is 1300–1400 °C and the pressure is 10^{-2} Pa. The angle of tilt of the director achieved is $\beta = 0-30°$ and the orienting film withstands heating to 500 °C.[159]

Treatment of Sputtered Geo or Sio Films with a Solution of Lecithin

Plates treated by one of the methods described in previous examples are immersed in an alcoholic solution of lecithin (1 wt.%) and are then dried at 80 °C for 30 min. The angle of tilt β achieved increases to 60–90° and the azimuthal alignment is retained; the alignment does not change on heating to 200 °C.[7]

3. The Homeotropic Alignment of NLC

Deposition of Multilayers of α Cetylacrylic Acid by the Langmuir–Blodgett Method

Glass plates with an electrode pattern are washed in hot chromic acid mixture in water and are dried in a centrifuge. They are then immersed in a 60 × 15 × 8 cm^3 bath filled with deionised water on the surface of which 0.1 cm^3 of a 0.1% solution of α-cetylacrylic acid in heptane has been deposited. With the aid of a mobile barrier, an aligned monolayer of α-cetylacrylic acid is formed on the surface of water, whose surface tension then diminishes from 71 to 40 mJ m^{-2}. The plates are withdrawn from the bath, displacing the barrier so that the surface tension of water remains constant. They are then kept at 110 °C for 10 min. The orienting properties of the layer are retained up to 200 °C.[191]

Treatment of the Supports by Carboxylatochromium Complexes

Glass plates with an electrode pattern are washed as in the previous experiment and are then immersed in a solution of stearatochromium chloride [chromolin {Edoran in original—(Ed.of Translation)}] (0.1 wt.%) for 30–40 s, after which they are kept at 120 °C for 20 min. The orienting capacity of the layer is retained up to 400 °C.[50]

4. The Relation Between the Alignment Parameters and the Electro-optical Characteristics of the NLC

The choice of a particular type of alignment of NLC in liquid crystal displays is achieved depending on the electro-optical effect employed, the properties of the NLC, and the required parameters and design of the apparatus. Thus, in order to attain the *B*-effect, the "guest–host" effect (using dyes), and the cholesteric–nematic transition in thin layers, an initial homeotropic orientation is required. However, electro-optical effects involving the creation of an initial homogeneous alignment with $\beta = 0$, particularly with a twist structure for which the azimuthal directions of the director at the upper and lower supports form an angle which is usually close to $\pi/2$, are employed much more frequently.

The alignment parameters, especially the initial tilt angle of the director, exert a significant influence on the electro-optical characteristics of the NLC. Thus, with increase of the deviation from $\phi = 0$ or $\phi = \pi/2$, the threshold and controlling potentials diminish and the rapidity of the response improves; however, the contrast of the image and the steepness of the voltage–contrast characteristic are then somewhat impaired[142,220–221] and the range of angles of observation also diminishes considerably for displays based on the twist effect.[143] At the same time the use of a rigorously homogeneous or homeotropic alignment can lead to the appearance of various defects in the image caused by the equal probabilities of the rotation of the director in opposite directions under the influence of the electric field[148,149,222] and also by the curving of the potential field lines at the edges of the electrodes.[149,152] In preparing the displays, one therefore endeavours to achieve a small (by 1–5°) deviation of the director from $\phi = 0$ or $\phi = \pi/2$.

An interesting possibility for the attainment of optimum electro-optical characteristics has been demonstrated by the alignment effects under the conditions of a weak anchoring of the NLC to a solid surface.[133,223–225] A decrease of the anchoring energy W_ϕ promotes not only a decrease of the threshold potential and of the response time but also an increase of the steepness of the voltage–contrast characteristic, the overall effect of which makes it possible to increase the information capacity of the displays. For the twist effect, the realisation of this version is complicated by the additional requirement of a high anchoring energy W_α compared with the volume energy of twisting in order that the supports can maintain the twist deformation of the NLC.

---o0o---

Thus intensive investigation of the orientation of NLC led to a diminution of the gap between theoretical studies in the physical chemistry of surfaces and the applied developments in the field of liquid crystal devices. The methods available at present make it possible to achieve a reliable specific alignment of NLC of various types. At the same time, a complete understanding of the mechanisms of the alignment process has not so far been achieved. In the immediate future questions concerning the interaction of NLC with a solid surface should apparently remain in the centre of attention of investigators. In particular, the study of electro-optical effects in NLC, under the conditions of their weak anchoring to the surface, in order to develop procedures for the attainment of the optimum characteristics of the indicator devices is of special interest.

Conducting Compounds Based on Phthalocyanine Derivatives

V.B.Zhukhovitskii, M.L.Khidekel', and K M.Dyumaev

The methods of synthesis and the physicochemical properties of partly oxidised metallophthalocyanines and porphyrins are surveyed and described systematically. Special attention has been devoted to the electrical conductivities of these compounds and also to the analysis of the influence of various factors on the latter.
The bibliography includes 93 references.

I. INTRODUCTION

The first organic metals, compounds in which electron transfer in the solid phase takes place via the organic component of the molecule, were first obtained in the 1960's. These substances are of considerable scientific and practical interest[1,2] and naturally a new field devoted to them, combining the methods of organic chemistry and solid state physics, has developed rapidly. The principal requirements which must be met in the specific synthesis of organic metals, the methods of their preparation, as well as their properties and structure have been examined in a number of investigations (see, for example, Refs.3–9).

The presence of the metallic state was first demonstrated rigorously for the quinolinium–TCNQ and *N*-methylphenazinium-TCNQ compounds, where TCNQ is tetracyanoquinodimethane.[10] The electrical conductivities σ of these complexes at room temperature are approximately $10^2\ \Omega^{-1}\ cm^{-1}$ and their temperature variation in the range 200–300 K is of the same character as for metals. A remarkable property of these complexes is an anomalously high dielectric constant.[11] Even higher values of σ, amounting to $2 \times 10^3\ \Omega^{-1}\ cm^{-1}$, have been observed in the tetrathiofulvalene–TCNQ[12] and (tetrathiotetracene)$_2$ I_3 [13] systems. In this case the metallic state is stable down to 40–60 K. It has been possible to stabilise the metallic state to the very lowest temperatures for the first time in the hexamethylenetetraselenofulvalene–TCNQ,[14] (tetraselenotetracene)$_2$Br, and (tetraselenotetracene)$_2$Cl [15–17] compounds. An important advance in this field has been the synthesis of organic superconducting systems: $(TMTSF)_2PF_6$, $(TMTSF)_2AsF_6$, and $(TMTSF)_2ClO_4$, where TMTSF is tetramethylenetetraselenofulvalene, and also bis(ethylenedithiolo)-tetrathiofulvalene iodides.[6,18–21] The conduction in all these compounds takes place in the organic component of the complexes. The organic component is also conducting in partly oxidised polymers with a system of covalent bonds.[5,22]

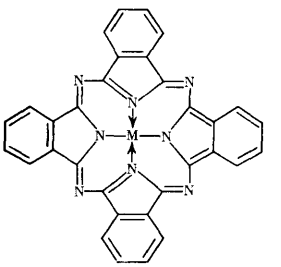
On the other hand, a class of partly oxidised inorganic complexes, exhibiting a conductivity of the metallic type [for example, $K_2Pt(CN)_4Br_{0.3}.3H_2O$] is known.[1] The molecules of these compounds have a square-planar structure and electron transfer in their specimens takes place via the metal–metal bond.

It has been found in recent years that conductivity of the metallic type obtains also in coordination compounds–partly oxidised phthalocyanines and their analogues. There are several possibilities for electron transfer in these substances: via the organic ligand with a branched system of conjugated bonds, via the complex-forming metal ion, and via the oxidant.

The aim of the present review is to survey the available data on the metal complex phthalocyanines and porphyrins exhibiting metallic properties and also to discuss the possibilities for further research in this field in order to obtain complexes with a high conductivity.

The electrical properties of phthalocyanines began to be investigated a fairly long time ago. In 1947 Eley and Vartanyan found independently that metal derivatives of phthalocyanines are semiconductors.[23] Extensive studies on the physicochemical properties of these macrocyclic compounds were then initiated. Interesting data in this field have already been obtained at the present time, particularly as regards the dark conductivity and photoconductivity of phthalocyanines and the influence on the latter of various chemical and physical factors.[24–29] The dependence of the conductivity on the temperature and pressure[22,30] and the role of the metal and of the adsorption of oxygen[31–37] and other gases[28,36] have been investigated and the infrared, ultraviolet, and EPR spectra of phthalocyanines have been examined; many of them have been studied by X-ray diffraction;[23,24,27,38–44] the electronic structure of phthalocyanines and the mechanism of the conduction in the latter have been discussed.[23,24,28,44–46] Phthalocyanines have been proposed as promising photoconductors for use in photocells with a blocking layer, as sensitisers for inorganic semiconductors, and as thin-film electrodes.[45,47]

The synthesis of phthalocyanines with metallic and not semiconducting properties has arisen as a new stage; this was achieved by synthesising partly oxidised phthalocyanines and their analogues.[48–50]



metallophthalocyanine

Partial oxidation of various phthalocyanines and porphyrins leads to a new class of highly conducting organic compounds. A characteristic feature of their crystal structure is the presence of regular stacks consisting of electron donors and

acceptors. The distances between the molecules in the stacks comprising the donors are significantly smaller than the van der Waals distances and considerably smaller than the distances between the stacks themselves. As a result, the conducting electron system in such compounds is quasi-one-dimensional. The electrical conductivity is markedly anisotropic; it is a maximum along the long axis of the crystal and is smaller by several orders of magnitude in the transverse direction.

The salts $NO(BF_4)$ and $NO(PF_6)$,[51] tetracyanoquinodimethane,[52] chloranil, bromanil, and molecular bromine and iodine[53-59] have been used as reagents for the partial oxidation of phthalocyanines and porphyrins. Elemental iodine proved to be the most suitable oxidant; the reason for this selectivity is that iodine forms a large number of reduced species (I^-, I_3^-, I_5^-), which enables the donor systems to acquire the most favourable degree of partial oxidation. In addition, all three forms of reduced iodine are comparatively easy to identify by Raman spectroscopy.[60,61]

Metallophthalocyanines (MPc) and metalloporphyrins are oxidised under identical conditions. The reactions are reversible and the equilibrium is displaced towards the starting materials on heating the dry product *in vacuo*.[62]

$$MPc + (x/2)\,I_2 \rightleftharpoons MPcI_x$$

II. SYNTHETIC METALS BASED ON PARTLY OXIDISED PHTHALOCYANINES

Methods of synthesis of polycrystalline and single crystal specimens of partly oxidised phthalocyanines have now been developed. In order to obtain the polycrystalline forms, powdered metallophthalocyanines are mixed with iodine in chlorobenzene; iodinated phthalocyanines are collected by centrifugation, washed with hexane, and dried in an inert atmosphere. The products are black polycrystalline substances with different stoichiometries; the conditions of synthesis have been described.[62]

$NiPcI_{1.0}$ single crystals are grown in an H-shaped tube by the diffusion method from solutions of NiPc and iodine either in 1,2,4-trichlorobenzene or in 1-chloronaphthalene.[50] The iodination of NiPc single crystals does not lead to $NiPcI_x$ single crystals, since the formation of a complex entails the impairment of the structure and decomposition of the crystal. The Raman spectra of $NiPcI_x$ exhibited an intense absorption at 107 cm^{-1}, which is characteristic of the polyiodide I_3^-. Bands due to I_2 or I_5^- (212 and 167 cm^{-1} respectively) were not detected in the spectra, which indicates the absence of these forms from the products.[49,50,60] This finding has also been confirmed by ^{129}I Mössbauer spectroscopy.[49]

The results of measurements of the conductivities of the polycrystalline specimens are presented in Table 1. Such conductivities include effects due to intraspecies contact resistance, but they are nevertheless comparable with those of other organic metals. It is noteworthy that the single crystal conductivities of the organic metals obtained at the present time usually exceed the conductivities of the powder by a factor of 10^2–10^3. In view of this, the data in Table 1 show that the phthalocyanines are promising electron donors for the formation of highly conducting organic molecular crystals.

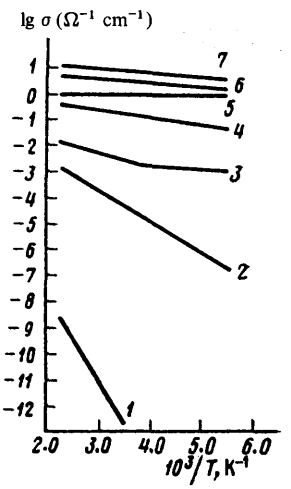

Figure 1. Variation of the electrical conductivities of pressed polycrystalline specimens with $1/T$: 1) CuPc; 2) $FePcI_{3.85}$; 3) $FePcI_{2.7}$; 4) $CoPcI_{0.6}$; 5) $NiPcI_{0.59}$; 6) $PtPcI_{0.93}$.

The temperature variation of the electrical conductivities of the pressed polycrystalline specimens is illustrated in Fig.1, which shows for comparison also the variation of the conductivity of unoxidised polycrystalline copper-phthalocyanine.

The interaction of iodine with $PcLnPc_{ox}$, where Pc_{ox} is the oxidised phthalocyanine ligand and Ln represents tervalent lanthanide elements such as Lu, Y, La, etc., has been investigated. The addition of iodine leads to a sharp increase of the electrical conductivity of the powder. Thus, for Ln = Pr, Sm, or Eu, the conductivities of the pressed specimens of the iodine complexes are higher by one order of magnitude relative to the unoxidised specimens and, in the case where Ln = Tb, Er, Tm, or Lu, the conductivity is higher by 3–4

orders of magnitude.[63,64] Iodinated complexes of di(phthalocyaninato)neodymium(III), i.e. $H[Nd^{III}(Pc)_2I_x]$, exhibit a high conductivity. When $x = 1,3$, the conductivity of the pressed polycrystalline specimen at room temperature is $6.4 \times 10^{-2}\ \Omega^{-1}\ cm^{-1}$, whereas for $x = 1.8$ it amounts to $8 \times 10^{-1}\ \Omega^{-1}\ cm^{-1}$.[65] On the basis of these results, the authors[63,64] suggested that iodide ions penetrate into the crystal lattice and form charge-transfer complexes having added to the nitrogen mesoatom of the macroring of the phthalocyanine ligand.

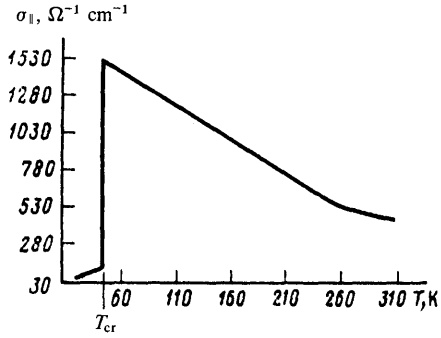

Figure 2. Temperature variation of the electrical conductivity of $NiPcI_{1.0}$ single crystals.[62]

Data on electrochemical transformations and on the conductivity of the products have been reported in the literature.[66,67]

Fig. 2 illustrates the temperature dependence of the electrical conductivity of $NiPcI_{1.0}$ single crystals in the direction of the stacks. At room temperature the conductivity of 65 specimens varied in the range 260–750 $\Omega^{-1}\ cm^{-1}$, the mean amounting to 550 $\Omega^{-1}\ cm^{-1}$. The temperature T_{cr} varies only slightly for different crystals and usually amounts to 90–100 K, although it reaches 52 K for some specimens.[62] When the specimen is cooled to a temperature below T_{cr}, the conductivity falls sharply. Such behaviour is comparable to that of the temperature dependence of the conductivity of the tetrathiofulvalene–TCNQ organic metal and shows that there is a Peierls transition or a first-order transition. The Raman spectra of the specimens show that in this transition the average degree of oxidation of NiPc remains unchanged down to 4 K.[62] The conductivity of the crystals cooled to a temperature below T_{cr} does not return to the initial value when they are reheated to the initial room temperature. On repeated cooling of the specimens, the Peierls transition takes place at a higher temperature T_{cr}.[62]

Later investigations showed that microcracks appear in the $NiPcI_{1.0}$ crystals on cooling. The sharp decrease of conductivity, which has been attributed to the Peierls transition, is in fact associated precisely with this phenomenon. When $NiPcI_{1.0}$ crystals, mounted without mechanical stresses on thin silvered graphite filaments, are cooled, the conductivity increases to a maximum value of $5 \times 10^3\ \Omega^{-1}\ cm^{-1}$ at 25 K (Fig. 3). On further cooling, the conductivity gradually falls, but its value does not tend to zero even at 0.1 K, in contrast to other molecular crystals.[68]

Whereas both in conducting complexes of this kind and in the Krogmann salt $[K_2Pt(CN)_4Br_{0.3}.3H_2O]$[69] the transport properties may be almost fully attributed to the metal while the ligands play only an indirect role in the electron transfer, in organic metals of the phthalocyanine series the ligands are actually responsible for conduction. The metal ion in such a complex modifies markedly the properties of the ligand but is not involved directly in the transport process itself.[49,60] In the synthesis of a conducting complex the ligand and not the metal is oxidised; electron transport takes place mainly via the highly conjugated π-electron clouds of the ligand. The delocalisation of the charge carriers along the stack of phthalocyanine molecules is indicated by the appearance in the EPR spectrum of a band, narrowed by the exchange interaction between the ligand π orbitals, with a g-factor of 2.032, i.e. close to the g-factor for the free electron.[70,71]

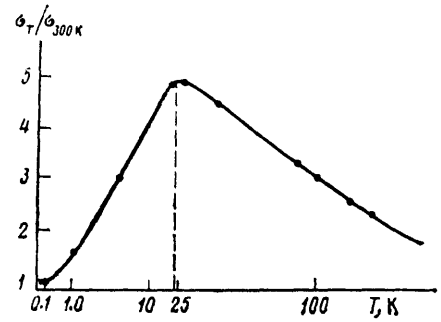

Figure 3. Temperature variation of the electrical conductivity of $NiPcI_{1.0}$ single crystals.[68]

The cross-sectional area of the phthalocyanine molecule is 2.5 times greater than that of the conducting stacks of known organic metals.[49] It is therefore of interest to compare the properties of individual charge carriers in $NiPcI_x$ and other conducting compounds obtained within the framework of the one-electron band theory of activity. According to this theory, the conductivity is related to the free path length λ and to the cross-sectional area of the conducting stack a by the equation[50,62]

$$\sigma = 2e^2\lambda/\pi\hbar a$$

where e is the electronic charge. For $NiPcI_{1.0}$ at room temperature, λ = 3.3–8.2 Å, which is equivalent to 1.0–2.3 intermolecular distances. These values are comparable to those for other highly conducting quasi-one-dimensional systems; 2.1–2.8 intermolecular distances for (tetrathiotetracene)$_2I_3$; 1.6–2.5 for hexamethylenetetraselenofulvalene–TCNQ; 0.4–0.6 for tetrathiofulvalene–TCNQ; 0.6 for $K_2Pt.(CN)_4Br_{0.3}.3H_2O$; 0.15 for quinoline–$(TCNQ)_2$.[62] Hence one may conclude that the large cross-sectional area of the $NiPcI_{1.0}$ molecules is not the cause restricting the attainment of a conductivity higher than the value obtained.

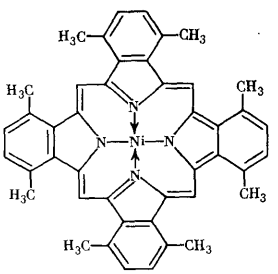
In conclusion one must note that at present there are no literature data for the influence of the crystalline modification of phthalocyanines on the electrical conductivities of their partially oxidised forms, although they would be of considerable theoretical and practical value.

III. SYNTHETIC METALS BASED ON PARTLY OXIDISED PORPHYRINS

The study of organic metals based on porphyrins is of great interest, since their structural wide variety permits a whole series of important conclusions and generalisations. Here we

shall discuss synthetic metals based on nickel 1,4,5,8,9,12, 13,16-octamethyltetrabenzoporphyrinate Ni(OMTBP), nickel tetrabenzoporphyrinate Ni(TBP), metallo-octaethylporphyrins M(OEP), and nickel tetramethylporphyrinate Ni(TMP).

The oxidation of Ni(OMTBP) with iodine in 1,2,4-trichlorobenzene yields, in particular, dark red $Ni(OMTBP)I_{1.08}$ crystals. Oxidation with iodine in chlorobenzene results in the formation, apart from the above crystals, of bronze needles having the composition $Ni(OMTBP)I_{2.0}$. The stoichiometric ratio of these complexes apparently depends on the solvent and the crystal growth conditions, but $Ni(OMTBP)I_{1.08}$ crystals almost always predominate.[60,72,73] The mixture of crystals is separated by physical methods on the basis of the colour and shape of the crystals.



Nickel 1,4,5,8,9,12,13,16-octamethyltetrabenzoporphyrinate

The Raman spectra of these compounds contain bands corresponding to the resonance absorption by the polyiodide I_3^-.[50] The degree of oxidation is 0.36 for $Ni(OMTBP)I_{1.08}$ and 0.97 for $Ni(OMTBP)I_{2.9}$.

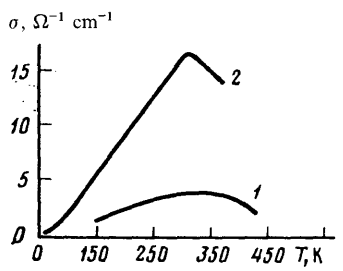


Figure 4. Temperature variation of the electrical conductivity of $Ni(OMTBP)I_x$ single crystals.[50]

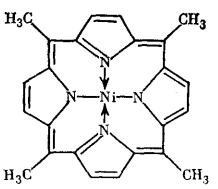
The temperature variation of the conductivity in the direction of the stacks is illustrated in Fig. 4 for $Ni(OMTBP)(I_3)_{0.36}$ and $Ni(OMTBP)(I_3)_{0.97}$. On decrease of temperature below 350 K, the conductivity of the complex $Ni(OMTBP)(I_3)_{0.36}$ resembles that of metals. It increases slowly, reaching a maximum at 300 K; when the specimen is cooled, the conductivity diminishes. The temperature variations of the conductivities of $Ni(OMTBP)(I_3)_{0.97}$ and $Ni(OMTBP)(I_3)_{0.36}$ are analogous. Thus a change in the degree of partial oxidation for the Ni(OMTBP) systems leads only to a quantitative alteration of the function $\sigma(T)$ without changing at the same time its qualitative character.[50] The values of σ at room temperature and the shapes of the $\sigma(T)$ curves for $NiPcI_{1.0}$ and $Ni(OMTBP)I_x$ differ markedly from one another, which shows that slight structural changes in the macroring can alter significantly the properties of the organic metal.

Both compounds having the composition $Ni(OMTBP)I_x$ are, as shown above, conducting materials whose crystals are made up of stacks of partly oxidised macrorings in which electron transport is ensured by the ligands. The EPR spectra of the single crystals at different temperature have a line with a g-factor of 2.012.[62] This value is comparable with the analogous parameter for radicals and demonstrates the delocalisation of π electrons in the direction of the ligand stacks. $\lambda = 0.C6$ of the intermolecular distance has been obtained for $Ni(OMTBP)(I_3)_{0.36}$; magnetic susceptibility data and the results of X-ray diffraction analysis have been discussed in two investigations.[50,60] Since only very small crystals of $Ni(OMTBP)(I_3)_{0.97}$ are at present available, it has not been possible to carry out crystallographic studies on this substance.

Diffusion oxidation of Ni(TMP) with iodine leads to acicular $Ni(TMP)I_{1.0}$ crystals.[74] This substance is stable up to 70 °C, losing iodine at a higher temperature. It has been established by Raman spectroscopy that the degree of oxidation of $Ni(TMP)I_{1.0}$ is 0.33.



nickel tetramethylporphyrinate

The iodine chains in the $Ni(TMP)I_{1.0}$ crystals are arranged parallel to the axes of the porphyrin stacks and are located within the channels formed by the methyl and pyrrole hydrogen atoms. The EPR spectrum consists of a narrow anisotropic signal with $g = 2.0067$. The narrow line in the spectrum indicates the oxidation of the ligand:

$$Ni(TMP)I_{1.0} = [Ni(TMP)]^+ + [Ni(TMP)]_2(I_3)^- .$$

The free path length for $Ni(TMP)I_{1.0}$ is equal to 0.5 of the intermolecular distance.[74]

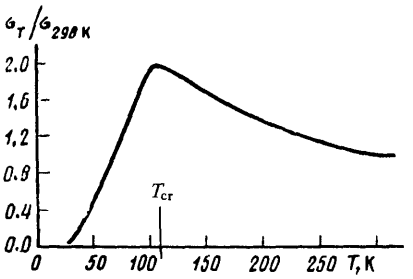


Figure 5. Temperature variation of the electrical conductivity of $Ni(TMP)I_{1.0}$ single crystals.[74]

The temperature dependence of the conductivity of the $Ni(TMP)I_{1.0}$ crystals is illustrated in Fig. 5. The plot shows that, with decrease of temperature from room temperature to $T_{cr} = 110$ K, the conductivity acquires a metallic character; on further reduction of temperature, the conductivity

becomes thermally activated. On reheating and recooling of the specimen, hysteresis is not observed.[74]

Apart from the $Ni(TMP)I_{1.0}$ crystals, yet another complex of tetramethylporphyrin has been described, namely Ni(TMP)–TCNQ. Its crystals are made up of alternating donor and acceptor stacks. It has been observed that the infrared spectrum of the complex consists of a superposition of the spectra of the individual compounds. The conductivity of the Ni(TMP)–TCNQ crystals in the direction of their long axis has not been established accurately. It is only known that it does not exceed 10^{-5} Ω^{-1} cm^{-1} at room temperature.[75]

Table 2. The conductivities of polycrystalline $M(OEP)I_x$ specimens at 300 K.[76]

x	σ, Ω^{-1} cm^{-1}	E_a, eV
	$H_2(OEP)I_x$	
5.8	$3\cdot10^{-7}$	—
3.3	$2\cdot10^{-7}$	0.51
3.0	$1\cdot10^{-7}$	—
2.1	$2\cdot10^{-8}$	—
1.1	$1\cdot10^{-8}$	—
	$Cu(OEP)I_x$	
3.5	$6\cdot10^{-3}$	0.16
2.9	$4\cdot10^{-3}$	—

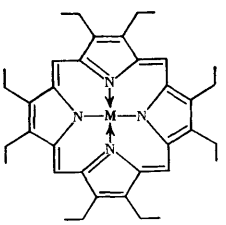
0.4	$1.5\cdot10^{-4}$	0.18

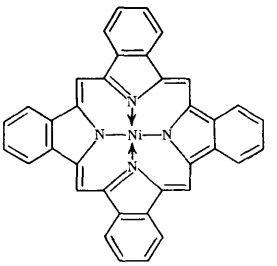
The products of the partial oxidation of metallo-octaethylporphyrins having the composition M(OEP), where M = Ni, Cu, or H_2, are of considerable interest.



metallo-octaethylporphyrin

They are important because the macroring (OEP) has a much less strained structure than in Pc and TBP. The complexes $M(OEP)I_x$ have been obtained by two procedures: the first by heating the complex M(OEP) with a (2–8)-fold excess of iodine for 24 h in an evacuated sealed tube and the second by mixing cooled solutions of M(OEP) and I_2 in chloroform; the product is obtained in the form of bright red single crystals.[76] The Raman spectra demonstrated the presence of iodine in the form of I_5^- (band at 167 cm^{-1}); consequently the degree of oxidation is $\rho = x/5$. The conductivity data for pressed polycrystalline $M(OEP)I_x$ specimens are presented in Table 2. In the course of the partial oxidation of M(OEP) an electron can be removed either from the *d* orbital of the metal or from the π orbital of the porphyrin ligand. ERP data have shown that the preferential oxidation of the ligand takes place,[76] which apparently means that the metals (Ni and Cu) do not play the main role in the conduction process.

A striking example of the fact that insignificant chemical transformations in the molecule entail a significant change in the physical properties of the synthetic metals is provided by the complex $Ni(TBP)I_{1.0}$, which differs from $Ni(OMTBP)I_{1.08}$ by the absence of eight methyl substituents and from $NiPcI_{1.0}$ by the replacement of the nitrogen mesoatoms by methylidyne groups.



nickel tetrabenzoporphyrinate

Raman spectra revealed the presence of an absorption at 107 cm^{-1}, which corresponds to I_3^- and the absence of the bands at 212 and 167 cm^{-1} characteristic of I_2 and I_5^- respectively. Thus the degree of oxidation is $\rho = 0.33$. The temperature dependence of the conductivity of $Ni(TBP)(I_3)_{0.33}$ single crystals is illustrated in Fig. 6. The compounds exhibit metallic properties in the temperature range from 300 to 95 K with a conductivity maximum of 600 Ω^{-1} cm^{-1}. On decrease of temperature below 95 K, $Ni(TBP)I_{1.0}$ becomes a semiconductor. Measurements of the conductivity of 200 $Ni(TBP)I_{1.0}$ single crystals at room temperature showed that $\sigma = 150–330$ Ω^{-1} cm^{-1}.[77] The free path length for $Ni(TBP)\cdot I_{1.0}$ single crystals is 2.1–4.3 Å or 0.66–1.3 intermolecular distances; for comparison, we may note that $\lambda = 60$ Å or 24 intermolecular distances for metallic nickel.[77]

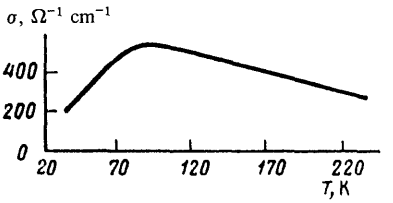


Figure 6. Temperature variation of the electrical conductivity of $Ni(TBP)I_{1.0}$ single crystals.[77]

In contrast to $Ni(OMTBP)I_{1.08}$ and $NiPcI_{1.0}$, in which charge transfer is associated with the delocalised π orbitals of the macroring, $Ni(TBP)I_{1.0}$ is a partly oxidised complex in which charge transport takes place via both the ligands and the complex-forming metal ions. The $[Ni^{II}(TBP)^+]$ cation can undergo electronic tautomerism, being converted thereby into $[Ni^{III}(TBP)]$. Thus the complex $Ni(TBP)I_{1.0}$ is a "connecting link" between purely organic and inorganic conducting coordination compounds. This is confirmed by EPR data. For the majority of the iodinated metalloporphyrins,

the g-factor is independent of temperature and is approximately equal to that for the free electron; the EPR signal is narrow and its width is also independent of temperature, which shows that the charge transfer in $NiPcI_{1.0}$, Ni(OMTBP)$.I_x$, and Ni(TMP)$I_{1.0}$ takes place via the ligand. In contrast to this, the g-factor and ΔH for Ni(TBP)$I_{1.0}$ are greater at room temperature and depend markedly on temperature.[78]

IV. FILM AND POLYMERIC CONDUCTING MATERIALS BASED ON PHTHALOCYANINES

The deposition of films of conducting dyes such as phthalocyanines can alter significantly the electronic-optical properties of various materials. Thus the metal-free phthalocyanine is used to sensitise amorphous selenium in xerography and silicon dioxide in the preparation of phototransistors. The efficiency of the operation of solar batteries can be increased by depositing a film of phthalocyanine or porphyrin. The only factor which limits at the present time the employment of these films is their low intrinsic conductivity.[79,80] Oxidation with iodine increases appreciably the conductivity of the film.[79] Fig.7 illustrates the temperature dependence of the conductivity of an $NiPcI_x$ film. Evidently, both after cooling and heating from room temperature, the $NiPcI_x$ film becomes more of an insulator. The decrease of conductivity on heating can be accounted for by the diffusion of iodine; the cause of its decrease on cooling is so far obscure. These data are inconsistent with the temperature variation of the conductivities of analogous complexes measured by Martinsen et al.[68] Iodination of thin PcCo, PcCu, and PcPb films increases their conductivity to 10^{-3}–10^{-1} Ω^{-1} cm^{-1}.[81]

The polymerisation of $M(OH)_2Pc$, where M = Si, Ge, or Sn, at 300–400 °C in a high vacuum (10^{-3} mmHg) (Fig.8) leads to the corresponding phthalocyaninato-polysiloxanes and the corresponding polygermoxanes, and polystannoxanes in satisfactory yields.[82,83] The polymers are stable in air; iodine can be removed by heating *in vacuo* above 100 °C. The degrees of polymerisation are $n_{SiPc} \geq 120$, $n_{GePc} \geq 60$, and $n_{SnPc} \geq 115$. Raman spectroscopy demonstrated the presence of the alloying component in the form of I_3^- together with a small amount of I_5^-. The conductivities of the $\{[M(Pc)O]I_x\}$ polymers vary in the sequence $\sigma_{Si} > \sigma_{Ge} > \sigma_{Sn}$, which is apparently associated with increasing interplanar distances, amounting to 3.33 Å for Si–O–Si, 3.51 Å for Ge–O–Ge, and 3.95 Å for Sn–O–Sn.

The conductivities of the specimens obtained depend on the concentration of the alloying component (Fig.9) and temperature.[82,84] The conductivities of the $\{[M(Pc)O]I_x\}$ polycrystalline species at 300 K are listed in Table 3; they are comparable to the analogous parameters for $MPcI_x$, M(OMTBP)I_x, and M(TBP)I_x.

Figure 7. Temperature variation of the electrical conductivity of an $NiPcI_x$ film.[77]

The EPR spectra show that the partial oxidation involves the ligand orbitals without affecting the metal atom.[84] It is known that the single crystal conductivity of quasi-one-dimensional materials in the direction of molecular stacks is usually 10^2–10^3 times greater than the conductivity of polycrystalline specimens. It is therefore possible that the complexes $\{[M(Pc)O].I_x\}_n$, where M = Si or Ge, have metallic properties in the form of single crystals.

Partial oxidation of the quasi-one-dimensional complexes $[Al(Pc)F]_n$ and $[Ga(Pc)F]_n$ with iodine ensures a high conductivity (0.01–0.1 Ω^{-1} cm^{-1}). The iodination of $[M(Pc)F]_n$ was carried out at room temperature, or by keeping $[M(Pc)F]_n$

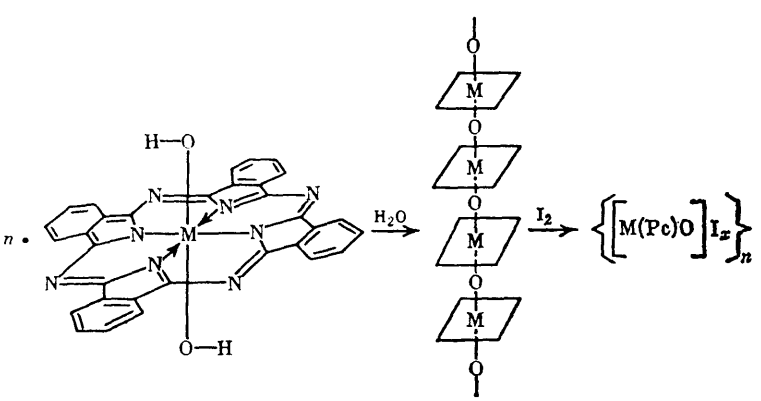

Figure 8. Schematic illustration of the preparation of $\{[M(Pc)O]I_x\}_n$.

in I_2 vapour for 7–21 days until the attainment of constant weight, or by stirring a suspension of $[M(Pc)F]_n$ in a solution of I_2 in hexane for 24 h. Raman spectroscopy demonstrates the presence of I_3^- (the band at 106–108 cm^{-1}) and the absence of I_2 and I_5^-.[85,86] The conductivities of the specimens obtained were measured on discs at 295 K (Table 4).

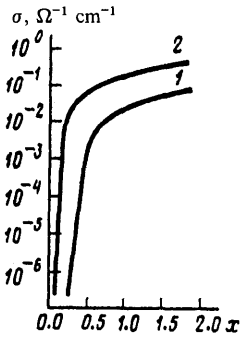

Figure 9. Dependence of the electrical conductivity of $\{[M(Pc)O]I_x\}_n$ on the iodine concentration: 1) M = Si; 2) M = Ge.[84]

Table 3. The electrical conductivities of polycrystalline $\{[M(Pc)O]I_x\}_n$ specimens at 300 K.[84]

Compound	σ, Ω⁻¹ cm⁻¹	E_a, eV
$[Si(Pc)O]_n$	$3\cdot10^{-8}$	—
$\{[Si(Pc)O]I_{0.5}\}_n$	$2\cdot10^{-2}$	—
$\{[Si(Pc)O]I_{1.4}\}_n$	$2\cdot10^{-1}$	0.04
$\{[Si(Pc)O]I_{4.6}\}_n$	$1\cdot10^{-2}$	—
$\{[Si(Pc)O]Br_{1.0}\}_n$	$6\cdot10^{-2}$	—
$\{[Ge(Pc)O]_n$	$<10^{-8}$	—
$\{[Ge(Pc)O]I_{1.8}\}_n$	$3\cdot10^{-2}$	0.08
$\{[Ge(Pc)O]I_{1.9}\}_n$	$5\cdot10^{-2}$	0.06
$\{[Ge(Pc)O]I_{1.94}\}_n$	$6\cdot10^{-2}$	0.05
$\{[Ge(Pc)O]I_{2.0}\}_n$	$1\cdot10^{-1}$	—
$\{[Sn(Pc)O]\}_n$	$<10^{-8}$	—
$\{[Sn(Pc)O]I_{1.9}\}_n$	$1\cdot10^{-6}$	—
$\{[Sn(Pc)O]I_{5.5}\}_n$	$2\cdot10^{-4}$	0.68

The conductivities of $\{[Al(Pc)F]I_x\}_n$ are higher than those of the gallium derivatives for high values of x, which is correlated with the greater interplanar spacings in the Ga polymer compared with the Al derivative and constitutes apparently yet another piece of evidence showing that the conductivity is ensured by the inter-ring overlap of the π orbitals. The highest conductivity obtained is 5 Ω^{-1} cm^{-1} for $\{[Al(Pc)F]I_{3.3}\}_n$; the conductivity of $\{[M(Pc)F]I_x\}_n$ is equal to or even greater than that of the SiO analogues. It is believed,[85,86] that this can be accounted for by the higher purity of $[M(Pc)F]_n$ compared with $[Si(Pc)O]_n$.

A characteristic feature of the structure of $\{[Ga(Pc)F]I_x\}_n$ is that the phthalocyanine rings cover one another, while in other structures they are displaced by an angle of 40° and above (Fig. 10). For this arrangement of the ligands in the stack of $\{[Ga(Pc)F]I_x\}_n$ molecules, a greater degree of overlap of the π orbitals between them should be ensured. This is apparently the explanation of the conductivity of 0.12 Ω^{-1} cm^{-1} of pelleted $\{[Ga(Pc)F]I_{0.93}\}_n$, which is extremely high even when account is taken of the interplanar distance (3.86 Å). For comparison, we may note that the conductivity of $NiPcI_{1.0}$ is 0.7 $\Omega^{-1}cm^{-1}$ for a distance between the molecules of 3.24 Å.[87]

Table 4. The electrical conductivities of polycrystalline $\{[Al(Pc)F]I_x\}_n$ and $\{[Ga(Pc)F]I_x\}_n$ specimens at 295 K.[85,86]

I/Al	σ, Ω⁻¹ cm⁻¹	I/Ga	σ, Ω⁻¹ cm⁻¹
0.00	$1.5\cdot10^{-4}$	0.00	10^{-6}
0.21	$1.8\cdot10^{-2}$	0.17	$1.9\cdot10^{-4}$
0.29	$1.5\cdot10^{-2}$	0.62	$1.7\cdot10^{-2}$
0.38	$2.0\cdot10^{-2}$	0.77	$4.4\cdot10^{-2}$
0.87	0.70	0.97	$7.2\cdot10^{-2}$
1.0	0.13	0.98	$8.6\cdot10^{-2}$
1.5	0.19	2.3	0.15
2.4	0.63	—	—
3.3	5.0	—	—

Among the partly oxidised quasi-one-dimensional complexes Al(Pc)Y and Ga(Pc)Y, where Y = F, Cl, or OH, we may note materials doped with $[BF_4]^-$, $[PF_6]^-$, and $[SbF_6]^-$. Owing to the presence of residual water in the initial phthalocyanine, the exact composition of the product of the oxidation of Al(Pc)OH by $NO[PF_6]$ is not known.[51] The reaction of Al(Pc)F and Ga(Pc)F with $NO(BF_4)$ and $NO(PF_6)$ proceeds rapidly in dry CH_3NO_2 or CH_2Cl_2 with formation of complexes having the composition $[M(Pc)F]Y_x$, where M = Al, Y = $[PF_6]$, and x_{max} = 0.9 or M = Ga, Y = $[PF_6]$, and x_{max} = 0.9. These compounds are thermally stable up to 110 °C; in a stream of dry nitrogen the decomposition begins at 125 °C.

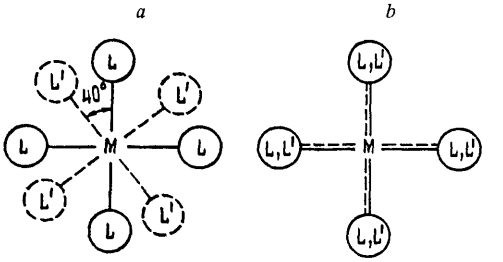

Figure 10. The arrangement of the ligands in the stack: *a*) 40° displacement; *b*) 0° displacement.

A characteristic feature of these compounds is their stability on prolonged exposure to atmospheric oxygen. Thus the conductivity of the complex $\{[Al(Pc)F][PF_6]_{0.59}\}_n$ diminished by 0.1 Ω^{-1} cm^{-1} after it had been kept in air for a month, while that of the complex $\{[Al(Pc)F][BF_4]_{0.44}\}_n$ remained unchanged at 3×10^{-2} Ω^{-1} cm^{-1} after it had been kept for a year in the air. This feature is the opposite of the behaviour of the complexes $[M(Pc)F]_n$ oxidised by iodine,[88] which lose iodine with time. Thus, although the conductivity

of polyfluorometallophthalocyanines oxidised with $NO[BF_4]$ or $NO[PF_6]$ is ten times lower than that of $\{[M(Pc)F]I_x\}_n$, they are of considerable interest in view of their high stability.[89]

The partial oxidation of metallophthalocyanines and porphyrins is an important chemical method for the preparation of new synthetic metals. Elemental iodine, which has a large number of reduced forms, is used as a convenient reductant more frequently than others.

The ligands play the main role in the electrical conduction in iodinated metallophthalocyanines and metalloporphyrins. The metal ion in such a complex influences the properties of the ligands but is not involved directly in charge transfer. An exception is $Ni(TBP)I_{1.0}$, in which charge transfer takes place via both the ligands and the metal [in contrast to $Ni(OMTBP)I_x$, $M(TMP)I_{1.0}$, and $NiPcI_{1.0}$, where the charge is transferred only via the organic ligand]. Thus slight changes in the structure of the ligands exert a significant influence on the electrical properties of the system. It is of interest to note that in certain cases homogeneous complex catalysts incorporating a transition metal ion and a ligand with an extensive system of conjugated bonds also transfer an electron to the substrate via the ligand (the so-called peripheral mechanism).[90-92]

It has been shown in relation to the complexes $Ni(OMTBP)I_x$ that a change in the oxidation state does not affect the qualitative character of the dependence of σ on T and influences only the absolute magnitude of the conductivity. One may claim that the interplanar distances in the stacks and the steric disposition of the molecules in the latter play an important role in the conduction process. In other words, by changing these parameters, it is possible to regulate the conductivities of phthalocyanine and porphyrin systems.

In the mid 1970's it was suggested that in the future the importance of phthalocyanines may be extremely significant in fields such as those of one-dimensional conductors and superconductors.[93] There is no doubt that this prediction has come true as regards metallic conductivity. Whether or not superconductors will be obtained on the basis of phthalocyanines remains a problem for further research.

The Application of Cyclopalladated Compounds in Synthesis

A.D.Ryabov

The review is devoted to the application in organic synthesis of organopalladium compounds with an intramolecular coordinate bond. Reactions with alkenes, alkynes, carbon monoxide, isocyanides, organolithium and organomagnesium compounds, and other reagents are examined. The mechanisms of these processes are discussed.
The bibliography includes 129 references.

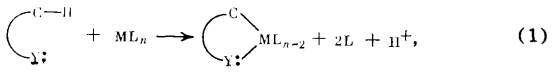
I. INTRODUCTION

The discovery of the reactions involving the cyclometallation of organic compounds by transition metal complexes,[1] leading to the formation of transition metal–carbon and metal–donor atom bonds, i.e.



(1)

initiated the wide-scale and comprehensive investigation of cyclometallated molecules. One of the causes of the continuous interest in these substances is the possibility of modelling many catalytic reactions involving transition metal complexes in which the formation of labile metal–carbon bonds has been postulated as the key stages.[2] A large number of cyclometallated complexes have been synthesised in recent years, which has been reflected in review articles.[3-7] The chemistry of cyclometallated compounds† soon outgrew the limits of purely model problems and these complexes have come to be used independently in organic synthesis. Their employment makes it possible to achieve absolute regioselectivity and, in the case of σ-aryl complexes and related compounds, *ortho*-substituted products, which are otherwise difficult to synthesise, can be obtained.

This review summarises the literature data concerning the application of cyclometallated complexes in organic synthesis. Since palladium(II) complexes are most widely used, attention has been naturally concentrated on the reactions of these compounds. The review also includes certain processes which are potentially important for organic synthesis. The methods of synthesis of cyclopalladated complexes as well as procedures for the cleavage of palladium–carbon bonds, leading to the liberation of the organic fragments of the complexes, are briefly described.

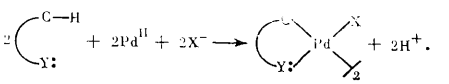
†Cyclopalladated compounds or cyclopalladated complexes have been recently referred to also as palladocycles. All these equivalent terms are used in this review.

II. THE SYNTHESIS AND DISSOCIATION OF PALLADOCYCLES

These problems have been examined in detail in a number of reviews.[3-7] Only general approaches to the synthesis of the cyclopalladated complexes used in organic synthesis are briefly described below. This is done, in particular, also in order to emphasise the availability of the initial compounds of the type of di-μ-chlorobis(cyclometallated ligand)dipalladium(II).

Direct Palladisation

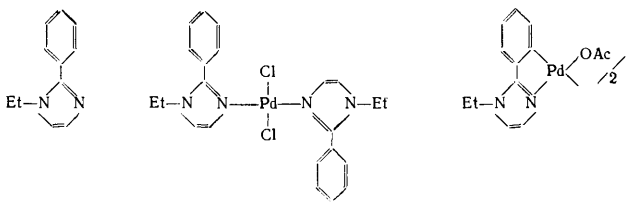
The reaction involves the direct interaction of the organic ligand with palladium(II) salts:



(2)

M_2PdCl_4, M_2PdCl_4–MOAc, and $Pd(OAc)_2$, where M = Li or Na, are used. The palladation is carried out in methanol, ethanol, acetone, dioxan, chloroform, acetic acid, and binary aqueous organic mixtures. As a rule, the palladation reaction takes place smoothly at room temperature, but in a number of instances heating is necessary. The "mildest" metallating agent is lithium or sodium tetrachloropalladate(II); the M_2PdCl_4–alkali metal acetate or amine system is frequently more effective. The acetate anion functions as a general base, which facilitates the dissociation of the C–H bond.[8]

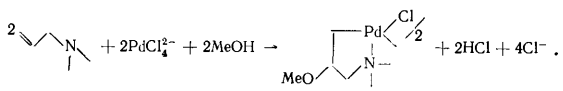
In those cases where the treatment of the ligand with M_2PdCl_4 does not lead to cyclopalladated products (the so-called bisadducts $PdCl_2L_2$ are then usually formed), palladium(II) acetate may prove to be effective. For example, Li_2PdCl_4 reacts with 1-ethyl-2-phenylimidazole(I), giving rise to the bisadduct (II), while the required cyclometallated complex (III) is obtained via the reaction of compound (I) with palladium(II) acetate in boiling acetic acid.[9]



(I) (II) (III)

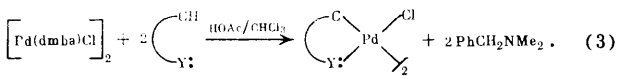
In a number of instances complexes of the type $PdCl_2L_2$ can be converted into cyclopalladated products of the type $[Pd(L-H)Cl]_2$ by heating or treatment with bases (see, for example, Shaw and co-workers[10,11]).

Direct palladation makes it possible to obtain complexes with aromatic, pseudoaromatic, and aliphatic ligands. The last can also be synthesised from allylamines[12] and allyl sulphides[13] by treating them with $PdCl_4^{2-}$ in the presence of nucleophiles:



Ligand Exchange

The essential feature of a recently proposed method[14] consists in the interaction of any *ortho*-palladated complex with the free ligand, which leads to a new palladocycle:



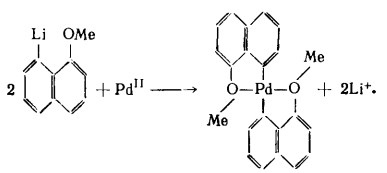
(3)

Here and henceforth $[Pd(dmba)Cl]_2$ represents di-μ-chlorobis(*NN*-dimethylbenzylamine-C^2,*N*)dipalladium(II) $[Pd(C_6H_4CH_2NMe_2)Cl]_2$. Acetic acid is an essential component of the reaction mixture; in its absence there is no exchange. The method makes it possible to obtain complexes with donor N and P atoms; ligands with oxygen-containing donor groups do not react.

This method is particularly convenient for the synthesis of compounds which can be obtained by the direct palladation of the corresponding ligands, in particular for the synthesis of di-μ-chlorobis(*N*,*N*-diethyl-4-nitrobenzylamine-C^2,*N*)-dipalladium(II).[14]

Transmetallation

The method consists in the treatment of the ligand with a suitable organolithium compound, which gives rise to the lithio-derivative of the latter, to which the metal salt is then added. Complexes of 1-methoxynaphthalene are synthesised in this way, for example:[15]



The use of organolithium compounds for such purposes has been considered in detail in a review.[5]

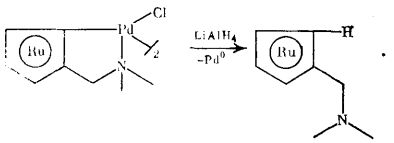
Another promising method involves the interaction of organomercury compounds with zerovalent palladium complexes of the type $Pd(PPh_3)_4$ or Pd_2(dibenzylideneacetone)$_3$.[16,17] These reactions proceed via the oxidative addition mechanism; two reviews are devoted to their characteristics.[18,19]

Thus it follows from the above discussion that cyclopalladated compounds are fairly readily available; they are stable in air and can be stored indefinitely. All these factors create conditions for the application of these complexes in organic synthesis.

Processes accompanied by the dissociation of the metal–carbon σ-bond in the metallocycle are no less important because in many instances the interaction of the initial complex with any substrate leads to the formation of a new complex with a modified cyclometallated organic ligand. In order to use such processes in synthesis, it is necessary to have at ones disposal selective methods which make it possible to decompose the metallocycles in such a way that the modified organic ligand can be readily isolated. Some of these methods are described below.

Reduction with Lithium Tetrahydroaluminate

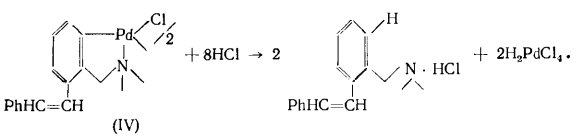
In organic solvents, for example in dry diethyl ether, the reduction of palladocycles by $LiAlH_4$ leads to the formation of the free ligand and zerovalent palladium, as happens, in particular, in the case of a ruthenocene derivative:[20]



The use of $LiAlD_4$ leads to selective deuteriation. $NaBH_4$ and H_2 are used as other reductants.

Acidolysis

The palladium–carbon bond in the compounds considered dissociates in the presence of strong protic acids of the type of HCl, $HClO_4$, HNO_3, etc. For example, treatment of compound (IV) with hydrochloric acid in aqueous dioxan solution leads to the formation of the free ligand and the $PdCl_4^{2-}$ anion:[21]



(IV)

Acidolysis in Acetic Acid Induced by the Chloride Ion

As a rule, dimeric cyclopalladated compounds do not decompose in acetic acid. However, the monomeric complexes, i.e. the products of the cleavage of the chloride bridges by triphenylphosphine, undergo acidolysis in acetic acid in the presence of LiCl:[22,23]

This results in the formation of an insoluble palladium(II) complex and the free ligand. The *ortho*-deuteriated products are obtained in DOAc.[23]

III. REACTIONS WITH ALKENES

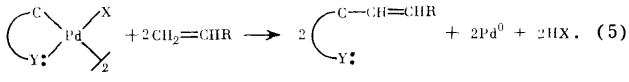
The possibility of the interaction of the cyclopalladated complexes with alkenes, involving the formation of the products of the formal substitution of palladium(II) by the vinyl group, was indicated for the first time in a review,[24] whose author concluded that styrene reacts readily with $[Pd(dmba)Cl]_2$ in acetic acid at room temperature with formation of 2-dimethylaminomethylstilbene:

$$[Pd(dmba)Cl]_2 + 2PhCH{=}CH_2 \rightarrow 2o\text{-}Me_2NCH_2C_6H_4CH{=}CHPh + 2Pd^0 + 2HCl. \quad (4)$$

This communication was followed by a large number of reports devoted to the reactions of palladocycles with alkenes; the results of these studies are summarised in Table 1.

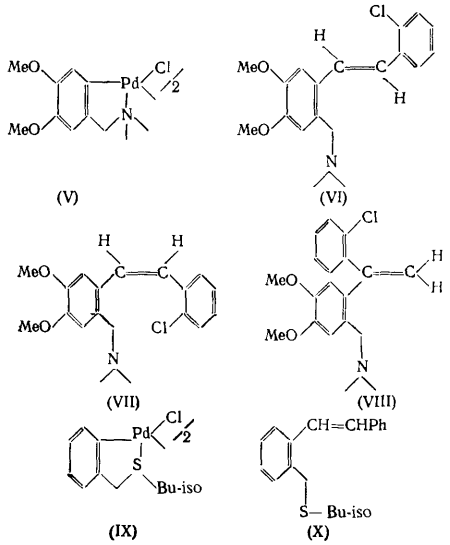
The Stoichiometry and Products of the Reaction

The reactants interact in molar proportions of 1:1, i.e. one palladocycle reacts with one alkene molecule:



(5)

Reactions of type (5) are oxidation-reduction processes and are accompanied by the reduction of palladium(II) to zerovalent palladium. Only α-olefins react. The process proceeds stereospecifically: palladium is substituted by the α-carbon atom of the alkene and the product has the *E*-configuration. This is indicated by the spin–spin coupling constants of the olefin protons $^3J(HH)$, which amount to 15–17 Hz.[25] The infrared spectra of the products contain the band due to the deformation vibrations of the *trans*-HC=CH bonds at 950–990 cm^{-1}.[21] The only exception known hitherto is that of the reaction of compound (V) with *o*-chlorostyrene.[25] In this case the *Z*-stilbene (VII) and 1,1-diarylethylene (VIII) are obtained together with the main product (VI). However, the amount of the last two impurities does not exceed 5% of the content of the main product (VI). The impurities can be readily removed by recrystallising the corresponding hydrochlorides from ethanol:



(V) (VI) (VII) (VIII) (IX) (X)

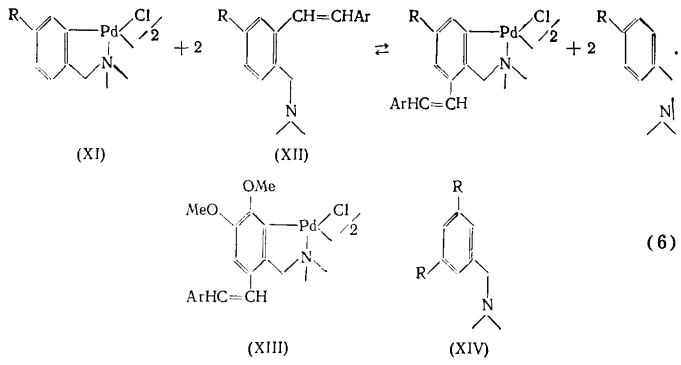
The reaction of [Pd(ba)OAc]$_2$(di-μ-acetatobis(benzylidene-aniline-C^2,N)-dipalladium(II) [Pd(C_6H_4CH=NPh)OAc]$_2$ with methyl acrylate (Table 1, No. 8) exhibits a different stoichiometry, namely one palladocycle reacts with two molecules of the alkene. The structure of the reaction product was established in this case by X-ray diffraction.[37]

The side products in this reaction are most frequently the free ligands formed as a result of the dissociation of the initial complexes. For example, in the interaction of the complex (IX) with styrene in boiling *o*-xylene in the presence of NEt_3 the yields of *trans*-2-(isobutylthiomethyl)-stilbene (X) and $PhCH_2SBu$-iso are 21 and 76% respectively.[26] In acetic acid there is also a possibility of the secondary palladation of the arylolefins formed. Thus the reaction of compound (XI) with *para*-substituted styrenes in an acetic acid–benzene mixture involves the formation, together with the free stilbenes (Table 1, No. 4), of the palladation products of the latter (XII).[21] The complexes (XII) are obtained either as a result of the direct palladation of stilbenes by palladium(II) or as a result of the ligand exchange [reaction (6)]. The exchange reaction, whose nature is analogous to that of reaction (3), explains the

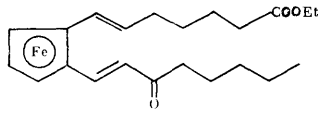
appearance of free ligands in acetic acid media:[21]



(6)

Reaction (6) leads to the non-productive consumption of the initial complex and to a decrease of the yield of the final product. Its suppression increases the yields of stilbenes.[25] In the reactions of compounds (V) with styrenes the hypothetical complex (XIII) can hardly exist for purely steric reasons, since the products of the palladisation of 3,5-dialkylbenzyl-*NN*-dimethylamines (XIV), containing Pd–C bonds in the *ortho*-position relative to the alkyl substituent, do not exist.[27]

The causes of the formation of the free ligands in the absence of acetic acid are less understandable. It has been assumed that[28] they are obtained as a result of the cleavage of the Pd–C bonds in the initial complexes under the influence of the hydrochloric acid liberated in the course of reaction (5), since in the presence of tertiary amines, which are potential HCl acceptors, the free ligands are not formed. However, subsequently, for example, in the study of Fuchita et al.[26], it was shown that the dissociation takes place also in the presence of amines. The role of the latter in reaction (5) remains altogether obscure. This is further confirmed by the formation of the product (XV) in 10% yield on ketovinylation of the ferrocene derivative (Table 1, No. 22) in the absence of NEt_3.[29]



(XV)

Overall, reaction (5) is a variant of the familiar reactions involving the arylation of olefins by hydrocarbons (the Fujiwara–Moritani reaction)[30,31] or organometallic compounds (the Heck reaction)[32,33] in the presence of palladium(II) salts:

$$ArM + H_2C{=}CHR + Pd^{II} \rightarrow ArHC{=}CHR + M^+ + H^+ + Pd^0, \qquad (7)$$

where M = H or HgX. As in reaction (5), the aryl group adds to the least branched carbon atom involved in the double bond and the product has the *E*-geometry. Thus reaction (5) can serve as a convenient model of the Fujiwara–Moritani or Heck processes, in which the initial complex contains a stable palladium–carbon bond.

The Nature of the Cyclopalladised Complex and the Olefin

Table 1 shows that a whole series of palladocycles with chelating donor atoms of different types (Table 1, Nos. 1–17) react with olefins. Derivatives of *NN*-dialkylbenzylamines (Table 1, Nos. 1–7), benzylideneamines, and anilines (Nos. 8–10) have been studied in greatest detail. The donor atoms in the reacting complexes are those of nitrogen, oxygen, and sulphur. Five- and six-membered palladocycles react. The aliphatic complexes with a nitrogen donor atom also enter into the reaction (Table 1, Nos. 18 and 19), while the analogous complexes with an S donor atom in the ring are unreactive.[34] Palladocycles such as ferrocene, ruthenocene, and cyclopentadienyltetraphenylcyclobutadienecobalt derivatives (Table 1, Nos. 20–25) also react readily with olefins. The possibility of the asymmetric palladation of these compounds[35] creates conditions for the synthesis of enantiomeric and diastereoisomeric vinyl compounds (Table 1, Nos. 21 and 22).

As mentioned above, only α-olefins undergo reaction (5). Branched alkenes, for example pent-3-en-2-one, do not interact with $[Pd(dmba)Cl]_2$. On the other hand, the terminal alkene 3-phenylbut-3-en-2-one reacts and the yield is 80%.[28] Substituents at the double bond exert a weak influence on the yields of the vinylation products (see, for example, Horino and Inoue[36]). On the whole, the yields are determined more by the nature of the initial complex than by that of the alkene. As a rule, if reaction (5) involving any alkene proceeds with a satisfactory yield then it also proceeds fairly smoothly with other alkenes of different types. The exceptions are the $[Pd(dmba)Cl]_2$ analogues already mentioned. These complexes react readily with vinyl ketones (Table 1, Nos. 1–3 and 5) in boiling benzene or toluene in the presence of tertiary amines but under these conditions they are inert with respect to olefins without keto-groups.[21,25,37]

The vinylation of *NN*-dialkylbenzylamine complexes by these alkenes can be carried out only in the presence of carboxylic acids; it has been noted that the reaction is significantly accelerated in the presence of sodium or lithium perchlorate.[21]

Reaction Conditions

Reaction (5) is usually carried out with an aromatic hydrocarbon as the solvent (benzene, toluene, and xylenes) in the presence of a tertiary amine, usually NEt_3 (method A), or in acetic acid to which benzene or methylene chloride are added to increase the solubility of the initial complexes (method B). The reaction is performed at 75 °C and above by method A and at lower temperatures by method B. The reaction time is determined by the nature of the initial palladocycle and can vary within wide limits. As a rule,[21,25,28] the vinylation of benzylamine derivatives is accelerated in the presence of acetic acid but sometimes the reaction does not proceed in this solvent.[34]

The rates of reactions catalysed by acetic acid increase markedly when lithium, sodium, or magnesium perchlorate is added to the acetic acid solutions.[21,38] Their catalytic effect consists in the fact that they react with acetic acid via reaction (8) and the real catalyst of reaction (5) is

perchloric acid:

$$MClO_4 + HOAc \overset{K_s}{\rightleftharpoons} MOAc + HClO_4. \quad (8)$$

The equilibrium in Eqn. (8) is strongly displaced to the left: for $[NaClO_4] = 0.1$ M, the $HClO_4$ concentration is only $\sim 2 \times 10^{-5}$ M ($K_s = 4.3 \times 10^{-9}$ M). The cyclopalladised complexes are stable at such low $HClO_4$ concentrations and do not decompose under these conditions. The addition of small amounts of $HClO_4$ to the reaction mixture also increases the rate of reaction.[38]

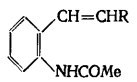
The Synthesis of Analogues of Prostaglandins

Table 1 presents examples of the reactions of alkenes with cyclopalladated complexes isolated beforehand in a pure state. At the same time, it is possible to carry out the vinylation of the palladocycles formed *in situ*. Holton[39] used this approach to synthesise prostaglandins. The palladisation of the enamine (XVI) in a mixture of ethylene-chlorohydrin and dimethyl sulphoxide (DMSO) leads to the bicyclic cyclometallated complex (XVII) with a five-membered palladocycle; without being isolated in a pure state, the latter is treated with n-pentyl vinyl ketone. The vinyl ketone (XVIII) was obtained as a result. It can then be converted by traditional chemical methods[39] into Corey's lactone-diol (XIX), which is a precursor of prostaglandin $PGF_{2\alpha}$.[40]

The ketovinylation of the products of the asymmetric palladation of ferrocene derivatives is also a key stage in the synthesis of models of natural prostaglandins.[29] The metallation of 2-(6-ethoxycarbonyl-1-dimethylaminohex-1-yl)-1-(3-oxo-oct-1-en-1-yl)ferrocene (Table 1, No. 22) with subsequent mild reduction to the methiodide (XX) with $NaBH_4$ leads to compound (XXI).

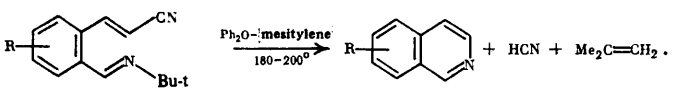
The Synthesis of Heterocycles

The vinylation of *ortho*-palladised compounds, which leads, in particular, to *ortho*-substituted stilbenes, is a convenient method of synthesis of compounds of this class (see, for example, Becker[41]). However, there is an additional interest in analogous products owing to the possibility of their employment to synthesise heterocyclic compounds. Several examples are presented below. Treatment of compound (XXIIa) with concentrated HCl for several minutes results in the formation of quinoline in high yields.[36] Quinaldine and carbostyril respectively have been obtained analogously from compounds (XII, b and c):[36]

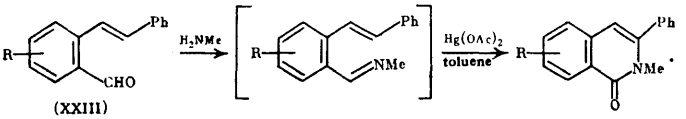


(XXII): a) R=CH(COEt)$_2$; b) R=COMe; c) R=COOMe.

A synthetic approach to substituted isoquinolines, starting with the products of the reactions of *ortho*-palladised Schiff bases with acrylonitrile (Table 1, No. 10), has been proposed recently:[42]

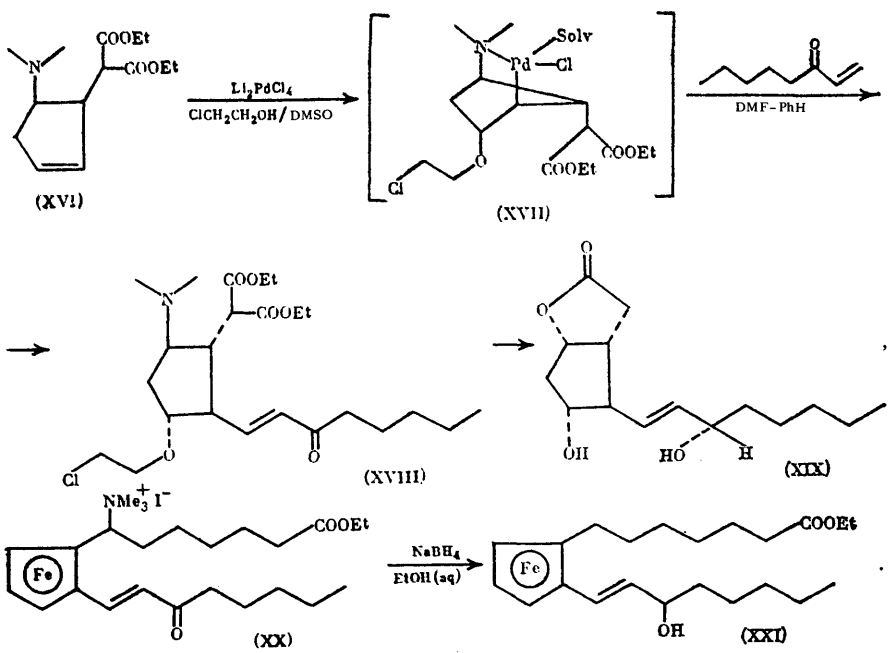


3-Arylisoquinolones can be obtained[43] in accordance with the scheme



(XXIII)

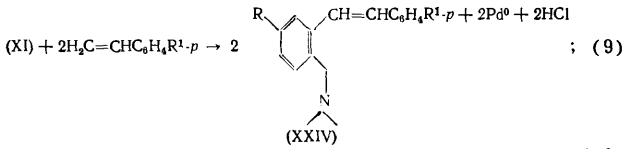
The starting compounds are synthesised as shown in Table 1 (No. 9). The above methods are attractive,



because of their simplicity and the high yield of the required products.

The Reaction Mechanism

The kinetics of the reactions of cyclopalladated complexes with alkenes have been investigated in relation to the interaction of the complex (XI) with *para*-substituted styrenes in acetic acid:[38,44]



$$(XI) + 2H_2C{=}CHC_6H_4R^1\text{-}p \rightarrow 2\ (XXIV) + 2Pd^0 + 2HCl \quad ; \quad (9)$$

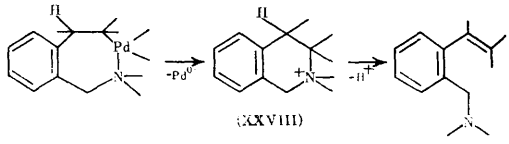
$$d[(XXIV)]/dt = k_2[(XI)][H_2C{=}CHC_6H_4R^1\text{-}p]. \quad (10)$$

The rate of reaction is described by the kinetic equation (10). An interesting feature of reaction (9) is the large positive salt effect. In the presence of tetrabutylammonium, sodium, lithium, and magnesium perchlorates, k_2 increases sharply. The catalytic effect increases in the above series of cations from left to right and the increase reaches almost two orders of magnitude for $[Mg(ClO_4)_2] = 0.1$ M.

It has been shown[38,44] that the effect of the salt is associated with the existence of equilibrium (8) in acetic acid. Perchloric acid catalyses the process in conformity with a kinetic equation of the type $k_2 = k_3 + k_4[HClO_4]$, i.e. the reaction proceeds via two parallel pathways—the "solvolytic" pathway (k_3) and the acid-catalysed pathway (k_4). Since reaction (9) does not occur in the absence of acetic acid, it is assumed that the solvolytic pathway is promoted by acetic acid. The electrophilic catalyst E (acetic and perchloric acids for the k_3 and k_4 pathways respectively) interacts with the bridging chloro-ligands of the initial complex [Eqn. (11)], which facilitates the coordination of palladium(II) to the alkene molecule:

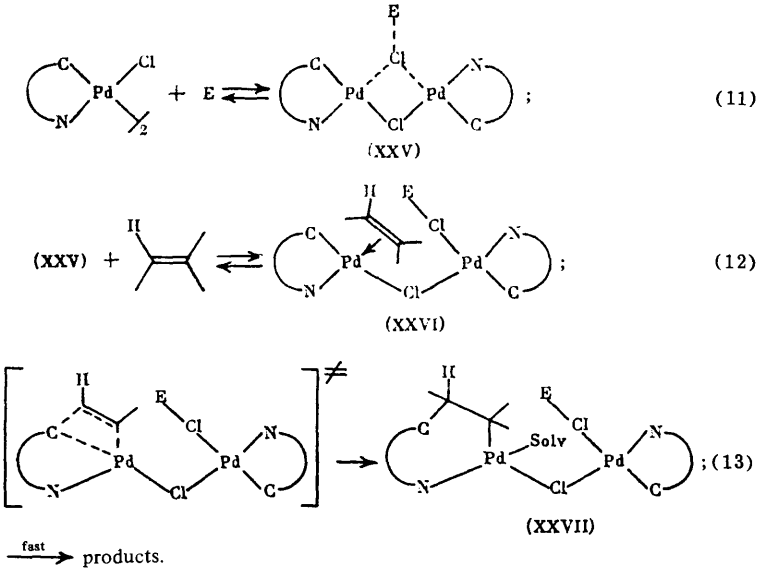
Generally speaking the intermediate complex (XXV) can have only one bridging ligand: similar compounds have been recently characterised by X-ray diffraction methods.[45] Subsequently compound (XXV) reacts reversibly with the alkene to form the π-complex (XXVI). The latter undergoes the rate-limiting π-σ rearrangement via a cyclic four-centre transition state. This is indicated by the low absolute values of the Hammett parameters $\rho(R^1)$ and $\rho(R)$ obtained, which do not exceed unity, and also by the low enthalpies of activation $\Delta H^{\neq}$.[38]

The elimination of hydrogen from the intermediate complex (XXVII), which leads to the final products, is a rapid stage. This is indicated by the kinetic isotope effect $k_2(PdCHCH_2)/.k_2(PhCHCD_2) = 1$. It has been suggested[25,38] that hydrogen is removed in the form of palladium hydride HPd^+ as a result of 1,3-elimination. The same mechanism operates in the Fujiwara–Moritani and Heck reactions [see Eqn. (7)].[46–48] Another possibility for the conversion of the complex (XXVII) into the reaction product involves the reductive elimination of zerovalent palladium, which leads to tetrahydroisoquinoline derivatives of type (XXVIII). The latter are fairly labile and readily undergo the Hofmann rearrangement to arylolefins in the presence of bases:[49]



(XXVIII) (14)

The mechanism (11)–(13) is probably valid in broad outline also for other palladocycles. There may be differences in the method of incorporation of the alkene in the coordination sphere of palladium(II). The olefin can in principle substitute the donor atom in cyclopalladated complexes, which results in their dechelation. Unfortunately, it is difficult to distinguish this possibility by direct kinetic methods from the reaction pathway examined above.



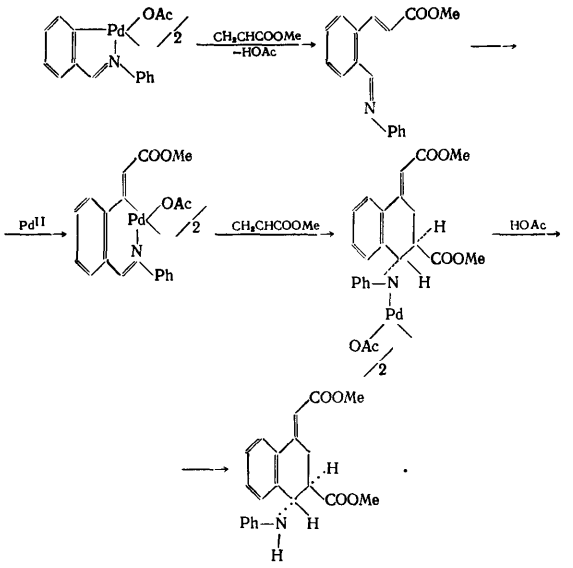
(XXV) (11)

(XXVI) (12)

(XXVII) (13)

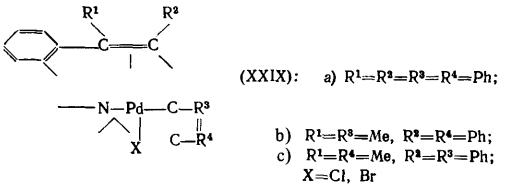
(XXVII) $\xrightarrow{fast}$ products.

In conclusion we shall consider the "double" insertion mechanism[37] (Table 1, No. 8). The usual formation of the arylolefin is followed by its secondary vinyl palladation. Next comes the insertion of a second methyl acrylate molecule and intramolecular addition of the palladium–carbon bond to the C=N double bond. Finally the Pd–N covalent bond formed undergoes homolysis or acidolysis by the acetic acid, which appears in the course of the first vinylation stage:[37]

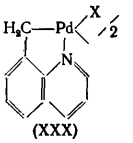


IV. REACTIONS WITH ALKYNES

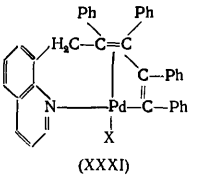
Cyclopalladised compounds readily react with disubstituted alkynes of the type $RC{\equiv}CR'$ ($R = R' = Ph$; $R = Ph$, $R' = Me$), forming double insertion products.[50] For example, $[Pd(dmba)Cl]_2$ is then converted into the complex (XXIXa) with a rarely encountered nine-membered palladocycle. The asymmetric alkyne PhC_2Me gives rise to a mixture of the isomeric complexes (XXIXb) and (XXIXc), each of which has been isolated in a pure state:



(XXIX): a) $R^1=R^2=R^3=R^4=Ph$;
b) $R^1=R^3=Me$, $R^2=R^4=Ph$;
c) $R^1=R^4=Me$, $R^2=R^3=Ph$;
X=Cl, Br

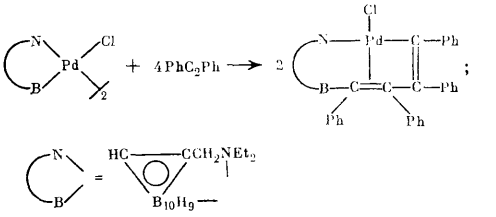


(XXX)

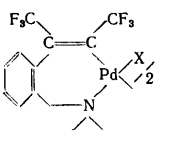


(XXXI)

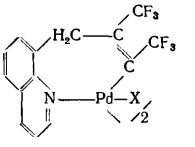
The structure of compounds (XXIXb, X = Br) and (XXIXc, X = Cl) has been established by X-ray diffraction. Tolane reacts with compound (XXX), also giving rise to the double insertion product (XXXI); hexaphenylbenzene is formed as a side product. The yield of compound (XXXI) depends on the reaction time and it has been assumed on this basis[50] that the complex (XXXI) can be an intermediate in the trimerisation of tolane. The reaction of compound (XXX) with PhC_2Me leads to a mixture of 1,2,4-trimethyl-3,5,6-triphenylbenzene and 1,3,5-trimethyl-2,4,6-triphenylbenzene in proportions of 7:3; the yield of the analogue (XXXI) does not exceed 1% in this case.[50] Double insertion products are also formed in the interaction of tolane with the *B*-palladated *o*-carbaborane:[51]



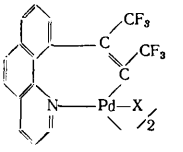
Cyclopalladised derivatives of benzo[*h*]quinoline, azobenzene, and *NN*-dimethyl-1-naphthylamine do not react with PhC_2Ph.[50] Nor has it been possible to obtain the products of the insertion in the Pd–C bond of one PhC_2Ph molecule. On the other hand, in the case of hexafluorobut-2-yne the monoinsertion products (XXXII)–(XXXV) are formed exclusively.[50,52,53]



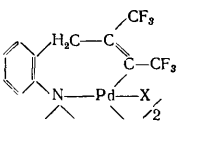
(XXXII)



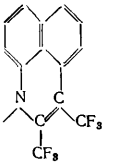
(XXXIII)



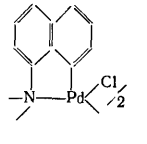
(XXXIV)



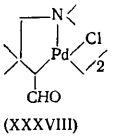
(XXXV)



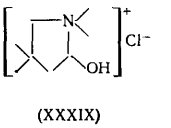
(XXXVI)



(XXXVII)



(XXXVIII)



(XXXIX)

The unusual compound (XXXVI), obtained as a result of the dissociation of the N–Me bond, has been isolated in the reaction of compound (XXXVII) with $CF_3C_2CF_3$.[50] Tolane does not react with the aliphatic cyclopalladated complex (XXXVIII), but treatment of the latter with phenylacetylene leads to 3,3-dimethyl-4-dimethylaminobutanal, whose hydrochloride has the cyclic structure (XXXIX).[54]

The reactions examined in this Section lead in most cases to new palladocycles and only sometimes to new free organic compounds. However, all these processes are extremely promising, since their products are difficult to obtain by other methods. We may note that, whereas the vinylation of palladated ligands (Section III) is characteristic of palladium(II) compounds only, the insertion of alkynes is also observed for other cyclometallated complexes of platinum group metals. In particular PhC_2Ph gives rise to the complex $\{\overline{Rh[(PhC=CPh)_2C_6H_4PPh_2]}PPh_3\}$,[55,56] while $CF_3C_2CF_3$ produces $\{\overline{Ru[(CF_3C=CCF_3)_2C_6H_4PPh_2]}(\eta\text{-}C_5H_5)\}$,[57] i.e. complexes with eight-membered metallocycles are formed.

There are no data concerning the mechanisms of the interaction of alkynes with palladocycles. However, the mechanism of the double insertion of PhC_2Ph, leading to compounds of type (XXIX), is probably of special interest. The fact that it has not been possible[50] to detect the mono-insertion products suggests the possibility of the synchronous addition of two alkyne molecules to the palladium–carbon bond.

V. REACTIONS WITH CARBON MONOXIDE

The ability of carbon monoxide to react with compounds containing metal–carbon bonds is well known (see, for example, the relevant reviews[58,59]). Cyclopalladated complexes, to the reactions of which with CO this Section is devoted, are not exceptional.

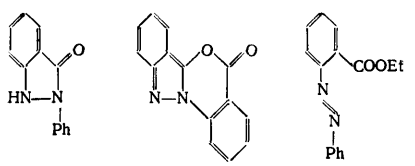
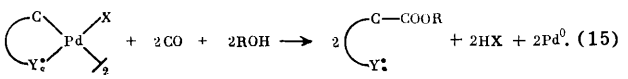
The Stoichiometry and Products of the Reactions

Examples of the reactions of cyclopalladated complexes with carbon monoxide are presented in Table 2. As a rule, one palladocycle absorbs one CO molecule. The carbonylation is accompanied by the reduction of palladium(II) to zerovalent palladium. In contrast to the reactions with alkenes, which yield isotypical compounds, the structure of the products of the carbonylation of palladocycles cannot always be predicted unambiguously. For example, depending on the carbonylation conditions, the products (XL)–(XLII) are formed from the *o*-metallated azobenzene[60,61] (Table 2, Nos. 2–4).



(XL) (XLI) (XLII)

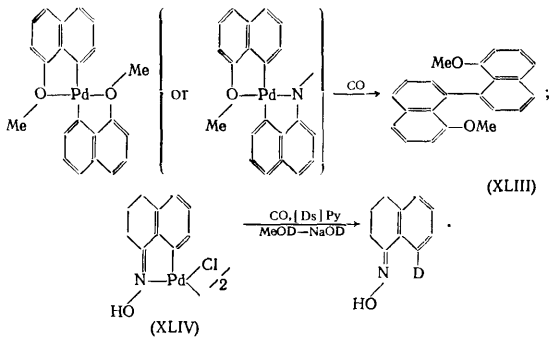
We may note that the formation of the lactone (XLI) is a fairly rare instance of a reaction with the stoichiometry palladocycle : CO = 1 : 2. The same large assortment of products is formed from palladated derivatives of benzilideneaniline (Table 2, Nos. 5–7). Table 2 shows that specific products are formed as a rule from each concrete complex. The most characteristic carbonylation pathway involves the formation of esters in alcohols:



(15)

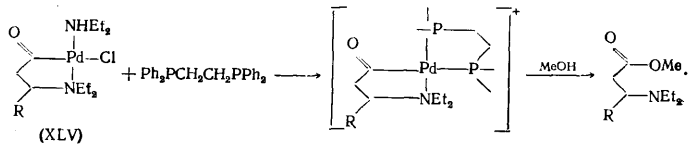
Esters are obtained from cyclopalladated azobenzenes (Table 2, No.4), benzylideneanilines (No.6), the 1-methyl-1-phenylhydrazones of formaldehyde (No.13) and acetaldehyde (No.15), acetanilides (No.18), certain oximes (Nos.19 and 20), aliphatic compounds (No.21), pyrroles (No.22), ferrocene (Nos.23–27), ruthenocene (No.28), and cyclopentadienyltetraphenylcyclobutadienecobalt (No.29).

In a number of instances the "carbonylation products" of palladocycles do not contain carbon monoxide at all. Thus the carbonylation of derivatives of 1-methoxynaphthalene results in the quantitative formation of 8,8′-dimethoxy-1,1′-binaphthyl (XLIII).[15] The study of the interaction of palladated oximes with CO showed[62,63] that the free ligand is formed under certain conditions. This "reductive carbonylation" reaction has served as the basis of a method of synthesis of selectively deuteriated vinyl[62] and aryl[63] oximes. For example, the reaction of the palladocycle (XLIV) with CO in solution in MeOD in the presence of [D_5]pyridine leads to the selective formation of the oxime of 8-deuterio-1-tetralone.[63] This method has advantages over the traditional procedure involving the reduction of $LiAlD_4$ in which the palladised oximes are reduced to amines:[64]



Carbonylation Conditions

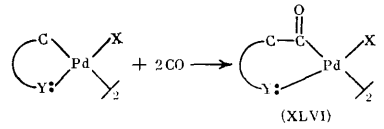
Depending on the nature of the initial palladocycle and the character of the products expected, the following solvents are used: benzene, chlorobenzene, xylenes, methanol, ethanol, water, and a xylene–aniline mixture. A wide range of carbon monoxide pressures are used: from simple bubbling with CO at atmospheric pressure to 150 atm. The reaction time and temperature are also varied within wide limits. The carbonylation is carried out under homogeneous and heterogeneous (when the solubility of the initial complex is low) conditions, sometimes in the presence of triphenylphosphine. It might have been supposed that PPh_3 is necessary to increase the solubility of the initial palladocycles as a result of the formation of soluble monomeric complexes of the type [Pd(L–H)Cl(PPh_3)];[65] however, in a number of instances even homogeneous carbonylation does not take place in the absence of the PPh_3 [66,67] and the conversion of the acyl complex (XLV) into an ester in MeOH takes place only in the presence of $Ph_2PCH_2CH_2PPh_2$.[68] These examples show that phosphines can play an important role in the carbonylation process.



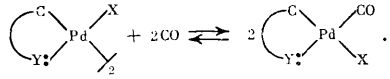
The Reaction Mechanisms

The kinetics of the carbonylation of cyclopalladated compounds have been investigated. The majority of the mechanisms of the interaction with CO postulated are based on the structure of the final products, i.e. the proposed schemes merely clarify the pathways leading to the formation of the final compounds. However, since the majority of similar stages with participation of CO have been thoroughly investigated for other related systems (see, for example, Refs.58, 59, and 69), the reaction mechanisms appear on the whole to be fairly convincing.

Evidently the key stage in all the reactions listed in Table 2 is the insertion of CO in the palladium–carbon σ-bond, which results in the formation of a six-membered cyclic acyl complex (XLVI).



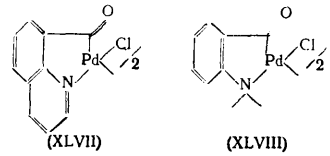
(16)



(17)

The insertion can be preceded by the equilibrium stage involving the rupture of the bridging ligands in accordance with Eqn.(17). Such monomeric cyclopalladated complexes with CO have been described for derivatives of certain oximes and 8-methylquinoline.[70–72] However, in these cases they are not converted further either into compound (XLVI) or into carbonylation products.

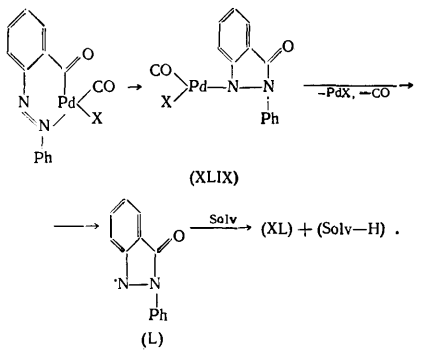
The five-membered acyl complexes (XLVII) and (XLVIII) are known and are obtained by the direct palladisation of the corresponding aldehydes on treatment with Na_2PdCl_4 in ethanol.[73] The reactions of the alkenes RHC $=CH_2$ (R = H, Me, or Et) with $PdCl_2(PhCN)_2$ in the presence of CO and diethylamine lead to the analogous complexes (XLV).[68,74] The increased stability of the complexes (XLV), (XLVII), and (XLVIII) can be accounted for by the presence of the stable five-membered palladocycle:



In particular, compound (XLV) undergoes further reactions only under special conditions[68] (see above). Six- and seven-membered acyl complexes of palladium(II) are significantly less stable and spontaneously enter into further reactions whose sequence is determined by the nature of the initial complex and the medium. Thus stage (16), which is common to all the complexes, is followed by processes typical for the compounds of the given type. We shall consider certain examples.

1. *Palladated azobenzenes.* At high CO pressures (up to 150 atm) in ethanol, 2-aryl-3-indazolinones (XL) are formed preferentially, apparently as a result of the intramolecular addition of the palladium–acyl fragment to the N=N double bond in the intermediate acyl complex, which leads to the amide complex (XLIX).[61] The latter can be converted into the final product (XL) either in the course of the protolysis of the Pd–N bond by ethanol or during

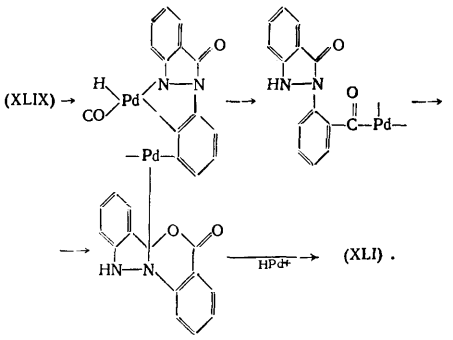
the "oxidative homolysis" of this bond with formation of the radical (L), which is capable of abstracting hydrogen from the solvent molecule. Examples of oxidative homolysis are well known. [75,76]



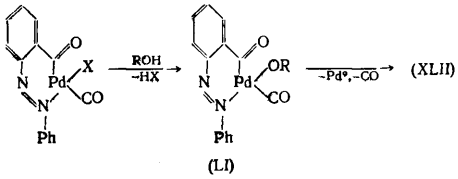
(XLIX)

(L)

The formation of the lactone (XLI), the product of the "double insertion" of CO, can be explained by the repeated palladation of the neighbouring aromatic ring. The key stage in this sequence of reactions is the intramolecular addition of acylpalladium to the carbonyl oxygen of the amide group. The subsequent 1,4-elimination of palladium hydride leads to a lactone (XLI):

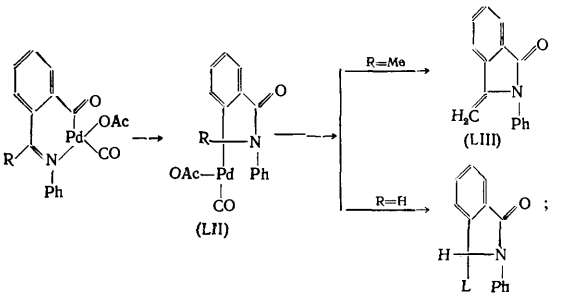


The esters (XLII) are formed as a result of the ethanolysis of compound (XL) [60] or, and we believe this to be more probable, in the course of the reductive decomposition of the complex (LI). We may note that compounds (XL) and (XLII) are also formed in the carbonylation of the analogous azobenzene complexes of platinum(II): [77]



(LI)

2. *Palladated Schiff bases.* The structure of the carbonylation products of these compounds (Table 2, Nos. 5–7) is determined by the presence of the azomethine double bond to which the palladium–acyl group adds. [60] The pathways leading to the further transformation of the σ-derivative (LII) depend on the nature of the substituent R at the C=N double bond and on the presence of an extraneous nucleophile. When R = H, palladium(II) is formally substituted by the nucleophile: by the acetoxy- or carboxy-group, when the reaction is carried out in an inert solvent or in alcohol respectively, and also by the PhNH group when the reaction is carried out in the presence of aniline. When R = Me, the reaction pathway changes and the alkene (LIII) is formed in the course of the 1,3-elimination of palladium:



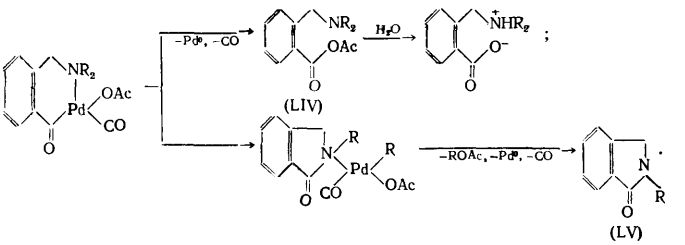
(LII)

(LIII)

L = OAc, OR', NHPh.

The carbonylation of other cyclopalladated complexes containing the N=N and C=N double bonds proceeds analogously to the carbonylation of azobenzene and azomethine derivatives. The principal stages considered above obtain in the reactions of other related complexes and, in conformity with the structure of the final carbonylation products, it is easy to determine the entire sequence of reactions of CO with the given specific palladocycle.

3. *Complexes of NN-dialkylbenzylamines.* Zwitter-ionic products (Table 2, No. 16) are formed in the hydrolysis of the mixed anhydrides (LIV). The formation of the phthalimidine (LV) is accompanied by the dissociation of the N–Me bond. It has been suggested [60] that the nitrogen–carbon bond is ruptured as a result of the 1,2-alkyl shift from nitrogen to palladium. It is of interest that the formation of compound (XXXVI) examined above can involve exactly the same mechanism.

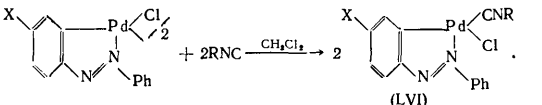


(LIV)

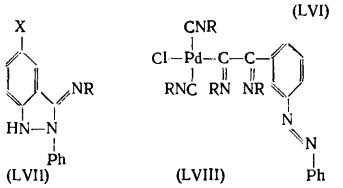
(LV)

VI. REACTIONS WITH ISOCYANIDES AND CARBON DIOXIDE

The reactivity of the isocyanides (CNR) with respect to the transition metal–carbon bond [78] is in many respects analogous to that of carbon monoxide, which is isoelectronic with isocyanides. Under mild conditions, isocyanides, taken in stoichiometric amounts, react [79] with dimeric o-palladised derivatives of azobenzenes, forming the monomeric complexes (LVI):



(LVI)



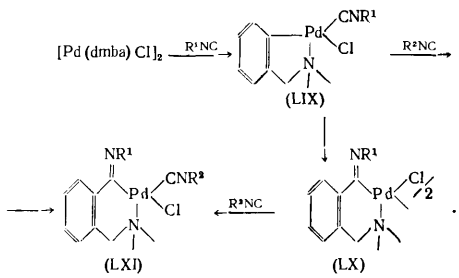
(LVII)

(LVIII)

X = H, OMe; R = Bu-t, C_6H_{11}, C_6H_4Me-o

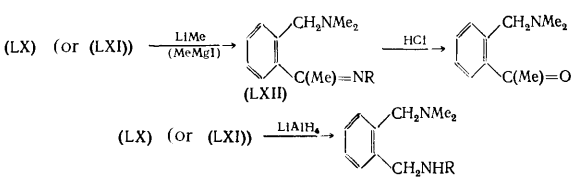
Heating of compounds (LVI) in toluene (at 100–130 °C) leads to 3-imino-2-phenylindazolines (LVII) in 67–90% yields and the process involves the reduction of palladium(II) to zero-valent palladium. The product (LVII) is not formed in the reaction with an excess of *o*-tolyl isocyanide and the complex $[Pd(C_6H_4N{=}NPh)(o\text{-}MeC_6H_4NC)_4Cl]$ is obtained.[79] A similar product has been isolated[80] in the interaction of an excess of cyclohexyl isocyanide with di-μ-chlorobis(azobenzene-C^2,N)dipalladium(II), i.e. $[Pd(azb)Cl]_2$ or $[Pd(C_6H_4N{=}NPh)Cl]_2$. It has been suggested[80] that two molecules of the isocyanide are inserted during the reaction in the Pd–C bond, which results in the formation of compound (LVIII).

The interaction of $[Pd(dmba)Cl]_2$ with isocyanides[81] is presented schematically below:

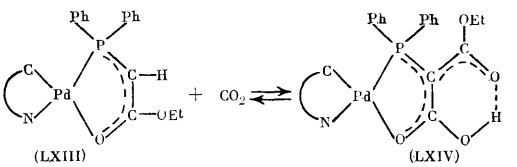


Treatment of the initial complex with a stoichiometric amount of *o*-tolyl isocyanide affords the monomer (LIX). When compound (LIX) is heated in tetrahydrofuran (THF), the coordinated isocyanide is inserted intramolecularly in the Pd–C bond with formation of the iminoacyl complex (LX). The monomer (LIX) can react with an isonitrile of another type with formation of compound (LXI). The ease of insertion of the isocyanides CNR as a function of the nature of the substituent R diminishes in the sequence *o*-tolyl > phenyl > t-butyl. This series shows that the reactivity of the isocyanide is determined by electronic and not steric factors.[81]

The new six-membered iminoacyl palladocycles (LX) and (LXI) are obtained in high yields and this has stimulated their employment as important intermediates for the synthesis of a number of *ortho*-substituted compounds. In particular, the reaction with methyl-lithium or methyl-magnesium iodide leads to the Schiff bases (LXII),[81] whose acid hydrolysis gives rise to the corresponding ketones and reduction with $LiAlH_4$ affords the corresponding diamines:

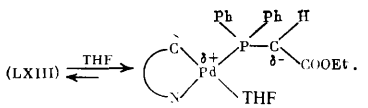


Instances of the insertion of CO_2 in the Pd–C bond in cyclopalladated complexes have not so far been described in the literature. Nevertheless, it is useful to consider one interesting reaction of carbon dioxide. It has been shown recently that the complexes (LXIII) are capable of binding CO_2 reversibly.[82,83] Bubbling of dry CO_2 through their solutions in THF for several seconds leads to the insertion of CO_2 in the PC–H bond and the formation of new complexes of type (LXIV) in which chelation via the oxygen atom of the ester has been replaced by chelation via an oxygen atom of carbon dioxide:



C N = benzyldimethylamine (a) or 8-methylquinoline (b)

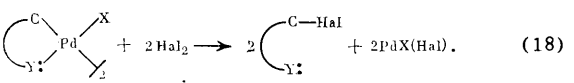
The structure of one of these complexes (LXIVb) has been established by X-ray diffraction.[83] The addition of CO_2 is fully reversible: the initial complex (LXIII) is reformed in a stream of argon and the process can be repeated several times. Despite the fact that the palladocycle is not involved directly in the reaction, in its absence, for example in the case of *cis*-$Pt[Ph_2PCHC(O)OEt]_2$, there is no binding of CO_2. It is believed[83] that the strong *trans*-influence of the σ-linked carbon of the metallocycle has a labilising effect on the Pd–O bond and the carbanionic carbon atom of the reactive 1,3-dipolar form of the complex attacks a carbon dioxide molecule:



VII. HALOGENATION

The reactions of halogens with aromatic hydrocarbons as a rule lead preferentially to *para*-substituted aryl halides.[84] The use of *ortho*-metallated complexes makes it possible to alter radically the halogenation selectivity of and to obtain *ortho*-substituted compounds exclusively.

Examples of the action of halogens (Cl_2, Br_2) on cyclopalladated complexes are summarised in Table 3. The reactions proceed in conformity with the equation



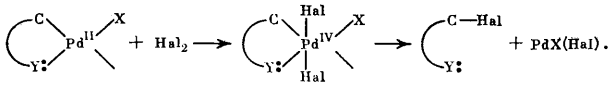
The solvents are aqueous dioxan, methylene chloride, and chloroform. Palladium(II) is not reduced during the reaction. As a result, repeated palladation of the halogenated ligand is possible, which is the cause of the appearance of the 2,6,2′,6′-tetrachloroazobenzene.[85,86] When the reaction time is reduced, 2-chloro-, 2,6-dichloro-, and 2,6,2′-trichloro-azobenzenes are obtained. In contrast to chlorination, polysubstituted products are not formed on bromination.[86]

Only palladium(II) complexes enter into a reaction of type (18). Di-μ-chlorobis(azobenzene-C^2,N)diplatinum(II) is resistant to the action of halogens and the Pt–C bond is not ruptured.[86] In the interaction with halogens of other cyclometallated complexes of platinum group metals, in particular iridium(III) and rhodium(III),[87–89] only the C–H bonds of the metallocycles are chlorinated or brominated, while the M–C bonds remain unchanged. For example, the chlorination of the doubly metallated complex $\{IrCl[P(OC_6H_3Me\text{-}o)_2(OC_6H_4Me\text{-}o)](PEt_3)_2\}$ proceeds with formation of $\{IrCl[P(OC_6Cl_3Me\text{-}o)_2(OC_6H_4Me\text{-}o)](PEt_3)_2\}$.[89]

Table 3. Halogenation of cyclopalladated complexes.

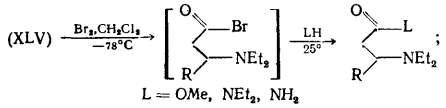
No.	Complex	Halogen	Product (yield, %)	Solvent	Refs.
1	$[Pd(azb)Cl]_2$	Cl_2	 (39)	water–dioxan	[86]
2	То же	Br_2	 (29)	ditto	[86]
3		Cl_2	 (60)	ditto	[129]
4	 R = H, Me	Cl_2	mixture of mono-, di-, and poly-chlorinated products	ditto	[129]
5		Br_2	 (70)	CH_2Cl_2	[36]
6		Br_2	 (35)	$CHCl_3$	[36]
7		Br_2	 (43)	CH_2Cl_2	[29]
8		Br	$\{PdBr_2[PPh_2(C_6H_4Br)]_2\}$, $PdBr_2(PPh_3)_2$	PhH	[91]

The mechanism of the halogenation of palladocycles has not been specially investigated. It may be that the reaction proceeds via the oxidative addition of the halogen to palladium(II) with formation of an octahedral palladium(IV) complex (see, for example, Murenik and Pross[90]), while reductive elimination affords the final products:



The mechanism involving the electrophilic attack by the halogen directly on the palladium–carbon bond might serve as an alternative.

The bromination of acyl derivatives of the palladocycles (XLV) is used to synthesise amides and esters.[68] The intermediate acyl bromides are not isolated; the yield of the final reaction products is quantitative.



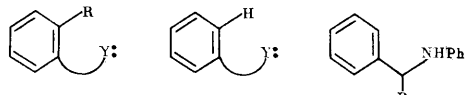
L = OMe, NEt_2, NH_2

Fenton[91] demonstrated the possibility of the chlorination of palladocycles by CCl_4. He obtained the complex $[Pd(o\text{-}ClC_6H_4PPh_2)(PPh_3)Cl_2]$ with an *ortho*-chlorinated ligand from the complex $[Pd(C_6H_4PPh_2)Cl(PPh_3)]$ with a four-membered ring.

Examples of the effective iodination of palladocycles are so far lacking. A report of the possibility of the iodination of dimethylaminomethylferrocene has been reported recently,[92] but the reaction conditions and yields of products are not indicated.

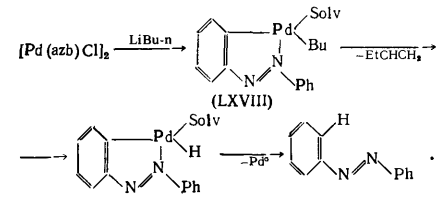
VIII. ALKYLATION, ACYLATION, AND PHOSPHINATION

The *ortho*-alkylated products of the general type (LXV) have been obtained in yields of 22–76% by treating $[Pd(azb)Cl]_2$, $[Pd(dmba)Cl]_2$, and $[Pd(ba)Cl]_2$ with organolithium compounds of the type LiR, where R = Me or Ph, in ether at 0–5 °C.[93,94] The free ligands (LXVI) are formed as side products (up to 38%), while in the case of the benzylideneaniline derivative, compound (LXVII) is formed in addition.



(LXV) (LXVI) (LXVII)

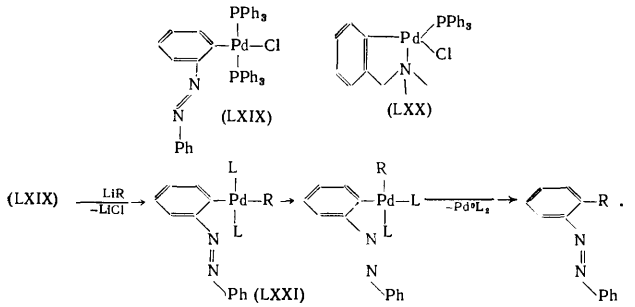
If the group R in the organolithium compound contains β-hydrogen atoms, then the fraction of the reduction products (LXVI) increases significantly. In particular, in the reaction of LiBu-n with $[Pd(azb)Cl]_2$ the yields of compounds (LXV) and (LXVI) are 5 and 89% respectively and in the case of $[Pd(ba)Cl]_2$ the yields of compounds (LXV) and (LXVII) are 1 and 64% respectively. The appearance of reduction products in large amounts when the hydrocarbon group R contains a β-hydrogen atom is associated with the intermediate formation of hydride complexes,[94] whose decomposition leads to compounds (LXVI).



(LXVIII)

In those cases where the group R contains no β-hydrogen atoms, the possibility of the homolysis of the Pd–C bond in the initial complexes has been postulated[94] to account for the formation of compounds (LXVI), although cyclopalladated compounds show no tendency towards spontaneous homolytic decomposition. From our point of view, it is more likely that in this case the homolysis is induced by the groups R

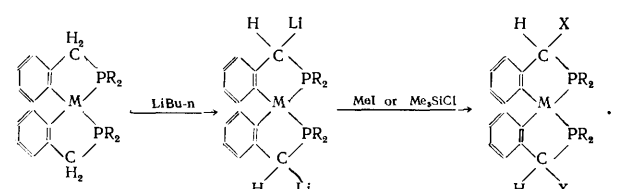
in the intermediate aryl-alkyl or aryl-aryl complex of type (LXVIII). The stability of such compounds increases in the presence of phosphine ligands and it has been found, in conformity with this fact, that the formation of side products in the alkylation of palladocycles is suppressed in the presence of PPh_3; the yields of compound (LXV) increase to 90%.[94] The optimum results are obtained for the ratio $PPh_3 : Pd = 4$. Under these conditions, $[Pd(azb)Cl]_2$ and $[Pd(dmba)Cl]_2$ exist in the forms (LXIX) and (LXX) respectively.[95,96] The mechanism of the alkylation reaction [in relation to compound (LXIX) with $L = PPh_3$] involves the formation of compound (LXXI),[94] its *trans–cis* isomerisation, and reductive elimination:[97,98]



Other phosphorus-containing ligands, for example $P(Bu\text{-}n)_3$, $Ph_2PCH_2CH_2PPh_2$, and $P(OPh)_3$, are less effective as inhibitors of side processes than PPh_3. Apart from organolithium compounds, the Grignard reagents MeMgBr, PhMgBr, and $H_2C = CHMgBr$ have been used. In the last case *o*-substituted arylolefins, analogous to those obtained in the reactions of palladocycles with alkenes (see Section III), are formed.[94]

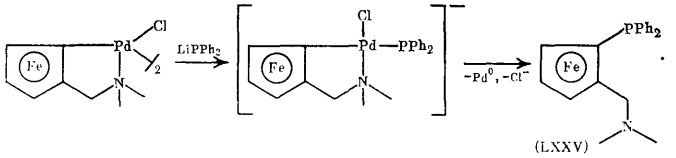
The alkylation of $[Pd(ba)Cl]_2$ by secondary organolithium compounds leads to compounds (LXV) in low yields even in the presence of PPh_3 and is accompanied by the secondary–normal isomerisation of the alkyl group.[99] We may note that the "double" alkylation of $[Pd(ba)Cl]_2$, i.e. the repeated palladation of compound (LXV) and treatment with LiR followed by the acid hydrolysis of the reaction products, leads to 2,6-disubstituted aromatic aldehydes which are difficult to obtain by other methods.[94] Treatment of palladised 2-pyridylferrocene in benzene with LiBu-n and LiPh afforded o-substituted products in yields of 34 and 27% respectively.[66] The alkylation of the iminoacyl complexes (LX) and (LXI) was considered above.

The interaction of n-butyl-lithium with the complexes (LXXII) proceeds via a different pathway.[100] The M–C bond is not then involved, the methylene groups of the complexes being substituted by lithium. Treatment of compound (LXIII) with methyl iodide or trimethylsilyl chloride results in the modification of the cyclometallated ligands in the complexes (LXXIV):



M = Pd, Pt; R = Me, Ph;
X = Me, Me_3Si

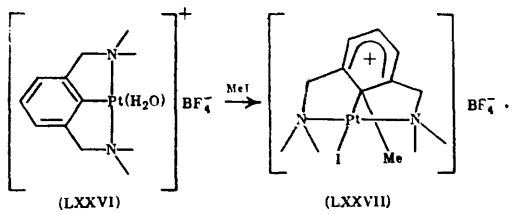
The phosphination of palladocycles is on the whole carried out analogously to alkylation, but in this case the complex is treated with $LiPPh_2$.[101] If the initial cyclopalladation of the substituted ferrocene is carried out asymmetrically, then the enantiomeric ligand (LXXV) with planar chirality is formed:



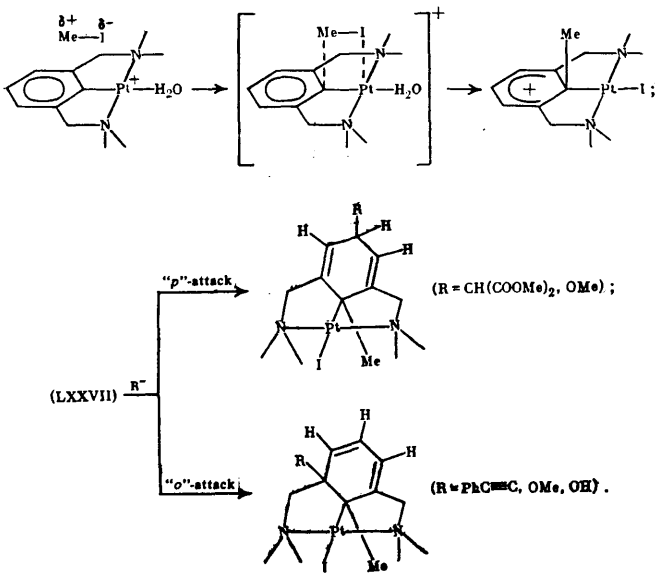
Such ligands have found extensive applications, particularly in the asymmetric cross-coupling reactions of Grignard reagents and organic halogeno-derivatives catalysed by palladium and nickel complexes.[102,103] The highest stereoselectivity is ensured when the ligands L contain elements of planar chirality.[103]

$$R{-}\underset{\underset{Me}{|}}{CH}{-}MgBr + R'Br \xrightarrow{LM} R{-}\underset{\underset{Me}{|}}{CH}{-}R' + MgBr_2 .$$

Direct alkylation of cyclometallated complexes by alkyl halide is so far known for platinum(II) complexes.[104] The reaction of compound (LXXVI) with an excess of methyl iodide in acetone leads to the unusual product (LXVII) whose structure has been established by X-ray diffraction. The central atom of the complex had a slightly distorted square-planar configuration, while the aryl ligand has the boat form.

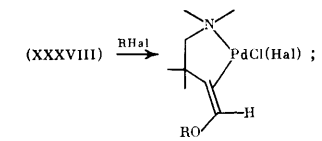


The addition of MeI is reversible: in the presence of NaX (X = Cl, Br, or I) the product is $\{PtX[C_6H_3(CH_2NMe_2)_2\text{-}oo']\}$ in aqueous solutions, while the initial complex (LXXVI) is regenerated in boiling water or aqueous acetone solution. An excess of NaCN decomposes the complex (LXXVII) with formation of $oo'\text{-}(Me_2NCH_2)_2C_6H_3Me$.[105] It is most likely that the mechanism of the formation of compound (LXXVII) involves the direct addition of methyl iodide to compound (LXXVI):[104]



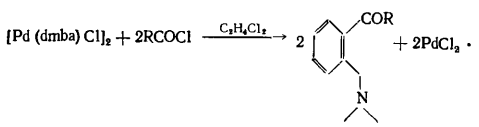
The cationic complex (LXXVII) gives rise to *para*- and *ortho*-addition products on reaction with the strong bases $CH(COOMe)_2^-$, $PhC\equiv C^-$, MeO^-, and HO^-.[105] Depending on the reaction conditions, the "*para*"- or "*ortho*"-attack may be made to predominate. Treatment of these complexes with powerful non-coordinating acids (except for $R = PhC_2^-$) leads to a high yield of the initial compound (LXXVII).

In the interaction of compound (XXXVIII) with allyl bromide and benzyl chloride the hydrocarbon fragment attacks the carbonyl oxygen atom of the complex, which results in the formation of a complex without a palladium–carbon σ-bond:[54]

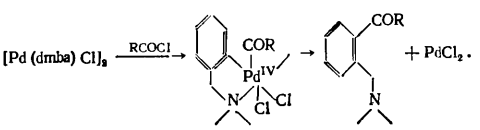


$R = CH_2CH{=}CH_2, CH_2Ph$; Hal = Cl, Br.

The acylation of dimers of type $[Pd(dmba)Cl]_2$ leads to aryl ketones:[106]



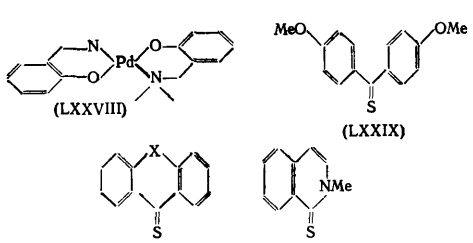
On the one hand, acyl and benzoyl chlorides and, on the other, unsubstituted *ortho*-palladised *NN*-dialkylbenzylamines as well as their analogues with electron-donating substituents enter into the reaction. The yields of aryl ketones are 25–93%. Palladocycles with a chlorine atom in the ring are unreactive. The acylation mechanism[106] involves oxidative addition with the intermediate formation of palladium(IV) and the subsequent reductive elimination of palladium(II) chloride:

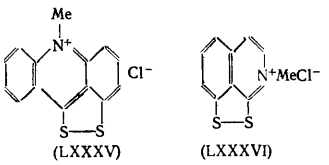


The interaction of palladocycles with acyl halides has also been described by Clark et al.[107]

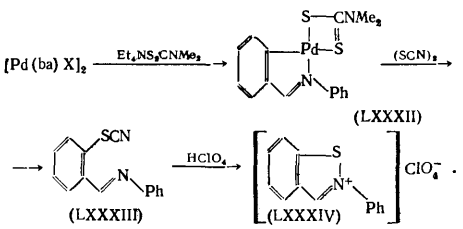
IX. OTHER REACTIONS

The anodic oxidation of $[Pd(azb)OAc]_2$ and $[Pd(dmba)OAc]_2$ does not result in the formation of any isolatable organic products.[108] On the other hand, the oxidation of $[Pd(dmba)Cl]_2$ with *m*-chloroperbenzoic acid in methylene chloride at 0 °C followed by treatment with $NaBH_4$ in methanol leads to a palladium(II) complex of salicylaldimine (LXXVIII) in 35% yield.[109]





Cyclopalladation is a key stage in the syntheses of derivatives of isothiazoles and 1,2-dithiols[110] from metallated benzylideneaniline, 2-pyridylbenzene, benzo[*h*]-quinoline, and the sulphur-containing arenes (LXXIX)–(LXXXI). The pathway leading to isothiazoles is illustrated below using as an example the reaction of palladised benzylideneaniline. The initial complexes are treated with tetraethylammonium *NN*-dialkyldithiocarbamate, which converts them into the monomers (LXXXII):



On treatment with thiocyanogen in chloroform, the latter give rise to the thiocyanates (LXXXIII) and the very sparingly soluble complex $[Pd(Me_2NCSS)SCN]_2$. Compounds (LXXXIII) are stable only in the case of 2-pyridylbenzene and benzo[*h*]quinoline, but treatment of even unstable intermediates with perchloric acid leads to isothiazoles of type (LXXXIV). In the case of compounds (LXXXb) and (LXXXI) best results are achieved when the analogues (LXXXII) react with *N*-sulphenylmorpholine chloride, which results in the formation of the 1,2-dithiols (LXXXV) and (LXXXVI). The yields of isothiazoles and 1,2-dithiols are 25–90 and 81–91% respectively.

A pathway to *ortho*-deuteriated aromatic ketones has been proposed by Alper.[111] Refluxing of the *ortho*-palladated compounds (LXXIX) and $O=C(C_6H_4Me\text{-}p)_2$ in MeOD for 18 h leads to $O=C(C_6H_4X\text{-}p)(C_6H_4D\text{-}o\text{-}X\text{-}p)$, where X = OMe or Me, in yields of 82 and 84% respectively. The transamination of complexes of Schiff bases has been described.[112]

---o0o---

The reactions considered indicate the extensive possibilities of the application of cyclopalladated compounds and also the related complexes of other transition metals in organic sythesis. Their use is of greatest interest in the preparation of organic compounds which are difficult to obtain by other procedures and also of enantiomeric and diastereoisomeric molecules. Bearing in mind that chiral palladocycles are also used for the separation of racemates, for example, those of tertiary phosphines,[113,114] one may hope that this field of chemistry, which is developing at the frontier between organic and organometallic chemistry as well as metal complex catalysis, will undergo further natural development.

Metal Complex Catalysts for the Hydrogenation of Aromatic and Heterocyclic Compounds

E.A.Karakhanov, A.G.Dedov, and A.S.Loktev

The application of metal complex catalysts (in homogeneous and heterogenised forms) to the hydrogenation of aromatic and heterocyclic compounds is examined.
The bibliography includes 128 references.

I. INTRODUCTION

The study of the hydrogenation of aromatic and heterocyclic compounds constitutes an important (from both practical and theoretical standpoint) and at the same time a complex problem. There are numerous literature data on the hydrogenation of the above compounds (see, for example, Smith,[1] Bel'skii and Shostakovskii,[2] Kreile et al.,[3] and Mashkina[4]), but these concern mainly only heterogeneous-catalytic reactions, requiring as a rule the use of fairly severe conditions, which entails in its turn a decrease in the selectivity of the processes.

A much smaller number of studies have been devoted to the hydrogenation of aromatic and heterocyclic compounds in the presence of metal complex catalysts apparently owing to the difficulty of selecting metal complexes capable of activating aromatic and heterocyclic compounds and at the same time remaining resistant to the poisoning activity of the latter. Nevertheless the synthesis and employment of metal complexes as hydrogenation catalysts (homogeneous and particularly heterogenised catalysts which possess simultaneously the advantages of homogeneous and traditional heterogeneous catalysts) is extremely promising, since it permits the process to be carried out under mild conditions, which significantly increases the yield of products and the reaction selectivity.

The advantages and disadvantages of metallic and metal complex catalysts combined with the theoretical development of a general approach to the investigation of the characteristic features of catalytic reactions of organic compounds in the presence of these systems in the course of various processes (deuterium–hydrogen exchange, hydrogenation, oxidation, etc.) have been considered in a number of publications (see, for example, Refs.5–17).

Hydrogenation is one of the first reactions carried out using metal complex catalysts. A number of reviews have been devoted to this question (for example, those of James,[18] Coffy,[19] and McQuillin,[20] in which mainly the hydrogenation of compounds containing bonds of the olefinic type is discussed. This review deals with the available literature data for the hydrogenation of aromatic and heterocyclic compounds in the presence of metal complex catalysts—both homogeneous and heterogenised. Instances of the hydrogenation of unsaturated substituents are excluded from consideration if such hydrogenation does not entail the hydrogenation of the aromatic or heterocyclic ring.

II. CATALYSTS FOR THE HYDROGENATION OF AROMATIC HYDROCARBONS

1. Catalysts Active under Hydroformylation Conditions

Dicobalt octacarbonyl was the first metal complex catalyst used for the hydrogenation of aromatic and heterocyclic compounds.[21] However, its use requires the reaction to be carried out in the presence of an excess carbon monoxide pressure and hydrocarbonylation can therefore occur to a greater or lesser extent together with the hydrogenation reaction.

Benzene and its alkyl-derivatives are hardly hydrogenated under hydroformylation conditions.[22,23] For example, only a slight degree of conversion of benzene into hydroxymethylcyclohexane has been noted[22] to occur at 200 °C and an initial pressure of the $CO : H_2 = 1 : 1$ mixture of 300 atm.†

Hydrogenation under hydroformylation conditions has been studied in greatest detail for condensed polycyclic aromatic hydrocarbons[21,23–26] (Table 1). Overall, the hydrogenation of polycyclic aromatic hydrocarbons proceeds more readily than the hydrogenation of benzene and the rings condensed with two or several other aromatic rings are mainly hydrogenated. Thus anthracene is readily converted into 9,10-dihydroanthracene (Table 1).

The low activity of dicobalt octacarbonyl in the hydrogenation of naphthalene and phenanthrene should also be noted. In addition, the naphthalene and phenanthrene system formed in the hydrogenation of polynuclear aromatic compounds are as a rule fairly resistant to further reduction[23] (Table 1).

The absence of stereoselectivity in the hydrogenation reactions under hydroformylation conditions has been demonstrated for 9,10-dimethylanthracene;[24] *cis*- and *trans*-9,10-dihydro-9,10-dimethylanthracenes are formed in approximately equal amounts. The addition of tributyl phosphite does not increase the selectivity but lowers the activity of the catalyst and *cis–trans* isomerisation is not observed.

The deuteriation of polycyclic aromatic compounds in the presence of the $D_2 : CO = 1 : 1$ mixture at approximately

† Here and henceforth the initial pressure at room temperature before heating the reaction mixture is quoted.

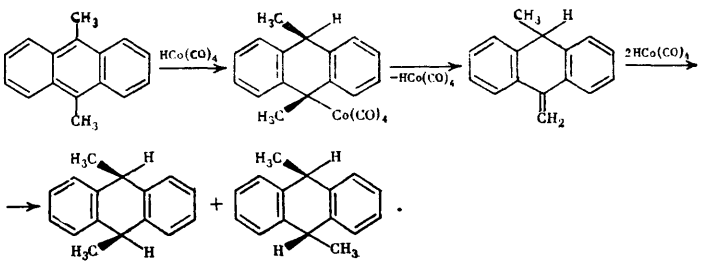
200 °C, which is catalysed by $Co_2(CO)_8$, has been investigated.[27] Anthracene and anthraquinone are converted into 9,9,10,10-tetradeuterio-9,10-dihydroanthracene, pyrene undergoes reduction and H–C exchange in the 4- and 5-positions, while phenanthrene does not react.

Table 1. Hydrogenation of condensed polycyclic aromatic hydrocarbons under hydroformylation conditions*.

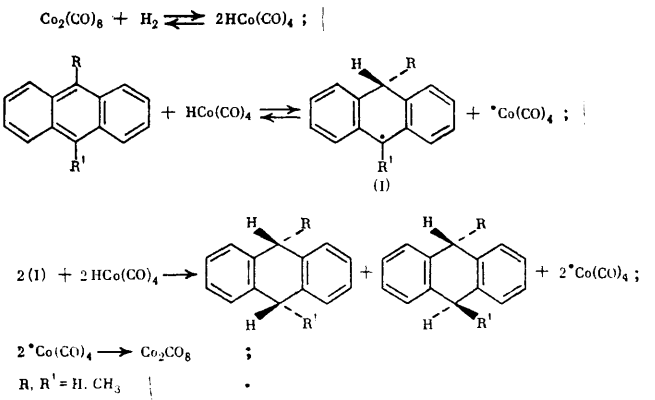
Substrate	Hydrogenation products (yield, %)
Phenanthrene**	9,10-Dihydrophenanthrene (7); 1,2,3,4-tetrahydrophenanthrene (1)
Naphthalene	Tetralin (16)
2-Methylnaphthalene	Methyltetralins (43)
1,1-Binaphthyl	Is not hydrogenated
Acenaphthene	2a,3,4,5-Tetrahydroacenaphthene (45)
Fluorene	Is not hydrogenated
Anthracene	9,10-Dihydroanthracene (99)
Naphthacene	5,12-Dihydronaphthacene (70)
Chrysene	5,6-Dihydrochrysene (24)
Fluoranthrene	1,2,3,10c-Tetrahydrofluoranthrene (54)
Triphenylene	Is not hydrogenated
Pyrene	4,5-Dihydropyrene (69)
Perylene	1,2,3,10,11,12-Hexahydraperylene (72)
Coronene	Is not hydrogenated

*Catalyst—dicobalt octacarbonyl, 1–5 mole %, 150–200 °C, 200 atm pressure of $H_2 : CO = 1 : 1$ mixture (2 : 1 in the case of phenanthrene).
**According to the results of Wender et al.;[21] in the remaining cases the data of Freedman et al.[23] were used.

In order to establish the mechanism of the hydrogenation reaction, a study has also been made of the reduction of anthracene and 9,10-dimethylanthracene by the stoichiometric amount of $HCo(CO)_4$.[24] It has been shown that anthracene is hydrogenated to 9,10-dihydroanthracene to the extent of 25% at 25 °C, while 9,10-dimethylanthracene is 99% hydrogenated with formation of 35% of the *cis*-isomer and 65% of the *trans*-isomer of 9,10-dihydro-9,10-dimethylanthracene. The following reaction mechanism, which explains the formation of the *cis*- and *trans*-products, has been put forward:



At the same time, it is believed[28] that organometallic intermediates are not formed in the hydroformylation of polycyclic aromatic compounds. This conclusion is based on the analysis of data for the deuteriation of anthracene and pyrene under deuterioformylation conditions[27] as well as the following facts: (1) the absence of hydroxymethylation products from the reaction mixture after the hydrogenation of polycyclic aromatic compounds under hydroformylation conditions and (2) the easier hydrogenation of 2-methylnaphthalene or acenaphthene compared with naphthalene[23] and of 9,10-dimethylanthracene compared with anthracene[24] despite the steric hindrance. A radical reaction mechanism has therefore been put forward:[28]



2. Catalysts of the Ziegler Type

A number of studies on the hydrogenation of aromatic hydrocarbons in the presence of Ziegler catalysts have been described in the literature.[31–41] It is noteworthy that data[29] concerning the catalytic activity of a number of transition metal salts in the course of the hydrogenation of aromatic compounds have been refuted in another study.[30] The addition of aluminium alkyls or aluminium hydrides to the reaction mixture containing transition metal ions increases sharply the activity of the catalyst. Overall, catalysts of the Ziegler type make it possible to carry out the hydrogenation under much milder conditions than in the presence of $Co_2(CO)_8$. Thus the addition of aluminium alkyls or aluminium hydrides to cobalt and nickel carboxylates makes it possible to obtain catalysts for the hydrogenation of benzene which are active at temperatures of approximately 50 °C and pressures of approximately 30 atm.[31]

The hydrogenation of benzene under mild conditions (30 °C, 2 atm) has been studied using the triethylaluminium–cobalt acetylacetonate system.[32] On the basis of EPR studies, it has been suggested that the zerovalent cobalt complex decomposes with formation of clusters which directly propagate the hydrogenation reaction.

The reduction of iron, cobalt, and nickel acetylacetonates with sodium and lithium tetrahydroborates and lithium tetrahydroaluminate makes it possible to obtain benzene hydrogenation catalysts which are active at 30 °C and 1 atm.[33] Catalysts for the hydrogenation of benzene, toluene, and xylene have been obtained by the reduction of cobalt, nickel, and copper complexes of salicylaldehyde with $LiAlH_4$ using metal : aluminium ratios ranging from 1 : 1 to 1 : 7.[34]

The addition of triethylaluminium to transition metal 2-ethylhexanoates or naphthenates yields active catalysts for the hydrogenation of aromatic compounds.[35,36] The catalysts are prepared in solvents which show no tendency towards complex formation, such as heptane, benzene, etc.; this is accompanied by the evolution of a gas containing 95% of ethane. The maximum catalytic activity in the case of nickel is attained for the Al : Si = 3 : 1–4 : 1 ratios. The activity in the hydrogenation of benzene diminishes in the sequence Ni ≥ Co > Fe > Cr > Cu. In mixtures containing 0.3–0.5 mole % of nickel 2-ethylhexanoate for an initial hydrogen pressure of approximately 70 atm and temperatures in the range 150–200 °C, fairly rapid and quantitative reduction of benzene to cyclohexane, of phenol to cyclohexanol, and of dimethyl phthalate to dimethyl hexahydrophthalate takes place. The hydrogenation of pyridine to piperidine, of

dimethyl terephthalate to dimethyl hexahydroterephthalate, and of naphthalene to tetralin and decalin proceeds less actively.[35]

The stereoselectivity of the hydrogenation reaction in the presence of a system containing nickel has been pointed out.[37] o-Xylene has been hydrogenated to 66% of *cis*-1,2-dimethylcyclohexane and 34% of *trans*-1,2-dimethylcyclohexane. It has been possible to hydrogenate polystyrene to a product with a 15% content of cyclohexane rings by weight at 150 °C and an H_2 pressure of 100 atm. Physicochemical investigation has demonstrated that the nickel in the catalyst is reduced to the zerovalent diamagnetic state.[37]

Table 2. Hydrogenation of aromatic hydrocarbons in the presence of the cobalt 2-ethylhexanoate/$AlEt_3$ catalyst.[38]

Substrate	a *	Al:Co	τ, h	α **, %	Products (composition, %)
Benzene	0.25	2	30	63	Cyclohexane (100)
o-Xylene	0.2	2	15	50	1,2-Dimethylcyclohexane (*cis*-70, *trans*-26)
m-Xylene	0.2	2	22	40	1,3-Dimethylcyclohexane (*cis*-63, *trans*-37)
p-Xylene	0.1	2	24	55	1,4-Dimethylcyclohexane (*cis*-63, *trans*-37)
Biphenyl	0.05	2	20	100	Bicyclohexyl (81); phenylcyclohexane (19)
Naphthalene	0.05	2	18	100	Decalin (*cis*-43, *trans*-11), tetralin (37)
Tetralin	0.1	2	66	100	Decalin (*cis*-66, *trans*-34)

*Substrate: catalyst molar ratio.
**Degree of conversion.

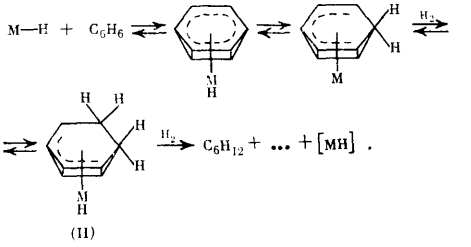
The analogous system based on cobalt 2-ethylhexanoate has been investigated[38] (Table 2). The hydrogenation was carried out at 20–30 °C at a hydrogen pressure of 65 atm. In addition a study has been made of the hydrogenation of a number of polar compounds at an initial hydrogen pressure of 50–60 atm. Phenol is 25% hydrogenated at 45 °C in the course of 20 h to give a mixture of 98% of cyclohexanol and 2% of cyclohexanone. Diethyl phthalate has been 95% hydrogenated at 20 °C during 16 h and the products were found to contain 83% of diethyl *cis*-hexahydrophthalate and 17% of the *trans*-isomer. The same workers[38] showed in a study of competitive hydrogenation that olefins and naphthalene prevent the hydrogenation of benzene.

The hydrogenation of benzene and its alkyl derivatives in the presence of acetylacetonate, cyclopentadienyl, and dimethylglyoximate complexes reduced with trialkylaluminium has been studied.[39,40] The relative activities of different complexes in the benzene hydrogenation reaction[40] vary in the following sequence:

$$Ni(C_5H_7O_2)_2 > Co(C_5H_7O_2)_2 \geqslant Cu(C_5H_7N_2O_2)_2 > Fe(C_5H_7O_2)_3 > Fe(C_5H_5)_2 > > Mn(C_5H_7O_2)_2 > VO(C_5H_7O_2)_2 > Ni(C_5H_7N_2O_2)_2 > (C_5H_5)_2TiCl_2 > Cr(C_6H_7O_2)_3 .$$

Here C_5H_5 = cyclopentadienyl, $C_5H_7O_2$ = acetylacetonate, and $C_5H_7N_2O_2$ = dimethyl glyoximate. The apparent activation energy for the hydrogenation of benzene in the presence of iron and nickel acetylacetonates does not vary with the Al : metal ratio; consequently the number of active complexes and not the "energy relations" of the process vary. The experimental activation energy for the hydrogenation of benzene in the presence of acetylacetonate complexes diminishes in the sequence[41] Cu > Ni > Fe > Cr > Mo when the Al : metal ratio is 8 : 1 for Cr, Fe, and Ni and 6 : 1 for Cu and Mo. In the hydrogenation of benzene, toluene, *o*-xylene, and mesitylene in the presence of nickel and iron acetylacetonates the activation energy diminishes with increase of the number of alkyl substituents, while in the presence of chromium and molybdenum acetylacetonates it increases.[41]

At 150 °C in the presence of nickel acetylacetonate the hydrogenation reaction is of first order with respect to hydrogen, while the order with respect to benzene varies from a fraction less than unity to zero; in the presence of chromium acetylacetonate the reaction order with respect to hydrogen is less than unity.[41] On the basis of their results, the authors[39] proposed the following mechanism for the benzene hydrogenation reaction assuming that the metal hydride is the active catalytic species:



(II)

It has been suggested that the rate-limiting stage is the activation of the hydrogen molecule involving the formation of the hydride (II).

3. Metal Complexes Containing Unsaturated and Aromatic Hydrocarbons as Ligands

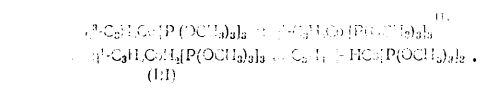
A large number of studies have been devoted to the hydrogenation of aromatic hydrocarbons in the presence of complexes containing unsaturated hydrocarbons as ligands.

The catalytic activity of pentamethylcyclopentadienyl complexes has been investigated in the hydrogenation of olefins and aromatic hydrocarbons.[42–45] Di-μ-chlorobis[chloro(pentamethylcyclopentadienyl)rhodium] $[Rh(\eta^5\text{-}C_5Me_5)Cl_2]_2$ is an active catalyst of the hydrogenation of aromatic hydrocarbons; its iridium analogue is much less active. A heterolytic mechanism has been proposed for the activation of hydrogen, since the catalyst is active in the presence of 15 moles of NEt_3 per mole of the catalyst. The base is required to bind the HCl evolved in the activation of H_2 and to promote the formation of rhodium hydride.[44] The intermediate formation of partial reduction products has not been observed in the hydrogenation of benzene.

Table 3 presents the results of the hydrogenation of a number of aromatic compounds in the presence of $[Rh(\eta^5\text{-}C_5Me_5)Cl_2]_2$ at 50 °C and a hydrogen pressure of 50 atm. A fairly high stereoselectivity has been noted in the hydrogenation of xylenes. The ratio of the *cis*- and *trans*-isomers in the hydrogenation products is 6.2 : 1.0 for *o*-xylene, 3.8 : 1.0 for *m*-xylene, and 2.0 : 1.0 for *p*-xylene. An increase in the number of alkyl substituents hinders the hydrogenation of the aromatic ring. In terms of the relative rates of hydrogenation alkylbenzenes can be arranged in the following sequence:[45] benzene (1.00) > toluene (0.94) > *o*-xylene (0.70) > ethylbenzene (0.58) > mesitylene (0.35) > s-butylbenzene (0.25) > durene (0).

Extensive studies have been carried out on the hydrogenation of various aromatic compounds in the presence of $\eta^3\text{-}C_3H_5Co[P(OCH_3)_3]_3$ and related catalysts.[46–53] The possibility of the hydrogenation of benzene under mild conditions has been demonstrated: 25 °C, p_{H_2} = 1 atm, $\eta^3\text{-}C_3H_5Co$.

.$[P(OCH_3)_3]_3$ catalyst.[47] The complex is stable in approximately 20 benzene hydrogenation cycles and then decomposes into inactive species. Even at low partial hydrogen pressures and in the initial stages of the reaction, partially hydrogenated benzenes were not detected. During 24 h from the start of the reaction, a visible decomposition of the complex, accompanied by the breakdown of homogeneity, is not observed. On decomposition of the complex, phosphite and $HCo[P(OCH_3)_3]_4$ are detected in solution. It has been suggested[48] that the π-allyl ligand is eliminated when the complex decomposes:

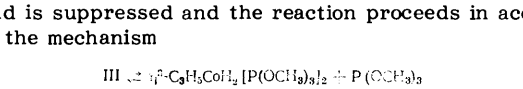


(III)

Table 3. Hydrogenation of aromatic compounds in the presence of the di-μ-chlorobis[chloro(pentamethylcyclopentadienyl)rhodium] catalyst.[44]

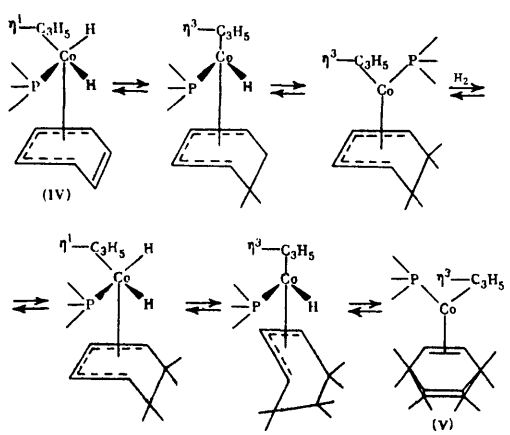
Substrate	Reaction products (yield, %)
Styrene	Ethylbenzene (97); ethylcyclohexane (3)
Phenylacetylene	Styrene (7)
Anisole	Methoxycyclohexene (19); methylcyclohexane (6)
Phenol	Cyclohexanone (1); cyclohexene (0.5)
Methyl benzoate	Methyl cyclohexanoate (75); toluene (8)
Acetophenone	Cyclohexyl methyl ketone (100)
Benzophenone	Dicyclohexyl ketone (50); cyclohexyl phenyl ketone (15); dicyclohexylmethanol (10)
NN'-Dimethylaniline	*NN*'-Dimethylcyclohexylamine (73)
Nitrobenzene	Aniline (96); cyclohexane (4)
Fluorobenzene	Fluorocyclohexane (14); cyclohexane (38)
Bromobenzene	Cyclohexane (10)
Iodobenzene	Cyclohexane (2); benzene (3)
Anthracene	Tetrahydroanthracene (70); octahydroanthracene (22), perhydroanthracene (3)

In the presence of an arene, the *cis*-elimination of the ligand is suppressed and the reaction proceeds in accordance with the mechanism

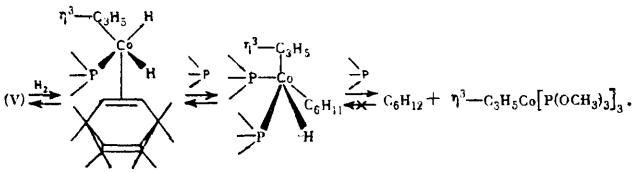


(IV)

Benzene is hydrogenated in the intermediate complex (IV) in accordance with the mechanism:[48]



(V)



The above scheme accounts for the absence of the products of the partial reduction of the aromatic benzene ring from the reaction mixture and for the high *cis*-stereoselectivity of the hydrogenation of substituted benzene derivatives. It has been noted[48] that the rate of hydrogenation of benzene is much higher than that of cyclohexene.

*Reaction conditions: 20 °C, 1 atm H_2, 0.112 mmol of catalyst.

**Catalyst : substrate molar ratio.

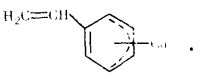
The results of the study of hydrogenation in the presence of η^3-$C_3H_5Co[P(OCH_3)_3]_3$ have been surveyed[49] (Table 4). In the presence of this system, polycyclic hydrocarbons are hydrogenated less effectively than benzene. Electron-accepting substituents deactivate the aromatic ring: fluorobenzene and nitrobenzene were not hydrogenated, since the reaction requires a high π-donor capacity of the aromatic ring. Nucleophilic substituents are in their turn bound preferentially to the metal atom, preventing the hydrogenation of the aromatic ring, as happens, for example, in the case of phenylacetonitrile, triphenylphosphine, and benzonitrile. The oxidation-reduction interaction of the catalyst with

chlorobenzene prevents the hydrogenation of the latter. Protonation of the catalyst leads to the unstable complex η^3-$C_3H_5CoH[P(OCH_3)_3]_3^+$, which decomposes with evolution of propene. For this reason, it has not been possible to hydrogenate phenol and benzoic acid.

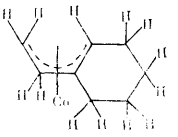
The influence of steric hindrance following the introduction of alkyl substituents into the benzene ring and the consequent resistance of 1,2,3,4-tetramethylbenzene and hexamethylbenzene to hydrogenation have been noted.[49]

When the competitive hydrogenation of a mixture of benzene and hex-1-ene is carried out,[49] the ratio of the hydrogenated aromatic hydrocarbon and hexane is 7 : 10 and appreciable amounts of cyclohexene are formed. Thus alkenes are bound to the catalyst less strongly than aromatic hydrocarbons and the alkene which has failed to react can competitively displace the products of the partial reduction of aromatic hydrocarbons.

The hydrogenation of styrene leads to the formation of approximately equal amounts of vinylcyclohexane, ethylbenzene, and ethylcyclohexene for a low degree of conversion. This composition of the reaction products can be accounted for by the competitive displacement of the partly hydrogenated products. On the other hand, there is a possibility (by virture of steric factors) of the following type of interaction with the catalyst:



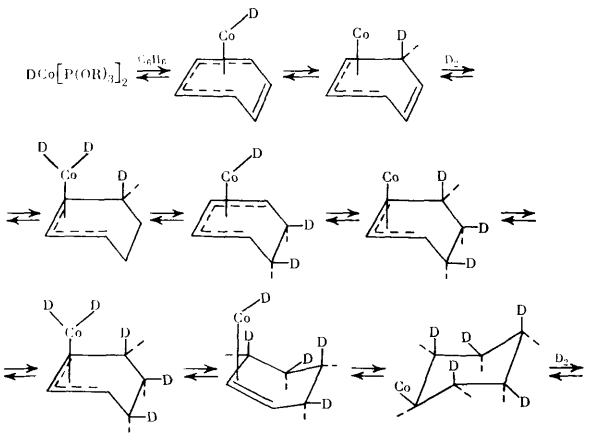
After the addition of four hydrogen atoms, the intermediate

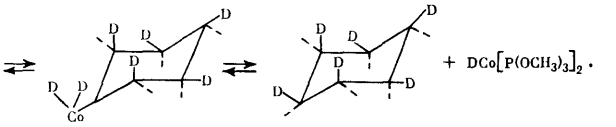


is formed and, after combining with a further two hydrogen atoms, the latter can give rise to vinylcyclohexane and cyclohexenylethane.

Experiments on the deuteriation of benzene using perdeuteriobenzene[49] demonstrated the absence of H–D exchange involving the aromatic ring; thus the hydrogen addition stage is irreversible. The absence of deuterium from the propene evolved after the decomposition of the complex indicates the irreversibility of the decomposition of the latter. Deuteriation of benzene and hydrogenation of C_6D_6 lead to the formation of *cis*-stereoisomers. The deuteriation of the side chain in alkylbenzenes has also been observed.[49,50]

A mechanism has been proposed for the *cis*-deuteriation reaction:[51]

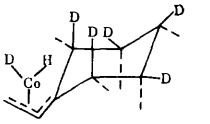




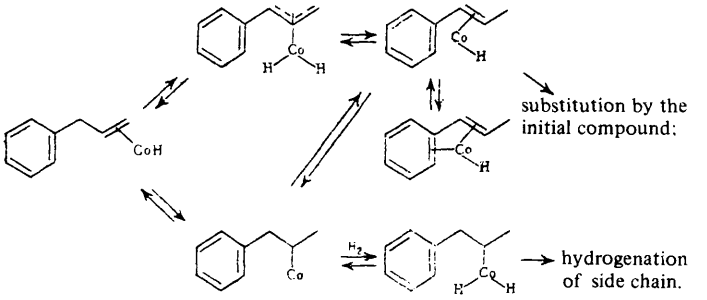
It has been shown that the 14-electron complex, capable of interacting with arenes as η^4-ligands, is catalytically active.

The hydrogenation and deuteriation of aromatic alkyl derivatives in the presence of η^3-$C_3H_5Co[P(OCH_3)_3]_3$ has also been studied.[52] The occurrence of *cis*-deuteriation and of the H–D exchange involving the n-alkyl substituents has been noted; the t-butyl substituent is not deuteriated. Alkyl- and alkenyl-cyclohexenes are formed in the presence of hexene.

The deuteriation of the side chain in substituted benzenes proceeds via the formation of the intermediate complex



according to Bleeke and Muetterties.[52] The same workers[52] explained the complex composition of the allylbenzene hydrogenation products by competing reactions involving the isomerisation of the intermediates and their displacement by the starting material in accordance with the following mechanism:



It has been shown[52] that η^3-$C_8H_{13}Co[P(OCH_3)_3]_3$ also catalyses the hydrogenation of benzene and a rapid stage involving the elimination of η^3-cyclo-octenyl ligand is observed. The hydrogenation mechanism proposed by Hirsecorn et al.[48] has been revised on the basis of the study of the intermediates in the hydrogenation of toluene in the presence of this complex.

According to Bleeke and Muetterties,[52] the catalytically active species is formed via the mechanism

$$\eta^3\text{-}C_8H_{13}Co[P(OCH_3)_3]_3 \rightleftarrows \underset{\text{(VI)}}{\eta^3\text{-}C_8H_{13}Co[P(OR)_3]_2} + P(OR)_3 ;$$

$$\text{(VI)} \xrightarrow{H_2} \underset{\text{(VII)}}{HCo[P(OR)_3]_2} + C_8H_8 ;$$

$$\text{(VII)} \xrightarrow{P(OR)_3} \underset{\text{(VIII)}}{HCo[P(OR)_3]_3} \overset{H_2}{\rightleftarrows} \underset{\text{(IX)}}{H_2Co[P(OR)_3]_3} ;$$

$$\text{(VIII)} \xrightarrow{P(OR)_3} \underset{\text{(X)}}{HCo[P(OR)_3]_4} .$$

In the absence of the arene, the inactive complexes (IX) and (X) are obtained, while in its presence hydrogenation takes place via the mechanism

$$HCo[P(OR)_3]_2\ (\eta^4\text{-}C_8H_8) \rightleftarrows \eta^3\text{-}C_8H_{13}Co[P(OR)_3]_2 \overset{H_2}{\rightleftarrows}$$
$$\rightleftarrows \eta^3\text{-}C_8H_{13}CoH_2[P(OR)_3]_2 \rightleftarrows HCo[P(OR)_3]_2\ (\eta^4\text{-}C_8H_8) \text{ etc.}$$

The main disadvantages of the η^3-$C_3H_5Co[P(OCH_3)_3]_3$ catalyst are its low stability and low activity.

Attempts have been made[53] to increase the stability and activity of the complexes by varying the ligand environment. The relative rates of hydrogenation of benzene in the presence of a series of phosphine and phosphite complexes are as follows:

η^3-$C_3H_5Co[P(OCH_3)_3]_3$ (1), η^3-$C_3H_5Co[P(OC_2H_5)_3]_3$ (2),
η^3-$C_3H_5Co[P(OCH_3)_3]_2P(OC_3H_7\text{-iso})_3$(4),
η^3-$C_3H_5Co[P(CH_3)_3]_3$ (5), η^3-$C_3H_5Co[P(OC_3H_7\text{-iso})_3]_3$ (30),
η^3-$C_3H_5Co(CO)_3$ (0), $ONCo[P(OC_3H_7)_3]_3$ (0).

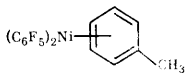
The increase of the activity of the complex was accompanied by a decrease of its stability. The complexes investigated contain the allyl ligand, which reacts readily ($\eta^x \rightleftarrows \eta^{x-2}$) as well as phosphine or phosphite ligands, which ensure a high electron density at the metal atom promoting the activation of H_2, and dissociate with a low activation energy.

However, the suggested intermediate $C_3H_5CoH_2L_3$ decomposes readily to an inactive hydride. Therefore a more stable catalyst would be one containing an η^x-ligand or a redox-ligand, which has either undergone ready conversion into the η^{x-2}-form or has been involved in electron transfer between the metal and the ligand; these transformations must not be accompanied by the elimination of the H ligand. The ON ligand, for example, is of this type but the complex containing it proved to be inactive in hydrogenation.[53]

It has been possible to synthesise the stable complex[54] η^6-$C_6(CH_3)_6$Ru-η^4-$C_6(CH_3)_6$, which is capable of catalysing the hydrogenation of benzene at 90 °C and a pressure of 2–3 atm. The hexamethylbenzene ligand proved to be resistant to both hydrogenation and competitive displacement by the substrate and the reaction products. The stereoselectivity of the complex was found to be lower than that of η^3-$C_3H_5Co[P(OCH_3)_3]_3$. The ratio of the *cis*- and *trans*-isomers is 9 : 1 and 9 : 2 respectively after the hydrogenation of *o*- and *p*-xylenes. In the hydrogenation of benzene and xylenes considerable amounts of cyclo-olefins were detected. For benzene, *o*-xylene, and *p*-xylene, the amounts are 5, 40, and 55% respectively. In the presence of η^6-$C_6(CH_3)_6$Ru-η^4-$C_6(CH_3)_6$, intense H–D exchange takes place. The hydrogenation of C_6D_6 and the deuteriation of C_6H_6 involve the formation of cyclohexanes containing between zero and 12 deuterium atoms, $C_6H_6D_6$ predominating. The catalyst ligands are also deuteriated. The deuteriation of the alkyl substituent predominates in toluene.[54]

The stability of the complex is determined by the resistance of the ligands to reduction by hydrogen. The transition of the arene to the η^4-state in bis(hexamethylbenzene)ruthenium(0) requires a low activation energy (16 kcal mole^{-1}).[55] In complexes where the activation energy for this process is higher, the hydrogenation of benzene is difficult, as happens for example, in the case of $CH_3C_6H_5TiAl_2Cl_8$.[55]

η^6-Toluenebis(pentafluorophenyl)nickel(II) proved to be a catalyst capable of hydrogenating benzene and toluene at 100 atm at 25 °C:[56]



It is fairly unstable and decomposes with formation of nickel and C_6F_5H.

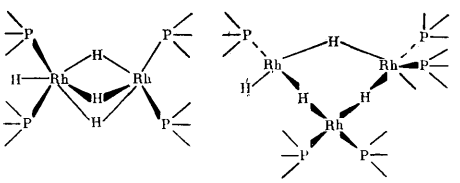
The reduction of the complex $RuCl_2(C_6Me_6)(PPh_3)$ with sodium tetrahydroborate, lithium tetrahydroaluminate, or an isopropyl alcohol solution of sodium carbonate leads to the formation of $RuHCl(C_6Me_6)(PPh_3)$, which is capable of hydrogenating benzene even at room temperature.

Treatment of the complex $[RuCl_2(\eta^6\text{-}C_6Me_6)]_2$ with a solution of sodium carbonate in isopropyl alcohol makes it possible to obtain the complex $[(\eta^6\text{-}C_6Me_6)Ru(\mu\text{-}H_2)(\mu\text{-}Cl)Ru(\eta^6\text{-}C_6Me_6)]Cl$. Benzene is hydrogenated to cyclohexane in the presence of this catalyst, the turnover number of the reaction amounting to 4.1 min^{-1}. At 50 °C and a pressure of 50 atm in the course of 36 h, the catalyst effects the quantitative hydrogenation of styrene to ethylcyclohexane, of anisole to methoxycyclohexane, of methyl benzoate to methyl cyclohexanoate, and of acetophenone and benzophenone to the corresponding cyclohexyl ketones. The hydrogenation of phenol to cyclohexanol, of nitrobenzene to aniline, of dimethylaniline to cyclohexylamine, and of phenylacetylene to ethylbenzene and styrene proceeded less vigorously.[58] Halogenobenzenes were converted into cyclohexane. The halogeno-substituent was retained in the cyclohexane ring only in the case of fluorobenzene.[58]

The complex η^3-$C_3H_5RhL_2$, where L = $P(OC_3H_7\text{-iso})_3$, is an extremely short-lived catalyst of the hydrogenation of aromatic hydrocarbons.[59] The complexes where L = $P(OEt)_3$ and $P(OMe)_3$ are inactive. The above complexes interact with hydrogen in accordance with the mechanism

$$6H_2 + 3\,\eta^3\text{-}C_3H_5RhL_2 \rightarrow 3C_3H_8 + (HRhL_2)_3;$$
$$7H_2 + 3\,\eta^3\text{-}C_3H_5RhL'_2 \rightarrow 3C_3H_8 + H_3RhL'_4 + (HRhL'_2)_2.$$

The clusters formed under these conditions are capable of catalysing the hydrogenation of benzene and alkylbenzenes to the corresponding cyclohexanes. The hydrogenation of *p*-xylene proceeds with the intermediate formation of *cis*-1,4-dimethylcyclohexane, while *o*-xylene is hydrogenated more slowly, the *cis*- and *trans*-isomers being formed in equimolar amounts. In the hydrogenation of benzene derivatives containing unsaturated substituents of the olefinic type, both the aromatic ring and the substituent are reduced. It is of interest to note that the above compounds prevent the hydrogenation of benzene when they are introduced jointly into the reaction mixture.[60] Deuteriation in the presence of these complexes involves vigorous deuterium–hydrogen exchange. According to Sivak and Muetterties,[60] the bridged hydrides



function as the catalytic species.

The *p*-tolyl complexes $(p\text{-tol})_4Cu_2Rh_2$ and $(p\text{-tol})_4Au_2Rh_2$ are active in the hydrogenation of benzene and naphthalene at 1 atm at 20 °C.[61]

$(RhCl.cyclo\text{-}octadiene)_2$, reduced with an equimolar amount of n-butyl-lithium, catalyses the hydrogenation of benzene to cyclohexane and of naphthalene to *cis*- and *trans*-decalins under normal conditions; styrene and phenylacetylene are reduced to ethylcyclohexane, while stilbene is reduced to 1,2-dicyclohexylethane.[62]

A complex of analogous activity has been obtained by the reaction[63]

$$RhCl(H_2C{=}CH_2)_2 + \text{n-BuAuLiEt}_2O \rightarrow Au^0/Rh^0.$$

Hydrogenation catalysts which incorporate unsaturated hydrocarbon ligands in the coordination sphere during the reaction or after appropriate treatment have been described in a number of investigations.[64–68]

The coupled hydrogenation of arenes together with alkenes or dienes has been achieved in the presence of the system $AlR_3 + Co(C_5H_7O_2)_2 + P(C_4H_9)_3$, where $C_5H_7O_2$ = acetylacetonate.[64] The hydrogenation of benzene is ten times faster than that of cyclohexene, which is formed in apreciable amounts together with cyclohexane in the benzene hydrogenation reaction. After the complete conversion of alkenes or dienes into saturated hydrocarbons, the hydrogenation of arenes ceases. The activity of the catalyst increases as the temperature is reduced from 30° to 5 °C. $H_3Co[P(C_4H_9)_3]_3$ also catalyses the joint hydrogenation of arenes and alkenes, but its activity is lower. σ-Alkylcobalt, containing one or two phosphite ligands and an arene, has been suggested as the catalytically active species.[64]

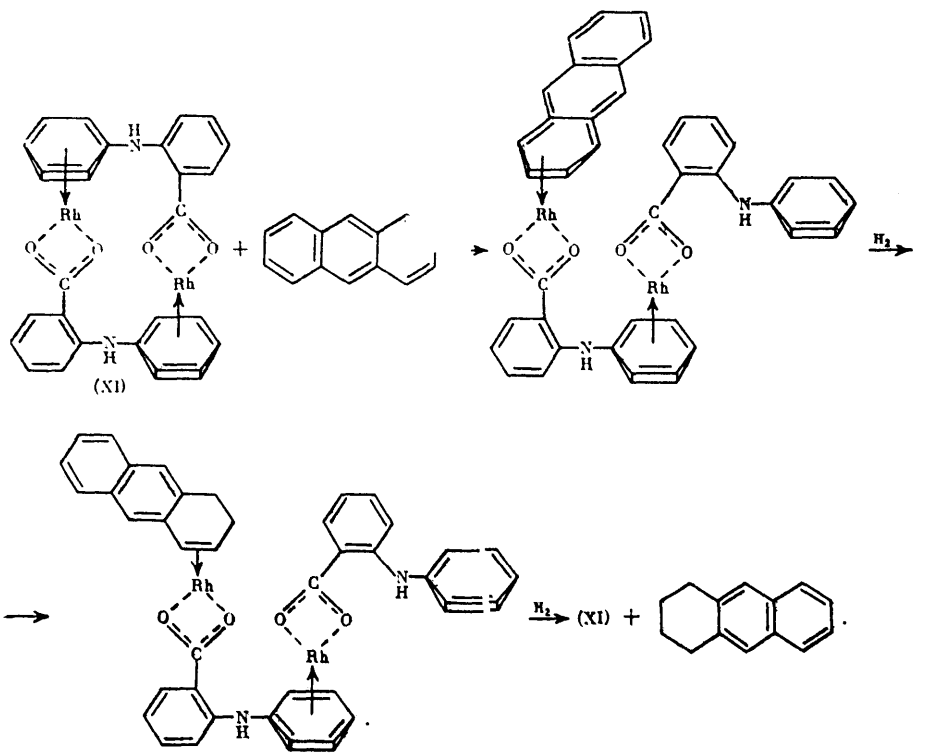
The complexes $(Al)(MR)Co(ML)_2$ (where Ar = aromatic hydrocarbons, R = alkyl, M = Li, MgBr, or AlR_2, and L = chelating ligands with carbonyl or imino-groups), $Co(PR_3)(RCH{=}CH_2)_2(AlEt_3)$ (where R = alkyl or aryl), and $Co(1,5,9\text{-}trans,trans,cis\text{-}C_{12}H_{18})(AlEt_3)$ are also capable of effecting the coupled hydrogenation of arenes and alkenes under mild conditions, benzene being hydrogenated to cyclohexene with a selectivity of 25–30%.[65]

Chlorotris(triphenylphosphine)rhodium (Wilkinson's complex) is incapable of catalysing the hydrogenation of aromatic compounds because of the presence of ligands with a tendency towards a dative interaction. However, the hydrogenation of benzene has been observed in the presence of Wilkinson's complex subjected to preliminary oxidation in a benzene solution. Cyclohexane is apparently formed as a result of the reduction of the aryl ligand in the intermediate oxidised complex.[66]

4. Metal Complexes with Ligands of the Aminoacid Type

The possibility of hydroxylating polycyclic aromatic compounds in the presence of rhodium complexes with strong π-donor systems such as naphthacene and *N*-phenylanthranilic acid has been demonstrated.[69] The rhodium complex of naphthacene makes it possible to hydrogenate the latter at 80 °C and a hydrogen pressure of 50 atm in dimethylformamide solution with formation of 1,2,3,4-tetrahydronaphthacene and a small amount of *sym*-octahydronaphthacene. Anthracene is hydrogenated to 1,2,3,4-tetrahydroanthracene under the same conditions in the presence of the rhodium complex of *N*-phenylanthranilic acid; the yields are fairly high also at room temperature and atmospheric pressure.[69]

The rhodium complexes of *N*-phenylanthranilic acid, other aminoacids, and aromatic carboxylic acids are active in the hydrogenation of naphthalene, phenol, and other aromatic hydrocarbons as well as their derivatives.[70–72] Experiments were performed at 20 °C and atmospheric pressure using a dimethylformamide solution of the catalyst. The initial rates of hydrogenation in the rhodium–*N*-phenylanthranilic acid system[72] decrease in the sequence anthracene > fluorene > fluoranthrene > naphthalene > pyrene > chrysene > benzene. Naphthalene is hydrogenated successfully to tetralin and decalin, benzene is hydrogenated to cyclohexane, and anthracene is hydrogenated to 1,2,3,4-tetrahydroanthracene. The structure of the complex was investigated by a wide variety of physicochemical methods.[73,74] A mechanism for the hydrogenation of anthracene has been proposed on the basis of investigations of the H–D exchange reaction of anthracene:[72]



In conclusion of the Sections devoted to the metal complex catalysts for the hydrogenation of aromatic hydrocarbons, it is necessary to consider catalytic systems of a kind which strictly speaking do not form part of any of the types examined.

The chlorobishexa-1,5-dienerhodium complex has been used for the hydrogenation of arenes under conditions of catalysis with phase transfer.[75] The hydrogenation of a number of phenyl and benzyl ketones, benzene, phenol, and naphthalene has been investigated under mild conditions. The selectivity of the reaction was not always sufficiently high.

A system containing a hydrogen activator and a catalyst for the transfer of the activated hydrogen to the substrate has been proposed.[76,77] The use of Adams platinum as the hydrogen activator and titanium chloride complexes with various ethers as hydrogen transferring agents made it possible to hydrogenate benzene at room temperature and atmospheric pressure. Apart from cyclohexane, appreciable amounts of cyclohexene and cyclohexadiene are formed in the mixture and their relative amounts are not influenced by the duration of the hydrogenation process. Catalytically active species $[HTiL_{4-n}Cl^{+}_{n-1}]Pt$ arises in the reduction of the complex cation $TiL_{4-n}Cl^{+}_{n-1}$ by molecular hydrogen in the presence of PtO_2. The insertion of benzene in the Ti–H bond and the subsequent hydrogenation of the complex formed led to the formation of the reaction products.[76]

5. Polymer-containing Catalysts

The attempts to eliminate certain disadvantages of the homogeneous metal complex catalysts which limit their industrial application led to the creation of complexes containing organic and mineral polymers and macroligands. Whereas the mineral polymers are mainly used as heterogenising supports bound chemically to the metal complex, two applications are possible for organic polymers: either for the heterogenisation of the complex or for the synthesis of metal complexes with monodentate and polydentate macroligands whose solubility can often be varied reversibly depending on the stage of the process. A description of the properties of the metal-polymer complexes and the applications of catalysts can be found in other reviews.[78,79] The hydrogenation of aromatic hydrocarbons in the presence of these systems has been vigorously studied recently.

Systems which are tentatively similar to Ziegler catalysts and are capable of hydrogenating C_6–C_{30} aromatic hydrocarbons have been obtained by impregnating a suitable inorganic carrier having surface hydroxy-groups with a transition metal salt and subsequent treatment with trialkylaluminium or a similar compound.[80–82] A mechanism has been proposed[82] for the formation of intermediate active species of the type

where M = Fe, Ni, Co, or Cu and M′ is a Group I–III metal atom. Although the authors do not quote experimental data confirming rigorously the formation of such species, their hypothesis agrees with data obtained in a study[79] devoted to analogous catalysts.

In the interaction of polystyrene with (η^6-cyclo-octa-1,3,5-triene)(η^4-cyclo-octa-1,5-diene)ruthenium(0) the ligands are substituted by the benzene rings of polystyrene.[83,84] The resulting complex is an active catalyst of the hydrogenation of aromatic compounds (Table 5). Ru_2-1,3-diphenylpropane, obtained by a similar procedure from diphenylpropane, exhibits an analogous activity.[84] The increase of the number of benzene rings to more than two per metal atom lowers the activity of the catalyst.

A number of studies have been devoted to catalysts based on complexes of anthranilic and *N*-phenylanthranilic acid using polymeric macroligands. The rhodium and ruthenium complexes of *N*-phenylanthranilic acid, bound to phosphinated polystyrene or an inorganic carrier, catalyse the hydrogenation of benzene, anthracene, and 6-ethylchrysene.[85] The catalyst is obtained by the interaction of the finished complex with the carrier.

Another approach to the synthesis of the deposited complex is possible, namely by treating chloromethylated polystyrene with anthranilic or *N*-phenylanthranilic acid and then with a metal salt, this being followed by the reduction of the intermediate complex.[86–89] The catalyst prepared using *N*-phenylanthranilic acid did not show catalytic activity; an active catalyst was obtained from anthranilic acid. The rhodium and ruthenium catalysts effect the hydrogenation of benzene

at room temperature and a hydrogen pressure of approximately 2 atm. Under more severe conditions (100 °C, 20 atm H_2) the palladium catalyst permits the hydrogenation of benzene and *p*-xylene.

The rhodium complex of anthranilic acid bound to chlormethylated polystyrene has been studied in detail[90] (Table 6). According to the results of elemental analysis, the molar ratio of the anthranilate anions and rhodium in the catalyst is 3 : 1. The metal atoms are mainly distributed on the surface of the carrier. Only 3% of the chloromethylated groups of the initial polymer react with anthranilic acid. Analysis by X-ray electron spectroscopy (AXES) shows that the oxidation state of rhodium in the complex is +1. It is of interest that the nickel analogues are inactive in the hydrogenation of aromatic compounds.[91]

Table 7. Hydrogenation of aromatic compounds in the presence of rhodium complexes of carboxyl-containing polymers.[92,93,126]

*Here and henceforth PAA = polyacrylic acid and STMC = styrene–maleic acid copolymer.
**Turnover number of reaction.

Effective catalysts for the hydrogenation of the aromatic ring of benzene and its derivatives[92,93,126] (Table 7) have been obtained from rhodium complexes of carboxyl-containing polymers—such as polyacrylic acid and the styrene—maleic acid copolymer. The catalyst is prepared by adding rhodium tetrahydroborate to a solution containing the polymer and a rhodium salt. Under mild conditions (atmospheric pressure, 30 °C), it has been possible to hydrogenate benzene quantitatively to cyclohexane with a selectivity of 100%. The catalysts are extremely active in the hydrogenation of phenol to cyclohexanol and cyclohexanone. Apart from the reactions listed in Table 7, these catalysts are active in the hydrogenation of benzaldehyde, benzyl alcohol, and t-butylbenzene.

Treatment with hydrogen of the complex $Rh_2Cl_2(C_2H_4)_2$ deposited on chlormethylated and phosphinated cross-linked polystyrene[94] or of $Rh_2Cl_2(CO)_4$ deposited on the same polymer,[95] on SiO_2, or on polyphenylsiloxane, with both supports modified by phosphine groups,[96] leads to the formation of finely dispersed metallic rhodium which is active in the hydrogenation of benzene. Wilkinson's complex on modified SiO_2 and polyphenylsiloxane is not reduced and does not effect the hydrogenation of benzene.[96]

The formation of rhodium clusters has been detected in benzene solution following the interaction of $Rh_6(CO)_{16}$ with a film of cross-linked phosphinated polystyrene. At 80 °C and 1 atm the resulting catalyst reduces benzene with a low degree of conversion.[97] Aggregation of the clusters leads to an increase of the activity of the catalyst. The relation between the degree of aggregation of the hexa-atomic rhodium clusters and the catalytic activity has been studied.[98] The catalyst was prepared by impregnating silica gel with an $Rh_6(CO)_8$ solution and drying. Benzene was hydrogenated in a flow system. It has been shown[98] that particles with diameters less than 1.4 nm, consisting of six rhodium atoms, are catalytically inactive. The most active particles are 1.4–2.0 nm in size and contain 2–3 hexa-atomic clusters.

Catalysts having the general formula

$$\left[\left(\begin{array}{c}-CH_2-CH_2-N- \\ \\ R\end{array}\right)_n MX_q\right]_m$$

$R = H;\ C_{1-7}^{alkyl},\ C_6H_5CH_2CH_2,\ (CH_3)_3SiCH_2CH_2,$

$CH_3CO,\ C_6H_5CO;\ n = 2, 4, 8, 16,\ m = 4–200;$

$X = Cl, Br;\ q = 2, 4;\ M = Pt(IV), Pd(II), Ni(II), Co(II), Fe(III)$.

(the metal : nitrogen ratio varies from 1 : 2 to 1 : 16) are capable of effecting the quantitative hydrogenation of benzene to cyclohexane at 50 °C and a 100 atm pressure.[99]

The hydrogenation of *p*-nitrophenol at room temperature and atmospheric pressure with formation of 4-aminocyclohexanol has been described.[100] A catalyst prepared on the basis of rhodium, ruthenium, or iridium and polyvinylpyrrolidinone was used for this purpose.

Numerous studies have been devoted to the hydrogenation of aromatic compounds in the presence of metal complexes of polyamides. The first investigations in this field refer to the hydrogenation of benzene in the presence of a platinum–polyamide catalyst prepared on the basis of polymers obtained from caprolactam, hexamethylenediamine, and the β-lactam of β-aminosebacic acid.[101] A high yield of cyclohexene has been noted in some instances. The occurrence of two-point adsorption of benzene on the active centres has been suggested.

Dini et al.[102] also noted the selectivity of platinum–polyamide catalysts in the hydrogenation of benzene to cyclohexene. The reaction was carried out in a pulse apparatus at 140–190 °C. The authors explained the low degree of adsorption of hydrogen on the catalyst by the fact that the catalytically active species are compounds of platinum in which the degree of oxidation is non-zero.

The metal–nylon complexes catalysing the hydrogenation of benzene have been investigated.[103–106] Detailed study of the platinum–nylon complex[104] has shown that the optimum composition of the catalyst is attained when there are eight peptide groups per platinum atom. The authors suggest that it is unlikely that stable eight-membered chelate complexes are formed under the reaction conditions[104] and the complex apparently contains one peptide group. It has been shown that, when halogen substituents are introduced into the benzene ring, the rate of hydrogenation diminishes, which has been attributed to a decrease of the ionisation potential and the formation of an unduly stable substrate–catalyst complex.[102] Apart from the change in the ionisation potential of the substrate, steric hindrance plays a significant role in the hydrogenation of alkylbenzenes.

The hydrogenating activities of various metals in the nylon complexes have been examined.[105,106] It has been shown that the capacity for the formation of complexes with nylon varies in the sequence Pt > Pd > Rh > Ir, while the activities of the nylon complexes in the hydrogenation of benzene vary in the sequence Ir > Pt > Rh > Pd. The optimum ratio of the number of polyamide units to that of the metal atoms is four for rhodium and palladium, in contrast to platinum, the activity of the palladium complex proving very low in the hydrogenation of benzene. However, one should note that sufficiently rigorous evidence has not been presented[102–106] for the existence of complexes in the course of the reaction; one cannot rule out the possibility that the metallic phase is active.[107,108]

The hydrogenation of benzene on atomically dispersed platinum on nylon has been investigated[107,109] and the influence of the specific surface on the activity has been demonstrated.[107] The unusually high selectivity of the platinum–nylon catalyst with respect to cyclohexene has been explained by the weak adsorption of benzene on the catalyst.[109] It has been suggested that benzene forms a π-bond with only one metal atom. In this case hydrogen does not add as a result of a surface reaction (as in the metal) but involves the bonds conjugated with those participating in the formation of the π-complex. The double bond which has not been hydrogenated remains unavailable for the addition of hydrogen.

III. HYDROGENATION OF HETEROCYCLIC COMPOUNDS

Many fewer studies have been made of the hydrogenation of heterocyclic compounds on metal complex catalysts. The reason for this is apparently the risk that the formation of stable complexes of heterocycles with the metal ion might deactivate the complex. Since hydrogenation under severe hydroformylation conditions makes it possible to avoid the poisoning effect of even sulphur-containing heterocycles, this reaction has been studied to the greatest extent. Thus the hydrogenation of furan derivatives has been described.[21] At 180 °C and pressures of the H_2 + CO (2 : 1) mixture of about 200 atm in the presence of $Co_2(CO)_8$ furan is converted in the course of 4 h into 2-tetrahydrofurfuryl alcohol to the extent of 35%, while 2,5-dimethylfuran is converted into 2,5-dimethyltetrahydrofurfuryl alcohol to the extent of 23%.

The hydroformylation of 5,6-dihydro-4*H*-pyrans is accompanied by the saturation of the pyran ring.[110] The product consisted of 78% of 2-hydroxymethyltetrahydropyran, 8% of 3-hydroxymethyltetrahydropyran, and 3% of tetrahydropyran. In addition, reactions of other dihydropyrans have been investigated at a pressure of the mixture of equimolar amounts of carbon monoxide and hydrogen of 300 atm and a temperature of 190 °C in the presence of dicobalt octacarbonyl.[110]

Table 8. Hydrogenation of thiophen and its derivatives under hydroformylation conditions*.[111]

Substrate	a**	τ, h	Reaction product (yield, %)
Thiophen	14.7	5	Thiophan (50)
Thiophen	5.9	4	Thiophan (66)
2-Methylthiophen	22.7	5	2-Methylthiophan (77)
2-Ethylthiophen	9.1	3	2-Ethylthiophan (82)
2,5-Dimethylthiophen	18.3	5	2,5-Dimethylthiophan
2-Thenyl alcohol	15.0	4	2-Methylthiophen (24); 2-methylthiophan (57)
2-Acetylthiophen	15.6	9	2-Ethylthiophen (52); 2-ethylthiophan (26)

*Temperature 180 °C, pressure of H_2 : CO = 2 : 1 mixture 22 atm, catalyst–dicobalt octacarbonyl.
**Substrate : catalyst molar ratio calculated per metal atom.

The reduction of thiophen derivatives under hydroformylation conditions has been described[111] (Table 8). Sometimes cobalt is introduced in the form of the carbonate instead of the octacarbonyl, but in all cases the active species is cobalt hydrocarbonyl. It is especially interesting that substituted thiophens are reduced more readily than thiophen itself. It has been shown that the hydrogenation is irreversible, this being indicated by the stability of thiophan under the reaction conditions.[111]

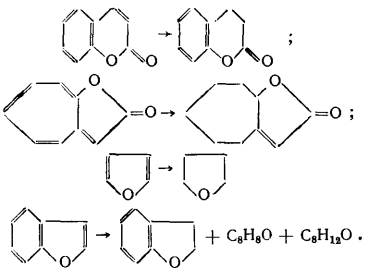
The hydrogenation of nitrogen-containing heterocycles has been investigated in the presence of various metal carbonyls and carbonyl phosphite complexes.[22,26,112–115] Pyridine is converted into a mixture of *N*-formyl- and methyl-pyridines at 200 °C under a pressure of an equimolar mixture of carbon monoxide and hydrogen of 410 atm.[112] At a lower pressure (213 atm), dihydro-derivatives of 2-methyl- and 2-phenylindoles have been obtained[113]. In both cases cobalt was introduced into the reaction mixture in the form of the metal or salts.

It has been shown[25,26,114,115] that the carbonyl and carbonyl phosphine complexes promote the preferential hydrogenation of the heteroring in bicyclic and polycyclic nitrogen-containing heterocycles.

Catalysts of the Ziegler type, which are also frequently used under severe conditions, have been used mainly for the hydrogenation of pyridine heterocycles. Thus the hydrogenation of pyridine to piperidine has been described.[32,34] Quinoline[116] is hydrogenated in the presence of cobalt acetylacetonate activated with AlR_3 (where R = alkyl or alkoxy-group) with formation of 78% of 1,2,3,4-tetrahydroquinoline, 9% of 5,6,7,8-tetrahydroquinoline, and 2% of decahydroquinoline (cobalt : aluminium = 10, H_2 pressure 68 atm, 90–100 °C). Only 17% of 1,2,3,4-tetrahydroquinoline is formed under the same conditions in the presence of diethyl sulphide.

The catalyst based on cobalt 2-ethylhexanoate makes it possible to hydrogenate furan to tetrahydrofuran to the extent of 95% at 20 °C and an H_2 pressure of 50–60 atm in the course of 4 h.[35]

Table 4 shows that the catalyst η^3-$C_3H_5Co[P(OCH_3)_3]_3$ is capable of hydrogenating oxygen-containing heterocycles under mild conditions.[49] The following reactions have been carried out using this catalyst:[49]

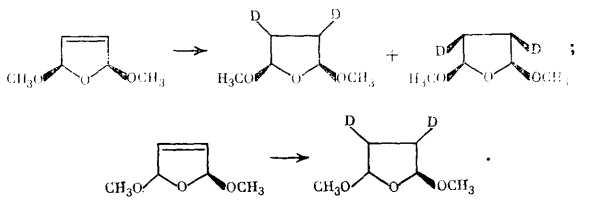


Overall, the hydrogenation is slow and the yields of reaction products are low.

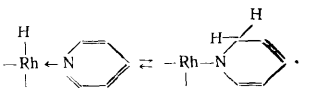
It has been stated[71,117] that the rhodium complexes of anthranilic and *N*-phenylanthranilic acids, L-tyrosine, aspartic acid, and α-piperidinoacetophenone oxime catalyse the hydrogenation of pyridine, quinoline, pyrrole, furan, dibenzofuran, and thiophen.

Chlorotris(triphenylphosphine)rhodium, which is known to be inactive in the hydrogenation of benzene, has been used for the stereoselective deuteriation of the double bond in

substituted 2,5-dihydrofurans.[118] 2,5-Dimethoxy-2,5-dihydrofurans are deuteriated in the *cis*-positions, the *cis*-isomer giving rise to a mixture of products:



Treatment of the complex $RhCl_3Py_3$ (where Py = pyridine) with sodium tetrahydroborate in dimethylformamide leads to the formation of $Py_2DMF.RhCl_2BH_4$.[119,120] The complex is capable of catalysing the reduction of pyridine to piperidine and of quinoline to 1,2,3,4-tetrahydroquinoline; the reaction proceeds under mild conditions at low rates. Isoquinoline and indole are not reduced. It is believed that the hydrogenation begins with hydrogen transfer:[20]



This is followed by the addition of hydrogen to the hydropyridine complex.

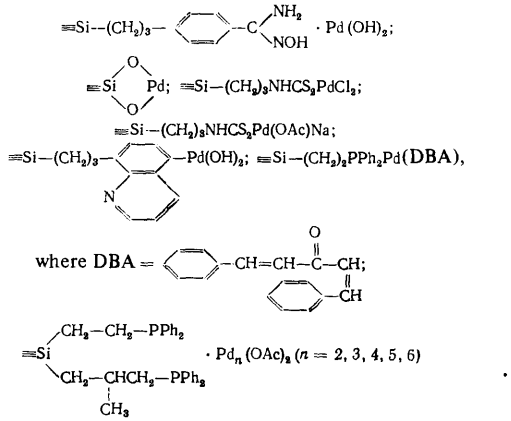
The hydrogenation of quinoline using metallophthalocyanine catalysts at temperatures in the range 300–400 °C and pressures up to 200 atm takes place selectively with formation of 1,2,3,4-tetrahydroquinoline.[121] The hydrogenation of thiophen and sulpholene in the presence of mononuclear and polynuclear palladium complexes containing ligands of different types linked to silica gel has been investigated.[122–124] Sulpholene is readily reduced to sulpholan, while thiophen is reduced with much more difficulty to thiophan (1 atm H_2, 20 °C, in isopropyl alcohol). The activation of H_2 has been suggested as the rate-limiting stage for the mononuclear complexes. Enhancement of the electron-donating properties of the ligand lowers the instability constant of the complex and the equilibrium concentration of the hydride formed in accordance with the equation

$$\equiv Si-L-Pd^{II} + H_2 \rightleftarrows [\equiv Si-L-Pd^{II}-H]^- + H^+.$$

The rate of hydrogenation of sulpholene is reduced as a consequence.

With increase of the number of palladium atoms in the cluster complex from 2 to 6, its activity in the hydrogenation of sulpholene also rises, but the activity in the hydrogenation of thiophen changes only slightly. The low activity of the catalysts in the hydrogenation of thiophen can be explained by the difficulty of activating the substrate and the poisoning of the catalyst by the reaction product, the complex being decomposed in certain instances in accordance with the mechanism

In the hydrogenation reaction in dimethylformamide, which is capable of entering into a complex formation reaction in competition with the metal, the catalysts are more stable. Enhancement of the electron-donating properties of the ligands in the mononuclear complexes promotes an increase of the stability of the complexes in the hydrogenation of thiophen, since the ability of the metal ion to coordinate to the sulphur heteroatom is then reduced.[122–124] The following compounds have been used as catalysts:



The catalysts prepared from carboxyl-containing polymers and platinum-group metal salts, which exhibited an activity in the hydrogenation of benzene, proved to be extremely active and selective in the hydrogenation of oxygen-containing compounds[92,93,125–128] (Table 9).

Table 9. Hydrogenation of heterocyclic compounds in the presence of catalysts prepared from carboxyl-containing polymers.[92,93,125–128]

Substrate	Catalyst*	t, °C	n**, h^{-1}	Reaction product (yield, %)
Furan	Rh-STMC	30	52	Tetrahydrofuran (100)
2-Methylfuran	Rh-STMC	30	113	2-Methyltetrahydrofuran (100)
Benzofuran	Pd-STMC	30	53	2,3-Dihydrobenzofuran (100)
1,4-Benzodioxan	Rh-PAA	30	7	Hexahydro-1,4-benzodioxan (32)
6-Nitro-1,3-benzodioxan	Rh-PAA	20	4	5-Amino-1,3-benzodioxan (75)
Furfural	Rh-PAA	20	44	Tetrahydrofurfuryl alcohol (96)

*For the significance of the abbreviations, see Table 7.
**The turnover number of the reaction.

Mention should also be made of the hydrogenation of pyridine, quinoline, and furan derivatives under the conditions of catalysis with phase transfer in the presence of rhodium complexes.[75] Fairly high yields of the hydrogenation products were then achieved.

---o0o---

The above analysis of data for the hydrogenation of aromatic compounds in the presence of metal complex catalysts shows that, despite the large amount of experimental data available, the possibilities for the selection of effective catalysts for the hydrogenation of aromatic hydrocarbons are small. The point is that the rational employment of metal complex catalysts requires the use of comparatively mild conditions, whereupon their ability to propagate processes at high rates is most fully realised, the process being at the same time highly selective and involving a small expenditure of energy. However, the use of active catalysts for the hydrogenation of the above compounds, such as the hydroformylation Ziegler catalysts and some of the complexes

with unsaturated hydrocarbon ligands, requires fairly severe reaction conditions. On the other hand, complexes active under mild conditions are frequently relatively unstable.

In the case of heterocyclic compounds the choice of metal complex hydrogenation catalysts is still more limited apparently owing to the low stability of the majority of the metal complexes investigated and acted upon by heterocycles. The successful solution of this problem involves the selection of a suitable ligand environment for the metal ion, which would stabilise it in the catalytically active state and would thus counteract the poisoning effect of the heterocycle; such stabilising activity of certain ligands can be demonstrated in the deuterium–hydrogen exchange involving thiophen and its derivatives.[15]

Overall, among the catalysts considered in this review, the most stable and effective under mild conditions and sufficiently universal is the rhodium complex of *N*-phenylanthranilic acid. Effective and "technological" catalysts on a polymer carrier have been based on it and it has been established reliably that the metal in such catalysts is in fact present in the form of a complex.

Catalysts based on carboxyl-containing polymers have also exhibited a high activity in the hydrogenation of aromatic and heterocyclic compounds under mild conditions.

The instances quoted above of the successful application of polymer-containing complexes in the hydrogenation of aromatic and heteroaromatic compounds show that the most promising procedure is the creation of effective metal complex catalysts on the basis of polymer-containing complexes, particularly with organic polymers and copolymers, which not only make it possible to heterogenise the catalyst when this is necessary but also can ensure its high stability by functioning as polydentate macroligands.

Intermediate Compounds and Intermediate Reactions in the Synthesis of Oligonucleotides

V.F.Zarytova and D.G.Knorre

The principal features of the phosphorylation of nucleosides and other alcohols by phosphoric acid monoesters and diesters in the presence of the most widely used condensing agents (arenesulphonyl chlorides, arenesulphonyl azolides, carbodiimides, mixtures of arenesulphonyl chlorides with azoles and pyridines) are described. Data concerning the intermediate compounds and intermediate reactions in the oligonucleotides synthesis as well as model processes, obtained mainly with the aid of ^{31}P NMR, are discussed.
The bibliography includes 67 references.

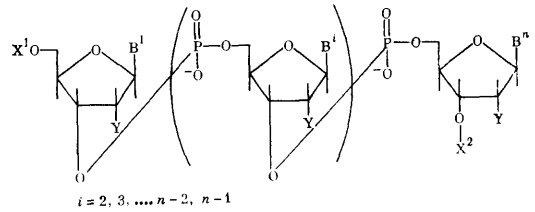
I. INTRODUCTION

Oligonucleotides having the general structure



$i = 2, 3, \ldots, n-2, n-1$

[X^1 and X^2 = H or $OP(O)O^-$, Y = H or OH, and B = nitrogen-containing heterocycles, usually adenine, guanine, cytosine, uracil and thymine] are fragments of the most important class of biopolymers—nucleic acids: DNA when K = H or RNA when Y = OH. Their chemical synthesis is one of the central tasks of bio-organic chemistry. Oligonucleotides are intermediate oligomers in the chemical-enzymic synthesis of genetic material. Their role as a research tool in molecular biology and genetic engineering has been continuously growing.

The main and frequently repeated stage in any method for oligonucleotide synthesis is the formation of new phosphoester (internucleotide) bonds between the monomers or the intermediate oligomers. Until recently, the main advances in the synthesis of oligonucleotides were achieved with the aid of phosphoester condensations, i.e. using the reaction between the hydroxy-group of one component (the OH-component) and the phosphate group of another component (the P-component), which takes place in the presence of condensing agents. Arenesulphonyl chlorides ($ArSO_2Cl$) and arenesulphonyl azolides [tetrazolides ($ArSO_2Tet$ and 3-nitro-1,2,4-triazolides ($ArSO_2NTr$)] have been most widely used as the latter. During the initial period of the establishment of the chemistry of oligonucleotides, dicyclohexylcarbodiimide (DCC) was widely used. Oxidation-reduction condensing agents, mainly a mixture of triphenylphosphine and di(2-pyridyl) disulphide have also been successfully employed.

The first serious advances in the chemical synthesis of oligonucleotides involved the development of the so-called phosphodiester method of synthesis in which the P-component is the phosphomonoester and the condensation product is the phosphodiester. Khorana and coworkers[1,2] achieved by this procedure the first syntheses of genes, using DCC and arenesulphonyl chlorides as the condensing agents. However, at the end of the 1970's there was an abrupt return to the phosphotriester method of synthesis in which the P-component is the diester and the condensation product is the triester. In the latter case the internucleotide phosphate is blocked by some kind of protective group, for example, the *p*-chlorophenyl group. Despite the necessity to remove the blocking groups from the internucleotide phosphate in the last stage, this has resulted in an overall significant simplification and acceleration of the synthetic procedure as a result of the acceleration of the intermediate condensations and the simplification of the purification of the intermediate oligomers. The employment of the phosphotriester method became effective as a result of the appearance of new condensing agents—arenesulphonyl azolides[3-8] and mixtures of arenesulphonyl chlorides with nucleophilic catalysts, namely tetrazole,[6] 3-nitro-1,2,4-triazole,[9,10] dimethylaminopyridine,[11-13] and *N*-methylimidazole.[10,14-19]

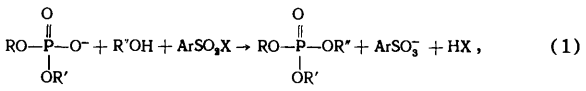
The importance of the phosphoester condensations in the chemistry of nucleotides led to interest in the study of their mechanism. A number of hypotheses concerning the nature of the intermediate species involved in these processes have been put forward by the founders of the chemistry of nucleic acids—Todd, Michelson, and Khorana. Systematic studies became possible following the appearance of the pulsed ^{31}P NMR method, which makes it possible to follow the course of the phosphoester condensations by recording the accumulation of the main and side products as well as certain intermediates.

The aim of the present review is to give an account of the present ideas about the mechanism of the formation of phosphoesters with the aid of condensing agents; these ideas are to a large extent based on studies of the intermediates and intermediate reactions in the oligonucleotide synthesis carried out by the authors of this review and their coworkers.

II. THE PRINCIPAL STAGES OF PHOSPHOESTER CONDENSATIONS

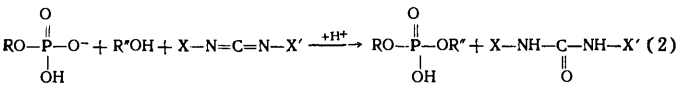
The phosphoester condensations are coupled reactions involving the formation of phosphoesters and transformations of the condensing agents. In the case of arenesulphonyl chlorides and arenesulphonyl azolides such a reaction is the

hydrolysis of the condensing agents and the overall condensation equation can be formulated thus:



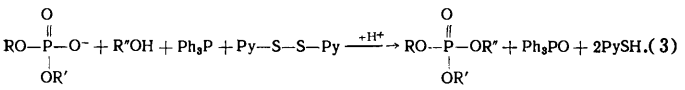
(1)

where X = Cl, the tetrazole residue, or the 3-nitro-1,2,4-triazole residue. In the case of DCC and other disubstituted carbodiimides, the formation of the phosphodiester is accompanied by the hydration of the condensing agent with formation of the corresponding disubstituted urea:



(2)

(for DCC, X, X' = cyclo-C_6H_{11}). In the oxidation-reduction condensation one component of the pair is reduced and the other is oxidised, for example:



(3)

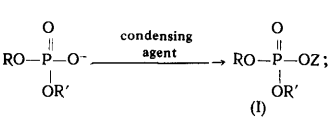
In scheme (1) and (3) R' = H (for the phosphodiester condensation) or is an organic group (in the phosphotriester condensation). Depending on the solvents employed, the ions can exist as individual species or as ion pairs; here and below they are represented without the corresponding counterions.

In conformity with the general ideas concerning the mechanisms of the coupled reactions,[20] reactions (1)–(3) should proceed via the formation of intermediates, which arise on interaction of the condensing agent (which behaves as the inductor) with one of the components to be condensed. It has come to be assumed that this interaction takes place with the P-component. The ability of all the condensing agents enumerated above to react with the P-component in the absence of the OH-component supports this view. On the other hand, these condensing agents either do not react at all with the OH-component under the conditions of phosphoester condensations, as happens in the case of DCC, or they are known *a priori* to give rise to side products. Thus arenesulphonyl chlorides and arenesulphonyl azolides sulphonate the OH-component via the reaction

However, hitherto it has not been possible to detect the products of the direct interaction of the condensing agents enumerated above with the P-component in any one instance; only the products of the subsequent reactions have been found.

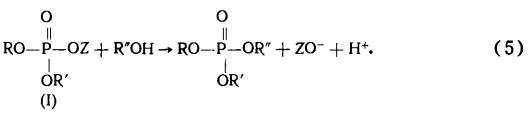
Thus the first problem which arises in the study of the mechanism of phosphoester condensations is that of the nature of the active intermediate species formed directly on interaction of the molecules of the condensing agent and the P-component and also of the mechanism of this interaction (see Section II).

It has been suggested[21] that the species formed are powerful electrophiles capable of phosphorylating the OH groups (Z is a fragment of the condensing agent):



(4)

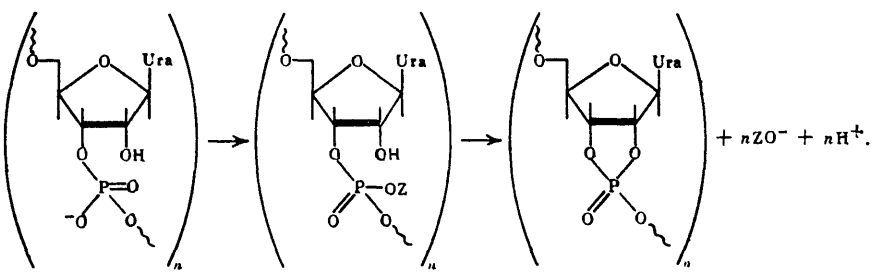
(I)



(5)

(I)

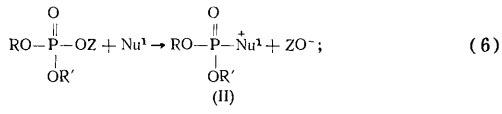
As an example of a process in the course of which the primary products of the interaction of the phosphate with the condensing agent are consumed mainly in the reaction with the OH groups, one may quote the interaction of the condensing agents triisopropylbenzenesulphonyl chloride (TPS) and DCC with the cetavlon salt of polyuridylic acid and dimethylformamide (DMF).[22] In both cases the disappearance of the signals due to the internucleotide phosphate and the appearance of signals of the cyclic phosphotriester groups, which have undergone a significant downfield shift, are observed in the ^{31}P NMR spectra, in conformity with the reaction in accordance with the scheme



The spatial proximity of the phosphate and 2'-hydroxy-groups favours reaction (5), which is in this instance intramolecular.

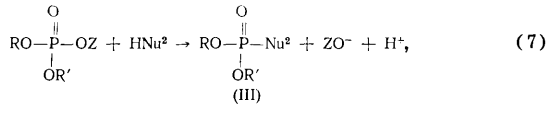
However, under the conditions of the formation of internucleotide bonds, this simple mechanism of the phosphoester condensation does not operate. In this case the reaction of the species (I) with the molecules of the OH-component is intermolecular and the system contains other nucleophiles more powerful than the OH-component.[2]

Among the nucleophiles competing with the OH-component for reaction with compound (I), mention should be made in the first place of pyridine, which has been used until very recently as the solvent,[21] in virtually all phosphoester condensations, and also certain other nitrogen-containing heterocycles, which have come to be employed in recent years to accelerate phosphoester condensations, namely tetrazole, 3-nitro-1,2,4-triazole, *N*-methylimidazole, and 4-*NN*-dimethylaminopyridine (DMAP). It is to be expected that in their presence the reaction proceeds preferentially via the following pathway:



(6)

(II)

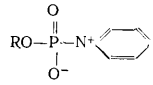


(7)

(III)

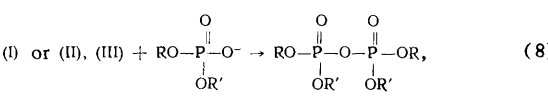
where Nu^1 = pyridine, 4,4-DMAP, or *N*-methylimidazole, HNu^2 = tetrazole or 3-nitro-1,2,4-triazole, R' = H or Ar, and R = protected nucleoside residue.

Compounds (II) and (III) should be fairly powerful phosphorylating agents, the former by virtue of the positive charge on the nitrogen atom and the latter as a result of the fairly high electron-accepting capacities of the tetrazole and nitrotriazole rings. The possible role of phosphorylpyridinium derivatives having the structure



as intermediates in phosphoester condensations has been pointed out by Michelson.[21] The second question of major importance for the understanding of the mechanisms of phosphoester condensations is therefore that of the role of compounds of types (II) and (III) and the formation of new phosphoester linkages, in first place of their reactivity in relation to alcohols. The data available on this question will be examined below (in Section III).

Together with the heterocyclic nucleophiles mentioned above, during the initial phase of the process the reaction mixture contains the P-component which has not reacted and which is also a nucleophile, as a rule stronger than the OH-component. The interaction of the molecules of the P- component with compounds (I)–(III) leads to their consumption with formation of pyrophosphate:

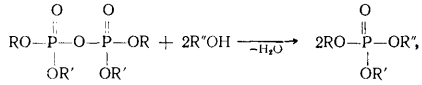


(8)

preventing thereby the formation of new phosphoester linkages. In the phosphotriester condensation this entails the formation of the pyrophosphotetraester, which lacks nucleophilic properties. Vigorous phosphorylation of the OH-component is possible only after the complete consumption of the P-component via reaction (8).

In the phosphodiester condensation the situation is significantly complicated as not only the initial P-component but also the pyrophosphodiester formed from it via reaction (8) and even the required reaction product (the phosphodiester) are nucleophiles. For the effective phosphorylation of the OH-component, it is necessary that both the P-component itself and all its nucleophilic derivatives should be fully exhausted. These reactions are described in Section (IV) in connection with the consideration of the general mechanism of the phosphodiester condensation.

As can be seen from the simplest example of reaction (8), in the first phase of the process the active intermediates of types (II) and (III) are consumed in the first place via their reactions with the P-component. In the second phase of the process, where new internucleotide bonds are mainly formed, the species (II) and (III) are regenerated from pyro- and poly-phosphates. This requires the involvement of nitrogen-containing heterocycles, which do not compete with the OH-component for compounds (II) and (III), since the interaction with these compounds is an exchange process which does not lead to the consumption of these species. Furthermore, the condensing agent can also participate in this process. For example, it follows from the stoichiometric equation of the reaction of pyrophosphodiester or pyrophosphotetraester with the OH-component,

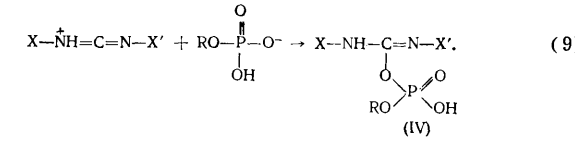


that the completion of the reaction requires the binding of the water molecule, i.e. the involvement of the condensing agent is essential.

The mechanisms of the regeneration of compounds (II) and (III) are also significantly different in phosphodiester and phosphotriester condensations; they will be considered separately in Sections (IV) and (V).

III. THE INTERACTION OF THE P-COMPONENT WITH CONDENSING AGENTS

According to Khorana,[23–25] in the case of disubstituted carbodiimides, the first condensing agents widely introduced into practical oligonucleotide chemistry, the primary product of the interaction of the P-component with the condensing agent is the corresponding *O*-phosphorylisourea (IV). Since phosphorylation in the presence of carbodiimides is strongly suppressed by basic amines, it has been suggested that the reaction proceeds between the protonated form of the carbodiimide and the phosphoester anion.[21,23–26]

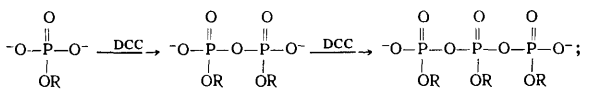


(9)

(IV)

However, compound (IV) could be neither isolated nor even detected in the reaction mixture. The primary product which can be isolated from the reaction mixture is the pyrophosphate. The subsequent reaction in the case of phosphomonoesters leads to the accumulation of trisubstituted triphosphate.[26] This result was subsequently used in other investigations[27–29] in which the reaction between 3'-acetylthymidine 5'-phosphate and DCC in pyridine was followed by

means of ^{31}P NMR, because the chemical shifts of the compounds formed, and in the case of the triphosphate also the structure of the spectrum, differ significantly and the behaviour of each component of the reaction mixture can be followed separately (Figs. 1 and 2):



R = 3'-acetyl-5'-thymidinyl.

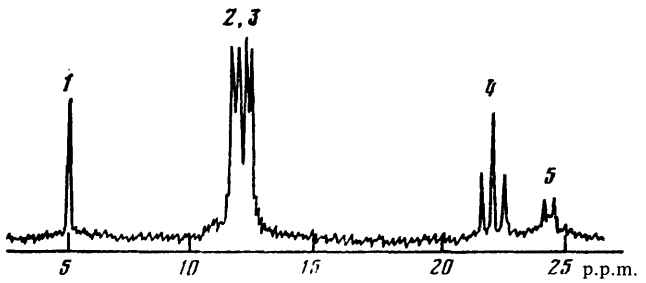


Figure 1. ^{31}P NMR spectrum of the reaction mixture obtained in the interaction of 0.15 M pT(Ac) with 1.5 M DCC in pyridine after 1 h from the start of the reaction: *1*) signal of the pyridinium derivative of pT(Ac); *2*) and *3*) signals of the terminal phosphorus atoms of the trinucleoside triphosphate and the tetranucleoside tetraphosphate; *4*) signals of the central phosphorus atom of the trinucleoside triphosphate; *5*) signals of the central phosphorus atoms of the tetranucleoside tetraphosphate.[37]

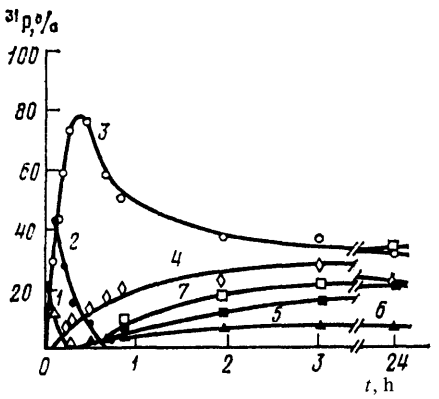

Figure 2. Kinetic curves for the interaction of 0.15 M Pt(Ac) with 1.5 M DCC in pyridine: *1*) initial mononucleotide; *2*) dinucleoside pyrophosphate; *3*) trinucleoside triphosphate; *4*) tetranucleoside tetraphosphate; *5*) *N*-pyrophosphorylurea; *6*) pyridinium derivative of pT(Ac); *7*) unidentified product.[37]

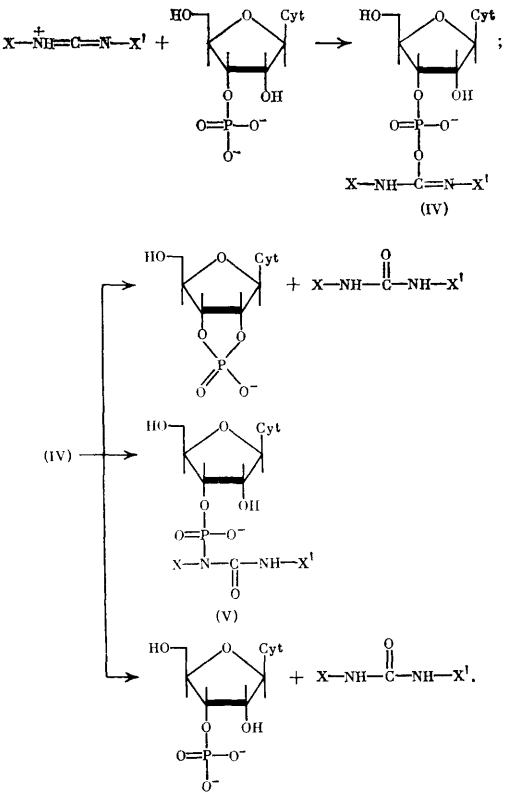
The kinetic test of mechanism (9) was carried out[30] in relation to the reaction of cytidine 2'(3')-monophosphate (CMP) with a water-soluble carbodiimide, namely *N*-cyclohexyl-*N'*-β-(*4-methylmorpholino*)*ethylcarbodiimide toluene-p-sulphonate* (henceforth abbreviated to CME-carbodiimide) in aqueous solution. In this case the reaction product is mainly cytidine cyclic 2',3'-phosphate (cCMP), which is apparently formed directly from the active intermediate (IV) as a result of the spatial proximity of the activated phosphate and the 2'-hydroxy-group. The formation of pyrophosphate is not observed in this instance. The accumulation of a certain amount of *N*-cytidylyl-ME-urea (V), which can be regarded as the product of the isomerisation of *O*-cytidylyl-CME-isourea (IV), was recorded.[30] It is significant that the rate of consumption of CME-carbodiimide is much higher than the rate of accumulation of the CMP reaction products. This shows that the reaction of CME-carbodiimide with CMP involves the formation of an intermediate, which, together with transformation into cCMP and compound (V), can hydrolyse with reformation of the initial CMP. In the light of the Khorana mechanism, the complete process mechanism can be represented as follows:

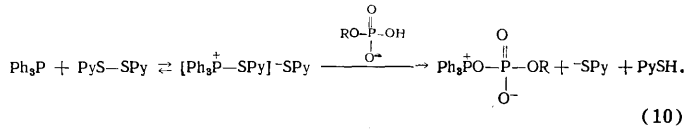


CME-carbodiimide is consumed via a first-order reaction with respect to both components, the effective reaction rate constant depending on the pH and the rate of reaction being proportional to the product of the concentrations of the protonated form of CME–carbodiimide and the double ionised form of CMP.[30]

In the reaction of CME–carbodiimide in aqueous solution with nucleoside 5'-phosphates at low concentrations of the latter, the hydration of carbodiimide is the main reaction pathway, in contrast to the reaction of nucleoside 2'(3')-CMP.[31] It has been shown[32] that, in the interaction of adenosine 5'-monophosphate, labelled with ^{18}O in the phosphate group, with DNA in pyridine in the presence of a large excess of $H_2^{16}O$, the labelled oxygen passes almost quantitatively to the dicyclohexylurea formed. This is also definite evidence in support of the intermediate formation of a compound of type (IV).

Thus all the available data agree with the mechanism proposed by Khorana and coworkers,[23–26] i.e. with the primary formation of *O*-phosphorylisourea.

The following mechanism of the formation of active phosphorylating species has been proposed for condensation in the presence of the triphenylphosphine–dipyridyl disulphide pair:[33,34]



(10)

The primary product detected by ^{31}P NMR in the case of 3′-*O*-acetylthymidine 5′-phosphate is, as in the case of carbodiimides, the corresponding pyrophosphate, which is subsequently converted into the triphosphate.[35] When dipyridyl disulphide is mixed with triphenylphosphine, no changes are observed in the ^{31}P NMR spectrum of the reaction mixture, which implies that, even if the process does proceed in accordance with scheme (10), the equilibrium in the first stage is strongly displaced to the left. The process has not been studied in detail.

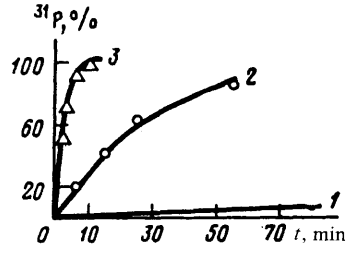


Figure 3. Kinetic curves for the formation of a tetrasubstituted pyrophosphate in the reaction of 0.1 M (ClC_6H_4). .pT(Lev)(triethylammonium salt) and 0.2 M TPS in chloroform at 30 °C in the presence of various additives: *1*) 0.4 M triethylamine; *2*) 0.4 M pyridine; *3*) 0.4 M *N*-methylimidazole.[18]

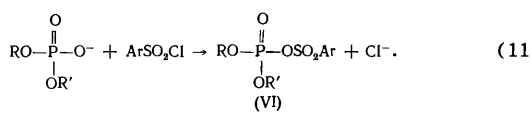
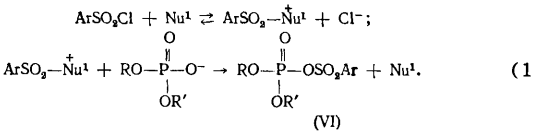
The first phase of the phosphoester condensation has been studied most thoroughly for arenesulphonyl chlorides and arenesulphonyl azolides. In both phosphodiester and phosphotriester condensations, the product of the interaction of the initial P-component with the condensing agent is the corresponding pyrophosphate.[17,27–29,36–43] In the reaction of phosphomonoesters with $ArSO_2Cl$, the pyrophosphodiester formed reacts to produce a trisubstituted triphosphate. The subsequent reactions of the latter will be considered in the next Section. The kinetics of the primary reaction with TPS have been investigated in the reaction involving 3′-O-acetylthymidine 5′-phosphate [pT(Ac)] and P^1P^2-di(3′-O-acetyl-5′-thymidinyl) pyrophosphate in pyridine. In both cases the reaction is of first order with respect to TPS and the P-component, which proves the involvement of only one molecule of the latter in the rate-limiting stage. This is in full agreement with the hypothesis of Corby, Todd, and Khorana,[44–46] according to which the primary product of the reaction of arenesulphonyl chloride with phosphates is a mixed anhydride of the phosphate and the arenesulphonic acid formed in accordance with the reaction



(11)

(VI)

However, reaction (11) is complex and requires the participation of a nucleophilic catalyst.[18] It has been shown for the reaction of the p-chlorophenyl ester of 3′-*O*-levulinylthymidine 5′ phosphate [(ClC_6H_4)PT(Lev)] with TPS in a 7 : 1 chloroform–acetonitrile mixture that the formation of pyrophosphate is not detected at 30 °C in the course of 2 h, while in pyridine the process is completed in several minutes. Fig. 3 shows that the reaction is appreciably accelerated after the addition of a small excess (relative to TPS) of pyridine and to an even greater extent after the addition of *N*-methylimidazole; the addition of similar amounts of triethylamine leads merely to an insignificant accumulation of pyrophosphate. The nucleophilicity of these three bases varies in precisely the same sequence. Thus nucleophilic catalysis plays an appreciable role in the formation of the mixed anhydride (VI). The reaction apparently proceeds in accordance with the following mechanism:



(12)

(VI)

In conformity with this hypothesis, the application of the infrared spectroscopic method to a mixture of TPS or tosyl chloride with dimethylaminopyridine, which is also widely used as a nucleophilic catalyst, in methylene chloride revealed the formation of the arenesulphonyldimethylaminopyridinium derivative, which is apparently stabilised owing to the formation of a quinonoid structure:[47]

In the case of pyridine and *N*-methylimidazole such a derivative could not be detected, most probably because equilibrium (12) is greatly displaced to the left. Thus arenesulphonyl chlorides proved to be insufficiently powerful electrophiles to interact directly with the weakly nucleophilic anion of the phosphodiester, at least in solvents with a low dielectric constant.

The interaction apparently becomes possible with more nucleophilic phosphomonoesters in more polar solvents. Thus pT(Ac) reacts with TPS in DMF. However, the addition of pyridine significantly accelerates the reaction.[48]

The detected product of the interaction of arenesulphonyl azolides (the tetrazolide and 3-nitro-1,2,4-triazolide) with the P-component is also the corresponding pyrophosphate;[17,40–43] by analogy with the reaction of arenesulphonyl chlorides, one can suppose that the primary product is the same mixed anhydride (VI). In methylene chloride the interaction of (ClC_6H_4). .pT(Lev) with toluene-*p*-sulphonyl tetrazolide is slow but is significantly accelerated after the addition of pyridine.[43] Presumably in this instance the phosphodiester is sulphonated by the arenesulphonylpyridinium derivative. The formation of the pyrophosphate in pyridine on reaction of TsTet with (ClC_6H_4)pT(Ac) is significantly accelerated after the addition of toluenesulphonic acid and is almost fully blocked after the addition of an excess of triethylamine.[41] These effects agree well with the stoichiometric equation for the formation of the

arenesulphonylpyridinium derivative:

$$ArSO_2Tet + Nu^1 + PyH^+ \rightleftarrows ArSO_2\text{–}\overset{+}{N}u^1 + TetH + Py. \qquad (13)$$

Equilibrium (13) should be displaced to the left following the addition of a strongly basic amine and to the right after the addition of an acid.

The formation of the mixed anhydride (VI) is the rate-limiting stage in the formation of pyrophosphate. Kinetic measurements apparently do not make it possible to reach a definite conclusion concerning the mechanism of the subsequent transformation of compound (VI) into the pyrophosphate. It can take place either as a result of the direct interaction of compound (VI) with a second molecule of the P-component [Eqn.(14)][13,43] or via the preliminary formation of a phosphorylpyridinium or phosphorylazolium derivative [Eqns.(15) and (16)], as has been postulated in a number of investigations:[6,9,10,16]

$$RO\text{–}\overset{\overset{O}{\|}}{\underset{\underset{OR'}{|}}{P}}\text{–}O^- + RO\text{–}\overset{\overset{O}{\|}}{\underset{\underset{OR'}{|}}{P}}\text{–}O\text{–}SO_2Ar \rightarrow RO\text{–}\overset{\overset{O}{\|}}{\underset{\underset{OR'}{|}}{P}}\text{–}O\text{–}\overset{\overset{O}{\|}}{\underset{\underset{OR'}{|}}{P}}\text{–}OR + ArSO_3^-; \qquad (14)$$

(VI)

$$RO\text{–}\overset{\overset{O}{\|}}{\underset{\underset{OR'}{|}}{P}}\text{–}O\text{–}SO_2Ar + Nu^1 \rightleftarrows RO\text{–}\overset{\overset{O}{\|}}{\underset{\underset{OR'}{|}}{P}}\text{–}\overset{+}{N}u^1 + ArSO_3^-; \qquad (15)$$

$$RO\text{–}\overset{\overset{O}{\|}}{\underset{\underset{OR'}{|}}{P}}\text{–}\overset{+}{N}u^1 + RO\text{–}\overset{\overset{O}{\|}}{\underset{\underset{OR'}{|}}{P}}\text{–}O^- \rightleftarrows RO\text{–}\overset{\overset{O}{\|}}{\underset{\underset{OR'}{|}}{P}}\text{–}O\text{–}\overset{\overset{O}{\|}}{\underset{\underset{OR'}{|}}{P}}\text{–}OR + Nu^1. \qquad (16)$$

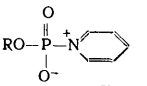
The sharp acceleration of the formation of the mixed anhydrides (VI) in the presence of pyridine and *N*-methylimidazole was interpreted above as a result of the significantly faster reaction (12) compared with the direct reaction (11). This means that the amines indicated are significantly more active than the phosphoester anions and attack the tetrahedral sulphur atom in $ArSO_2Cl$. It is logical to suppose that qualitatively the same relative rates obtain in the attack by the same nucleophiles on the tetrahedral phosphorus atom in compound (VI), i.e. reaction (15) predominates significantly over reaction (14) and the main pathway to the formation of the pyrophosphate is via stages (15) and (16).

In the case of phosphomonoesters the formation of the pyrophosphate and its subsequent conversion into the trisubstituted triphosphate and longer polyphosphates takes place on treatment with $ArSO_2Cl$ in DMF in the absence of nucleophilic catalysts. However, the addition of pyridine accelerates the process significantly, i.e. in the reaction with phosphomonoesters arenesulphonylpyridinium is also a stronger sulphonating agent than $ArSO_2Cl$.

IV. PYRIDINIUM DERIVATIVES AND AZOLIDES OF PHOSPHOESTERS

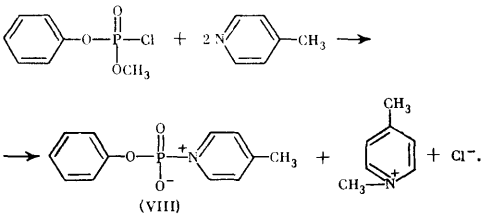
The most detailed information about the role of derivatives of type (II) as active intermediates phosphorylating the hydroxy-groups of the OH-component have been obtained in the study of the phosphodiester condensation in pyridine.

On treatment of phosphomonoesters (nucleoside 5'-phosphates, phenyl phosphate, nitrophenyl phosphate, etc.) with an excess of TPS[27–29] or with a cross-linked poly(styrenesulphonyl chloride) in pyridine,[49] ^{31}P NMR spectra revealed a virtually quantitative conversion of the esters into derivatives whose spectrum consisted of a singlet displaced upfield by ~5 p.p.m. compared with the initial ester. Detailed data for the chemical shifts and structure of the ^{31}P NMR spectra of phosphate esters and their derivatives have been published.[50] Nucleoside 5'-phosphates undergo the same reaction on treatment with an excess of a mixture of triphenylphosphine and dipyridyl disulphide in pyridine.[35,51,52] The comparatively slight change in the chemical shift on formation of these derivatives indicates the retention of the tetrahedral configuration of the phosphorus atom. The necessity for the presence of pyridine to ensure their formation suggests that they are phosphorylpyridinium derivatives having the structure



(VII)

Direct proof of this structure has been found for the derivative of phenyl phosphoric acid (VIII); which had been obtained by the following reaction for this purpose:[52,53]



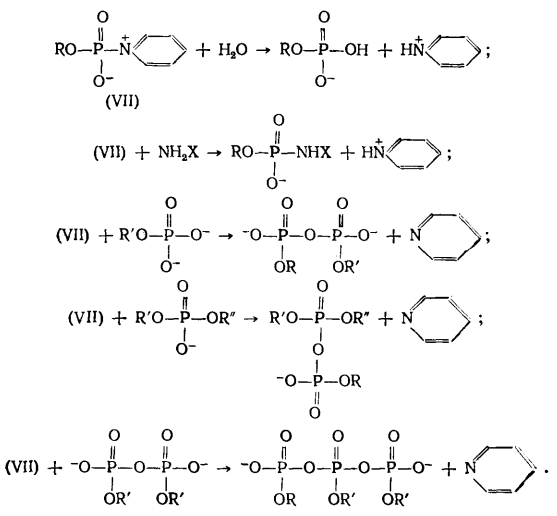
(VIII)

The splitting of both the ^{31}P signal by the α-protons of the picolinium derivative and of the ^1H signal of the α-protons by the phosphorus nucleus ($^3J_{PNCH} = 5.5$ Hz) has been observed in the NMR spectra at −50 °C. This demonstrates the presence of a chemical bond between the phosphorus atoms and the γ-picoline residue. The chemical shifts for both the α-protons and the protons of the γ-methyl group are displaced downfield relative to picoline itself, which is due to the appearance of a positive charge near the picoline fragment. With increase of temperature, exchange is observed between free picoline and the derivative, which leads to the merging of the signals of both the α- and γ-methyl protons (Fig.4) in the spectra of free picoline and compound (VIII) and also to the disappearance of the splitting of the ^{31}P NMR signal by α-protons†.

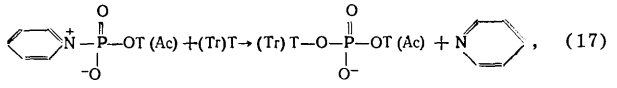
At room temperature compound (VII) reacts vigorously with water, amines, phosphomonoesters, phosphodiesters, and substituted pyrophosphates, all the reactions reaching completion after less than 1–2 min (the time necessary to record the ^{31}P NMR spectrum.

---

†The absence of such splitting under the conditions of the phosphoester condensations at room temperature in the presence of an excess of pyridine made it impossible in the first studies of the formation and reactions of compound (VII) to give preference to structure (VII) proposed by Michelson[21] and, in conformity with the hypothesis of Todd[45] and Khorana,[26,54] this compound was regarded as the corresponding metaphosphate $ROP\overset{O}{\underset{O}{\diagdown\!\!\diagup}}$.



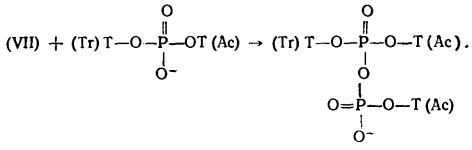
The reaction with alcohols takes place somewhat more slowly. In this instance it is possible to obtain with the aid of ^{31}P NMR the kinetic curve for the consumption of compound (VII) and to determine the rate constant. For the reaction



(17)

it amounts to 7.3×10^{-3} litre mol^{-1} at 30 °C and to 0.8×10^{-3} litre mol s^{-1} at 2 °C.[51] The rate constant depends significantly on the nature of the OH-component, which shows that the process proceeds via an associative mechanism. Thus the rate constant for the reaction of the same derivative at 2 °C with ethylenecyanohydrin is 11.3×10^{-3} litre mol^{-1} s^{-1}.[51]

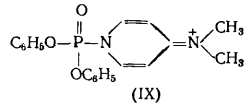
In the reaction of compound (VII) with alcohols the ^{31}P NMR spectra reveal the accumulation not of the phosphodiester but of the pyrophosphotriester—the product of the interaction of the phosphodiester formed with yet another molecule of compound (VII):



Pyrophosphotriesters have two non-equivalent phosphorus atoms, one of which is asymmetric; the ^{31}P NMR spectrum exhibits a complex signal, which consists of the superposition of the signals of two *AB* spin systems of two diastereoisomers[55,56] (Fig. 5).

It has been shown for the P-tetrazolide of pT(Ac) that the tetrazolides of phosphomonoesters are less reactive by at least two orders of magnitude on the analogous derivative of type (VII).[13]

The question of the reactivity of phosphodiester derivatives of types (II) and (III) has been investigated[11,12,40–43] on model systems—derivatives of diphenyl phosphoric acid obtained by treating diphenyl phosphorochloridate by the corresponding heterocycles. The 4-*NN*-dimethylaminopyridinium derivative was chosen as an example of a compound of type (II). When $(PhO)_2POCl$ is treated with DMAP in methylene chloride, the signal of the initial compound disappears from the ^{31}P NMR spectrum and another signal appears, which is split at −40 °C by the α-protons of the dimethylaminopyridinium fragment.[11] The signals of H_α, H_β, and CH_3 in the ^1H NMR spectrum are displaced downfield relative to the corresponding DMAP signals owing to the appearance of a positive charge in the DMAP fragment. This made it possible to identify the compounds formed as diphenyl phosphoryldimethylaminopyridinium derivatives, which apparently have the quinonoid structure



(IX)

Compound (IX) is extremely reactive with respect to alcohols. Thus the addition of ethylenecyanohydrin results in an almost instantaneous transformation into 2-cyanoethyl diphenyl phosphate.[11]

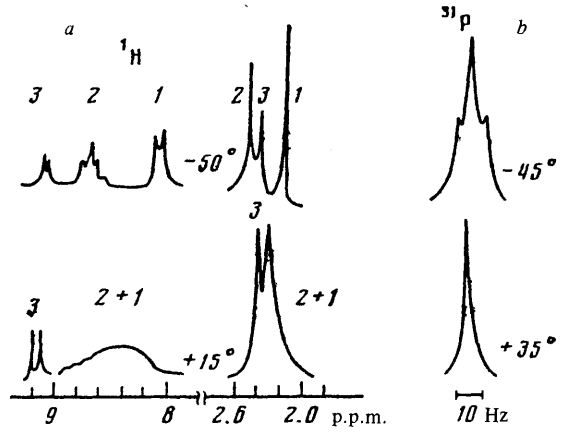


Figure 4. *a*) The structure of the ^1H NMR signals of the α-protons and γ-methyl groups as a function of temperature; *1*) of γ-picoline; *2*) of compound (VIII); *3*) of *N*-methyl-γ-picolinium; *b*) the structure of the ^{31}P NMR signals of compound (VIII) as a function of temperature. The spectra were recorded 1.5 h after the start of the reaction of phenyl methyl phosphorochloridate with 2 equivalents of γ-picoline in methylene chloride at room temperature.[52]

It must be emphasised that the analogous derivatives of phosphomonoesters are significantly less reactive with respect to alcohols than the pyridinium derivatives.[11–13] The greater stability of derivatives of DMAP is associated both with its higher basicity compared with pyridine and with the possibility of additional stabilisation via the formation of a quinonoid structure. The sharp increase of reactivity on passing from dimethylaminopyridinium derivatives of phosphomonoesters to derivatives of phosphodiesters is due to the fact that the former are zwitter-ions, while the latter carry an uncompensated positive charge.

Diphenyl phosphotetrazolide has been chosen as an example of compounds of type (III). When diphenyl phosphorochloridate is treated with tetrazole in dioxan in the presence of triethylamine, the ^{31}P NMR spectrum, measured after the precipitation of triethylammonium chloride, reveals a signal at 21.5 p.p.m., which differs significantly from that of the initial substance (5.5 p.p.m.).[41] The position of the signal makes it possible to identify the compound formed as diphenyl

phosphotetrazolide.[50] The addition of (Tr)T as the OH-component to the reaction mixture leads to the conversion of the tetrazolide of diphenylphosphoric acid into the corresponding phosphotriester (Tr)TOP(O)(OPh)$_2$. In the absence of bases the reaction is fairly slow. The data presented in Fig.(6) show that the reaction is significantly accelerated after the addition of pyridine and to an even greater extent after the addition of γ-collidine, which is a stronger base. The addition of triethylamine leads to an instantaneous conversion of the tetrazolide of the phosphodiester into the phosphotriester.[41,57]

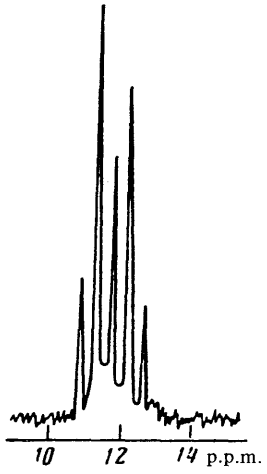

Figure 5. ^{31}P NMR spectrum of the pyrophosphotriester obtained on interaction of 0.0075 M (Tr)T with 0.15 M pyridinium derivative (VII) after 80 min from the start of the reaction.[29]

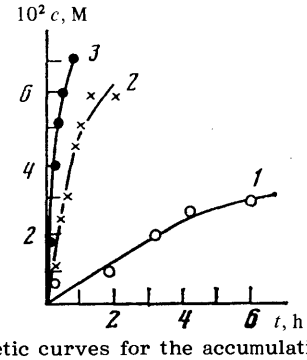

Figure 6. Kinetic curves for the accumulation of the phosphotriester (Tr)TOP(O)(OPh)$_2$ in the interaction of 0.08 M tetrazolide of diphenyl phosphoric acid with 0.01 M (Tr)T in dioxan at 30 °C: *1*) without additives; *2*) in the presence of 0.04 M pyridine; *3*) in the presence of 0.04 M γ-collidine.[57]

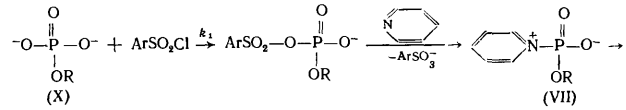
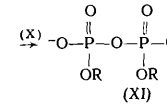
Thus species of types (II) and (III) are extremely reactive with respect to alcohols and there are grounds therefore for regarding them as the direct precursors of new phosphoester groups in phosphoester condensations.

V. THE MECHANISM OF PHOSPHODIESTER CONDENSATIONS

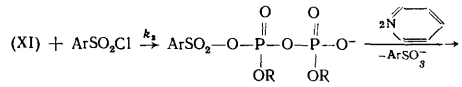
The mechanism of phosphodiester condensations has been investigated in greatest detail in relation to TPS as the condensing agent. The study of the complete system containing the P-component, the OH-component, and the condensing agent was preceded by a detailed investigation of the reaction of the P-component with the condensing agent in the absence of the OH-component. When 3′-*O*-acetylthymidine 5′-phosphate is acted upon by TPS in pyridine, the same sequence of reactions is initially recorded[27–29] as for DCC[58] (Fig.2).

It has been shown for the reaction of pT(Ac) and the pyrophosphate O[pT(Ac)]$_2$ formed from it that the order of the reaction with respect to both components is close to unity,[39,59] i.e. the rate-limiting stage of the process is the interaction of the condensing agent (apparently in the form of its pyridinium derivative) with one molecule of the phosphate or pyrophosphate. The product of the reaction of the pyrophosphate is triphosphate (XII). This indicates the conversion of the mixed anhydride of the pyrophosphate and the arenesulphonic acid into a mononucleotide derivative, which then attacks the pyrophosphate which has not yet reacted. After the consumption of the pyrophosphate, the accumulation of nucleoside 5′-phosphorylpyridinium in the reaction mixture begins. At the same time the accumulation of a certain amount of the tetrasubstituted tetraphosphate (XIII) is observed. Overall, the process kinetics can be described satisfactorily by the following scheme:

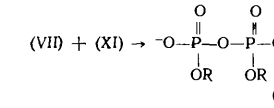


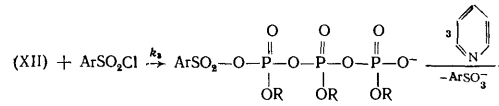


(18)

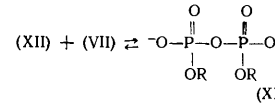


(19)





(20)



(21)

The Table presents the rate constants for the first three stages of the interaction of PT(Ac) and TPS at 5 °C and the entropies and enthalpies of activation estimated for these processes.[39]

In formulating reactions (18)–(21) and in calculating the rate constants for stages (18)–(20), no account was taken of the observed[46] significant accelerating effect of pyridine on the formation of pyrophosphates and polyphosphates. The species attacking the anions of the phosphomonoester (X), the pyrophosphate (XI), and the triphosphate (XII) is appar-

ently the arenesulphonylpyridinium cation $ArSO_2\overset{+}{N}\langle$. The rate constants listed in the Table are complex and represent the values of the true rate constants for the elementary

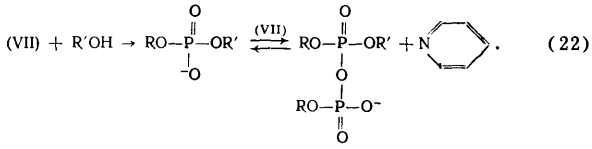
reactions of compounds (X)–(XII) with $ArSO_2-\overset{+}{N}$ multiplied by the constant concentration of pyridine and the equilibrium constant for the process

Kinetic parameters of reactions (18)–(20) at 5 °C.[39]

Reaction	$10^3 k$ litre mol^{-1} s^{-1}	$\Delta H^{\neq}$, kcal mol^{-1}	$\Delta S^{\neq}_0$, e.u.
(18)	11	9.8	−31.7
(19)	7	9.9	−32.6
(20)	1.1	9.7	−37.2

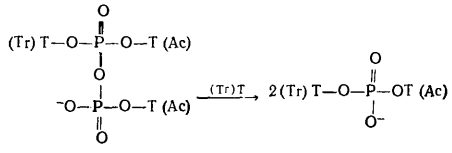
The pyrophosphate (XI) is only slightly less reactive with respect to TPS than the initial phosphomonoester.[59] The triphosphate is less reactive by an order of magnitude[59] and the decrease of the rate constant is largely associated with the decrease of the entropy of activation.

In the complete system the same sequence of transformations of the P-component is initially recorded. As compound (VII) appears in the reaction mixture, the formation of new internucleotide bonds becomes possible. However, as already stated, the phosphodiester formed reacts almost instantaneously with yet another molecule of compound (VII), forming the pyrophosphotriester (XIV):[55,56]

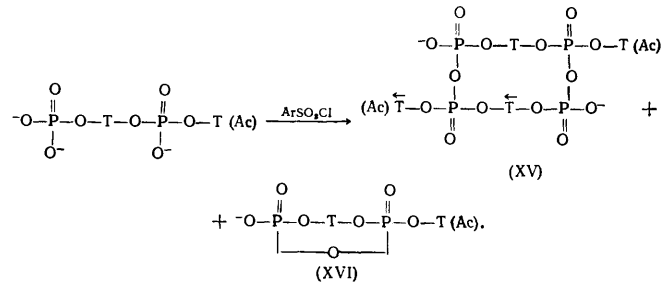


(22)

Pyrophosphotriesters are weak phosphorylating agents, the rate constants for the interaction of which with alcohols in pyridine are lower by two orders of magnitude than for the reactions of compound (VII) with the same alcohols. Thus the rate constant for the reaction



in pyridine at 30 °C is 9×10^{-5} litre mol^{-1} s^{-1}, while that for reaction (17) under the same conditions is 7.3×10^{-3} litre mol^{-1} s^{-1}.[39] Hence, even in the simplest case of the phosphodiester condensation designed to obtain a dinucleoside monophosphate, one of the two molecules of the two active phosphorylating derivative (VII) formed is converted into a significantly less reactive form. The situation is impaired even more when the P-component or the OH-component (or both) contains phosphodiester groups. If the OH-component is not a nucleoside but an oligonucleotide, compound (VII) formed from the P-component reacts in the first place with the phosphodiester groups and only when these have been converted into pyrophosphotriester groups does the reaction with hydroxy-groups proceed to an appreciable extent. Thus a large excess of compound (VII), which increases with increase of the length of the OH-component, is necessary.[38] On the other hand, when the P-component is an oligonucleotide, then, in the presence of a small excess of the condensing agent, pyrophosphotriester groups will form in it instead of the phosphorylpyridinium groups. When the dinucleotide pTpT(Ac) is acted upon by a small excess of TPS, the formation of compounds (XV) and (XVI) is mainly observed.[56–62] These are less reactive [the rate constants for the reactions with (Tr)T at 30 °C in pyridine are 0.6×10^{-4} and 2.8×10^{-4} litre mol^{-1} s^{-1} respectively]:[39]



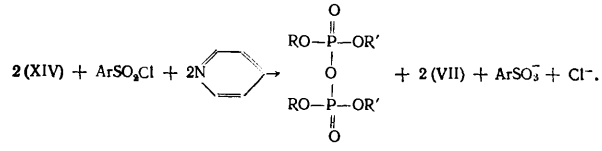
(XV)

(XVI)

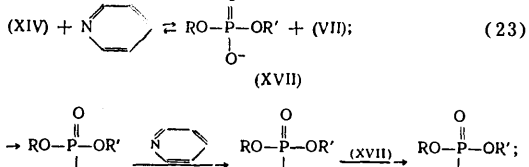
(The arrow above T denotes the direction from the 5′-OH group to the 3′-OH group of thymidine).

Compounds (XV) and (XVI), which have been obtained in DMF in the absence of pyridine, are so resistant to the action of nucleophiles that they can be separated chromatographically in aqueous solution.[62] There are therefore grounds for the assumption that their reaction with the OH-component in pyridine solution is feasible as a result of the nucleophilic catalysis by pyridine,[63] i.e. as a result of some reversibility of the second stage of reaction (22). This is also true of compound (XIV); as can be seen from the rate constants for the reactions of these pyrophosphotriesters with (Tr)T, for this purpose it is sufficient if less than 2% of compound (VII) is present in equilibrium with compounds (XIV), which is outside the limits of the sensitivity of the ^{31}P NMR method.

The highly reactive phosphorylpyridinium form is also regenerated from the pyrophosphotriester on treatment with an excess of the condensing agent.[55] The overall reaction is

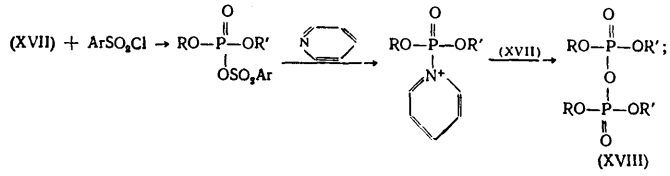


Its mechanism can be represented in the following manner:



(23)

(XVII)

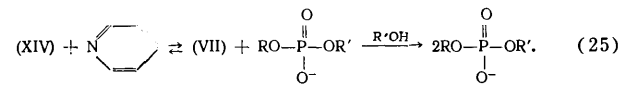


(XVIII)

R=(Tr)T, R′=T(Ac). (24)

It is noteworthy that the rate constant for the reaction of compound (XVII) with TPS, i.e. the rate-limiting stage of reaction (24), is 3.1×10^{-3} litre mol^{-1} s^{-1} at 5 °C, i.e. is only four times smaller than for the reaction with pT(Ac).[39]

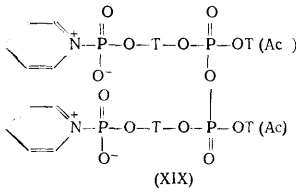
In the presence of a small excess of the condensing agent, when the rate of reaction (24) is low, the dominant pathway leading to the conversion of compound (XIV) into the diester may be the reaction



(25)

Reactions (23) and (24) lead to the conversion of the phosphodiester into the pyrophosphotetraester (XVIII), which can react to some extent with the OH-component, giving rise to the phosphotriester as the side product in the phosphodiester condensation.

The pyrophosphotriesters (XV) and (XVI) apparently undergo analogous reactions. In the presence of a sufficient excess of TPS, the dinucleotide pTpT(Ac) is converted into the compound[60-62]



(XIX)

containing the highly reactive phosphorylpyridinium groups [the rate constant for the reaction with (Tr)T at 30 °C is 6.3×10^{-3} litre mol^{-1} s^{-1}].[39]

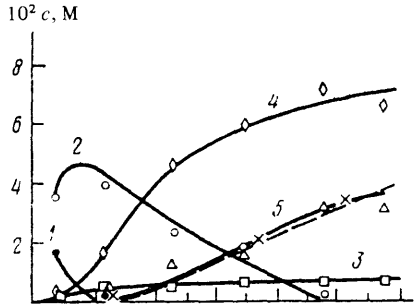


Figure 7. Kinetic curves for the interaction of 0.15 M Pt(Ac) with 0.15 M (Tr)T and 0.42 M TPS in pyridine: *1*) O[pT.(Ac)]$_2$; *2*) trinucleoside triphosphate; *3*) tetranucleoside tetraphosphate; *4*) pyridinium derivative of pT(Ac); *5*) the pyrophosphotriester (XIV).[51]

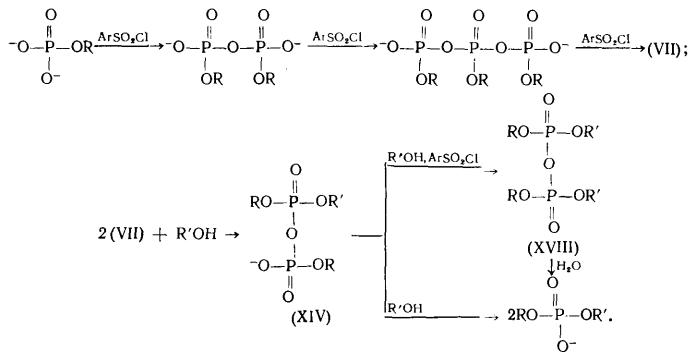
The reaction of compound (VII) with hydroxy-groups makes the main contribution to the formation of new phosphodiester groups.[52] Fig. 7 presents the kinetic curves for the accumulation of compounds (VII) and (XIV) in the reaction of pT(Ac) with (Tr)T in the presence of TPS at 2 °C. At the same time, the kinetic curve for the accumulation of compound (XIV) as a result of reaction (17), the rate-limiting stage in the formation of compound (XIV), has been calculated from the rate constant presented above for this reaction (dashed curve in Fig. 7). Evidently the calculated and experimental curves agree satisfactorily. Consequently the contribution of the reaction of the OH-component with other reactive species to the formation of phosphodiester is insignificant.

Thus even in the simplest case of the interaction of the P-component containing one phosphate fragment and the OH-component without phosphate groups, the mechanism of the phosphodiester condensations is fairly complex and is described by reactions (18)–(25), the majority of which consist of several elementary stages. The principal stages in the phosphodiester condensation in pyridine, detected by ^{31}P NMR, are presented schematically below:

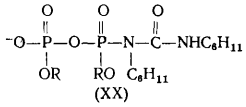


Regardless of the presence of the OH-component, the phosphomonoester undergoes a successive transformation into a substituted pyrophosphate and then into the corresponding triphosphate and the pyridinium derivative (VII). In the presence of the OH-component the derivative (VII) interacts with the latter via reaction (22), forming the trisubstituted pyrophosphate (XIV); the latter is capable of interacting with the OH-component, whereupon the phosphodiester accumulates but at a rate approximately eighty times lower than compound (VII).[39]

In the presence of a sufficient excess of the condensing agent reactions (23) and (24) result in the accumulation of compound (XVIII). However, when the reaction mixture is decomposed with water, this compound readily hydrolyses to the free phosphodiester.[36,58]

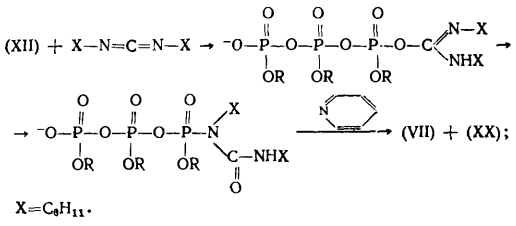
When pT(Ac) reacts in pyridine with a triphenylphosphine–dipyridyl sulphide mixture, the same sequence of transformations of the P-component to pyrophosphate, triphosphate, and finally the derivative (XIV) is observed.[51] The main pathway leading to the formation of phosphodiester group is in this instance also reaction (22).[51]

The reaction of pT(Ac) with DCC in pyridine is more complex. Both in the complete system and in the absence of the OH-component, the same sequence of transformations of the phosphomonoester into the corresponding pyrophosphate and triphosphate is observed. However, even in the absence of the OH-component, the final composition of the reaction mixture is more complex than for TPS and a triphenylphosphine–dipyridyl disulphide mixture. Together with compound (VII), a considerable amount of the triphosphate (XII) and the tetraphosphate (XIII) is retained and certain other derivatives, a considerable fraction of which consists of the ureido-derivative of the pyrophosphates (XX), are also detected:[58]



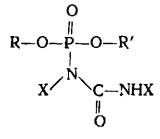
(XX)

This derivative, which should be regarded as the product of the isomerisation of the corresponding *O*-phosphoryldicyclohexylisourea in the light of Khorana's mechanism,[25] begins to accumulate after the complete consumption of the pyrophosphate, i.e. its formation is most probably associated with the reactions of the triphosphate. One of the possible mechanisms of such a reaction consists of this following sequence of stages:



$X = C_6H_{11}$.

When the reaction is carried out in the presence of the OH-component, the formation of compound (VII) is in fact not detected (Fig. 8) and the formation of compound (XX) is appreciably suppressed. By virtue of the absence of compound (VII), the free phosphodiester begins to accumulate in the system and is converted into the pyrophosphotetraester only to an insignificant extent. In the final reaction mixture most of the phosphodiester is present in the form of the ureido-derivative:



This derivative is only slowly hydrolysed by water to the corresponding phosphodiester and dicyclohexylurea.

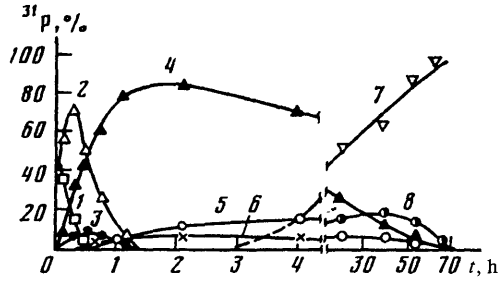


Figure 8. Kinetic curves for the interaction of 0.15 M pT(Ac) with 0.3 M (Tr)T and 1.5 M DCC at 22 °C in pyridine: *1*) the pyrophosphate O[pT(Ac)]$_2$; *2*) trinucleoside triphosphate; *3*) tetranucleoside tetraphosphate; *4*) the pyrophosphotriester (XIV); *5*) (Tr)TpT(Ac); *6*) signal intensity in the region of 5 p.p.m.; *7*) ureido-derivative of dinucleoside phosphate; *8*) the tetrasubstituted pyrophosphate (XVIII).[37]

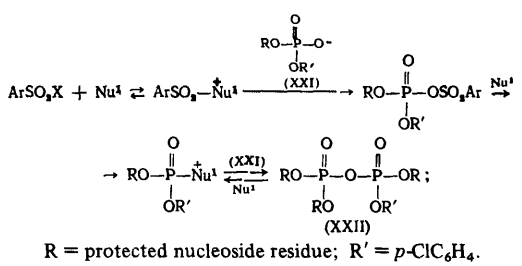
VI. THE MECHANISM OF THE PHOSPHOTRIESTER CONDENSATIONS

Depending on the nature of the condensing agent, the first phase in the phosphotriester condensation is described by Eqn. (11) or (12) and then by Eqns. (15) and (16), i.e., overall, it can be represented by the equation



R = protected nucleoside residue; R′ = *p*-ClC$_6$H$_4$. (26)

This process is analogous to reaction (18) in the phosphodiester condensation. However, in contrast to this reaction, the pyrophosphate (XXII) does not undergo further transformations under the influence of the condensing agent, i.e. processes analogous to reactions (19)–(21) are absent in the phosphotriester condensation.

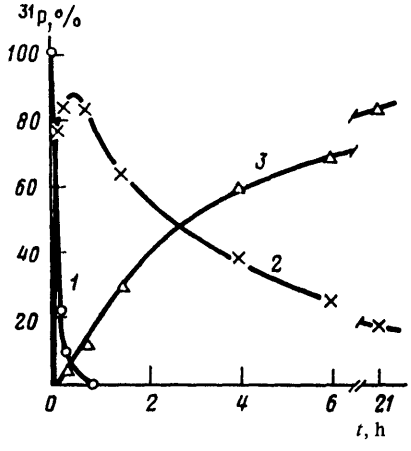


Figure 9. Kinetic curves for the reaction of 0.1 M (Tr)Tp.(C$_6$H$_4$Cl) with 0.1 M T(Ac) and 0.3 M TPS in pyridine at 30 °C: *1*) initial diester; *2*) the tetrasubstituted pyrophosphate (XXII); *3*) the triester (Tr)OTO – P(O)(OC$_6$H$_4$Cl) – OT(Ac).[42]

The inability of the pyrophosphate (XXII) to react with the condensing agent, except for the reaction analogous to reaction (19), necessitates at the same time the presence of another pathway leading to the transformation of the pyrophosphate into an active derivative of type (II) or (III). It is reasonable to suppose that this takes place analogously to the interaction of the pyrophosphotriester with the OH-component via a reaction analogous to reaction (25):

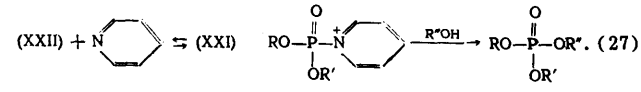

Fig. 9 presents the kinetic curves for the accumulation of the pyrophosphotetraester and the phosphotriester and for the consumption of the initial phosphodiester in the reaction of

(Tr)Tp(C_6H_4Cl) with T(Ac) in pyridine in the presence of a three-fold excess of TPS. The curves were obtained with the aid of ^{31}P NMR.[42] It is seen that, whereas the first phase of the reaction, i.e. the accumulation of the pyrophosphate, is completed in less than 1 h, the second phase takes more than 24 h. Such a prolonged contact of the OH-component with the condensing agent leads to undesirable side processes, for example, the sulphonation of the OH-component. There is no reason to doubt the extremely high electrophilicity of the species (XXIII), which carries an uncompensated positive charge. The low rate of the second phase of the reaction in pyridine is apparently associated with the fact that the species (XXIII), formed as an ion pair with the phosphodiester anion, interacts preferentially with the latter, which greatly displaces the equilibrium in the first reaction of process (27) to the left.

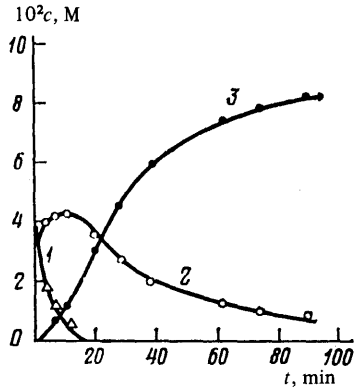

Figure 10. Kinetic curves for the interaction of 0.1 M (ClC_6H_4)pT(Ac) with 0.1 M (NCC_2H_4)$_2$pT, 0.3 M TPS, and 0.3 M tetrazole at 20 °C in pyridine: *1*) (ClC_6H_4)pT(Lev); *2*) the pyrophosphotetraester; *3*) the phosphotriester

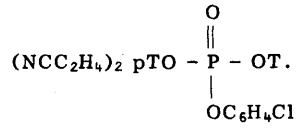

[17]

In conformity with the foregoing, the effective catalysts of the second phase of the phosphotriester condensation proved to be compounds of two types. Firstly, these are compounds of the "pyridine" type, namely DMAP[12,13,17] and *N*-methylimidazole.[17,18] Being significantly stronger nucleophiles than pyridine, these compounds apparently give rise to species of type (II), which are significantly more stable than compounds (XXIII). Secondly, tetrazole[17,41,43] and 3-nitro-1,2,4-triazole[17] proved to be catalysts of this kind. They give rise to uncharged phosphodiester derivatives of type (III). As an illustration, Fig.10 presents kinetic curves for the reaction of (ClC_6H_4)pT(Lev) with (NCC_2H_4)$_2$pT in pyridine in the presence of a threefold excess of an equimolar mixture of TPS and tetrazole.[17] The reaction takes place to an extent greater than 70% in 1 h. As in the eactions of TPS in pyridine the absence of other catalytic additives, more than 90% of the pyrophosphate accumulates in the first phase of the reaction and the latter is then converted into the phosphotriester. In the light of these data, a sharp acceleration of the phosphotriester condensation following the replacement of arenesulphonyl chlorides by arenesulphonyl tetrazolides[4,5] can be accounted for most probably by the fact that tetrazole, catalysing the second phase of the process, is produced in the first phase. Similar kinetic curves, involving the formation of up to 90% of the pyrophosphate in the first phase, have been obtained also for all the other catalysts enumerated.[17]

In order to establish the role of pyridine in the stage involving the formation of the phosphotriester from the pyrophosphate, the latter was obtained in the form of a solution in methylene chloride from (ClC_6H_4)pT(Ac) in the presence of TPS and (Tr)T as the OH-component. In the absence of pyridine, the reaction stops at this point; the addition of pyridine or γ-picoline leads to the formation of the dinucleoside phosphate. On the other hand, the addition of benzo-1,4-diazabicyclo[2.2.2]octene, whose $pK_a = 5.6$ and is close to that of pyridine, does not lead to the synthesis of the phosphotriester, which shows that in the given stage pyridine plays primarily the role of a nucleophilic catalyst.[43,56]

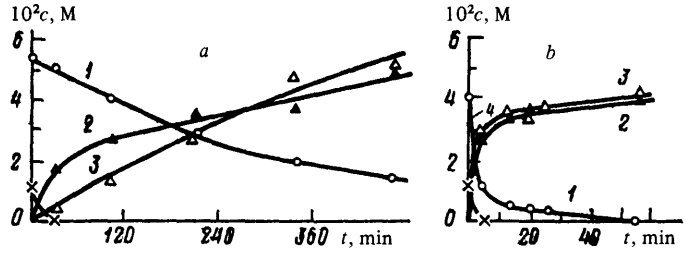

Figure 11. Kinetic curves for the reactions at 30 °C in pyridine; *a*) reaction of 0.05 M tetraphenyl pyrophosphate and 0.01 M diphenyl phosphorochloridate with 0.11 M (Tr)T; *b*) reaction of 0.04 M tetraphenyl pyrophosphate and 0.01 M diphenyl phosphorochloridate with 0.12 M (Tr)T in the presence of 0.25 M tetrazole; *1*) tetraphenyl pyrophosphate; *2*) the phosphotriester (Tr)TOP(O)$(OPh)_2$; *3*) diphenyl phosphoric acid; *4*) diphenyl phosphorochloridate.[41]

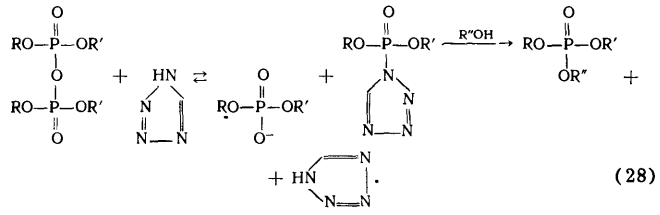
The catalytic role of tetrazole has been demonstrated in relation to the model reaction of tetraphenyl pyrophosphate with (Tr)T.[41] In order to rule out the possible influence of the condensing agent, tetraphenyl pyrophosphate was obtained by the reaction of diphenyl phosphoric acid with diphenyl phosphorochloridate. A small excess of the latter ensured the absence of undesirable traces of moisture from the system. After the addition of (Tr)T, diphenyl phosphorochloridate disappears in the course of several minutes and a gradual conversion of the pyrophosphate into diphenyl phosphate and the phosphotriester (Tr)Tp$(OC_6H_5)_2$ is observed (Fig.11*a*). The addition of tetrazole simultaneously with (Tr)T leads to the acceleration of the process by a large factor (Fig.11*b*); the reaction is completed in less than half an hour instead of several hours. If triethylamine is added simultaneously with tetrazole, the reaction is completed faster than it is possible to record the ^{31}P NMR spectrum, i.e. in less than 1–2 min. The diphenyl phosphotetrazolide signal is not recorded in either case, in agreement with the rapid interaction of this compound with the OH-component noted in

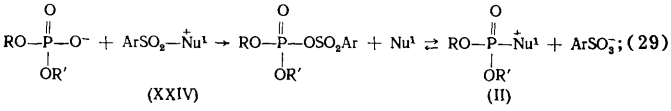
Section (III). Overall, the transformation of the pyrophosphate into the phosphotriester in the presence of tetrazole can be represented by the following scheme:



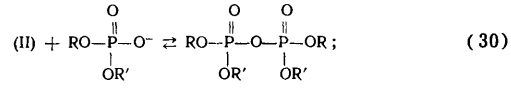
(28)

The equilibrium in the first stage of reaction (28) is greatly displaced to the left, because the addition of tetrazole to a pyrophosphate solution does not result in the appearance of a signal due to the tetrazolide of the phosphodiester in the ^{31}P NMR spectrum. The presence of a strong base should shift the equilibrium to the right (the proton is bound), which may account for the sharp acceleration of the interaction of tetraphenyl pyrophosphate with (Tr)T in the presence of tetrazole following the addition of triethylamine. However, the second stage also contributes to the acceleration of the process and this stage is likewise accelerated by triethylamine, as stated in Section III.

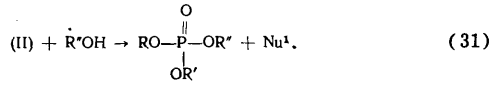
Taking into account the foregoing, including the fact that the $ArSO_2\overset{+}{N}\swarrow$ derivative of the condensing agent and not the condensing agent itself interacts with the initial phosphodiester, the overall mechanism of the phosphotriester condensation in the presence of TPS and pyridine or an analogous catalyst can be formulated as follows:



(29)



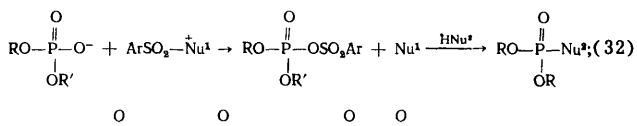
(30)



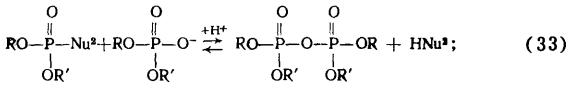
(31)

In the first phase of the reaction, the species (II) react preferentially via pathway (30), which leads to the accumulation of the pyrophosphotetraester. As the initial phosphodiester is consumed, the process is switched to pathway (31) to an increasing extent. Presumably in the second phase of the reaction, where reaction (30) is reversed as a result of the sharp decrease of the concentration of the phosphodiester, the main bulk of the product is formed via reactions (29) and (31).

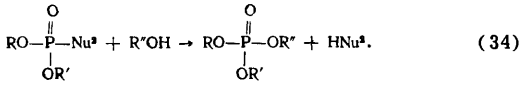
An analogous scheme can also be formulated for catalysis by tetrazole or nitrotriazole:



(32)



(33)



(34)

Since it is sufficient to have catalysts of the "pyridine" type for the occurence of the first phase of the reaction, including the formation of the derivative (XXIV), in phosphotriester condensations pyridine can be fully replaced by *N*-methylimidazole, while acetonitrile, dioxan, and many halogeno-hydrocarbons can be used as solvents.[10,15-18]

In contrast to this, tetrazole cannot convert the arenesulphonyl chloride into an active derivative of type (XXIV). In order that the reaction of the arenesulphonyl chloride with tetrazole, leading to the formation of the arenesulphonyl tetrazolide, should occur, a strong base must be present; in pyridine such interaction does not take place under the conditions of the phosphotriester condensation.[6] At the same time, as stated in Section (II), strongly basic amines prevent the formation of the mixed anhydride (VI) from arenesulphonyl tetrazolides and the phosphodiester. In catalysis of the phosphotriester condensation by tetrazole and nitrotriazole, pyridine, which is essential for the formation of compound (XXIV), must therefore be used as the solvent. Furthermore, pyridine is involved as a base in the reverse reaction (33) and reaction (34).[43]

It is noteworthy that, whereas the pyrophosphotetraester behaves as a typical intermediate in terms of the character of the kinetic curves (Figs.9 and 20), it is strictly speaking not an intermediate. Reactions (30) and (33) are not intermediate processes but constitute reversible side reactions. Their suppression can significantly accelerate the process. The question whether the pyrophosphotriester can be formed when the phosphotriester condensations are carried out on insoluble polymeric carriers, where the P-component is fixed on the carrier while the OH-component is in solution,[19,64-67] remains open.

Functional Microanalysis by Chromato-spectrometric Methods

Ya.L.Kostyukovskii and D.B.Melamed

Chemical reactions involving the most important functional groups and yielding easily detectable compounds are discussed. The possible development of a system of functional microanalysis of organic compounds on the basis of chemical reactions, thin-layer and column liquid chromatography, and spectrometric methods is considered.
The bibliography contains 296 references.

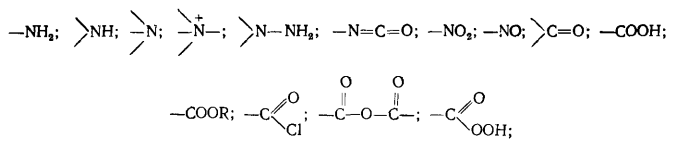
I. INTRODUCTION

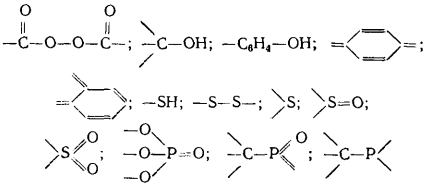
Analytical reactive chromatography includes chemical methods of preparing derivatives of the substances to be analysed, chromatographic separation, and detection of the derivatives. Reactive methods have greatly widened the scope of traditional chromatographic methods, and are now widely used in the analysis of organic compounds in the environment, in industrial and agricultural practice, in medicine, pharmacology, etc. Reactive chromatography is especially valuable for the determination of trace amounts of various substances in complex mixtures. It has also proved very successful as a method of functional analysis.

In recent years there have been two main trends in the development of organic functional analysis: the establishment of micro-methods of determining functional groups[1-3] and the application of these methods in conjunction with chromatographic separation.

Gas-chromatographic methods of functional analysis have been developed and reported most extensively.[4-6] On the other hand existing information on the combination of thin-layer chromatography (TLC) and column liquid chromatography with various methods of detection (in particular, spectrometric) has not yet been systematically reviewed, and the procedures have not been discussed as potential methods of functional analysis. The prospects of these methods are wider than those of gas-chromatographic methods, because they are applicable in principle not only to volatile compounds but also to involatile (and even to relatively unstable) compounds. The combination of chemical reactions (to produce easily detectable derivatives) and of the high resolving power offered by TLC and by column liquid chromatography, including detection by spectrometric methods, should provide an adequate foundation for a system of functional analysis of organic compounds in amounts of a few nanograms.

In this review we shall examine the chemical reactions used to prepare derivatives of the most important functional groups found in organic compounds:





and we shall generalise the most important results of recent work on the determination of the derivatives by a combination of TLC (or column liquid chromatography) and mass spectrometry, u.v. and visible spectrometry, and spectrofluorimetry.

II. FOUNDATIONS OF REACTIVE CHROMATO-SPECTROMETRIC ANALYSIS

Many chemical reactions have been used to convert the substances to be analysed into easily separable and detectable derivatives. Most of these studies have been directed towards reactive column chromatography. Their main outcome has been the identification of the optimum conditions for the synthesis of derivatives of organic compounds of various classes. The chemical reactions used for the functional analysis in conjunction with chromato-spectrometric methods can be applied either before the chromatographic separation (in order to convert the functional groups of the substances to be analysed into more easily separable and detectable derivatives), or after the separation (in order to reveal the functional groups).

The chosen chemical reactions should be selective towards the various functional groups, but in practice this requirement is not always met. Therefore in the analysis of complex samples a more reliable identification is obtained by using more than one reaction.

Two main schemes can be used for the analysis: 1) preparation of the derivatives, followed by chromatographic separation and spectrometric determination, and 2) chromatographic separation followed by chemical reaction and spectrometric determination. Depending on the chosen path, different requirements are specified for the reactions. In the analysis by the first scheme the derivatives are prepared by using reagents which give stable, easily separable, and

easily detectable products in almost quantitative yield.[7-10] Chromatospectrometric methods are often used with derivatives which absorb strongly in the u.v. and visible regions of the spectrum. Mass spectrometry, a powerful method of identification, can be used in principle to determine any derivative, but in practice the method is most successful with substances which form a large number of molecular ions and of characteristic fission ions.[11-15,19-21]

The derivatives are usually prepared outside the chromatographic assembly, but in some cases they have been prepared directly on the plate (for TLC) or in the liquid chromatograph, using fast reactions. Derivatives of multifunctional compounds are prepared by reactions at one or more groups: preferably the latter, since this improves the selectivity of the chromatospectrometric method. The preparation of derivatives from the substances to be analysed before carrying out the separation by liquid chromatography is often very effective, because it assists not only the separation and detection but also the interpretation of the results, thus greatly enhancing the reliability of the analysis.

In the second scheme the substance to be analysed is chromatographed first, and then the components are identified on plates or in eluates after being converted into easily detectable compounds by various chemical reactions. The choice of reactions for making visible the compounds on the TLC plates is relatively simple, but more stringent requirements apply to the reagents used in liquid chromatographs: the reaction must be fast, especially if used in a continuous process, and the excess of reagent should not interfere with the detection.[7,9,10] Many new models of liquid chromatographs are fitted with reactors for the preparation of easily detectable compounds.[7,9,10,16] The separation before the preparation of derivatives should be done under chromatographic conditions compatible with the properties of the functional groups of the substances to be analysed. Thus ion-exchange chromatography or reversed phase chromatography with ion pairing[7,10,17,18] are often used with acidic or basic compounds.

The most reliable method of identifying the separated components or their derivatives is mass spectrometry.[11,19-21] After separation of the mixture by TLC or column liquid chromatography the eluates of the various fractions are concentrated before being injected into the mass spectrometer. The more advanced systems offer a combination of a gas chromatograph, a mass spectrometer, and a computer. Some recently developed systems have even wider analytical capabilities, and include a liquid chromatograph, a mass spectrometer, and a computer.[11,20,22] However, so far these systems have been used only in development work, or to confirm the results of other analytical methods. More often the functional groups of the separated components are identified by u.v. spectrophotometry or spectrofluorimetry, or (in the case of TLC) by visual methods or with the help of a densitometer or other similar device.[7,9,10,18,23] In complex systems detection at two or more wavelengths has been recommended[24,25] as an alternative to recording the full absorption or fluorescence spectrum.

Chromato-spectrometric methods offer a very high sensitivity: the detection limit is 10^{-9}–10^{-12} g for mass spectrometers and fluorimeters (10^{-20} g if a laser is used), 10^{-8}–10^{-9} g for u.v. spectrophotometers, and 10^{-5}–10^{-7} g for visual assessment of the colour.

The quantitative determination of the identified substances is carried out by conventional chromatographic and spectrometric methods.[7,9,11,18,23,24,26,27]

The success of chromato-spectrometric methods of analysis is largely determined by the care taken in sample preparation, which is a difficult and critical stage of the process, especially in the determination of trace amounts of compounds in real samples from the environment, biological materials, food products, etc. This is because of the need to extract the trace impurities from a complex mixture in which the concentration of the wanted components is many times smaller than that of the other components.

A detailed discussion of methods of preparation and preliminary examination of samples for analysis is beyond the scope of the present review. Some relevant data are collected in Refs. 7 and 28–32. We shall only mention some of the more important details which we consider essential to a successful chromato-spectrometric analysis. An important aid to the extraction of substances for analysis is the use of mixed solvents of different polarity, and also of mixtures of counterions, which facilitate the removal of polar organic compounds. Reversed phase, ion-exchange, and gel permeation chromatography methods are also of interest.[7,9,11,28-30] Various forms of micro-distillation (especially under reduced pressure) from media at a suitable pH can also be used in the separation of volatile substances.[7,9,29,30,32] Extreme purification is usually laborious, and can lead to loss of material, for which allowance should be made when choosing a suitable method of analysis. By using chromato-spectrometric methods, involving a preliminary conversion of the compounds into their derivatives, the extract purification procedure can often be greatly simplified.[8-10,27,30] The reproducibility of the process can be improved by simultaneous analyses of experimental and of control samples prepared from the experimental samples by removing the compounds for analysis.[30,33]

A very important precaution is a preliminary study of the effect of acids, alkalis, oxidisers, and temperature on the substances for analysis, and also an elemental analysis and a determination of the spectral characteristics.[3,13,34] Often the compounds are available only in small quantities, insufficient for a detailed preliminary study. However, it is essential to obtain as much information as possible on the nature of the substances for analysis during the preparation and preliminary examination of the sample.

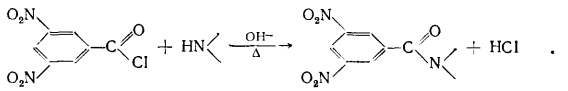
III. METHODS OF IDENTIFYING ORGANIC COMPOUNDS THROUGH FUNCTIONAL GROUPS

The success of the chromato-spectrometric methods of functional analysis depends on the quality of the chromatographic separation. In the determination of low-molecular-weight compounds in complex mixtures better results are obtained by chromatographing the derivatives. For example, in mass spectrometry the analysis of the derivatives is more effective than the analysis of the compounds themselves.[11-13,15,20,21] Many reagents for the various functional groups have been proposed: they all contain a fairly large group of aromatic or heterocyclic fragments which enhance the absorption of the molecule in visible and u.v. light or produce fluorescence. The "screened" functional groups can be identified after suitable chemical treatment (for example, hydrolysis). Compounds which are efficiently separated by TLC and column liquid chromatography methods are often analysed directly.

1. The $-NH_2$ and $>NH$ Groups

Many reagents and reactions for preparing derivatives of primary and secondary amines have been suggested. Acylation reactions are most frequently used, often at high temperatures and in the presence of catalysts (inorganic bases, tertiary amines, crown ethers, etc.). The most commonly used acylating agents are the acid halides of aromatic carboxylic acids and sulphonic acids.

Derivatives which absorb strongly in the u.v. are obtained by using 4-nitro-, 3,5-dinitro, 4-methoxy-, 4-dimethylamino-, 4-dimethylamino-3,5,-dinitrobenzoyl chlorides, and also 4-biphenyl-, 4-(4′-nitrophenylazo)benzene-, 4-(4′-dimethylaminophenylazo)benzenecarbonyl chlorides, etc.[7,8,10,14,35] The reactions follow the general scheme



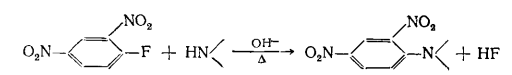
Usually the yield is almost quantitative and the resulting amides are stable, easily extracted by organic solvents, and have an absorption coefficient in the u.v. region of about 14 000.[8,10,14] Mixtures of amides are easily separated by TLC or by column liquid chromatography. Many stationary phases and solvent systems have been used for these separations. Visual detection, and detection by mass spectrometry, can be used as well as u.v. spectrometry.[8,9,14,18,21,23,26,29,35,36] The sensitivity of detection of di- and polynitrobenzamides can be enhanced by treatment with alkali and acetone (Yanovskii reaction), which gives strongly coloured compounds.[38]

Derivatives which absorb strongly in the u.v. are obtained from the acid halides of aromatic sulphonic acids: 4-methyl-, 4-iodo-, 4-dimethylamino-, 4-(phenylazo)-, 4-(4′-*N*,*N*-dimethylaminophenylazo)benzenesulphonyl chloride, etc.[8,10,14,21] The reaction scheme is

Substituted sulphonamides are formed also by the reaction with trinitrobenzenesulphonic acid.[37,39] As a rule the sulphonamides absorb less strongly than the corresponding benzamides in the u.v.[10]

Compounds containing $-NH_2$ and NH groups form derivatives when treated with 1-dialkyl(C_1–C_5)aminonaphthalene-5-sulphonyl chlorides, *N*-methyl-2-anilinonaphthalene-6-sulphonyl chloride (mansyl chloride), 2-*p*-chlorosulphophenyl-3-phenylindone (disyl chloride), 4-(1-oxy-3-phenylinden-2-yl)benzenesulphonyl chloride, and 1,3-naphthoylenebenzimidazole-6-sulphonyl chloride.[7,10,14,27,40] Mixtures of sulphonamides are separated by TLC and column liquid chromatography methods, using a variety of stationary phases and eluents, and are detected by fluorescence, visual colour, u.v. absorption, and mass-spectrometrically.[14,18,26,27,36,41–43] Reactions with 1-dimethylaminonaphthalene-5-sulphonyl chloride (dansyl chloride) are widely used to identify primary and secondary amines, aminoacids (AA), aminophenols, and phenols.[10,14,27,44] We have shown that dansyl chloride can also be used to determine unsaturated amines.[44] The main advantage of dansylamides over other sulphonamides is the ease of separation and identification of the derivatives. Recommended conditions for the determination of dansylamides are given in Refs.12, 14, 18, 21, 27, 42, 43, and 45.

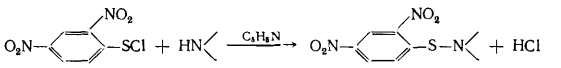
Other compounds including a relatively mobile halogen atom are also used to prepare derivatives, in particular 2,4-dinitrofluorobenzene, 2,4-dinitrochlorobenzene, 2,4-dinitro-5-fluoroaniline, 7-fluoro- and 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD chloride), and others.[8,10,14,15,33,46,47] 2,4-Dinitrofluorobenzene has been most widely used in practice, because it forms derivatives which absorb strongly in the u.v. and are easily separated under a variety of chromatographic conditions:



The analytical results have been confirmed by mass spectrometry.[8,14,26,37,48]

NBD chloride, which forms fluorescent NBD amides also absorbing strongly in the visible and u.v. spectra,[8,14,33,49,50] has been used almost as widely. Various amines and aminoacids give coloured derivatives (yellow, orange, or red) which can be used as an additional identifying criterion.[33,49,50] NBD–amine mixtures are easily separated by TLC and column liquid chromatography, and identified by fluorescence, colour, light absorption in the u.v., and mass spectrometry.[15,26,33,51–55] We have shown that NBD chloride is superior to dansyl chloride in a number of characteristics, including selectivity of the determination and stability of the derivatives.[27,55]

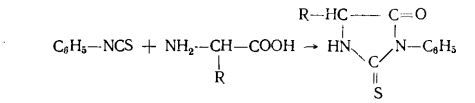
Another compound with a mobile halogen atom is 2,4-dinitrobenzoylsulphenyl chloride, which forms derivatives which absorb in the u.v.:



These derivatives are separated by TLC, for example on silica gel or Siluphol in the benzene–cyclohexane–chloroform–ethanol system.[35,36]

Other reagents have been suggested for preparing derivatives from $-NH_2$ and $>$NH groups, but they are used far less often.[8,57,58] They include 9-fluorenylmethylchloroformate, which gives fluorescent compounds, and *N*-(chloromethyl)phthalimide and *N*-(chloromethyl)isatin, which give products with a strong u.v. absorption.

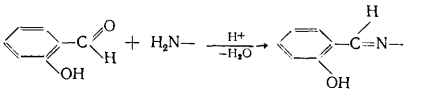
The large group of substituted iso- and isothiocyanates forms derivatives with amines. They include phenyl- and 4-(6-methylbenzothiazol-2-yl)phenyl isothiocyanates, phenyl-, naphthyl-, and 4-phenylazobenzoyl thiocyanates, etc.[7,8,18,21,34,35] These are most commonly used to identify aminoacids by forming thiohydantoins:



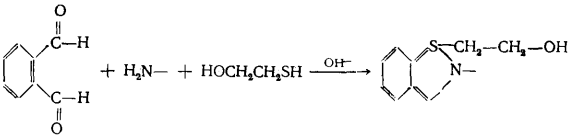
These compounds are readily separated by TLC and column liquid chromatography methods, and determined by u.v. absorption. Analytical results have been confirmed mass spectrometrically.[10,26,59–61]

Amino groups can also be identified by the formation of fluorescent compounds with fluorescein-, 9-acridyl-, and 4-dimethylamino-1-naphthalyl isothiocyanates or with 4-(6-methylbenzothiazole-2-yl)phenyl isocyanate or 2-(4-isothiocyanatophenyl)-3-phenylindone.[7,10,14,27,62]

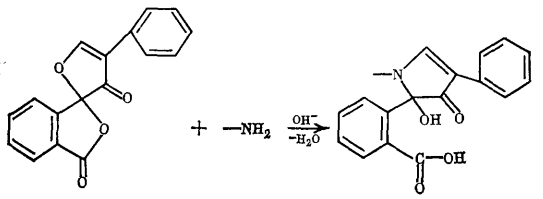
Amines (especially the primary) react vigorously with reagents containing a carbonyl group, for example with 4-dimethylamino- and 2,4-dinitrobenzaldehydes, or with salicylaldehyde:[8,35,38]



The resulting azomethynes react with diphenylboric anhydride to give complexes easily separated by TLC.[10,63] *o*-Phthalic aldehyde (*o*-PA) has been used frequently: in the presence of some thio-compounds (for example, monothioglycol) it forms fluorescent cyclic compounds which can be separated chromatographically:[10,27,51,64–67]



The identification of primary amino groups and AA with 4-phenyl-*spiro* (furan-2,3H-1-phthalan)-3,3'-dione (fluram)[10,14,27,35,68,69] is also of interest:



The resulting, strongly fluorescent compounds are easily separated by TLC or column liquid chromatography.[10,14,27,35,68,69]

Fluram and *o*-PA can be used as reagents for the derivatisation of secondary amines after conversion into primary amines, for example by treatment with NaOCl and 2,2'-thiodiglycol.†

Chromato-spectrometric methods of functional analysis can be applied to compounds in which $-NH_2$ or $>NH$ groups can be produced by appropriate chemical reactions. They include pesticides, therapeutic products, and toxic and carcinogenic compounds.[7,9,10,18,27,30,54] For example, methods of converting carcinogenic nitrosamines into the corresponding secondary amines and identifying the latter as dansyl amides or NBD amides have been developed.[33,42,49,55] These derivatives have been used in the detection of nitrosamines in the environment by combined chromatographic and mass spectrometric analysis.[15,45,55,70]

Chromatographic separation before derivatisation is preferred in the functional analysis of AA and aromatic or heterocyclic amines. TLC of aminoacids is usually carried out on silica gel, aluminium oxide, cellulose, polyamides, or ion-exchange resins (for example, Fixion or Dowex) in various systems containing phenols, organic acids, and ammonia.[23,26,50,71-76] Some aliphatic amines and AA are well separated by high-performance TLC methods on chemically bonded phases of the RP-18 type.[73,77,78]

Aromatic amines are separated on a thin layer of silica gel, alumina, polyamide, cellulose, and also on ion-exchange resins and on silica gel impregnated with phenols, oxalates, acetates, sulphates, chlorides, and surface-active substances, using different solvent systems.[23,26,71-74,79,80] A study of the dependence of the chromatographic mobility of amines on their structure has been reported.[26,79]

Various reagents have been suggested for the visualisation of compounds containing $-NH_2$ and $>NH$ groups, both universal (iodine, $KMnO_4$, $K_2Cr_2O_7$, phosphomolybdic and phosphotungstic acids, H_2SO_4, $SbCl_3$, $SbCl_5$, pH indicators, etc.) and relatively specific in action. The latter include solutions of ninhydrin, fluram, *o*-PA, NBD chloride, $Ca(OCl)_2$ in conjunction with KI, a mixture of acetylacetone and formaldehyde, etc.[14,26,27,53,73-75,78]

Aromatic amines can also be determined by the following reactions: coupling with diazotised sulphanilic acid, 4-nitroaniline, etc., diazotisation and coupling with phenols (say), or treatment with 4-dimethylaminobenzoic and cinnamaldehyde. U.v. spectrophotometry is used for detection.[18,26,38,71,78,81] Some aromatic and heterocyclic amines show spontaneous fluorescence.[53,82]

Ion-exchange liquid chromatography has been used most commonly in the separation of AA, but also (on a few occasions) for aliphatic amines. The great importance of AA in biology has stimulated the development of automatic and semi-automatic AA analysers, which can be used also to determine some other amino compounds (mono-, di-, and polyamines#). The most commonly used stationary phases include Amberlites, Apinexes, Biorex, Sephadexes, Partisil SCX, etc.; various buffer systems are used as eluents. The eluates are treated with ninhydrin, *o*-PA, fluram, NBD chloride, or other developers, and their colour is noted visually or measured spectrophotometrically or spectrofluorimetrically.[9,10,27,83-85] The high-performance liquid chromatography method (usually in the reversed-phase mode) is now often used in the analysis of AA and aliphatic amines on Lichrosorb RP-18, Permaphase ODS, Sorbax C_8 or ODS, μ-Bondapak C_{18}, and other stationary phases with aqueous-alcoholic mixtures often containing counter-ions: the addition of counter-ions has been shown to improve the separation of AA.[10,17,18,76,85-90] The separated compounds are usually derivatised with ninhydrin or *o*-PA, and the resulting derivatives are determined using u.v. or fluorescence detectors.§

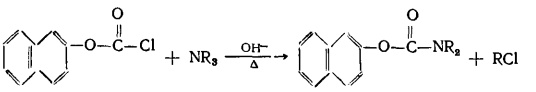
Extensive studies of the separation of aromatic amines by high-performance liquid chromatography have been reported. Various stationary phases and eluents have been proposed, and u.v. detectors have been used to identify the amines.[7,10,81,91-94] Mass spectrometric methods have also been used for detecting aromatic amines after their separation.[13,20,95,96]

Amides are usually analysed after being converted into the corresponding amines. In principle the formation of hydroxamic acids could be used to detect the amides after separation.[23,38]

The very large number of chemical reactions proposed for the derivatisation of primary and secondary amines allows an easy choice of the best variant for the separation of particular systems. It is often convenient to prepare fluorescent derivatives and separate them by TLC: a simple method, which offers a high sensitivity in the identification of these functional groups.

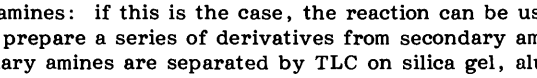
2. The N and $>\overset{+}{N}$ GROUPS

The chromato-spectrometric analysis of these groups has not yet been adequately developed. Some tertiary amines have been determined through their derivatives formed by the reaction with pentafluorobenzyl- or 2-naphthylchloroformate:[10,97]



A likely intermediate step in this reaction is the dealkylation of the amines: if this is the case, the reaction can be used also to prepare a series of derivatives from secondary amines.

Tertiary amines are separated by TLC on silica gel, aluminium oxide, or other sorbents. The solvent systems usually contain ammonia and dichloroethane. The separated compounds are made visible by the Dragendorf reagent, K_2PtCl_6, chloranil, tetranitromethane, tetracyanoquinonedimethane, tetracyanoethylene, etc.[2,3,14,26,98,99] With tetracyanoethylene the reaction is



†see A.Himuro, Analyt.Chim.Acta, 1983, 147, 317.

#see N.Sauem and E.Ronald, J.Chromatogr., 1983, 256, 313.

§see R.Cunico and T.Schlabach, J.Chromatogr., 1983, 266, 461; R.Simpson, J.Chromatogr., 1983, 261, 407.

The separation of tertiary amines by high-performance liquid chromatography relies on the use of mobile phases containing counter-ions, for example 9,10-dimethoxyanthracene-2-sulphonate or acridone-2-sulphonate.[9,10,18,100,101]

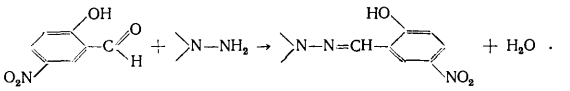
Compounds containing the $\geqslant\overset{+}{N}-$ group are separated by TLC on silica gel, aluminium oxide, or cellulose, with mobile phases usually containing hydrochloric, acetic, citric, or other acids. Visualisation is carried out by treating the plate with Dragendorf's reagent or with K_2PtCl_6.[3,23,102-104]

Quaternary ammonium compounds are chromatographed on ion-exchange resins, for example Partisil SCX, Amberlite CG-50, or Zeokart 226, with eluents containing counter-ions of the naphthalene- or anthracene-2-sulphonate type.[9,85,105-107]

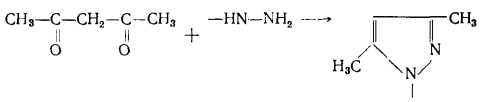
Efficient separation of these substances, including long-chain compounds, is achieved by the high-performance liquid chromatography method on Nucleosil-5 $N(CH_3)_2$, using the hexane–chloroform–ethyl acetate system as the solvent, or on Nucleosil CN with an aqueous solution of methanol containing *p*-toluenesulphonic acid.¶

3. The $\geqslant N-NH_2$ Group

Compounds containing this group (alkyl- and arylhydrazines, acid hydrazides, etc.) can be analysed chromatospectrometrically by preparing relatively stable and easily separable compounds. Thus, hydrazines react with 5-nitro-2-hydroxybenzaldehyde to give[8,10,21,38]



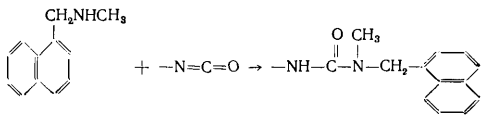
Alkylhydrazines react with acetylacetone to give pyrazolone derivatives:[8,10,21]



The fast reaction of the $\geqslant N-NH_2$ group with carbonyl compounds can be used to identify this group by using aldehydes and ketones. The hydrazines are usually separated (before derivatisation) by high-performance liquid chromatography on phases of the μ-Bondapak C_{18} or Aminex type, with various eluents.[18,108,109]

4. The −N=C=O Group

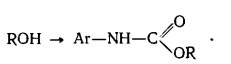
As was said above, isocyanates are used to form derivatives with amines: the same reaction can be used to identify the isocyanates. 9-(*N*-methylaminomethyl)anthracene or *N*-methyl-1-naphthalenemethylamine are most often used:[110,111]



Other reagents for isocyanates include *N*-4-nitrobenzyl-*N*-alkylamines, aminophenols, 1-(2-pyridyl)- and 1-(2-methoxyphenyl)piperazines, which form derivatives with a strong u.v. absorption.[112-116]

¶ see M.Kudon, J.Chromatogr., 1983, **261**, 293.

Aromatic isocyanates react with alcohols by the scheme



The derivatives are easily separated chromatographically, and identified by u.v. spectrometry.[110,112-116]

The −N=C=O group can be detected after separation (for example, by high-performance liquid chromatography on μ-Bondapak C_{18} or Lichrosorb RP-18, using mobile phases of aqueous acetonitrile or methanol): detection in this case is by u.v. or i.r. spectroscopy.[2,10,21]

Isocyanates (and also isothiocyanates) can also be identified chromato-spectrometrically after hydrolysis to the corresponding amines.

5. The $-NO_2$ and −NO Groups

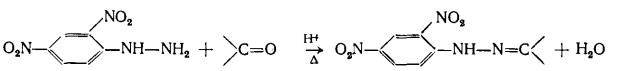
Chromato-spectrometric methods relying on a preliminary separation by TLC or high-performance TLC on RP-2 or RP-18 silica gel, acetylcellulose, etc. have been applied to the analysis of nitrocompounds. The solvent systems usually include methanol, ethanol, and acetonitrile.[26,117,120] The presence of the NO_2 group causes a fairly strong u.v. absorption, which can be used for detecting the nitro compounds on chromatographic plates or in eluates.

Aromatic di- and polynitro compounds can be made visible by the Yanovskii reaction, or by treating them with *N*,*N*-diethylaniline or Na_2SO_4.[117-119] Nitro compounds are separated, for example, by reversed phase liquid chromatography on Lichrosorb RP-18 or RP-8, using aqueous solutions of alcohol or of acetonitrile as the mobile phase. U.v. detectors are used for their identification.[91,120,121] Analytical results have been confirmed mass-spectrometrically.[122,123]

A few studies of the identification of the NO group by chromato-spectrometric methods have been reported. Various *N*-nitrosamines have been determined (after denitrosation) through the resulting nitrite ion and amino group.[33,42,55] Nitroso compounds can be converted into nitro compounds or into hydrazines by oxidising or reducing treatment respectively.

6. The $\geqslant C=O$ Group

Most of the work on the preparation of derivatives of carbonyl compounds has been on the reaction with hydrazines (in particular, phenylhydrazine and its derivatives):[8-10,21,35,124]



Similar reactions are obtained with azobenzene-4-carboxyhydrazine and with the Girard reagent:[10,35]

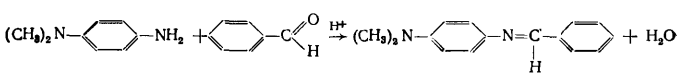
By using dansyl-, mansyl-, and NBD-hydrazines, 2-phenylacetyl-1,3-indandione-1-hydrazine, isonicotinylhydrazine, or other compounds, strongly fluorescent hydrazones have been obtained.[7,10,21,54,125,126] Silica gel, aluminium oxide, and cellulose can be used as sorbents for the TLC of hydrazones.[3,26,127,128] These compounds are detected by their colour, by fluorescence, or by u.v. absorption.[26,124,126-128] Hydrazones have also been separated by high-performance liquid chromatography and identified by u.v. or fluorescence detection.[10,

[126, 129–133] Good results were obtained, for example, by using Sorbax ODS and a mixture of acetonitrile and water.†

Derivatives of carbonyl compounds which absorb in the u.v. are obtained by condensation with substituted hydroxylamines and semicarbazides, for example with 4-nitrobenzyloxyamine:[10, 13, 21]

The conditions for the chromatographic separation of oximes and semicarbazones have been discussed.[9, 21, 26, 35, 134, 135] The mass spectra of many hydrazones and oximes give a convenient identification of these compounds.[10, 21, 126, 134, 136]

Aldehydes react easily with primary amines, for example with *N*,*N*-dimethyl amino-1,4-, 1,3-, and 1,2-phenylenediamine, ethylenediamine, aminopiperidine, etc.[8, 35, 124, 137] These reagents are useful in practice for the functional analysis of aldehydes because the resulting Schiff's bases are strongly coloured and absorb in the u.v. region of the spectrum. Aromatic aldehydes react as follows:



α-Dicarbonyl compounds and α-keto-acids form fluorescent quinoxazolones with 1,2-phenylenediamine.[8, 136–140] Both the Schiff's bases and the quinoxazolones are easily separated by chromatographic methods.[35, 137–140] Aldehydes (unlike ketones) react with 5,5-dimethylhydroresorcinol (dimedon) to give coloured compounds which can be separated by TLC.[13, 35, 141, 142] The α-oxomethylene group is identified by the formation of fluorescent compounds by the reaction with *N*-methylnicotinamide chloride. The products are separated by thin-layer or column chromatography.[9, 10, 143] Aliphatic aldehydes form fluorescent lutidines by reacting with acetylacetone and primary amines.[26, 27, 53, 144]

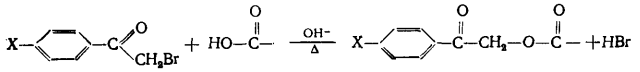
Substances containing a carbonyl group can be separated before derivatisation by TLC on silica gel, alumina, or cellulose, usually with a system of solvents of widely different polarities. Visualisation by universal or by relatively specific reagents is possible (for example, *o*-aminobiphenyl or other aromatic amines).[26, 32, 135, 145]

Good results have been obtained in the separation of carbonyl compounds by normal or reversed phase liquid chromatography on various stationary phases. Detection was by u.v. absorption or, after treating the eluent with *o*-phenylphenol, *N*-methylnicotinamide chloride, etc., by a fluorescence detector.[9, 131, 135, 143, 146, 147] The results have been confirmed mass spectrometrically.[11, 13, 136, 148]

Substances containing the >C=O group are often determined by derivatisation followed by detection in the u.v. or visually (by colour). Fluorescent derivatives are very seldom used in spite of the much higher sensitivity which they offer. This may be due to the difficulty of preparing the necessary reagents.

7. The –COOH and –COOR Groups

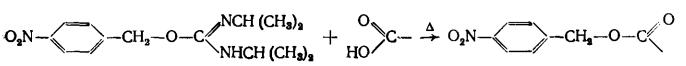
Derivatives of carboxylic acids are often prepared from phenacyl halides, for example 4-bromo-, 4-methoxy-, 4-nitro-, or 4-phenylazo-*N*,*N*-dimethylaminobenzeneazophenacyl bromides:



†see S.Slavin, J.Liq.Chromatogr., 1983, **6**, 425.

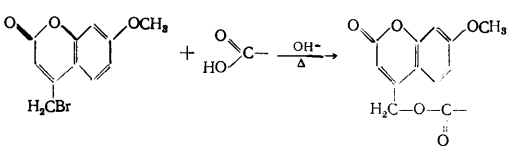
Phenacyl esters absorb strongly in the u.v. (absorption coefficient ~18 000),[7–9, 10, 35, 135, 149, 150] and naphthacyl esters, formed from compounds with a carboxylate group by the action of 2-naphthacyl bromide or 1-bromoacetylpyrene, are fluorescent.[10, 151, 152] TLC of these derivatives is carried out on silica gel (Lichrosorb RP-18) in various solvent systems (benzene–ethyl acetate, dimethylformamide–water, etc.).[26, 135, 150, 153] Separation is by liquid chromatography, for example in the reversed phase mode on μ-Bondapak C_{18}, μ-Porasil C_{18}, Lichrosorb RP-18, or Radialpak AC_{18} by the gradient elution method. The compounds are detected by mass spectrometry or by using fluorescence or u.v. detectors.[151, 152, 154–160]

An interesting method of identification of carboxylic acid groups by u.v. spectrophotometry relies on converting the acids (including long-chain acids) into benzyl or nitrobenzyl esters. The reaction is carried out by using the appropriate bromides, or 4-nitrobenzyl-3-*p*-tolyltriazine, or *p*-nitrobenzyl-*N*,*N*'-diisopropylisourea:[7, 8, 10, 135, 149]



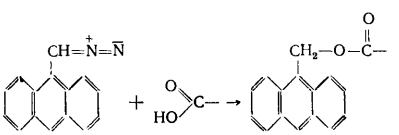
These esters are stable and easily separated by TLC or column chromatography on a variety of phases.[9, 18, 26, 135, 149]

Fluorescent esters, which are of interest for the identification of the carboxyl group, can be prepared by the reaction with chloromethylisatin or chloromethylanthracene, *N*-(chloromethyl)- or *N*-(chloromethyl-4-nitro)phthalimides, 4-bromomethyl-7,8-benzocoumarin, and 4-bromethyl-7-acetoxy- or 4-bromomethyl-7-methoxy coumarins.[8, 54, 58, 138, 161–166]



The conditions for separating these esters by various methods have been reported,[54, 162–168] including liquid chromatography on Partisil C_{18} or Nucleosil $10C_{18}$ with elution gradients in an aqueous methanol solution.

Fluorescent derivatives of acids are obtained also by the action of diphenyl-, 1-naphthyl-, 1-(4-biphenyl)-, or 9-anthryldiazomethanes:



The resulting compounds are separated by liquid chromatography (for example, in the reversed phase), using fluorescence or u.v. detection methods.[7, 169–172]

9-(Hydroxymethyl)anthracene, which forms fluorescent esters easily separable by chromatography, has been suggested[173] as a reagent for the carboxyl group.

The ability of carboxylic acids to react with amines (in particular, 1-naphthylamine, *p*-aminophenol, and 9,10-diaminophenanthrene) to give amides has also been used in practice.[174, 175] Separation was by liquid chromatography on μ-Bondapak C_{18} or Nucleosil C_{18}, with an aqueous solution of methanol as the eluent and fluorescence or u.v. detection. Compounds containing the –COOH and –COOR groups form

hydroxamic acids with hydroxylamine, which are easily separated and identified by their colorimetric reactions with tervalent iron.[1,2,26,38]

Derivatives obtained from polyfunctional compounds containing a carboxylic group have been discussed in many papers. Thus α-ketoacids react with 2,4-dinitrophenylhydrazine,[7-9,26,153,176] o-phenylenediamine,[8,10,138-140,177] and *N*-methylnicotinamide chloride.[9,10,143] Some hydroxyacids produce fluorescent compounds with resorcinol and 2-naphthol.[27,53,138]

Many publications discuss the chromatographic separation of substances containing −COOH and −COOR groups before derivatisation. Low-molecular-weight acids are separated by TLC on silica gel, alumina, polyamide, cellulose, starch, and other sorbents by using a system of solvents usually including alcohols, ethers, and bases (ammonia, diethylamine, etc.).[26,80,153,178-182] Long-chain acids are usually separated on silica gel impregnated with undecane or dodecane by using a system of solvents containing acetonitrile, dimethylformamide, and formic or acetic acid.[26,80,153] The thin-layer separation of esters of saturated carboxylic acids is carried out similarly.[26,153,180,183,184] Saturated acids are easily separated from unsaturated acids by TLC on silica gel impregnated with Ag^+.[18,26,182]

Silica gel or aluminium oxide with various solvent systems, often including methanol, formic and acetic acid, ammonia, etc. are used for the separation of aromatic acids.[26,80,185] The *p*-, *m*, and o-substituted aromatic acids are separated by TLC by using polyamide with aqueous solutions of α-cyclodextrins.[186]

Di- and polyacids are often separated on unmodified silica gel, but better results are obtained on silica gel or kieselguhr impregnated with poly(ethylene glycols), using solvent systems which include alcohols, tetrahydrofuran, formic or acetic acid, and ammonia.[3,26,153,188]

Many reagents have been proposed for determining the acids separated by TLC, but the universal reagents (iodine, pH indicators, phosphomolybdic acid, etc.) are still the most widely used.[26,153,178,180,184,185] Di- and polyacids form coloured complexes with Cu^{2+} salts, and fluorescent derivatives with dicyclohexylcarbodiimide.[187,188]

These acids are separated by reversed-phase (column) liquid chromatography, using counter-ions.[7,17,146,157,182,189-194] Other forms of chromatography have also been used (in particular, ion-exchange chromatography), and various analytical procedures have been recommended.[16,31,182,195-203]

The esters of saturated acids are usually separated by reversed-phase liquid chromatography, for example on Lichrosorb RP-18 or Bondapak C_{18}, using aqueous solutions of methanol or acetonitrile as the mobile phase.[9,18,182,194,204]

Unsaturated acids are chromatographed on Corasil P, Porasil A, Partisil 10 or 20, Spherisorb 5W, and other sorbents, containing 2–5% Ag^+. Silver nitrate is added also to the mobile phase by using aqueous organic solvents.[9,18,205-207]

The best conditions for the column liquid chromatography of polycarboxylic acids have been identified.[18,91,157,182,197,203] The visualisation of the acids after separation is usually straightforward: it relies on the absorption of the acids in the i.r. and near-u.v. regions of the spectrum, the absorption at the shorter wavelengths being the more effective for aromatic acids.[18,91,189,190,199,202,205,206,208] Some acids have been determined by treating the eluates with o-nitrophenol, Ce^{4+} salts, etc.[7-10,18,182] Complex samples have been successfully analysed by chromato-mass spectrometry, using column liquid chromatography for the separation stage.[11,13,136,148,209,210]

Thus both schemes of chromato-spectrometric analysis can be used to determine substances containing −COOH groups, depending on the properties of the sample.

8. The 
Groups

Anhydrides and acid chlorides are determined by the methods used for acids after converting them into the corresponding derivatives or into the acids. Some of these compounds form phenylmethane dyes when treated with *p*-dimethylaminobenzaldehyde and *N*,*N*-dimethylaniline on silica gel.[211]

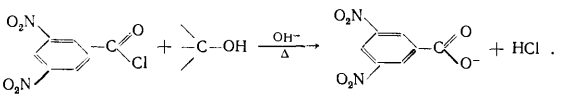
Hydroperoxides and peroxides can be identified after reduction to the acids. Chromato-spectrometric methods of analysis of these compounds have been proposed, even without derivatisation, by using normal or reversed-phase TLC in conjunction with detection by u.v. absorption.[18,26,212-215]

For example, the hydroperoxides of the linoleic acid isomers are well separated on Spherisorb Si 60 with the ethanol–hexane system.# The sensitivity of the analysis can be increased by adding sodium iodide or aromatic mono- and diamines to the eluent.[9,215,216]

The column liquid chromatography method has been applied[18] to hydroperoxides after converting them into ethers.

9. The $\geq$C–OH Group

The most extensive studies have been carried out on the reactions of alcohols with 4-methoxy-, 4-methylthio-, and 3,5-dinitrobenzoyl chlorides, by the scheme[2,7-10,32,35,135,217]

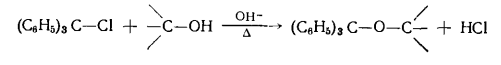


The resulting esters are more stable than the corresponding amides.

Coloured and strongly u.v.-absorbing esters (absorption coefficient ~14 000), suitable for the identification of the alcohols, are obtained by treating the sample with 4-(4′-nitrophenylazo)benzene- and 4-(4′-dimethylamino phenylazo)-benzenecarbonyl chlorides; separation is by TLC, usually on silica gel, and also on starch, cellulose, or talc, with various solvent systems.[26,32,218] Reversed-phase liquid chromatography on μ-Bondapak C_{18}, Lichrosorb RP-18, etc. has also been applied successfully to the separation of esters: elution was with aqueous solutions of alcohols, and detection by mass spectrometry or u.v. spectrophotometry.[7-10,135,219]

Sulphonyl chlorides (except 4-iodobenzenesulphonyl chloride and disyl chloride) are not often used to prepare alcohol derivatives. Disyl chloride forms strongly fluorescent esters.[9,21,40,220,221]

Alcohols also react with other compounds containing a relatively mobile halogen atom, for example with 2,4-dinitrofluorobenzene, 2,4-dinitrobenzenesulphene chloride, and triphenylchloromethane (trityl chloride).[2,35,135,222] In the latter case the reaction is

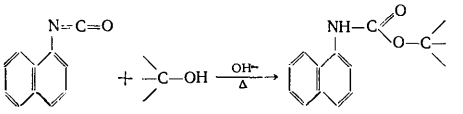


#see J.Koskas, J.Chromatogr., 1983, **258**, 2880.

We note that ethers of this type, unlike the corresponding amine derivatives, are insoluble in acids.[10]

Fluorescent derivatives, suitable for identification, are formed by primary alcohols with 1-ethoxy-4-(dichloro-5-triazinyl)naphthalene, which also contains mobile halogen.[7,10]

Stable esters which absorb u.v. radiation or fluoresce according to the choice of reagent have been obtained by the reaction of alcohols with isocyanates. The preparation of these derivatives with phenyl-, *o*-nitrophenyl-, *p*-toluenesulpho-, 1-naphthylanthranyl-, and 4-(6-methylbenzothiazol-2-yl)phenylisocyanates has been reported:[2,13,35,62,223]



These esters can be separated by TLC on silica gel, MNSilG, Lichrosorb RP-18, and other sorbents, with different solvent systems.[26,62,223,224] Satisfactory separation is obtained by reversed-phase column liquid chromatography on Lichrosorb RP-18 and silica gel C_{18} with gradient elution by mixtures of acetonitrile and methanol with water; determination is by fluorescence or u.v. detection.[9,35,62,223] The separation of these esters by normal-phase chromatography has also been reported.[9,18,225] An interesting analytical scheme[3,226] relies on the reaction of C_1–C_6 alcohols with hydrogen sulphide and potassium hydroxide to give alkyl xanthates, which can be separated in a thin layer of microcellulose with a butanol–water–ammonia eluent and identified by u.v. spectrophotometry.

Compounds containing the –CH(OH)–CH(OH)– group are identified by the formation of coloured cyclic derivatives with aldehydes and fluorescent derivatives with naphthalene- and phenanthreneboric acids.[177,227]

Many aliphatic alcohols are separated chromatographically by TLC before derivatisation. The sorbents for the separation of the lower alcohols are silica gel, aluminium oxide, or cellulose, and for the higher alcohols silica gel or kieselguhr impregnated with paraffin oil. In the latter case aqueous-organic solvent systems are used.

Glycols and polyhydric alcohols are chromatographed on silica gel impregnated with ammonium borate or on magnesium silicate, aluminium oxide, etc.[3,26,153,178,228] Visualisation of these alcohols after separation by TLC or column liquid chromatography is usually by universal reagents.[3,26,135,178,228] Selective reagents have also been used, including sodium metavanadate and 8-hydroxyquinoline, which form coloured derivatives.[2,26,135]

Substances containing the $\geq$C–OH group have been separated by reversed-phase column liquid chromatography on Partisil-5 ODS, Sorbax ODS, etc., with aqueous-organic eluents, and identified by using u.v. detectors.[16,18,138,147,229,230] Equally good results were obtained by normal-phase, ion-exchange, and other forms of chromatography.[231,232] Sephadex LH-20 has been used to separate short-chain from long-chain alcohols.[219,231]

Polyhydric alcohols have been separated on Partisil A, Aminex A27, and other sorbents with various eluents, and identified by u.v. absorption or visually (by colour) after reaction with acidified $K_2Cr_2O_7$ solutions.[3,9,18,31] The determination of alcohols in eluates by a luminescence method with hydrogen peroxide and cobalt luminal has been reported.[233] In complex systems the presence of alcohols has been confirmed by mass spectrometry.[11,13,148]

Thus in the analysis of alcohols it is usually preferable to develop a colour or a derivative which absorbs in the u.v. before carrying out the chromatographic separation.

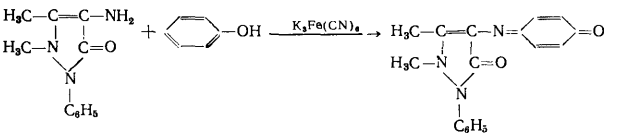
10. The $-C_6H_4-OH$ Groups

One of the most widely used methods of preparing derivatives of phenols and of alcohols is the reaction with substituted benzoyl chlorides, especially 4-nitro- and 3,5-dinitrobenzoyl chlorides.[2,9,10,18,32,35] Derivatives obtained by the reaction with the acid chlorides of sulphonic acids are also used to identify the phenyl groups. Thus 4-iodo- and 4-azobenzenesulphonyl chlorides give products which absorb in the u.v., while fluorescent products are obtained with dansyl and disyl chlorides.[7,9,27,35] Dansyl chloride is used most often, giving dansyl esters under conditions similar to those used in the preparation of dansylamides but at a higher pH. Polysubstituted derivatives are obtained from polyphenols and from aminophenols.[7,21,27,54,234] The products are separated either immediately after the reaction or after extraction and concentration by TLC or by high-performance TLC or column liquid chromatography, and are determined by u.v. absorption, fluorescence, or mass spectrometrically.[7,10,20,54,234] Chromato-spectrometric methods based on dansyl chloride are now widely applied in the analysis of various contaminants, therapeutic products, pesticides, and other compounds containing phenolic hydroxide or reacting to give phenols.[10,18,27,54,68]

Fluorescent or u.v.-absorbing derivatives recommended for determining phenols include the compounds with 2,4-dinitrofluoro- (or chloro-) benzene, *p*-(5-fluoro-2,4-dinitrophenylazo)-*N*,*N*-dimethylaniline, 1-ethoxy-4-(dichloro-5-triazinyl)-naphthalene, and others.[7–9,35,235] More specific derivatives, with u.v. absorption and colour, are formed by the reaction with diazonium salts:[2,3,38,236,237]

Diazonium salts prepared from 4-nitrobenzoic or sulphanilic acid or from 4-aminobenzonitrile are most often used in this reaction. The azophenols are efficiently separated by TLC on silica gel or by reversed- or normal-phase column chromatography (for example, on Lichrosorb RP-18 with an aqueous solution of methanol): detection is visual, by colour.[7,32,236–238]

Coloured quinoneimines are formed by the reaction of phenols with 4-aminoantipyrine:[2,3,32,38]



The separation of the quinoneimines is straightforward: either by TLC on silica gel or by reversed-phase of normal-phase column chromatography with photometric detection.[26,32,233,239] For example, complex mixtures of phenols can be separated as quinoneimines on μ-Bondapak C_{18} and on μ-Bondapak CN with an aqueous solution of methanol or a mixture of hexane and tetrahydrofuran as the mobile phase§.

The most interesting of the substances less frequently used for the determination of phenols is 1-nitroso-2-naphthol, which reacts with some substituted phenols to form fluorescent compounds easily separated chromatographically.[3,27,53]

The separation of phenol derivatives prepared directly on a chromatographic plate by treatment with a solution of Fast Blue BB has been reported.[240]

§see G.Blo, J.Chromatogr., 1983, 257, 69.

Many papers describe separations of phenols before derivatisation. The TLC of these materials is carried out on silica gel, RP-18 silica gel, or silica gel impregnated with polyamines or with vaseline, surface-active substances, or $AgNO_3$, and also on polyamide, cellulose, volcanic tuff, Dowex 50W, etc. Mixtures of organic solvents, buffer systems, and solutions of α-cyclodextrin are used as the mobile phase.[26,72,241-246]

Polybasic phenols are separated on silica gel or aluminium oxide with eluents which usually include chloroform and methanol.[26,247-249] After separation the phenols are made visible by treatment with universal reagents.[26,54,135,244,247] Coloured or fluorescent compounds are formed by treating the phenols with solutions of Ce^{4+}, Fe^{3+}, or Th^{4+} salts.[3,38,135,241] Diazonium and antipyrine salts (with $K_3Fe(CN)_6$) are more specific for phenols.[2,3,7,26,246] Polybasic phenols can be detected by their reaction with monochloroamines.[2,3,38,248,249]

Phenols are more commonly separated before derivatisation by reversed-phase column liquid chromatography on chemically bonded stationary phases: μ-Bondapak C_{18}, Ultraspher C_{18}, Sorbax ODS, etc., with aqueous solutions of acetonitrile or methanol (often containing buffer systems, acetic acid, or counter-ions) as the eluent.[250-258] The phenols can also be separated by normal-phase chromatography on μ-Bondapak NH_2 or CN, μ-Porasil, Lichrosorb Si 60, Zipax CN, Sorbax Sil, and Sephasorb HP; the mobile phase is a mixture of organic solvents, including hexane, heptane, chloroform, isopropanol, etc.[18,23,252,257,258] The chromatographic separation is improved by impregnating the stationary phase with solutions of Fe(III) or of 8-hydroxyquinoline.[260] The phenols are identified by mass spectrometry, u.v. and i.r. spectrophotometry, or spectrofluorimetry.[9,13,20,239,252,256-258]

As in the case of acids, both schemes of chromato-spectrometric analysis can be used successfully for the determination of phenols.

11. The  and Groups

Quinones can be detected by oxidation, using their reaction with 2,4-dinitrophenylhydrazine, aromatic amines, polybasic phenols, and cyanoacetic ester,[1,3,10,38] but these methods are seldom compatible with separation, possibly because of the ease of reduction to the corresponding phenols.

The reaction of benzo- and naphthaquinones with benzoylsulphinic acid produces coloured and fluorescent dihydroxydiphenyl- or dihydroxyphenylnaphthylsulphones, which can be separated by TLC on silica gel or Siluphol.[247,261]

Silica gel, silica gel impregnated with $AgNO_3$, polyamide, or other sorbents can be used to separate quinones before derivatisation.[26,262] Analysis by column liquid chromatography (usually in the reversed-phase mode) is carried out on Porasil C_{18} or on Permophase ODS, with aqueous-organic eluents and u.v. detection.[9,18,239,263]

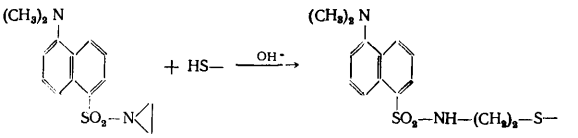
12. The −SH and −S−S− Groups

So far only a few derivatives compatible with the chromato-spectrometric determination of −SH compounds (or of compounds in which the −S−S− group has been reduced to −SH) have been reported.

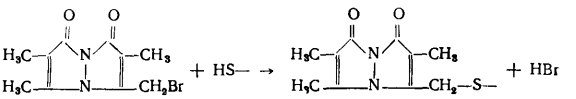
The interaction of thiols with S,S'-dithio-bis-(2-nitro)-benzoic acid at pH 8 produces coloured disulphides which can be separated, for example, by reversed-phase column liquid chromatography on Lichrosorb RP-18 with a methanolic phosphate buffer (pH 8.0); identification is by u.v. detection.[9,264]

2,4-Dinitrothioethers (produced by the reaction of thiols with 2,4-dinitrochlorobenzene) are easily separated by high-performance liquid chromatography on Lichrosorb RP-18 with an aqueous solution of acetonitrile. ¶

Thiols react with dansyl aziridene to give stable derivatives which are easily separated chromatographically:[8,265]



Monobromobimane reacts with thiols as follows:



The resulting compounds are fluorescent, and easily separable by chromatographic or electrophoretic methods.[266-268]

Fluorescent derivatives suitable for the analysis of thiols are obtained also from the reaction with 9-acridyl-, *N*-(*p*-2-benzimidazyl)phenyl-, and *N*-(7-dimethylamino-4-methylcoumarinyl)maleimides.[138,269,270] A new reagent for the preparation of fluorescent derivatives has recently been proposed: ammonium 7-fluorobenzo-2-oxa-1,3-diazole-4-sulphonate, which reacts with the −SH group at ~60 °C and pH ~9.5. Like NBD chloride, to which it is structurally similar, this preparation is relatively stable and is itself non-fluorescent. The analytical conditions for the column liquid chromatography of these compounds are discussed in Ref. 271.

Many papers describe the separation of thiols and disulphides by TLC before derivatisation. Silica gel or mixtures of silica gel with palladium chloride, aluminium oxide, or cellulose are used as sorbents.[26,80,272-274]

Visualisation of the −SH and −S−S− groups on the plates or in the eluates is possible both with universal and with more specific reagents: the complex of dithiofluorescein with *o*-hydroxymercurybenzoic acid, mixtures of sodium azide and iodine, mixtures of 3,5-di-t-butyl-1,2-benzoquinone and ferric chloride, and mixtures of 6,6'-dihydroxy-2,2'-dinaphthyl disulphide, the Dragendorf reagent, hydrogen sulphide solutions, and potassium hydroxide in aqueous butanol.[26,274-277]

Substances containing the −SH and −S−S− groups can be separated by column liquid chromatography (especially the reversed-phase variant) on μ-Bondapak C_{18}, Spherisorb ODS, HC Pellosil ODS, and other sorbents, with aqueous-alcoholic solutions at controlled pH.[10,138,278,279] The electrochemical detector[10,278-280] is found to be useful in the identification of these compounds.

Reagents for detecting thiols (after separation) by the colour or the fluorescence of the resulting compounds are proposed also in Refs. 281–284. Thus a mixture of *o*-phthalic aldehyde and taurine or other primary amine is shown to produce fluorescent isoindoles.

13. The  Groups

Compounds containing these groups are analysed mainly by TLC methods, with separation before derivatisation, using both pure and impregnated silica gel or aluminium oxide and

¶ see H.Langenhove, J.Chromatogr., 1983, **257**, 170.

various solvent systems.[26,80,272,273,285] Iodine, tetracyanoethylene, 2,3-dichloro-5,6-dicyano-1,3-benzoquinone, and other reagents are used for visualisation on the TLC plate.[26,80,273] If necessary, the analytical results are confirmed mass spectrometrically.[272,273,286]

14. The $-O-P(=O)(-O)-O$ Group

Separation of alkyl and aryl phosphates before derivatisation is carried out by TLC on silica gel or cellulose with various eluents, including benzene, methanol, and chloroform, and visualisation is by hydrolysis to the PO_4^{3-} anion followed by reaction (for example) with ammonium molybdate or vanadate to give coloured compounds.[26,287,290]

The separation before derivatisation of compounds containing these groups by normal- and reversed-phase column liquid chromatography with u.v. detection has been reported.[10,291,292]

15. The $-C-P<$ and $-C-P(=O)<$ Groups

Only a few reports of the chromato-spectrometric identification of groups containing the C–P bond have been published. Direct separation of a series of phosphonic acids has been achieved by TLC, with visualisation by oxidation to the PO_4^{3-} anion and reaction with ammonium molybdate or other similar reagent. Column chromatography has also been used, with various detectors.[26,289,293,294]

Some results on the determination of these groups are quoted in discussions of analytical methods for organophosphorus insecticides and their degradation products.[10,18,138,295,296]

IV. CONCLUSIONS

The results examined in this review show that a large volume of experimental information on the functional microanalysis of organic compounds by a combination of chemical reactions, chromatographic separation, and spectrometric identification is now available. Chromato-spectrometric methods are of interest for the determination of very small amounts (10^{-9}–10^{-11} g) of organic substances of various types, and their potential performance in this respect is far superior to that of classical methods of functional analysis.

Relative assessments of the reagents used in chromato-spectrometric methods have not so far been compiled: this hinders the choice of the best reagent for the analysis of complex mixtures. We have therefore combined published data and experimental results obtained in our laboratory to produce a list of some of the characteristics of the most commonly used reagents, which are often known to be the optimum choice for specific chromato-spectrometric analyses (see Table). This tabulation should prove useful in the selection of reagents for the analysis of various types of material.

Reactive chromato-spectrometric methods have found practical applications in the micro-analysis of many organic substances for functional groups, but the scope of their exploitation is still far from reaching its full potential. An effort is needed to extend the area of practical application of chromato-spectrometric methods, preferably by simplifying the various stages and the automation procedures of the analysis.

Characteristics of some reagents used in chromato-spectrometric methods.

Reagent	Application: before separation	Application: after separation	Groups	Method of detection
3,5-Dinitro- or 4-nitrobenzoyl chloride	+	–	$-NH_2$; >NH, >C–OH; $-C_6H_4-OH$	Col., u.v., MS
Dansyl chloride	+	–	$-NH_2$; >NH; $-C_6H_4-OH$	U.v., fl., MS
2,4-Dinitrofluorobenzene	+	–	$-NH_2$; >NH; –SH; >C–OH; $-C_6H_4-OH$	Col., u.v., MS
NBD chloride	+	+	$-NH_2$; >NH	Col., u.v., fl MS
Phenyliso- or phenylisothiocyanate	+	–	$-NH_2$; >NH; $-C_6H_4-OH$; >C–OH	U.v., MS
o-Phthalic aldehyde	+	+	$-NH_2$	U.v., fl.
4-Phenyl-*spiro*(furan-2), 3H-1′-phthalan-3,3′-dione (fluram)	+	+	$-NH_2$	Fl., u.v.
Ninhydrin	–	+	$-NH_2$	Col., u.v.
Diazotised sulphanilic acid or 4-nitroaniline	+	+	$-C_6H_4-NH_2$; $-C_6H_4-OH$	Col., u.v.
Dragendorf reagent	–	+	>N; $>\overset{+}{N}-$	Col.
N-4-Nitrobenzyl-*N*-propylamine	+	–	$-N=C=O$	U.v.
Acetone and NaOH	–	+	$-C_6H_3(NO_2)_2$ and $-C_6H_2(NO_2)_3$	Col., u.v.
2,4-Dinitro- or 4-nitrophenylhydrazine	+	–	>C=O	Col., u.v., MS
Dansylhydrazine	+	–	>C=O	Fl., u.v., MS
4-Nitrobenzyloxyamine	+	–	>C=O	U.v., MS
N′-Methylnicotinamide chloride	+	+	$-CH_2-C(=O)<$	Fl.
Dimedon	+	–	$H-C(=O)<$	Col., fl.
N,*N*′-Dimethylamino-4-aniline	+	–	$H-C(=O)<$	Col.
4-Bromo- or 4-nitrophenacyl bromide	+	–	–COOH	U.v., MS
2-Naphthacyl bromide	+	–	–COOH	Fl., u.v., MS
p-Nitrobenzyl-*N*,*N*′-diisopropylisourea	+	–	–COOH	Col., u.v.
4-Bromomethyl-7-methoxycoumarin	+	–	–COOH	Fl., u.v.
1-Naphthyl- or 9-anthryldiazomethane	+	–	–COOH	Fl., u.v.
o-Phenylenedimaine	+	–	$-C(=O)-C(=O)-$	Fl., u.v.
Ce^{4+} salts	–	+	–COOH; >C–OH; $-C_6H_4-OH$	Fl.
Na vanadate and 8-hydroxyquinoline	–	+	>C–OH	Col.
4-Aminoantipyrine	+	+	$-C_6H_4-OH$	Col.
5,5′-Dithio-*bis*(2-nitro)benzoic acid	–	+	–SH	Col.
Tetracyanoethylene	–	+	=S; =S=O; $>S(=O)_2$; >N	Col., MS
Ammonium molybdate	–	+	$-O-P(=O)(-O)-O$	Col.

Symbols denoting the methods: U.v., by absorption in the u.v. region of the spectrum; Fl., by fluorescence; MS, by mass spectrometry; Col., by visual colour.

Further work on the development of a rational system of functional micro-analysis of organic compounds by chromatospectrometric methods is needed. Substantial improvements in the sensitivity of the determination (in particular, by fluorimetric and mass spectrometric methods) should result from the use of analytical lasers.

Catalysis by Metalloporphyrins of Reactions Involving Oxidation by Molecular Oxygen and Oxygen-containing Compounds

N.S.Enikolopyan, K.A.Bogdanova, L.V.Karmilova, and K.A.Askarov

Data on the catalysis by metalloporphyrins of reactions involving the oxidation of organic compounds by molecular oxygen, iodosobenzene, sodium hypochlorite, hydroperoxides, and peracids are surveyed and analysed. The possible mechanisms of the catalytic action of metalloporphyrins in these systems are proposed. The promising trends in the research designed to create, on the basis of metalloporphyrins, new catalytic systems for the selective oxidation of organic compounds under mild conditions are outlined.
The bibliography includes 188 references.

I. INTRODUCTION

Metalloporphyrin compounds[1-26] constitute the prosthetic groups in many enzymes—oxygenases, peroxidases, and others.[27-34] In particular, haemin forms part of the composition of cytochromes P-450, which are responsible for the detoxication of living organisms and which effect the hydroxylation of saturated and aromatic hydrocarbons and the epoxidation of olefins by molecular oxygen in their cells. The unique structure of metalloporphyrins, which contain the planar porphyrin ring with an extensive π-conjugation system and a central variable-valence metal ion,[7,8,35,36] determines their high catalytic activity. Oxygen-containing compounds such as hydroperoxides[37-43] and iodosobenzene[44-47] can successfully replace oxygen as the corresponding electron donor [acceptor] in selective oxidation reactions catalysed by cytochromes P-450.

The problem of modelling the catalytic functions of cytochromes P-450 by synthetic metalloporphyrins is of crucial importance at the present time. Its solution will make it possible to create new catalytic systems for the selective oxidation of organic compounds by molecular oxygen under mild conditions. The development of highly selective industrial methods of synthesis of epoxides and alcohols is an important task in present day chemistry.

One of the central aspects of the relevant research involves the study of the mechanisms of the catalytic action of metalloporphyrins in reactions involving the oxidation of organic substrates by molecular oxygen and oxygen-containing compounds. The understanding of these mechanisms will assist

in the further development of studies designed to create new effective catalytic systems, based on metalloporphyrins, for selective oxidation. Furthermore, investigation of the mechanisms of the catalytic action of synthetic metalloporphyrins should help in understanding the mechanisms of the action of porphyrin-containing enzymes which have not so far been elucidated. This is very important not only for the development of biochemistry but also for chemotherapy.

The possible mechanisms of the catalytic action of metalloporphyrins in the oxidation of organic compounds by molecular oxygen, iodosobenzene, sodium hypochlorite, hydroperoxides, and peracids are proposed in this review on the basis of current ideas and the analysis of experimental data for such systems.

II. REACTIONS INVOLVING MOLECULAR OXYGEN

The results of studies of the catalysis by metalloporphyrin complexes of reactions involving oxidation by molecular oxygen have already been surveyed.[25] Here we shall not consider these data again and the bibliography of the previous review will be merely supplemented by a number of publications[24,48-89] and the possible mechanisms of these reactions will be discussed.

As a rule, metalloporphyrins initiate the radical chain autoxidation of organic substrates (alkanes, olefins, and aldehydes) via the following mechanism. Molecular oxygen is coordinated to the metal ion of the metalloporphyrin (P–M), forming a charge-transfer complex whose electronic structure depends on the nature of the metal. This can be both a superoxide complex, for example (Py)TPhP-$Co^{3+}...O_2^-$ [90-98] (where Py = pyridine and TPhP = tetraphenylporphin ligand) and a peroxide complex, whose formation has been suggested for TPhP-$Mn^{4+}...O_2^{2-}$.[98-101] These complexes initiate the chain in the autoxidation of organic substrates, abstracting the mobile hydrogen from the latter:

$$P\text{-}M^+ \ldots O_2^- + RH \rightarrow P\text{-}M^+ \ldots O_2H^- + R^\cdot ,$$

where RH is the oxidisable substrate. In the case of olefins, the initiation of the autoxidation is also possible as a result of the addition of the superoxide (or peroxide) complex to the double bond:

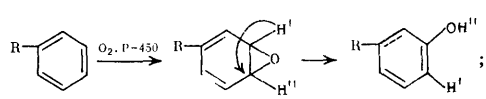
$$P\text{-}M^+ \ldots O_2^- + \rangle C{=}C\langle \rightarrow -\overset{|}{C}-\overset{|}{C}\cdot- \quad (-O-O-M^+\text{-}P)$$

Fe(III)-protoporphyrin (IX) (haemin) is known to occur as the prosthetic group in the composition of mono-oxygenating enzymes–cytochromes P-450 (the complexes of their reduced forms with carbon monoxide have a characteristic Soret absorption band at 450 nm). The nature of the axial ligand linked to haemin cannot be regarded as firmly established. It has been suggested that the iron ion in cytochrome P-450 is linked to cysteine and histidine residues.[27]

Cytochromes P-450 catalyse the following reactions involving oxidation by molecular oxygen:[102]

(1) hydroxylation of aliphatic hydrocarbons;

(2) hydroxylation of aromatic hydrocarbons with formation of an intermediate epoxidation product and the migration of hydrogen atoms:[103,104]



; (1)

(3) epoxidation of olefins;

(4) mono-oxygenation of sulphur- and nitrogen-containing organic compounds.

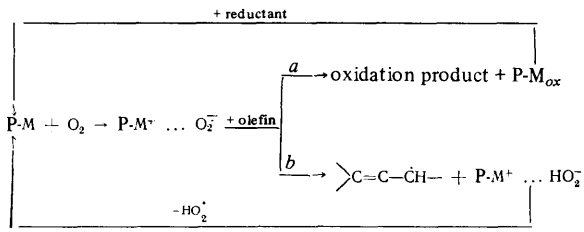
It is noteworthy that both in the cells of living organisms and under laboratory conditions cytochromes P-450 act as mono-oxygenating enzymes only in the presence of a reductant, which is necessary to reduce the second atom of the oxygen molecule to water. The overall equation of the mono-oxygenation reaction is:[102]

$$S + O_2 + DH_2 \rightarrow SO + D + H_2O ,$$

where S is the substrate and DH_2 the reducing agent. The respiratory chain of mitochondria, NADH (nicotinamide-adenine dinucleotide) or NADPH (nicotinamide-adenine dinucleotide phosphate), reduced flavins, and tetrahydropteridines can play the role of reductants.

It is striking that the modelling of the mono-oxygenating activity of cytochromes P-450 by metalloporphyrin complexes has been achieved only in the presence of a suitable electron donor. The results of these studies are presented in Table 1. Only in the presence of a reductant in the system does the metalloporphyrin act as an agent transferring one of the atoms of molecular oxygen to the oxidisable substrate. In the absence of a reductant, the free-radical chain autoxidation is initiated with formation of a set of products characteristic of this process.[110]

The mechanism of the processes occurring in model systems consisting of a metalloporphyrin, oxygen, and an oxidisable substrate can be represented as follows. A superoxide (or peroxide) complex, which is capable of initiating the free-radical chain oxidation by abstracting a mobile hydrogen atom from the substrate molecule (or by adding to the double bond of the olefin) (pathway *b* in the scheme below), is formed initially. In addition, the complex functions as an agent transferring oxygen to the oxidisable compound (pathway *a*), although this process cannot be regarded as truly catalytic because the metalloporphyrin is then converted into the oxidised form and is immediately eliminated from the system. The added reductant regenerates the active form of the metalloporphyrin and completes the catalytic cycle of the model oxygenation reaction. However, under these conditions there is a possibility of the formation of secondary products via the interaction of the oxidation product with the reductant.



The model mono-oxygenating systems are much less active than the natural enzymes. Thus in the presence of TPhP-MnCl the yields of the olefin oxidation products range from 3 to 32% after 24 h and between 1.7 and 32 catalytic cycles are accomplished during this period (Table 1). TPP-MnCl is most active in the oxidation of steroids, where 170–230 catalytic cycles take place in 1–3 h and the yield of the product reaches 78–82%.[48,49] The activity of haemin in the oxidation of cyclohexane in an aqueous acetone medium is less than that of the natural hydroxylating system by a factor of 50,[108] while in the hydroxylation of aniline in a highly alkaline medium it is less by a factor of 4.[109] The higher effectiveness of natural cytochromes P-450 compared with the model systems is apparently associated with the fact that the protein component of the enzyme ensures the optimum spatial orientation of the substrate with respect to the oxygen complex of

haem and at the same time creates the optimum micro-environment for the active centre (for example, the necessary basicity).[109]

Table 1 shows that the character of the products and the selectivity of the oxidation reactions in the presence of the model catalytic system depend significantly on the nature of the reductant. A mild reducing agent, such as sodium ascorbate, makes it possible to achieve the epoxidation of olefins (cyclohexene, hex-1-ene, 2,3-dimethylbut-2-ene, and styrene) with 100% selectivity,[77] while in the presence of powerful reducing agents, namely sodium and tetra-n-butylammonium tetrahydroborates, the reaction usually results in the formation of a mixture of saturated alcohols and ketones[48, 49, 106] (only Δ^5-steroids give rise to single products—5-α-hydroxysteroids).

Cyclohexene differs from other unsaturated hydrocarbons by the presence of allyl oxidation products—cyclohex-2-en-1-ol,[84, 105, 106] and cyclohex-2-en-1-one.[107] The influence of the nature of the reductant on the composition of the reaction products has also been traced in relation to cyclohexene: a

Table 1. Oxidation of organic compounds by oxygen at room temperature in the presence of TPhP-MnCl and a reductant.

Notation: τ is the reaction time and α_o and α_c are the yields of the product recalculated in terms of the compound oxidised and the catalyst respectively.

*The catalyst was OEP-RhCl, where OEP = octaethylporphyrin ligand.
**1-Methylimidazole was added to the system.
***Two-phase system containing a phase transfer agent (methyltrioctylammonium chloride).
****The catalyst was haemin.

mixture of cyclohexanol and allyl alcohol is obtained in the presence of $NaBH_4$,[105] when gaseous hydrogen and colloidal platinum are used, the products are epoxycyclohexane and an αβ-unsaturated ketone,[107] while epoxycyclohexane is formed on treatment with sodium ascorbate.[77] Saturated hydrocarbons are oxidised in the presence of the model catalytic systems with formation of alcohols and ketones.[77,107,108]

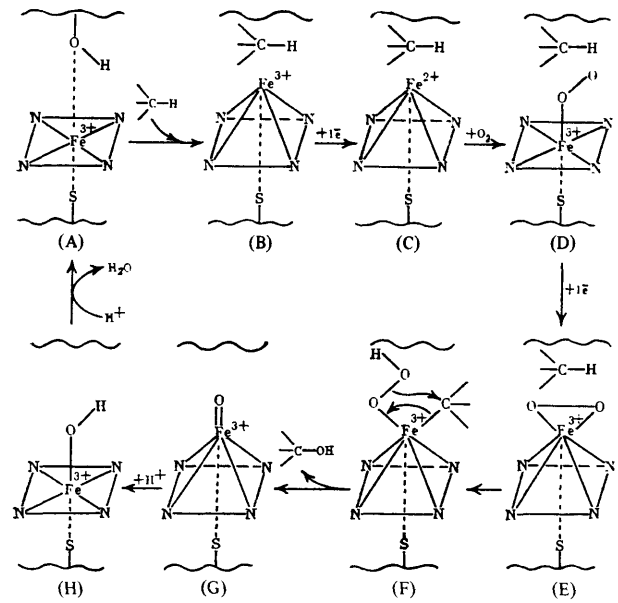
A characteristic feature of the oxidation of olefins on treatment with the model systems is an increase in the rate of reaction with increasing nucleophilicity of the double bond. Thus the rate of oxidation in the O_2–TPhP–MnCl–$NaBH_4$ system increases in the sequence ethylene < propene < hex-1-ene < hex-2-ene;[48,49] in the O_2-TPhP–MnCl–sodium ascorbate two-phase system containing a phase-transfer agent, the reactivity of olefins increases in the following sequence: hex-1-ene < cyclohexene < 2,3-dimethylbut-2-ene < styrene;[77] in the O_2–TPhP-MnCl–$(NBu_4)BH_4$ system 1-phenylpropene is more reactive than styrene;[106] in the O_2–TPhP-MnCl–H_2–colloidal platinum system, *cis*-oct-2-ene is oxidised approximately 18 times faster than hex-1-ene.[107] The very high reactivity of trisubstituted steroid olefins in oxidation by the O_2–TPhP-MnCl–$NaBH_4$ system cannot apparently be explained solely by the nucleophilic properties of the double bond. We shall return to this problem later. The analogous influence of electron-donating substituents on the rate of mono-oxygenation has been noted also for enzyme systems.[111]

Another feature of the oxidation of olefins in the presence of the model catalytic systems is the regioselectivity of the process. The oxidation involves the most substituted carbon atom: only secondary alcohols and ketones are formed from asymmetrically substituted olefins (oct-1-ene, styrene, 1-phenylpropene,[106] propene, and hex-1-ene[48,49]).

The third feature is the significant role of steric factors, which is indicated by the activity of *cis*-oct-2-ene being greater by an order of magnitude than that of its *trans*-isomer in the oxidation reaction catalysed by the O_2–TPhP-MnCl–H_2–colloidal platinum system.[107]

The mechanism of the action of hydroxylating enzyme systems based on cytochromes P-450 has not so far been established. The nature of the oxidising agent has not been determined by direct procedures in any of the systems. Several mechanisms have been discussed in the literature.[41,102,112–118] One of these, presented below (Scheme 1),[102] reflects in our view the electrophilic nature of the reaction most convincingly. The catalytic cycle begins with the conversion of the hexacoordinate Fe^{3+} complex in a low-spin state (A) into a pentacoordinate Fe^{3+} complex in a high-spin state (B) as a result of the binding of the hydrocarbon to be oxidised by the protein component of the enzyme. The one-electron reduction of compound (B) leads to a pentacoordinate Fe^{2+} complex in a high-spin state (C) capable of binding oxygen with formation of a low-spin Fe^{3+} superoxide complex (D). The states (A), (B), (C), and (D) have been thoroughly characterised,[115,119] but the mechanism of the transfer of oxygen from the complex (D) to the substrate being oxidised has not been finally elucidated.

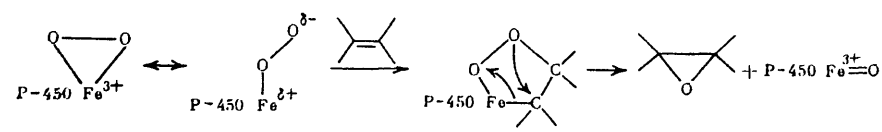
Scheme 1



The addition of a second electron to (D) can lead to the formation of the Fe^{3+} peroxide complex (E). The mechanism of this addition has also not been established hitherto. Presumably the porphyrin ligand gives up an electron, being converted simultaneously into a porphyrin radical-cation. The heterolytic cleavage of the C–H bond is accompanied by the simultaneous opening of the Fe^{3+}–peroxo bond and leads to a very unstable alkyl Fe^{3+} hydroperoxide (F), which decomposes with formation of the oxidation product – an alcohol and the Fe^{3+} oxo-complex (G). The latter hydrolyses to the Fe^{3+} hydroxo-complex (H), the initial complex (A), and water.

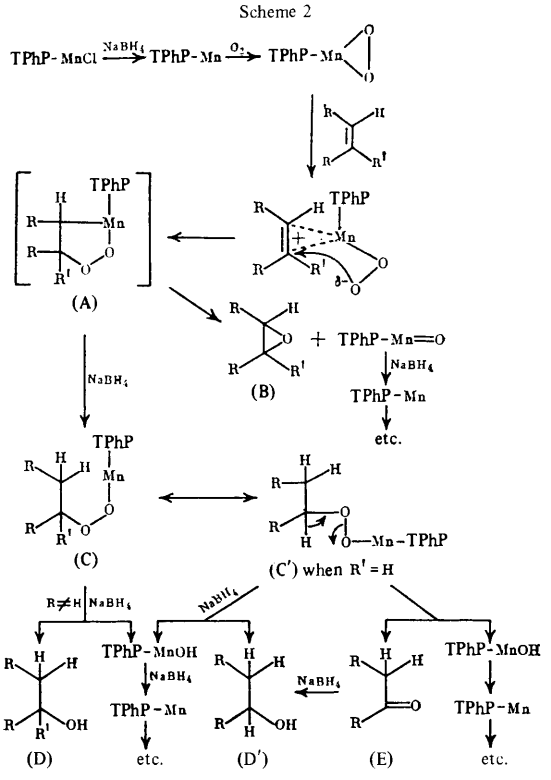
This mechanism agrees with the large isotope effect (k_H/k_D = 11.5) in the norbornane hydroxylation reaction in the presence of cytochromes P-450,[120] which presupposes the activation and cleavage of the C–H bond. This scheme also agrees with the formation of the Fe^{3+} oxo-complex, detected in the two-electron oxidation of chloroperoxidase.[121] The intermediate formation of the same complex has been postulated in the hydroxylation of hydrocarbons by hydrogen peroxide in the presence of iron ions.[122]

The mechanism of the epoxidation of olefins and aromatic compounds in the presence of cytochromes P-450 presupposes[102] the insertion of an olefin molecule in the 1,3-dipolar metal–peroxo bond of the complex (E) (Scheme 1) with formation of an intermediate five-membered ring, which decomposes into an epoxy-compound and an oxo-complex. Aromatic epoxides then rearrange to phenols.



A mechanism of the oxidation of olefins in the presence of the O_2–TPhP-MnCl–reductant model system has been proposed,[49] which takes into account all the characteristic features of this process, namely the influence of the nature of the reductant on the composition of the reaction products, the formation of a single product (a tertiary alcohol from trisubstituted olefins and a ketone and a secondary alcohol from mono- and di-substituted olefins) when powerful reductants are used, and the regioselectivity of the oxidation and the dependence of the rate of the latter on the nucleophilicity of the double bond and steric factors (Scheme 2).

Scheme 2



In the first stage of the process the reductant (in the given instance $NaBH_4$) converts TPhP-Mn^{3+}Cl into TPhP-Mn^{2+}, which interacts with molecular oxygen to form an oxygen complex having the peroxide structure: TPhP-Mn^{4+}...O_2^{2-};[98-101] according to Hansen and Hoffman,[100] the Mn^{4+} ion in this complex lies 0.5 Å above the plane of the porphyrin ligand. The nucleophilic olefin is coordinated to the most electrophilic component of this complex – the Mn^{4+} ion, after which the olefin molecule is inserted in the dipolar Mn-peroxo bond with formation of the cyclic intermediate (A). The regioselectivity of the reaction is determined by the laws governing electrophilic addition. The epoxide (B) can be formed as a result of the disproportionation of the intermediate (A). When weak reductants are used, the epoxide is the only product of the reaction. However, in model systems containing a powerful reductant, the reductive cleavage of the Mn–C bond in the cyclic intermediate (A) apparently takes place with formation of a peroxide complex (C or C'). The subsequent reactions of this complex should depend on the degree of substitution of the carbon atom linked to the peroxy-group. The reduction of the O–O bond in the complex (C) with a tertiary carbon atom by sodium tetrahydroborate leads to the tertiary alcohol (D) and TPhP-MnOH, which enters into a new catalytic cycle. The peroxide complex for the secondary carbon atom (C') is capable, on the one hand, of being reduced by $NaBH_4$ to the secondary alcohol (D') and TPhP-MnOH and, on the other hand, it can disproportionate to the ketone (E) and TPhP-MnOH. An alternative pathway to the formation of secondary alcohols involves the reduction of the ketone (E) by sodium tetrahydroborate.

The order in which the Mn–C and O–O bonds are ruptured in the cyclic intermediate (A) is unimportant, since in both cases the ketone (E) and the alcohols (D) and (D') are formed as primary products without manganese.

Although this mechanism is so far only tentative, it must be emphasised that all its stages have reasonable analogies. Thus reactions involving the disproportionation of secondary peroxides to the carbonyl compounds (C') → (E) and the reduction of M–C bonds by tetrahydroborate (A) → (C) are known.[123,124]

Analysis of the products of the oxidation of olefins in the presence of model catalytic systems (Table 1) permits the conclusion that model systems containing milder reductants, for example, sodium ascorbate, are closer in their action to natural cytochromes P-450: the intermediate (A) disproportionates in their presence with formation of epoxy-compounds via the reaction (A) → (B).

The oxidation of tertiary olefins, in particular of the steroids D-androst-5-en-3β-ol and D-cholest-5-en-3β-ol, by the O_2-TPhP-MnCl–$NaBH_4$ system leads to a single product (corresponding to a tertiary alcohol) via the reaction (C) → (D), since the formation of a ketone is in this instance impossible. The high reactivity of steroids in this reaction is apparently associated not only with the enhanced nucleophilicity of the double bond owing to the presence of substituents but also with the reduced energy of the C=C bond owing to the strain in the molecular structure of the steroids. This facilitates the formation of the cyclic intermediate complex (A), i.e. diminishes the activation barrier to the reaction.

Presumably the oxidation of saturated hydrocarbons in the presence of metallo-porphyrin catalytic systems proceeds via the intermediate formation of a hydroperoxy-compound, which then decomposes and is converted into an alcohol or ketone. It may be that this mechanism is also responsible for the formation of the products of the allyl oxidation of cyclohexene by the O_2–TPhP-MnCl–$NaBH_4$ system.

In conclusion of this Section, it must be emphasised that the above mechanisms make it possible to regard the selective oxidation of hydrocarbons by molecular oxygen in the presence of cytochromes P-450 and synthetic metalloporphyrins as a special case of reactions which are accelerated in the presence of transition metal complexes and involves the insertion of a molecule of the coordinated substrate in the metal–nucleophile bond (polymerisation, hydrogenation, hydroformylation and other processes belong to reactions of of this kind).[125]

III. OXIDATION BY IODOSO-COMPOUNDS

Metalloporphyrins catalyse the oxidation of hydrocarbons by iodosobenzene[126-134] without the involvement of reductants (Table 2). The results presented show that the catalytic effects of the Mn-porphyrins, on the one hand, and Fe- and Cr-porphyrins, on the other, are different. The difference is manifested in the first place in the composition of the reaction product. Fe- and Cr-porphyrins usually catalyse the selective epoxidation of olefins and the hydroxylation of saturated and aromatic hydrocarbons. Cyclohexene is an exception, being oxidised in the presence of Fe-porphyrins predominantly to an epoxide (75–95%) with formation of a small amount of cyclohex-2-en-1-ol (5–25%);[126,127] mainly

Table 2. Oxidation of hydrocarbons by iodosobenzene in the presence of metalloporphyrins at 25 °C in solution in CH_2Cl_2.

*Yield expressed as a percentage relative to iodosobenzene; the yield expressed in relation to the catalyst is given in brackets (our calculation based on the authors' data).

**The overall yield with respect to cyclohexene is 2.2%.

***Solution in benzene.

****Without a solvent.

cyclohex-2-en-1-ol (75%) is formed in the presence of TPhP-CrCl with a smaller amount of cyclohex-2-en-one (21%) and only 4% of epoxycyclohexane.[128] On the other hand, Mn-porphyrins catalyse the non-stereospecific epoxidation of stilbene[130] and the oxidation of saturated and aromatic hydrocarbons[127,130,131,133] with formation of a large set of products and, when the reaction is carried out in chlorinated solvents, chloro-products are also formed. Another difference between the effects of Mn-porphyrins, on the one hand, and Fe- and Cr-porphyrins, on the other, concerns the stereospecificity of the olefin epoxidation reaction. The epoxidation of *cis*-stilbene in the presence of TPhP-FeCl and TPhP-CrCl[126,128,129] results in the exclusive formation of *cis*-stilbene oxide: *trans*-stilbene is converted in the presence of TPhP-CrCl solely into the *trans*-oxide (the reaction does not occur in the presence of TPhP-FeCl). In this reaction the Mn-porphyrin catalysts[130] do not exhibit stereospecificity – a mixture of the *cis*- and *trans*-oxides is formed in the oxidation of *cis*-stilbene.

The above data permit the conclusion that the mechanisms of the catalytic action of Mn-porphyrins, on the one hand, and the Fe- and Cr-porphyrins, on the other, in the oxidation of hydrocarbons by iodosobenzene are different: Mn-porphyrins catalyse a radical process, while Fe- and Cr-porphyrins act as oxygen atom-transferring agents. The hydroxylating and epoxidising iodosobenzene–P-FeCl (or P-CrCl) system constitutes a functional model of cytochrome P-450. Additional evidence of this is provided by the following facts: the TPhP-FeCl–PhIO system is effective in the dealkylation reactions of *NN*-dimethylaniline[135] and anisole,[43,136] which are characteristic of cytochromes P-450;[43, 137,138] in the hydroxylation of anisole by iodosobenzene and TFPhP-FeCl, it has been established by the isotope tracer method that hydrogen atoms migrate[127] [see Eqn.(1)], which is characteristic of the hydroxylation of aromatic hydrocarbons in the presence of cytochromes P-450;[104] furthermore, iodosobenzene successfully substitutes molecular oxygen and the reductant in oxidation reactions catalysed by these enzymes.[44,47]

In the PhIO–P-MCl systems agents responsible for direct oxygen transfer to the substrate are oxo-complexes of metalloporphyrins containing the metal in a high oxidation state.[126,128-131,139-144] It has been shown that the reaction of P-MCl with PhIO results in the formation of iodobenzene (absorption bands at 1018 and 999 cm^{-1} appear in the infrared spectra)[128,129] and the oxo-complex of the metalloporphyrin (the absorption band at 1026 cm^{-1} corresponds to the vibrations of the Cr=O bond[128] and that at 1060 cm^{-1} to the vibrations of the Mn=O bond[145]). The addition of labelled water $H_2^{18}O$ to the PhIO–TPhP-CrCl system results in the disappearance of the 1026 cm^{-1} band from the infrared spectrum and the appearance of a band at 982 cm^{-1} corresponding to the vibration of the $Cr=^{18}O$ bond. When norbornene is introduced, the epoxide containing 94% of ^{18}O is formed. Special experiments demonstrated that PhIO is not involved in oxygen exchange with $H_2^{18}O$ under these conditions.

Analogous results have been obtained in the presence of TPhP-MnCl[130] and TMP-FeCl (TMP is the tetramesitylporphin ligand).[141] In addition, a reliable instance of the transfer of an oxygen atom to the substrate undergoing oxidation from an oxo-metalloporphyrin is known. This is the reaction involving the oxidation of substituted phosphine by *cis*-dioxomolybdenum(VI)-tetra-*p*-tolylporphin:[146,147]

$$T\,(p\text{-}CH_3\text{-}Ph)\,P\text{-}Mo^{VI}\!\!\begin{matrix}O\\O\end{matrix} + PR_3 \rightarrow T\,(p\text{-}CH_3\text{-}Ph)\,P\text{-}Mo^{IV}{=}O + OPR_3.$$

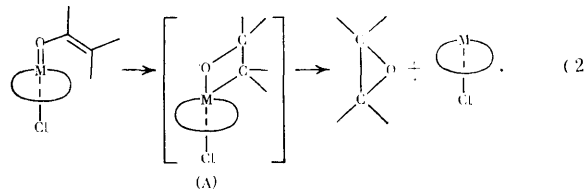
It has been shown recently[148] that the imido-complex of Mn-porphyrin effects direct oxidative amination of olefins, which leads to nitrogen-containing analogues of epoxides.

The oxo-complexes of metalloporphyrins formed when P-MCl interacts with iodosobenzene in solution in methylene chloride have been isolated at reduced temperatures; their structure and properties have been characterised by various methods (infrared, EPR, NMR, and Mössbauer spectroscopy, the spectroscopy in the visible region, and measurements of magnetic susceptibility.[128-131,140,141,149] The oxo-complex of chromium is stable at room temperature for several hours.[129] In the solid state the oxo-complex of manganese is stable for several days at 25 °C, but, on dissolution in aromatic and chlorinated hydrocarbons, it is rapidly reduced with formation of P-Mn^{3+}Cl.[130,131] Solutions of oxo-complexes of iron are unstable at room temperature.[140,141]

The entire set of data shows that the oxo-complexes of chromium and manganese contain a quintuply charged metal ion: Cl(TPhP)Cr^{5+}=O and Cl(TPhP)Mn^{5+}=O. However, it has been suggested[145] that, when TPhP-MnOAc reacts with iodosobenzene in solution in methanol, the oxo-complex of quadrivalent manganese, i.e. TPhP-Mn^{4+}=O, is formed. Study of the structure of the oxo-complex of iron,[141,150] permits the conclusion that it contains quadrivalent iron and the radical-cation derived from the porphyrin ligand: Cl(TMP)$^{\cdot}$. .Fe^{4+}=O. Although this structure does not in fact account for all the observed spectroscopic properties, it agrees with the results of a study[151] showing that the electrochemical oxidation of TPhPFe^{4+}(Cl)(OH) involves the porphyrin ligand and not the central metal ions; the process results in the formation of (TPhP)$^{\cdot}$Fe^{4+}(Cl)(OH). This behaviour of Fe-porphyrin arises because, according to theoretical calculations,[152] the energies of the lowest *d* orbitals of the iron ion and the a_{2u} orbitals of the TPhP ligand are similar. The energies of the *d* orbitals of the chromium and manganese ions are higher than those of the a_{2u} orbitals of TPhP and these complexes are therefore oxidised with participation of the central metal ion. It is noteworthy that the spectrum of the oxo-complex of iron, obtained by Groves et al.,[141] is analogous to that of compound I of horseradish peroxidase.

The mechanisms of oxygen transfer from the oxo-complexes of Mn-porphyrin, on the one hand, and Cr- and Fe-porphyrins, on the other, are apparently different. The PhIO–P-CrCl (or P-FeCl) oxidising system is characterised, apart from the features described above, also by a high specificity of the reaction in relation to *cis*-olefins, which indicates a major role of steric factors. Thus the PhIO–TPhP-FeCl system oxidises a mixture of *cis*- and *trans*-stilbenes with formation of only *cis*-stilbene oxide in 80% yield; *cis*-but-2-ene is six times more reactive than *trans*-but-2-ene; *cis*, *trans*, *trans*-cyclododecatriene gives rise to a 2:1 mixture of the *trans*- and *cis*-epoxides (i.e. the reactivities of both types of bonds are approximately the same), while the oxidation of this compound by *m*-chloroperbenzoic acid results in the formation of 98% of the *trans*-isomer.[129] In addition, data have been obtained[128] showing an increase of the reactivity of olefins with increasing nucleophilicity of the double bond (the reaction rates increase in the sequence stilbene < styrene < norbornene).

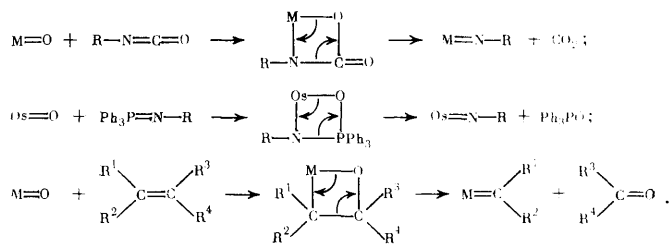
Taking into account all these features, one can put forward the following mechanism of the transfer of an oxygen atom from the oxo-complexes of Cr- and Fe-porphyrins to olefins. In the first stage an olefin molecule is coordinated to the central metal ion of the oxo-complex, after which the olefin is inserted in the metal–oxygen bond, with formation of a four-membered cyclic intermediate complex (A), which then disproportionates to the epoxide and a metalloporphyrin, the latter entering a new catalytic cycle:



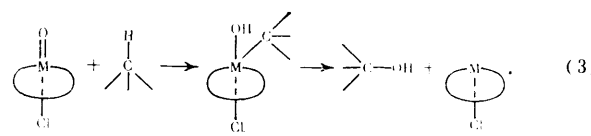
(2)

(A)

The formation of four-membered transition states has been postulated in a number of reactions of the oxo-complexes of metals,[102] including isocyanates, phosphine imines, and olefins:



The mechanism of the oxidation of saturated hydrocarbons by the oxo-complexes of Fe- and Cr-porphyrins can be represented analogously. The heterolytic cleavage of the C–H bond leads simultaneously to the rupture of the metal–oxygen bond. The complex (B) formed as a result of the reaction then decomposes into an alcohol and the metalloporphyrin:



(3)

(B)

It is difficult to account for the characteristic features of the cyclohexene oxidation reaction in the presence of Fe- and Cr-porphyrins, which deviates from this picture. An alcohol and even a ketone are formed together with the epoxide in the presence of Fe- and Cr-porphyrins, the proportions of the products being different in the two cases (Table 2). It may be that the competitive activation of the double bond [reaction (2)] and the allyl C–H bond [reaction (3)] takes place and the contributions of these reactions depend significantly on the nature of the metal in the oxo-complex.

According to the proposed mechanisms of the oxidation of olefins and alkanes by the oxo-complexes of Fe- and Cr-porphyrins, the transition complexes (A) and (B) are formed via reactions (2) and (3) without changes in the oxidation state of the metal ion but with dissociation of the M=O bond. Consequently the M=O bond in the porphyrin complex must be fairly labile in relation to heterolytic cleavage for reactions (2) and (3) to occur. There is reason to suppose that the M=O bond in the complex Cl(TPhP)Mn=O is more stable than in the corresponding iron and chromium complexes. The Mn^{5+} ion is apparently more electrophilic than the Cr^{5+} ion, since the Mn^{5+} radius should probably be smaller than the Cr^{5+} radius (in view of the lack of data for the dimensions of these ions owing to their extreme instability, we shall quote for the purposes of the comparison the radii of the Mn^{3+} and Cr^{3+} ions, which are respectively 0.62 and 0.64 Å or 0.68 and 0.71 Å.[153] Consequently the Mn^{5+}=O bond should be stronger than the Cr^{5+}=O bond. This is confirmed by the infrared spectroscopic data for the corresponding oxo-porphyrin complexes of manganese and chromium. The

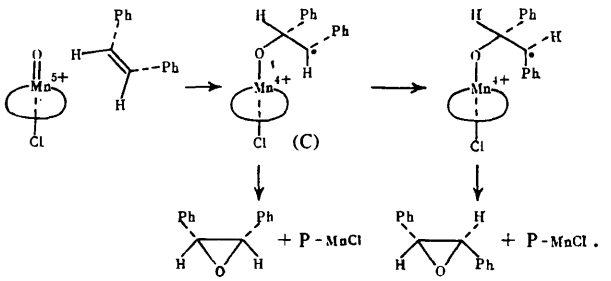
higher absorption frequency corresponding to the vibrations of the Mn=O group (ν = 1060 cm^{-1})[143] compared with the Cr=O group (ν = 1026 cm^{-1})[126,127] shows that the Mn=O bond is stronger and shorter. The quadrivalent iron ion present in the complex $Cl(TPhP)^{+}Fe^{4+}=O$ is less electrophilic than the quinquevalent manganese ion and the $Fe^{4+}=O$ bond is therefore stronger than the $Mn^{5+}=O$ bond. Although there are no infrared spectroscopic data for the vibration frequency of the $Fe^{IV}=O$ bond, the higher activity of $Cl(TPhP)^{+}Fe^{IV}=O$ compared with $Cl(TPhP)Cr^{V}=O$ in the olefin epoxidation reaction (Table 2), suggests that the $Fe^{IV}=O$ bond is more labile than the $Cr^{V}=O$ bond.

In the Cr^{5+}, Mn^{5+}, Fe^{4+} series, the best oxidant should be the manganese ion, which is indicated by the calculated ionisation potentials (the following ionisation potentials correspond to the $M^{4+} - e \rightarrow M^{5+}$ process: 76V for M = Mn and 73 V for M = Cr; 56 V for the process $Fe^{3+} - e \rightarrow Fe^{4+}$.[154] (The oxidation-reduction potentials of the corresponding porphyrin complexes have not been determined.) This suggests that there is a possibility of the reduction of quinquevalent manganese in the oxo-complex which leads to a radical species. This can be represented conventionally in the following manner:

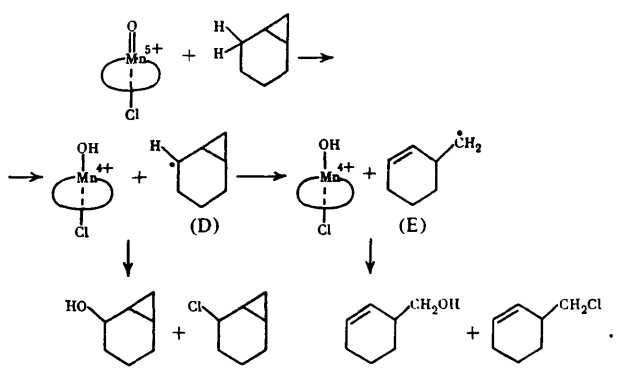
$$TPhP\text{-}Mn^{5+}\quad O \cdots TPhP\text{-}Mn^{4+}\cdots O\cdot .$$

Apparently these distinctive properties of the oxo-complex of Mn-porphyrin actually determine the radical mechanism of the transfer of an oxygen atom to the substrate undergoing oxidation, a characteristic feature of which is a change in the oxidation state of manganese on formation of the transition complex.

The homolytic rupture of the double bond of the olefin occurring in the reaction with (Cl)TPhP-Mn=O leads to the radical intermediate (C), the free rotation about the C–C bond in which is apparently responsible for the formation of a mixture of *cis*- and *trans*-isomeric products in the oxidation of *cis*-stilbene.[130]



On interaction with saturated hydrocarbons, the oxo-complex of the Mn-porphyrin apparently abstracts from them a mobile hydrogen atom. A tentative reaction mechanism is presented below for norcarane:[130]

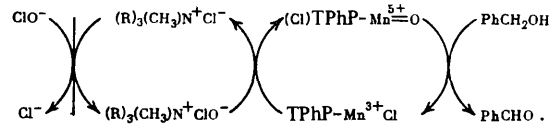


The norcaranyl free radical (D) formed can subsequently abstract one of the axial ligands from the complex TPhP-Mn.(Cl)(OH) or a chlorine atom from the chlorinated solvent and can also rearrange to the radical (E). The reactions of the radical (D) via several pathways are in fact responsible for the large assortment of reaction products.

It is seen from the foregoing that the specificity of the action of metalloporphyrins in the oxidation of hydrocarbons by iodosobenzene depends significantly on their structure and in particular on the nature of the central metal ion: thus, whereas Fe- and Cr-porphyrins catalyse selective oxidation, Mn-porphyrin initiates a radical process.

IV. REACTIONS OF ORGANIC COMPOUNDS WITH SODIUM HYPOCHLORITE

Metalloporphyrins are also effective catalysts of the oxidation of organic compounds by sodium hypochlorite in immiscible solvents in the presence of a phase transfer agent[155–158] (Table 3). The use of a porphyrin catalyst combined with a phase transfer agent gives rise to a powerful synergistic effect. Table 4 shows that, in the absence of one of the components of the catalytic system, the rate of oxidation of benzyl alcohol is appreciably reduced. The function of the phase transfer agent consists in transporting the oxidising ion ClO^{-} from the aqueous phase to the organic phase containing the substrate to be oxidised,[155] where the catalytic process actually takes place:



This oxidising system is very effective in the oxidation of alcohols and ethers to the corresponding aldehydes. Saturated hydrocarbons and olefins are oxidised fairly rapidly; for example, the degree of conversion of styrene in the presence of TPhP-MnOAc is 68% in 1 h,[156] the epoxide and other products being formed (Table 3).

The mechanism of the oxidation reaction involving sodium hypochlorite has not been investigated hitherto. However, one may suppose that it proceeds via the intermediate formation of the oxo-complex of the metalloporphyrin. Thus it has been shown[145] that the interaction of TPhP-MnOAc with NaClO results in the formation of a compound whose spectrum is analogous to that of the product of the reaction of TPhP-MnOAc with PhIO. Furthermore, the presence of chlorinated alkanes in the products of the oxidation of saturated hydrocarbons by the TPhP-MnCl–NaClO system[155] as well as the complete suppression of the reaction in the presence of the radical inhibitor 2,6-di-t-butyl-*p*-cresol[155] indicate a radical mechanism of the reaction. A similar mechanism is also characteristic of the TPhP-MnCl–PhIO system, which suggests that the active species involved in the two systems are identical.

V. THE INTERACTION OF OLEFINS WITH HYDROPEROXIDES AND PERACIDS

The reactions involving oxidation by hydroperoxide compounds and peracids in the presence of metalloporphyrins and metallophthalocyanines[133,136,141,159–168] (Tables 5–7) apparently proceed with participation of active species of a different kind than in the case of iodoso-compounds and sodium

hypochlorite. This is indicated, in particular, by the dependence of the proportions of the oxidation products on the nature of the oxidant (Table 7). In addition, according to Groves et al.,[141] the interaction of tetramesitylporphinatoiron chloride (TMP.FeCl) with perbenzoic acid and iodosobenzene results in the formation of compounds of different nature, manifesting different reactivities in the epoxidation of olefins.

It has been suggested recently that the reactions involving the transfer of oxygen from peroxy-compounds to the substrate being oxidised, catalysed by cytochromes P-450, proceed via the formation of a cytochrome–peroxy-compound complex.[169-171]

Notation: Pc = phthalocyanine ligand; W_e = content of epoxide in products.
*In benzene at 80 °C.

In the selective epoxidation of cyclohexene, *cis*- and *trans*-hex-2-enes, and isoprene with t-butyl hydroperoxide in the presence of the Cl(TPhP)Mo^{V}=O catalyst, towards the end of the induction period a complex was detected in the system by spectroscopy in the visible region, to which the structure (t-Bu–O–O)(TPhP)Mo=O was attributed.[159]

All these factors suggest that the first stage in the oxidation of hydrocarbons by hydroperoxides and peracids in the presence of metalloporphyrins and metallophthalocyanines is the formation of a catalyst–oxidant complex:

$$P\text{-}M^{n+} + ROOH \rightleftarrows [P\text{-}M^{n+}\cdot ROOH].$$

Such complexes have been described in the literature – these are the complexes of tetra(*p*-methoxyphenyl)porphinatoiron chloride T(*p*-CH_3O-Ph)P-FeCl with cumenyl hydroperoxide and substituted perbenzoic acids,[161] of T(p-X-Ph)P-Co (X = OCH_3, H, or Cl) with 1,2,3,4-tetrahydro-1-naphthyl, 1-methyl-1-phenylethyl, and t-butyl hydroperoxides,[172] of tetramesitylporphinatomanganese chloride with *m*-chloroperbenzoic acid,[173] and of Pc-Cu with cumenyl hydroperoxide.[174] In the last case it is assumed that the copper ion is not directly involved in the formation of the complex and that the complex formation reaction proceeds via the phthalocyanine ligand.[175]

The porphyrin and phthalocyanine complexes of molybdenum exhibit a high selectivity and stereospecificity in the epoxidation of olefins by hydroperoxides[159,160] (Table 5): the epoxidation of *cis*- and *trans*-hex-2-ene by t-butyl hydroperoxide in the presence of Cl(TPhP)Mo=O results in the formation of 97 and 99% of the *cis*- and *trans*-2,3-epoxides respectively;[159] the rate of epoxidation then depends on the nature of the olefin and increases with increasing nucleophilicity of the double bond.[160] On the other hand, in the presence of Fe-porphyrin catalysts the oxidation of olefins by hydroperoxides and peracids leads to the preferential formation of allyl oxidation products – unsaturated alcohols and ketones, and the content of epoxides is less than 1%[161] (Table 6).

Table 6. Dependence of the proportions of the cyclohexene oxidation products on the nature of the oxidant (catalyst–tetra-*p*-methoxyphenylporphinatoiron chloride).[161]

Oxidant	Proportions of products, %		
	epoxycyclohexane	cyclohex-2-en-1-one	cyclohex-2-en-1-ol
$(C_6H_5)(CH_3)_2CO_2H$	1	18	81
$(m\text{-}Cl-C_6H_4)CO_3H$	1	59	40
$(p\text{-}NO_2-C_6H_4)CO_3H$	1	51	49
C_6H_5IO	20	12	67

The complex of the metalloporphyrin or metallophthalocyanine with the hydro-peroxy-compound formed in the reaction system is converted via two pathways. On the one hand, it can epoxidise the olefin via a heterolytic mechanism (the oxidation state of the central metal ion does not change):

$$[P\text{-}M^{n+} \cdot ROOH] + \text{>C=C<} \rightarrow \text{>C(O)C<} + ROH + P\text{-}M^{n+}, \quad (4)$$

and, on the other hand, there is a possibility of the homolytic decomposition of the hydroperoxide via the following oxidation-reduction process:

$$[P\text{-}M^{n+} \cdot ROOH] \rightarrow P\text{-}M^{(n-1)+} + RO_2^{\cdot} + H^+, \quad (5)$$

followed by the oxidation of the olefin via a radical mechanism.

It is noteworthy that a homolytic oxidation pathway is postulated together with the heterolytic pathway in the reactions involving the oxidation of organic substrates by hydroperoxides and peracids and catalysed by cytochromes P-450.[40,45,115,176–179]

The selectivity of the epoxidation of olefins is determined by the relative contributions of the two competing pathways (4) and (5). The ratio of the Lewis acidity and oxidising capacity of the central metal ion determines its preferential involvement in a particular reaction. The more pronounced are the acidic properties of the metal ion the higher is the activity which it should exhibit in the heterolytic epoxidation reaction [reaction (4)] and the higher its oxidation-reduction potential the more effective should be its involvement in reaction (5). Electron-accepting substituents in the porphin ring of the catalyst and electron-accepting *trans*-ligands should enhance the acid properties of the central metal ion and hence should increase the activity of the catalyst in reaction (4).

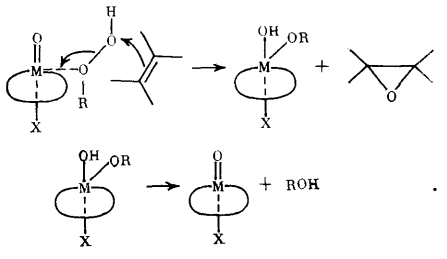
*Relative to the oxidant.

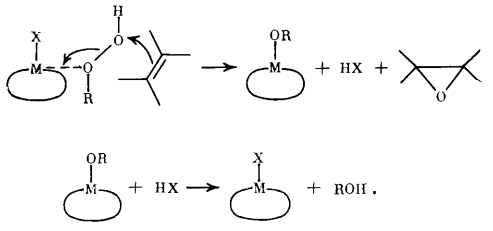
The higher selectivity of the epoxidation of olefins in the presence of the oxomolybdenum complexes of porphyrins and phthalocyanine compared with the Fe-porphyrin complexes (Table 5) is apparently associated with the fact that the Mo^{5+} ion, linked to the electron-accepting oxo-group, possesses a much higher Lewis acidity than tervalent iron (according to theoretical calculations,[180] the effective charge on the iron ion in TPhP-FeCl is +0.27).

Oxomolybdenumporphyrins and oxomolybdenumphthalocyanines also catalyse the radical oxidation of olefins by a hydroperoxy-compound; this is indicated by the fact that the selectivity of the epoxidation is not 100% (Table 5). This finding agrees with the fairly high oxidising capacity of the catalyst–$E_{1/2}(Mo^{5+}/Mo^{4+})$ = +0.11 V relative to the saturated calomel electrode has been obtained for (OH).(TPhP)Mo=O in DMF[181] [under the same conditions, $E_{1/2}$.(Fe^{3+}/Fe^{2+}) = −19 V [sic] for TPhP-FeCl [181]]. Fe-porphyrins catalyse preferentially the homolytic cleavage of the peroxide linkage [reaction (5)] and are almost inactive in the epoxidation reaction [reaction (4)].

By analogy with the mechanism of the action of molybenum oxide and vanadium oxide catalysts,[160,182–185] the mechanism of the transfer of peroxide oxygen from the complex P-M.ROOH to the olefin can be represented as follows. The function of the catalyst consists in displacing the electron density from the peroxide oxygen atoms, which increases the electrophilicity of the hydroperoxide and thus activates it with respect to the electrophilic attack by the olefin double bond:



The oxo-group of the catalyst fulfills the role of an intramolecular proton acceptor. In the absence of the M=O group, this role is apparently assumed by the axial ligand.



The olefin is apparently not coordinated to the metal ion of the catalytic centre. The reactivity of olefins having bulky substituents is determined mainly by steric factors and not by the nucleophilic properties of the double bond. Thus the epoxidation of isoprene by t-butyl hydroperoxide in the presence of (Cl)(TPhP)Mo=O results in the formation of 3,4-epoxy-3-methylbut-1-ene and 3,4-epoxy-2-methylbut-1-ene in proportions of 0.7 : 1.0, whereas in the reaction where $Mo(CO)_6$ is used as the catalyst the ratio is 4 : 1.[159] Similar steric effects have been noted in the oxidation of phosphines in the presence of TPhP.MoO_2: it has been shown that the rate constant is sensitive not to the electron-donating properties of the substituents R in the PR_3 molecule but to their size.[146]

According to kinetic data,[160] the reactions involving the epoxidation of cyclohexene and oct-1-ene by t-butyl hydroperoxide in the presence of Pc-MoO_2 in methylcyclohexane are of first order with respect to the hydroperoxide, the olefin, and the catalyst, i.e. epoxidation in accordance with reaction (4) takes place preferentially in the system. Apparently, apart from the fact that Pc-MoO_2 exhibits only a weak activity in reaction (5), the homolytic decomposition of the hydroperoxide is inhibited by the olefin and the solvent.

After the formation of the primary radical via reaction (5), the hydroperoxide decomposition process proceeds via the following mechanism:

$$2RO_2^{\cdot} \rightarrow 2RO^{\cdot} + O_2;\ RO^{\cdot} + RO_2H \rightarrow ROH + RO_2^{\cdot}.$$

In the presence of a solvent SH containing active C–H bonds or of an olefin, the kinetic hydroperoxide decomposition chain terminates:[160]

$$RO^{\cdot}(RO_2^{\cdot}) + SH \rightarrow ROH(RO_2H) + S^{\cdot},$$
$$S^{\cdot} + RO_2^{\cdot} \rightarrow SO_2R \rightarrow \text{products},$$
$$S^{\cdot} + O_2 \rightarrow SO_2^{\cdot} \rightarrow \text{products},$$

or

$$RO^{\cdot}(RO_2) + -CH_2-CH=CH_2 \rightarrow ROH(RO_2H) + -\dot{C}H-CH=CH_2,$$
$$-\dot{C}H-CH=CH_2 + RO_2^{\cdot} \rightarrow -CH(O_2R)-CH=CH_2 \rightarrow \text{products},$$
$$-\dot{C}H-CH=CH_2 + O_2 \rightarrow -CH(O_2^{\cdot})-CH=CH_2 \rightarrow \text{products}.$$

Indeed the rate of decomposition of t-butyl hydroperoxide in benzene and chlorobenzene is 8 times higher than in cyclohexane and methylcyclohexane.[160]

The formation of the products of the allyl oxidation of olefins, characteristic of catalysts active in the homolytic decomposition of hydroperoxide [reaction (5)], can be represented as follows:

$$-CH(O_2R)-CH=CH_2 \xrightarrow{\text{catalyst}} -CH(\dot{O})-CH=CH_2,$$
$$2-CH(\dot{O})-CH=CH_2 \rightarrow -\underset{\underset{O}{\|}}{C}-CH=CH_2 + -CH(OH)-CH=CH_2.$$

It is known that peracids effectively epoxidise unsaturated hydrocarbons.[186,187] Thus the selectivity of the epoxidation of cyclohexene by *m*-chloro- and *p*-nitroperbenzoic acids via the stoichiometric reaction is very high, amounting to 82–92% (Table 8). The introduction of the Fe-porphyrin catalyst into the system alters sharply the composition of the oxidation product and lowers their epoxide content to 1%. This is associated with the fact that the active decomposition of the peracids via reaction (5) in the presence of T(OCH_3-.Ph)P-FeCl suppresses the epoxidation reaction.

Table 8. Proportions of the products of the oxidation of cyclohexene by peracids.[161]

Catalyst	Oxidant	Yield*, %	Proportions of products, %		
			epoxycyclohexane	cyclohex-2-en-1-one	cyclohex-2-en-1-ol

*Relative to the oxidant.

Table 9. The yield* (%) of the products of the oxidation of cyclohexane by cumenyl hydroperoxide.[162]

Catalyst	TPhP-CoCl	TPhP-FeCl	THp-MnCl	TPhP-Os(CO)(Py)
Cyclohexanol	45	40	1	5
Cyclohexanone	23	20	0.5	2.5

*Relative to the hydroperoxide.

According to Mansuy and coworkers,[133,162] TPhP-FeCl, TPhP-CoCl, and TPhP-RhI effectively catalyse the oxidation of cyclohexane by cumenyl hydroperoxide with formation of cyclohexanol and cyclohexanone in proportions of 2 : 1. (CO)(Py)(TPhP)Os, TPhP-CrCl, and TPhP-MnCl show a lower activity in this reaction, while Cu^{II}-, Ni^{II}-, Zn^{II}-, and Mg^{II}-TPhP, TPhP-V^{IV}=O, and TPhP-Ti^{IV}=O are inactive (Table 9). It has been observed that Fe-porphyrins catalyse the oxidation of n-heptane by cumenyl hydroperoxide[133] with formation of alcohols and ketones. Presumably in these systems, the hydroperoxide undergoes homolytic decomposition via reaction (5) with subsequent involvement of cyclohexane and n-heptane in the radical process. This is indicated by a number of factors – the rapid decomposition of cumenyl hydroperoxide at the beginning of the reaction[162] and the activity of only those catalysts whose central metal ion is capable of undergoing a change in the oxidation state, which is essential for the occurrence of reaction (5). Indeed the central metal ion is involved in the oxidation-reduction cycles of Cr-, Mn-, Fe-, Co-, and Os-porphyrins, while the oxidation-reduction of Cu-, Zn-, Mg-, TiO-, and VO-porphyrins involves the porphyrin ring. In the case of TPhP-Ni the Ni^{2+} ion and the TPhP ligand are oxidised at the same potential (Table 10); according to Yamada and Kamiya,[172] TPhP-Ni and TPhP-Cu do not form complexes with hydroperoxides. Furthermore, the increase of the activity of the catalysts containing a tervalent metal ion with increase of their oxidising

capacity is consistent with the proposed homolytic decomposition of the hydroperoxide, i.e. TPhP-MnCl < TPhP-FeCl < TPhP-CoCl (Table 10).

*Potentials relative to the saturated calomel electrodes; reduction in DMF or dimethyl sulphoxide; oxidation in CH_2Cl_2 or butyronitrile.
**Irreversible oxidation.

Thus the mechanism of the oxidation of olefins by hydroperoxides is determined by the nature of the metalloporphyrin or metallophthalocyanine catalyst – the acid and oxidation-reduction properties of the central metal ion determine the reaction pathway, which involves either the activation of the hydroperoxide for electrophilic attack on the olefin or the homolytic decomposition of the hydroperoxide and subsequent free-radical oxidation of the olefin.

---o0o---

In conclusion, it must be emphasised that the presence in metalloporphyrin molecules of a central metal ion in different oxidation states and having in the *d* shell electrons with unpaired spins together with a planar porphyrin ligand having an extensive π-conjugation system gives rise to the possibility of a wide variety of different types of action by metalloporphyrins in reactions involving the oxidation of organic compounds by molecular oxygen and oxygen-containing oxidants: they can catalyse a selective oxidation reaction and can initiate free-radical oxidation.

The behaviour of metalloporphyrins in oxidation reactions depends very greatly on their structure, i.e. on the nature of the central metal ion and the porphyrin ligand. In particular, the replacement of the metal ion can alter radically the mechanism of the oxidation of organic substrates by oxygen-containing compounds.

Strictly speaking, metalloporphyrins are not true catalysts of the selective oxidation of organic compounds by molecular oxygen because a reductant is necessary for the regeneration of the catalyst and the completion of the catalytic cycle.

The reactions involving the epoxidation of olefins by iodosobenzene, sodium hypochlorite, and hydroperoxides, and other oxygen donors[188] in the presence of certain metalloporphyrins and phthalocyanines do not require a reductant and they can be regarded as truly catalytic.

The proposed mechanisms of the selective oxidation of organic substrates by molecular oxygen and iodosobenzene presuppose the formation of the peroxo- or oxo-complex of the metalloporphyrin respectively, the coordination of the substrate being oxidised to the metal ion in this complex, and its subsequent insertion in the metal-peroxo or metal-oxo bond. The porphyrin ligand apparently plays the very important role of an electron "buffer", stabilising the transition states of the catalytic process.

It is significant that the nature of the reductant determines the composition of the products of the oxidation of olefins by molecular oxygen. When weak reducing agents are used, the corresponding epoxy-derivatives are formed. Strong reductants effect the reductive cleavage of the M–C and O–O bonds in the cyclic intermediate complex, which leads to the formation of saturated alcohols and ketones.

From the standpoint of the solution of the problem of the creation of new catalytic systems for mild selective oxidation, we believe it is useful to investigate reactions involving the oxidation of organic compounds by molecular oxygen in the presence of metalloporphyrins and reductants. The choice of a suitable reductant is then crucial, since it determines the nature of the resulting oxidation product.

New Spectroscopic Methods in Gas-Phase Chemical Kinetics

O.M.Sarkisov and S.G.Cheskis

The possibilities provided by the application of advances in laser technology to the solution of problems in gas-phase chemical kinetics have been analysed. The basic principles of various laser methods for producing and recording active chemical species have been described. Examples of the use of lasers to study the reactions of radicals and excited species, in the diagnostics of complex chemical processes, and to carry out selective laser-chemical reactions have been examined.
The bibliography contains 110 references.

III. The use of lasers in gas-phase chemical kinetics 235

I. INTRODUCTION

Particular attention has been paid to different problems at various stages of the development of gas-phase chemical kinetics, depending on the state of the theory, practical requirements, and available methods of study. In recent years, a qualitative leap has been made in physicochemical methods of study. The production of lasers, particularly tunable lasers, has made it possible to develop effective methods both for studying a chemical reaction and for influencing it. These methodological possibilities have not only raised studies in traditional directions to a qualitatively higher level but have also defined new and promising problems in gas-phase chemical kinetics.

From the beginning of the development of gas-phase chemical kinetics, two main directions have existed: the study of the general regular features of the course of complex chemical reactions and the study of the elementary steps. The study of complex chemical reactions has shown that most of them consist of a set of elementary steps involving extremely reactive intermediate species — radicals. The general regular kinetic features of radical, chain, and chain branched reactions have been established. These general regular features have been demonstrated for oxidation, halogenation, and cracking reactions. A fundamental contribution to the development of this field was made by Semenov's general theory of chain reactions.[1,2]

The course of a chemical reaction is influenced considerably not only by the active species but also by the energy liberated in the exothermic elementary stages. Allowance for the liberated energy has led to the establishment of the regular features of the non-isothermal course of a reaction. A theory of thermal self-ignition has been developed.[2,3] In these theories, however, it has been assumed that the energy is liberated as heat, and that it can be characterised by a single temperature for all degrees of freedom.

Analysis of all the established regular features has shown that the study of complex chemical reactions cannot be restricted to kinetic measurements of the concentrations of stable species, but must include the recording of the radicals driving the reaction chain and the quantitative study of elementary reactions. The need for quantitative data on elementary reactions is increasing continuously, due to the increasing demands of practice, which requires increasingly reliable quantitative information on the mechanisms of chemical processes.

At the present time there are comparatively simple and general theoretical approaches for calculating the rate constants of elementary reactions taking place under the conditions of Maxwell–Boltzmann energy distribution for the species. These are the transition state method for direct bimolecular reactions and the statistical theory of unimolecular reactions (RRKM theory) and bimolecular reactions, which essentially uses the ideas of the transition state method. These theories give explicit expressions for reaction rate constants in terms of the parameters of the potential energy surfaces.[4-6] The accuracy with which these parameters are known is quite inadequate, however, so that the experimental determination of the rate constants of elementary reactions remains an important problem in gas-phase chemical kinetics.

The subsequent development of the theory of gas-phase chemical kinetics is related to the fact that different forms of the energy of molecules (translational, rotational, vibrational, and electronic excitation energy) are not equivalent from the viewpoint of overcoming the activation barrier. A large number of studies have shown that the breakdown of the Maxwell–Boltzmann distribution of the energy with respect to different degrees of freedom of the reacting species may have a significant influence on the course of a reaction. One clear example of this is provided by the discovery of the class of reactions with energy branching.[7-9] In reactions of this class, vibrationally excited products are formed in the elementary stages of chain propagation. These vibrationally excited species take part in chain branching in different ways. Many complex chemical processes must probably now be analysed with allowance for their energetic non-equilibrium character. The breakdown of the Maxwell–Boltzmann distribution may be brought about not only by a chemical reaction but also by physical methods, for example in plasmochemical and photochemical processes. The production of chemical lasers[10,11] has shown that chemical reactions can be used successfully to convert chemical energy into the energy of coherent optical radiation.

Simple allowance for the reactions of atoms and radicals is insufficient for the kinetic analysis of energetically non-equilibrium processes. It is necessary to know the rate constants of the microscopic processes involving reagents and products in definite quantum states. In this sense it can be said that gas-phase chemical kinetics has now reached the quantum level. Calculations on elementary reactions of this type generally require a detailed analysis of the dynamics of the process, which is not carried out when the transition state method and statistical theory are used.[4-6]

In principle, if quantum effects are insignificant (and this is fairly often the case), the solution of the corresponding problem for a given potential surface is possible using present-day computing methods, even if tens of atoms are involved in the process of chemical rearrangement. As noted above, however, there are practically no data on potential surfaces. Thus the development of theoretical ideas requires

experimental data on the energy distribution in the reaction products, on the intermolecular processes involved in the transfer of different forms of energy, on the intramolecular processes of the transfer of excitation, and on the reactions of species in definite quantum states.

Progress in laser technology has increased sharply the possibilities provided by photochemistry. In laser photochemistry there is extensive discussion of the question of whether selective chemical transformations can be carried out by organising a non-equilibrium state of definite character. An example of selective laser photochemical processes is provided by the separation of isotopes under the influence of laser radiation.[12] The study of the more general principles of selective laser photochemistry is now being carried out in three directions.

1. The selective rupture of molecular bonds in definite positions, and not according to statistical laws. For this it is necessary to develop a method for exciting "local modes" by a powerful short pulse so effectively that they undergo rupture before the energy acquired by the molecule in the pulse is able to undergo statistical redistribution.

2. The carrying out of endothermic reactions at low temperatures by the transfer to the reacting species of that form of energy which is most effective for overcoming the activation barrier.

3. Elementary processes of a new type, which have been called "chemical radiation collisions"[13] are now being discussed. In these new processes, reacting species and photons take part in reactions simultaneously. It should be emphasised that these are not the reactions of reagents excited by light, but reactions in which the powerful electromagnetic field of a light wave changes the potential surface of a system, and hence the probability of the reaction and the reaction channel. The development of studies in this direction is restricted by the need to use very powerful sources of monochromatic radiation.

In the establishment of gas-phase chemical kinetics, most attention has been paid to purely scientific questions, whereas at the present time, fundamental studies are closely related to practical requirements. For example, the study of chemical processes in the atmosphere is related to such practical problems as the preservation of the ozone layer and the purity of the troposphere (smog, acid rain, etc.). The problem of organising economic combustion processes which do not contaminate the environment can now be solved using the details of the chemical mechanism of combustion with allowance for non-equilibrium and hydrodynamic factors. To optimise the operation of the active media in various gas lasers, it is necessary to know the quantitative characteristics of the elementary processes involving the excited species. The search for new active media for chemical lasers is closely related to the study of the energy distribution of reaction products.

Moreover, the organisation of energetically non-equilibrium processes in which the energy is used in the form most effective for overcoming activation barriers may provide a promising route for the development of new processes for chemical technology.

II. METHODS OF LASER SPECTROSCOPY

The present section examines methods for producing and recording labile species (atoms, radicals, excited species). The examination will be restricted to existing methods based on developments in laser technology.

1. Methods of Recording Labile Species

Laser spectroscopy is now widely used for analytical purposes (see the published review[14]). Only those methods which are used in gas-phase chemical kinetics will be examined here.

Laser absorption spectroscopy (LAS). In classical spectroscopy, the absorption method is used successfully, and more frequently than other methods. It is sufficient, for example, to mention the achievements of kinetic spectroscopy combined with flash photolysis.[15] One of the main problems in absorption methods is to increase their sensitivity with a high spectral resolution. Classical light sources generally have insufficient power in a narrow spectral range, and this restricts the sensitivity of classical absorption spectroscopy.

The use of a laser as a light source in the absorption method makes it possible to increase sharply both the sensitivity of the method and the spectral resolution. This is related to the fact that laser radiation is highly monochromatic, directed, and intense. Lasers are now used in both the infrared and visible ranges. Thus a spectrometer has been developed, based on tunable semiconducting lasers, with a working spectral range of 4–20.5 μm and a spectral resolution of $\sim 10^{-3}$ cm^{-1}.[16] Typical parameters of the absorption method (and other methods) are given in Table 1.

Table 1. Comparative characteristics of laser spectroscopic methods.

Parameter	Methods				
	LAS	IRLS	LMR	FP	CARS
Time resolution, s	10^{-6}	10^{-6}	10^{-2}—10^{-3}	10^{-8}—10^{-9}	10^{-8}
Spatial resolution	1 mm	1 mm	1 mm	10^{-6} cm^{-3}	10^{-5}-10^{-6} cm^{-3}
Sensitivity, cm^{-3}	10^{12}—10^{13}	10^{8}—10^{10}	10^{8}—10^{10}	10^{9}—10^{10}	10^{13}—10^{14}
Spectral resolution, cm^{-1}	0.03	0.03	10^{-2}—10^{-4}	10^{-3}	10^{-2}—10^{-3}
Spectral range, μm	0.2—10	0.4—1.2 and 2.7—3.0	4.0—2000	0.2—1.0	infrared range

Laser magnetic resonance (LMR). The physical principles of LMR are similar to those of EPR. The energy of the laser quantum is chosen to be close to the energy gas (ΔE) between two levels of the fine structure in the case of atoms and two rotational or vibrational-rotational levels in the case of radicals. Resonance between ΔE and the energy of the light quantum is achieved using an external magnetic field. The radiation sources used are gas lasers in the sub-millimetre range (H_2O lasers, lasers with optical pumping) and in the infrared range (CO_2 and CO lasers).

The first laser magnetic resonance spectrometer (LMRS) in the sub-millimetre range was developed in the USA in 1970,[17] and the first LMRS operating in the infrared range, based on a CO_2 laser, was developed in 1975 in the Institute of Chemical Physics of the Academy of Sciences of the USSR.[18]

The high sensitivity of magnetic resonance methods is due primarily to the use of magnetic modulation and a synchronous detection system. A second factor increasing the sensitivity is the positioning of the reaction vessel inside the laser resonator. A theoretical analysis of in-resonator absorption in LMR has been carried out,[19] and the theory has been verified

experimentally.[20] It was found that there is an optimum value of the frequency of magnetic modulation (which is close to the frequency corresponding to the characteristic vibrational relaxation of the laser) at which there is a marked increase in the effective length of the optical path. The fact that this optimum frequency is close to the frequency of modulation of standard EPR spectrometers enabled Gershenzon and coworkers[21] to develop a new class of combined EPR–LMR spectrometers, based on standard radio-spectrometers. In this spectrometer, the gas specimen is present simultaneously in the resonator of the EPR spectrometer and in the resonator of the CO_2 laser. The parameters of the LMR method when used under continuous conditions are given in Table 1.

The possible use of LMR with a resolution of ~4 μs was recently demonstrated.[22] The relatively high sensitivity (~10^{11} SiH_3 radicals per cm^3) was achieved by signal accumulation.[22]

In-resonator laser spectroscopy (IRLS). IRLS was proposed by Soviet workers in 1970.[23] The method is based on the influence of the substance being studied on the parameters of laser radiation. In IRLS, the substance being studied, for example a gas with species having narrow absorption lines in the lasing band, is placed in the resonator of a laser with a broad amplification contour. The parameters of the active medium of the laser are selected in such a way that the amplification of the light intensity in it compensates the losses at the mirrors, but does not compensate the losses associated with the absorption being studied (these losses are distinguished by their frequency dependence). The losses at the mirrors correspond to broader bands, compared with the narrow absorption lines of the substance being studied.

The problems related to the analysis of the necessary conditions for obtaining high sensitivity have been described.[24] In IRLS it is possible to use media in which the width of the uniform lasing contour is much greater than the width of the absorption line in gases. It has been shown theoretically and experimentally that the intensity of lasing at the frequency of the absorption line will be described by the equation:

$$I = I_0 \exp\left(-\sigma n \frac{l}{L} ct\right)$$

where n is the concentration of the substance being studied; σ the photon absorption cross-section; c the velocity of light; l the length of the cell; L the length of the resonator; t the lasing time; and I_0 the intensity of the radiation at the start of lasing, which is assumed to be independent of the frequency. The intensity of lasing at other frequencies, not coinciding with the absorption lines, is practically independent of time.

This equation shows that the method is analogous to the absorption method; the optical path length is $(l/L)ct$. For a lasing time of 10^{-3} s and $l/L = 0.3$, the optical path length is 10^5 m. This long optical path length can be achieved with a reaction vessel with small geometric dimensions. At the same time, the brightness of the light source remains high, and it is possible to use spectrographs with a high spectral resolution.

The active media used in IRLS include glasses doped with neodymium, solutions of organic dyes, and alkali metal halide crystals with colour centres.

Laser induced fluorescence (LIF). The LIF method involves the laser excitation of the electronically excited states of atoms and molecules and the subsequent observation of fluorescence from these states. The intensity of the fluorescence in most cases is proportional to the population of the state excited by the light, and this makes it possible to measure the concentration of molecules in this state. The excitation sources used include pulse and continuous lasers, most frequently dye lasers. The fluorescence is usually observed in a direction at right angles to the line of propagation of the laser radiation. The applicability of the method is restricted by the need for a fairly high fluorescence yield. This last requirement, because of the existence of non-radiative deactivation of electronically excited states, restricts the possibilities provided by the method at fairly high pressures. In those cases where the LIF method is applicable, however, it is very effective. This is related to the fact that the method shows high time and spatial resolution and unique sensitivity. The high spatial resolution makes it possible to carry out a local analysis in a very small volume. Theoretically, this volume may amount to λ^3, where λ is the wavelength; in practice, a volume of ~10^3 μm^3 is easily achieved. The time resolution of the method is related to the duration of the pulse (reaching 10^{-12} s).

The highest sensitivity can be achieved using continuous lasers for the excitation; it is often possible to realise saturation conditions, that is conditions in which the species being studied exists for equal times in the excited and ground states. In this case, even a single atom can emit a large number of photons in one second, and this makes it possible to record single atoms.[25] The use of continuous lasers, however, has some disadvantages, such as the relatively small spectral range of operation (400–900 nm) and the low time resolution. For a number of problems, therefore, it is more appropriate to use pulse lasers (particularly in the ultraviolet range) in the LIF method.

The development of non-linear optics has made it possible to move far into the short-wave range of the spectrum using powerful pulse lasers and frequency-doubling crystals. A spectral range to 200 nm is now easily achieved. Lasing at much shorter wavelengths of the spectrum has also been described. For example, the production of non-tunable radiation in the region of 39 nm has been reported.[26]

Active Raman spectroscopy (ARS or CARS). This method is based on the fact that in a field of sufficiently intense light rays with frequencies ω_1 and ω_2 satisfying the condition $\Omega = \omega_1 - \omega_2$ (Ω is the frequency of the molecular vibrations), build-up of molecular vibrations with frequency Ω takes place. As a result, the light ray with frequency ω_1 begins to be scattered on the excited vibrations with the appearance of radiation at the anti-Stokes frequency ($\omega_a = \omega_1 + \Omega = \omega_2 + 2\Omega$). The sensitivity of the method depends on the intensity of the radiation at the frequency ω_a. To obtain sufficiently intense radiation at the frequency ω_a it is necessary that definite relationships between the wave vectors of the light rays with frequencies ω_1 and ω_2 be satisfied. This condition is most frequently satisfied by using collinearly propagating light rays with frequencies of ω_1 and ω_2. Although this configuration is easily realised, it lowers the spatial resolution of the method. There are however methods which make it possible to obtain high sensitivity together with good spatial resolution by this method. CARS has been described in detail.[27] The CARS method most frequently uses the second harmonic of a YAG:Nd^{3+} laser (frequency ω_1) and a tunable laser based on dye solutions (frequency ω_2).

2. Comparison of the Methods

The possibilities of using laser spectroscopy to solve problems in gas-phase chemical kinetics are determined by the following parameters: sensitivity, time resolution (which

characterises the speed of the method), spectral resolution (which makes it possible to record species in definite quantum states), spatial resolution (which shows the possibility of local analysis), and the spectral range of action of the method (which characterises the universality of the method). These characteristics of the methods show that a particular method is preferred for the solution of each problem. The parameters of the methods described above are given in Table 1. It should be emphasised that the figures given in Table 1 are not the best values, but typical values achieved in many studies. The sensitivity depends not only on the method but also on the absorption cross-section of the species being recorded. Since the values of the cross-sections are different for different molecules, the sensitivity of the methods is represented by a fairly wide range of values in Table 1.

Table 1 shows that the absorption method, and also the IRLS and LMR methods, do not make it possible to carry out a local analysis. In those cases where the reaction medium shows symmetry with respect to one of the axes, these methods can be used to analyse the distribution of the concentration of the species in space. A volume local analysis can be carried out only by LIF and ARS methods. These methods also have the highest time resolution. The LIF method has the highest sensitivity, although it is not very general, since the radiative channel for the relaxation of the excitation is often very weak. The ARS method, however, is fairly universal. The use of a tunable laser in this method makes it possible to select any frequency difference $\omega_1 - \omega_2$, so that ARS can be used to record any species in which there is an active Raman transition. A disadvantage of the ARS method is the relatively low sensitivity.

The absorption method and the LMR method are also fairly universal, since they cover the infrared range, in which the vibrational frequencies of many species lie. LMR can record only paramagnetic species, whereas the absorption method can record all species. The sensitivity of the LMR method is much higher, however. The combination of LMR and EPR in a single instrument increases the possibilities provided by LMR, since the measurement of the absolute concentrations by the LMR method can be carried out using EPR, for which a method for measuring absolute concentrations already exists. The LMR method, and also the absorption method using continuous lasers, have relatively low time resolution. Pulse versions of LMR and the absorption method have recently appeared, which make it possible to obtain a time resolution of $\sim 10^{-6}$ s.[16-22] One of the disadvantages of working in the infrared range is the sharp decrease in sensitivity in studies at high pressures, because of pressure broadening of the absorption lines. IRLS makes it possible to work with a high sensitivity at higher pressures. This method also has a fairly high time resolution. IRLS makes it possible to record with a high sensitivity not only absorption, but also the amplification of light when there is inversion of the population of the energy levels in the medium being studied. A disadvantage of the IRLS method is the restriction of the spectral range of applicability in the ultraviolet (to 350 nm).

Comparison of the parameters of the method described shows that the methods supplement one another. The parameters given in Table 1 for these methods show the type of problem for which it is appropriate to use a particular method. Thus ARS should be most widely used to probe flames. In combustion processes, the concentrations of even the labile species are generally relatively high, so that a high sensitivity is not required. For the solution of these problems, primary importance is also acquired by the characteristics of the ARS method, since it is universal, and permits local analysis. For the study of reactions involving radicals, laser spectroscopy in the infrared range is most widely used. It is convenient to use LMR to record radicals. LMR combined with EPR is particularly promising for the study of the kinetics of the reactions between two radicals.

For the study of processes involving very short-lived species, it is appropriate to use pulse methods such as IRLS and LIF, which give the required time resolution. Because of its unique sensitivity, it is also appropriate to use LIF to obtain information on the primary distribution of energy in an elementary chemical experiment.

Specific examples of the use of these methods will be described below.

3. Methods for Producing Labile Species

To study various processes involving labile species, it is necessary to have methods for obtaining them. The present examination will be restricted to laser methods for producing radicals and excited species. The most widely encountered method for obtaining radicals is by flash photolysis. The combination of this method with classical kinetic spectroscopy made it possible to begin the quantitative study of reactions involving radicals. In the classical version of the method, however, it was usually necessary to use a high energy flash to produce the photolysis; the light was not monochromatic. As a result of absorption, part of the light energy was used up in the dissociation of the molecule, and part was liberated in various degrees of freedom of the molecules and their fragments. The existence of excited species of different types and the non-isothermal conditions under which the reaction took place, often made quantitative studies difficult.

The use of the more sensitive methods of laser spectroscopy to record radicals makes it possible to lower considerably the energy of the radiation producing the photolysis. The replacement of the light source by a laser source makes it possible to use monochromatic radiation for the photolysis, and hence to obtain radicals (and other species) with a definite energy content. Another advantage of the use of lasers for the production of radicals and excited species is the possibility of producing the necessary concentration of labile species in a local volume in very short time intervals. If the labile species are recorded in a local volume with very short delay times between the irradiating and probing pulses, even lower irradiation pulse energies are required to produce a detectable concentration of labile species.

The simplest method fairly frequently used to obtain excited species is by direct one-photon optical excitation. This method is most frequently used in the infrared range for the selective excitation of the lower vibrational states of molecules.[28-30] For medium absorption cross-sections $\sigma = 10^{-18}$–10^{-20} cm^2 and existing laser powers, it is fairly easy to achieve saturation conditions, that is to transfer half of the irradiated molecules from the ground to the excited state. An analgous technique can be used to excite the electronic states of molecules in the visible and ultraviolet ranges. The possibilities in this case (from the viewpoint of the ease of obtaining high concentrations of excited species) do not differ greatly from the conditions in the infrared range.

Direct one-photon optical excitation can also be used to obtain excited species in higher vibrational levels. It is possible to use initial excitation of the molecule into an electronically excited state by a quantum of visible or ultraviolet light and subsequent internal conversion of the molecule from the excited electronic state into high vibrational levels of the ground state.[31] Another method involves the direct excitation by a quantum of visible light of the higher overtones of the vibrational transitions of a molecule. In spite of the fact that the cross-section of this process is small, the high power of the laser source makes it possible in a number of cases to

produce an appreciable concentration of molecules in states excited to high vibrational levels.[32,33]

The high power of laser radiation makes it possible to use multiphoton processes of different types to produce excited species. These processes include, for example, Raman scattering, in particular stimulated Raman scattering (SRS). In a number of cases it is possible to obtain up to 10^{16} photons at the Stokes frequency after one laser pulse. Since each photon at the Stokes frequency corresponds to one excited molecule, it can readily be seen that SRS can be used to obtain appreciable concentrations of excited species. It is particularly fortunate that when Raman scattering is used, it is possible to excite the levels of molecules corresponding to transitions which are inactive in the infrared spectrum and which therefore cannot be excited by direct optical excitation, for example the totally symmetric vibration (in particular, it is possible to excite the homonuclear diatomic molecules H_2, N_2, etc.).

Excited species are often produced by SRS under pre-threshold conditions at low pressures of the mixture being studied. Laser radiation with two frequencies in the visible range ω_1 and ω_2 is directed on to the object being studied, and the frequency difference corresponds to the frequency of the vibrational transition of the molecule being studied. The radiation of frequency ω_1 is usually the powerful radiation of a non-tunable laser (for example the second harmonic of a YAG : Nd^{3+} laser), and the radiation of frequency ω_2 is obtained by SRS in a high-pressure cell filled with the substance being studied. The use as the source of the radiation ω_2 of the frequency-tunable radiation of a dye laser (two-frequency coherent excitation (TCE) method[34] is promising. The multiphoton infrared excitation of molecules has been widely used.[35,36]

Methods for obtaining species excited to definite levels of internal degrees of freedom have not yet been considered. In a number of cases, however, laser methods also make it possible to obtain molecules with a velocity vector of definite magnitude and direction. If a molecule for which the line contour is determined by Doppler broadening is excited using a laser whose spectral width is appreciably smaller than the width of the absorption line, then only molecules moving at a definite velocity in the direction of the laser beam will be excited. For example, if the laser frequency corresponds to the frequency of the centre of the absorption line, only the molecules "at rest" will be excited.[37] Laser methods also make it possible to excite orientated molecules in definite fashion. Use is made of the polarisation of the laser beam, that is the fact that when radiation interacts with matter, selective excitation is undergone by those molecules for which the transition moment is parallel to the light polarisation vector. It is thus possible to study the reactions of molecules oriented in definite fashion and to investigate the influence of steric factors on the course of a reaction. Some examples will be given later.

III. THE USE OF LASERS IN GAS-PHASE CHEMICAL KINETICS

In this section, an attempt will be made, using specific examples, to demonstrate the possibilities provided by the use of lasers to solve problems in gas-phase chemical kinetics.

1. Elementary Reactions Involving Radicals

The modern development of the theory of chemical transformations, and the increasing demands being made by the chemical industry, require increasingly reliable and accurate quantitative data on the rate constants of elementary reactions. In addition, an important field of study has appeared, namely the chemistry of the atmosphere, in which traditional macro-kinetic methods are probably generally inapplicable, and the modelling of chemical processes by a set of elementary reactions is of decisive importance. Most gas-phase reactions involve the participation of atoms and radicals. The greatest experimental difficulties are encountered when recording polyatomic radicals. Table 2 gives examples of elementary processes of several types involving polyatomic radicals: a) reactions of radicals with stable molecules; b) reactions between radicals; c) processes involving the heterogeneous destruction of radicals. The examination has been restricted to several examples of reactions involving radicals consisting of three or more atoms.

Table 2. Some elementary reactions of radicals, studied by laser spectroscopy.

Radical	Reagent	Method
NH_2	NO [38—40]; O_2 [41, 42]; O_3 [43, 44]; C_2H_4, C_2H_2 [40]; HO_2; NH_2 [45]; CH_3 [46]	IRLS [38, 42, 43, 45]; LAS [41]; LIF [39, 40, 44, 46]
CHF	O_2, NO [47]	LIF [47]
HCO	O_2 [48, 49]; NO [48, 50]; H [51]; HCO [52]	IRLS [48-52]
HNO	NO, HNO [53]	IRLS [53]
PH_2	O_2 [54], PH_2 [55]	IRLS [54, 55]
HO_2	NO [56]; HO_2, O, Cl, OH [57,58]; ClO[59]; H[60]	LMR [56-60]
NF_2	NF_2 [61]; O, N, F, H [62]	LMR [61, 62]
CH_3O	O [63]	LIF [63]
$C_6H_5CH_2$	O_2, Cl_2 [64]	LIF [64]
NH_2	surface of quartz reaction vessel	IRLS [38]; LIF [40]
HO_2	ditto	LMR [65]

Note. Numbers in square brackets denote references (Ed. of Translation).

The high reactivity of radicals makes it difficult to obtain them in sufficiently high concentrations. Moreover, if it is nevertheless possible to create high concentrations of radicals, the study of the reaction of a radical with a molecule is always made difficult by the existence of quadratic reactions involving the interaction between radicals. Thus one of the basic features required of modern methods for studying elementary reactions is a high sensitivity. It can be seen from Table 2 that it is because of the low sensitivity of the CARS method that it is not usually employed for the quantitative study of elementary reactions. All the other methods discussed earlier are used to study elementary reactions.

An attempt will now be made to discuss the advantages and disadvantages of each method in relation to the problem being discussed in the present section. LMR is attractive primarily because of its universality and the possibility of recording (particularly for LMR using lasers in the sub-millimetre region of the spectrum) many paramagnetic species involved in an elementary reaction. In addition, the possibility of obtaining the EPR and LMR spectra simultaneously using combined LMR–EPR spectrometers facilitates the task of determining absolute concentrations in the study of the reactions of radicals, when the concentrations of the reacting species are comparable.

In a study[62] of the reaction $O + NF_2$ using a combined LMR–EPR spectrometer, [O], [NF_2], and [F] were recorded. This made it possible to obtain the rate constant of this reaction and to determine the main channel by which it takes place

$$O + NF_2 \rightarrow FNO + F$$

The following reversible reaction has been studied:[56]

$$HO_2 + NO \rightleftarrows OH + NO_2$$

This work[56] is of interest from the methodological viewpoint, since the concentrations of the species OH, HO_2, and NO_2 were measured. This made it possible to study the temperature dependence of the rates of both the forward and back reactions.

A disadvantage of the LMR method is its low time resolution. For this reason, LMR is combined with flow methods. When sufficiently rapid gas streams are used, the effective time resolution can be brought to $\sim 10^{-3}$ s. Nevertheless, in the study of a reaction under flow conditions, side processes of different kinds, for example heterogeneous processes, may be superimposed on the reaction being studied. It was noted above than an LMR method with a high time resolution has been developed.[22]

The IRLS and LIF methods have a fairly high time resolution (see Table 1). They can therefore be used in static systems with the flash production of radicals. The use of these methods, because of their high time resolution, makes it possible to avoid the influence of heterogeneous processes, that is to study a reaction in a time which is shorter than the diffusion time of the active species to the walls of the reaction vessel. An example is provided by the use of IRLS to study the reactions of PH_2 radicals.[54,55] Another important advantage of IRLS in the visible wavelength range is that it can be used at high pressures in the system. This makes it possible, for example, to measure the rate constants of fairly slow reactions. IRLS, combined with flash photolysis, has been used[42] to study the destruction of NH_2 radicals, formed by the photolysis of NH_3, in the presence of O_2. The total pressure in the system reached 570 mmHg, and in principle could have been even higher. This made it possible to estimate the rate constant of the reaction $NH_2 + O_2 \xrightarrow{k_1}$ products; $k_1 < 3 \times 10^{-18}$ $cm^3\ s^{-1}$. IRLS has also been used[66] to estimate the rate constant of an even slower reaction: $HNO + O_2 \xrightarrow{k_2}$ products; $k_2 < 8 \times 10^{-20}$ $cm^3\ s^{-1}$.

The main disadvantage of the IRLS method is its as yet short spectral range of action, which restricts the universality of the method. At the same time, the use of radiation in the infrared range within the framework of this method is now being developed, and this should extend considerably the possibilities provided by the method.

The data in Table 1 show that the LIF method has the highest limiting sensitivity. Although as already noted the requirement of a high fluorescence quantum yield restricts the number of species which can be followed by this method, it is widely used, particularly in other countries, to study the kinetics of chemical reactions. The method has been used to measure the rate constants of a large number of reactions involving both diatomic (OH, SH, CH, C_2, etc.)[67,68] and polyatomic (NH_2, CHF, CH_3O, $C_6H_5CH_2$, etc.) radicals. Some examples of reactions involving polyatomic radicals, which have been studied by LIF are given in Table 2.

LIF based on continuous dye lasers is fairly frequently used to measure reaction rate constants. As in the case of LMR, a flow system is used. An example of studies of this kind is provided by the measurement[40] of the rate constants of the reactions of the NH_2 radical with NO, NO_2, C_2H_2, C_2H_4, allene, etc.

The most promising development from the present viewpoint is the combination of LIF with laser flash photolysis. Thus the reaction $OH + C_2H_4$ has been studied in the temperature range 291–591 K at pressures of 50–600 mmHg.[69] The OH concentration was followed by LIF using a quasi-continuous dye laser, which produced a sequence of lasing pulses with a duration of 8–10 picoseconds and a repeat frequency of 246 MHz. This made it possible to study the kinetics of the destruction of the OH radicals formed in the photolysis of an $N_2O + H_2O$ mixture under the influence of the radiation from an excimer laser based on ArF. The initial OH concentrations measured immediately after the photolysing pulse were 5×10^9–10^{11} cm^{-3}. In this study,[69] LIF was used up to a pressure of 600 mmHg. This was made possible by the sensitivity reserve of the method, in spite of the appreciable quenching of the fluorescence of the radicals at this pressure. LIF has been used[70] to study the reaction† $OH + NO_2 + M \rightarrow HNO_3 + M$ at pressures up to 10 atm.

2. Elementary Processes Involving Excited Species

Elementary processes involving excited species are molecular collisions accompanied either by a change in the energy of the internal degrees of freedom of the colliding species or by chemical transformations. The study of the reactions of species in definite quantum states is closely related to the study of the energy distribution of the products of the elementary reactions. This relationship exists as a consequence of the principle of microscopic reversibility. The present section therefore examines three types of elementary process: a) processes involving the transfer and relaxation of the energy of the internal degrees of freedom in the collisions; b) the reactions of the excited species; and c) the energy distribution of the products of the elementary reactions.

Studies of these processes can make an important contribution to the development of ideas which make it possible to understand the type of reactions in which a particular form of energy is most effective for overcoming the activation barrier. At the same time, the existence of these ideas will probably make it possible to formulate more general regular features for complex energetically non-equilibrium chemical reactions. The study of the reactions of excited species will help in the investigation of the dynamics of the interaction of the species. The rate constants of elementary reactions obtained under Maxwell–Boltzmann distribution conditions in fact carry little information on the dynamics of the interaction of the species. The specification of definite quantum states of the reagents and products makes it possible to detect finer details of the dynamics of collisions and the influence of the characteristics of the potential energy surfaces on the dynamics.

Information on the energy distribution of the reaction products is particularly important. These data make it possible to resolve the question of the possibility of using these reactions as active media for transforming chemical energy into coherent radiant energy. In addition, quantitative data on the behaviour of excited species are necessary for an understanding of specific energetically non-equilibrium processes taking place in chemical lasers, plasmochemical reactors, the upper layers of the atmosphere, etc.

a) Processes involved in the transfer and relaxation of the energy of internal degrees of freedom in collisions

These processes are now being fairly widely studied in both physical and chemical laboratories. The experimental results and theoretical analyses of these processes have been given in detailed monographs.[71,72]

These processes will therefore be dealt with very briefly; the treatment will be restricted to a few types, to demonstrate the possibilities provided by laser technology. Table 3 gives examples of various processes of this kind, with an indication of the methods used to produce and record the excited species.

The first example in Table 3 demonstrates the possibilities provided by laser methods for both the production and recording of excited species. The TCE method used to

†Here, M represents an inert-gas molecule.

produce excited species is very promising. In particular, this method makes it possible to obtain appreciable concentrations of excited species not only in lower but also in higher vibrational excited states. The second example demonstrates the possibility of studying processes of vibrational–vibrational (v–v) exchange for isotopic molecules. LAS, because of its high spectral resolution, makes it possible to record both isotopic species. The last example shows that the processes involved in the transfer and relaxation of vibrational energy are now being studied not only for stable species, but also for radicals.

Table 3. Examples of processes of vibrational relaxation and energy redistribution studied by laser spectroscopy.

No.	Process	Method of excitation	Method of recording	Refs.
1	$CO_2(10^00)+CO_2(01^10) \rightarrow CO_2(11_10)+CO_2(00^00)$	TCE	CARS	[75]

**Here, M represents a molecule of He, Ar, CO, N_2, NH_3, O_2, or C_2H_4.

b) Reactions involving excited species

A large number of studies of reactions involving vibrationally or electronically excited species have now been carried out. The possibilities provided by the use of lasers in this field are illustrated by reactions of three types: the reactions of excited molecules with atoms, the reactions of excited molecules with stable molecules, and reactions involving the isomerisation and decomposition of excited molecules (Table 4).

Table 4. Examples of chemical reactions involving excited species.

No.	Reaction	Method of excitation	Refs.
1	$O+O_3(v) \rightarrow 2O_2$	CO_2 laser	[28]
2	$Br+CH_2F(v) \rightarrow HBr+CH_2F$	CO_2 laser	[29]
3	$Sr+HF(v) \rightarrow SrF+H$	HF laser	[30,77]
4	$NO_2^*+NO_2 \rightarrow 2NO+O_2$	Ar laser	[78,79]
5	$NO_2^*+CO \rightarrow CO_2+NO$	Dye laser	[80]
6	$NO_2^*+C_2F_4 \rightarrow CF_2O+CF_2+NO$	ditto	[79]
7	$O_3(v)+NO \rightarrow NO_2+O_2$	CO_2 laser	[81]
8	$O_3+NO(v) \rightarrow NO_2+O_2$	CO laser	[81]
9	$H_2C{=}CHCH_2NC+h\nu \rightarrow H_2C{=}CHCH_2CN$	Dye laser	[82]

*NO_2^* denotes an electronically excited NO_2 molecule.

Reaction No.1 was studied in Ref.28. The O_3 molecules were first excited by the radiation from a CO_2 laser (direct one-photon optical excitation (DOOE) into the first vibrational level of the vibrational modes ν_2 (or ν_1) and ν_3. The efficiency of the vibrational energy in overcoming the activation barrier of this exothermic reaction was determined.

Reaction No.2 was studied in Ref.29. DOOE was again used to produce the vibrationally excited species. The experiments showed that under the influence of the radiation of a CO_2 laser with a power of 20 W, the reaction rate increases by factors of several tens or hundreds (the increase is particularly marked at low temperatures). This increase in rate cannot be attributed to the participation in the reaction of only those vibrationally excited states of CH_2F which are excited directly by the laser radiation. This led the authors[29] to suggest that the increase in the rate of reaction is due to the participation in it of higher vibrationally excited states formed in processes of v–v exchange of energy. The authors showed that the vibrational energy is effective in overcoming the activation barrier of this reaction.

The study of the reactions of Sr atoms with the HF molecule in states with $v = 0$ or 1 (reaction No.3 in Table 4) is of considerable interest.[30,77] The reactivity of vibrationally excited HF molecules ($v = 1$) was studied using the so-called beam–gas configuration, that is the beam of Sr atoms from the furnace was directed into a cell containing hydrogen fluoride at a low pressure (~10^{-4} mmHg). The HF molecules were excited into the state with $v = 1$ by DOOE using an HF laser. The kinetics of the reaction were followed by LIF, by recording the reaction product SrF. It was found that the cross-section of this endothermic reaction ($\Delta H = 6.4 \pm 1.6$ kcal mole^{-1}) for HF ($v = 1$) is greater by at least four orders of magnitude than that for HF ($v = 0$).

The authors cited[30] compared their data with the results of a study of the dependence of the cross-section of reaction No.3 on the translational energy of the HF molecules. In this case, crossed molecular beams of Sr and HF were used. The reaction was again followed by LIF, from the product SrF. Comparison of the results of the two experiments showed that vibrational energy is apparently slightly more effective than translational energy in overcoming the activation barrier of the reaction.

Examples of the reaction of excited species with stable molecules are provided by the reactions of excited NO_2^* molecules with NO_2, CO, and C_2F_4.[78–80] In these studies, the NO_2 molecules were excited either by an argon laser or by dye lasers. The reaction $NO_2 + NO_2 \rightarrow 2NO + O_2$ is endothermic, whereas the reaction $NO_2 + CO \rightarrow CO_2 + NO$ is exothermic. Nevertheless, the rate constants of the reactions of the excited molecules NO_2^* with NO_2 and CO show the same dependence on the wavelength of the irradiating light. This fact is difficult to explain if it is assumed that only the vibrational form of the energy is effective in overcoming the activation barrier in these reactions.[79]

Table 4 also gives examples of processes involving the isomerisation of a molecule under the influence of laser radiation. The direction and rate of these reactions depend significantly on processes of intramolecular energy redistribution.

In a polyatomic molecule, even in the absence of collisions, as a result of the strong interaction of different degrees of freedom in a short time, relaxation processes take place, which wipe clean from the "memory" of the molecule those states in which it existed immediately after excitation, and these lead finally to some statistical distribution of the energy in the molecule. This raises the interesting question of whether it is possible to achieve conditions in which a chemical reaction is able to take place before the complete statistical redistribution of the energy. In this case it might be possible to control the directions of reactions by means of laser radiation. Thus one of the principal tasks in laser chemistry involves the investigation of the possibility of carrying out chemical reactions not according to statistical laws under the influence of a laser.

Until recently it was generally accepted that the processes involving the intramolecular redistribution of energy for polyatomic molecules at a sufficiently high level of excitation take place very rapidly (in times $\lesssim 10^{-12}$ s). This assumption was based, for example, on a large amount of experimental data on chemical activation, which are effectively explained by RRKM theory for unimolecular reactions. According to this theory, the energy of vibrational excitation of a molecule is able to undergo complete redistribution within the complex molecule, in times shorter than the characteristic time of the reaction, so that the decomposition obeys the laws of statistics. It has been suggested,[83,84] however, that in some cases the statistical theory (RRKM) effectively explains experiments on chemical activation because of the statistical character of the formation of the excited molecules.

A number of successful attempts have now been made to follow intramolecular processes of energy redistribution. These studies can be divided into two groups. The first group consists of studies of spectra containing bands which are assigned to the high overtones of the vibrations of polyatomic molecules. Highly sensitive methods of laser spectroscopy, IRLS and optico-acoustic spectroscopy, have made it possible to record the spectra of the overtones of the vibrations of a large number of molecules.[85,86] The width of the lines in these spectra is related to the lifetime of the excited state by the uncertainty relation. The recorded spectra generally relate to the overtones of the strongly anharmonic vibrations of C–H and N–H bonds. In most cases, the line width is large (for example 100 cm^{-1} for benzene[85]). This corresponds to lifetimes of the state of ~10^{-13} s. On the other hand, in a number of cases it is possible to observe the spectra of the high overtones of molecules with fairly narrow lines (for example, for NH_3 and C_2H_2 the line width is 0.3 cm^{-1} for excitation energies of ~2 eV).[86] This should apparently indicate a low rate of energy redistribution in this case. The second direction of studies involves the measurement of the rates of different unimolecular reactions of molecules which have been vibrationally excited as a result of the absorption of one quantum of laser radiation, and the comparison of the reaction rate constant obtained[33,82] with RRKM theory.

Table 5.

Reaction	Method of recording	References
$Ca(^1P_1) + HCl \rightarrow CaCl(A^2\Pi) + H$	LIF	[87]
$Ca(^1P_1) + HCl \rightarrow CaCl(B^2\Sigma) + H$	LIF	[87]
$O(^1D) + RH \rightarrow R + OH$	LIF	[88]
$HONO + h\nu \rightarrow OH + NO$	LIF	[37]

The unimolecular isomerisation of allyl isocyanate $H_2C{=}CH{-}CH_2NC$ has been studied.[82] The levels excited corresponded to the overtones of the vibrations of different C–H bonds in the molecule: saturated–alkene ($H_2C{=}$), unsaturated–alkene ($=CH-$), and methylene ($-CH_2-$). The excitation was carried out by placing the substance being studied in the resonator of a dye laser tuned to the wavelength corresponding to the absorption of the overtone being studied. The course of the reaction was followed by measuring the concentration of the reagents by an optico-acoustic method.

It was concluded[82] that the measured rate of isomerisation is slightly greater than that predicted by RRKM theory. Moreover, the reaction rate was found to depend markedly on the type of vibration excited (the highest rate was observed for the excitation of the vibrations of the $=CH-$ group). The results apparently indicate that on laser excitation, the allyl isocyanate molecule undergoes isomerisation more rapidly than the complete statistical redistribution of the energy within the molecule. It should be noted that although the observed deviations from RRKM theory are fairly small, their smallness, as pointed out by the authors cited,[82] may be related to different relaxational collision processes which "mask" the significant role of non-randomised states in the reaction.

c) The energy distribution of the products of elementary reactions

Examples of studies of this type are given in Table 5. As already noted, in the study of reaction No.3 (Table 4) by LIF, the molecules of the product SrF, formed in different quantum states, were recorded. The dependence of the distribution of the SrF molecules with respect to vibrational states on the direction of the polarisation of the radiation of the HF laser exciting the molecule of the HF reagent into the first vibrational level was observed. Thus when the polarisation of the laser beam was perpendicular to the direction of the beam of Sr atoms, the observed distribution of SrF molecules with respect to vibrational degrees of freedom for the reaction Sr + HF ($v = 1$, $J = 1$) corresponded to the following relationship: $v_0 : v_1 : v_2 = 1.00 : 0.63 : 0.29$. If however the polarisation of the laser beam was parallel to the direction of the beam of Sr atoms, the observed distribution was different: $v_0 : v_1 : v_2 = 1.00 : 0.72 : 0.13$. This experimental result agrees with theoretical predictions based on the assumption that the minimum in the reaction path for the reaction of HF with alkaline earth metal atoms corresponds to a bent configuration of the molecule.

It has also been shown[37,88] that laser methods can be used to study the influence of the relative orientation of the molecules of reagents on the energy distribution of the products. The reaction of Ca ($^1P_1$) atoms with the HCl molecule was studied.[88] The Ca atoms were excited into the state $^1P_1$ from the ground state $^1S_0$ using a dye laser with a wavelength of 422.6 nm. The atom beam–gas configuration (pressure ~10^{-4} mmHg) was used. The fluorescence of the CaCl molecules in the states $A^2\Pi$ and $B^2\Sigma$ formed in the course of the reaction was observed. It was found that when the polarisation of the exciting laser beam changed from the parallel (relative to the direction of the beam of Ca atoms) to the perpendicular, the intensity of the fluorescence from the state $B^2\Sigma$ decreased by 16%, and the fluorescence from the state $A^2\Pi$ increased by 7%. Since there were a large number of factors decreasing the selectivity of excitation, the authors cited pointed out that the significant influence of the geometry of the approach on the ratio of the channels by which the reaction takes place is being observed.

There have been a large number of studies of the distribution of the rotational and vibrational energy of OH radicals formed by the reactions of a $O(^1D)$ atom with different hydrogen-containing molecules. Thus the dynamics of the reaction of the $O(^1D)$ atom with saturated hydrocarbons has been studied.[89] Oxygen atoms in the singlet excited state $O(^1D)$ were obtained by the laser photolysis of ozone: $O_3 + h\nu \rightarrow O(^1D) + O_2(^1\Delta)$ using the radiation of the fourth harmonic of a YAG:Nd^{3+} laser (duration 7 ns). With a short (20 ns–0.5 μs) delay after the photolysing pulse, the energy distribution of the OH radical reaction product was probed by LIF (a dye laser with a pulse duration of ~10 ns was used).

The distribution of the energy in OH radicals, formed in the course of the reaction, among the vibrational and rotational degrees of freedom was measured. The data on the distribution of the rotational energy are of considerable interest. It was found that the distribution is "bimodal" in character, indicating the existence of two reaction channels. One channel corresponds to a rotational distribution in which only the levels with small quantum numbers J are extensively populated. This channel was interpreted as the direct abstraction of an H atom from the hydrocarbon. The second channel corresponds to a broad distribution, in which levels with high values of J are also extensively populated. The second reaction channel was interpreted by the authors cited as the insertion of an O atom into the hydrocarbon molecule with the formation of an excited alcohol molecule, and its subsequent decomposition. The high value of the surprisal parameter indicates that the decomposition of the alcohol molecule is non-statistical in character. The channel involving the abstraction of an H atom is more characteristic of the higher hydrocarbons C_3H_8 and $C(CH_3)_4$, whereas for CH_4 and C_2H_6 a large contribution is made by the reaction channel involving the formation of the excited alcohol molecule.

Important information on the dynamics of the elementary act can be obtained by using laser methods to study photodissociation processes. In this case, the decomposition of a molecule excited by light is often described as "a half collision", signifying that the study of the decomposition of the excited molecule as it were gives half of the information on the inelastic collision of molecules, which takes place via the formation of the same excited state as the photodissociation.

Laser methods have been used[37] to study the photodissociation of the molecule of *trans*-nitrous acid (HONO). The *trans*-HONO molecule was excited by laser radiation with a wavelength of 369 nm, and it decomposed rapidly to OH and NO. The HONO molecule decomposes so rapidly that the molecule is unable to undergo a significant change in its orientation in the time interval between the absorption of the light quantum and its decomposition. The distribution of the energy of the OH radical reaction product among the different degrees of freedom was studied by LIF. It was found that the Doppler contour of the LIF excitation lines of the OH radical has a split maximum, corresponding to a small fraction of OH molecules having their velocity vector directed at right angles to the direction of the laser beams. Because of the polarisation of the radiation of the photolysing laser, only the molecules orientated in such a way that the dipole moment of the transition was parallel to the direction of the polarisation were excited, so that it can be stated that the OH radicals formed in the photodissociation of HONO move apart chiefly in a plane perpendicular to the transition moment of the HONO molecule. Modelling of the line contour form of the fluorescence excitation spectrum showed that the average rate of divergence of the OH radicals was ~2.58 km s^{-1} (which corresponds to a translational energy of 4720 cm^{-1}). From momentum conservation considerations it was found that the translational degrees of freedom of the OH and NO fragments correspond to 72% of the energy liberated in the photodissociation. The distribution of the OH radicals with respect to the rotational degrees of freedom was studied for different directions of the polarisation of the radiation of the photolysing laser. This established that the axis of rotation of the OH radicals is oriented preferentially in a direction parallel to the transition moment of the HONO molecule. It was established that the effective rotational temperature of the OH radicals is close to room temperature, and that there exists a state of non-equilibrium between the levels of types F_1'' and F_2'' (components of spin–orbit splitting).

The above studies show that extensive and detailed information on the dynamics of the elementary act can be obtained by laser methods.

3. Diagnostics of Complex Chemical Reactions

Until recently, because of the lack of sensitive methods for recording radicals, conclusions about the mechanisms of complex chemical reactions were reached on the basis of macrokinetic measurements of the concentrations of the original reagents and the stable products. The appearance of direct methods for studying elementary reactions has made it possible to confirm conclusions about the mechanism of a complex reaction by experimental data on key elementary stages. This method of investigating a complex mechanism remains basic today. This is because even the methods of laser spectroscopy usually do not have sufficient sensitivity for the diagnostics of slow chemical reactions. For chain branched reactions, however, the diagnostics of unstable intermediate species can be successfully undertaken by the methods described above. Thus LMR has recorded the SiH_3 radical in a rarefield flame of $SiH_4 + O_2$ [89] or $SiH_4 + Cl_2$,[90] and also the HO_2 radical in a rarefied $H_2 + O_2$ flame.[91]

A more general approach to the investigation of the mechanisms of chain branched reactions is possible by carrying them out under conditions of stationary isothermal propagation of the reaction zone.[92–94] The macrokinetic characteristics in this case are given by the measured dependence of the rate of propagation of the reaction zone on the initial conditions. Concentrations of intermediate species sufficient for recording by the methods of laser spectroscopy are formed in the reaction zone. Combined measurements of the concentration profiles of the intermediate species and the rate of propagation of the reaction zone would probably make it possible, in a comparatively small number of experiments, to obtain sufficient information to establish reliably the reaction mechanism.

The possibilities provided by kinetic laser spectroscopy in the study of elementary reactions are leading to the development of another approach to the establishment of the mechanisms of complex chemical reactions. The essential feature of this approach is the "construction" of the mechanism of a complex reaction on the basis of a systematic study of the elementary reactions, after which it is tested to find out whether it can explain available data obtained by macrokinetic measurements. This approach has been used[66] to investigate the mechanism of the photo-oxidation of ammonia. This approach is generally very laborious, however.

Even greater difficulties arise in the description of combustion processes. In this case the complex reaction mechanism is influenced by the non-isothermal course of the process and by hydrodynamic factors. It is for this reason that the study of combustion processes requires laser methods which have a high spatial resolution. The CARS and LIF methods are preferred in the diagnostics of combustion processes.

The possibilities provided by the use of these methods to study combustion processes have been reviewed.[95] It may be noted that certain difficulties are also encountered when both CARS and LIF methods are used in the diagnostics of combustion. In the first place, difficulties in the application of these methods are introduced by a whole range of effects of stray light: the luminescence of the flame, the scattering of the laser beam on non-uniformities, the luminescence of aerosol particles under the influence of the laser beam, etc. These phenomena introduce particular difficulties in the application of the LIF method. Another difficulty associated with

its use is the quenching of the fluorescence. Although the high sensitivity of LIF combined with the fairly high concentration of the species also makes it possible to observe fluorescence which has been partly quenched (even by many orders of magnitude of the intensity), the indeterminate nature of the rates of quenching and their possible dependence on the concentrations of various substances in the flame make it difficult to obtain a reliable profile even for the relative concentration of the species being studied in the flame. At the present time, however, the so-called saturated LIF method [96,97] has been developed, in which the study of the dependence of the signal of partly saturated LIF on the power of the exciting laser makes it possible to determine the rate of quenching of the fluorescence and the relative concentration of the material being studied in a given local volume.

The absence of fluorescence quenching, the high universality, and the weaker influence of stray scattering of various kinds (since the observation is carried out in the anti-Stokes region of the spectrum) make the CARS method very convenient for the study of combustion processes. A disadvantage of the method is the existence of a non-resonance scattering signal, which restricts the possibilities provided by the measurement of the concentrations of those species which make up a small fraction of the main gas; at the same time, the improvement of the CARS method suggests that this difficulty will be overcome. [98]

Although absorption methods do not make it possible to measure local concentrations at a given point, they can be used in the study of so-called planar flames. In this case the spatial resolution may be fairly high. Here, it is appropriate to mention the possibilities provided by the use of IRLS, particularly in the version where Raman scattering is used. [99] In this case, in addition to the universality of the IRLS method, there is also the advantage that it is only weakly sensitive to losses which are weakly dependent on frequency, and is not sensitive to stray scattering.

In a large number of recent studies, laser methods have been used to investigate combustion processes. Only some of these will be mentioned. LIF has been used [100] to measure the OH and NH concentration profiles in a stoichiometric $CH_4 + N_2O$ flame. It was also possible to obtain the temperature profiles in this flame. LIF, LAS, and analysis of the products have been used [101] to study the formation of polycyclic aromatic hydrocarbons in rich $CH_4 + O_2$ flames.

The CARS method and other methods using Raman scattering induced by laser radiation are also widely employed in the study of flames. The use of CARS to measure the concentrations of N_2, O_2, H_2, H_2O, CO, CO_2, and CH_4 in a flame has been reported. [95] CARS has also been used to measure the temperature profiles in engines. [102]

4. Laser Chemical Technology

The demands being made of chemical technology are constantly increasing, due largely to various aspects of environmental protection. The question of the creation of a chemical technology without waste is now being considered. Selective laser photochemistry opens up promising routes for achieving this in certain cases. The possibilities provided by the use of laser photochemistry in chemical technology have been reviewed. [103–105]

This question can be examined briefly by considering several examples of selective laser-chemical reactions, given below:

Reaction	Method of excitation	References
$N_2 + O_2 + h\nu \rightarrow 2NO$	SRS	[106]
$2NO_2 + C_2F_4 \xrightarrow{h\nu} CF_2O + 2NO$	argon laser	[79]
$C_2H_4Cl_2 \xrightarrow{h\nu} C_2H_3Cl + HCl$	excimer laser	[107]

The binding of atmospheric nitrogen is an endothermic reaction. It represents the first example of a reaction involving vibrationally excited molecules obtained by laser methods. In Ref. 106, vibrationally excited nitrogen molecules were obtained by stimulated Raman scattering.

The oxidation of tetrafluoroethylene by nitrogen dioxide is an example of an exothermic reaction having an activation barrier. Thus at room temperature the dark reaction $NO_2 + C_2F_4$ takes place very slowly and non-selectively to give several products – fluorophosgene, tetrafluoroethylene oxide, perfluoroacetaldehyde, etc. When the isothermal (at 300 K) reaction is carried out under the influence of an argon laser, its rate increases by a factor of several tens, and the reaction takes place selectively to give the single product fluorophosgene. [79] It is possible to carry out this reaction selectively in another direction to give a product of practical importance, namely tetrafluoroethylene oxide. An unsatisfactory feature of this process is the fairly low quantum yield.

The third example is of interest in that laser radiation is used to bring about a chain reaction; in this case, therefore, the quantum yield of the product is very high ($\sim 10^3$). Laser photolysis only brings about chain initiation, and this makes it possible to carry out the reaction at lower temperatures than in thermal initiation. This leads to a decrease in the yield of side products, that is to an increase in the selectivity of the reaction. The advantage of the laser as photolysing source is that it is possible to achieve a high intensity of the monochromatic light which influences only the starting material, and does not bring about photolysis of the products.

Another promising application of lasers in chemical technology is the laser purification of materials. [108] The principles of laser purification are based on the selective action of the laser radiation on the impurities. The essential features of the method reduce to the conversion of the impurity molecules under the influence of radiation into species which can be readily removed from the reaction vessel. The photolysis of the impurities is carried out either by multiphoton dissociation under the influence of lasers in the infrared range or by one-photon dissociation using lasers in the visible or ultraviolet ranges. An example of the use of lasers in the infrared range is provided by a study [109] involving the selective multiphoton dissociation of organic impurities in $AsCl_3$ under the influence of a pulse CO_2 laser.

It should be noted that when multiphoton dissociation is used to purify gases, a larger proportion of the light energy of the laser is used up in heating the main material. In addition, the selectivity of action may be lowered as a result of collision processes at higher gas pressures. It may therefore be assumed that the use of lasers in the visible and ultraviolet ranges should be more promising for the laser purification of gases. The example of the use of an excimer laser to purify synthesis gas (a mixture of CO and H_2) from hydrogen sulphide can be considered. It is well known that, using catalysts, valuable materials can be obtained from synthesis gas; even extremely small quantities of H_2S impurity, however, poison the catalyst. It has been shown [110] that laser purification makes it possible to lower the concentration of sulphur-containing compounds in synthesis gas to below 10^{-7}, which is sufficient for effective operation of the catalyst. The authors cited [110] also carried out preliminary estimates of the economics of laser purification of the gas. They concluded that for an H_2S concentration below 10^{-6}, the use of excimer lasers to purify synthesis gas is economically favourable.

Phospha-alkynes—Compounds of Monocoordinate Phosphorus

E.A.Ishmaeva and I.I.Patsanovskii

The review gives a systematic account of and surveys the results of studies on compounds of monocoordinate phosphorus. The methods of synthesis of phospha-alkynes from phosphines and phospha-alkenes (by pyrolysis or low-temperature elimination), their structure and physico-chemical properties, and also their chemical behaviour in complex-formation and cycloaddition reactions are examined.
The bibliography includes 52 references.

I. INTRODUCTION

The synthesis of phosphaethyne (H−C≡P) in 1961[1] laid the foundation of the class of organophosphorus compounds (OPC) which are derivatives of monocoordinate phosphorus (phospha-alkynes). The first communication about the synthesis of a compound of this type (NaCP) dates back to 1894,[2] but subsequent attempts to reproduce the experiments described in that report were unsuccessful.[1]

The development of the chemistry of monocoordinate phosphorus was inhibited by the Mulliken–Pitzer hypothesis, according to which the existence of phosphorus derivatives resembling cyanides is impossible owing to the presence of vacant *d* orbitals in the phosphorus atom. Gier's study[1] disproved these views. When PH_3 was passed through a low-intensity electric arc between graphite electrodes, phosphaethyne (H−C≡P) was obtained. It is a colourless reactive gas, stable at temperatures below the triple point (−124° ± 2 °C) and at a reduced pressure (<30 mmHg).[1] The molecular weight, determined mass-spectrometrically, confirmed its composition and the addition of HCl at −110 °C with formation of dichloromethylphosphine confirmed the presence of a C≡P triple bond. The infrared spectrum of the solid specimen at −196 °C also corresponded to the H−C≡P structure.[1]

However, owing to the extreme instability of derivatives of monocoordinate phosphorus, only little attention has been devoted to their investigation during the last 15 years. Gier's data[1] have been confirmed and deuteriophosphaethyne has been obtained by an analogous procedure;[3] the microwave,[3] ultraviolet, infrared (IR), and NMR spectra[4-7] of phosphaethyne as well as its photoelectron spectrum (PES)[8] have been investigated and quantum-chemical calculations have been performed for the H−C≡P molecule.[9-11] As a result of the discovery of new methods of synthesis of phospha-alkynes, studies in this field have been developing at a higher rate only since the middle 1970's. Ten compounds of monocoordinate phosphorus and some of their deuteriated derivatives are now known; approximately 50 communications devoted to their synthesis and the study of their physicochemical properties have been published. The possibility of using phospha-alkynes in organic synthesis and in the chemistry of transition metal complexes has aroused much interest in the vigorous research into this class of OPC prosecuted at the present time.

Some information on the chemistry of phospha-alkynes is contained in reviews[12,13] devoted mainly to compounds of dicoordinate phosphorus. This review gives a systematic account and a survey of the results of studies on phospha-alkynes both in terms of the synthetic aspect and as regards their structure, physicochemical properties, and reactivity. It is noteworthy that experimental data on the synthesis and properties of phospha-alkynes have been frequently reproduced and have been confirmed by different groups of investigators. In this respect, the results of Matveev and coworkers[14-19] differ from them sharply, cannot be accepted as reliable, and are not considered in this review.

II. SYNTHESIS

Phospha-alkynes (I)–(X) (Table 1) are thermally unstable and very reactive compounds. With the exception of 3,3-dimethyl-1-phosphabutyne (VII), they are gases which are stable only at low temperatures in an inert atmosphere or at room temperature in a state of high rarefaction.

The methods of synthesis of phospha-alkynes known at present are based on the elimination of hydrogen halides, trialkylchlorosilane, or hexa-alkyldisiloxanes from substituted phosphines and compounds of dicoordinate phosphorus (phospha-alkenes). These methods can be divided into two groups: high-temperature pyrolysis and low-temperature elimination in the presence of solid alkali (Table 1). In cases where the starting compounds are di- or tri-halogenophosphines, a two-stage reaction has been proposed with formation of an intermediate phospha-alkene.

The majority of phospha-alkynes have been synthesised by high-temperature pyrolysis. Thus phosphaethyne (I) has been obtained by passing dichloromethylphosphine through a quartz tube 8 mm in diameter and 150 mm long, heated to 1000 °C, at a pressure of 2 mmHg.[20,21] 1-Phosphapropyne (II) has been synthesised analogously:[22,23]

$$MePCl_2 \xrightarrow[-HCl]{\Delta} \underset{(I)}{H-C\equiv P};$$

$$MeCH_2PCl_2 \xrightarrow[-HCl]{\Delta} [MeCH{=}PCl] \xrightarrow[-HCl]{\Delta} \underset{(II)}{Me-C\equiv P}.$$

Westwood et al.,[23] who used photoelectron spectroscopy as an

identification procedure, note that the formation of phosphapropyne (II) and HCl is not the only pathway to the decomposition of the initial dichloroethylphosphine. According to PES (the reaction products were introduced directly into the ionisation chamber of the spectrometer), the reaction mixture also contains the initial phosphine, PCl_3, C_2H_2, C_2H_4, and C_2H_6.[23] The isolation of compound (II) in a pure form therefore requires the successive employment of three low-temperature traps at −78 °C (for the separation of the initial phosphine), −126 °C (for the separation of PCl_3), and at the temperature of liquid nitrogen. When the last trap is heated, traces of C_2H_6 appear and these are followed by C_2H_4 and HCl, in order of their volatilities. Further heating yields phosphapropyne alone. Its yield is not more than 10%. As the pressure is reduced, the yield of compound (II) with respect to C_2H_4 increases. Phosphapropyne specimens can be stored without any changes at the temperature of liquid nitrogen in the course of a month.[23]

Table 1. The synthesis of phospha-alkynes (I)–(X).

Compound	Method of synthesis*	Reaction conditions		Refs.
		t, °C	p, mmHg	
HC≡P (I)	P	1000	2	[20]
DC≡P	P	1000	2	[20]
$CH_3C{\equiv}P$ (II)	P	900	0.05	[22,23]

$Me_3Si{-}C{\equiv}P$ (IX)	P	750	$2{\cdot}10^{-6}$	[29]
$CF_3C{\equiv}P$ (X)	P	—	—	[31]

*P = pyrolysis; E = elimination under the influence of alkali.

Cyanophosphaethyne (IV) has been synthesised from phosphaethyne (I).[20] The unpurified compound (I), obtained by pyrolysing dichloromethylphosphine, is passed through a trap, containing KOH pellets and cooled to −78 °C, in order to remove HCl and is then transferred together with cyanogen azide to a furnace at 700 °C and a pressure of 50 mmHg:

$$MePCl_2 \xrightarrow[-HCl]{\Delta} \underset{(I)}{HC{\equiv}P} \xrightarrow{\Delta,NCN_3} \underset{(IV)}{N{\equiv}C{-}C{\equiv}P}.$$

The authors suggest that pyrolysis of NCN_3 results in the formation of nitrile radicals which undergo a substitution reaction with phosphaethyne, giving rise to the final product (IV) in ~1% yield.[20]

Vinylphosphaethyne (V)[24] and ethynylphosphaethyne (VI)[25] have been obtained by the pyrolysis of the corresponding dichlorophosphines. In the latter case the initial phosphine is formed immediately in the reaction zone on pyrolysing a 2:1 mixture of 3-chloropropyne and phosphorus trichloride:

$$CH_2{=}CH{-}CH_2PCl_2 \xrightarrow[-HCl]{\Delta} \underset{(V)}{CH_2{=}CH{-}C{\equiv}P};$$

$$HC{\equiv}CCH_2Cl + PCl_3 \xrightarrow{\Delta} [HC{\equiv}CCH_2PCl_2] \xrightarrow{\Delta} \underset{(VI)}{HC{\equiv}C{-}C{\equiv}P}.$$

In the syntheses of phenylphosphaethyne (VIII)[26–28] and trimethylsilylphosphaethyne (IX),[29] the starting materials were compounds of dicoordinate phosphorus, both phospha-*alkynes* are formed in quantitative yields:

$$(Me)_3Si(Ph)C{=}PCl \xrightarrow[-(Me_3)SiCl]{\Delta} \underset{(VIII)}{Ph{-}C{\equiv}P};$$

$$[(Me)_3Si]_2C{=}PCl \xrightarrow[-(Me_3)SiCl]{\Delta} \underset{(IX)}{(Me)_3SiC{\equiv}P}.$$

Appel et al.[26] noted that the method of synthesis which they proposed makes it possible to isolate phenylphosphaethyne (VIII) in a pure form, which was impossible when benzyldichlorophosphine was used as the starting material owing to the large amount of impurities formed during its pyrolysis. However, even in the absence of impurities, the phospha-alkyne (VIII) is stable only at a low temperature, decomposing slowly above −50 °C (the half-life at 0 °C was 7 min).[26] The trimethylsilyl derivative (IX) is somewhat more stable and begins to decompose only at −10 °C; the half-life at room temperature is 50 min.[29] This compound can also be obtained by the pyrolysis of *P*-chlorobis(methylene)phosphorane:[30]

$$[Me_3Si]_2C{=}\overset{Cl}{\overset{|}{P}}{-}C[SiMe_3]_2 \xrightarrow{\Delta} \underset{(VIII)}{Me_3SiC{\equiv}P}.$$

The available information about the synthesis of trifluoromethylphosphaethyne (X) is extremely scanty.[31] The compound has been obtained by the pyrolysis of pentafluoroethylphosphine:

$$CF_3CF_2PH_2 \xrightarrow[-HF]{\Delta} \underset{(X)}{CF_3C{\equiv}P}.$$

The low-temperature elimination method makes it possible to synthesise phospha-alkynes which are unstable at high temperatures. Fluorophosphaethyne (III)[32,33] and 3,3-dimethyl-1-phosphabutyne (VII)[34] have been obtained in this way. Compound (III) is formed when the vapour of the initial trifluoromethylphosphine is passed through a spiral glass tube 10 mm in diameter and 400 mm long filled with solid potassium hydroxide, at room temperature and a pressure of 30 mmHg:

$$CF_3PH_2 \xrightarrow[-HF]{KOH} [CF_2{=}PH] \xrightarrow[-HF]{KOH} \underset{(III)}{FC{\equiv}P}.$$

An increase of the contact time between the initial phosphine and the alkali and a decrease of pressure lead to an increase of the content of fluorophosphaethyne (III) relative to the phospha-alkene.[32]

The initial reactant in the synthesis of the t-butyl derivative (VII) is a compound of dicoordinate phosphorus:[34]

$$\begin{matrix} Me_3SiO \\ Me_3C \end{matrix}\!\!>\!C{=}PSiMe_3 \xrightarrow[-[Me_2Si]_2O]{NaOH} \underset{(VII)}{Me_3C{-}C{\equiv}P}.$$

At room temperature solid sodium hydroxide is added slowly into a solution of the disilyl derivative in diethylene glycol dimethyl ether; the yield of compound (VII) is 76%. 3,3-Dimethyl-1-phosphabutyne (VII) is a colourless mobile liquid with a b.p. 61 °C and is the only representative of phospha-alkynes stable under normal conditions known at the present time.

The phospha-alkynes (I)–(IV), (VIII), and (IX) have been obtained by methods analogous to those described above.[35]

The high reactivity and thermal instability of phospha-alkynes precludes the synthesis of most of them by these methods in preparative amounts. Phospha-alkynes are even more unstable in the presence of the numerous impurities formed in the pyrolysis of the initial phosphines. In this sense the search for new methods of synthesis is undoubtedly an urgent problem in the chemistry of compounds of monocoordinate phosphorus.

III. STRUCTURE AND PHYSICOCHEMICAL PROPERTIES

The phospha-alkynes (I)–(X) have been investigated with the aid of various physicochemical methods: mass-spectrometry and microwave, photoelectron, IR, and NMR spectroscopy. Mass spectra have been used to identify the compounds and to determine their molecular weights. Microwave and photoelectron spectra have also been employed successfully for the same purpose. The microwave spectroscopic and PES methods, which make it possible to transfer in the course of experiments the substances from the synthetic zone directly into the spectrometer cell with rarefaction and at a low temperature, are the most convenient and in many instances the only methods available for the identification and analysis of compounds as unstable as phospha-alkynes. Because of the low stability of phospha-alkynes, IR and NMR spectroscopy are used to investigate them to a much lesser extent.

Table 2. The structural parameters of phospha-alkynes RCP.

(X)	CF_3	1.460	1.542	[31]

*X = atom of group R linked to the C_{sp} carbon atom.
**The parameter was taken from data for compound (II).[37]

The steric structure of phospha-alkynes has been established by a microwave spectroscopy (Table 2); they are structural analogues of the corresponding nitriles. Thus, like hydrogen cyanide, phosphaethyne has a linear structure and in both molecules the shortening of the C≡P and C≡N bonds[40] relative to single C–P and C–N bonds is almost the same (0.31 and 0.32 Å). The C–N [and C–P?] bond lengths in these compounds also differ little (1.0632 Å in HCN). A similar situation has been noted also[28,37,39] for alkyl and phenyl derivatives of phosphaethyne [compounds (II), (VII), and (VIII)] and the corresponding nitriles: the values of $r(C-C_{sp})$, namely 1.458 Å in MeCN and 1.451 Å in PhCN, differ little from those for the phospha-alkynes (II) and (VIII) (Table 2). On the other hand, the F–C bond in the F–C≡P molecule is much longer than in F–C≡N (1.262 Å) and is close to the value 1.279 Å observed in the F–C≡CH molecule.[38] A characteristic feature of phospha-alkynes which distinguishes them from nitriles is a weak sensitivity of the C≡P bond length to the substituent at the carbon atom (Table 2) – some shortening of the bond is observed only for the t-butyl derivative (VII). It has been noted[39] that, although the opposite tendency is observed in the series of a corresponding nitriles [$r(C\equiv N)$, Å: 1.156 in HCN, 1.157 in MeCN, and 1.159 in Me_3CCN], it is difficult to draw definite conclusions on this basis because of the assumptions made for phospha-alkynes (see the footnote to Table 2) and the possible experimental errors. However, the main tasks in the analysis of microwave spectra, namely the identification of representatives of the new class of OPC and an unambiguous demonstration of the structure with a C≡P triple bond, have been carried out.

Six phospha-alkynes have been investigated by PES (Table 3). In all the compounds, the first ionisation potential (IP) corresponds to the removal of an electron from a bonding π orbital localised predominantly at the C≡P group and the second ionisation potential corresponds to the removal of a non-bonding *n* electron localised at the phosphorus atom. The results of a comparative analysis of the PES of phospha-alkynes and the corresponding nitriles indicate the similarity of the electronic structures of the RC≡P and RC≡N molecules.[41] This is shown, for example, by the influence of substituents on the orbital characteristics, which are virtually identical in the series of phospha-alkynes and nitrides (Fig.1). Thus the stabilisation of the bonding π orbital is observed in both series and the observed order in the variation of the π(C≡)IP, namely H > F > Me > Me_3C, is due to the mesomeric (+*M*) effect of the substituents.[41] In both phospha-alkynes and nitriles, the IP of the *n* orbital decreases consistently in the sequence R = F, H, Me, Me_3C, in conformity with the increase of the +*I* effect of the substituent R.[41] On the other hand, in all the phospha-alkynes there is a greater shift towards lower ionisation potentials compared with nitriles than might have been supposed to result from substitution of the nitrogen atom by the less electronegative phosphorus atom.[41] Evidently the most important feature of phospha-alkynes is the increase in the latter of the $\pi - n$ separation compared with nitriles, which is a quantitative indication of the decrease of the $2p\pi-3p\pi$ overlap in these compounds compared with the $2p\pi-2p\pi$ overlap in the RC≡N molecules.[41] These data are clearly illustrated by the correlation orbital diagram (Fig.1).[41] The difference in the separation of the π and *n* levels between phospha-alkynes and nitriles noted above is manifested also in their chemical properties (Section IV).

Table 3. PES data for phospha-alkynes RCP.

Compound	R	IP[π(C≡P)], eV	IP[*n*(P)], eV	Refs.	Compound	R	IP[π(C≡P)], eV	IP[*n*(P)], eV	Refs.
(I)	H	10.79	12.86	[8]	(VII)	Me_3C	9.61	11.44	[41]
(II)	Me	9.89	12.19	[23]	(VIII)	Ph	8.68	11.76	[41]
(III)	F	10.57	13.55	[32]	(IX)	Me_3Si	9.9	10.9	[42]

There is very little information about the IR spectra of phospha-alkynes, probably because of experimental difficulties. The ν(C≡P) stretching vibration frequency varies within fairly broad limits: 1265 cm^{-1} for HC≡P,[1] 1660 cm^{-1} [33] or 1670.8 cm^{-1} [43] for FC≡P, and 1533 cm^{-1} for $Me_3C-C\equiv P$.[34] There are contradictions in the literature data for ν(C≡P) in the infrared spectrum of phosphaethyne. Johns et al.[4] altogether failed to observe the band at 1265 cm^{-1} and concluded that its assignment to ν(C≡P) was erroneous. A similar doubt was expressed also by Becker et al.[34] in connection with a comparison of the IR spectra of HC≡P[1] and $Me_3CC\equiv P$. In the light of the available limited data, the ν(C≡P) band in the IR spectra of phospha-alkynes appears to be non-characteristic.

Studies of the phospha-alkynes (I), (III), and (VII)–(IX) by ^{31}P and ^{13}C NMR have shown (Table 4) that, whereas the range of variation of the chemical shift of the signal due to the phosphorus nucleus in these compounds is about 300

p.p.m., the $\delta^{13}C$ chemical shift for the *sp*-hybridised carbon atom is more characteristic ($\Delta\delta \cong 50$ p.p.m.). It has been noted[7] that the spin–spin coupling constant $^1J(CH) = 211$ Hz in the ^{13}C NMR spectrum of phosphaethyne is directly related to the nature of the C≡P triple bond and shows that the hybridisation of the carbon atom in the HC≡P molecule is close to *sp* (calculation yields 43% of *s* character).

Important information about the polarity of phospha-alkynes has been obtained in their investigation by microwave spectroscopy. The experimental dipole moments of the compounds (μ_{exp}, D) are 0.39 for HCP,[3] 1.499 for MeCP,[37] 0.279 for FCP,[38] 3.44 for NCCP,[20] 1.183 for CH_2 = CHCP,[24] and 0.745 for HC≡CCP.[25] The significant difference between the dipole moments of HCP and HCN (μ_{exp} = 3 D) has been explained[3] by the lower electronegativity of the phosphorus atom compared with the nitrogen atom (2.1 and 3.0 respectively) and by the diffuseness of the unshared (lone) electron pair (LEP) of the phosphorus atom. Analysis of the dipole moments of the phospha-alkynes (I)–(VI) in terms of the vector-additive scheme made it possible to determine the polarity of the C≡P triple bond.[44] It has been noted[44] that the data for the polarity of the phospha-alkynes fit satisfactorily within the framework of the additive computational scheme after the correct selection of the corresponding models despite the view[20] that there are no signs of additivity. The polarity of the C≡P bond is almost independent of the substituent at the *sp* hybridised carbon atom and is characterised by a dipole moment of 0.7 ± 0.1 D in the direction from phosphorus to carbon. The opposite polarity of the C≡P bond in phospha-alkynes compared with the C≡N bond in nitriles is also indicated by the results of a quantum-chemical calculation for the HCP molecule,[10] according to which the carbon atom constitutes the negative end of the C≡P bond dipole: the charges on the H, C, and P atoms are respectively +0.226 e, −0.307 e, and +0.081 e.

IV. CHEMICAL PROPERTIES

The chemical properties of phospha-alkynes have been little investigated. It is known that these compounds rapidly polymerise on raising the temperature, forming solid resins.[1] At temperatures somewhat above those corresponding to their stability, phospha-alkynes interact with hydrogen halides to form halogenophosphines and phospha-alkenes:[1,26]

$$\underset{(I)}{H{-}C{\equiv}P} + HCl \xrightarrow{-110^\circ} MePCl_2;$$

$$\underset{(VIII)}{Ph{-}C{\equiv}P} + HCl \rightarrow PhCH{=}PCl.$$

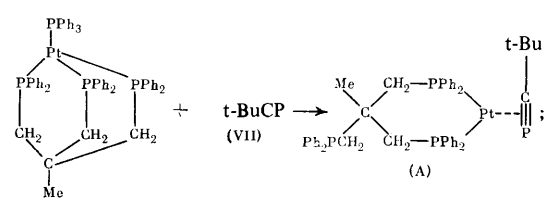
These reactions have been used to demonstrate the structure of the phospha-alkynes (I)[1] and (VIII)[26] obtained. In many of the studies quoted above the possibility of using phospha-alkynes in synthetic chemistry and in the transition metal complex chemistry is discussed. For example, it has been suggested that, owing to the large positive charge on the phosphorus atom (+0.48 e on P, −0.09 e on C, and −0.39 e on F), fluorophosphaethyne can function as an electron density acceptor in chemical reactions.[32] However, the low thermal stability of phospha-alkynes and the impossibility of synthesising them in preparative amounts preclude their wide-scale employment in practical chemistry. Only a series of transition metal complexes of the only phospha-alkyne stable under normal conditions, namely the t-butyl derivative of compound (VII),[45–49] and the cycloaddition reaction involving PhC≡P[27] have so far been investigated.

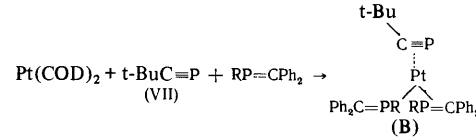
3,3-Dimethyl-1-phosphabutyne taken in excess forms cream-coloured semitransparent crystals of a 1:1 complex with zerovalent platinum at room temperature in benzene in a quantitative yield:[45]

$$Pt(C_2H_4)(PPh_3)_2 + t\text{-}BuC{\equiv}P \rightarrow Pt(PPh_3)_2(t\text{-}BuC{\equiv}P).$$

X-Ray diffraction analysis of the complex showed that the phospha-alkyne (VII) is coordinated "sideways" to the platinum atom, so that the LPE of the phosphorus atom hardly interacts with the metal (Fig. 2).[45] It was of interest that the C–P bond (1.672 Å) in the coordinated t-BuCP is appreciably longer than that in the free molecule of compound (VII) (1.544 Å). Elemental analysis of the ^{31}P NMR spectra of the complex are consistent with the structure presented.[45]

The synthesis of two new complexes of t-BuCP with zerovalent platinum, in which the phospha-alkyne is also coordinated "sideways" to the platinum atom, has been recently reported:[46,47]





Here COD = cyclo-octa-1,5-diene and R = mesityl. Structure (B) is the first example of a complex containing only

phospha-alkyne and phospha-alkene molecules as ligands, both molecules of the latter compound being coordinated to the platinum atom via the LEP of the phosphorus atom, in contrast to t-BuC≡P. A characteristic feature of the NMR spectra of all three complexes of compound (VII) with zerovalent platinum is the very low spin–spin coupling constant ^1J(Pt, P), which is 62 Hz for $Pt(PPh_3)_2$(t-BuCP),[45] 144 Hz for structure (A), and 115 Hz for structure (B),[46] which indicates a greater amount of *s* character of the LEP of the phosphorus atom in the coordinated phospha-alkyne (VII).[46]

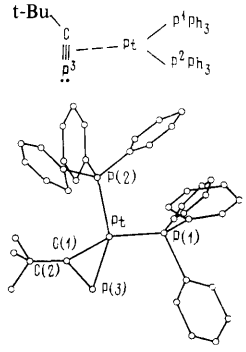


Figure 2. The structure of the complex of t-BuCP with zerovalent platinum.[45]

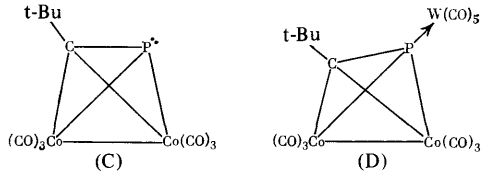
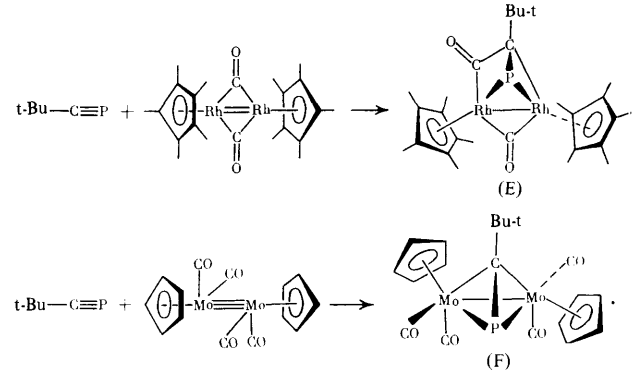
Equimolar amounts of t-BuCP and $Co_2(CO)_8$ react in tetrahydrofuran at room temperature with formation of the complex $Co_2(CO)_6$(t-BuCP) (C); it is a blood-red oil, which readily decomposes in air and in the light.[46] When the reaction is carried out in toluene with subsequent addition of tungsten pentacarbonyl, the crystalline complex $Co_2(CO)_6$(t-BuCP). .$W(CO)_6$ (D), which is stable in air and has m.p. 109–110 °C, is formed:[48]



Its structure, in which t-BuCP is a donor of six electrons, has been established by X-ray diffraction:[48] the bridging phospha-alkyne fragment and the two $Co(CO)_3$ groups form a tetrahedron, the phosphorus atom being coordinated to $W(CO)_5$. The C–P bond in the coordinated phospha-alkyne (VII) (1.695 Å) is much longer, as in the platinum complex, than in the free ligand. The shorter W–P bond in this complex compared with that in the familiar complex cis-$W(CO)_4$. .$(PMe_3)_2$ (2.502 Å) reflects, according to the authors,[48] an unusual hybridisation of the phosphorus atom in complex (D).

At −60 °C t-BuCP adds quantitatively to the metal–metal Rh=Rh and Mo≡Mo multiple bonds with formation of complexes (E) and (F), which are resistant to oxygen and atmospheric moisture:[49]

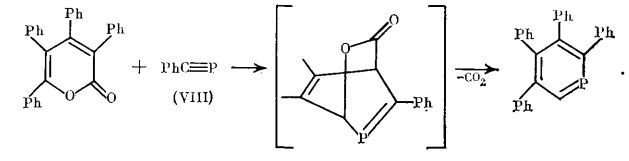
Scheme



The addition takes place in both cases at right angles to the metal–metal bond. X-Ray diffraction analysis of complex (F) showed[49] that its molecule contains the Mo_2PC tetrahedron; the length of the P–C bond increases to 1.713 Å, which is characteristic of a double bond.

The chemistry of the complexes of phospha-alkynes with transition metals constitutes a clear manifestation of an important feature of their electronic structure, noted in the analysis of the PES:[41] the much more significant separation of the π and *n* levels in phospha-alkynes than in nitriles. It is known for the majority of nitriles that they are coordinated to transition metals via the LEP of the nitrogen atom and that only some of them, having a powerful electron-accepting group at the carbon atom (for example, $CF_3C{\equiv}N$) add "sideways".[41] On the other hand, the coordination of the metal to the C≡P triple bond is characteristic of phospha-alkynes. The unshared electron pair of the phosphorus atom is involved only in complex (D) on formation of a bond with a tungsten atom, because the possibilities for coordination with participation of the π electrons of the C≡P bond have already been exhausted.[48]

An example of the involvement of a phospha-alkyne as a dienophile in the diene synthesis is provided by the [4 + 2]-cycloaddition of phenylphosphaethyne to α-pyrone and cyclopentadienone.[27] In both cases PhCP reacts at the instant of its evolution on thermolysis of the phospha-alkene $Ph(Me_3Si)C$ = PCl with the corresponding diene to form λ^3-phosphorines after the elimination of CO_2 or CO,[27] for example:



---o0o---

The data presented illustrate the first advances achieved in the chemistry of derivatives of monocoordinate phosphorus. The search for new methods of synthesis of stable phospha-alkynes and the improvement of the physicochemical experimental techniques will undoubtedly promote further successful development of research into this new and interesting field of the chemistry of OPC.

---o0o---

During the preparation of the manuscript for the press, several new publications appeared on the subject of this review.[50–52] A study of the PES of phosphaethyne and fluorophosphaethyne by the method of Green functions

showed that the ionisation of the 1π and 3σ MO in HCP and also of the 2π, 4σ, and 1π MO in FCP can be described within the framework of a one-particle ionisation pattern.[50] The vibrational-rotational spectrum of fluorophosphaethyne has been investigated.[51] The observed frequency $\nu(C\equiv P) = 1670.842\ cm^{-1}$ agrees with $\nu(C\equiv P) = 1670.8\ cm^{-1}$ determined previously.[43]

The reaction involving the [8 + 2]-cycloaddition of phenylphosphaethyne to 8-methoxyheptafulvene leads to the formation of the previously unknown 2-phospha-azulene:[52]

Substituted Ureas. Methods of Synthesis and Applications

T.P.Vishnyakova, I.A.Golubeva, and E.V.Glebova

Systematic data on the method of synthesis of ureas by the interaction of compounds containing the amino-group with organic isocyanates, of amines and alkyl halides with alkali metal cyanates, and of primary and secondary amines with phosgene, carbon dioxide, urea, or nitrourea and by the carbonylation of amines are presented. The reactions involving the alkylation of urea and its interaction with various compounds containing functional groups are considered. The advantages and disadvantages of various methods are noted. The principal and practical applications of substituted ureas, including their applications as additives to organic materials, are discussed.
The bibliography includes 314 references.

III. Applications of substituted ureas 254

I. INTRODUCTION

Substituted ureas have attracted attention because of the wide variety of their applications in industry, engineering, agriculture, and medicine;[1] they are widely used as pesticides and plant growth regulators, are effective additives, for different purposes, to hydrocarbon fuels and oils and polymeric materials, and they have found applications as medicinal preparations and dyes.

An enormous amount of factual data has now been accumulated on the methods of synthesis, properties, and applications of substituted ureas. However, hitherto there have been no review articles in the literature devoted to these compounds.

Kutepov's review[2] covers the literature up to 1961 and deals with the synthesis and reactions of only one group of compounds of this type—diarylureas. A review[3] dealing with the methods of synthesis, structure, and properties of a specific class of ureas, namely carbohydrate derivatives with carbamide fragments, was published in 1982. For this reason, carbohydrates containing derivatives of urea are not dealt with in this review.

The present communication is the first attempt at a survey and systematic account of the available literature data and the methods of synthesis and practical applications of substituted ureas.

II. METHODS OF SYNTHESIS OF SUBSTITUTED UREAS

The methods for the preparation of substituted ureas developed at the present time can be divided into eight principal groups.

1. The Interaction of Amino-compounds with Organic Isocyanates

In 1848 Würtz obtained symmetrical dimethylurea for the first time by treating methyl isocyanate with water.[4,5] Subsequently these results were confirmed: the corresponding symmetrical dialkylureas were obtained by decomposing methyl, ethyl, butyl, and isobutyl isocyanates with water.[6] The corresponding amines are formed as intermediates in these processes, reacting further with another isocyanate molecule:

$$RNCO \xrightarrow{H_2O} RNHCOOH \xrightarrow[-CO_2]{} RNH_2 \xrightarrow{RNCO} RNHCONHR .$$

The method has been used to synthesise substituted di(isocyanatophenyl)ureas by the reaction of 1-R-substituted 2,4-phenylene di-isocyanates with water in molar proportions of 2 : 1 and using ether as the solvent.[7]

The interaction of organic isocyanate with amines, for example, of phenyl isocyanate with methylaniline, ethylaniline, or diphenylaniline, leads to substituted ureas:[8]

$$C_6H_5NHR + C_6H_5NCO \rightarrow C_6H_5N(R)CONHC_6H_5 ;$$
$$R = CH_3,\ C_2H_5,\ C_6H_5 .$$

Table 1. The isocyanate method of synthesis of substituted ureas.

Initial compound	References
Amino-compounds	
Ammonia	[29—31]
Primary amines:	
saturated aliphatic	[12,15,32,33]
unsaturated aliphatic	[34]
aromatic	[8,23—25,32,35—39]

Saturated carbocyclic	[61]
Benzoyl isocyanate	[23,37,39]
Alkylphenylene isocyanates	[7]
Heterocyclic	[24]

The interaction of organic isocyanates with amines is nowadays the most widely used method of synthesis of asymmetric ureas. Various compounds containing the amino-group can enter into this reaction (Table 1). The reaction of alkyl isocyanates with hydroxylamines is widely used to obtain urea derivatives containing the hydroxy- or methoxy-group at one of the nitrogen atoms.[9-16]

The range of organic isocyanates used in this method is also extremely varied (Table 1).

The interaction of isocyanates with compounds containing the amino-group is as a rule carried out at room temperature or with cooling, sometimes with heating.[18,21-28] Equimolar amounts of the reactants or a slight excess of the organic isocyanates, more rarely an excess of the compounds containing the amino-group, are usually employed.

The process is normally performed in an organic solvent—benzene,[12,17-19,38] toluene,[14,25,39] xylene,[25] cresol,[23,24,53] chlorobenzene and dichlorobenzene,[12,25,52] methyl or ethyl alcohol,[54] dioxan,[23,52] tetrahydrofuran,[30,37,52,54,58] dimethylformamide (DMF),[19,22] ethanolamine,[27] acetonitrile,[13,30] and methylene chloride.[59,60] Water is sometimes used as the solvent because isocyanates react with water much more slowly than with amines.

The reaction of organic isocyanates with substituted amines proceed as a rule with high yields of substituted ureas, which are frequently nearly quantitative. However, it has been noted that secondary aliphatic-aromatic amines react with isocyanates to form unstable products, which decompose on heating. Diphenylamine does not react with isocyanates.[8]

It has been established that the molecular weight of the initial amine is only slightly reflected in the rate of its reaction with isocyanates. Aliphatic amines react much faster than aromatic amines. The reactivity of the isocyanate increases with increase of the electrophilicity of the substituent in its molecule.[44]

In order to improve the mass exchange between the individual components of the reaction mixture, *N*-aryl-*N'N'*-dimethylureas, where aryl = phenyl or *p*-chlorophenyl, have been synthesised in the presence of surfactants.[43] The yield of, for example, *N*-phenyl-*N'N'*-dimethylurea then amounted to 97.5%.[44]

Kinetic studies of the reactions of isocyanates with amines have been carried out.[62-67] The influence of substituents in the molecules of the isocyanate and the amine on the rate of reaction has been described and the reaction kinetics have been determined. However, hitherto there is no unanimous view concerning the reaction mechanism. It is believed[68] that the reaction proceeds in two stages. The first stage involves the formation of an activated complex, which is subsequently converted into the substituted urea by reacting with the amine. By analogy with the scheme proposed by Zahradnik,[69] the rearrangement of the intermediate complex into urea may be regarded as possible in principle:

$$RNCO + R'NH_2 \rightleftarrows \left[RN{=}C^{+}{-}O^{-} \cdots H_2NR' \right] \rightleftarrows \left[RN{=}C\begin{matrix} O^{-} \\ \diagdown \\ NH_2^{+} \cdots R' \end{matrix} \right] \rightarrow RNHC\begin{matrix} O \\ \diagdown \\ NHR' \end{matrix}$$

The thermodynamic data presented by Vorob'ev et al.[70] allow the possibility of the formation of a four-centre activated intermediate complex:

$$\begin{matrix} RN{=}C{=}O \\ H{-}NH{-}R' \end{matrix} \rightarrow \left[\begin{matrix} R{-}N{-}C{=}O \\ \vdots \quad | \\ H \cdots NHR' \end{matrix} \right] \rightarrow \begin{matrix} RN{-}C{=}O \\ | \quad | \\ H \quad NHR' \end{matrix}$$

2. The Interaction of Amines and Alkyl Halides with Alkali Metal Cyanates

Cyanic acid and alkali metal cyanates are fairly frequently used to obtain substituted ureas.[71-75] Würtz proposed for the first time in 1851 the alkylureas be obtained by evaporating to dryness a solution of the sulphuric acid salt of the corresponding amine and potassium cyanate.[71]

Subsequently the cyanate method of synthesis of substituted ureas was used in a number of investigations.[72-75] In particular, a large number of arylureas were obtained[72,73] by the reaction of the arylamine hydrochloride with sodium cyanate at 30 °C in glacial acetic acid with their subsequent separation in the form of a water-insoluble precipitate.

The reaction of alkyl halides with cyanate in aqueous DMF, described for the first time by Fukui et al.,[76] is a variety of the cyanate method of synthesis. The authors established that the composition of the reaction product is determined mainly by the presence of water in the reaction mixture. Thus, when dried reagents are used, only tributyl isocyanurate was obtained from butyl bromide in 84% yield, while in the presence of added water (0.56 of a mole per mole of butyl bromide) the yield of tributyl isocyanurate was 7% and that of symmetrical dibutylurea was 75%.[76]

The influence of the structure of the initial alkyl halide on the yield of substituted ureas has been investigated[77] and it has been established that the best yields of the required products are achieved when primary alkyl halides with a straight chain are employed; tertiary alkyl halides do not react. For example, unbranched alkyl bromides and alkyl chlorides react with potassium cyanate at 100–130 °C in DMF in the presence of an equimolar amount of water to form *NN*-dialkylureas in 90–96% yield.

By treating an alkyl chloride with potassium cyanate in DMF containing 5% of water at 100 °C, Argabright et al.[78] obtained monosubstituted ureas as well as the *NN*-disubstituted derivatives. The 1,5-disubstituted biuret is then formed as a side product and the formation of the 1,3,5-trisubstituted isocyanurate is not observed.

3. The Interaction of Primary and Secondary Amines with Phosgene

Symmetrical dialkyl-, diaryl-, and alkylaryl-ureas are obtained by treating the corresponding amines with phosgene. Several reviews devoted to the chemistry of phosgene, in particular its interaction with amines, are available.[44,67,79-84]

By passing phosgene through a saturated aqueous solution of aniline, Hoffman obtained for the first time diphenylurea:[85]

$$C_6H_5NH_2 + COCl_2 \rightarrow C_6H_5NHCONHC_6H_5 + HCl\ .$$

The reaction of phosgene with aniline was investigated by Japanese workers,[86] who established that aniline hydrochloride and the chloride of phenylcarbamic acid are formed together with diphenylurea.

Starting in 1875, Michler[87-92] began publishing communications on the treatment of primary and secondary amines with phosgene. Thus, by treating diphenylamine with phosgene in ligroin, he obtained diphenylcarbamoyl chloride $(C_6H_5)_2N{-}C\begin{matrix} O \\ \diagdown \\ Cl \end{matrix}$, which readily reacts with the initial amine to form a substituted urea. Thus it has been established that the reaction between the amine and phosgene proceeds in two stages, the hydrogen chloride evolved being combined with the amine to form the amine hydrochloride:

$$RR'NH + COCl_2 \rightarrow RR'NCOCl + RR'NH \cdot HCl\ ;$$
$$RR'NCOCl + RR'NH \rightarrow RR'N{-}CO{-}NRR' + RR'NH{\cdot}HCl\ .$$

Treatment of aqueous solutions of amines with a benzene solution of phosgene in the presence of alkali led to dimethyl-, diethyl-, and difurfuryl-ureas in quantitative yields.[93] In subsequent studies it was shown[94,95] that the reaction takes place successfully not only in aqueous solution but also in organic solvents.

In many instances it has been suggested that, in order to increase the yield of a substituted urea, the hydrogen chloride evolved during its synthesis be absorbed with the aid of special acceptor additives.[93,96-101] Alkalis, sodium and calcium carbonates, sodium acetate, and zinc and magnesium oxides[94,96-98] are used as hydrogen chloride acceptors in an aqueous medium, while in organic solvents the acceptors are triethylamine, dimethylaniline,[99-101] and other tertiary amines.

The literature data[84,102-107] show that the rate of reaction of amines with phosgene is extremely high and increases with increasing basicity of the initial amine. Kutepov and Rozanova were the first to investigate the mechanism of the reaction between phosgene and amines.[108,109] They believe that in the first stage of the reaction the nucleophile (the amine) adds to the powerful electrophile (phosgene) to form a 1:1 or 2:1 complex depending on the reactant ratio. The complex, being unstable, decomposes to form an *N*-substituted carbamoyl chloride or a di-*N*-substituted symmetrical urea. The carbamoyl chloride formed from the 1:1 adduct can split off hydrogen chloride to form the isocyanate. At the same time the carbamoyl chloride and the isocyanate formed from it interact with the amine to form a di-*N*-substituted symmetrical urea.

Japanese investigators[110] showed that the interaction of phosgene (in 10% excess) with aromatic amines (aniline, *p*-toluidine, and *p*-nitroaniline) and their hydrochlorides results in the rapid formation of the *N*-arylcarbamoyl chloride and the amine hydrochloride even at −15 °C. Only at temperatures above 0 °C do appreciable amounts of the diarylurea appear.

Other communications have also been devoted to the treatment of amines and their hydrochlorides with phosgene.[111-115] The most thorough studies on the treatment of primary, secondary, and tertiary amines with phosgene have been carried out by Strepikheev and co-workers,[67,116] who investigated the kinetics of the interaction of amines with phosgene and established that it is a complex chemical process consisting of several parallel-consecutive reactions.

In contrast to Kutepov and Rozanova, the authors believe that amines are not acylated directly on treatment with carbamoyl chlorides, but convert the latter into isocyanates:

$$RNHCOCl + RNH_2 \rightarrow RNH_3Cl + RNCO .$$

The free isocyanate then reacts with the excess amine to form a disubstituted urea.

The formation of ureas on treatment of amines with phosgene proceeds in accordance with the following scheme:

$$RNH_2 + COCl_2 \rightarrow RNHCOCl + HCl ; \quad (1)$$

$$RNH_2 + HCl \rightarrow RNH_3Cl ; \quad (2)$$

$$RNH_2 + RNHCOCl \rightarrow RNH_3Cl + RNCO ; \quad (3)$$

$$RNHCOCl \rightleftarrows RNCO + HCl ; \quad (4)$$

$$RNHCOCl + RNH_2 \rightarrow [RNCO] \rightarrow (RNH)_2CO ; \quad (5)$$

$$RNH_2 + RNCO \rightarrow (RNH)_2CO . \quad (6)$$

The amine hydrochlorides and disubstituted symmetrical ureas also react with phosgene to form the corresponding carbamoyl chlorides:

$$RNH_3Cl + COCl_2 \rightarrow RNHCOCl + HCl ; \quad (7)$$

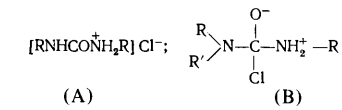
$$(RNH)_2CO + COCl_2 \rightarrow RNHCOCl . \quad (8)$$

In addition the isocyanates can polymerise [reaction (9)] and in certain cases the NCO group can be replaced by chlorine:

$$n\,RNCO \rightarrow (RNCO)_n . \quad (9)$$

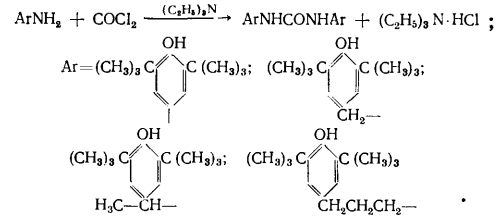
In the presence of an excess of phosgene substituted ureas are absent from the reaction mixture, which indicates a relatively low rate of reactions (5) and (6) compared with reactions (1) and (2). Consequently, in order to increase the yield of substituted ureas, it is necessary to use an excess of the amine and, in order to increase the rate of reaction, a hydrogen chloride acceptor must be employed.

Thus substituted ureas are obtained on treatment with phosgene as a result of the interaction of amines with intermediates—isocyanates and carbamoyl chlorides. Reviews concerning the mechanism of the last reaction are contradictory. The ammonide salts (A)[109] or the dipolar ions (B)[117,118] have been proposed as intermediates:



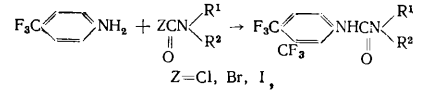
(A) (B)

Symmetrically disubstituted ureas can be obtained by treating sterically hindered aminophenols with phosgene in solution in benzene in the presence of triethylamine as the hydrogen chloride acceptor:[56]



The yield of substituted ureas decreases from 85 to 66% on passing from 4-aminophenol to 4-hydroxyphenylpropylamine. Together with substituted ureas, carbamoyl chlorides ArNHCOCl were isolated; the reaction proceeds via the intermediate formation of these compounds.

Some workers have suggested that substituted ureas be obtained by the reaction of amines with carbamoyl chlorides.[45,87,92,119] Thus *N'*-alkyl-*NN*-diphenylureas have been obtained in 90–98% yields from diphenylcarbamoyl chloride in an aqueous solution of C_2–C_4 alkylamines in acetone or toluene using hydrogen chloride acceptors—a tertiary amine or inorganic bases.[119] The corresponding ureas have been synthesised by the reaction of 3,4-bis(trifluoromethyl)aniline with dialkylcarbamoyl halides:[45]



where R^1 = H, a lower alkyl, alkenyl, or alkoxy-group and R^2 = a lower alkyl or alkenyl.

Substituted ureas containing a hydroxy-group at one of the nitrogen atoms have been obtained in satisfactory yields by the reaction of arylhydroxylamines with dialkylcarbamoyl chlorides.[9]

4. The Interaction of Amines with Urea and Nitrourea

Substituted ureas have been obtained in 50–80% yields by fusing urea together with amine hydrochlorides at ~180 °C or by refluxing in aqueous solution.[120-123] It has been

established that urea dissociates into ammonia and isocyanic acid, which reacts with the primary amine to give a monosubstituted urea; the latter splits off ammonia and is converted into the isocyanate, which again reacts with the amine to form a disubstituted urea:

$$H_2NCONH_2 \xrightarrow[-NH_3]{} HNCO \xrightarrow{RNH_2} RNHCONH_2 \xrightarrow[-NH_3]{} RNCO \xrightarrow{RNH_2} RNHCONHR .$$

It has been noted[124] that, by varying the amine : urea ratio, it is possible to obtain predominantly monosubstituted ureas.

Diphenylureas have been obtained by heating one part of urea with three parts of aniline at 150–170 °C.[125]

The study of various methods of synthesis of *NN'*-dimethylurea showed that the highest yield of the latter (80–90%) is obtained when methylamine reacts with urea.[126]

The method developed by Davis and co-workers[120–122] was subsequently widely used to synthesise *N*-alkyl(aryl)- and *NN'*-dialkyl(diaryl)ureas.[127–130] In order to increase the yield of substituted ureas, some workers recommend that the reaction be carried out between urea and amines in high-boiling solvents (cyclohexanol, phenol, or decalin[131–133]) or that the initial urea be made to interact with aqueous solutions of amine hydrosulphates or hydrophosphates.[134] Sometimes,[135] in order to obtain *NN*-dialkylureas of high purity, the reaction between urea and dimethyl- or diethyl-amine is carried out in an aqueous medium at 120–140 °C under pressure.

Asymmetric ureas are synthesised by transamination, for example, by the reaction of diarylurea with dimethylamine.[136]

A convenient method of synthesis of substituted ureas involves the reaction of amines with nitrourea.[137–140] Like urea, nitrourea is cleaved on heating with formation of isocyanic acid and nitramide:[137]

$$NH_2CONHNO_2 \rightarrow HNCO + H_2NNO_2 .$$

Since the nitro-group is an electron acceptor, nitrourea decomposes faster than urea. The corresponding substituted ureas have been obtained in 80–90% yields by the reaction of primary and secondary amines with nitrourea,[137] the yields being 10–30% higher than in the case of urea. It is noteworthy that nitramide, which decomposes into water and nitrous oxide under the conditions of the synthesis, promotes the shift of the equilibrium towards the formation of isocyanic acid and ultimately the formation of substituted ureas. Various substituted ureas have been obtained in 75–95% yields by the interaction of equimolar amounts of nitrourea with monoalkyl-, dialkyl-, and alkyl-aryl-amines in water.[138]

If the reaction between amines and nitrourea is carried out in 95% ethanol instead of water, then the yields of substituted ureas increase by 20–40%. The method is particularly effective when the solubilities of the initial amines in water are limited.[139]

N-Substituted ureas having the general formula $C_6H_5ZCH_2NHCONH_2$ (Z = cyclopropylene, cycolhexylene, or cyclopentylene) have been obtained by the method of Davis and Blanchard[137] in 30–50% yields.[140] A large number of substituted ureas have been synthesised by the reaction of sterically hindered aminophenols with nitrourea.[141]

Nitrosomethylurea also reacts with amines analogously to urea and nitrourea.[142] A series of *N*-alkylureas have been obtained in 70–90% yields with its aid:[142]

$$CH_3N(NO)CONH_2 \rightarrow CH_3NHNO + HNCO ;$$
$$CH_3NHNO \rightarrow N_2O + CH_3OH ;$$
$$HNCO + RNH_2 \rightarrow RNHCONH_2 .$$

5. The Interaction of Urea with Various Compounds

The methods of synthesis of *N*-alkyl and *NN*-dialkyl-ureas by the reaction of aldehydes and ketones with urea under oxygen pressure in the presence of nickel and cobalt catalysts are of interest.[143–145] The reaction is carried out at 60–150 °C, *N*-alkylurea and *NN*-dialkylurea being formed preferentially at 60–100° and 100–150 °C respectively. Thus 4-octadecylurea has been obtained in 75% yield from stearaldehyde[143] and s-butylurea has been obtained from ethyl methyl ketone in 77% yield.[145]

Mono- and di-alkylureas with an alkyl substituent having the iso-structure can by synthesised by the direct alkylation of urea with alcohols or olefins.[146–151] Thus a patent[146] suggests that urea be alkylated by tertiary alcohols using urea : alcohol : sulphuric acid (concentration 94% and above) molar ratios of 1 : 2 : 2. According to another patent,[147] the initial urea is to be alkylated by olefins containing a double bond at a tertiary carbon atom at 0 °C and using olefin : urea : sulphuric acid (90–100%) molar ratios of 1 : 4–5 : 2–2.5.

Different t-alkylureas have been obtained by the direct alkylation of urea with olefins in the presence of concentrated sulphuric acid as the catalyst,[148,149,152] The study of the reaction conditions showed that the best yield of alkylation products is achieved at temperatures between 0° and −5 °C, a sulphuric acid concentration of 96%, for molar ratios of urea, sulphuric acid, and the olefin of 1 : 2 : 4, and for a reaction time of 4–5 h.

The authors suggest that the alkylation of urea by olefins in the presence of sulphuric acid proceeds in two stages: an alkylsulphuric acid is formed in the first stage and alkylates urea further with regeneration of sulphuric acid.

In order to reduce the amount of sulphuric acid necessary for the reaction, it has been suggested[150] that some of it be replaced by $FeSO_4.7H_2O$.

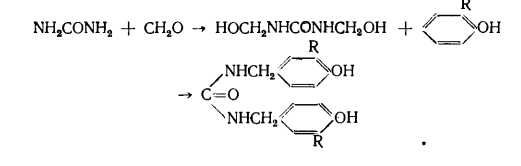
The use of a mixture of concentrated H_2SO_4 and methyl sulphate as the catalyst made it possible to obtain, by alkylating urea with isobutene, *NN'*-di(t-butyl)urea in 76.7% yield or *N*-t-butylurea in 29.6% yield relative to the initial urea.[151]

Certain symmetrical dibenzylureas are obtained by condensing phenols with urea and formaldehyde in the presence of acid catalysts.[152,155] The condensation of urea with formaldehyde to form mono(hydroxymethyl)urea in the first stage has been suggested:[155]

$$NH_2CONH_2 + CH_2O \rightarrow NH_2CONHCH_2OH .$$

The subsequent condensation with phenol in the presence of formic acid leads to *NN'*-di(4-hydroxybenzyl)urea.[155] Under these conditions, di(4-hydroxyphenyl)-methane is formed as a side product. The authors note that *N*-4-hydroxybenzylurea was not detected in any of the experiments.[155] On raising the temperature of the synthesis or on employing as the catalyst an acid stronger than formic, for example, hydrochloric, the formation of polymeric products sparingly soluble in organic solvents was observed.[155]

Alkylphenols have been condensed with urea and formaldehyde[153–155] in dearomatised petrol at 96–98 °C using 0.01% of concentrated hydrochloric acid as the catalyst. A large number of different *NN'*-dibenzylureas have been synthesised by this method in high yields:



An analogous reaction has been carried out with 2,6-di(t-butyl)phenol (DTBP).[56] In this process di[3,5-di(t-butyl)-4-hydroxyphenyl]methane and di(hydroxymethyl)urea polycondensation products are formed as side products. By varying the reaction conditions, namely the temperature (50–100 °C), the di(hydroxymethyl)urea : DTBP molar ratio (1 : 2.5–10), and the catalyst (HCOOH, KU-2 resin, HCl, sulphopolyphenyl ketone), the yield of substituted urea was raised only to 24%. The replacement of di(hydroxymethyl)urea by its dimethyl ether in this reaction (in order to prevent polycondensation) resulted in only a slight improvement of the yield of the required product—to 31%.

Table 2. Synthesis of substituted ureas by the catalytic carbonylation of amines.[164]

Amine	Catalyst	T, °C	Yield, %
Diethylamine	NiI_2	280	72
Butylamine	NiI_2	200	40–45
Ditto	$Mn_2(CO)_{10}$	180–200	47
Cyclohexylamine	$Mn_2(CO)_{10}$	180–200	58
Hexamethyleneamine	Co	200	—
Aniline	Co	200	75
Ditto	$Mn_2(CO)_{10}$	190	6
"	NiI_2	160	26
" *	Pd, Pd/C, $PdCl_2$	180	—
" **	Te	140	—

6. The Synthesis of Substituted Ureas by the Carbonylation of Amines

(a) Catalytic carbonylation of amines. Substituted ureas can be obtained by the catalytic carbonylation of amines,[156–162] using transition metals and their salts and carbonyls as catalysts (Table 2). The reaction is performed at 150–280 °C and a carbon monoxide pressure of 100–300 atm. Its products are *N*-formylureas and other substituted urea derivatives. This method has significant advantages over the method involving the treatment of amines by phosgene, used at present in industry, since it makes it possible to avoid the use of a poisonous component (phosgene) and in addition the carbonylation of amines results in the formation of hydrogen[156] and water[159–161] together with the required products and not hydrochloric acid as in the reaction with phosgene. The catalytic carbonylation of amines yields substituted ureas in a single stage under mild conditions.[163]

The large set of chemical substances of different kinds tested as catalysts shows that a purely empirical approach has been used. This is because the amine carbonylation process has been inadequately investigated.

Numerous mechanisms have been proposed for this reaction. They are as a rule contradictory and have not been confirmed by kinetic data. Thus it has been shown[166–168] that amines react with transition metal compounds to form charge-transfer complexes, which, on heating and on treatment with oxidants, are capable of undergoing deprotonation and homolytic decomposition with formation of the aminyl radical and a change in the oxidation state of the complex-forming agent. A chain reaction mechanism has been proposed in which the metal salts serve as the sources of radicals at the instant of reaction.[166] It has been suggested[169] that, in the presence of I_2 and $KMnO_4$, the reaction proceeds in accordance with an analogous mechanism.

Another carbonylation mechanism has been discussed by Dombek and Angelici,[170] who believe that $Fe(CO)_5$ reacts with the amine to form a carbamoyl complex, which is of key importance in the catalytic process. The reaction with $Mn_2(CO)_{10}$ [162] and certain other transition metal compounds, which are reduced to the metal under the reaction conditions (100–200 °C, 100 atm CO) and are capable of forming carbonyls, apparently proceeds analogously. The reaction results in the formation of either formamides or, when NiI_2, Co, or $Mn_2(CO)_{10}$ are used as catalysts, a mixture of formamides and substituted ureas; the latter are formed preferentially in the presence of $Mn_2(CO)_{10}$.

The composition of the products depends significantly on the nature of the amine. Thus it has been shown[156] that the carbonylation of lower aliphatic amines gives rise to only a small amount of ureas together with formamides, while aromatic amines produce only ureas.

It has been suggested[171,172] that ureas are formed in two stages via an intermediate formamide:

$$RNH_2 + CO \rightarrow RNHCOH \ ;$$

$$RNHCOH + H_2NR \rightarrow (RNH_2)_2CO \ .$$

Analysis of the views expressed in the literature on the mechanism of the amine carbonylation reaction shows that they require careful checks and investigation. Thus essentially the same mechanism has been proposed[158,166] for severe and mild conditions, although the reaction products are completely different. The high selectivity of the reaction as regards the formation of formamides under severe conditions and of urea under mild conditions is incompatible with a radical mechanism.

(b) Oxidative carbonylation of amines. In the amine carbonylation reactions examined above the catalyst either does not undergo a change in valence or is reduced with transfer of one electron. An interesting method of synthesis of substituted ureas involves the oxidative carbonylation of amines, which takes place on reduction of the metal complex (transfer of two electrons) or in a catalytic process in the presence of an additional oxidant. Apart from metal complexes, the reaction is catalysed by elemental sulphur and selenium. The oxidative carbonylation of amines is carried out under mild conditions, which is of practical interest.

Substituted ureas have been obtained in high yields by the reaction[173–175]

$$CO + S + RNH_2 \rightarrow RNHCONHR + H_2S \ .$$

The reaction involving aromatic amines takes place under mild conditions (100–160 °C, 20–40 atm), while that of aliphatic amines requires more severe conditions. The yield of ureas increases on raising the temperature and when a solvent (ethanol) is employed.

When selenium is used instead of sulphur, the reaction conditions become much milder (20 °C, 1 atm CO).[176] The yield of substituted ureas formed from primary amines is 95–99%, but that formed from secondary amines is much lower. Seleno-carbamates have been isolated as intermediates. It has been shown that the active carbonylating agent is selenium carbonyl.[177,178] An excess of oxygen in the CO + O_2 mixture leads to the precipitation of elemental selenium and the cessation of the catalytic reaction. It is believed[176] that the reaction takes place in at least two stages:

$$RNH_2 + Se + CO \rightarrow (RNH_3)^+ (RNHC(=O)Se)^- \ ;$$

$$(RNH_3)^+ (RNHC(=O)Se)^- + O_2 \rightarrow (RNH_2)_2CO + H_2O + Se \ .$$

Carbonylation of primary amines in the presence of silver acetate under mild conditions (0–25 °C, 55–100 atm) afforded *NN*-dialkylureas in almost quantitative yields.[157] Copper, zinc, cadmium, cobalt, and nickel acetates are inactive, while $Pd(Ac)_2$ is weakly active.

In the presence of $CuCl_2$, substituted ureas are obtained at room temperature and atmospheric pressure of CO:[179,180]

$$R^1R^2NH + CO + Cu^{II} \rightarrow R^1R^2NCONR^1R^2 + H_2O + Cu^I .$$

Since univalent copper complexes are readily reoxidised by oxygen, the overall reaction has the following form:

$$R^1R^2NH + CO + O_2 \xrightarrow{Cu^{I,II}} R^1R^2NCONR^1R^2 + H_2O .$$

The reaction can be performed in many solvents and in their absence. Piperidine and morpholine show the highest reactivity, while diethylamine, pyrrolidine, cyclohexylamine, and butylamine are less reactive.

It has been found[158] that, in the temperature range 25–110 °C at atmospheric pressure, the carbonylation of certain primary and secondary amines in the presence of $PdCl_2$ and $Hg(CH_3COO)_2$ is a stoichiometric oxidation-reduction reaction, which takes place in four stages:

(1) the formation from the amine and the metal salt of a compound having the character of a charge-transfer complex:

$$R_2NH + Hg(CH_3COO)_2 \rightarrow (R_2NH)_2Hg(CH_3COO)_2 .$$

(2) The interaction of the complex formed with CO accompanied by the insertion of the latter in the metal–nitrogen bond:

$$(R_2NH)_2Hg(CH_3COO)_2 + CO \rightarrow R_2NCHg(CH_3COO) + R_2NH \cdot CH_3COOH .$$

(3) The redox decomposition of the carbamoyl complex with formation of active radical species and the reduction of the metal ion:

$$R_2NCHg(CH_3COO) \rightarrow R_2NC\cdot + Hg(CH_3COO) .$$

(4) The recombination of the active species to the reaction products:

$$2R_2NC\cdot \rightarrow R_2NC{-}CNR_2 \xrightarrow{\Delta} R_2NCNH_2 + CO .$$

In a complex system comprising organic phosphines, quaternary ammonium bases, and tetraethylammonium chloride, palladium complexes effect the catalytic carbonylation of amines to *NN'*-disubstituted ureas in the presence of nitro-compounds as oxidants at 90 °C and a CO pressure of 1 atm.[181]

The synthesis of substituted ureas by the oxidative carbonylation of n-butylamine and piperidine in the presence of palladium(II) complexes, copper(I, II) complexes, or the highly active catalytic system comprising both copper(II) and palladium(II) complexes has been investigated.[163] The last catalytic system retains its activity in reactions with different amines in a number of solvents (dioxan, ethanol, pyridine, and acetonitrile). It has been established[163] that, in the presence of palladium complexes, the reaction proceeds via the formation of a carbonyl complex, which is subsequently converted, as a result of nucleophilic attack by the amine on the coordinated carbon monoxide, into a carbamoyl intermediate, whose redox decomposition is the rate-limiting stage of the process. The amine-copper(II) complexes greatly accelerate this decomposition. When bivalent palladium and copper complexes are used, a synergistic effect is observed.

Thus the oxidative carbonylation of amines is an effective and promising method of synthesis of substituted ureas. However, this reaction has so far been inadequately investigated. The studies which have been made are in the main preparative and the reaction mechanism has been scarcely investigated.

Symmetrical dialkyl- or diaryl-ureas have been obtained in 50–90% yields by condensing the corresponding amine with carbon dioxide at 100–300 °C and a pressure of 100–300 atm.[182–187]

7. Synthesis of Substituted Ureas and Acid Amides (Hofmann Rearrangement)

Hofmann found in 1881 that the reaction of amides with bromine in the presence of alkali results in the formation of 1,3-alkylacylureas, which are converted into alkylureas on subsequent treatment with nitric acid:[188,189]

$$CH_3CONH_2 \xrightarrow[-HBr,\ -H_2O]{NaOH+Br_2} CH_3CONa \xrightarrow[-NaNO_3,\ -HBr]{HNO_2} CH_3NCO \rightarrow$$
$$\rightarrow CH_3NHCONHCOCH_3 \xrightarrow[-CH_3COOH]{H_2O} CH_3NHCONH_2 .$$

The corresponding *NN*-dialkyl-*N'*-arylureas have been obtained in 20–60% yields from aromatic acid amides and secondary amines in the presence of potassium hypochlorite.[190]

III. APPLICATIONS OF SUBSTITUTED UREAS

Substituted ureas, which constitute some of the most important classes of chemical compounds, have found extensive applications in agriculture as plant growth regulators and pesticides, particularly herbicides. This question has been widely dealt with in the literature. A systematic account and a survey of data on the effectiveness of ureas as plant growth regulators and herbicides have been given in a review,[191] in which certain regularities in the herbicidal activity of substituted ureas as a function of their structure have been established. A bibiographic index of recommended pesticides and plant growth regulators, covering the literature up to 1979, has been published;[192] much space in it has been devoted to substituted ureas.

Studies in this field are developing vigorously; new communications on the efficiency of substituted ureas as herbicides,[12–14,17–19,36,38,41,42,193–210] and plant growth stimulators,[38,211–213] as well as fungicides,[17,19,22,205,213–215] insecticides,[23,24,37,39,216–218] bactericides,[60,213,219] and other pesticides,[16,34,220] promising for practical applications, are being published systematically.

Yet another field in which substituted ureas are widely employed is that of the manufacture of physiologically active substances[34,221–225] and medicinal preparations, mainly with tranquillising and anticonvulsant activities.[226–231] Various *N*-alkyl-*N'*-aminophenoxyureas are used in the treatment of asthma and other diseases of the respiratory tract[59,232] and substituted ureas are used as components of medicinal preparations for the treatment of cardiac diseases.[233]

Certain nitroureas exhibit anticancer and antileukaemic properties,[54,234–242] heterylcarbonylureas dissolve gall stones,[243] while indolylureas, amidinoureas, *N*-aryl-*N'*-imidazolidineureas, aminoethylureas, and piperidinylureas possess hypotensive properties.[58,244–248]

Sulphonylureas and 1-amidino-3-phenylureas exhibit dermatological properties.[249,250] The latter can also be used to reduce blood pressure[245] and in the treatment of

increased acidity and stomach ulcers;[251,252] *N*-alkyl-*N'*-dialkylaminoethylureas[253] and pyrazinylureas can also be employed in the treatment of gastrointestinal diseases;[254] certain substituted ureas are used as agents for the protection of the skin against boils.[255]

Certain phenylureas are capable of inhibiting the degradation of connective tissues in warm blooded animals and in man.[256] Ureas with nitrogen-containing heterocycles can be used as regulators of immune responses,[28] as antihelminthic preparations,[26,257] and as hypoglycaemic substances.[258,259]

Data concerning the use of substituted ureas for the dyeing of hair and keratin and cellulose fibres have been described in the literature;[260,261] 3-hydroxy-2,4-dimethylphenylurea is the most effective.[103,262] Substituted ureas are able to form complexes with certain metal ions and they are used in analytical chemistry as complex forming agents.[263,268] Certain urea derivatives (for example, the symmetrical diethylphenylurea under the name centramit) serve as stabilisers of smokeless powders;[152] 1,3-dialkylureas are used in the synthesis of sweetening agents and as sugar substitutes.[269]

Tetramethylurea is used as a solvent in polarography.[270] Urea derivatives are also employed as solvents for quinone or hydroquinone in the manufacture of hydrogen peroxide[271] and as solvents and catalysts in chlorination reactions.[164]

Substituted ureas can serve as the starting materials for the synthesis of polymers[61,221,222,272-276] and also surfactants.[277]

Substituted ureas have assumed special importance recently as effective additives to hydrocarbonfuel oils and polymeric materials. They have been studied in detail as antioxidants in various types of petrol for automobiles.[32,33,278-280] Thus the study of various derivatives of *p*-hydroxyphenylurea showed[278-280] that the substitution of hydrogen at the nitrogen atom by various aliphatic and aromatic groups leads to the appearance of an appreciable antioxidant effect, while *p*-hydroxyphenylurea itself does not inhibit the oxidative processes in petrols. *N*-Alkyl-*N'*-(*p*-hydroxyphenyl)ureas, *N*-(4-hydroxy-3-methylphenyl)-*N'*-phenylurea, and *N*-butyl-*N*-phenyl-*N'*-(*p*-hydroxyphenyl)urea, used at a concentration of 0.06%, exhibit the highest effectiveness.

The influence of *N*-(*p*-hydroxyphenyl)-*N'*-pentylurea and *NN'*-dipentylurea on the thermo-oxidative stability of TS-1 and T-2 reactive fuels has been investigated.[281] In contrast to their effect on petrols,[55] in reactive fuels the test compounds proved to be relatively ineffective; in their presence the decrease in deposit formation was only by 20–30% (the concentration of the additive was 0.05 wt.%).

The study of the influence of various alkyl- and alkylaryl-ureas on the thermo-oxidative stability of straight-run reactive fuels of the T-1 type showed that *N*-alkyl and *NN*-dialkylureas are the most effective and reduce deposit formation in the fuel by 80–90%.[141,282] It has been established that substituted ureas which effectively reduce deposit formation in the fuel have almost no influence on the oxygen absorption process; this apparently shows that the anti-deposit formation function of the test compound is not associated with the antioxidant activity and is due to a dispersing type of activity. Compounds in which a urea fragment, with its dispersing activity, and a typical antioxidant fragment, namely 2,6-di(t-butyl)phenol, are combined in one molecule are effective stabilisers of reactive fuels.[156,283-285] Certain *N'*-acylaminoacyl derivatives of *N*-substituted ureas are also highly effective in stabilising reactive fuels obtained by hydrogenation processes.[286]

Kuliev and co-workers[152-154] proposed *NN'*-di(alkylbenzyl)-ureas as antioxidant additives to energy oils. For example, the additive obtained by condensing a mixture of C_8–C_{12} alkylphenols with urea and formaldehyde (AZNII-11) has antioxidant properties in oils which are not inferior to those of antioxidants such as ionol and *p*-hydroxydiphenylamine.

Apart from antioxidant properties, some of the substituted ureas behave as corrosion inhibitors when added to fuels and oils.[287-288] Thus *N*-alkyl-*NN'*-di(carboxymethyl)ureas containing 15–45 carbon atoms, preferably with an unbranched hydrocarbon chain, for example *N'N'*-di(carboxymethyl)-*N*-octadecylurea $C_{18}H_{37}NHCON(CH_2COOH)_2$ have been proposed as effective corrosion inhibitors in light distillate fuels.[287]

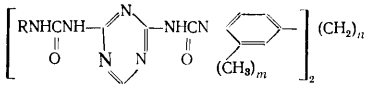
The alkenylsuccinimide based on urea (SIM), obtained by aminating alkenylsuccinic anhydride with urea, is used as a corrosion inhibitor in engine conservation oils for different purposes.[288,289] Its use ensures a high protective capacity and effective operating properties of the oils.

In many instances substituted ureas are used as detergent additives and additives preventing the formation of carbon deposits.[290,291] Monosubstituted ureas with an overall number of carbon atoms between 5 and 25 are used to remove carbon, varnish, and other deposits formed in the injection system of an internal combustion engine. Octadecyl-, dodecyl-, and 9-octadecynyl-ureas are the most effective (they are recommended for use in hydrocarbon fuels with a boiling range of 38–400 °C).

A reduction of the extent of deposition in the carburettor of an internal combustion engine is achieved by introducing into petrol additives which are products of the interaction of air-oxidised liquid paraffin and a substituted urea having the general formula $RNH(CH_2)_xNHCONH(CH_2)_xNHR'$, where $x = 2$–4 and R and R' are saturated secondary aliphatic C_{10}–C_{15} groups.[291]

Some investigors have successfully solved the problem of reducing the setting temperatures of diesel fuels with the aid of substituted ureas.[292,293] Compounds have the general formula $\begin{matrix}R_1\\R_2\end{matrix}\!\!>\!NCONH_2$ ($R^1 = C_3$–C_{20} alkyl groups, R^2 = phenyl), particularly *N*-phenyl-*N*-propylurea, produced a satisfactory result.[292] Alkylisoureas RNHCOR, where R = $\begin{matrix}\\\|\\NH\end{matrix}$ C_{16}–C_{20} alkyl groups, have also proved to be more effective depressors of the setting temperatures of diesel fuels.[293]

Compounds of urea and triazine having the general formula



where R = C_{16}–C_{22} aliphatic group and *m* and *n* = 0 or 1 have been proposed as thickening additives to high-temperature plastic lubricants,[40] while halogenoarylureas are effective hardening agents for epoxy resins.[294-296]

It has been suggested that benzylureas be used as antioxidants for certain polymers.[297] It has been established that 3-alkylbenzyl-1-phenylurea at a concentration of 0.1% is the most effective in tests in polypropylene.

An important problem which has been solved successfully with the aid of substituted ureas is that of the prevention of the cracking of rubbers under the influence of ozone.[298-300] Substituted ureas having the general formulae ArNHCONHAr' (Ar and Ar' are various aromatic groups), for example, *N*-naphthyl-*N'*-*p*-tolylurea,[298] and $R^1R^2NCONR^3R^4$ (R^1, R^2, R^3, and R^4 are hydrogen or hydrocarbon groups, two of which are alicyclic) have been proposed.[209] For example, *NN*-dicyclohexyl-*N'*-phenylurea at a concentration of 1.5% reacts with butadiene–styrene raw rubber to form a vulcanised rubber which hardly cracks under the influence

of ozone. Substituted ureas with the above structure do not dye or decolorise the raw material to which they are added.

Urea derivatives have been proposed as anti-ageing agents[301] and thermal stabilisers[302] for synthetic rubbers. Diphenylurea prevents the cross-linking of synthetic rubbers to a high degree of unsaturation.[303] It has also been stated that urea derivatives with aromatic and aliphatic acyl groups can function as thermal stabilisers not only for rubbers but also for plastics and oils,[304] while dihydroxyalkylureas can be used as modifying agents (chain lengthening agents) for urethane thermoelastoplastics.[305]

Derivatives containing urea residues have been patented as stabilisers preventing changes in the mechanical properties and colour of polyurethane resins, foam plastics, fibres, synthetic leather, and elastomers under the influence of sunlight, ultraviolet irradiation, or heat.[306]

It has been suggested that substituted ureas be used as stabilisers for higher ketone peroxides (vulcanising agents for polyester resins)[307] and as stabilisers preventing the formation of a sludge from hydrocarbons, lubricating materials, and fuels.[308]

Substituted ureas are used for the bleaching[309] of fabrics and for imparting hydrophobic properties to the latter,[310] for the impregnation[311] of synthetic fibres, and for the improvement of their formation.[312]

Data have appeared recently in the literature[313] demonstrating the possibility of using substituted ureas as additives imparting fire resistance to synthetic fibres. For example, for this purpose polyamide fibres have been impregnated with a solution containing urea or some of its derivatives, such as *NN*-diphenylurea, *N*-α-naphthylurea, and *NN*-dimethyl-*N'*-phenylurea.[313] *N*-Substituted derivatives of ethyleneurea can be used as ink stabilisers.[314] Inks containing substituted ureas are highly stable during use and storage and possess satisfactory physical properties.

---o0o---

Analysis of the literature data on the methods of synthesis of substituted ureas demonstrates their wide variety, but many of them suffer from various disadvantages which limit their application. Thus the amide method is characterised by low yields and the use of isocyanates for synthesis is difficult because they are not readily available, the condensation of hydroxymethylurea with phenols is accompanied by the formation of a large number of side products, while treatment of amines with phosgene makes it possible to obtain substituted ureas in high yields but the high toxicity of phosgene makes it difficult to work with this substance. From the standpoint of the ready availability of the starting material and simplicity, the interaction of urea or nitrourea with amines constitutes a convenient method of synthesis of substituted ureas but even this procedure suffers from certain limitations, because, depending on the amine employed, it gives rise to mono- or *NN*-disubstituted ureas. All these disadvantages and limitations must be taken into account in selecting the methods for the synthesis of particular urea derivatives.

The literature data which have been published recently show that, together with the traditional applications of substituted ureas (pesticides, medicinal preparations, and dyes), these compounds are highly effective as modifying and stabilising agents for various organic materials. One of the aims of the review is to draw the attention of investigators, working in the field concerned with the improvement of the quality of polymers and petroleum products with the aid of additives, to this promising class of compounds.

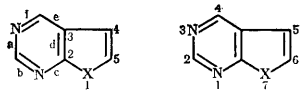
I. INTRODUCTION

Furo-, thieno-, and pyrrolo][2,3-*d*]pyrimidine derivatives occupy an important place among various heteroatomic bicyclic systems because they include compounds with different types of biological activity. Furthermore, these bicyclic compounds represent to a greater or lesser extent the structural analogues of biogenic purines and from this standpoint can be regarded as potential antimetabolites in nucleic acid metabolism. These data have served and continue to serve as a basis for the synthesis of a wide variety of derivatives of furo-, thieno-, and pyrrolo-[2,3-*d*]pyrimidines in order to discover physiologically active substances among them.

The IUPAC nomenclature and the numbering for these bicyclic systems, which we shall henceforth employ in the present review, are given below.



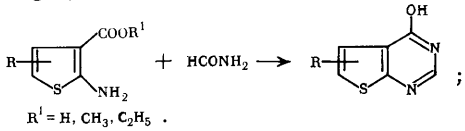
X = O, S, NH

Although the first communication on the synthesis of pyrrolo[2,3-*d*]pyrimidine appeared as early as 1911,[1] systematic studies on furo-, thieno-, and pyrrolo-[2,3-*d*]pyrimidines were begun 20–25 years ago. The methods of synthesis of these compounds can be divided into two groups: from derivatives of a five-membered heterocycle (furan, thiophen, and pyrrole) and from derivatives of a six-membered heterocycle (pyrimidine, oxazole, and thiazole).

II. METHODS OF SYNTHESIS

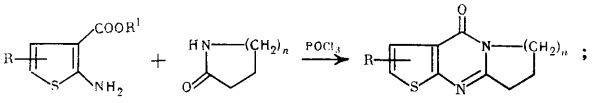
1. Methods of Synthesis from a Five-membered Heterocycle

Derivatives of 2-aminofurans, 2-aminothiophens, and 2-aminopyrroles containing the carbonyl or cyano-group in the 3-position in the five-membered ring have been widely used as the starting compounds for the synthesis of the bicyclic derivatives under consideration. Thus, when 2-aminothiophen-3-carboxylic acid or its esters are heated with formamide, 4-hydroxythieno[2,3-*d*]pyrimidines are formed in high yields:[2-8]



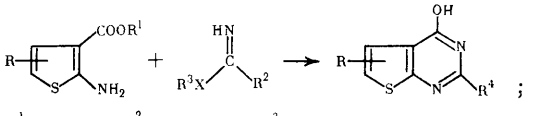
R^1 = H, CH_3, C_2H_5 .

Other workers[9] used the corresponding lactams instead of formamide; the yield of thienopyrimidine was 40–90%:



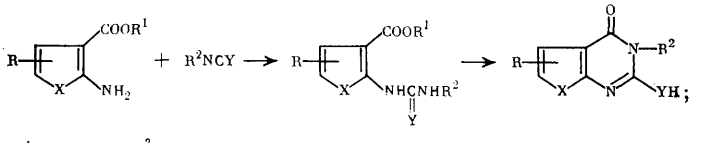
R^1 = H, C_2H_5; n = 1, 2, 3 .

The esters of 2-aminothiophen-3-carboxylic acid react with urea,[6,10] thiourea,[11] and iminoesters[11,13] to form the corresponding 2-substituted 4-hydroxythieno[2,3-*d*]pyrimidines:



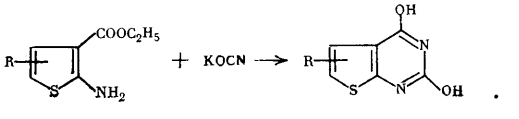
R^1 = CH_3, C_2H_5; R^2 = NH_2, Alk, Ar; R^3 = H, C_2H_5; R^4 = OH, SH, Alk, Ar; X = O, S .

The reactions of 2-amino-3-ethoxycarbonylthiophen with isocyanates,[14,15] isothiocyanates[11,16-25] and isoselenocyanates[26] lead to the formation of intermediate 3-ethoxycarbonyl-2-thienylureas (and the corresponding thioureas and selenoureas), which cyclise in an alkaline medium to the corresponding 2-substituted 3-alkyl(aryl)-4-hydroxythieno-[2,3-*d*] pyrimidines. An analogous reaction with isocyanate is known for 2-amino-3-methoxycarbonylfuran[27] and the corresponding pyrrole:[28]

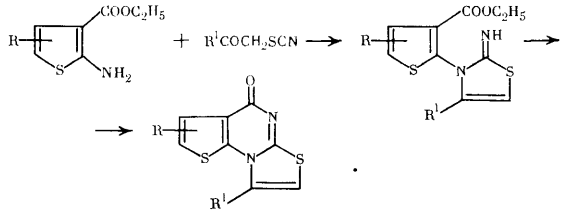


R^1 = CH_3, C_2H_5; R^2 = Alk, Ar; X = O, S, NH; Y = O, S, Se .

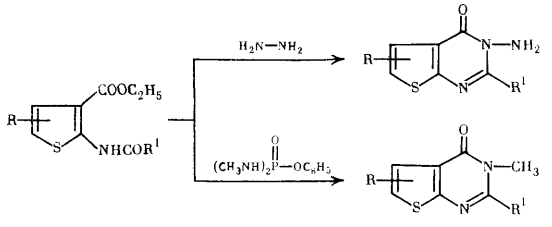
In an aqueous solution of potassium cyanate 2-amino-3-ethoxycarbonylthiophen cyclises 2,4-dihydroxythieno-pyrimidine in 70% yield:[29]



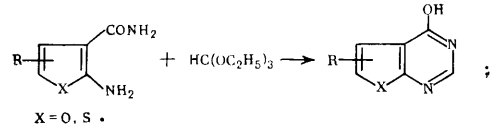
There is an interesting reaction between 2-amino-3-ethoxycarbonylthiophen and α-thiocyanatoacetone[30] or the corresponding acetophenone,[31] which results in the formation of the bicyclic thiazolothienopyrimidine system:



The interaction of 2-acylamino-3-ethoxycarbonylthiophen with hydrazine hydrate[32] or phenyl *NN*-dimethylphosphorodiamidate[33] results in the formation of 2-alkyl-3-amino- or 2-alkyl-3-methyl-4-oxo-thieno[2,3-*d*]pyrimidines respectively:

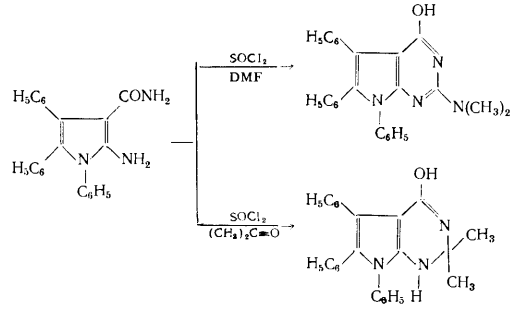


The 3-carbamoyl derivatives of the five-membered heterocycles can also participate in the cyclisation reactions. Thus 2-amino-3-carbamoylfurans[34,35] and the corresponding thiophens[5] react with orthoformic ester or with the acid itself[6] to form the corresponding 4-hydroxy-derivatives:

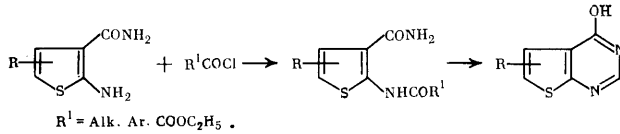


X = O, S.

On treatment with thionyl chloride in dimethylformamide (DMF), 2-amino-3-carbamoyl-1,4,5-triphenylpyrrole cyclises to 4-hydroxy-2-dimethylaminopyrrolo[2,3-*d*]pyridimine, while in acetone it cyclises to 2,2-dihydro-4-hydroxy-2,2-dimethylpyrrolopyrimidine:[36]

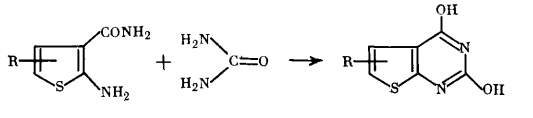


2,3-Substituted 4-hydroxythienopyrimidines can be synthesised from 2-acylamino-3-carbamoylthiophens:[6,37-39]

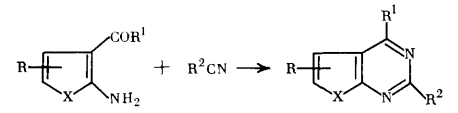


R^1 = Alk, Ar, $COOC_2H_5$.

When 2-amino-3-carbamoylthiophen is heated with urea, 2,4-dihydroxythieno[2,3-*d*]pyrimidine is formed in 40% yield:[6]

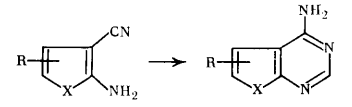


2-Amino-2-carbamoyl-, 2-amino-3-ethoxycarbonyl, and 2-amino-3-benzoyl-furans and the corresponding thiophens and pyrroles react with various nitriles to form the corresponding bicyclic compounds in 50–85% yields:[40]



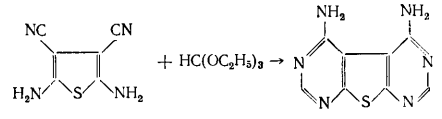
X = O, S, NH; R^1 = NH_2, $NHCH_3$, OC_2H_5, C_6H_5; R^2 = Alk, Ar.

When 2-amino-3-cyanofurans and the corresponding thiophens or pyrroles are used in the syntheses, it is possible to obtain systems containing the amino-group at the C(4) atom of the pyrimidine ring. Thus the corresponding 4-amino-derivatives have been obtained by heating 2-amino-3-cyanofuran and the corresponding thiophen or pyrrole with formamide,[41-44] orthoformic ester in the presence of ammonia,[45-49] or formamidine acetate:[50,51]

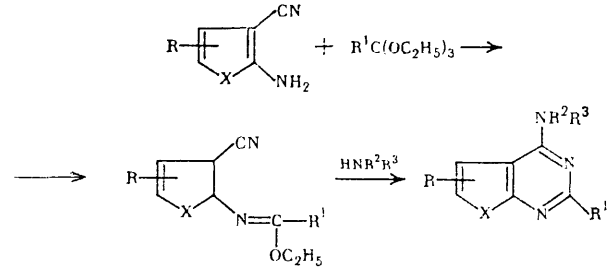


X = O, S, NH.

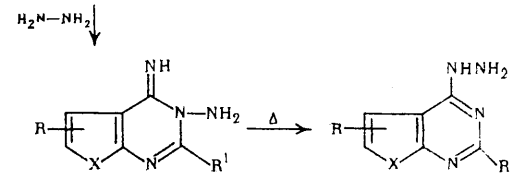
2,5-Diamino-3,4-dicyanothiophen reacts with orthoformic ester in the presence of ammonia and cyclises to 4,4'-diaminothieno[2,3-*d*;2',3'-*d*]dipyrimidine:[48]



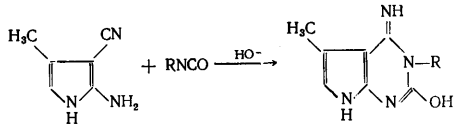
The first stage of the reaction of the corresponding furan or thiophen with orthoformic ester in the presence of ammonia usually involves the formation of 2-alkoxyethyleneimino-3-cyanofuran(or thiophen), which can be made to react with hydrazine[52] or substituted amines[53-56] to form the corresponding 4-amino-derivatives:



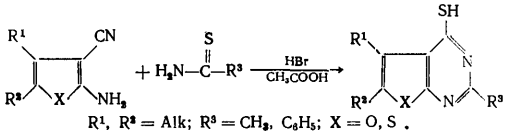
X = O, S; R^1 = H, Alk; R^2, R^3 = H, Alk, Ar;



2-Amino-3-cyanopyrrole cyclises on treatment with isocyanates in an alkaline medium to 3-alkyl-4-amino-2-oxopyrrolo[2,3-*d*]pyrimidine:[28]

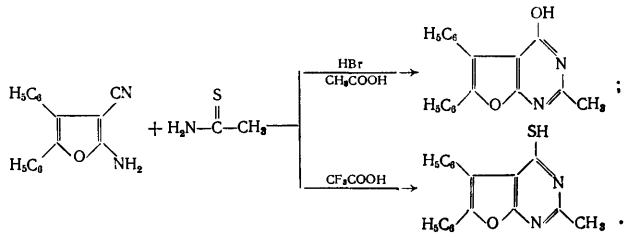


A study of the reaction of 2-amino-3-cyanofurans and the corresponding thiophens with thioamides established that the 4,5-dialkyl derivatives of these heterocycles in an acid medium give rise to 2-mercaptofuro- and 4-mercaptothienopyrimidines:[57]

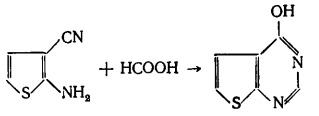


R^1, R^2 = Alk; R^3 = CH_3, C_6H_5; X = O, S .

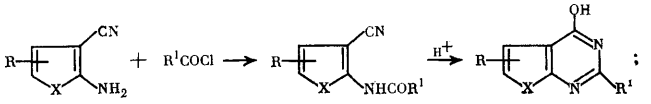
Under the conditions indicated above, 2-amino-3-cyano-4,5-diphenylfuran reacts with thioacetamide to form 4-hydroxyfuropyrimidine, while in the presence of trifluoroacetic acid it cyclises to 4-mercaptofuropyrimidine:



It is noteworthy that, on treatment with formic acid in the presence of sodium acetate, 2-amino-3-cyanothiophen also cyclises to 4-hydroxythieno[2,3-*d*]pyrimidine:[6]

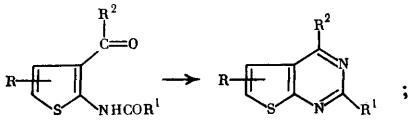


In an acid medium 2-acylamino-3-cyanofuran and the corresponding thiophens give rise to the corresponding 4-hydroxy-derivatives:[57]



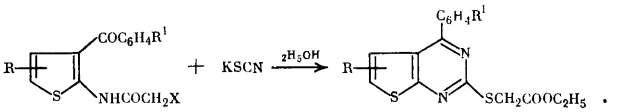
X = O, S; R^1 = CH_3 C_6H_5 .

2-Aminothiophen-3-carbaldehydes and the corresponding ketones have found an application in the syntheses of thieno-[2,3-*d*]pyrimidines. In the presence of ammonium acetate, ammonia, or formamide they cyclise to 2,4-dialkyl(aryl)thienopyrimidines:[6,58–62]

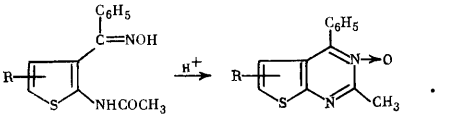


R^1 = Alk, Ar; R^2 = H, C_6H_5 .

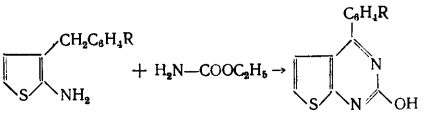
The reaction of 3-benzoyl-2-α-halogenoacylaminothiophen with potassium thiocyanate leads to the formation of 2-alkylthio-4-phenylthieno[2,3-*d*]pyrimidine:[63]



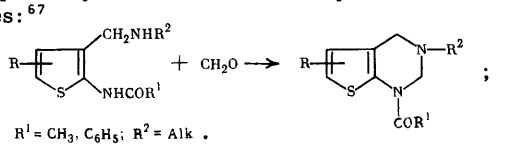
The oximes of 2-acylamino-3-benzoylthiophens cyclise in an acid medium to the corresponding *N*-oxides:[64,65]



In conclusion one may quote non-standard reactions whereby thiophens and pyrroles can be converted into thieno- and pyrrolo-pyrimidines. Thus 2-hydroxy-4-phenylthienopyrimidines have been obtained by heating 2-amino-3-benzylthiophen with urethane:[66]

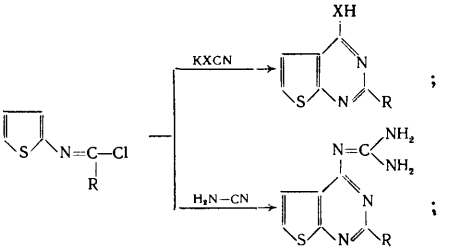


On treatment with formaldehyde, 2-acylamino-3-aminomethylthiophens cyclise to 1,2,3,4-tetrahydrothieno[2,3-*d*]-pyrimidines:[67]



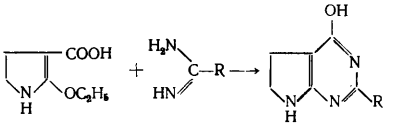
R^1 = CH_3, C_6H_5; R^2 = Alk .

The study of the reaction of *N*-(2-thienyl)chloroformamidines with isocyanates and cyanamide led to the synthesis of a series of 2-amino-4-substituted thienopyrimidines:[68]



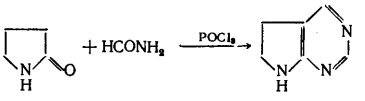
X=O, S, Se; R=N(CH_3)$_4$, N(CH_2)$_5$, N(CH_2CH_2)$_2$O .

3-Carboxy-2-ethoxy-4,5-dihydropyrrole reacts with urea, thiourea, or acetamidine to form the corresponding pyrrolopyrimidines, the yield of the product varying in the range from 5 to 70% depending on the character of the reactant:[69,70]

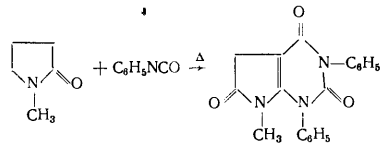


R=OH(4%); H(71%); SCH_3(5%), NH_2(59%); CH_3(40%) .

On treatment with formamide in the presence of phosphoryl chloride, 2-pyrrolidinone is converted into 5,6-dihydropyrrolo[2,3-*d*]pyrimidine:[71]

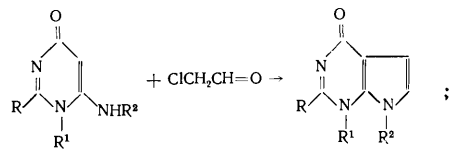


When 1-methyl-2-pyrrolidone is heated with phenyl isocyanate, 5,6-dihydropyrrolopyrimidine is formed:[72]



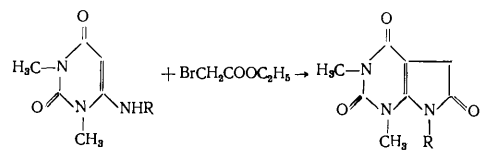
2. Methods of Synthesis from Six-membered Heterocycles

In this synthetic procedure, either pyrimidines without substituents at the C(5) atom but with different functional groups (hydroxy-, mercapto, and amino-groups) at the C(2), C(4), and C(6) atoms of the pyrimidine ring or the corresponding 5-substituted 6-hydroxy-, 6-amino-, and 6-mercapto-pyrimidines are usually employed. In the first case α-halogenocarbonyl compounds are used as the second component and the reaction with these substances can proceed both via the C(5) atom of the pyrimidine ring and via the 6-hydroxy-, 6-mercapto-, or 6-amino-group. Thus 2-substituted 6-amino-4-hydroxypyrimidines react with chloroacetaldehyde to form the corresponding pyrrolopyrimidines:[73-75]

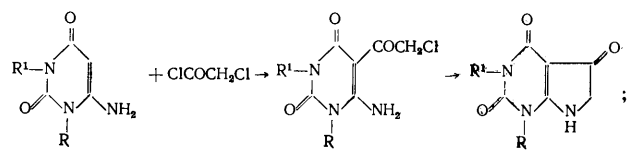


R=OH, SH, SCH_3, NH_2; R^1=H, CH_3; R^2=H, Alk.

On treatment with bromoacetic ester, 6-amino-1,3-dimethyluracil cyclises to 2,4,6-trioxopyrrolopyrimidine:[76]

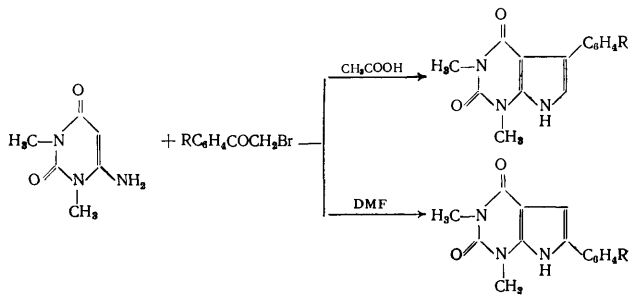


Chloroacetyl chloride also reacts with 6-aminouracils to form 5-acyl derivatives, which cyclise to 2,4,5-trioxopyrrolopyrimidines:[75,77]



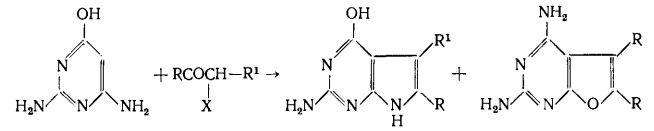
R=H, CH_3, C_2H_5, C_6H_5; R^1=H, CH_3.

Japanese workers[76,78] have shown that 6-amino-1,3-dimethyluracil reacts with phenacyl bromides via two different pathways depending on the conditions. 5-Phenyl- and 6-phenyl-pyrrolo[2,3-*d*]pyrimidines are formed in the presence of acetic acid and in DMF respectively:



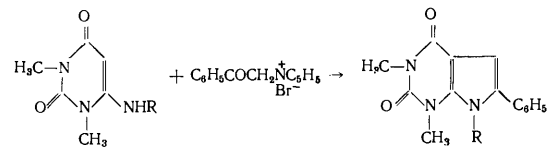
Evidently in the former case a molecule of hydrogen bromide is split off by reaction with the amino-group and in the latter case by reaction with the C(5)–H bond in the pyrimidine ring.

In the interaction of 2,4-diamino-6-hydroxypyrimidine with α-halogenoketones there is a possibility of the formation of both pyrrolo- and furo-[2,3-*d*]pyrimidines. Indeed, depending on the character of the ketone, either a mixture of these compounds or only one of the possible products is formed:[79]

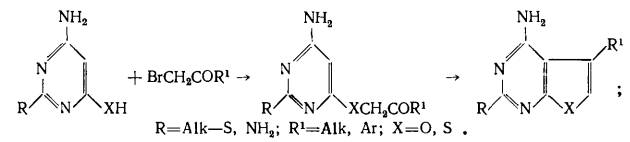


X=Cl, Br; R=H, C_6H_5, Alk; R^1=H, CH_3.

Instead of the α-halogenocarbonyl compounds, the corresponding pyridinium salts are sometimes employed. Thus 6-amino-1,3-dimethyluracil reacts with phenacylpyridinium bromide to form 6-phenylpyrrolopyrimidine:[80]

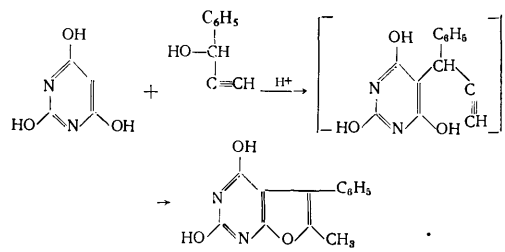


Certain 6-hydroxy- and 6-mercapto-pyrimidines can be alkylated at the hydroxy- and mercapto-groups with subsequent cyclisation to the corresponding furo-[81] or thieno-pyrimidine:[82,83]

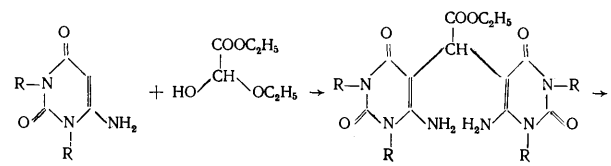


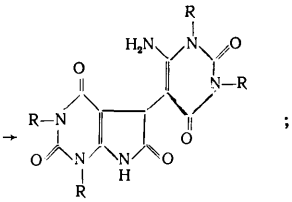
R=Alk—S, NH_2; R^1=Alk, Ar; X=O, S.

Instances of the employment of reactive hydroxy-compounds in the syntheses of furo- and pyrrolo-pyrimidines are known. Thus, when α-phenylpropargyl alcohol is heated with barbituric acid in the presence of sulphuric acid or boron trifluoride, 2,4-dihydroxy-6-methyl-5-phenylfuro[2,3-*d*]pyrimidine is formed in 75% yield:[84]



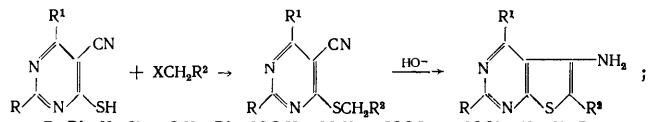
The reaction of ethyl glyoxalate with 6-aminouracils is of the type of aldol condensation and involves the formation of a bispyrimidine which cyclises under the influence of sodium bicarbonate to pyrrolo[2,3-*d*]pyrimidine:[85]





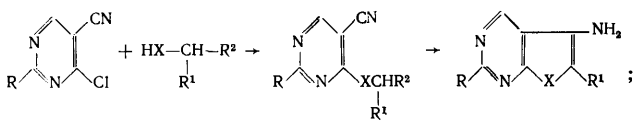
R=H, CH_3 .

Among the pyrimidines containing a substituent at the C(5) atom of the pyrimidine ring, the 5-cyano- and 5-ethoxycarbonyl derivatives are used in the syntheses of thieno- and pyrrolo-pyrimidines. Thus 5-cyano-6-mercaptopyrimidine can be alkylated by alkyl halides containing an active methylene group to form the 5-alkyl derivatives. The latter frequently cyclise in an alkaline medium to 5-aminothieno-[2,3-*d*]pyrimidines:[86,87]



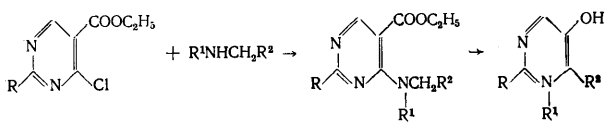
R, R^1=H, CH_3, C_6H_5; R^2=COC_6H_5, $COCH_3$, $COOC_2H_5$, COOH; X=Cl, Br .

When 6-chloro-5-cyanopyrimidines react with the corresponding mercapto- or amino-derivatives, intermediate 6-alkylthio- or 6-alkylamino-5-cyanopyrimidines are formed. These can be cyclised by a procedure analogous to that described above:[88,89]



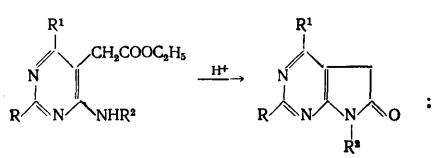
R=CH_3; R^1=$CH_2COOC_2H_5$; R^2=$COOC_2H_5$; X=S; R=C_6H_5; R^1=CN, $CONH_2$; R^2=H; X=NH, NCH_3 .

The reaction of 6-chloro-5-ethoxycarbonylpyrimidines with glycine derivatives leads to the formation of 5-hydroxypyrrolo[2,3-*d*]pyrimidines:[90-95]



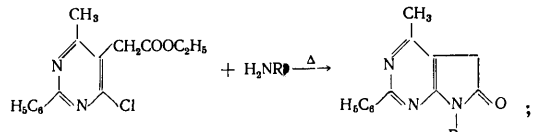
R=Alk, Ar; R^1=H, Alk; R^2=CN, $COOC_2H_5$.

Derivatives of pyrimidine-5-acetaldehydes and pyrimidine-5-acetic acids are widely used in the synthesis of pyrrolo-[2,3-*d*]pyrimidines. As stated previously,[1] the first synthesis of pyrrolo[2,3-*d*]pyrimidine was achieved on the basis of 4-aminopyrimidine-5-acetic acid. Several other early investigations in this field have been described:[96-99]



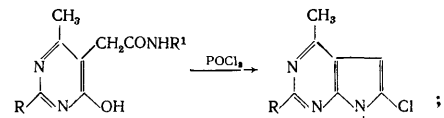
R=CH_3, C_6H_5, OH; R^1=H, OH; R^2=H, CH_3 .

When ethyl 6-chloropyrimidine-5-acetate is refluxed with amines, 6-oxopyrrolopyrimidines are also formed:[100,101]



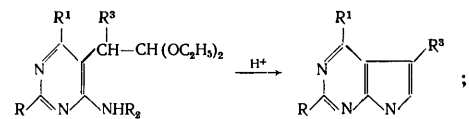
R=$CH_2CH_2OCH_3$, $CH_2C_6H_4Cl$-*p*, NH_2 .

6-Hydroxypyrimidine-5-acetamides cyclise on treatment with phosphoryl chloride to 6-chloropyrrolo[2,3-*d*]pyrimidines:[102-104]



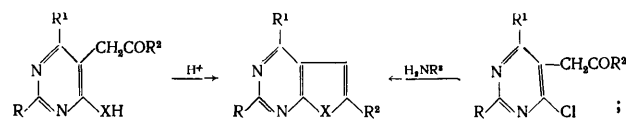
R=CH_3, $CH_2C_6H_4OCH_3$-*p*; R^1=Alk .

Many instances of the synthesis of pyrrolo[2,3-*d*]-pyrimidines from the acetals of 6-aminopyrimidine-5-acetaldehydes are described in the literature:[105-115]



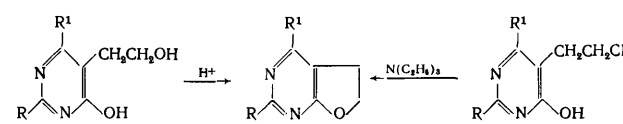
R=OH, SH, NH_2, H, Alk; R^1=H, OH, NH_2, Cl; R^2=H, Alk; R^3=H, CH_3 .

5-Acetonyl-6-hydroxypyrimidines and the corresponding 6-mercapto- and 6-amino-derivatives undergo an analogous reaction in an acid medium.[104,116-120] On the other hand, when 5-acetonyl-6-chloropyrimidines are heated with amines, pyrrolopyrimidines are formed:[118,121]



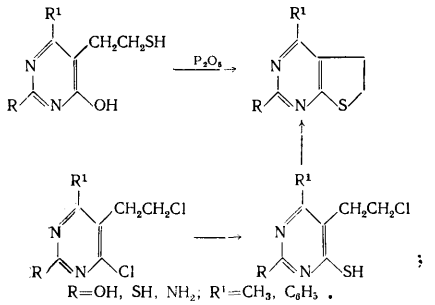
R=OH, SH, NH_2, $N(CH_3)_2$, H, CH_3, C_6H_5, $C_6H_5CH_2$; R^1=OH, Cl, CH_3, C_6H_5; R^2=CH_3, C_6H_5; R^3=Alk, Ar .

5-β-Hydroxy-, 5-β-halogeno-, and 5-β-mercapto-alkylamino-derivatives and 5-β-hydroxy-, 5-β-halogeno-, and 5-β-mercapto-ethyl derivatives of 6-hydroxy-, 6-amino-, or 6-chloro-pyrimidines have found applications in the syntheses of 5,6-dihydrofuro-, 5,6-dihydrothieno-, and 5,6-dihydropyrrolo-[2,3-*d*]pyrimidines. Thus, on treatment with thionyl chloride or sulphuric acid, 5-β-hydroxyethyl-6-hydroxypyrimidine cyclises to 5,6-dihydrofuropyrimidine.[122-127] The same compound can be obtained by treating 5-β-chloroethyl-6-hydroxypyrimidine with triethylamine:[128-130]



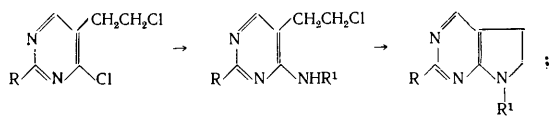
R=OH, SH, NH_2, $N(CH_3)_2$, SCH_3, H; R^1=OH, Cl, H, CH_3, C_6H_5 .

5,6-Dihydrothieno[2,3-*d*]pyrimidines have been obtained both from 6-hydroxy-5-β-mercaptoethylpyrimidine by treatment with phosphorus pentoxide and from 5-β-chloroethyl-6-chloropyrimidine by reaction with thiourea:[130-132]



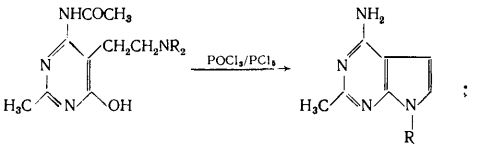
R=OH, SH, NH_2, R^1=CH_3, C_6H_5 .

5-β-Chloroethyl-6-chloropyrimidines can be made to react with amines to form the 6-amino-derivatives, which cyclise to 5,6-dihydropyrrolopyrimidines:[123,133–135]



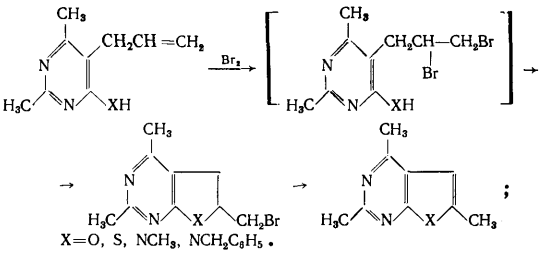
R=Cl, H, CH_3; R^1=Alk, Ar.

It is of interest to note that 7-alkylpyrrolo[2,3-*d*]-pyrimidine has been obtained by heating 5-β-dialkylamino-ethyl-6-hydroxypyrimidine with phosphoryl chloride and phosphorus pentachloride at 110 °C:[136]



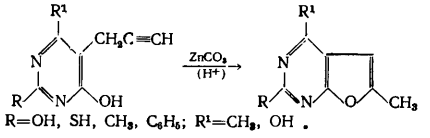
R=CH_3, C_2H_5 .

A convenient method of synthesis of furo-, thieno-, and pyrrolo-[2,3-*d*]pyrimidines from 5-allyl-6-hydroxy-, 5-allyl-6-mercapto-, and 5-allyl-6-amino-pyrimidines has been discovered recently.[137–139] When the above derivatives are brominated, 5-(2′,3′-dibromopropyl)pyrimidines are formed and then cyclise on refluxing in alcohol or DMF to the corresponding 6-bromomethyl-5,6-dihydro-derivatives. On treatment with sodium methoxide, these compounds give rise to 6-methylfuro-, 6-methylthieno-, and 6-methylpyrrolo-pyrimidines:



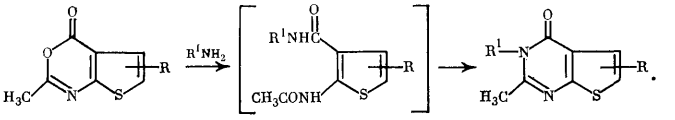
X=O, S, NCH_3, $NCH_2C_6H_5$.

It is known[140] that 6-hydroxy-2,4-dimethyl-5-propargyl-pyrimidine and 6-hydroxy-2-phenyl-5-propargylpyrimidine are converted into 6-methylfuro[2,3-*d*]-pyrimidines on treatment with zinc carbonate. An analogous reaction has been observed for 5-propargylbarbituric acid and the corresponding thiobarbituric acid in the presence of sulphuric acid:

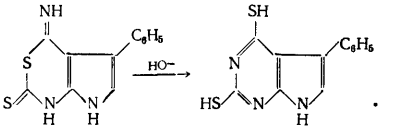


R=OH, SH, CH_3, C_6H_5; R^1=CH_3, OH .

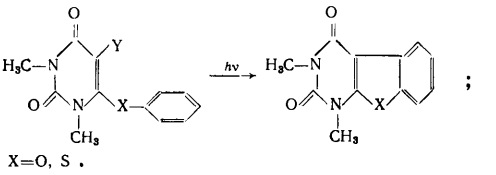
Only a few instances of the synthesis of thienopyrimidines from thieno[2,3-*d*]oxazines are described in the literature.[141–145] The intermediate 2-acylamino-3-carbamoylthiophens, which cyclise to thienopyrimidines on treatment with phosphoric acid, have sometimes been isolated in this process:



On treatment with alkali, 4-imino-5-phenyl-2-thiono-pyrrolo[2,3-*d*]thiazine rearranges to 2,4-dimercapto-6-phenylpyrrolo[2,3-*d*]pyrimidine:[146]

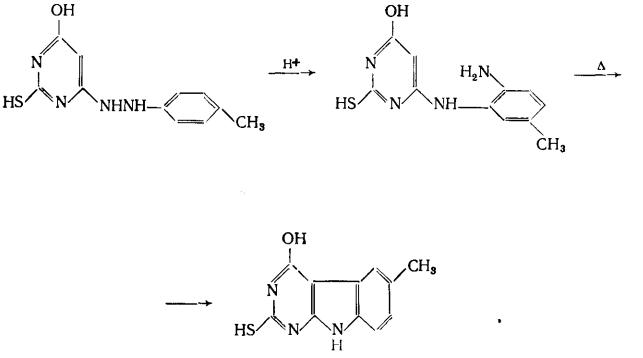


It has been observed[147] that the photolysis of 5-iodo-1,3-dimethyl-6-phenoxyuracil leads to the formation of a furo-pyrimidine in 1% yield, but the 6-phenylthio-analogue cyclises to the corresponding thienopyrimidine in 42% yield:

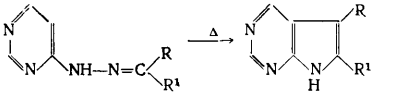


X=O, S .

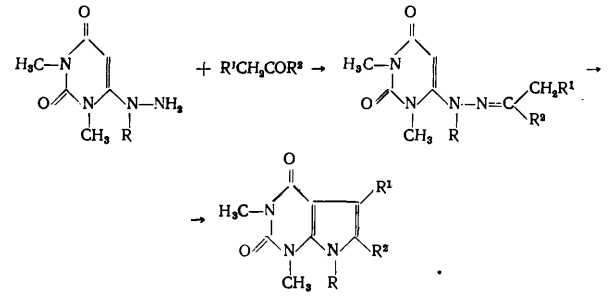
Mention should also be made of the method of synthesis of pyrrolopyrimidines from pyrimidinylhydrazines and hydrazones by analogy with the Fischer indole synthesis. Thus, on treatment with acids, 2-mercapto-6-*p*-tolylhydrazinouracil, gives rise to the stable 6-*o*-aminoanilino-2-mercaptouracil, which undergoes intramolecular cyclisation:[148]



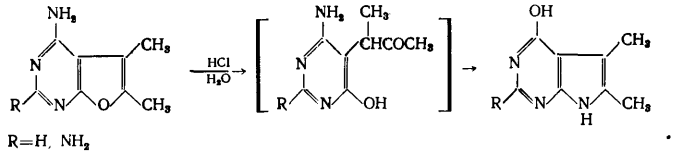
4-Pyrimidinylhydrazones undergo an analogous reaction on refluxing in ethylene glycol, but the yields are then low:[149]



The interaction of 6-hydrazino-1,3-dimethyluracil with ketones in ethylene glycol also affords pyrrolo[2,3-*d*]-pyrimidine:[150,151]



When an attempt was made to hydrolyse 4-aminofuro[2,3-*d*]-pyrimidine to the 4-hydroxy analogue with hydrochloric acid, 4-hydroxypyrrolo[2,3-*d*]pyrimidine was obtained.[152] Evidently the furan ring is opened during the reaction with the subsequent closure of the pyrrole ring. 2,4-Diamino-5,6-dimethylfuro[2,3-*d*]pyrimidine undergoes the same reaction:[79]

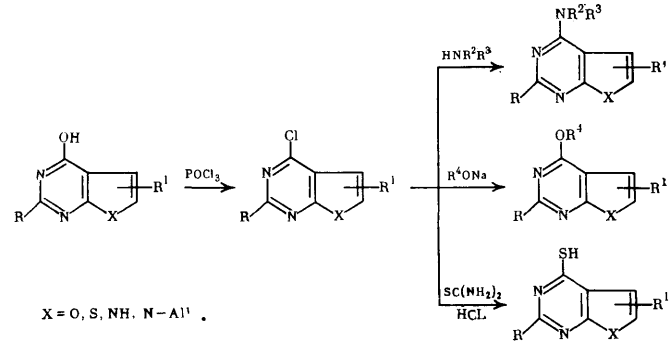


R=H, NH_2

III. CHEMICAL REACTIONS

Consideration of the electronic structures of furo-, thieno-, and pyrrolo-[2,3-*d*]pyrimidines shows that the pyrimidine ring in thse compounds is capable of nucleophilic substitution, while the C(5) and C(6) atoms of the five-membered rings are susceptible to attack by electrophiles.

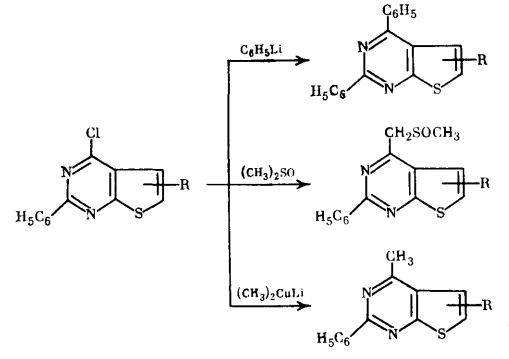
Thus the pyrimidine component of the molecule readily enters into reactions characteristic of pyrimidines. 4-Hydroxyfuro-, 4-hydroxythieno- or 4-hydroxypyrrolo-pyrimidines are readily converted into the 4-chloro-derivatives on treatment with phosphoryl chloride.[4,8,13,16,34,38,73,97,106-109,117-119,121,153-157] Next it is possible to obtain the 4-amino-, 4-hydrazino-, 4-alkoxy-, and 4-mercapto-derivatives of furo-, thieno-, and pyrrolo-[2,3-*d*]pyrimidines from these compounds by standard methods:[4,10,13,16,34,38,106,107,117-119,121,153-158,163,164]



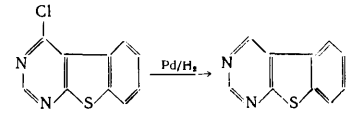
X = O, S, NH, N–Alk .

2,4-Dihydroxythieno[2,3-*d*]pyrimidines react with phosphoryl chloride to form 2,4-dichloro-derivatives, which are converted into a mixture of 4-amino-2-chloro- and 2-amino-4-chloro-thieno[2,3-*d*]pyrimidines on treatment with an alcoholic solution of ammonia at 100 °C.[156]

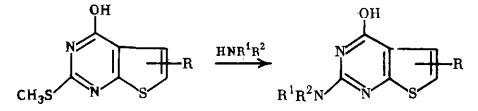
4-Chloro-2-phenylthieno[2,3-*d*]pyrimidine reacts with phenyl-lithium to form 2,4-diphenyl derivatives in 65% yield, the reaction with dimethyl sulphone affords the 4-methane-sulphinylmethyl derivative (80%), and the reaction with lithium dimethylcuprate gives rise to the 4-methyl derivative (82%):[16]



On treatment with [hydrogen and] a palladium catalyst, 4-chlorobenzothieno[2,3-*d*]pyrimidine loses a chlorine atom and is reduced to benzothieno[2,3-*d*]pyrimidine:[8]

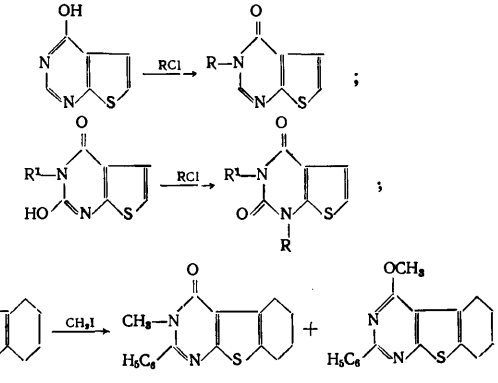


When 4-hydroxy-2-methylthiothieno[2,3-*d*]pyrimidine is acted upon by various amines, the corresponding 2-amino-derivatives are obtained:[165]



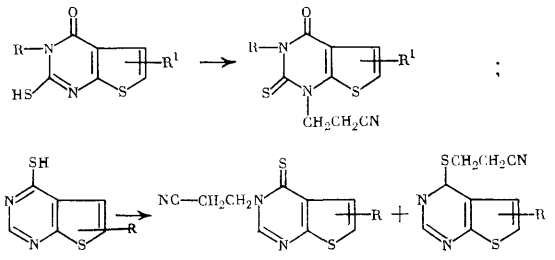
$-NR^1R^2 = N(CH_2)_5$, $N(CH_2CH_2)_2O$, $N(CH_2CH_2)_2NCH_3$, $NH(CH_2)_2OH$, $NHNH_2$.

A study of the alkylation of hydroxythieno[2,3-*d*]-pyrimidines yielded the following results: 4-hydroxythieno- and 2-hydroxo-4-oxothieno-pyrimidines react with alkyl halides to form *N*-derivatives, but 4-hydroxy-2-phenylthieno-pyrimidine reacts with methyl iodide in the presence of sodium hydride to form a mixture of the *N*(3)- and *O*-methyl derivatives in proportions of 1 : 1:[6,16]

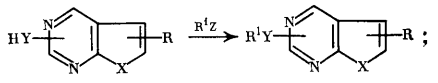


The cyanoethylation of 3-alkyl-2-mercapto-4-oxothieno-[2,3-*d*]pyrimidine proceeds via a nitrogen atom of the pyrimidine ring,[18] while 4-mercaptothienopyrimidine reacts

with acrylonitrile to form a mixture of *N*- and *S*-alkyl derivatives:[166]

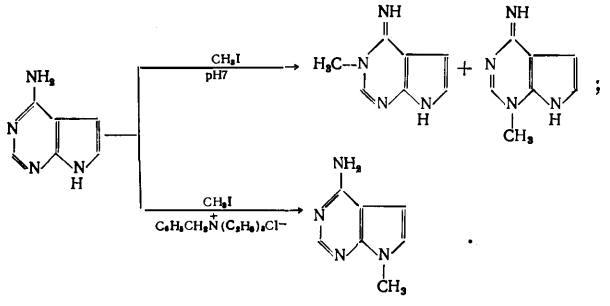


4-Mercaptothieno-, 2-mercaptothieno-, 2-selenothieno-, and 4-mercaptopyrrolo-[2,3-*d*]pyrimidines react with alkyl halides to form only the *S*(*Se*)-alkyl derivatives:[10,17,20,26,156,166–169]

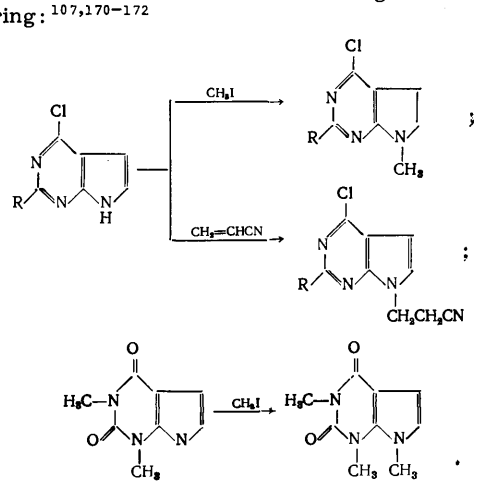


R^1 = Alk; X = S, NH; Y = S, Se; Z = Cl, Br, I.

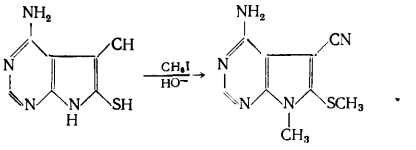
The study of the alkylation of 4-aminopyrrolo[2,3-*d*]-pyrimidine by methyl iodide yielded a 1 : 1 mixture of *N*(1)- and *N*(3)-methyl derivatives. However, the selective methylation of this compound involves the nitrogen atom of the pyrrole ring:[114]



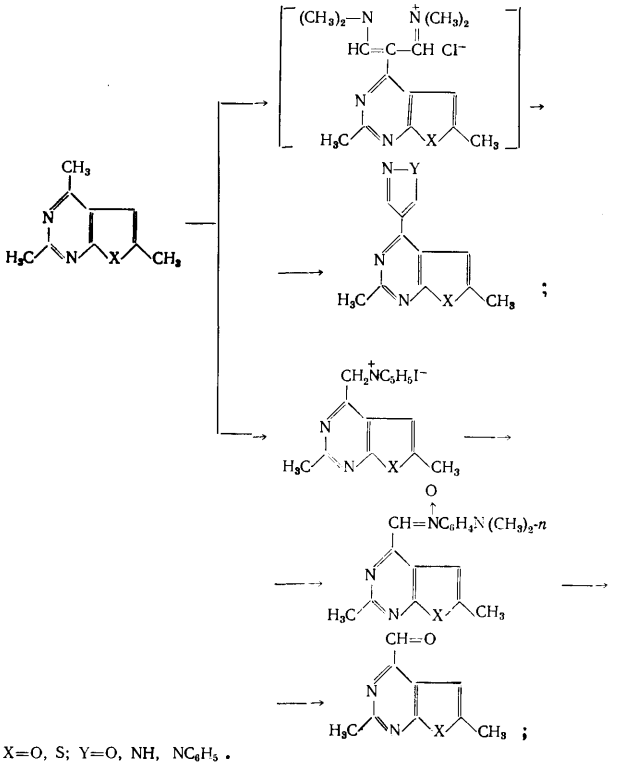
Like 2,4-dihydroxy-1,3-dimethylpyrrolo[2,3-*d*]pyrimidine, 4-chloropyrrolo[2,3-*d*]pyrimidine is methylated or cyanoethylated in an alkaline medium at the nitrogen atom of the pyrrole ring:[107,170–172]



The reaction of 4-amino-5-cyano-6-mercaptopyrrolo[2,3-*d*]-pyrimidine with methyl iodide results in the formation of 6-methylthio-7-methylpyrrolopyrimidine:[45]

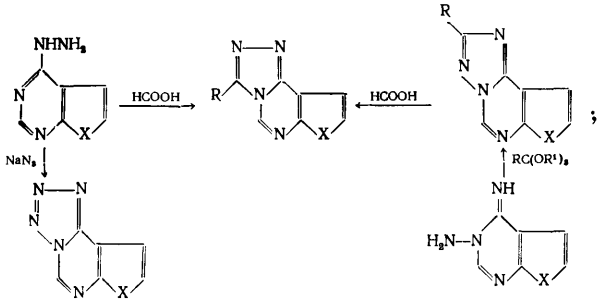


Certain reactions of the methyl group in 2,4,6-trimethyl-furo-, and 2,4,6-trimethylthieno-[2,3-*d*]pyrimidines have been investigated. Thus the corresponding pyrimidine-4-aldehydes have been obtained from these compounds by the Kröhnke method. It has been demonstrated by ^{1}H NMR that the most reactive methyl group at the C(4) atom of the pyrimidine ring is oxidised as a result of this reaction. The same methyl group reacts with Vilsmeier's reagent to form an unstable derivative of malonodialdehyde, which cyclises to 2,6-dimethyl-4-(4′-oxazolyl)- or 2,6-dimethyl-4-(4′-pyrazolyl)-furo(thieno)[2,3-*d*]pyrimidine on treatment with hydroxylamine or hydrazine:[173]



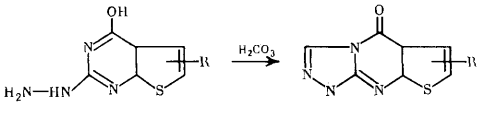
X=O, S; Y=O, NH, NC_6H_5.

Tricyclic systems can be obtained from certain furo- and thieno-pyrimidines by virtue of the presence of substituents in the pyrimidine ring. Thus, on treatment with formic acid or its ortho-ester, the 4-hydrazino-derivatives give rise to triazolothienopyrimidines,[10,38,52,156,174–176] while on treatment with sodium azide the products formed are tetrazolothieno-pyrimidines.[10,38,156,174,175] 3-Amino-4-iminofuropyrimidines and the corresponding thieno-derivatives cyclise on treatment with orthoformic or orthoacetic ester to the isomeric triazolo-derivatives, which undergo the rearrangement shown in the scheme below when acted upon by formic acid:[52,176]

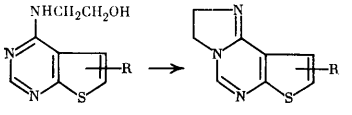


X=O, S; R=H, CH_3; R^1=CH_3, C_6H_5 .

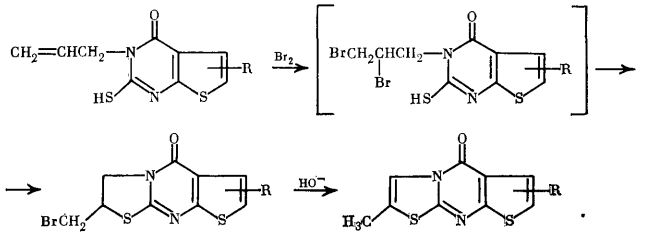
When acted upon by carbonic acid, 2-hydrazino-4-hydroxythieno[2,3-*d*]pyrimidine also cyclises to the corresponding triazolothienopyrimidine:[165]



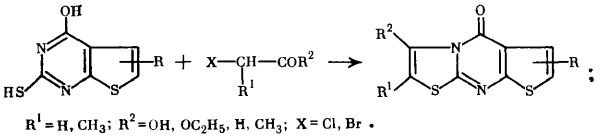
Imidazolinothienopyrimidine has been obtained from 4-β-hydroxyethylaminothieno[2,3-*d*]pyrimidine:[38,175]



3-Allyl-2-mercapto-4-oxothieno[2,3-*d*]pyrimidines are convenient starting materials in the synthesis of thiazolothienopyrimidines. On treatment with bromine, these compounds give rise to the corresponding tricyclic systems:[18,23-25,177,178]

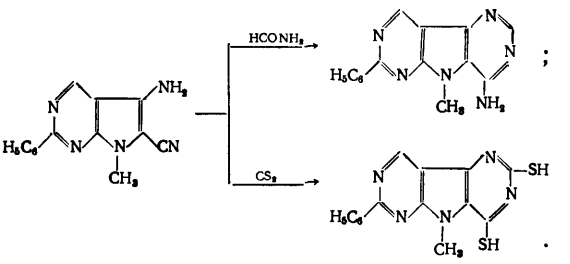


The same system can be obtained by the reaction of α-halogenocarbonyl compounds with 4-hydroxy-2-mercaptothieno[2,3-*d*]pyrimidines:[179]

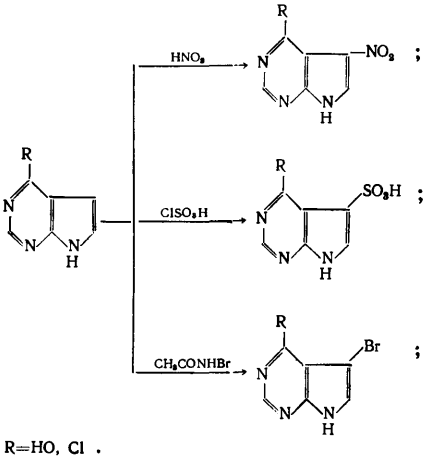


R^1=H, CH_3; R^2=OH, OC_2H_5, H, CH_3; X=Cl, Br .

Tricyclic heteroatomic systems have also been synthesised with participation of substituents in the five-membered ring. Thus 5-amino-6-cyano-2-phenylpyrrolo[2,3-*d*]pyrimidine reacts with formamide to form the corresponding aminopyrrolo[2,3-*d*;4,5-*d'*]dipyrimidine, while the reaction with carbon disulphide yields the dimercapto-derivative:[89]

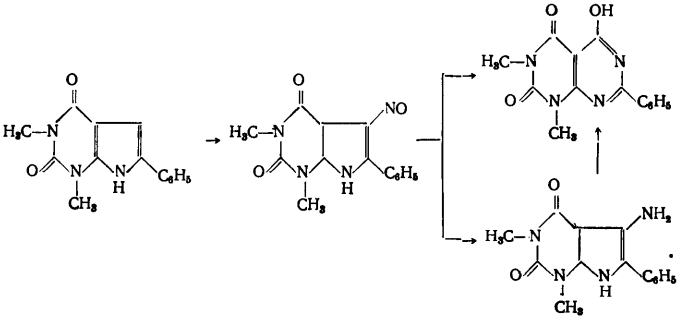


In considering reactions involving electrophilic substitution in the pyrrole ring, mention should be made of a study[157] in which 4-hydroxy- and 4-chloro-pyrrolo[2,3-*d*]pyrimidines were nitrated, chlorosulphonated, and brominated. In all cases the reaction involves the β-position in the pyrrole ring:



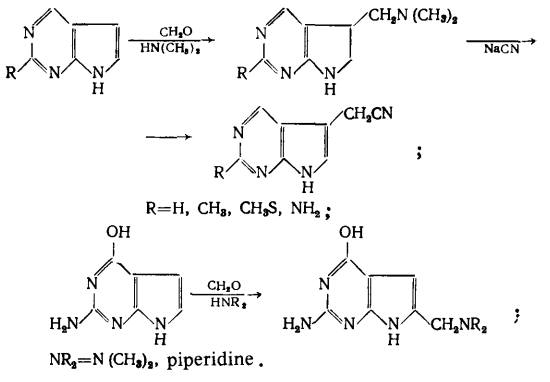
R=HO, Cl .

The nitrosation of 1,3-dimethyl-6-phenylpyrrolo[2,3-*d*]-pyrimidine also takes place in the β-position of the pyrrole ring.[78] Subsequently the 5-nitroso-derivative can undergo the Beckmann rearrangement with formation of a pyrimidopyrimidine. The reduction of the nitroso-group results in the formation of 5-aminopyrrolopyrimidine which also rearranges to a pyrimidopyrimidine on treatment with lead acetate:[180]

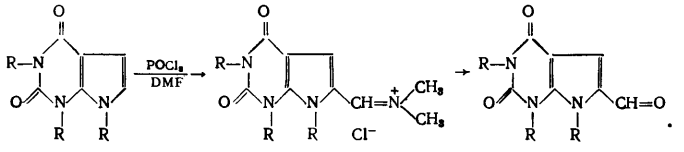


Pyrrolopyrimidines undergo the Mannich reaction, but the available literature data are somewhat contradictory. 2-Substituted pyrrolo[2,3-*d*]pyrimidines react with formaldehyde and dimethylamine in the presence of sodium acetate to form the 5-dimethylaminomethylene derivatives,[181] which can be converted into 5-cyanomethylenepyrrolopyrimidines. However, it has been reported[113] that 2-amino-4-hydroxypyrrolo-[2,3-*d*]pyrimidine reacts with formaldehyde and dialkylamines

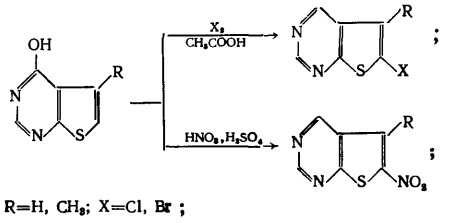
in the presence of acetic acid to form the 6-dialkylaminomethylene derivative:

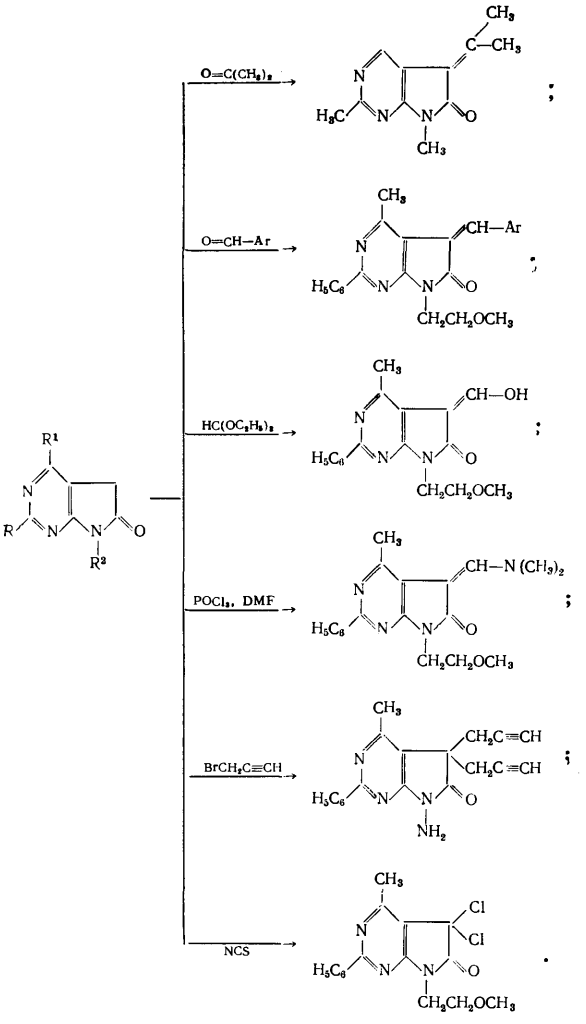


1,3,7-Trialkyl-2,4-dioxopyrrolo[2,3-*d*]pyrimidine reacts with Vilsmeier's reagent also in the α-position in the pyrrole ring to form the corresponding aldehyde:[182]



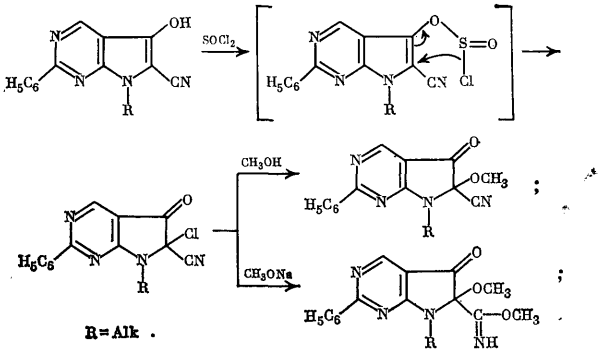
Certain electrophilic substitution reactions of 4-hydroxythieno[2,3-*d*]pyrimidines which involve the α-position in the thiophen ring, have been investigated:[6,61,174]



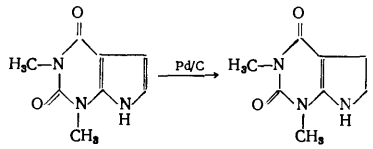


It has been observed that the methylene group in the pyrrole ring of 6-oxopyrrolopyrimidines is very reactive and reacts with aldehydes,[101] ketones,[98] propargyl bromide,[100] orthoformic ester, Vilsmeier's reagent, and *N*-chlorosuccinimide[101] to form the corresponding 5-substituted 6-oxopyrrolo[2,3-*d*]pyrimidines.

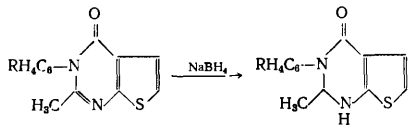
Kim and Santilli[183,184] investigated the reaction of thionyl chloride with 7-alkyl-6-cyano-5-oxo-2-phenylpyrrolo[2,3-*d*]-pyrimidines and established that it involves the oxicative chlorination at the α-position in the pyrrole ring:



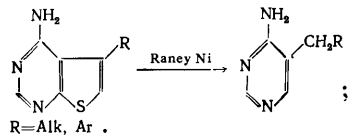
Several instances of the reduction of thieno- and pyrrolopyrimidines in the presence of various catalysts have been described in the literature. When 1,3-dimethyl-2,4-dioxopyrrolo[2,3-*d*]pyrimidine is treated with a palladium catalyst, the corresponding 5,6-dihydro-derivative is formed in 66% yield:[185]



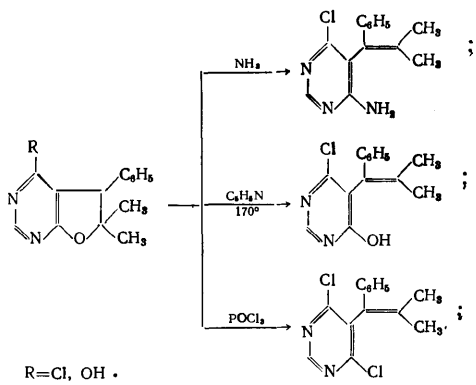
Sodium tetrahydroborate reduces 2-methyl-4-oxo-3-phenylthieno[2,3-*d*]pyrimidine to the 1,2-dihydro-derivative:[186]



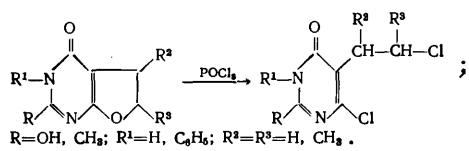
4-Aminothieno[2,3-*d*]pyrimidine containing a substituent in the 5-position in the thiophen ring gives rise to a 4-amino-5-substituted pyrimidine on treatment with Raney nickel:[47-49]



Among other reactions involving the opening of the five-membered ring, mention may be made of the formation of 5-vinylpyrimidines from the corresponding 5,6-dihydro-6,6-dimethyl-5-phenylfuropyrimidines on treatment with ammonia or phosphoryl chloride:[34,187]

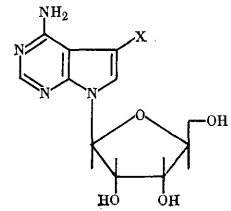


When acted upon by phosphoryl chloride, certain 5,6-dihydrofuropyrimidines give rise to 6-chlor-5-β-chloroethylpyrimidines:[130,188]



IV. BIOLOGICAL PROPERTIES

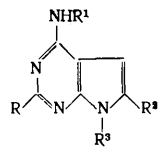
It was discovered in the 1960's that the antibiotics tubercidin, toyocamycin, and sangivamycin are derivatives of pyrrolo[2,3-*d*]pyrimidine:[51,189-191]



X = H (tubercidin)
X = CN (toyocamycin)
X = $CONH_2$ (sangivamycin)

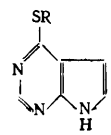
Toyocamycin actively inhibits the growth of various microorganisms,[192-194] tubercidin exhibits an analogous activity,[195,196] while sangivamycin shows a distinct antitumour activity, becoming involved in DNA and RNA synthesis.[191,197] There exists a good review on these antibiotics.[198]

4-Aminopyrrolo[2,3-*d*]pyrimidine is also an inhibitor of the growth of various micro-organisms[73] and its derivatives possess bactericidal,[111] hypotensive, anticonvulsant, and tranquilising properties[107,160] and exhibit an antimitotic activity.[121]



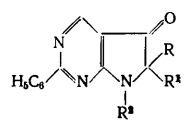
R=H, CH_3, OH, H, NH_2; R^1, R^3=H, Alk, Ar; R^2=H, CH_3

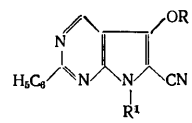
4-Mercaptopyrrolo[2,3-*d*]pyrimidine is the 5-deaza-analogue of the familiar antitumour preparation 6-mercaptopurine, but it does not exhibit a pronounced anticancer activity. Nevertheless 4-alkylmercaptopyrrolopyrimidines do possess antineoplastic properties.[167-169]



R=H, Alk, $(CH_2)_n CONHR^1$;
R^1 = aminoacid residue

Among 5-hydroxy-2-phenylpyrrolo[2,3-*d*]pyrimidines, compounds have been discovered which act on the central nervous system as depressants.[92-95,184]

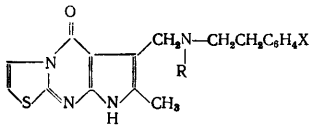


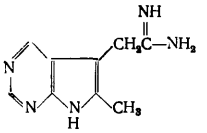


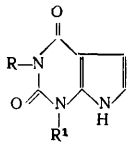
R=Cl, OCH_3, OC_6H_5, OC_3H_7-iso; R=H, CH_3, $SO_2C_6H_5$; R^1=CH_3, R^1=CN, $C(OCH_3)$=NH; R^2=Alk C_2H_5, C_4H_9

5-Alkylaminomethyl derivatives of thiazolopyrrolopyrimidines prevent the formation of blood clots,[199] while 5-amidinomethyl-6-methyl-7*H*-pyrrolo[2,3-*d*]pyrimidine has a powerful ganglion stimulating activity.[200]

It has also been reported that 1,3-dialkyl-2,4-dioxopyrrolo[2,3-*d*]pyrimidines exhibit sedative and antipyretic activities.[151]

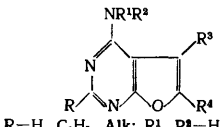




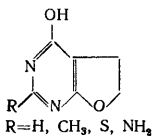


R, R¹=Alk

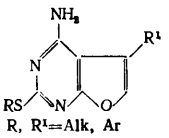
There are also biologically active compounds among furo-[2,3-*d*]pyrimidines. Thus 4-aminofuro[2,3-*d*]pyrimidines are muscle relaxants[119] and exhibit sedative, antihistamine, and diuretic properties.[53,54] 2-Substituted 4-hydroxy-5,6-dihydrofuropyrimidine reduces the cholesterol content in the blood,[127] while 2-alkylthio-4-aminofuro[2,3-*d*]pyrimidine shows an antiulcer activity:[81]



R=H, C_6H_5, Alk; R^1, R^2=H, Alk, Ar; R^3, R^4=Alk, Ar, NO_2.

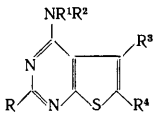


R=H, CH_3, S, NH_2



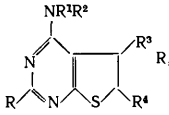
R, R^1=Alk, Ar

Numerous compounds with a wide variety of different types of physiological activity have been discovered among synthetic thienopyrimidines. Derivatives of 4-aminothieno[2,3-*d*]pyrimidines exhibit bactericidal, trichomonacidal,[13] antiradiation, antimalarial,[43] antihistamine,[153] acaricidal, insecticidal, and fungicidal properties[161,162] and prevent the formation of clots.[29]



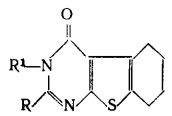
R=Ar, NH—Alk; R^1, R^2=H, CH_3, $(CH_2)_2$, NH—Alk, $SO_2C_6H_5$, OC_6H_5, Ar, Alk; R^3, R^4=H, CH_3, $(CH_2)_4$

4-Amino-5,6-dihydrothieno[2,3-*d*]pyrimidines possess sedative, diuretic, and antihistamine activities and function as muscle relaxants.[56,163,164]

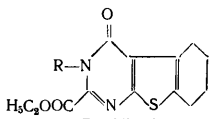


R, R^1, R^2, R^3, R^4=H, Alk, Ar

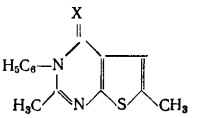
Depressants of the central nervous system, diuretics, and hypotensive, antipyretic,[144,145] analgesic, sedative,[30] antiallergic,[37,39] and hypnotic[201] substances have been discovered among 4-oxothienopyrimidines.



R=CH_3, C_2H_5; R^1=H, CH_3, C_6H_5.

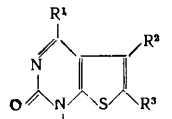


R=Alk, Ar

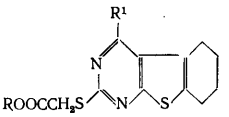


X=O, NC_6H_5

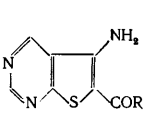
4-Aryl-2-oxothienopyrimidines also exhibit analgesic and diuretic activites;[58,66] 2-alkylthio-4-aryl derivatives show anticlotting, antipyretic, and analgesic activities and reduce the sugar content in the blood.[63] 5-Amino-6-carboxythieno-[2,3-*d*]pyrimidine exhibits bactericidal, analgesic, and diuretic activities and has an antipyretic effect.[86]



R=H, Alk; R^1=Ar; R^2=H, CH_3; R^3=H, CH_3, Cl, NO_2.



R=H, CH_3, C_2H_5; R^1=Ar



R=Ar, NR_2

Thus the foregoing findings permit the conclusion that derivatives of furo-, thieno-, and pyrrolo-[2,3-*d*]pyrimidines are of considerable interest as physiologically active substances, which has attracted the attention of numerous investigators to these compounds.

Metal Carbonyl Complexes with Ligands of Biological Origin

A.A.Ioganson

The methods of synthesis, structure, and physicochemical and chemical properties of transition metal carbonyl derivatives containing biological ligands, namely porphyrins, nucleic bases and nucleosides, aminoacids, and peptides, are examined. The possibility of using metal carbonyl complexes with biological ligands in various branches of chemistry is discussed. The bibliography includes 124 references

INTRODUCTION

The rapid growth of interest in recent years in the chemistry of transition metal complexes with ligands of biological origin is due to the extremely important role which metal ions play in a wide variety of biological processes.[1-6] The multifunctionality of metal ions in biological systems is undoubtedly associated with the wide variety of the chemical and stereochemical characteristics of the complexes formed by metals with protein molecules. The problem of the elucidation of the nature of the metal–protein interaction has therefore assumed special importance. Model compounds which are usually inorganic coordination compounds containing ligands of the acido-type in addition to biological ligands, namely porphyrins, amides, aminoacids, low-molecular-weight peptides, etc., are usually employed for the solution of this complicated problem. However, these complexes do not as a rule contain atoms or groups changes in the characteristics of which would permit fairly reliable inferences to be drawn about the steric and electronic features of the molecules investigated. Furthermore, the interaction of metal ions with biomolecules in an aqueous medium, usually employed for the synthesis in an investigation of inorganic complexes, is hardly an adequate model for the real interactions within the bulky protein molecules, which possess appreciably hydrophobic properties.

Numerous organometallic complexes of transition metals of various bioligands have been obtained in recent years. One can apparently speak of the establishment at the present time of a new branch of science—*bioorganometallic chemistry*, which is concerned with the study of transition metal complexes which contain, apart from the bioligands, at least one organic group linked to the metal atom via a metal carbon bond. Vitamin B_{12} is a representative of this class of compounds discovered in nature.

In contrast to inorganic coordination compounds, organometallic complexes are as a rule volatile and soluble in organic solvents. This makes possible a wide-scale use of methods such as mass spectrometry, NMR involving different nuclei, various types of vibrational spectroscopy, etc., for their investigation. Metal carbonyl complexes constitute a large class of such compounds. The presence in these substances of carbonyl groups linked to the metal atom, which are very sensitive to changes in the electronic and stereochemical characteristics of the metal atom and its ligand environment, and have highly characteristic infrared and Raman spectroscopic properties, makes it possible to establish in many instances the character of the metal–ligand bonds and the disposition of the ligands around the central metal atom.

Thus organometallic compounds of transition metals with ligands of biological origin have many important advantages over traditional inorganic compounds. It therefore appears likely to be useful to employ them as model systems for the investigation of the interaction between metal atoms and the active centres of protein molecules. It is noteworthy that the reactions with carbon monoxide, leading to the formation of metal carbonyl complexes, have already found extensive applications in the study of the properties of natural metal–porphyrin systems and their synthetic models.

The study of organometallic complexes with bioligands proved useful for the modelling of various catalytic processes *in vivo* with participation of metalloenzymes, for example, the fixation of nitrogen, the oxidation of alkanes, etc. Derivatives of metal carbonyls can also be used to introduce transition metals into protein molecules as labels, to impart new transport properties to biomolecules, and, in particular, to increase their solubility in organic solvents and fats, and as intermediates in the synthesis of proteins and other biologically active compounds. Furthermore, it appears useful to use metal carbonyl derivatives for the synthesis and study of biologically active complexes of those transition metals whose content in the biosphere increases as a result of anthropogenic factors.

This review deals with the results of studies in recent years on the synthesis and chemical and physicochemical properties of derivatives of metal carbonyls with certain most important biological nitrogen-containing ligands: porphyrins, nucleic bases and nucleosides, aminoacids, and peptides. So far as the present author is aware, no reviews devoted to this branch of chemistry have been published hitherto with the exception of the paper by Tsutsui,[7] which considers mainly the results of the author's studies of metal carbonyl porphyrin complexes. The present author thought it desirable to include in this review certain data on non-carbonyl organometallic aminoacid and peptide complexes of

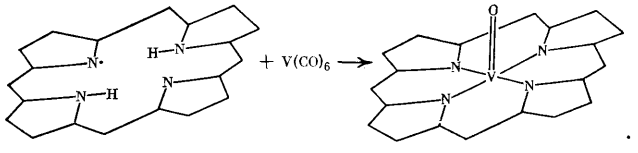
transition metals whose methods of synthesis and properties are close to those for the analogous metal carbonyl compounds.

II. PORPHYRIN DERIVATIVES OF METAL CARBONYL COMPOUNDS

Two discoveries at the beginning of the 1950's served as a direct stimulus for the investigation of metal carbonyl porphyrin complexes. The organometallic nature of one of the most important natural biologic reactive compounds, the vitamin B_{12} coenzyme, was established. In this compound the cobalt atom, coordinated to a corrin macroring which largely resembles the porphyrin macroring, is linked via a σ-bond to an alkyl carbon atom.[8,9] In addition, it has been elucidated that the cause of the deactivation of haemoglobin by carbon monoxide is the formation of a stable iron-porphyrin carbonyl complex the stretching vibration frequency of the C≡O bond of which in the infrared spectrum [ν(CO) = 1970 cm^{-1}] is close to the analogous frequencies of other derivatives of iron carbonyl.[10]

The study of the reactions of metal carbonyls with various porphyrins, initiated in the middle of the 1960's,[11,12] not only made it possible to synthesise a number of new metalloporphyrin complexes but also led to the establishment of certain hitherto unknown characteristics of the behaviour of porphyrin macrorings.

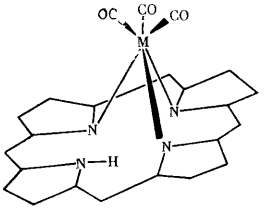
When vanadium hexacarbonyl reacts with H_2MP† in an inert atmosphere in decane at 170 °C, all the carbonyl groups are split off, the metal atom is oxidised, and the vanadyl complex (MP)V = O is formed:[13,14]



An analogous complex has been obtained[15] by the interaction of H_2AEP with (η^5-C_5H_5)V(CO)$_4$. The nature of the oxidant both in the reactions quoted above and in other processes involving a change in the oxidation state of the metal atom has not been elucidated. The most probable source of oxygen is apparently CO, which can disproportionate at high temperatures in the presence of transition metals.

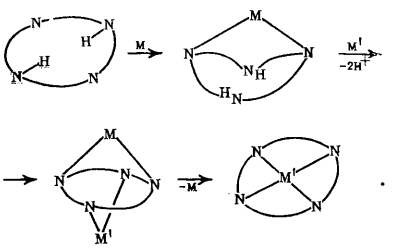
Heating of chromium hexacarbonyl and H_2MP in decane at 170 °C leads to the formation of chromium(II) porphyrinate (MP)Cr and complexes of the same composition have been obtained by heating H_2PP with nickel and cobalt carbonyls.[12,14] However, when H_2TPP interacts with Mo(CO)$_6$ in decalin, more extensive oxidation of the metal atom takes place and the oxomolybdenum complex (TPP)MoO(OH) is formed.[16]

A series of unusual complexes have been obtained in the reactions of porphyrins with Group VII metal carbonyls. Depending on the reactant ratio, mono- or bi-metallic complexes are formed on heating H_2MP or H_2TPP and $M_2(CO)_{10}$ (M = Tc or Re) in decane or decalin.[17-22] In the presence of a deficiency of the carbonyl, the monometallic compounds (HL)M(CO)$_3$(I), where L = MP and M = Tc or Re or L = TPP and M = Re, have been obtained. The infrared spectra of the complexes (I) contain two (three for Tc derivatives) ν(CO) bands at 2010–2025 and 1875–1900 cm^{-1}, which are characteristic of complexes of the type XM(CO)$_3$L$'_2$ (X = Hal, Alk, or Ar and L$'$ = Py or amine) and a ν(NH) band at 3350–3380 cm^{-1}. At room temperature the ^{1}H NMR spectra show the signal of one proton linked to the pyrrole nitrogen atom in the range δ = −4.0–−5.0 p.p.m., as well as the signals of the non-equivalent methylidyne and β-pyrrole hydrogen atoms. With increase of temperature, the signals of the methylidyne and β-pyrrole hydrogen atoms merge in the ^{1}H NMR spectra, indicating a dynamic behaviour of the metal tricarbonyl groups in relation to the porphyrin macroring. The free energy of activation for this process, involving the complex (HMP)Tc(CO)$_3$, is $\Delta G^{\neq}$ = 19.3 ± 2 kcal mol^{-1}.[23] On the basis of spectroscopic data, it has been suggested that the metal atom in complex (I) is not located in the plane of the porphyrin ring and is linked to only three pyrrole nitrogen atoms.



(I) M = Tc, Re

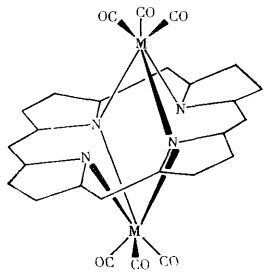
The effect of copper(II) acetate on (HMP)Re(CO)$_3$ at room temperature leads to the substitution of the rhenium tricarbonyl group and the formation of copper porphyrinate.[22] It has been reported[24] that unstable bimetallic complexes are formed in the analogous reactions with Ag^+, Hg^{2+}, and Pb^{2+} salts. These data agree well with the mechanism proposed previously[25] for the insertion of metal ions in porphyrin rings. It has been suggested that one of the metal atoms is initially coordinated to several nitrogen atoms of the macroring, which results in a breakdown of the coplanarity of the latter, after which the attack by the second metal atom from the opposite side of the macroring leads to the formation of an unstable bimetallic complex, which is rapidly converted into a stable metalloporphyrin:



†The following notation has been adopted for porphyrins in the present study: H_2MP = dimethyl ether of *meso*-porphyrin IX, H_2AEP = aetioporphyrin, H_2TPP = tetraphenyl-*meso*-porphin, H_2PrTPP = tetrakis(*p*-isopropylphenyl)-*meso*-porphin, H_2PP = dimethyl ether of protoporphyrin IX, H_2HeP = dimethyl ether of haematoporphyrin X, H_2OEP = octaethylporphyrin, MeHOEP = *N*-methyloctaethyl-porphyrin, and EtHOEP = *N*-ethyloctaethylporphyrin. To simplify the representation, the double bonds and substituents in the porphyrin macrorings have been omitted in the reaction schemes and structural formulae.

Treatment of porphyrins with an excess of Group VII metal carbonyls results in the formation of the bimetallic complexes $L[M(CO_3)]_2$ (II), where L = MP or TPP and M = Tc or Re, whose infrared spectra are analogous to those of compounds (I) in the ν(CO) region.[17-24] The reaction proceeds via the intermediate formation of monometallic complexes (I), which are capable of combining with yet another metal tricarbonyl group. Thus treatment of the monorhenium complex $(HMP)Re(CO)_3$ with technetium carbonyl yielded the mixed bimetallic complex $(MP)[Tc(CO)_3][Re.(CO)_3]$.[21,22,26] The bimetallic compounds (II) are probably thermodynamically more stable than (I). It has been found[21] that $(HMP)Tc(CO)_3$ disproportionates irreversibly in boiling decalin with formation of $(MP)[Tc(CO)_3]_2$ and the free porphyrin.

The structure of two bimetallic compounds $(TPP)[M(CO)_3]_2$ (M = Tc or Re) has been established by X-ray diffraction.[21,26,27]



(II) M = Tc, Re

The metal tricarbonyl groups are located on both sides of the planar porphyrin macroring and each metal atom, separated from the plane of the porphyrin by ~1.40 Å, is linked to only three nitrogen atoms. Thus in these compounds the porphyrin behaves as a hexadentate ligand. The metal–nitrogen distances are non-equivalent: one of them (2.15 Å for M = Re and 2.142 Å for M = Tc) corresponds to the M–N σ-bond and the other two, whose lengths are ~2.40 Å, are apparently the M ← N donor–acceptor bonds. The distances between the metal atoms (3.127 Å for M = Re and 3.101 Å for M = Tc) are close to the metal–metal bond lengths in the dinuclear decacarbonyls $M_2(CO)_{10}$, but calculation of the number of electrons shows that there should be no direct metal–metal covalent bonding in complexes (II).

The oxidation-reduction properties of the tetraphenylporphyrin complexes (I) and (II) for M = Re have been investigated by polarographic methods.[28-31] In solutions in CH_2Cl_2 or dimethylformamide the complexes undergo two-electron oxidation and reduction in stages at a platinum electrode with formation of chemically stable products in each stage. The polarographic waves for the complexes are analogous to the waves for reversible oxidation-reduction processes involving the free porphyrin:

$$H_2L^{2+} \xleftarrow{-e^-} H_2L^{+} \xleftarrow{-e^-} H_2L \xrightarrow{+e^-} H_2L \xrightarrow{+e^-} H_2L^{2-}.$$

However, the potentials are displaced towards more positive values for the cathodic processes and more negative values for the anodic processes. The ease of reduction decreases in the sequence

$$(TPP)[Re(CO)_3]_2 > (HTPP)Re(CO)_3 > H_2TPP,$$

which indicates the involvement of the rhenium tricarbonyl groups in the delocalisation of the charge of the porphyrin ring. The electrochemical oxidation of complex (I) is irreversible and leads to the formation of a bimetallic product, probably with a structure similar to that of compounds (II).

The reaction of $(TPP)[Re(CO)_3]_2$ with $SbCl_5$ at −70 °C in CH_2Cl_2 led to the isolation of three thermally unstable ionic complexes which are sensitive to moisture: $\{(TPP)[Re.(CO)_3][Re(CO)_3Cl]\}^+[SbCl_6]^-$ (III), $\{(TPP)[Re(CO)_3.Cl]_2\}^{2+}2[SbCl_6]^-$ (IV), and $\{(TPP)[Re(CO)_3]_2\}^+[SbCl_6]^-$ (V). In inert solvents all these compounds decompose with regeneration of the initial compound (II). It has been suggested that compounds (III) and (IV) possess Re–Cl bonds. The structure of the cation in the complex (V), elucidated as a result of X-ray diffraction analysis, proved to be very similar to that of the uncharged complex (II), but the distance between the rhenium atoms, which is 2.95 Å, enabled the authors[32] to conclude that an Re–Re bond passing through the aperture in the porphyrin macroring, is present in this compound. Such structures of the pseudorotaxane type had not been known previously.

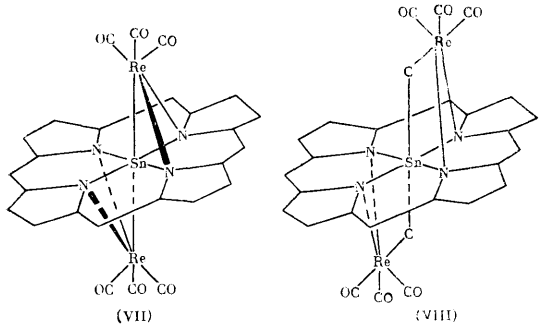
Prolonged heating of complexes (II, L = MP, M = Tc or Re) leads to the formation of insoluble products containing metal carbonyl groups with ν(CO) = 2044 and 1925 cm^{-1}. The structure of these compounds is unknown, but it has been suggested that they are polymers formed as a result of the coordination of the metal atoms to the ester groups linked to the porphyrin ring.[18]

On refluxing H_2OEP with $ClRe(CO)_5$, $BrRe(CO)_5$, or $[BrRe(CO)_4]_2$ in decalin, dark red crystalline ionic compounds $[H_3OEP]^+[Re_2(CO)_6X_3]^-$ (VI) (X = Cl or Br) were obtained together with the bimetallic complex of type (II). Solutions of these complexes in CH_2Cl_2, tetrahydrofuran, or methyl acetate are stable, but in alcohols, acetone, or in water they rapidly decompose with liberation of the free porphyrin. Prolonged heating of compound (VI) in aprotic solvents leads to the formation of the monorhenium complex (I). It has been established by X-ray diffraction of compound (VI, X = Cl) that the latter has no direct bond between the porphyrin macroring and the rhenium atoms. It is noteworthy that, on heating $ClRe(CO)_5$ and H_2TPP in decalin, complexes of type (VI) are not formed and only $[H_4TPP]^{2+}.2Cl^-$ has been isolated as a result of the reaction.[33,34]

Several unusual compounds have been obtained as a result of the reactions of $Re_2(CO)_{10}$ with tetraphenylporphyrin derivatives of non-transition metals. On heating $Re_2(CO)_{10}$ and $(TPP)SnCl_2$ in decalin at 180 °C, a dark-green crystalline complex $(TPP)Sn[Re(CO)_3]_2$ (VII) is formed and a symmetrical structure with an Re–Sn–Re bond chain has been proposed for it.[35] Compounds of analogous composition have also been obtained on interaction of rhenium carbonyl with zinc, magnesium, and calcium porphyrinates, although it is unlikely that the ions of these metals can form σ-bonds with the rhenium atoms.

A comparatively slight decrease of the temperature of the reaction between $Re_2(CO)_{10}$ and $(TPP)SnCl_2$ (decalin, 160–165 °C) led to the formation of another, red complex $(TPP).Sn[CRe(CO)_3]_2$ (VIII) whose structure has been established by X-ray diffraction.[36] Two carbide C atoms, each of which is linked to the tin atom located at the centre of the porphyrin macroring and to the $Re(CO)_3$ group, were found in this compound. The Sn–C bond length is close to that of a

single bond, while the short C–Re distances (1.75 Å) led to the conclusion[36] that the bond between these atoms has the character of a triple bond.

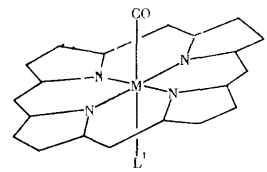


(VII) (VIII)

The C–Sn–C linear fragment is perpendicular to the plane passing through the four nitrogen atoms and the tin atom; the Sn–C–Re angle is 138.5°. Formally the rhenium atoms in complexes (VII) and (VIII) are electronically and coordination unsaturated since only three CO groups are linked to each of them, apart from the Sn or C atoms. However, the infrared spectra of these complexes show identical ν(CO) frequencies of 2000, 1995 and 1920 cm^{-1}, which are close to the analogous frequencies in the spectra of compounds of the type $XRe(CO)_3L_2$, where L is a neutral nitrogen-containing ligand. It is therefore logical to suppose that the Re atoms in the complexes (VII) and (VIII) undergo electronic and coordination saturation as a result of interaction with the pyrrole nitrogen atoms and (or) the π-electron system of the porphyrin ring, despite the fact that the rhenium atoms in complex (VIII) are separated from the plane of the ring by more than 3.5 Å.

The reactions of the iron carbonyls $Fe(CO)_5$ and $Fe_3(CO)_{12}$ with H_2MP and H_2PP proceed with elimination of all the CO groups and the formation of non-carbonyl iron (III) complexes.[12,14] Nevertheless the chemistry of iron-porphyrin carbonyl complexes has been studied in fair detail,[2] since there are many parallelisms in the behaviour of CO and O_2 in relation to natural systems such as haemoglobin, myoglobin, etc. By virtue of the ease of monitoring by means of infrared spectroscopy, the greater strength of the Fe–CO bond compared with Fe–O_2, and the absence of side processes, the reactions of both natural haems and their synthetic models with CO are widely used to elucidate the steric and electronic characteristics of these molecules. It has been established[37,38] that deuteriohaem and (TPP)Fe combine in succession with two CO molecules in inert solvents, but one of them is readily substituted on treatment with nucleophiles such as histidine, pyridine, etc. It has been established by X-ray diffraction that the Fe–C–O fragment in (TPP)Fe(CO)Py is linear and is arranged at right angles to the plane of the macroring,[39] while in the carbonylated natural haems the Fe–C–O angle is 135–145°.[40,41]

The ruthenium-porphyrin carbonyl complex, to which the formula (TPP)Ru(CO)Cl had been attributed initially,[42] has been obtained by treating an ethanol solution of $RuCl_3$ with CO and H_2TPP. Subsequent investigations[43,44] showed that this compound, which is also formed when H_2TPP is refluxed with $[Ru(CO)_3Cl_2]_2$ or $Ru_3(CO)_{12}$ in organic acids or benzene, contains no chlorine atoms and its composition is in fact (TPP)RuCO (IX). Coordination-unsaturated complexes of type (IX) have also been obtained from H_2MP, H_2AEP, and H_2PrTPP. These are brick-red crystalline compounds, stable in air, whose infrared spectra contain one ν(CO) band at ~1940 cm^{-1}. In solutions complexes (IX) combine with one molecule of the electron-donating solvents to form unstable 1:1 adducts from which the compounds LRu(CO)L' (X), where L = MP, AEP, or PrTPP have been obtained on treatment with the nucleophiles L' = pyridine, 2-methylpyridine, and 4-t-butylpyridine. It has been established by ^1H NMR[44–48] that compounds (X) (L = PrTPP) are capable of undergoing readily the intermolecular exchange of the ligand L' for the free nuclecphile present in solutions. For L' = 3,5- and 4,5-dimethylpyridazine, an intramolecular interchange of the two positions of the coordinated L' was observed,[48] its rate being 20–85 times greater than the rate of the intermolecular exchange.



(X) M = Ru
(XI) M = Os

Reactions involving the substitution of the CO groups in complexes (IX) and (X) by other ligands have been hardly investigated. It has been established[49] that, when a solution of (MP)RuCO in benzene is treated with NO at room temperature, the dinitrosyl complex $(MP)Ru(NO)_2$ is formed in a quantitative yield. When an attempt was made to brominate (OEP)Ru(CO)Py in the presence of an excess of KCN, the ionic complex $K^+[(OEP)Ru(CN)_2]^-$ was obtained.[50] Irradiation of (AEP)Ru(CO)Py solutions in pyridine or benzene with visible or ultraviolet light led to the formation of the dimer $[(AEP)RuPy]_2$, which the authors believe to contain the metal–metal double bond.[51]

Two communications concerning the X-ray diffraction analysis of the product of the reaction $Ru_3(CO)_{12}$ with H_2TPP have been published. The first of these,[52] in which the compound is described as a dicarbonyl complex (TPP).$Ru(CO)_2$ with non-linear Ru–C–O groups (with an Ru–C–O angle of 153.3°) and very long Ru–C distances (2.04 Å), is probably wrong. In the second communication,[53] the structure (X), where L' = EtOH, was attributed to the same complex recrystallised beforehand from a $CHCl_3$ – EtOH mixture. According to the former data,[52] the ruthenium atom is at the centre of the porphyrin macroring, the distance between the Ru atom and the oxygen atom of the coordinated ethanol molecule is 2.21 Å, the Ru–C bond length is 1.77 Å, and the Ru–C–O angle is 180°.

Similar parameters of the Ru–CO fragment have been observed also for the crystal structure of the complex (TPP)Ru(CO)Py,[53,54] but in this compound the Ru atom is displaced from the plane of the porphyrin macroring by 0.079 Å in the direction of the CO group.

At pH close to 7 the complex (MP)RuCO forms a 1:1 adduct with apomyoglobin. The study of the ultraviolet and visible spectra of this adduct led to the hypothesis that the distal histidine of apomyoglobin interacts with the Ru–CO group, deflecting the carbonyl group from the axis perpendicular to the plane of the porphyrin ring.[55] An analogous effect has been observed in the ruthenium carbonyl complex of the natural myoglobin.[56]

A brick-red dicarbonyl complex $(OEP)Ru(CO)_2$ has been obtained in a quantitative yield by treating benzene solutions of (OEP)Ru(CO)THF) or (OEP)Ru(CO)(EtOH) with CO. Analogous compounds have been obtained from H_2TPP and its derivatives containing the isopropyl or trifluoromethyl groups in the *para*-positions in the benzene rings. All

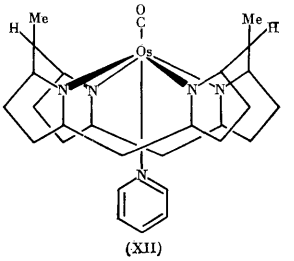
these compounds readily split off one CO molecule on storage or treatment with nucleophiles, for example, t-butylpyridine. As was to be expected, the ν(CO) band in the infrared spectra of the dicarbonyl complexes is at a much higher frequency (~1990 cm^{-1}) than in the spectra of compounds (IX) and (X) (~1940 cm^{-1}).[57]

The compounds (OEP)Ru(CO)(SR), where R = Et, CMe_3, or $CH_2CH_2CO_2Me$, which are possible models of the product of the addition of the CO group to the reduced cytochrome P 450, have been obtained by the reaction of (OEP)RuCO with mercaptide anions. The observed decrease of the ν(CO) frequency in the infrared spectra by 30 cm^{-1} and the upfield shift of the signals in the ^1H NMR spectra compared with complexes (IX) permit the conclusion that there is charge transfer from the negatively charged thiolate group to the Ru atom and (or) the porphyrin macroring.[58]

The osmium monocarbonyl complexes (XI) are much more stable than their iron and ruthenium analogues. They are formed when OsO_4 and H_2OEP are heated above 200 °C in the monomethyl ether of diethylene glycol with subsequent addition of nucleophiles L' [59] or on treatment of (OEP)OsPy with CO.[60] The complexes (OEP)Os(CO)L'(L' = MeOH, EtOH, THF, Py, PPh_3, or $AsPh_3$) are red or violet crystalline substances, stable in air, and comparatively stable in solutions. The ν(CO) frequencies in their infrared spectra increase from 1897 cm^{-1} for L' = THF to 1926 cm^{-1} for L' = PPh_3, which indicates a decrease of the strength of the M–CO bond with increasing π-acceptor capacity of the substituent L'. When compound (XI, L' = Py) is treated with the stronger π-acceptor $P(OMe)_3$, both pyridine and CO are substituted and (OEP)Os$[P(OMe)_3]_2$ is formed.

Comparison of the ν(CO) frequencies of the carbonyl pyridine complexes of metals of the iron triad (OEP)M(CO)Py, namely 1902 cm^{-1} for M = Os, 1932 cm^{-1} for M = Ru, and 1970 cm^{-1} for M = Fe, demonstrate unambiguously an increase of the capacity of the metal atom for the reverse transfer of electron density to the CO group in the sequence Fe < Ru < Os. These data agree well with the increase of the thermal stability of the complexes in the same sequence.

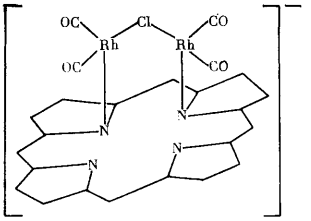
The electrochemical oxidation of the complex (XI, L' = Py) leads to the formation of the cation $[(OEP)Os(CO)Py]^+$ in which the presence of the Os^{3+} species has been postulated.[61] The reduction of this compound with sodioanthracene in THF does not entail a change in the oxidation state of the metal atom: after the addition of MeI to the reduced solution, the complex (XII), containing, according to X-ray diffraction data, a non-planar tetrapyrrole ligand (the angle of inflection along the axis passing through the sp^3-hybridised C atoms is 142°), was isolated. The Os atom lies 0.18 Å above the plane of the four pyrrole nitrogen atoms. The decrease of the ν(CO) frequency to 1963 cm^{-1} in the infrared spectrum of compound (XII) is probably associated with the decrease of the reverse electron donation by the metal atom to the orbital of the non-conjugated dimethylporphyrin ligand.[62]



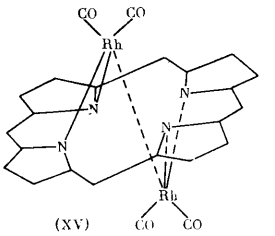
(XII)

The structure of the porphyrin complexes of rhodium depends greatly both on the reaction conditions and on the nature of the porphyrin. The reaction of $[Rh(CO)_2Cl]_2$ and H_2TPP in boiling benzene yielded the monocarbonyl complex (TPP)Rh(CO)Cl (XIII) and the σ-phenyl compound (TPP)Rh(Ph)Cl;[42,63] only a non-carbonyl product is formed in acetic acid.[64] The complex (XIII) is also obtained on treatment of (TPP)RhCl with CO under mild conditions (25 °C, 1 atm).[65]

In benzene at 20 °C H_2OEP reacts with $[Rh(CO)_2Cl]_2$ to form a dark-green product, to which the formula $H^+[(OEP).Rh_2(CO)_4Cl]^-$ (XIV) [ν(CO): 2045, 2035, 1983, and 1950 cm^{-1}] was attributed on the basis of spectroscopic data.[66] Complex (XIV) is comparatively unstable and is readily oxidised in air, being converted into the red (OEP).RhCl.$2H_2O$. In CH_2Cl_2 compound (XIV) splits off HCl and forms the neutral bimetallic product (OEP)$[Rh(CO)_2]_2$ (XV).[67,68] X-Ray diffraction analysis of compound (XV) showed that it contains two $Rh(CO)_2$ groups each of which is linked to two nitrogen atoms located on different sides of the macroring; the short metal–metal distance (3.094 Å) suggests the occurrence of interaction between the metal atoms via the aperture in the macroring.[69]

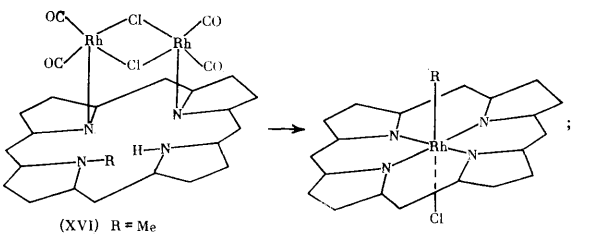


(XIV)



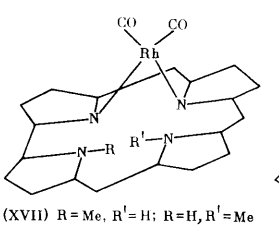
(XV)

Treatment of MeHOEP with $[Rh(CO)_2Cl]_2$ in benzene results in the formation of the dark-violet (MeHOEP) $[Rh(CO)_2Cl]_2$ (XVI) [ν(CO): 2075, 2050, 2010, and 1980 cm^{-1}].[70] Slight heating of compound (XVI) in $CHCl_3$ or its chromatography on a Al_2O_3 column entail a profound rearrangement of the molecule accompanied by the migration of the alkyl group to the Rh atom and the formation of the non-carbonyl complex $(OEP)Rh(CH)_3Cl$. The analogous reaction of rhodium carbonyl chloride with EtHOEP immediately results in the formation of (OEP)Rh(Et)Cl.

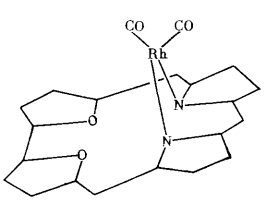


(XVI) R = Me

The reactions of $[Rh(CO)_2Cl]_2$ with corrole and dioxacorrole yielded the neutral monometallic complexes (XVII) and (XVIII) in which the macrorings play the role of bidentate four-electron ligands. It has been suggested that complexes of this type can be used as models of vitamin B_{12}.[71]



(XVII) R = Me, R' = H; R = H, R' = Me



(XVIII)

The stable monocarbonyl complexes LIr(CO)Cl have been obtained by the reactions of H_2L (L = MP or HeP) with π-olefin derivatives of iridium in alcoholic solutions or with $[Ir(CO)_3Cl]_2$ in acetic acid.[68,72] The CO group [ν(CO) ≅ 2060 cm^{-1}] is retained when these compounds are acted upon by pyridine, acids, and dilute solutions of alkalis; the dissociation of the Ir–CO bond, accompanied by a change in the oxidation state of the Ir atom, occurs only after prolonged heating of the complexes or on treatment with $NaBH_4$ or concentrated solutions of alkalis.

The bimetallic complex (OEP)$[Ir(CO)_3]_2$ (XIX) has been obtained by the reaction of $[Ir(CO)_3Cl]_2$ with H_2OEP in benzene. Its structure is probably analogous to that of the rhenium complex (II). The bis(chlorotricarbonyliridium) complex (MeHOEP)$[Ir(CO)_3Cl]_2$ (XX), whose structure is apparently close to that of compound (XIV), is formed from MeHOEP under the same conditions. When compound (XIX) is refluxed in $CHCl_3$, the monocarbonyl complex (OEP)Ir.(CO)Cl is obtained, while compound (XX) is converted into the σ-methyl derivative (OEP)$Ir(CH_3)Cl$.[73]

Thus the study of the metal–porphyrin carbonyl complexes revealed many previously unknown characteristic features of porphyrin macrorings:

1) A high capacity for coordination, which makes it possible to obtain stable bi- and tri-metal complexes in which the porphyrin functions as a hexa- and octa-dentate ligand.

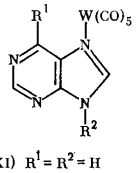
2) Stereochemical non-rigidity and the ability of the substituents at the pyrrole nitrogen atoms both to migrate between the pyrrole rings and to be transferred to the metal atom.

3) The ability of the π-electron system of the porphyrin not only to interact actively with the *d* orbitals of the metal atom at the centre of the macroring but also to form bonds with metal atoms located at a considerable distance from the plane of the porphyrin.

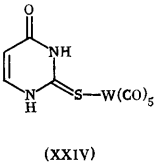
III. COMPLEXES OF METAL CARBONYLS WITH NUCLEIC BASES AND NUCLEOSIDES

Nucleic bases and nucleosides HL react with derivatives of metal carbonyls to form stable complexes in which they are usually linked to the metal atom via N → M donor–acceptor bonds.[74,75]

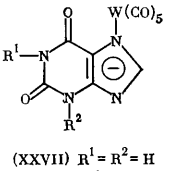
When $W(CO)_5$(THF) was acted upon by HL, neutral pentacarbonyl complexes $(OC)_5W(HL)$ (XXI–XXIV) were obtained. Reactions of this type also take place with the anions of nucleic bases. The charged complexes $[(OC)_5WL]^-$, isolated in the form of salts with the Na^+ or Ph_4As^+ cations [compounds (XXV)–(XXIX)], are formed in such cases. On the basis of spectroscopic data (Table 1), it has been established that adenine and adenosine are coordinated to the metal atom via a nitrogen atom in the five-membered heterocycle and not via the amino-group. An analogous coordination has been suggested for purine, theophylline and xanthine derivatives, while in the thiouracil complexes (XXIV) and (XXIX) the base is linked to the metal atom via an S–W bond.[74]



(XXI) $R^1 = R^2 = H$
(XXII) $R^1 = NH_2$, $R^2 = H$
(XXIII) $R^1 = NH_2$, R^2 = ribose



(XXIV)



(XXVII) $R^1 = R^2 = H$
(XXVIII) $R^1 = R^2 = Me$

Analysis of the infrared spectra of complexes (XXI)–(XXIII) in the region of ν(CO) vibrations shows that, in terms of their donor–acceptor properties, the nucleic bases are close to nitrogen-containing Lewis bases such as pyridine.[76] There is virtually no difference between the type *E* frequencies of the neutral complexes (XXI) and (XXII), on the one hand, and the ionic complexes (XXV) and (XXVIII), on the other, which unambiguously demonstrates the delocalisation of the negative charge over the organic part of the complex anion. At the same time the slightly lower ν(CO) frequencies of type A_1 in the infrared spectra of the ionic complexes indicate a partial transfer of electron density from the herterocycle to the d_π orbitals of the tungsten atom.

Table 1. Parameters of the infrared spectra [in $CHCL_3$, ν(cm^{-1})] of complexes of tungsten carbonyl with nucleic bases and nucleosides.[74,75]

Compound	Base LH	C≡O			C=O	NH_2

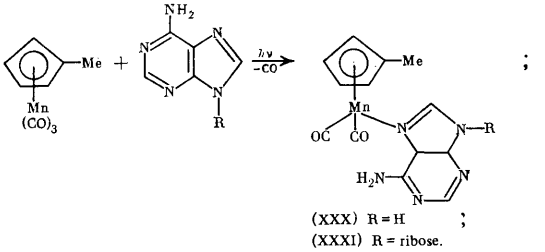
*in ethanol.

The ethylenediamine complex of molybdenum *cis*-$Mo(CO)_4$(en) reacts with adenine, guanine, and theophylline salts at 110 °C with substitution of one CO group and the formation of the ionic complexes $K^+[Mo(CO)_3(en)L]^-$. The CO group is also substituted in the photochemical reactions of $(\eta^5\text{-}MeC_5H_4)Mn(CO)_3$ with adenine and adenosine:[74]

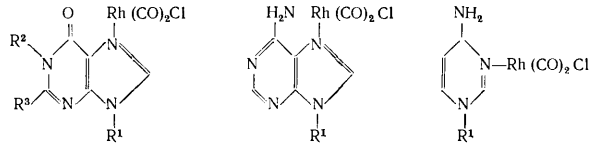


(XXX) R = H ;
(XXXI) R = ribose.

The higher ν(CO) frequencies in the infrared spectrum of the nucleoside complex (XXXI) (1910 and 1832 cm^{-1}) compared with the nucleic base complex (XXX) (1895 and 1825 cm^{-1}) indicate the electron-accepting character of the ribose fragment. An analogous conclusion can be reached from the comparison of the ν(CO) frequencies of the tungsten complexes (XXIII)–(XXII) (see Table 1).

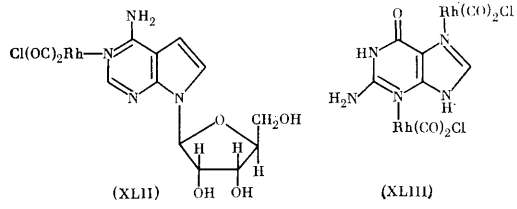
The dinuclear rhodium carbonyl chloride $[Rh(CO)_2Cl]_2$ reacts with nucleic bases with the opening of the chloride bridges and the formation of the monometallic complexes

$(OC)_2RhCl(HL)$ (XXXII)–(XLI), of which the infrared spectroscopic parameters are given in Table 2.[75]



(XXXII)–(XXXVII) (XXXVIII) (XXXIX)–(XLI)

Complex (XLII) with $\nu(CO)$ = 2075 and 2000 cm^{-1} has been obtained by the reaction of $[Rh(CO)_2Cl]_2$ with 7-desaza-adenosine (tubercidine). The reaction with guanine leads to the formation of the bimetallic complex having $\nu(CO)$ = 2103, 2080, 2040, 2012, and 2000 cm^{-1}, for which the structure (XLIII), having two independent $Rh(CO)_2Cl$ groups linked to the imidazole and pyrimidine nitrogen atoms, has been proposed.[75]



(XLII) (XLIII)

In the reactions with $ClM(CO)(PPh_3)_2$ (M = Rh or Ir), the anions of nucleic bases and nucleosides L^- behave as one electron ligands, substituting the chlorine atom and forming the neutral complexes $M(CO)(PPh_3)_2L$ (XLIV)–(LVI), whose properties are listed in Table 3.[74] In contrast to the rhodium complexes, the iridium compounds are more reactive and form adducts with oxygen both in solutions and in the crystalline state.

The complexes $Rh(CO)(PPh_3)_2L$ (LVII) [$\nu(CO)$ = 1986 cm^{-1}] and (LVIII) [$\nu(CO)$ = 1983 cm^{-1}], in which the anions of nucleic bases add to the metal atom via the sulphur atom, have been obtained by treating $ClRh(CO)(PPh_3)_2$ with potassium 6-mercaptopurinate and 2-thiouracil respectively. The metal hydride complex $HIr(CO)(PPh_3)_2L$ (LIX) with $\nu(CO)$ = 2047 cm^{-1} and $\nu(IrH)$ = 2155 cm^{-1}, in which the dianion of 6-mercaptopurine is apparently a two-electron chelate ligand, has been obtained by the reaction of potassium 6-mercaptopurinate with Vaska's complex $ClIr(CO).(PPh_3)_2$. In a neutral medium two 6-mercaptopurine molecules add to Vaska's complex and $HIr(CO)(PPh_3)_2L_2$ (LX) [$\nu(CO)$ = 2055 cm^{-1}, $\nu(IrH)$ = 2180 cm^{-1}], from which one molecule of the nucleic base is split off on treatment with KOH, the complex being converted into compound (LIX). The reaction of $ClIr(CO)(PPh_3)_2$ with 2-thiouracil yielded the complex (LXI), the infrared spectrum of which contains two $\nu(CO)$ bands at 2055 and 2034 cm^{-1}.[74] Judging from the high $\nu(CO)$ frequencies, this compound is also a hydride, i.e. $HIr(CO)(PPh_3)_2$, and the presence of two $\nu(CO)$ bands in the infrared spectra is probably associated with the formation of various isomers of compound (LXI) in the course of the reaction.

In conclusion of this Section, one may note that, despite the fact that the data available at present are limited, the use of metal carbonyl complexes has proved useful in securing

additional information about the active centres of purine and pyrimidine bases involved and about the electronic donor–acceptor properties of the monomeric fragments of nucleic acids.

IV. METAL CARBONYL COMPLEXES WITH AMINOACID AND PEPTIDE LIGANDS

Metal complexes of aminoacids and peptides have served for more than 100 years as models of the products of the reactions of metals with proteins and as models of biological systems in which the properties of proteins have been modified by the addition of metal atoms to them.[2,77,78] The synthesis and study of the properties of organometallic compounds containing aminoacid and peptide ligands opens up new possibilities for the determination of the mechanism of the interaction of protein systems with transition metal atoms.[79,80]

Three types of metal carbonyl derivatives incorporating aminoacids and peptide fragments are known at the present time:

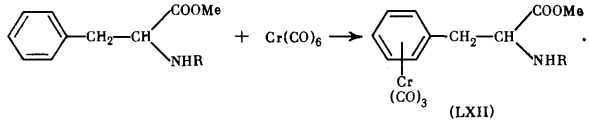
1) π-Complexes based on aminoacids and peptides.

2) Compounds formed as a result of the condensation of aminoacids with the ligand at the metal atom.

3) Metal carbonyl complexes formed as a result of the coordination of the metal atom to the functional groups of aminoacids and peptides.

1. π-Complexes Based on Aminoacids and Peptides

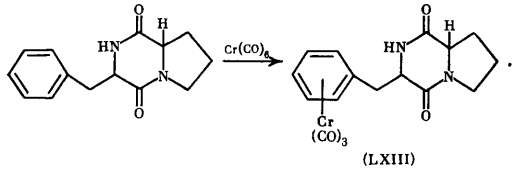
Aminoacids and peptides whose side chains incorporate an organometallic fragment belong to compounds of this class. It has been established recently[81] that derivatives of aromatic aminoacids with protected carboxy- and amino-groups readily react with chromium hexacarbonyl in ethereal or water-tetrahydrofuran media, forming the corresponding η^6-arene-chromium tricarbonyl complexes:



(LXII)

Derivatives of phenylalanine (LXII) are thermally unstable: R = CHO, m.p. 90 °C; R = CMeO, m.p. 99 °C; R = C(t-Bu)O, m.p. 130 °C. The analogous reactions with tryptophan and tyrosine derivatives lead to the formation of less stable compounds.

Stable π-complexes (LXIII) have been obtained by the reactions of $Cr(CO)_6$ with diastereoisomeric cyclic peptides whose composition includes a phenylalaninate fragment, no racemisation of the peptides being observed in the course of the reactions.



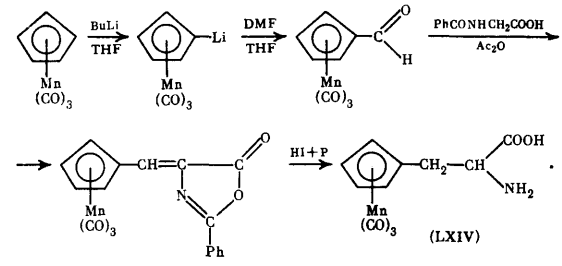
(LXIII)

LL, $[\alpha]_D$ -73.6° LL, $[\alpha]_D$ -90.4°, m.p. 228°

LD, $[\alpha]_D$ +51.2° LD, $[\alpha]_D$ +57.6°, m.p. 218°

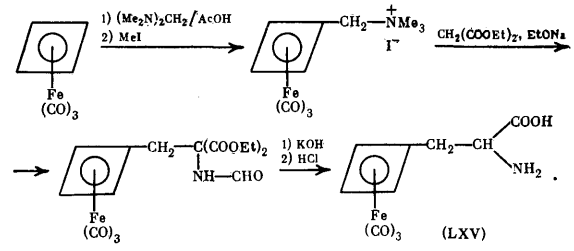
The formation reactions of the π-arene derivatives of metal carbonyls can probably serve as a good test of the presence of aromatic rings in various natural products.

Organometallic aminoacids can be obtained also directly from the corresponding π-complexes of transition metals. Thus cymantrenylalanine (LXIV) has been synthesised from η^5-cyclopentadienylmanganese tricarbonyl in 60% yield (m.p. 230 °C):[82]



(LXIV)

Another method has been used[82] to obtain (η^4-cyclobutadienylalanine)iron tricarbonyl (LXV) in 30% yield (m.p. 220 °C, with decomposition):

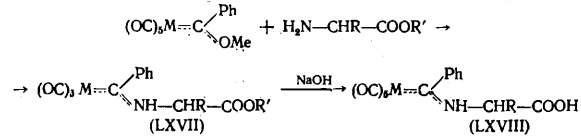


(LXV)

The properties of metal carbonyl aminoacids are apparently close to those of the usual aromatic aminoacids. It had been established earlier that the non-carbonyl analogue of these compounds, namely ferrocenylalanine $(\eta^5\text{-}C_5H_5)Fe[\eta^5\text{-}C_5H_4.CH_2CH(NH_2)COOH]$ (LXVI), which has been synthesised by a method[83] close to that used for the synthesis of compound (LXV), behaves in many reactions in the same way as phenylalanine. It enters into metabolic hydroxylation reactions and reactions involving coupling to glucuronic acid[84,85] and it can participate in peptide synthesis reactions.[86] Compound (LXVI) has been inserted in natural peptides such as encephalin and bradykinin.[82,87] The arene complexes of transition metal carbonyls are similar in many respects to ferrocene derivatives, but, by virtue of the presence of the M–CO groups in the molecules, it is much easier to follow the behaviour of these compounds in various processes. It therefore appears useful to employ metal carbonyl aminoacids as labels in protein molecules.

2. Compounds Formed as a Result of the Condensation of Aminoacids with the Ligand at the Metal Atom

Among compounds of this type, the carbene derivatives of Group VI metal pentacarbonyls, obtained by Fischer and Weiss[88–90] as a result of the condensation of aminoacid esters with phenyl(methoxy)carbene-chromium and tungsten pentacarbonyls have been most thoroughly investigated:



(LXVII) (LXVIII)

The complexes are formed readily at 20 °C in ether. Compounds (LXVII) and (LXIII) are readily fusible crystalline or oily substances, stable in air, and readily soluble in

polar organic solvents (Table 4). The ester groups in compounds (LXVII) are readily hydrolysed on treatment with alkalis and the acids (LXVIII) formed can participate in peptide synthesis reactions. A series of consecutive reactions involving the condensation of compound (LXVIII) with aminoacid esters in the presence of *N*-hydroxysuccinimide and dicyclohexylcarbodiimide yielded di-, tri-, and tetrapeptide complexes, which decompose on treatment with CF_3COOH at room temperature with liberation of the free peptide:

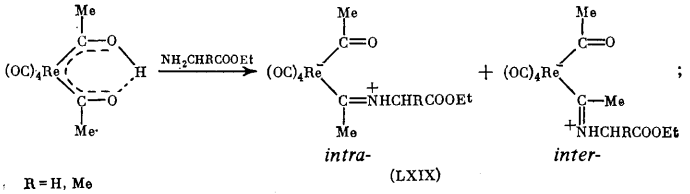
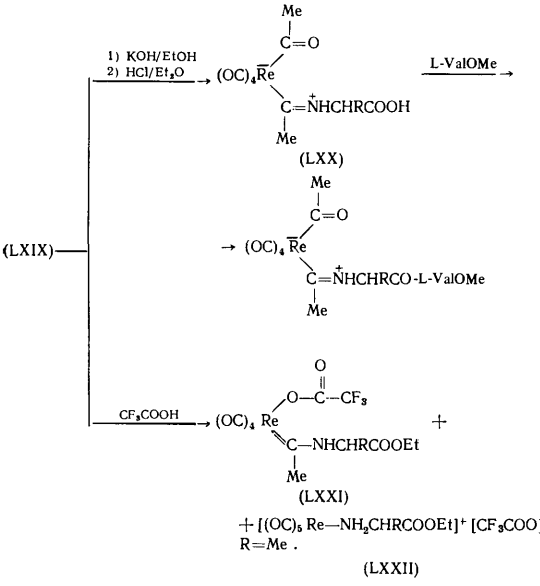
The organorhenium analogue of acetylacetone, namely tetracarbonyl rhena-acetylacetone, reacts with aminoacid esters in CH_2Cl_2 to form the isomers of the corresponding dipolar complexes (LXIX):



R = H, Me

The crystal structure of the *inter*-isomer (LXIX, R = H) is illustrated in Fig. 1. Hydrolysis of compound (LXIX) leads to the formation of the corresponding acids (LXX), which are capable of participating in subsequent condensation reactions with aminoacid esters. Complexes (LXIX) and (LXX) are much more stable than the related chromium and tungsten complexes (LXVII) and (LXVIII). When compound (LXIX) is acted upon by CF_3COOH, the neutral carbene complex (LXXI) and the ionic complex (LXXII), in which an ethyl alaninate molecule is coordinated to the metal atom via the amino-group, are formed:[91]



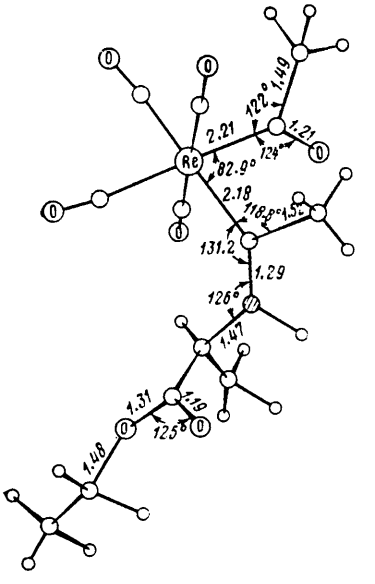


Figure 1. The structure of *inter*, *cis*-$(OC)_4Re[C(O)Me]$. $.[C(Me)(L\text{-}AlaOEt)]$.[91]

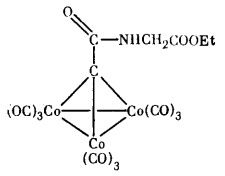
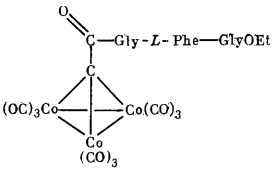
Instances of the addition of aminoacids and peptides to transition metal cluster compounds containing an active carbon atom are known. When the ionic complex $[(CO)_9$. $.Co_3CCO] + [PF_6]^-$ was allowed to react with ethyl glycinate in CH_2Cl_2, the neutral carbamide derivative (LXXIII), melting at 117 °C, was obtained. The tripeptide complex

(LXXIV) has been synthesised by an analogous reaction.[92]

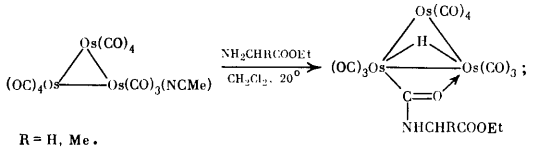


(LXXIII)



(LXXIV)

The chiral carbamide complexes (LXXV) have been obtained by the reaction of $Os_3(CO)_{11}(NCMe)$ with glycine and alanine esters.[93]



R = H, Me.

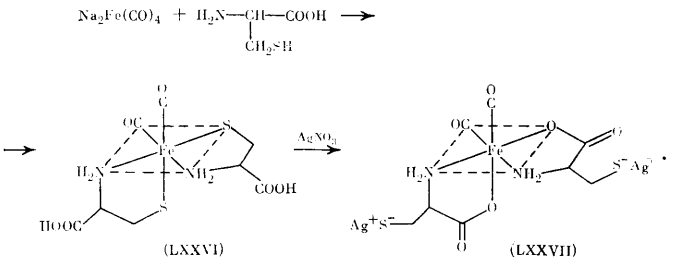
(LXXV)

With the aid of aminoacid esters deuteriated at the nitrogen atom, it has been established that the hydride bridge in compound (LXXV) is formed as a result of hydrogen transfer from the amino-group.

3. Metal Carbonyl Complexes Formed as a Result of the Coordination of the Metal Atom to Functional Groups in Aminoacids and Peptides

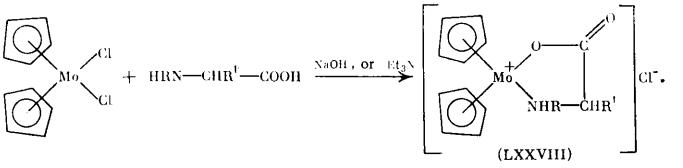
Complexes in which the aminoacid fragments are directly linked via their functional groups to the metal atom constitute the most thoroughly investigated class of organometallic aminoacid derivatives. In these compounds the aminoacids can behave as either monodentate one-electron (for coordination to the carboxyl oxygen) or two-electron (for coordination to the amino-group substituents) or as three-electron chelate or bridging ligands. The functional groups of aminoacids are coordinated to metal atoms comparatively readily and the problem of the synthesis of organometallic aminoacid complexes reduces mainly to the problem of the solvent in which both the aminoacids and the initial organometallic compounds are equally readily soluble.

The first aminoacid metal carbonyl complex, namely dicysteinatoiron dicarbonyl, was synthesised as early as 1933,[94] but its structure was not established until the end of the 1960's after detailed spectroscopic investigations.[95,96] The red crystalline product (LXXVI), obtained by the reaction of cysteine with $Na_2Fe(CO)_4$, contains chelating aminoacid ligands coordinated to the iron atom via the amino-group and the sulphur atom. The presence in the infrared spectrum of compound (LXXVI) of bands at 1717 and 1690 cm^{-1} indicates the presence of free COOH groups in this complex. Treatment of solutions of compound (LXXVI) with silver salts leads to a rearrangement of the chelating ligands and the cysteinate groups in the resulting green complex (LXXVII) are linked to the iron atom via the nitrogen and oxygen atoms: ν(COO) = 1608 and 1417 cm^{-1}. The increase of the stretching vibration frequencies of the CO groups at the iron atom after the change in the coordination of the aminoacid ligand, i.e. ν(CO) = 2030 and 1978 cm^{-1} for compound (LXXVI) and 2050 and 1990 cm^{-1} for compound (LXXVII), unambigously demonstrates the more pronounced electron-accepting character of the carboxylate group compared with the sulphide group:



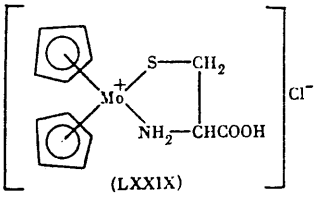
(LXXVI) (LXXVII)

The organometallic aminoacid complexes of molybdenum were first synthesised from dicyclopentadienylmolybdenum dichloride:[97]

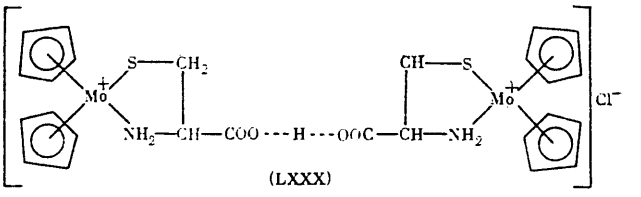


(LXXVIII)

where HRNCHR'CO = Gly, L-Ala, L-Phe, L-Val, L-Leu, L-Ile, L-Pro, L-Met, L-Ser, CH_3NHCH_2CO, or $CH_3NHCH_2.CH_2CO$. The complexes (LXXVIII) are crystalline substances stable in air and resistant to the action of strong acids. The study of the ^1H NMR spectra of these compounds showed that the hydrogen atoms at the α-carbon atoms readily exchange with D_2O in weakly alkaline solutions. When Cp_2MoCl_2 is treated with cysteine, two products are formed: the monomer (LXXIX) and the dimer (LXXX), in which the cysteinate ligands are coordinated to the molybdenum atom via the sulphide and amino-groups. The reaction of Cp_2MoCl_2 with cystine is accompanied by the dissociation of the S–S bonds and leads to the formation of compound (LXXIX).

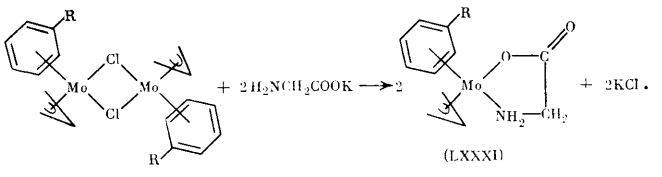


(LXXIX)



(LXXX)

The red crystalline glycinate complexes (LXXXI, R = H or Me) have been obtained by treating bis(η^6-benzene-η^3-allylmolybdenum chloride with potassium glycinate:[98]



(LXXXI)

In contrast to the dicyclopentadienyl compounds (LXXVIII), the complexes (LXXXI) are decomposed by acids with liberation of propene.

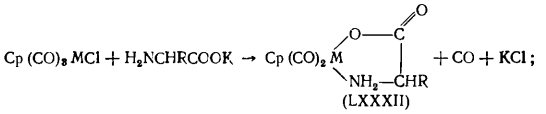
*With decomposition.
**Ind = η^5-indenyl.

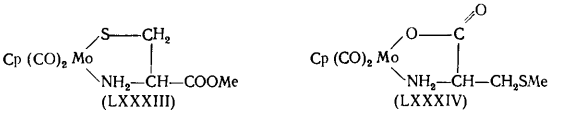
An analogous approach has been used to synthesise η^5-cyclopentadienyl-molybdenum and -tungsten dicarbonyl complexes with chelating aminoacid ligands:[99,100]



M=Mo, W

The complexes (LXXXII) (Table 5) are comparatively stable crystalline substances soluble in polar organic solvents. Since the metal atom in these compounds is chiral, the complexes exist in the form of two stereoisomers, which can be separated chromatographically. The structure of one of these complexes, established by X-ray diffraction, is illustrated in Fig. 2.

Cysteine and its methyl ester react with $Cp(CO)_3MoCl$ to form the complexes (LXXXIII) with a chelate N,S-ring, but the analogous reaction with *S*-methylcysteine leads to the formation of compound (LXXXIV) with the ligand coordinated via the N and O atoms.[100,101]



As for the iron cysteinate complexes (LXXVI) and (LXXVII), the infrared spectra of the molybdenum derivatives show a significant increase of the ν(CO) frequencies on passing from complexes with N,S-coordination of the ligand to the N,O-isomers: 1947 and 1850 cm^{-1} for compounds (LXXXIII) and 1967 and 1867 cm^{-1} for compounds (LXXXIV) respectively. Thus the type of coordination of the cysteinate fragment to the metal atom can be readily established on the basis of the infrared spectra of the carbonyl complexes in the ν(CO) region.

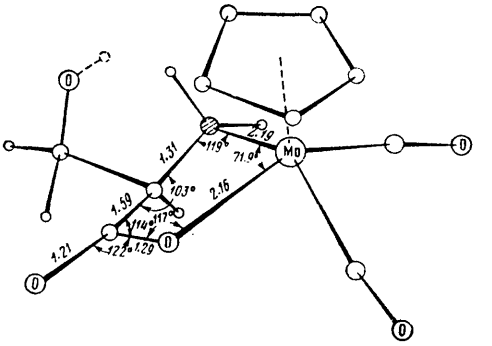


Figure 2. The structure of η^5-cyclopentadienyldicarbonyl-(L-serinato)molybdenum $Cp(CO)_2Mo(L\text{-}SerO)$.[100]

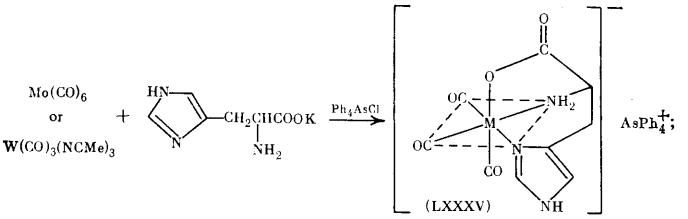
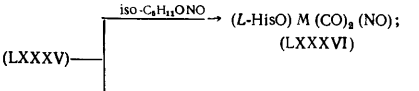
The reactions of $Mo(CO)_6$ or $W(CO)_3(NCMe)_3$ with potassium histidinate in alcoholic solutions lead to the formation of the ionic tricarbonyl complexes (LXXXV) in which the histidinate anion behaves as a five-electron tridentate ligand. By treating them with isopentyl nitrite or allyl bromide, it is possible to obtain the neutral dicarbonyl histidinate compounds (LXXXVI) and (LXXXVII) respectively:[102]



M = Mo, ν(CO) 1895, 1763, 1730 cm^{-1}; M = W, ν(CO) 1877, 1737 cm^{-1}.



(LXXXVI), M=Mo, ν(CO) 2014, 1913 cm^{-1}; (LXXXVII), M=Mo, ν(CO) 1937, 1846 cm^{-1}; M=W, ν(CO) 1927, 1837 cm^{-1}.

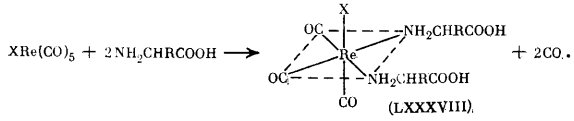
The tungsten pentacarbonyl complexes with aminoacid ligands linked to the metal atom only by the amino-group are relatively unstable. They can be obtained[103] by irradiating tungsten hexacarbonyl and aminoacid esters with ultraviolet light in non-polar solvents, for example:

$$W(CO)_6 + NH_2CHRCOOMe \xrightarrow[C_6H_6]{h\nu} (OC)_5W(NH_2CHRCOOMe) + CO;$$

R=CH_2CHMe_2, ν (CO) 2072, 1925 and 1893 cm^{-1}; ν (COO) 1738 cm^{-1}.

The dipeptide pentacarbonyl complex $(OC)_5W$-Gly-GlyOH, which decomposes on heating above 80 °C, has been obtained by the photochemical reaction between $W(CO)_6$ and glycylglycine.[103] In polar solvents, aminoacid compounds of the type $(OC)_5WL$ readily split off a ligand molecule.

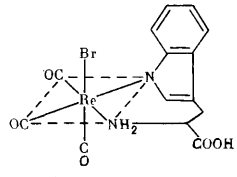
The reactions of aminoacids and their derivatives with rhenium carbonyl complexes have been studied in detail. When rhenium pentacarbonyl halides and α-aminoacids are refluxed in dioxan, stable bisaminoacid complexes (LXXXVIII) with a facial disposition of the non-carbonyl ligands at the metal atom are formed:[104–107]



(LXXXVIII)

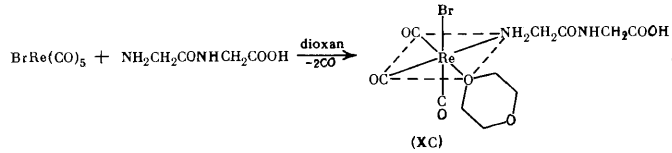
where $NH_2CHRCOOH$ = GlyOH, DL-AlaOH, DL-LeuOH, DL-ValOH, DL-β-Ph-α-AlaOH, or DL-β-2-thienyl-α-alanine. Compounds of the same type have been obtained with certain β-aminoacids: β-AlaOH, DL-β-Ph-β-AlaOH, and DL-β-2-thienyl-β-alanine.[104–107] The analogous manganese compounds are formed in the reactions of manganese carbonyl halides with GlyOH and AlaOH.[108] The study of the kinetics of the formation of the complexes (LXXXVIII) showed that the reaction proceeds preferentially via a dissociation mechanism and its rate is determined by the rate of dissociation of CO.

The monoaminoacid complex (LXXXIX), in which a tryptophan molecule is coordinated to the rhenium atom via both the amino-group and the indolyl nitrogen atom, has been obtained by the reaction of $BrRe(CO)_5$ with tryptophan.[106]



(LXXXIX)

The reactions of $BrRe(CO)_5$ with cysteine and threonine led to the formation of complexes of type (LXXXVIII), in which these potentially tridentate aminoacids are coordinated to the metal atom only via the amino-groups.[109] In the reaction of $BrRe(CO)_5$ with glycylglycine in boiling dioxan, two CO molecules are also evolved, but the resulting complex (XC) incorporates only one dipeptide molecule coordinated via the amino-group, while the other vacant site is occupied by a solvent molecule:[110,111]

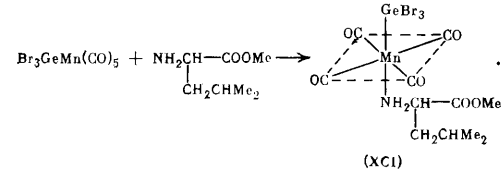


(XC)

The additional interaction between the peptide CONH group and the rhenium atom apparently plays a decisive role in stabilising complex (XC). The impossibility of the addition of a second glyglycine ligand to the metal atom can hardly be due to steric hindrance, because the more bulky β-indolylacetic acid gives rise to a disubstituted product of type (LXXXVIII) in an analogous reaction with $BrRe(CO)_5$.[107] The approach of a second dipeptide molecule to the rhenium atom in complex (XC) is apparently hindered by purely electrostatic factors.

The complexes (LXXXVIII)–(XC) are yellow oily or solid amorphous substances, which are resistant to the action of oxygen and water. At the same time they are hygroscopic and readily form solvates on reaction with both water and polar organic solvents such as dioxan, alcohols, acetone, etc. Aqueous solutions of the complexes give an acid response and can be titrated with alkalis. The infrared spectra of compounds (LXXXVIII)–(XC) in polar organic solvents show the absorption band due to the free COOH group in the range 1700–1730 cm^{-1} and three intense ν(CO) bands near 2030, 1910, and 1890 cm^{-1}, indicating a facial configuration of the CO groups linked to the rhenium atom.

The introduction of a strong π-acceptor substituent at the metal atom weakens the M–CO bond in the *trans*-position relative to the substituent and promotes the substitution of the carbonyl group by n-donor ligands. Thus, treatment of $Br_3GeMn(CO)_5$ by the methyl ester of leucine yielded the relatively unstable bimetallic complex (XCI) with the *trans*-configuration of the non-carbonyl ligands, the infrared spectrum of which contains ν(CO) bands, at 2082 and 2002 cm^{-1}, which are characteristic of the local D_{4h} symmetry of the $M(CO)_4$ group:[112]

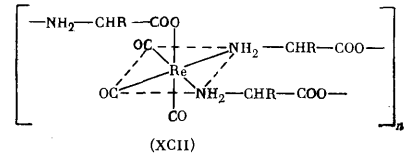


(XCI)

However, when the stannyl derivatives of rhenium carbonyl, namely $X_3SnRe(CO)_5$ (X = Cl or Br), are treated with aminoacid esters, the Sn–Re bond is ruptured and the disubstituted carbonyl halide complexes of type (LXXXVIII) are formed.[113] The reaction probably proceeds in such cases via the intermediate ionic complexes $[(OC)_5ReNH_2CHRCOOR']^+ . [SnX_3]^-$, resembling the complex (LXIX) examined above. A stable aminoacid compound with an Sn–Re bond has been obtained by the reaction of $SnCl_2$ with the bis(ethyl leucinate) derivative of rhenium carbonyl chloride:[113]

$$fac\text{-}ClRe(CO)_3[NH_2CH(CH_2CHMe_2)COOEt]_2 + SnCl_2 \rightarrow$$
$$\rightarrow fac\text{-}Cl_3SnRe(CO)_3[NH_2CH(CH_2CHMe_2)COOEt]_2.$$

In the interaction of salts of α-aminoacids with rhenium pentacarbonyl bromide or on treatment of solutions of the complexes (LXXXVIII) with KOH, the bromine atom is substituted and the polymeric compounds (XCII) are formed, in which the aminocarboxylate fragments function as bridges between the metal atoms:[104,114]

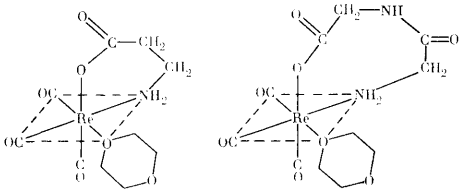


(XCII)

These are solid amorphous substances, which soften at 70–120 °C and are readily soluble in THF, $CHCl_3$, acetone, and alcohols. The cryoscopic determination of the molecular weight of the DL-α-phenylalaninate derivative, carried out in dioxan, showed that the number of units *n* in the polymer

molecule is close to four. The infrared spectra of the complexes (XCII) are analogous to those of compounds (LXXX-VIII), but, instead of the band due to the COOH group, they exhibit in the region of 1730 cm^{-1} bands associated with the vibrations of a bound COO group near 1650 and 1400 cm^{-1}.

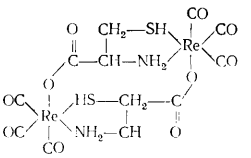
The reaction of $BrRe(CO)_5$ with salts of β-alanine and glycylglycine lead to the formation of the crystalline chelate complexes (XCIII) and (XCIV) respectively, which are sparingly soluble in organic solvents.[104,105,110,111]



(XCIII) (XCIV)

The complex (XCIII) is formed in polymers also on direct interaction between $BrRe(CO)_5$ and β-alanine in boiling dioxan. On the other hand, the reaction between $BrRe(CO)_5$ and salts of β-aminoacids containing an aromatic substituent (the phenyl or 2-thienyl group) at the β-carbon atom lead only to polymeric products of type (XCII).

Treatment of $BrRe(CO)_5$ with potassium DL-cysteinate yielded[109] a pale brick-red amorphous product (XCV), readily soluble in polar organic solvents. Solutions of this compound cannot be titrated with either alkalis or acids and the complex is inert with respect to nucleophiles. Determination of its molecular weight (by cryoscopy in dioxan) showed that it is a dimer. On the basis of these data as well as the analysis of the infrared spectra, it was suggested that all the functional groups of the aminoacid ligand in compound (XCV) are linked to the metal atom.

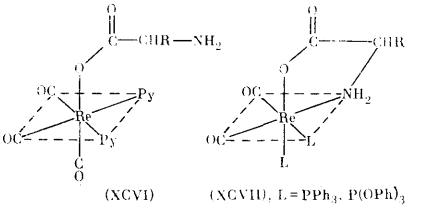


(XCV)

The analogous reaction of $BrRe(CO)_5$ with the potassium salt of DL-threonine gave rise to the colourless tetramer $\{(OC)_3ReNH_2CH[CH(Me)OH]COO\}_4$, whose solutions give an alkaline response. Probably not all the amino-groups in this compound are linked to the metal atoms.

The Re–N bonds in the aminoacid derivatives of rhenium carbonyl are comparatively weak and are readily ruptured in the presence of stronger Lewis bases L = Py, PPh_3, or $P(OR)_3$. Treatment of compounds of type (LXXXVIII) with L leads to the liberation of the free aminoacids and the formation of the complexes $BrRe(CO)_3L_2$, whose structure depends both on the nature of L and on the characteristics of the aminoacid ligands.[104,107,115] The reactions with pyridine in all cases give rise to *cis*-$BrRe(CO)_3(Py)_2$, while the reactions with $P(OPh)_3$ give rise to *trans*-$BrRe(CO)_3.[P(OPh)_3]_2$. The pathway followed in the reactions between compounds (LXXXVIII) and PPh_3 depends on the steric characteristics of the aminoacid ligands. When the complexes (LXXXVIII) with small aminoacid ligands such as glycine or β-alanine are acted upon by PPh_3, the product is *cis*-$BrRe(CO)_3(PPh_3)_2$, while the reactions with the complexes containing more bulky aminoacids, such as, for example, valine or leucine lead to *trans*-$BrRe(CO)_3(PPh_3)_2$. In the intermediate cases (α-alanine, β-phenyl-β-alanine, threonine) a mixture of the *cis*- and *trans*-isomers of $BrRe(CO)_3(PPh_3)_2$ was obtained. The sensitivity of the reactions of compounds (LXXXVIII) and PPh_3 to the steric effects of the aminoacid ligands is very great: the replacement of the phenyl group in β-phenyl-α-alanine by the 2-thienyl group alters the geometry of the substitution product. These results lead to the possibility of using aminoacid derivatives of metal carbonyls for the specific synthesis of complexes with a given structure.

The structure of the complexes formed when the polymeric compounds (XCII) are treated with nucleophiles also depends on the nature of L.[114,115] Pyridine ruptures the Re–N bond and the resulting mononuclear products (XCVI) contain an aminocarboxylate fragment coordinated to the metal atom only via the oxygen atom.

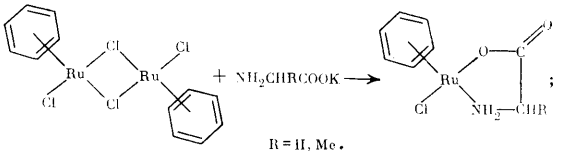


(XCVI) (XCVII), L = PPh_3, $P(OPh)_3$

The complexes (XCVI) are colourless crystalline substances melting above 200 °C and readily soluble in polar organic solvents and water. The aqueous solutions have an alkaline response and can be titrated with HCl. The infrared spectra are seen to contain three intense ν(CO) bands in the range 1900–2030 cm^{-1} and ν(COO) bands at 1645 and 1390 cm^{-1}. It was not possible to convert compounds (XCVI) into chelate complexes even by prolonged refluxing in dioxan.

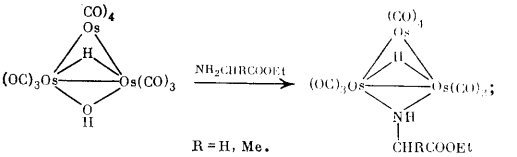
On the other hand, the reactions of compounds (XCII) with PPh_3 and $P(OPh)_3$, i.e. with nucleophiles exhibiting an appreciable π-acceptor capacity, lead to the formation of the chelate dicarbonyl complexes (XCVII)–crystalline products which are soluble in polar and organic solvents but are insoluble in water. Complexes of type (XCVII) with six-membered chelate rings have been obtained from compounds (XCII) having β-aminoacid ligands and also on treating $BrRe(CO)_3(NH_2CH_2CH_2COOH)_2$ with $P(OPh)_3$. The infrared spectra of all the complexes (XCVII) each show two ν(CO) bands at 1940 and 1860 cm^{-1} for L = PPh_3 or 1965 and 1880 cm^{-1} for L = $P(OPh)_3$ and ν(COO) bands at 1640 and 1400 cm^{-1}.[114]

The aminoacid derivatives of Group VIII metals have been less thoroughly investigated. The preparation of η^6-benzeneruthenium complexes with chelating glycinate and alaninate ligands has been reported:[116]



R = H, Me.

When $HOs_3(OH)(CO)_{10}$ is treated with the ethyl esters of glycine and α-alanine, compounds with an unusual imide bridge group are formed:[93,117]



R = H, Me.

A series of mononuclear crystalline dicarbonyl complexes with the chelating aminocarboxylate ligands $(OC)_2\overline{RhNHRCHR'COO}$ (XCVIII), where NHRCHR'COOH = GlyOH, L-AlaOH, β-AlaOH, DL- and L-LeuOH, L-HisOH, L-TyrOH, SerOH, DL- and L-PheOH, and p-$HOC_6H_4NHCH_2COOH$, have been obtained[118–120] by the reactions of aminoacids with the dinuclear rhodium carbonyl chloride $[Rh(CO)_2Cl]_2$ in benzene. It has been observed that these compounds readily react with tetracyanoethylene to form 1:1 adducts. The nucleophiles L, which consist of amines, 2,2'-bipyridyl, and o-phenanthroline, substitute both CO groups in the complexes (XCVIII), while treatment of the latter with L = PPh_3 or $AsPh_3$ in benzene or acetone entails the substitution of only one CO group and the formation of the monocarbonyl compounds $L(CO)\overline{RhNHRCHR'COO}$ (XCIX). The complexes (XCIX) can also be obtained by treating a mixture of $RhCl_3 . xH_2O$ and PPh_3 in benzene with aminoacids in an atmosphere of CO. The reactions of compounds (XCVIII) with PPh_3 in chloroform leads to the elimination of the aminoacid ligands and the formation of $[Rh(CO)(PPh_3)Cl]_2$ and an analogous result is obtained when gaseous HCl or HBr are passed over the solid complexes (XCIX). On the other hand, when gaseous chlorine is bubbled through a suspension of $(Ph_3P)(CO)\overline{RhNH_2CHR'COO}$ (R = H or Me) the bond between the aminoacid ligand and the metal is retained and an ionic complex is formed to which the composition $[Ph_3P)(CO).\overline{RhNH_2CR'ClCOO}]^{2+}.2Cl^-$ has been attributed.[120]

The data examined in this review show that aminoacids and their derivatives can form complexes having a wide variety of structures with transition metals in low oxidation states under comparatively similar conditions. By virtue of their ambident nature, the aminoacid fragments can function as terminal ligands coordinated to the metal atom via the N or O atoms, can participate in the formation of metallocycles, and finally can serve as bridges between two metal atoms. Arene π-complexes can be obtained from aromatic aminoacids. In all these reactions the metal atoms show a tendency to retain their 16- or 18-electron valence shell, which greatly facilitates the determination by spectroscopic methods of the structures of the complexes formed.

Derivatives of rhenium carbonyl, which exhibit an enhanced stability and contain numerous CO groups, some of which are retained under the conditions of the substitution reaction and which have a fixed octahedral configuration of the ligands around the metal atom, are especially convenient as model compounds for the study of the reactions of protein molecules with transition metal compounds. With the aid of these compounds, it has been possible to discover the importance of the steric features of the aminoacid ligands and their influence on the chemical properties of aminoacid complexes.

The formation of comparatively stable metal carbonyl aminoacid complexes and the possibility of a subsequent ready dissociation of the metal–nitrogen bonds on treatment with nucleophiles suggest the likely usefulness of the employment of the metal carbonyl groups for the protection of the amino-groups in the synthesis of peptides and in other reactions of biological compounds containing aminoacid fragments.

The possibilities inherent in the application of organometallic compounds in biochemistry are by no means exhausted by the examples quoted in this review. Reports have been published recently concerning the synthesis of metal carbonyl complexes with biological ligands such as vitamins,[121] monosaccharides,[122] steroids,[123] etc. Certain natural products, which are difficult to obtain otherwise, have been synthesised successfully with the aid of metal carbonyls, for example, one of the insect pheromones whose molecule includes the vinylallene group.[124]

There is no doubt that further development of bioorganometallic chemistry will make a significant contribution to our understanding of the role of metals in biological processes. Furthermore, studies in this field should provide a basis for a search for a new type of catalyst and for the development of fundamentally new technological processes, the conditions in which will be similar to those in reactions occurring in living organisms in the presence of metalloenzymes.

The Macrokinetics and Rheokinetics of the Hardening of Oligomers

A.Ya.Malkin

The review deals with the investigation and phenomenological description of the macrokinetics of the hardening of reactive oligomers and the change in their rheological properties observed in the course of this process. Attention has been concentrated on the establishment of a relation between the macrokinetics and rheokinetics of the hardening process. The influence of deformation on the hardening kinetics is examined and the role of non-isothermal effects induced by various factors as well as the formulation of the hydrodynamic problems concerning the flow of liquids with variable rheological properties are discussed. The bibliography includes 143 references.

I. INTRODUCTION

The hardening of reactive oligomers (RO), i.e. the transition from the comparatively non-viscous liquid to a solid infusible material, is one of the principal technological processes associated with the chemistry of macromolecular compounds and is widely used in various branches of modern industry, including aerospace engineering, machine engineering, power engineering, etc. This process occurs in the manufacture of reinforced plastics of all types, plays an important role in the deposition of protective and insulating coatings, and recently has found application in the preparation of constructional components. The wide variety of the structures of RO and the possibility of their comparatively simple combination with various fillers and reinforcing elements are responsible not only for the extremely broad spectrum of the properties of the final products and articles made from them but also for different versions of the kinetics of the reactions occurring during the hardening of RO as well as the topology of the structures produced. Many problems associated with the chemistry of RO have been considered not only in hundreds of original communications but also in reviews.[1]

At the same time there exists an important aspect of the general problem of the investigation of the RO hardening processes which has so far been comparatively little reflected in the scientific literature, although there can be no doubt about its fundamental and technological importance. This concerns the general features of the time variation of the rheological properties of RO during the hardening process, so that there arises a single macro- and rheo-kinetic problem which involves the establishment of a correspondence between the macrokinetics of the hardening process and the change in the rheological properties of the RO as a consequence of this process. The terms "kinetorheology" or "rheokinetics", first proposed in 1976 [2] and then used in Soviet literature,[3] aptly reflect the range of processes which should be considered in studies on the kinetics of the variation of rheological properties; however, it is essential to establish a relation between the rheokinetics and macrokinetics of a chemical process.[4] Certain aspects of this problem, considered in the literature up to 1980, were dealt with in a previous review.[5] This review is devoted to a more detailed discussion of the problems associated with the macrokinetics and the rheokinetics of the hardening of oligomers; mainly the literature data of the last five years are considered.

The study of the rheokinetics of the hardening reactions of RO is of dual interest. On the one hand, measurement of the rheological properties of the reaction mass in the course of the process constitutes a way of following the latter. On the other hand, the intrinsic characteristics of the rheological properties are of direct technological interest: in the field of the conservation of the fluid state—for the assessment of the possibility and ways of filling the mould or the impregnation of the reinforcing structure; after the formation of an involatile product—for the direct assessment of the mechanical (operational) properties.

It is noteworthy that many methodological procedures and experimental methods used to investigate the rheokinetics of the hardening of RO are related to or are analogous to the procedures and methods employed in the technology of processes such as the "monomeric" or "cast" moulding, where the final product is a linear polymer below the melting point and not a cross-linked polymer.[6-9] This enhances the generality of the rheokinetic problem and at the same time poses a new question concerning the role of deformation in chemical processes leading to the formation of the final product. Furthermore, the role of the non-isothermal conditions in hardening processes,[10-12] which is due to the significant exothermicity of the chemical reactions, leading to hardening, as well as the dissipative heat evolution during the flow of highly viscous liquids and the heating from an external source, must be emphasised. The non-isothermal nature of the process itself leads to a series of new phenomena which are of general importance for its kinetics and mechanics.[10,11]

II. CHANGES IN THE RELAXATION STATES DURING HARDENING

The rheokinetic transformations during the hardening of RO are associated not only with a change in the molecular structure of RO (with increase in the chain length and/or the degree of branching) but also (and possibly primarily) with relaxational transitions occurring even under isothermal conditions at the moulding temperature T_m as a consequence of the shift of the glass point T_g of the polymer formed. This fundamental approach was formulated more than ten

years ago and has been developed in numerous investigations.[13-20] Its essential feature is illustrated in Fig. 1, which presents the relaxation processes as a function of T_m in a schematic form. Several main situations are possible. Firstly, the temperature T_m may be higher than the glass point of the final product $T_{g,\infty}$ which is thus in a highly elastic state. During the hardening process, the initial liquid loses its fluidity at some instant as a consequence of the formation of a gel (there is a transition from the fluid to the highly elastic state) and the reaction is completed in the gel. Secondly, T_m may be lower than $T_{g,\infty}$ and a gel is then formed initially (i.e. there is a transition from the fluid state to the highly elastic state) and this is followed by the conversion of the gel into a glass as a consequence of the further progress of the reaction involving the formation of cross-links. Thirdly, at still lower values of T_m, the reaction mass can vitrify before the formation of the gel, which results in the cessation of the structure formation process at an extremely early stage. Fourthly and finally, T_m may be below the glass point of the starting material $T_{g,0}$ and the hardening reaction does not then occur at all.

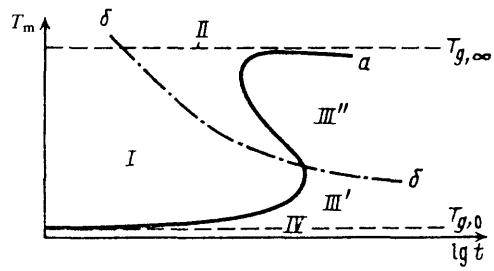

Figure 1. The relaxation states and transitions in the oligomer hardening processes.[18]

The possible situations are clearly seen from the temperature–time diagram (Fig. 1), which has been subdivided into a number of regions by the vitrification lines of the starting material ($T_{g,0}$) and the final product ($T_{g,\infty}$), the line of the gel formed (line *aa*), and the gelation line—the line corresponding to the transition from the fluid to the highly elastic state (line *bb*). Correspondingly I represents the region of the fluid (liquid) state, II the region of the highly elastic state, III′ the vitreous liquid, III″ the vitrified elastomer, and IV the region corresponding to the existence of the vitreous reactive starting material which does not, however, react. The pathway followed by the isothermal reaction is represented by the horizontal line, which intersects lines *aa* and *bb*; at the instant corresponding to this intersection, relaxation transitions take place, which are observed, for example, by the attainment of maxima in the tangent of the mechanical loss angle tan δ.[13]

A rheological method for monitoring the process can be chosen accordingly on the basis of the position of the T_m = const. line (the "reaction pathway"). In region I this is viscometry but, as line *bb* is approached, the viscosity increases without limit and the material loses its fluidity. In all the remaining regions the state of the reaction mass can be inferred from the modulus of elasticity and the tangent of the mechanical loss angle. We may note further that I is the region where the material is "live", i.e. is in a state where it is possible to impart to it the required form; in region II the chemical reaction may continue; in regions III–IV the reaction is significantly arrested possibly long before the attainment of the state of equilibrium. This implies in addition that the properties of the resulting product may depend to a very great extent on the reaction pathway (i.e. on the character of the time variation of the temperature) and that they can be altered by raising the temperature relative to T_m.[21-23]

The diagram presented in Fig. 1 is fairly universal and its configuration is therefore important for various systems capable of hardening and it is also important to establish the exact form of the transitions line. The last problem is evidently associated, primarily, with the description of the macrokinetics of the hardening process and, secondly, with the specification of the character of the dependence of the transition temperatures on the composition (and structure) of the oligomeric products. The first of these problems is of general importance for the problem considered here and the next Section of the review is devoted to it. The second problem was dealt with in a fairly general form by Enns and Gillham[18] and therefore merits further analysis and solution in relation to the principal classes of hardening systems.

III. THE MACROKINETICS OF THE HARDENING PROCESS

1. General Characteristics

A description of the kinetics of the hardening of reactive oligomers is one of the central problems in this field, whose solution makes it possible, firstly, to draw inferences about the chemistry of the process, secondly, to introduce a quantitative parameter in order to compare various materials, and, thirdly, to justify the predictions of the course, productivity, and efficiency of real technological processes. Here there is a possibility of two significantly different approaches: the kinetic and macrokinetic approaches. In the first case the changes in the concentrations of particular reactive groups are inferred by direct physical or spectroscopic methods. This procedure is quite evident and yields clear results, but is by no means always effective from the standpoint of the assessment of the extent and degree of hardening and also the characterisation of the products obtained. This is associated with the fact that the hardening process consists of a set of very many reactions, occurring both simultaneously and consecutively and that the same reactions (reactions of the same chemical type) can lead to the formation of materials with completely different properties, since the topology of the products of isotypical reactions may be fundamentally different.[1,24-26] This method for the estimation of the extent of the hardening reaction is therefore undoubtedly of independent importance, but by no means always leads to an exhaustive solution of the problem.

The macrokinetic method, based on the observation of the time variation of a particular integral parameter reflecting the entire set of the chemical reactions occurring in the hardening of the oligomer, is more widely used and is apparently more effective in practice. Here it is possible to indicate in principle three main methodological approaches. In the first, the concentration of the reactive groups is measured by a chemical or physicochemical method and its time variation is described by a suitable equation regardless of which reactions are undergone by these groups and without specifying in detail the individual stages of the chemical process. In the second method, which may be

called "calorimetric", one measures the time variation of the total heat of reaction and the question which particular possible reaction makes a given contribution to the observed heat change is not discussed. Thus, if the total heat of the hardening reaction is Q and an amount of heat $q(t)$ has been evolved at time t, then the quantity $\beta_c = q(t)/Q$ is adopted as the "calorimetric" degree of conversion β_c.

Such an estimate is very widely used in practice but it has an unambiguous physical significance only when Q does indeed correspond to the overall transformation. This can occur (naturally for a sufficiently long observation) when the final product remains in the highly elastic state. On the other hand, when the reaction mass vitrifies before the completion of the hardening process, then the quantity Q corresponding to the attainment of line *bb* in Fig. 1 is found to depend on the temperature T_m and the quantity β_c, calculated as the ratio $q(t)/Q(T)$, does not characterise the degree of reaction, because different degrees of reaction correspond to the same value of the ratio at different temperatures.[27,28]

The third common method for the estimation of the degree of reaction is based on the measurement of a particular physical characteristic of the substance which depends on the degree of reaction, for example, the viscosity, the modulus of elasticity, hardness, etc. Thus, if the modulus of elasticity of the starting material is G_0, that of the final product (in the highly elastic state) is G_∞, and that of the reaction mass at a certain instant is $G(t)$, then the quantity $\beta_r = [G(t) - G_0]/(G_\infty - G_0)$ may be adopted as the "rheological" extent of reaction β_r. An additional consideration supporting the introduction of this measure of the degree of hardening may be the familiar concept according to which the modulus of elasticity of oligomers capable of being hardened is related to the density of the network of cross-links.[23-25]

It is noteworthy that in the general case one cannot expect β_c and β_r to be identical or to agree with other possible characteristics of the macrokinetics of the hardening process, because these quantities may reflect different reactions of the test substance.

It has been shown that the instant of the attainment of the gel point in no way affects the values of β_c, β_r, as well as other measures of the extent of the hardening reaction employed in the literature. However, this instant (the reaction time corresponding to it will be designated by t^*) is always of independent interest for the physical chemistry and technology of reaction oligomers; t^* also constitutes a macrokinetic measure of the extent of the hardening process and its temperature variation is an important characteristic of the reaction. The value of t^* must therefore be estimated by other procedures, for example, from the instant of the attainment of the maximum in $\tan\delta$ [13,15] or from the instant when the viscosity η reaches a certain arbitrary high level,[29] or when one can assume that $\eta \to \infty$.

The appearance of a residual equilibrium (relaxation) modulus of elasticity or modulus of high elasticity may serve as reliable evidence for the attainment of the gel point, i.e. for the formation of a continuous three-dimensional network.[30] Naturally, it is fairly difficult to determine experimentally whether a non-zero component of the modulus has appeared. The instant when the modulus of elasticity reaches a certain not very high but easily measurable value, for example 10^3 Pa, may be adopted as an experimentally unambiguous (but more arbitrary) criterion of the attainment of t^*.

It is of interest to note that the time t^* determined in this way is correlated[30] (at least in certain cases) with another arbitrary but also unambiguously determined time, namely that when $\tan\delta = 1$ is attained. The latter estimate may be particularly valuable in practice, because it has been established for nine different thermoreactive resins[31] that the times t^* determined by the standardised ASTM method (the resin to be hardened is slowly stirred by hand with a wooden rod and t^* is assumed to correspond to the instant when the rod breaks owing to the high viscosity of the mass) and as the point at which the true (G') and imaginary (G'') components of the modulus of elasticity become equal (i.e. $\tan\delta = 1$) are similar for systems in which t^* varies over a very wide range—from 1 to 1000 min. Bearing in mind the arbitrary nature of the estimate of t^* from the strength of the wooden rod, it becomes evident that the method based on the measurement of the modulus of elasticity is naturally preferable (if one disregards the fact that it requires an expensive measuring technique). The choice of frequency is important for the measurement of the modulus of elasticity, because t^* depends on the frequency. Indeed an increase of the frequency by an order of magnitude corresponds to a shift of the point t^*, at which $G' = G''$, approximately by 1 min along the time axis, which corresponds to a frequency dependence of the relaxation transition point. A frequency of 1.6 Hz ($\omega = 10$ rad s^{-1}), which is approximately equal to the rate of shear used in tests by the ASTM method, is therefore recommended as "standard".[31]

The method of estimating t^* as the time when $\tan\delta = 1$ is very clear and unambiguous; however, generally speaking, it should not be correlated with other methods. Thus in a study of the hardening of unsaturated polyester resins it was found[27] that the point at which $\tan\delta = 1$ coincides with the gel point found by the ASTM method only at low hardening temperatures; with increase of temperature, $\tan\delta = 1$ is reached earlier than the maximum in the loss modulus G'' characterising the instant of the transition.

It is thus evident that, just as one cannot expect a complete correspondence between β_c and β_r, the values of t^* estimated by different methods may not agree owing to the arbitrary nature of the methods employed; only the estimate of t^* from the time when $\eta \to \infty$ is absolute, but the very determination of the attainment of the situation (which can be achieved only asymptotically) also involves greater or smaller errors.

As regards the method used to describe the $\beta(t)$ relation, the essential feature of the macrokinetic approach used to solve this problem is expressed by the equation[4,10]

$$\dot{\beta} = K_0 f(\beta) e^{-U/RT} , \qquad (1)$$

where K_0 is a normalising multiplier, U the activation energy for the hardening process, and $f(\beta)$ a macrokinetic function. The reason for its introduction is that it includes only one variable parameter, namely the degree of reaction β, i.e. in this approach one deliberately ignores the different, possibly very complex, variants of the hardening reaction as a multi-stage process or as a reaction proceeding via several parallel pathways, etc., all this being approximately generalised by the single factor β.

Generally speaking, this approach does not guarantee success and one cannot claim *a priori* that it is applicable in all possible situations. However, the experience gained in describing the hardening processes involving a very large number of oligomers demonstrated the fruitfulness of this approach and the possibility, when the form of the function $f(\beta)$ has been selected appropriately, of describing with its aid all situations encountered in reality. Thus the problem reduces to an appropriate selection of the type of macrokinetic function $f(\beta)$.

Apparently the most general approach to the choice of the function $f(\beta)$ has been proposed by Kamal and Souraur[32,33] and Progelhof and Throne,[34] who formulated a macrokinetic hardening equation [Eqn.(1)] in the isothermal case as follows:

$$\dot{\beta} = (k_1 + k_2\beta^m)(1-\beta)^n \qquad (2)$$

where k_1, k_2, m, and n are empirical constants and k_1 and k_2 can vary with temperature in different ways, while m and n are independent of temperature.

In contrast to many early investigations,[35-38] where an nth order equation was proposed for the description of the macrokinetics, i.e. it was assumed that $f(\beta) = (1-\beta)^n$, Eqn.(2) takes into account explicitly the autoacceleration or autocatalytic effect, expressed by the first multiplier on the right-hand side of Eqn.(2), which is important for hardening reactions.

An undoubted advantage of Eqn.(2) is its general character, while its disadvantage is its extreme generality, since four "adjustable" constants are as a rule too many to achieve an unambiguous macrokinetic characteristic of the hardening process. In most cases it is therefore sufficient to employ simpler relations which are special cases of Eqn.(2).

Thus the macrokinetics of the formation of polyamide-6 are described by an equation of the autocatalytic type but in a much simpler form, which is obtained from Eqn.(2) when $m = n = 1$ on the assumption that the reaction rate constant obeys the Arrhenius relation as a function of temperature:[9,39-42]

$$\dot{\beta} = K_0 e^{-U/RT}(1-\beta)(1+C\beta)\ , \qquad (3)$$

where there are only two "adjustable" parameters, K_0 and C, which vary as a function of the conditions of the synthesis, i.e. the concentrations of the catalyst and the activator, the nature of the active centres, etc., while U is the activation energy for the polymerisation process.

The macrokinetics of the formation of polyamide-12 from dodecalactam are described by a first-order equation without an autocatalytic term, i.e. in this case $C = 0$;[8,9,41] however, this is of course an exceptionally simple and atypical case.

There is no doubt that Eqn.(2) represents the most general case, but in practice it is nevertheless desirable to have fairly simple values of the constants m and n.

2. The Macrokinetics of Structure Formation in the Principal Types of RO

We shall now consider the principal results of the application of the macrokinetic method to the description of the hardening of the RO described in the literature. The most important and most frequently investigated case, to which the greatest number of communications have been devoted, is the hardening of epoxide resins. It has been shown that Eqn.(2), where β has been most often determined from the results of calorimetric measurements, is entirely suitable for this case with the constants $m = n = 1$.[32,33,43,44] This conclusion terminates a fairly prolonged controversy concerning the character of the macrokinetic equation for the description of the hardening of epoxide resins, because earlier various publications proposed equations for $f(\beta)$ of zero,[45] first,[46] and fractional[47] orders in the degree of reaction. The conclusion that the hardening reactions of epoxide resins proceed with autoacceleration, reached by Kamal,[33] can also be found in Rozenberg's paper[48] (on the basis of data obtained calorimetrically, i.e. β_c), and was later confirmed also by the rheological method,[49] i.e. on the basis of β_r. In the last study β was determined for the hardening of the diglycidyl ether of bisphenol-A with dicyanogendiamine and it was established that the constant k_2 in Eqn.(2), characterising the autoaccelerating effect of the reaction, is fairly high, but the autoacceleration effect degenerates with increase in the concentration of the hardening agent.

The question of the temperature variation of the rate or duration of the structure formation reaction is important (in both practical and theoretical respects). Here one must emphasise that the effective activation energy U can be determined by various methods, which generally speaking can yield different results depending on the choice of conditions in comparing the values of the given parameter under non-isothermal conditions. Thus U found from the gelation time, i.e. from the gel point t^*, may not agree with the value determined from the temperature variation of the maximum rate of change of β or from the time coresponding to the attainment of a specific level of the values of β, etc. Whether or not the values of U found by different methods agree depends on the form of the macrokinetic equation for $\dot{\beta}$ and on the presence or absence of an influence by temperature on the constants which it includes.

The discrepancy between the values of U found from different characteristic points has been demonstrated very clearly in a study[50] where it was found that $U = 55$ kJ mol^{-1} when it is calculated from the point corresponding to the onset of gel formation, $U = 66$ kJ mol^{-1} when found from the most rapid increase of the modulus of elasticity (the rigidity of the material), $U = 83$ kJ mol^{-1} when found from the instant corresponding to the completion of the rapid increase of the modulus, and, finally, $U = 103$ kJ mol^{-1} when found from the time of attainment of the final value of the modulus. The observed monotonic increase of U as one moves from the beginning to the end of the reaction is fairly striking, because it apparently shows that the two constants which determine the macrokinetics of the structure formation process nevertheless vary with temperature in different ways, so that a single value of U does not exist. In this respect an unusual simple exception is provided by the situation described by Malkin et al.,[49] who found that the autoacceleration constant is independent of temperature and the effective activation energy (70 kJ mol^{-1}), determined from $\dot{\beta}$ (or from the rate constant $K = K_0 e^{-U/RT}$) proved to be identical with the values calculated from the temperature variation of $1/t^*$ and from calorimetric data published previously.[46]

However, one should note that in Eyerer's study[51] the activation energy calculated from spectroscopic data for different stages of the reaction with bisphenol-A and dicyanogendiamine was also found to be the same in all cases but its value was 84 kJ mol^{-1}. The significantly smaller value $U = 51$ kJ mol^{-1}, obtained[19] for the reaction of a mixture of diglycidyl ethers with 2,4-tolylene-1,1'-bis-3,3-dimethylurea contrasts significantly with the high values of U quoted above.

Naturally the specific value of U depends on the detailed composition of the reaction mass, because the rate-limiting reaction may be various. Thus the effective activation energy for an epoxyorganoelemental oligomer, hardened with oligobutoxytitanophosphoroxan, found from the temperature variation of $1/t^*$, varied in the range 47–60 kJ mol^{-1} as a function of the content of the hardening agent.[52]

Somewhat more detailed results of a macrokinetic study of the structure formation process in epoxide resins (without specification or the hardening composition) have been given in a communication[53] based on certain earlier results of calorimetric studies.[54-56] The authors[53] observed, firstly, that the curves obtained by the method of differential

scanning calorimetry show two "humps", which correspond to the existence of two different main reactions and, secondly, that the $\beta(t)$ relation is described in different ranges of β by different macrokinetic equations; a first-order equation, where $U = 56.6$ kJ mol^{-1}, proved to be fairly suitable for $\beta > 0.3$. For low values of β, the rate of reaction is described by an extremely complex equation incorporating two constants which vary with temperature in different ways, so that there is no single activation energy.

Apparently if one follows the "averaging" procedure, then $U \cong 84$ kJ mol^{-1}, which should be adopted[46,57,58] as the most reliable (most frequently quoted in the literature) value of U for the reactions of epoxide resins; however, it has been pointed out[57] that cases are possible where the temperature variation of the rate of reaction (or t^*) is not described by the Arrhenius relation at all and in another communication[58] even lower values of U have been quoted. (Other values of U and different methods for describing the temperature variation of the hardening of epoxide resins were mentioned above.)

In conclusion of the discussion of the macrokinetics of the hardening of epoxide oligomers, we shall note also certain facts associated with this reaction. Firstly, one should approach the estimation of β_c with caution, since account must be taken of the very considerable (almost by a factor of two) variation of the specific heat and thermal diffusivity in the hardening process.[44] Secondly, the extent of reaction at the gel point β^* varies very appreciably as a function of composition (functionality) of the reaction mass, but as a rule deviates significantly from theoretical estimates. Thus $\beta^* = 0.3-0.47$ for tetrafunctional compounds (instead of the theoretical value of 0.58), which is associated in the general case with failure to take into account the role of secondary reactions.[57] Values of β^*, varying to a very large extent as a function of the recipe for the hardening of the composition, have been published.[59] Naturally, one may not expect agreement between the values of β^* and the instant of the appearance of the gel fraction in the reaction system.[52] In the general case this is apparently associated with the heterogeneity of the network formed.[50,60]

In connection with the development of the "oligomer" technology, numerous studies on the formation of polyurethanes have been carried out. The macrokinetics of this process have been frequently described by a power relation,[61,62] where $n = 1.5$, which was dictated primarily by the convenience of the solution of hydrodynamic problems involving the use of this equation,[62-64] although the authors who proposed it[61] noted themselves that it yields an insufficiently accurate approximation to the real picture of the phenomenon. The kinetics of the formation of polyurethanes have been described[65] by a second-order equation on the basis of the results of measurements by differential scanning calorimetry (DSC). A more complex two-term equation, reflecting both the forward second-order reaction and the reverse first-order reaction, has also been proposed.[66]

In reality the reaction under discussion is fairly complex and a second-order equation, which seemingly should be sufficiently effective at least when a bifunctional hardening agent is employed, is inapplicable to the entire polymerisation process, although it can describe successfully shorter or longer parts of the process.[67] As in the previous case, the most complete and exact description of the $\beta(t)$ relation for polyurethanes can be achieved when a macrokinetic equation of type (2) is employed. However, a significantly new aspect of this equation has been discovered precisely in relation to polyurethanes, namely it was found[68] that the constant $C < 0$ in Eqn. (3), which is the main special case of Eqn. (2). This means that the hardening reaction does not in principle go to completion: when $\beta = C^{-1}$, the rate of the process falls to zero, i.e. the reaction stops at this value of β and this happens under both isothermal and adiabatic polymerisation conditions.

The third main system to which numerous studies on the macrokinetics of the hardening process have been devoted consists of unsaturated polyester resins. In essence, an equation of type (3) has in fact been formulated precisely for such substances as well as epoxide resins,[32,44,69,70] although a simpler power equation had been used in the very earliest publications.[71] Later studies confirmed the validity of the macrokinetic equation (3).[27,28,72-76]

It is of interest to note the following results of these studies. Firstly, the sum of the exponents $m + n = 2$, which reduces the number of "adjustable" constants. Secondly, m and n are almost independent of temperature (the variation of m and n with temperature has been indicated only by Han and Lem[27]). Thirdly, whereas both k_1 and k_2 depend on temperature very markedly, their ratio, characterising the autoacceleration effect in the hardening process, is almost insensitive to changes in temperature. The effective activation energy calculated by many investigators from k_2 is in the range 76 ± 3 kJ mol^{-1}; Han and Lem also quote a value of U calculated from k_2 which is significantly higher (approximately 103 kJ mol^{-1}) than that found from the temperature variation of k_1. Only Yap and Williams[77] quote an appreciably lower value $U \cong 40$ kJ mol^{-1}, found from the temperature variation of the dynamic modulus of elasticity measured at a fixed frequency.

The values of m and n found by different workers are quoted below:

m	0.25	0.33	0.45	0.49
n	1.75	1.67	1.55	1.51
References	[32]	[69]	[70]	[27]

It is of particular interest to note that the critical gel point β^*, defined as the instant when $\eta \to \infty$, depends to a large extent on temperature.[27,28] Apparently this is associated with the influence of temperature on the degree of heterogeneity of the polymer structure formed.

There have been few studies devoted to the macrokinetics of the hardening of systems other than the three enumerated above. These are primarily studies concerning the hardening of the methylphenylsiloxane oligomer[78,79] and other low-molecular-weight organosilicon rubbers.[80] Although limited regions of variation of β can be described by nth order equations (in particular those where $n = 2$),[78] nevertheless extended ranges of values of β necessitate the employment of a macrokinetic equation of type (2) or (3). Incidentally, in certain cases, similarly to what has been observed for polyurethanes, there is a possibility of a situation where $C < 0$.[80]

It is also possible to find other examples of studies on the kinetics of structure formation in various products (not necessarily hardening): in certain instances this can be cyclisation,[81] the copolymerisation of organsiloxane oligomers,[82] various intrachain transformations,[15,83,84] etc. However, the experimental data quoted in these and other reports have not been subjected to a realistic quantitative macrokinetic analysis, in view of which their consideration is somewhat outside the framework of the present review.

Problems associated with the non-isothermal nature of volumetric data occupy an important place in the consideration of the macrokinetics of hardening processes.[10-12]

There is a possibility of three sources of non-isothermal conditions: heat exchange with the ambient medium, the exothermicity of the reaction, and the dissipation of the work due to external friction. When non-isothermal macrokinetics are considered, the cause of the local change in temperature is insignificant, but the external source of heat usually plays a smaller role than the internal sources. The factor associated with dissipative heat evolutions will be considered below in the section devoted to the rheology of the RO. Here we shall concentrate attention on the exothermic effects, particularly since in many cases of practical importance hardening can occur under virtually adiabatic conditions and the temperature rise due to the exothermic nature of the reaction can exceed 100 °C.[85]

It is therefore extremely important to have at one's disposal a method for calculations on hardening under non-isothermal conditions. It is based on the integration of Eqn.(1) taking into account the familiar $T(t)$ relation or the relation specified by the course of the process itself; such a relation is simply formulated in an adiabatic regime:[10,11]

$$T(t) = T_0 + \frac{Q}{c\rho}\beta \quad ,$$

where Q is the total heat of reaction, c the specific heat, ρ the density, and T_0 the initial temperature. In the general case the factor $c\rho$ can depend on T, which requires an independent consideration. When this expression is substituted in Eqn.(1), we obtain an equation containing only one unknown function $\beta(t)$, which can be found by numerical methods. Naturally, the function $T(t)$ is then also found without difficulty. In essence, a completely analogous approach is applicable when the temperature variation of $\dot{\beta}$ is described by a non-exponential equation, for example the familiar Williams–Lundell–Ferry equation.[86] Such a generalised approach is applicable also in the calculation of the variation of viscosity under non-isothermal conditions.[59,87]

The calculation of $\beta(t)$ and $T(t)$ not in an adiabatic regime but under conditions involving partial removal of the heat of reaction to the ambient medium is more complex but quite feasible at the present level of development of computer techniques.[8]

The change in the temperature of the system in the hardening of RO plays such an important role that on this basis it is possible to propose a method for the monitoring and regulation of the technological process by measuring the temperature at separate points in the material being hardened.[88]

Various aspects of the problem of non-isothermal polymerisation (and hardening) have been considered in detail in reviews.[10–12] Here we should like to mention only one phenomenon associated with non-isothermal conditions—the frontal propagation of the reaction as a consequence of the exothermic nature of the process occurring during its "ignition" in a certain local region,[12,89,90] which is one of the most effective methods of carrying out the hardening process. This phenomenon is of general importance and may arise in reactions of different types—radical polymerisation,[91] polymerisation in suspension,[92] etc. It has been shown recently[93,94] that frontal polymerisation can also occur in a combined process, namely when the heat evolution due to the crystallisation of the product formed is superimposed on the exothermic effect of the polymerisation reaction. Although it is still obscure whether such a "running wave" can arise in the hardening process, there is no doubt about its possibility for the related "chemical moulding" process in the activated ionic polymerisation of lactams.

In concluding this section we may note that the macrokinetics of the hardening process in both isothermal and non-isothermal cases can be deduced fairly simply if the reaction takes place in the kinetic region. On passing to the diffusion-controlled region, the situation becomes fundamentally more complex until even the adiabatic temperature rise, characterising the extent of reaction, begins to depend on the rate of stirring characterised by the Reynolds number.[95] Nevertheless, from the standpoint of the mathematical modelling of the RO hardening process as a whole, which is central to the aim of the present review, the situation is simplified by the fact that, so long as the reaction takes place in the supply channels where the flow (and mixing) take place, the viscosity of the medium is low, the material is homogeneous, and one can assume that the initial stages of the hardening process take place in the kinetic region. After the mould in which the RO hardening process proper is completed has been filled, there is no flow at all, the reaction takes place in a non-deformable material, and its macrokinetics therefore reflect the situation which, although possibly in fact complex, is similar for comparable conditions, i.e. for various recipes and different geometrical dimensions of the article.

IV. THE RHEOLOGY (RHEOKINETICS) OF THE HARDENING PROCESS

Two rheological methods are most widely used to follow the kinetics of structure formation in oligomers: from the change in viscosity η and from the change in the modulus of elasticity G, the latter being susceptible to measurement also in the dynamic regime of periodic oscillations.[4,5] The general character of the variation of η and G with time t is illustrated in Fig. 2, the scheme referring to the case where $t > t^*$ and the system undergoing hardening is in a highly elastic (or gel-like) state, so that the hardening reaction can go to completion. It is striking that the modulus of elasticity begins to increase before the time t^* has been reached. This phenomenon is observed when the initial oligomers have a chain sufficiently long to manifest its flexibility or when the formation of cross links is accompanied by an increase in chain length (by a continued increase) when the reactive end groups interact. In such cases the appearance of the condition $G \neq 0$ is due to the formation of physical entanglements, contributing to the network structure, which is formed as a whole as a consequence of the existence of nodes of not only chemical but also physical nature.[96] It is likewise of interest to note that the attainment of t^* is not as a rule reflected in the character of the increase of the modulus, whereas viscosity rises very sharply as this point is approached: at $t \to t^*$ the material loses its fluidity ($\eta \to \infty$).

The character of the variation of the modulus of elasticity during the hardening process, largely discussed in the previous Section, where the quantity β_r, calculated from the relative change in the modulus of elasticity during the hardening process, was proposed as one of the possible parameters for the estimation of the extent of reaction. This in essence exhausts the problem of the macrokinetic description of the hardening process in terms of the change in the modulus of elasticity, particularly if we consider in addition that the measurement of the modulus G belongs to the same series of physical methods for monitoring the RO hardening process as the methods for following the hardening kinetics: by a dielectric procedure from the change in the dielectric constant and in the tangent of the dielectric loss angle (fairly numerous communications have

been published on this topic; among them, mention may be made of those of Badalov et al.[97] and Siemon et al.[98]), from the change in the electrical conductivity of the composition,[99] from the spin–spin relaxation time measured by the pulsed NMR method,[100] from the change in the refractive index,[101] etc.

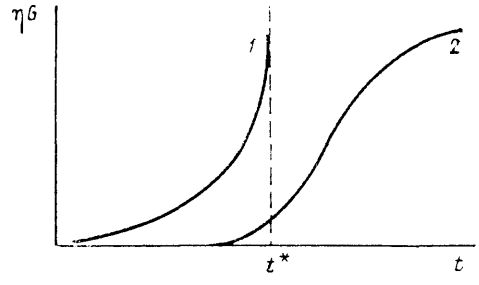

Figure 2. Character of the variation of the viscosity (curve *1*) and the modulus of elasticity (curve *2*) with time in the oligomer hardening process.

However, viscometric measurements in the region where $t < t^*$ are of independent importance. Firstly, in this region all the methods based on the measurement of the density of the network of cross links are unsuitable (because at this stage of the hardening process there is as yet no network); secondly, the measurement of the $\eta(t)$ relation is central for the technological monitoring of the "liveness" and quality of the RO and compositions based on them; thirdly, the quantitative estimate of the $\eta(\beta)$ relation constitutes the basis for the solution of all the hydrodynamic problems associated with flow in the casting channels, with the filling of the mould, etc.; fourthly, and finally, measured viscosities can be compared directly with the molecular characteristics of the test substance, particularly when one is considering not structure formation but an increase in chain length in the interaction of the end groups or in polymer-analogue transformations within the chain.

At the present time equations of two types for the description of the $\eta(t)$ relation in the hardening of RO are being discussed. In equations of the first type it is assumed explicitly that, when $t \to t^*$, the viscosity increases without limit. In equations of the second type a sharp, usually exponential, increase of viscosity is also postulated, but the equation itself formally does not have a singularity.

Among the equations of the first type, power expressions which follow from scaling ideas are of greatest interest:[102–105]

$$\eta \propto (\beta^* - \beta)^{-s} \quad . \tag{4}$$

Equations of this type are applicable over a very narrow range of β near β^* when $(\beta^* - \beta)/\beta^* \ll 1$; since it can be assumed that $\beta \propto t$ over such a narrow range of values of β, instead of Eqn.(4) one formulates a relation which is analogous in structure:

$$\eta \propto (t^* - t)^{-s} \quad , \tag{5}$$

where s is a constant, which, according to the available measurements[105] for two systems of different chemical types, amounts to 0.78 ± 0.05 and this result agrees with the theoretical estimate obtained by Monte Carlo methods.[105]

As regards the question of the relation between the viscous properties of the hardening RO and its molecular characteristics, this has been studied most systematically and solved for polyurethanes, probably because hitherto this has been virtually the only system to which the "oligomeric" moulding method, requiring serious quantitative calculations, has been applied on an industrial scale.

According to the available data,[62,106,107] the dependence of the viscosity η on the weight-average molecular weight $\bar{M}_w$ is expressed by the formula

$$\eta = A\bar{M}_w^a \exp\left(\frac{E}{RT}\right) \quad , \tag{6}$$

where A, a and E are constants. In this approach it is most important that $\bar{M}_w$ should be unambiguously related to the degree of reaction and one obtains $\bar{M}_w \to \infty$ when $\beta \to \beta^*$ and hence $\eta \to \infty$, i.e., firstly, in Eqn.(6) the existence of the gel point is expressed explicitly and, secondly, it is possible to establish an unambiguous function $\eta(\beta, T)$. The latter has been achieved by Castro and co-workers,[108,109] who showed that the entire set of experimental data for the $\eta(\beta, T)$ relation can be described by the generalised formula[108,109]

$$\frac{\eta(\beta, T)}{\eta_0(T)} = \left(\frac{\beta^*}{\beta^* - \beta}\right)^{A + B\beta} \quad , \tag{7}$$

where η_0 is the initial viscosity of the system. Here the influence of temperature on the viscosity has been expressed by the relation $\eta_0(T)$, provided of course that one disregards the influence of temperature on the hardening kinetics. It is also of interest to note that in all the instances investigated the constants A and B assumed the "universal" values $A = 3.5$ and $B = -2.0$.

The existence of such a generalised relation $\eta(\beta, T)$ is specially remarkable, since the reaction under discussion was not carried out under homogeneous conditions but was accompanied by phase separation;[108,110] nevertheless, it has been possible to find a general law governing the variation of viscosity which is valid during the period from the start of the reaction directly until the attainment of the gel point, i.e. for a change of viscosity within a range corresponding to five decadic orders of magnitude.[106]

It is at present difficult to say whether this approach can be extended to other RO. In a qualitative form the answer should probably be yes, but the search for optimum specific quantitative relations still remains an independent and laborious problem. In this respect one must emphasise that there is a possibility of specific problems for each system. For example, in the hardening of polyesters not only an increase of β^* with increasing temperature accompanied by the corresponding displacement of the $\eta(\beta)$ relation towards higher values of β but also the possibility of a flow of the polymer, albeit with a lower viscosity, under conditions where $\beta > \beta^*$, associated with the formation of a highly heterogeneous suspension, has been observed.[27] In the hardening of epoxide resins at different temperatures it was established[58] that the $\eta(t)$ relations can be superimposed by a vertical shift of the plot by an amount a_η and a horizontal shift by an amount a_t. The effective activation energy for viscous flow can be found from the temperature variation of a_η and the corresponding activation energy for the cross-linking process can be found from the corresponding temperature variation of a_t.

Equations of the second type, proposed for the description of the variation of viscosity in the hardening of RO, do not take into account explicitly the existence of the gel point, which is clearly seen in the most widely used of the

equations:[32,33]

$$\eta=\eta_0 \exp(kt) \quad , \tag{8}$$

where η_0 is the initial temperature-dependent viscosity and k a constant characterising the influence of the rate of the chemical reaction on the increase of viscosity, which depends in its turn on temperature, so that one can write

$$\eta_0=\eta_\infty \exp(E/RT) \quad , \tag{9}$$

$$k=k_\infty \exp(U/RT) \quad . \tag{10}$$

Evidently the influence of temperature on viscosity is manifested to a greater extent via k than via η_0, because in the former case the exponential function occurs twice. It also follows from Eqn.(8) that $\eta \to \infty$ only when $t \to \infty$, so that it would seem that the gel point does not exist. Naturally, this is only a formal conclusion, since evidently it is almost always possible to adopt as t^* the time corresponding to the attainment of a certain constant level of viscosity; however, in the solution of applied problems Eqn.(8) may prove to be more convenient than the formulae examined previously, which are formally more rigorous. The equation with argument β can be formulated analogously:

$$\eta=\eta_0 \exp(k'\beta) \quad , \tag{11}$$

$$k' = k'_\infty \exp(E'/RT) \quad . \tag{12}$$

The use of Eqns.(8)–(12) makes it possible to extend the $\eta(t)$ relation readily to the case of hardening under non-isothermal conditions, which has been analysed in detail in a review,[5] so that this question will not be considered here.

Equations of type (11) have indeed been used successfully to describe real hardening systems. Thus Eqn.(11) describes with satisfactory accuracy[53] the $\eta(\beta)$ relation for the hardening of epoxide resins with viscosity varying over a range of three decadic orders of magnitude; here it was found that $k' = 14.1 \pm 1.2$. On the other hand, the effective activation energy E reflecting the temperature variation of viscosity proved to be 90.8 kJ mol^{-1}, which exceeded appreciably the activation energies found from β_c (these were discussed above). This finding is the evident consequence of the fact that E "incorporates" the activation energy for the chemical reaction and viscous flow and these quantities are not additive.[4,111,112]

In view of the practical importance of formulae of the exponential type, it is of interest to establish correlations between their constants and the characteristics of the compositions based on the RO. This is an extremely promising procedure for the quantitative estimation of the quality of the initial materials to be hardened. Numerous instances referring to this approach have been described.[59] In essence, a method for the estimation of the efficiency of catalysts of the formation of polyurethanes in a chain propagation reaction has been proposed on the basis of an analogous idea but without a mathematical treatment.[113]

The use of rheological methods for the investigation of the macrokinetics of the hardening of RO gives rise to certain questions concerning the role of the rate of deformation, namely (1) does the rate of shear $\dot{\gamma}$, at which measurements are made, influence the character of the $\eta(t)$ relation, i.e. the kinetics of the process; (2) what is the form of the rheological equation, i.e. of the dependence of the effective viscosity on the rate of shear $\eta(\dot{\gamma})$ for different stages in the hardening of RO. Apparently there is no general answer to these questions and the answers can be different depending on the nature of the reaction mass.

As regards the role of the rate of shear $\dot{\gamma}$, it has been found that $\dot{\gamma}$ does not usually influence the rate of increase of viscosity. At any rate special studies of this question, referring to the formation of polyurethanes, have shown[108] that, even under phase separation conditions, neither a change in $\dot{\gamma}$ nor a transition from continuous to periodic (only at the instant of the measurement of viscosity) deformation influence the observed character of the increase of viscosity $\eta(t)$. Apparently this situation corresponds to polymerisation under homogeneous conditions, while on passing to the heterogeneous region one should expect deformation to influence the rate of hardening. Thus it has been demonstrated theoretically[114] that in diffusion-controlled reactions an increase of mechanical stresses entails an increase of the rate of the chemical reaction. However, in practice, at least in one instance which has been investigated,[115] exactly the opposite picture has been observed: under phase separation conditions (where the polymer formed was insoluble in the reaction medium), an increase in the rate of deformation led to a significant retardation of the reaction.

However, one should note that the amount of experimental data concerning this problem is very small and the available information is not unambiguous. Thus the data quoted in certain communications[116,117] about the influence of deformation on the rate of radical polymerisation are hardly reliable, since, in the deformation regimes employed in the relevant investigations, dissipative heat evolutions apparently occurred to an extent sufficient to cause the change in rate described above as a result of the deviation from isothermal polymerisation conditions (for a description of the role of dissipative heating, see below).[118]

On the other hand, in general the kinetic role of deformation in RO polymerisation and hardening processes has been clearly studied inadequately: neither the scale nor the limits of the manifestation of the influence of deformation on these processes are known at present.

The influence of the periodic shear deformation on the rate of hardening of RO belongs to the same series of phenomena. This effect was first described a fairly long time ago[119] and it was emphasised that periodic deformation influences not only the kinetics of the hardening process but also the properties of the final products. Subsequent publications[120–122] confirmed these observations; however, here too the question of the quantitative description and limits of this phenomenon remains on the whole open.

An unusual instance of the influence of deformation on the RO hardening kinetics is the situation where intense deformation leads to significant heat evolution, which increases in its turn the temperature of the reaction mass and hence appreciably accelerates the hardening reaction. Observations of this kind have been described in two communications[123,124] and subsequently a complete quantitative theory was developed. It explained this effect, agreed with experiment, and virtually ruled out the need for the consideration of deformation as a direct kinetic factor and it related the role of deformation solely to the non-isothermal conditions in the hardening process caused by it.[125–128] This effect can accelerate the hardening of RO by a factor of many tens but only by virtue of the internal non-isothermicity of the process.

Yet another question related to this range of problems is that of the character of the $\eta(\dot{\gamma})$ relation for RO. In the initial stages of the hardening process reactive oligomers are as a rule Newtonian liquids[109,129] which show no elasticity, although anomalous cases are possible.[130] On the whole, in terms of their rheological properties, RO do not differ from any other polymeric materials[131] and the questions associated with the specific features of the behaviour of filled compositions based on the RO have already been discussed.[5] In the solution of applied

problems associated with the chemical moulding of articles from RO, the flowing liquid is usually seen to be Newtonian but with a viscosity which depends on time or on the degree of reaction;[62,63,129,132] sometimes the so-called power law is employed[64] (similarly to what is done in almost all cases where theoretical problems associated with the flow of thermoplastics are considered[133]). The most complete rheological equation of state of this kind includes terms taking into account the existence of a flow region with a constant (most Newtonian) viscosity and also the transition to the flow region (at sufficiently high rates of shear) described by a power law,[64] the effect of the anomalously viscous flow being determined by the dimensionless product $\lambda\dot{\gamma}$, where the relaxation time λ itself depends on the degree of reaction. The onset of this effect shifts towards lower rates of shear the higher the value of λ, i.e. the greater the extent of the hardening process. Next, for filled compositions based on RO, it is necessary to take into account the existence of the yield point,[134] which incidentally has to be done also for any other filled polymer melts (this question has been discussed in detail in an earlier review[5] and for this reason there is no need to dwell on it here).

Although in the absolute majority of instances where the rheology of RO is the subject under discussion their viscous properties are considered, in reality the question should be understood in a broader sense and other characteristics of such media should also be considered. In the first place mention should be made of their elasticity which is characterised by the appearance of normal stresses σ_W.[131] In an earlier communication[135] it was already stated that the elasticity of the material varies in the region of structure formation to a much greater extent than its viscosity. Few measurements have been made of the changes in the elasticity of RO in the hardening process,[27,28] but they all demonstrate both the role of the normal stresses and the methodological difficulties associated with the measurements of σ_W and the treatment of the results of the measurements: during the hardening process, the volume of the RO diminishes, which looks like the manifestation of negative σ_W, although in reality it is not associated with such stresses, which appear in the shear flow of viscoelastic liquids and are of intrinsic interest from the standpoint of the rheology of polymers and the rheokinetics of structure formation in RO.

V. THE FLOW OF REACTIVE OLIGOMERS

The development of the technology of chemical "reactive" moulding aroused interest in a new class of hydrodynamic problems—the flow of liquids whose rheological properties vary with time. The closest analogue of these problems is provided by problems of non-isothermal flow, where viscosity varies with temperature. In the case of RO non-isothermal conditions constitute only one of the aspects of a more complex general problem of flow with a variable viscosity and it is not even the most important aspect. In essence one is dealing with classical hydrodynamic problems in a new formulation.

Within the framework of the present review, it would be inappropriate to consider the mathematical aspect of the problem but it is useful to deal with fundamental starting points. The general formulation of problems concerning the flow of liquids with a variable viscosity has been described in a number of communications,[62–64,66,129,132,136–140] in which the underlying ideas were in essence identical. They involve the introduction into the equilibrium equation for the variation of viscosity either with time or with the degree of reaction; in the latter case it is necessary to consider in addition the kinetic equation for the extent of reaction. The non-isothermal process conditions, caused not only by heat exchange with the walls but also by the dissipative heat evolutions and the exothermic heat of the hardening reaction, do not introduce any fundamental complications into the solution of the problem,[132] although the size of necessary calculations increases. In all cases it is naturally necessary to employ a fairly powerful computer technique in order to obtain quantitative results. The choice of the rheological equation of state does not play a significant role either. However, the formulation of dynamic boundary conditions on the walls of the channel is of fundamental importance. The usual adhesion hypothesis is by no means satisfactory in all cases. The point is that for hardening compositions a time is always attained where $\eta \to \infty$, which corresponds to the formation of a stationary layer sticking to the walls of the channel, which grows with time until the entire channel is "grown over" by a mass incapable of flowing, which in principle rules out the possibility of a steady flow. To ensure the possibility of a steady flow, it is therefore necessary to adopt the hypothesis of slip near the wall.[64,134]

A rigorous formulation of problems concerning the flow in channels of liquids with varying rheological properties, in flows both with and without a head pressure, makes it possible to determine all the significant hydrodynamic characteristics—such as the distribution of velocities, degrees of reaction, and temperatures along the cross-section and length of the channel, as well as the length corresponding to complete reaction. The latter concept does not occur in normal hydrodynamics, but in this instance it is significant, because it characterises the length of the channel necessary for the attainment of a specified degree of reaction β even at the most unfavourable point (for hardening RO, it must be evidently smaller than β^*). The concrete results of calculations associated with such problems are extremely non-trivial and are frequently unexpected; they demonstrate the existence of extremely unusual characteristics of the flow, but their consideration constitutes a separate task and here it is useful to limit the description to initial problems in the formulation and not to undertake a hydrodynamic analysis.

However, whereas problems concerning flow in filled channels are fairly clear in their formulation, those associated with flow in an incompletely filled channel or with the flow of a hardening liquid having a free surface at the front of the flow are not quite so self-evident. Clearly, for the technology of chemical moulding, this problem is no less important than that of the steady flow through fully filled channels, which necessitated the analysis of such problems.

From numerous direct observations, it has long been known that in the region of the front of the flow there exists the so-called "fountain" effect,[63,66,141–143], which consists in the spreading of the liquid from the axial zone to the walls and this leads to a significant equalisation of the residence times of various particles of the liquid in the channel and hence to a considerable change of the entire hydrodynamic arrangement compared with a one-dimensional flow. Thus the flow near the front becomes two-dimensional in contrast to the one-dimensional flow in a filled channel. A rigorous formulation of this problem is very complex and virtually all the investigators dealing with it have pointed out that there is no need for such a rigorous approach, because it is sufficient to adopt an approximate empirical model of the flow of liquid from the centre to the wall based on experimental data[66] and the specification of the flow pattern in the front in greater detail does not introduce

fundamental changes into the final picture. Since there is no doubt that the fountain effect exerts a significant influence on the entire situation in the filled channel (or mould), including the distribution of residence times, degrees of reaction, and molecular and rheological characteristics of the test substance, the choice of an adequate model of this phenomenon remains an extremely important problem in the theory of chemical moulding.

---o0o---

The initiation and development of the modern technology of the production of polymer articles by chemical moulding have generated a whole series of new problems. The chemical problems associated with the requirements which must be met by the properties of the resulting material have been supplemented by physicochemical problems associated with the necessity to ensure specified hardening kinetics and also mechanical problems, since the rheological characteristics of the products and the characteristics of the flow of the moulded compositions have a decisive influence not only on the properties of the final product but sometimes even the very feasibility of the technological process.

Overall, all these factors make it possible to construct a mathematical model of the hardening of RO and compositions based on them, which enables us to achieve the most important aim (on passing to large-scale technology): to control the process in order to ensure the required quality of the material in combination with the optimisation of the techno-economic process parameters. The transition from general characteristics, which in many respects have already been elucidated, to concrete quantitative results, which can be used in practice requires nevertheless very careful laboratory studies for an adequate quantitative description of the rheology of RO and the macrokinetics of the hardening process in relation to specific materials. The industrial realisation of the results of such research ensures the development of a stable and effective technological reaction-moulding process.

Three-membered Metallocycles

S.P.Gubin

The results of structural and theoretical studies on cluster compounds with a framework in the form of a triangle made up of metal atoms are examined, a systematic account is given of the types of three-membered metallocycles in which the number of electrons is different from the "magic" number, and the causes of their stability are analysed. The influence of the ligand shell and of the formation of multiple bonds on the stability of three-membered metallocycles is demonstrated.
The bibliography includes 169 references.

I. INTRODUCTION

The chemistry of cluster compounds, a field undergoing vigorous development at the present time,[1] is at the junction between a number of other fields of science: inorganic chemistry, organoelemental chemistry, catalysis, biochemistry, colloidal chemistry, the physics of ultradisperse systems, the physics of surfaces, and electronic materials science†.

†In the USSR two All-Union Discussion Seminars were held on the chemistry and physics of cluster compounds (1979 and 1981) as well as the Ist All-Union Conference on the chemistry of clusters together with the Ist All-Union Seminar on "clusters in catalysis" (1983). The proceedings of the seminar and the conference have been published in special issues of the journals Izv.Sirbir.Akad.Nauk SSSR, Ser. Khim. (Bulletin of the Siberian Division of the USSR Academy of Sciences, Chemistry Series), 1982, Issue 4, No.9, and Koord.Khim. (Coordination Chemistry), 1984, **10**, No.5.

The term cluster compounds is given to those metal compounds whose molecules contain a framework of metal atoms at distances permitting a direct metal–metal interaction, surrounded by a framework of ligands;[2] the characteristics of the electronic structure of two-centre metal–metal bonds of different multiplicity have been investigated in detail in relation to a series of dinuclear metal complexes[3] (see also other communications[4-9]). Cluster compounds are divided into small (N = 3–12)#,[10-13] medium (N = 13–40),[14-15] large (N = 41–100),[16] and ultralarge or "giant" (N > 100). The framework in cluster molecules can consist of metal chains of different lengths and with different degrees of branching,[17-19] metallocycles,[20] metalloskeletons,[21] metallopolyhedra, as well as combinations of the above structural elements. Cluster

#Here and henceforth N represents the nuclearity of the cluster, i.e. the number of metal atoms constituting the framework of the cluster compound.

compounds are characteristic of transition metals,[22] lanthanides and actinides,[23] and the majority of non-transition metals.[24,25] Heterometallic cluster compounds containing two,[27-30] three,[31] and more different kinds of metal atoms in the molecular skeleton are being vigorously investigated.[26] The metal framework in cluster compounds is as a rule coated by a dense layer of ligands, both terminal and bridging§, which may consist of individual atoms (H,[32,33] Cl, Br, I,[34-36] S, Se, Te [37,38]), groups of atoms (CR,[39] EL [40]), or molecules (CO,[41,42] NO,[43] olefins, arenes [44-47]), etc. Monoatomic ligands (H, C, N, S, P, etc.) can sometimes be located within the metallic framework surrounded on the outside by other ligands.[48-51] On the other hand, the so-called "ligand-free" metal clusters can exist under specific specially created conditions in both condensed and gas phases in the form of ultradisperse metallic systems[52,53] or "naked" cluster ions.[24]

A profound analogy between cluster compounds of metals and skeletal and polyhedral compounds of non-metallic elements such as boron, phosphorus, arsenic, etc. has been noted.[54] The principle of isolobal correspondence[55] makes it possible, for example, to "substitute" boron atoms in the polyhedron by metal-containing groups with formation of polyhedral metalloboranes[56]—compounds which occupy an intermediate position between the skeletons of non-metallic elements and cluster compounds of metals.

Analysis of the trends in the development of the chemistry of cluster compounds permits the conclusion that for each element in the Periodic System it is probably possible to obtain molecular compounds with frameworks in the form of chains, rings, skeletons, or polyhedra made up of atoms of the given element. In other words, examination of the geometrical structure,[57] electronic structure,[58,59] and the energy relations[60] of the known cluster compounds does not reveal any fundamental factors prohibiting the formation, on the basis of any element of the Periodic System, of molecular compounds having the simplest structural elements specified above. In this sense the chemistry of cluster compounds is the "organic" chemistry of non-carbon elements.

The synthesis,[61] reactivity,[62] electrochemistry,[63,64] dynamics,[65,66] and stereochemistry[67,68] of cluster compounds of metals have been examined in a series of review articles. It has been shown that the coordination of the ligands to several metal centres in the cluster¶ as a rule differs significantly from the coordination of the same ligands in mononuclear complexes.[69,70] In this connection the use of cluster compounds and materials as catalysts, both homogeneous and heterogeneous, constitutes one of the leading trends in research into catalysis.[71-74] Clusters enter into the composition of a new class of biocatalysts—polynuclear oxidation-reduction enzymes (ferredoxins,[75] ferritins,[76] etc.) and play a key role in a series of most important biological processes, such as oxidation,[77] the fixation of atmospheric nitrogen, etc.[78,79]

It has been established that, together with the cluster compounds of metals, many solids (materials) without molecular structure also contain discrete cluster groups made up of metal atoms separated from one another by non-metallic elements (ligands). For example, cluster groups are the principal structural elements of the so-called "Chevrel phases", which are ultraconducting materials with high critical fields;[80,81] chains made up of metal atoms are the principal structural element of quasi-one-dimensional conducting materials;[82] materials of the type "claspol" containing metal clusters in polymer matrices have been produced.[83]

The intermediate position of cluster compounds between the thoroughly investigated mononuclear and coordination compounds, on the one hand, and compact metals, which have been just as thoroughly investigated, on the other, and the fact that they possess a set of properties differing from both the former and the latter[84] necessitates a vigorous development of theoretical ideas concerning the nature of the bonds in cluster molecules.[85-92] However, despite considerable advances, the questions of the electronic structure of cluster compounds are actually the most controversial at the present time†.

In order to deduce the general rules, extensive experimental data are necessary; although the number of cluster compounds which have been isolated and characterised is fairly large, for many types of clusters, in particular those of moderate and high nuclearity, only 1–2 examples are known, as a rule comprising one metal and ligands of one type.[93]

In contrast to this, cluster compounds having a framework in the form of three-membered metallocycles are widely distributed, have been obtained for the majority of metals, and have ligands of different types. Furthermore, in cluster compounds with a high nuclearity most of the faces of the polyhedra in the metal framework are triangular and three-membered metallocycles can therefore model to some extent the properties of more complex clusters. Within the framework of the rule of skeletal electron pairs,[85] the triangle made up of metal atoms is the principal structural element in the group of polyhedra (the tetrahedron, the trigonal bipyramid, etc.), each having 12 skeletal electrons and in this sense, can be regarded as the *nido*-structure in relation to the tetrahedron and the *arachno*-structure in relation to the trigonal bipyramid.[94] Furthermore, a triangle made up of metal atoms is the simplest element of close packing on the surface of certain faces of metallic crystals; here there is also a possibility of modelling properties, in particular in problems of the interaction of adsorbed substrates with the surfaces of metals.[95,96]

Accordingly, the possible relations between the structure of cluster compounds, the number of cluster valence electrons (CVE), the number and nature of the ligands, and the position of the element in the Periodic System are analysed in this review in relation to the widely distributed "simplest" cluster molecules, having a framework made up of three-membered metallocycles, which have been studied in detail. The relevant conclusions are compared with the results of quantum-chemical calculations on the electronic structures of triangular clusters.

---

§ In designating the bridging character of a bond, the Greek letter μ is placed before the symbol representing the given ligand; if the number of metal atoms to which the ligand is bound is greater than two, numerical designations are used, for example μ_3-H, μ_4-PPh, etc.

¶ Henceforth cluster compounds will be referred to for brevity as "clusters" and in those cases where it will be necessary to note the properties of clusters as representatives of the class of coordination compounds, we shall employ the term "complexes".

† A detailed critical examination of various approaches to the description of the electronic structure of cluster compounds has been carried out in the review of Yu.L.Slovokhotov and Yu.T.Struchkov (in this issue of the Journal).

II. THREE-MEMBERED METALLOCYCLES HAVING THE "MAGIC" NUMBER OF VALENCE ELECTRONS

The electronic structure of triangular molecular systems has been frequently investigated as the simplest case of cluster interactions. The "magic" number of cluster valence electrons for three-membered metallocycles is 48; here each metal atom at the apex of the triangle assumes the 18-electron configuration.

The absence of bridging ligands and a high symmetry make the trinuclear cluster ruthenium and osmium carbonyls convenient reference compounds for structural, spectroscopic, and theoretical studies on three-membered metallocycles. The $M_3(CO)_{12}$ molecules, where M = Ru or Os, have the structure of an equilateral triangle with D_{3h} symmetry:[97,98] each metal atom is linked to four terminal CO groups; two of these are equatorial and are located in the plane of the ring, while the other two are perpendicular to this plane (Fig.1). The carbonyl groups are almost linear; the deviation of the axial CO groups from linearity is appreciably greater than for the equatorial groups, probably owing to the repulsion of the oxygen atoms of the neighbouring ligands, whose van der Waals radius is greater than that of carbon. The M–C bond lengths also differ somewhat: the axial CO ligands are in the *trans*-positions relative to one another and have longer M–C bonds, while the equatorial CO groups are in the *trans*-position relative to the metal–metal bond and, as a consequence of the π-acceptance, they can shorten somewhat the M–C bond. Overall, 12 CO ligands are distributed in such a way that the resulting ligand polyhedron is an anticubo-octahedron (Fig.1*b*).[94]

The selection rules for the $Os_3(CO)_{12}$ molecule (D_{3h} symmetry space group) predict two vibrational modes for the metal–metal bond: A_1 (fully symmetrical vibration) and E (doubly degenerate vibration). Analysis of the Raman spectra of $Os_3(CO)_{12}$ in the low-frequency range (30–200 cm^{-1}) showed[99] that, among the 12 frequencies active in the Raman spectrum, the two most intense frequencies can be assigned to ν(M–M): A'_1 at 158 cm^{-1} and E' at 117 cm^{-1}; the contribution of the deformations of the M–C bond to the

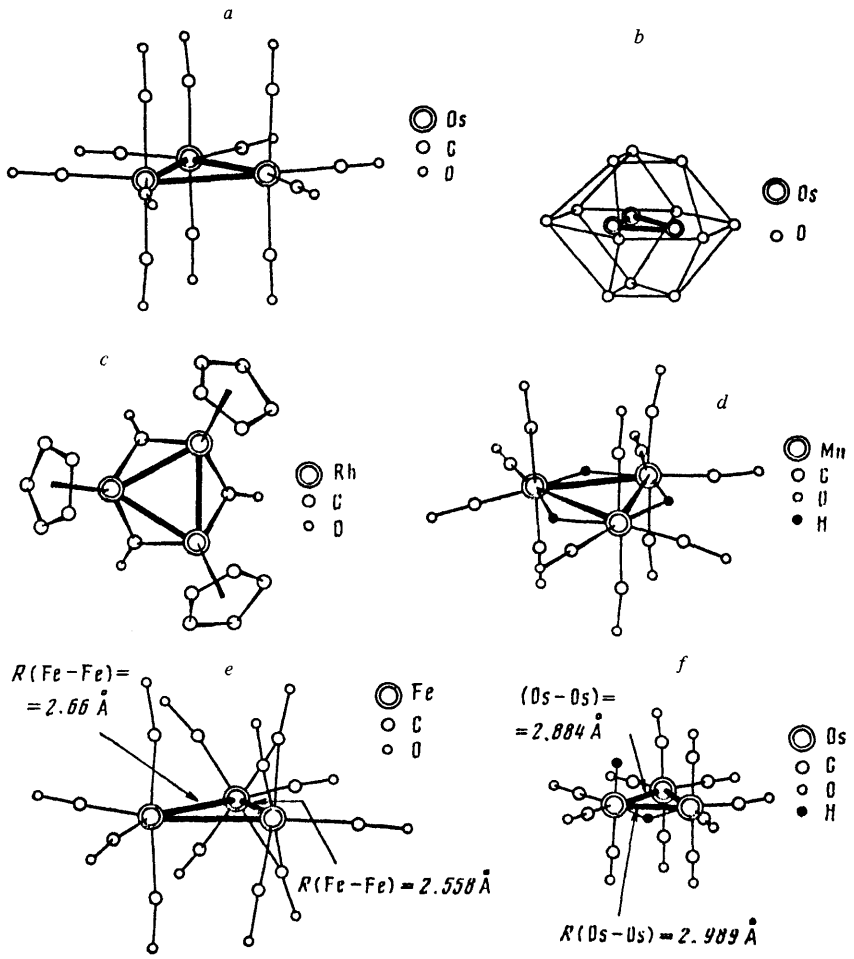

Figure 1. The structure of three-membered metallocycles with 48 CVE and having no μ_3-ligands: *a*) $Os_3(CO)_{12}$; R(Os–Os) = 2.877 Å; R(Os–C_{ax}) = 1.946 Å; R(Os–C_{eq}) = 1.912 Å;[98] *b*) the anticubo-octahedron as the ligand polyhedron of the $M_3(CO)_{12}$ molecule;[94] *c*) $Rh_3(\mu\text{-}CO)_3(Cp)_3$; R(Rh–Rh) = 2.62 Å; R(Rh–C_{Cp}) = 2.24 Å; R(Rh–C_{CO}) = 2.00 Å;[102] *d*) $Mn_3(\mu\text{-}H)_3(CO)_{12}$; R(Mn–Mn) = 3.111 Å; R(Mn–H) = 1.72 Å; R(Mn–C_{ax}) = 1.854 Å; R(Mn–C_{eq}) = 1.789 Å;[101] *e*) $Fe_3(\mu\text{-}CO)_2(CO)_{10}$;[120] *f*) $Os_3(CO)_{11}(\mu\text{-}H)(H)$.[124]

potential energy of these vibrational modes has been estimated at 20% (A_1') and 50% (E'). It is striking that calculation of the force constants for the Os–Os bond yielded two very similar values: $f_{Os-Os} = 0.91 \times 10^{-3}$ dyn A^{-1} when account is taken of the contribution of all the ligands and $f_{Os-Os} = 0.93 \times 10^{-3}$ dyn A^{-1} when no account is taken of the ligands. The analogous calculation for $Ru_3(CO)_{12}$ yielded $f_{Ru-Ru} = 0.82 \times 10^{-3}$ dyn A^{-1} in full agreement with the general tendency towards the weakening of the M–M bond on moving along the Groups of the Periodic System from below upwards. We may also note that $\nu_{A_1'}/\nu_{E'} \cong \sqrt{2}$, which agrees well with the theory for the vibrations of the M_3 triangle as a whole without taking into account the interaction with the ligands.

In the region of the stretching vibration frequencies of the CO ligand (1800–2100 cm^{-1}) the spectra of $M_3(CO)_{12}$, where M = Ru or Os, show absorption bands due solely to the terminal CO ligands;[99] on dissolution, only slight changes take place in the positions and intensities of the CO vibration bands, which indicates the preservation in solution of the principal symmetry elements of these molecules, found for crystalline specimens.

It is possible to detect rapid exchange processes in solutions of the above compounds on the NMR time scale, but the rates of these processes for ruthenium and osmium carbonyls differ very significantly. At 10 °C the ^{13}C NMR spectrum of a solution of $Os_3(CO)_{12}$ consists of two lines (due to the axial and equatorial CO ligands) with a 1 : 1 intensity ratio and corresponds to a structure of this compound in the crystal with D_{3h} symmetry. On heating, the above signals are broadened; the coalescence point is at ~70 °C; at 100 °C a single broad signal corresponding to the positional exchange of the CO ligands (axial–equatorial) is observed.[100] It is striking that in $Ru_3(CO)_{12}$ solutions this type of exchange is observed over the entire experimental temperature range down to −100 °C. Several hypotheses concerning the mechanism of the exchange process have been put forward.[65,66]

Tables 1–4 list the main types of the homo- and heteroelement and three-membered metallocycles, each containing 48 CVE. Evidently, the ruthenium and osmium carbonyls examined above are in essence compounds with identical structural characteristics in which the metal-containing fragments are linked to one another by metal–metal bonds. In all the remaining cases there is a certain number of bridging ligands in the ring. Typical examples of the cluster structures listed in Table 1 are illustrated in Fig. 1.

The hydride $Mn_3(\mu\text{-H})_3(CO)_{12}$ has a structure closest to the $M_3(CO)_{12}$ structures, where M = Ru or Os. Six axial and six equatorial CO ligands are linked to the equilateral triangle of Mn atoms.[101] The difference consists only in the fact that three bridging hydrogen atoms are located along the metal–metal bonds in the plane of the triangle#. The rhodium compound $Rh_3(\mu\text{-CO})_3(Cp)_3$ is less symmetrical, although it does possess an idealised threefold symmetry axis; the bridging CO ligands and $\eta^5\text{-}C_5H_5$ groups are located on different sides relative to the equilateral Rh_3 triangle.[102] In the equilateral triangle of Fe atoms in the $Fe_3(CO)_{12}$ molecule, one metal atom has the same geometry (two axial and two equatorial CO ligands) as the metal atoms in $M_3(CO)_{12}$, where M = Ru or Os. However, the other two metal atoms are linked by strongly asymmetric bridges made up of CO ligands.[103] Despite this, the CO ligands are close packed on the surface of the Fe_3 ring and form an idealised cubo-octahedron.[66]

$Co_2Os(\mu\text{-CO})(CO)_{10}$	[26]

The $Os_3(CO)_{11}(\mu\text{-H})(H)$ cluster is the least symmetrical among those examined above. One axial CO group has been replaced by the H ligand, while the second hydrogen atom is of the bridging type and is located in the equatorial plane. The corresponding Os–Os distance is greater by 0.112 Å than the lengths of the other two Os–Os bonds.[104]

The lengthening of the Mn–Mn bond is typical of clusters where no bridging groups other than μ-H are present along the edge.

Many stable 48-electron three-membered metallocycles are centred on one or two sides on various μ_3-ligands (Tables 3 and 4) in which the key atom can be both a carbon atom and the atoms of other elements. The structures of the most typical compounds of this type are presented in Figs. 2 and 3.

A series of clusters with a μ_3-CR ligand are illustrated in Fig. 2*a* by means of the two most typical examples. In the $Co_3(CO)_9(\mu_3\text{-}CCH_3)$ cluster an sp^3-hybridised carbon atom is located above the three cobalt atoms of the equilateral Co_3 triangle; the three cobalt atoms are linked to it via single Co–C bonds directed at a 60° angle relative to the plane of the triangle. The tetrahedral environment of the carbon atom is somewhat distorted because the Co–C–Co angles are on average only ~80°. All the atoms are electronically and coordinatively saturated, so that the $Co_3(CO)_9CR$ cluster group is always diamagnetic.[105]

The formation of the frontier orbitals of the $Co_3(CO)_9(\mu_3\text{-}CH)$ cluster from the orbitals of the $Co_3(CO)_9$ and CH fragments is shown schematically in Fig. 4, the scheme having been taken from Schilling and Hoffman.[106] The frontier orbitals of the planar $Co_3(CO)_9$ fragment with C_{3v} symmetry have been obtained by adding three electrons to the frontier molecular orbitals of the $Fe_3(CO)_9$ fragment; it is assumed that this does not entail significant changes in the electronic structure except for the alteration of the order of the orbitals with $2a_1$ and $1a_2$ symmetry, which have similar energies. The three orbitals of the CH group are hybridised in such a way that one-low-lying orbital, having an electron pair, is directed towards the side opposite to that of the C–H bond, while the other two orbitals, which are degenerate *p*-type orbitals, are perpendicular to the C–H bond and have one electron. It is striking that the orbital with a_1 symmetry, which is unsuitable for bonding to the group located over the centre of the ring, becomes the highest occupied orbital in the cluster.

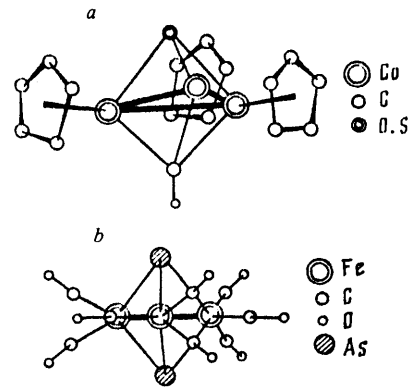

Figure 3. The structure of three-membered metallocycles with 48 CVE each having two μ_3-ligands: *a*) $Co_3(Cp)_3(\mu_3\text{-}CO)(\mu_3\text{-}E)$ [113,114] [E = O: R(Co–Co) = 2.37 Å, R(Co–C_{CO}) = 1.78 Å, R(Co–O) = 2.00 Å; E = S: R(Co–Co) = 2.452 Å]; *b*) $Fe_3(CO)_9(\mu_3\text{-}As)_2$;[115] R(Fe–Fe) = 2.62 Å; R(Fe–C) = 1.80 Å; R(Fe–As) = 2.348 Å.

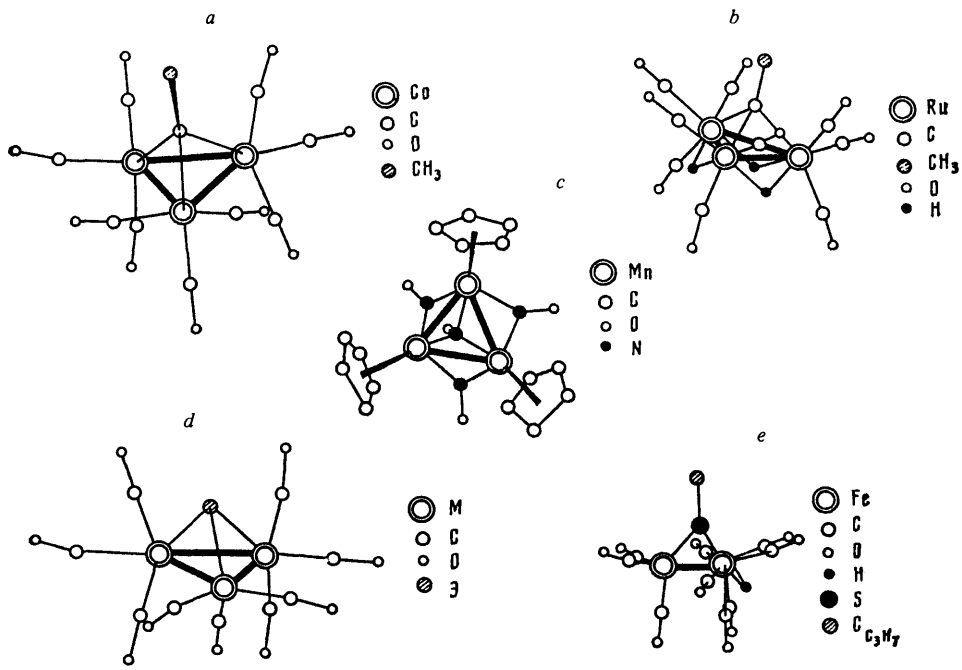

Figure 2. The structure of three membered metallocycles with 48 CVE each having one μ_3-ligand: *a*) $Co_3(\mu_3\text{-}CCH_3)(CO)_9$;[39] R(Co–Co) = 2.467 Å; R(Co–C_{apic}) = 1.90 Å; R(Co–C_{CO}) = 1.80 Å; R(C–CH_3) = 1.53 Å; *b*) $Ru_3(CO)_9(\mu\text{-}H)_3(\mu_3\text{-}CCH_3)$;[127] R(Ru–Ru) = 2.842 Å; R(Ru–C_{apic}) = 2.083 Å; R(Ru–H) = 1.72 Å; *c*) $Mn_3(\mu\text{-}NO)_3(Cp)_3(\mu_3\text{-}NO)$;[108] R(Mn–Mn) = 2.506 Å; R(Mn–N_{μ_3}) = 1.929 Å; R(Mn–N_{μ}) = 1.848 Å; *d*) $FeCo_2(CO)_9(\mu_3\text{-}E)$ [57] [E = S: R(M–M) = 2.55 Å, R(M–E) 2.16 Å; E = Se: R(M–M) = 2.58 Å, R(M–E) = 2.29 Å; E = Te: R(M–M) = 2.60 Å, R(M–E) = 2.47 Å]; *e*) $Fe_3(CO)_9(\mu\text{-}H)(\mu_3\text{-}SC_3H_7\text{-iso})$;[46] R(Fe–Fe) = 2.657 Å; R(Fe–S) = 2.143 Å; R(Fe–H) = 1.80 Å.

Many compounds with the $(CO)_9Co_3C$ fragment, linked to various groups R such as H, halogen, alkyl, arylalkyl, halogenoalkyl, alkoxy, etc., as well as organometallic and other analogous groups are known.[40] The "organic chemistry" of the μ_3-C atom linked to the $Co_3(CO)_9$ fragment has been studied in detail.[39] Tables 3 and 4 show that the μ_3-C bridges are widely distributed in the chemistry of three-membered metallocycles. Fig.2 illustrates the structure of the $Ru_3(CO)_9(\mu\text{-}H)_3(\mu_3\text{-}CCH_3)$ cluster, whose composition differs from that of the cobalt cluster examined above by the presence of three bridging hydrogen atoms; the latter are not located in the plane of the Ru_3 ring, as happens, for example, in the structure of the hydride $Mn_3(\mu\text{-}H_3(CO)_{12}$, but deviate in the direction opposite to that of the side of the metallocycle centred on the μ_3-CCH_3 group. The molecule has approximately the C_{3v} symmetry.[107]

Clusters with NO ligands are so far comparatively rare (see, for example, Feltham and Enemark[43]). Fig.2*c* illustrates the structure of the compound $Mn_3(\mu\text{-}NO)_3(Cp)_3.(\mu_3\text{-}NO)$.[108] The molecule has the C_{3v} symmetry; in its base is located the equalateral Mn_3 triangle, each side of which is spanned by a bridging NO group which is not located in the plane of the ring: the deviation of the NO group from the plane of the ring is ~47°. On the opposite side, the ring is centred on the μ_3-NO ligand. The planar Cp rings deviate from the plane of the triangle by an angle of ~17° towards the side opposite to that of the μ-NO ligands. Overall, this arrangement results in a fairly close symmetrical packing of the ligands around the Mn_3 triangle.

The centering of the three- and four-carbon faces in clusters with a high nuclearity on chalocogenide ligands is very common; three-membered metallocycles with μ_3-chalcogenide ligands are therefore of special interest. Fig.2*d* presents the structures of the most typical representatives of these compounds. The structure of the clusters $Co_2Fe(CO)_9(\mu_3\text{-}X)$, where X = S, Se, or Te, are isotypical; the molecules have approximately the C_{3v} symmetry, and one of the sides of the Co_2Fe ring is centred on the X group; the ring is in essence an equalateral triangle. The differences in the M–M bond length are within the limits of the accuracy of the method, which is not surprising bearing in mind that the covalent radii of the Fe and Co atoms are virtually identical (1.165 and 1.162 Å).[109,110] Fig.2 shows that the metal–metal distances depend on the nature of the chalogen and increase with the increase of the radius or the μ_3-X group. We may note that the chalcogen atom in the μ_3-arrangement provides only four electrons for the formation of bonds with the metal atoms; it retains a free electron pair located in an orbital directed to the "outside" at right angles to the plane of the ring. It can be detected experimentally: such clusters behave like the usual two-electron-donating ligands and are capable, for example, of substituting the CO group in chromium carbonyl with formation of a derivative of the usual type—cyclo-$FeCo_2(CO)_9[\mu_3\text{-}S.Cr(CO)_5]$.[111]

Table 4. Three-membered homo- and hetero-elemental metallocycles each having two μ_3-ligands (48 CVE).

$Fe_3(CO)_9(\mu_3\text{-}As)_2$	[115]
$Fe_3(CO)_9[\mu_3\text{-}SnFe(CO)_2(Cp)]_2$	[57]

In contrast to this, the μ_3-SR group (where R is an organic substituent) provides five electrons for the formation of bonds with metal atoms. Fig.2*e* illustrates the structure of the cluster compound $Fe_3(CO)_9(\mu\text{-}H)(\mu_3\text{-}SC_3H_7\text{-iso})$; the Fe atoms form an almost equilateral triangle, the bridging hydride being directed to the side opposite to that of the μ_3-SR group and linking symmetrically two Fe atoms.[112]

The centering of the three-membered rings on the μ_3-ligands on two sides renders the ligand shells in such cluster molecules more compact and probably increases their stability. Examples of triangular clusters with two μ_3-ligands are presented in Table 4; certain structures are illustrated in Fig.3.

The centering of the triangular face on μ_3-CO ligands is frequently observed in cluster compounds with high nuclearity; such examples are encountered much more rarely among the triangular clusters considered in this review. A rare structurally characterised example of the coordination of the oxygen atom as a μ_3-ligand, which provides four electrons for the formation of bonds with metal atoms, occurs in the $Co_3Cp_3(\mu_3\text{-}CO)(\mu_3\text{-}O)$ cluster. Owing to the small radius of the oxygen atom, the principal Co–O, Co–Co, and Co–C_{CO} bond lengths in the molecule are somewhat shortened.[113]

This can be seen fairly clearly from a comparison of the corresponding distances in the isoelectronic and isostructural cluster $Co_3Cp_3(\mu_3\text{-}CO)(\mu_3\text{-}S)$,[114] in which the Co–Co bond length is greater almost by 0.1 Å.

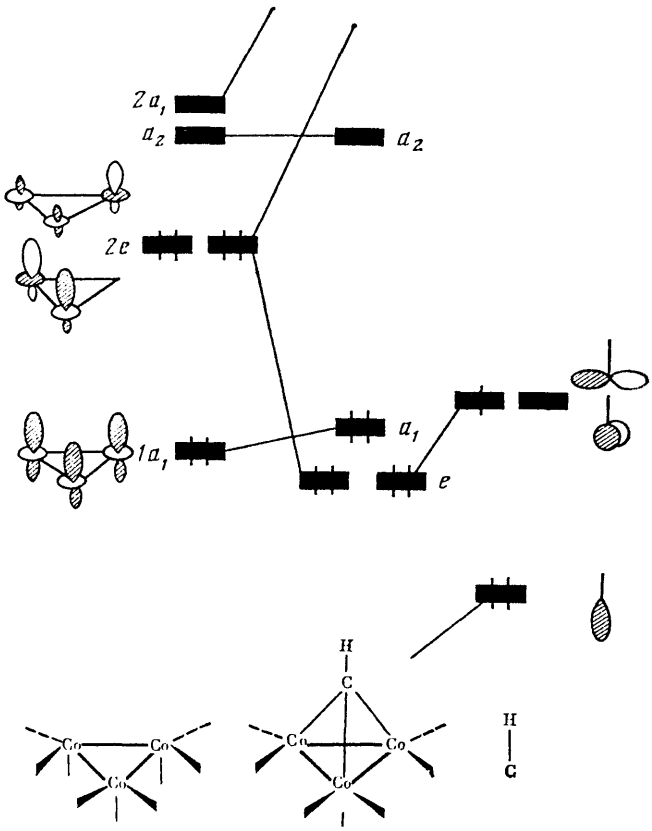

Figure 4. The frontier orbitals of the $Co_3(CO)_9(\mu_3\text{-}CH)$ cluster.[106]

Finally in the last of the structures considered (Fig. 3*b*), namely that of the $Fe_3(CO)_9(\mu_3\text{-}As)_2$ cluster, each of the two arsenic atoms behaves as a three-electron ligand and the Fe_3 triangle is centred on them on two sides.[115]

Thus three-membered metallocycles, each having 48 CVE, are fairly common; the homometallic compounds are characteristic of transition elements with the d^7–d^9 electronic configuration; in heterometallic clusters the range of elements is wider—they can incorporate Pt(d^{10}), W, or Cr(d^6). The metal framework in cluster compounds of this type can be surrounded by ligands differing significantly in both their electronic and steric properties. The majority of the cluster compounds presented in Tables 1–4 possess π-acceptor linear carbonyl ligands; together with these, π-donor ligands are also present, namely ligands such as S, Cp, Sr, NR, etc., as well as ligands incapable of additional π-interaction with the metal framework, of the type of CR, B-NEt_3, etc.

It is noteworthy that Tables 1–4 list clusters without CO ligands, for example, $Co_3Cp_3(\mu_3\text{-}NO)_2$ and $Rh_3Cp_3[\mu_3\text{-}CN.(C_2H_5)_2]_2$, as well as the $Ir_3(PF_3)_9(\mu_3\text{-}P)$ cluster in which there are no M–C bonds at all. A definite preference for either ligands or metals in the formation of compounds of this type should probably not be expected. The existence of a large number of cluster compounds with carbonyl ligands, which have been synthesised and investigated, is not due to their special properties but apparently arises because in the initial stages of the development in this field metal carbonyls were most often employed as the starting compounds in the synthesis of clusters.

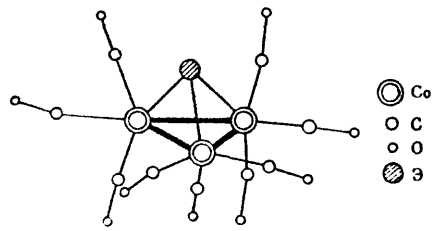

Figure 5. The structure of the $Co_3(CO)_9(\mu_3\text{-}E)$ clusters;[109,110] E = S: R(Co–Co) = 2.64 Å, R(Co–E) = 2.14 Å; E = Se: R(Co–Co) = 2.62 Å, R(Co–E) = 2.28 Å.

III. TRIANGULAR CLUSTERS WITH AN EXCESS OF VALENCE ELECTRONS

Several examples of entirely stable structurally characterised triangular metallocycles containing more than the magic number of valence electrons are known. Examples of such compounds are presented in Table 5. It is striking that they all have at least one μ_3-ligand.

In the first place we shall consider paramagnetic compounds, each having 49 CVE. The structure of the $Co_3(CO)_9(\mu_3\text{-}E)$ clusters, where E = S or Se [109,110] (Fig. 5), is based, like that of the diamagnetic 48-electron analogues $Co_2Fe(CO)_9.(\mu_3\text{-}E)$, where E = S or Se, on an equilateral triangle made up of metal atoms and centred on an apical chalcogenide ligand in accordance with a tetrahedral motif. The molecules have the idealised C_{3v} symmetry. The larger radius of the selenium atom compared with that of the sulphur atom increases the Co–E distance, but hardly affects the length of the Co–Co bond. However, it has been noted[110] that the metal–metal distances in the 49-electron clusters are greater (by 0.08 Å for E = S and 0.04 Å for E = Se) than in the isostructural 48-electron clusters $Co_2Fe(CO)_9(\mu_3\text{-}E)$, where E = S or Se. Consequently the appearance of an unpaired electron entails an appreciable increase of the metal–metal bond length. It has been concluded[110] that the highest

half-filled MO in the $Co_3(CO)_9(\mu_3\text{-}E)$ cluster, where E = S or Se, has a strongly antibonding character in relation to the metal–metal bonds of the Co_3 triangle.

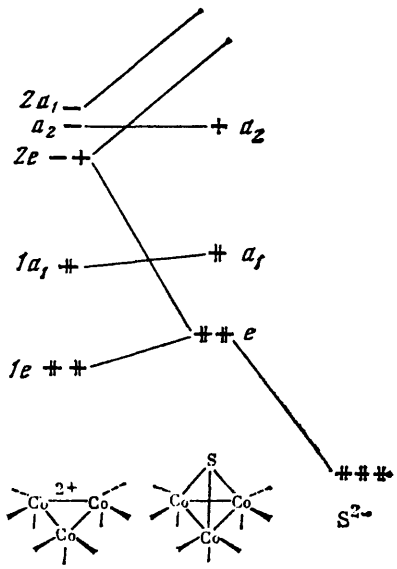

Figure 6. Diagram illustrating the interaction of the orbitals in the formation of the $Co_3(CO)_9(\mu_3\text{-}S)$ cluster.[106]

Fig. 6 illustrates a scheme for the construction of the frontier molecular orbitals of the $Co_3(CO)_9(\mu_3\text{-}S)$ cluster from the orbitals of the $[Co_3(CO)_9]^{2+}$ and S^{2-} fragments.[106] The low-lying fully occupied *p* orbitals of the S^{2-} group interact strongly with the 1*e* orbitals of the $[Co_3(CO)_9]^{2+}$ fragment and conversely the $1a_1$ and a_2 orbitals hardly undergo a change in their positions on formation of the cluster. Apparently the unpaired electron is located in the a_2 orbital of the cluster, which is antibonding in relation to the metal–metal bonds (Fig. 6). Calculations have shown that, when an electron enters this orbital, the overlap populations between the cobalt atoms diminish by a factor greater than 2, which in fact leads to the observed increase of the metal–metal distance.

More detailed experimental information about the nature and spatial orientation of this orbital has been obtained from EPR spectra;[110] the spectra of both solutions of the $Co_3(CO)_9.(\mu_3\text{-}E)$ clusters, where E = S or Se, and the single crystals of the diamagnetic isostructural compounds $FeCo_2(CO)_9(\mu_3\text{-}E)$, containing 0.5% of the isomorphous paramagnetic $Co_3(CO)_9.(\mu_3\text{-}E)$ clusters, have been investigated. The EPR spectrum of a single crystal with E = Se consists of 22 lines due to the hyperfine interactions of the unpaired electron with the three ^{59}Co nuclei ($J = 7/2$). Detailed analysis of the EPR spectra[110] showed that the unpaired electron is located in the non-degenerate antibonding MO disposed in the plane of the Co_3 triangle and made up predominantly of the $3d_{xz}$ orbitals of the Co atom without an appreciable contribution by the *s* orbitals. The hyperfine splitting constant $[A_{11}] = 77.0$ G calculated on this basis is in good agreement with the experimental value $[A_{11}] = 74.3$ G. The hyperfine splitting constant for the $Co_3(CO)_9(\mu_3\text{-}S)$ cluster is smaller by only 2%, i.e. $[A_{11}] = 72.8$ G, than for the selenium compound, which undoubtedly demonstrates yet again the strongly antibonding character of the a_2 orbital and its location in the plane of the ring orthogonally in relation to the *s*, *p*, and *d* orbitals of the apical chalcogen atom.

The compound $Cp_3Ni_3(\mu_3\text{-}S)_2$ [159] having 53 CVE also belongs to the group of paramagnetic triangular clusters. Here the Ni–Ni distances have been increased to 2.80 Å. The stability of the cluster is determined by the density of the ligand packing and the two μ_3-S bridges spanning the metal atoms. The same causes are apparently responsible for the stability of the analogous cobalt cluster $Co_3Cp_3(\mu_3\text{-}S)_2$, which has three electrons less; the Co...Co distances have likewise been increased, to 2.687 Å.[114]

If the μ_3-bridges spanning the metal atoms to form a triangle cannot be formed for one reason or another under the conditions of the synthesis, the presence of 50 CVE in the molecule leads to the rupture of one M–M bond and the conversion of the framework of the cluster from a metallocycle into a metallochain; as a rule, this is not a linear chain but a "wedge" with the angle at the central atom in the range 80–100°; as it were, a slightly open triangle is obtained. A detailed discussion of such molecules is outside the framework of this review.

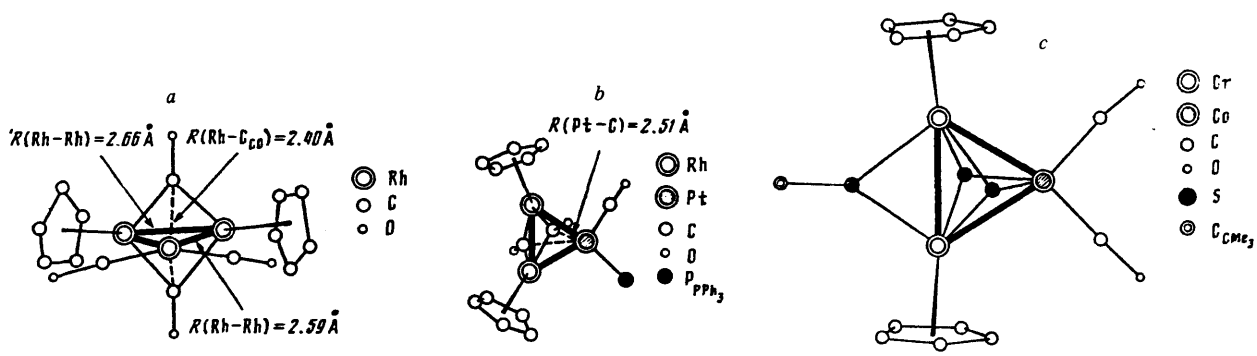

Figure 7. The structure of clusters each having 46 CVE: *a*) $Rh_3(\mu\text{-}CO)_2(CO)_2(Cp)_2$;[144] *b*) $Rh_2Pt(\mu\text{-}CO)_2(CO)(Cp)_2(PPh_3)$;[142] $R(Rh–Rh) = 2.65$ Å; $R(Rh–Pt) = 2.65$ Å; *c*) $Cr_2Co(Cp)_2(CO)_2[\mu\text{-}SC(CH_3)_3](\mu_3\text{-}S)_2$;[143] $R(Cr–Cr) = 2.62$ Å; $R(Cr–Co) = 2.59$ Å; $R(Co–S) = 2.20$ Å; $R(Cr–S_{\mu_3}) = 2.30$ Å.

IV. STABLE THREE-MEMBERED METALLOCYCLES WITH A DEFICIENCY OF VALENCE ELECTRONS

Analysis of structurally characterised triangular clusters has shown that three-membered metallocycles with less than 48 CVE are encountered no more rarely than clusters with the magic number of CVE. In order to discover the cause of the stability of such compounds, we shall examine in greater detail their abundance and the characteristics of their structure.

1. Three-Membered Metallocycles having 46 CVE

Table 6 presents examples of triangular clusters, each having 46 CVE. The homoelemental compounds are represented by rhodium clusters, but most of the compounds are heterometallic clusters each containing two metal atoms with the d^7–d^9 configuration and one Pt atom. In all cases the molecules contain bulky phosphine or Cp ligands together with the CO groups.

Table 6. Homo- and hetero-elemental three-membered metallocycles each having 46 CVE.

Formula	Refs.
$Rh_3(\mu\text{-}PPh_2)_3(CO)_5$	[140]
$Rh_3(\mu\text{-}PPh_2)_3(CO)_3(PPh_3)_2$	[141]
$[Rh_3(\mu\text{-}CO)_2(CO)_2(Cp)_2]^-$	[144]
$Mo_2Fe(Cp)_2(CO)_8$	[26]
$Cr_2Co(Cp)_2(CO)_2(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2$	[143]
$PtFeW(CO)_6(\mu_3\text{-}CR)(Cp)(PEt_3)$	[125]
$Pt_2W[\mu\text{-}C(OMe)Ph](CO_6[P(t\text{-}Bu)_2)Me]_3$	[57]
$PtFe_2(CO)_8(PR_3)_2$	[125]
$PtFe_2(CO)_9(PR_3)$	[145]
$PtFe_2(CO)_8COD$	[125]
$PtCo_2(CO)_7L_2$	[46, 146]
$PtRu_2(CO)_8(diphos)$	[125]
$PtOs_2(CO)_7(PMePh_2)_3$	[26]
$PtRu_2(CO)_7(PPh_3)_3$	[26]
$PtRh_2(\mu\text{-}CO)_2(COD)(\eta^5\text{-}C_5Me_5)_2$	[142]
$PtRe_2(\mu\text{-}H)_2(CO)_9(PRh_3)$	[26]
$AuRe_2(\mu\text{-}H)(CO)_9(PPh_3)$	[26]
$PtRh_2(\mu\text{-}CO)(\mu_3\text{-}CO)(PPh_3)(\eta^5\text{-}C_5Me_5)_2$	[142]

The cluster species $[Rh_3(\mu\text{-}CO)_2(CO)_2Cp_2]^-$ and $Rh_2Pt.(\mu\text{-}CO)_2(CO)Cp_2(PPh_3)$ can be regarded as the products of the addition of the isoelectronic groups $[Rh(CO)_2]^-$ and $Pt(CO)PPh_3$ to the double bond of the dimer $Cp_2Rh_2(\mu\text{-}CO)_2$ (Figs. 7*a* and 7*b*). Both structures have definite features in common: the CO bridging ligands are not in the same plane with the rhodium atoms in both cases and are inclined in the direction of the third metal atom, so that, for example, the angle between the Rh(1)–Rh(2)–C(5) plane and the plane of the ring is 77.5°; an analogous situation has been observed in a Pt cluster (Fig. 7).

Formally the same result, i.e. the presence of 46 CVE, can be achieved when the framework of the cluster contains one metal atom with the d^8–d^9 configuration and two metal atoms with the d^6 configuration, the structure of one such compound being illustrated in Fig. 7*c*. This is also a product of addition, in this instance of the $Co(CO)_2$ fragment, to a dimeric chromium complex; it is believed[143] that the high exchange interaction parameter ($-2J = 530$ cm^{-1}) is satisfactorily correlated with the shortening of the Cr–Cr distance (2.617 Å).[143] Fig. 7*c* shows that the Cr_2Co triangle is surround by a shell of adjoining ligands; whereby a more complete shielding of the metallic framework against the possible (under the conditions of synthesis) attachment of additional ligands is apparently achieved.

We may note that the appearance of the 47th electron in the cluster $Cr_2Fe(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2(CO)_3$ with an analogous composition leads to a significant "loosening" of one Fe–Cr bond in the triangle (the distances are 2.726 and 3.010 Å respectively).[160]

Furthermore, 46-electron clusters can also be achieved when the triangle contains two Pt atoms and one W atom[57] and also three different atoms (Pt, Fe, and W).[125] The number of such combinations is likely to become fairly large in the future.

2. Three-Membered Metallocycles having 44 CVE

The decrease of the number of CVE in triangular cluster compounds is achieved in two ways—by a gradual accumulation in the framework of atoms of elements lying to the right or to the left of metals with the d^8 electronic configuration. The homoelemental cluster compounds each containing 44 CVE are represented by the Pd and Pt as well as Ir triangular metallocycles (Table 7). The 42-electron triangles considered in the next subsection, are typical for the first two elements; sometimes the reversible addition of yet another two-electron ligand with formation of 44-electron three-membered metallocycles is possible.[161] The very fact of the existence of the equilibrium of the type $Q_{42}CVE + L \rightleftharpoons Q_{44}CVE$ shows that the number of CVE is not the only factor determining the stability of cluster compounds of this type.

Table 7. Homo- and hetero-elemental three-membered metallocycles each having 44 CVE.

Formula	Refs.
$Cr_2Fe(\mu\text{-}OR)_2(CO)_4(Cp)_2$	[149]
$Mo_2Pt(CO)_4(Cp)_2(PPh_3)_2$	[125]
$[Ir_3(H)_6(\mu\text{-}H)\{P(C_6H_{11})_3\}_3Py_3]^{2+}$	[57]
$Pt_2Fe(CO)_8[P(OPh)_3]_3$	[57]
$Pt_2Ru(CO)_5(PR_3)_3$	[147]
$Pt_2Ru(CO)_4(PR_3)_4$	[26]
$Pt_2Os(CO)_5(PR_3)_3$	[26]
$Pt_2Cr[\mu\text{-}C(OMe)Ph](CO)_6(PR_3)_2$	[150]
$Pt_2W[\mu\text{-}C(OMe)Ph](CO)_6(PR_3)_2$	[150]
$Pt_3(\mu\text{-}CO)_3(PR_3)_4$	[57]
$[Pt_3(CO)_3(\mu\text{-}CO)_3]^{2-}$	[57]
$Pd_3[CNC(CH_3)_3]_5(\mu\text{-}SO_2)_2$	[57, 46]
$Pd_3(\mu\text{-}CO)_3(PPh_3)_4$	[46]

Heterometallic triangular clusters are presented in Table 7. A characteristic example of such compounds is the $Pt_2W.[\mu\text{-}C(OMe)Ph])CO)_6[P(t\text{-}Bu)_2Me]_2$ cluster, whose structure is illustrated in Fig. 8*a*. The Pt_2W triangle is equilateral; the planar carbene ligand lies in a plane perpendicular to that of the Pt_2W ring and passing through the W atom and the centre of the Pt–Pt bond; the CO ligands are of the semi-bridging type with markedly different distances to the Pt and W atoms; overall, the metallic framework of the cluster is strongly shielded against external influences by virtue of the branched ligand environment.

If is of interest to compare the structures of two clusters—$FeCr_2(\mu\text{-}OR)_2(CO)_4(Cp)_2$ and $FePt_2(CO)_5[P(OPh)_3$ (Figs. 8*b* and 8*c*). Both compounds contain the electronically saturated $Fe(CO)_4$ group symmetrically linked to the corresponding bimetallic fragments. Evidently, formally the same result (44 CVE) can be achieved via two significantly different pathways. The qualitative schemes for the distribution of electrons among the MO in the clusters indicated have been examined by Eremenko et al.[149] and Johnson and Benfield[94] respectively. The fact that both the Fe atom in the $Fe(CO)_4$ group and the M–M bonds opposite it are strongly sterically shielded owing to the close packing of branched ligands, which is clearly seen from a projection of the structure of the cluster illustrated in Fig. 8*d*, is striking.

One must note that, although the majority of the triangular metallocycles presented in Table 7 contain CO groups as ligands, there exists an example of a cluster compound without CO ligands, namely $Pd_3[CNC(CH_3)_3]_5(SO_2)_2$ [155] as well as a cluster which altogether lacks M–C bonds, namely $\{Ir_3(H)_6 .(\mu\text{-}H)[P(C_6H_{11})_3]_3Py_3\}^{2+}$. [57]

3. Three-Membered Metallocycles having 42 CVE

Table 8 presents examples of cluster compounds which each have 42 CVE; evidently these compounds can be divided into two groups—the cluster compounds of Group VI and VII transition elements and the larger group of platinum, palladium, and rhodium compounds. Fig. 9 illustrates the structures of some of the cluster compounds having 42 CVE each.

The cluster cation $[Mo_3(Cp)_3(\mu\text{-}S)_2(\mu_3\text{-}S)]^+$ is very compact; one side of the Mo_3 triangle is shielded by the μ_3-S ligand, while the other is shielded by three μ-S groups, which deviate markedly from the plane of the ring; from the outside, each Mo atom is coordinated to a planar Cp ring (Fig. 9*a*). On the other hand, the formation of a stable 42-electron platinum cluster apparently does not require the complete shielding of the metallic triangle by a close-packed ligand shell; it is sufficient that the bulky substituents should prevent the mutual approach of the two Pt_3 rings, along the three-fold axis passing through the centre of the ring, to distances sufficient for the formation of prismatic structures with weak metal–metal bonds between the rings.

Table 8. Three-membered metallocycles each having 42 CVE.

Formula	Refs.
$[Re_3(\mu\text{-}Cl)_3Cl_9]^{3-}$	[151]
$[W_3(\mu_3\text{-}O)(\mu\text{-}OAc)_6(H_2O)_3]^{4+}$	[152]
$[Mo_3(\mu\text{-}S)_3(\mu_3\text{-}S)(Cp)_3]^+$	[156]
$Pt_3[\mu\text{-}CNC(CH_3)_3]_3[CNC(CH_3)_3]_3$	[154]
$Pt_3(\mu\text{-}CO)_3(PR_3)_3$	[46]
$Pt_3[\mu\text{-}C(OCH_3)C_6H_4CH_3]_3(CO)_3$	[157]
$Pt_3[\mu\text{-}C(OCH_3)C_6H_5]_3[P(CH_3)_3]_3$	[157]
$Pt_3(H)_6[P(Bu\text{-}tper)_3]_3$	[153]
$Pd_3(\mu\text{-}CO)_3(PPh_3)_3$	[46]
$Rh_3(\mu\text{-}H)_3[P(OCH_3)_3]_6$	[158]

A typical example of such compounds is illustrated in Fig. 9*c*. Each platinum atom has one terminal CO ligand and is linked to its neighbours by a bridging carbene ligand; the carbene ligands are almost planar and each such plane is

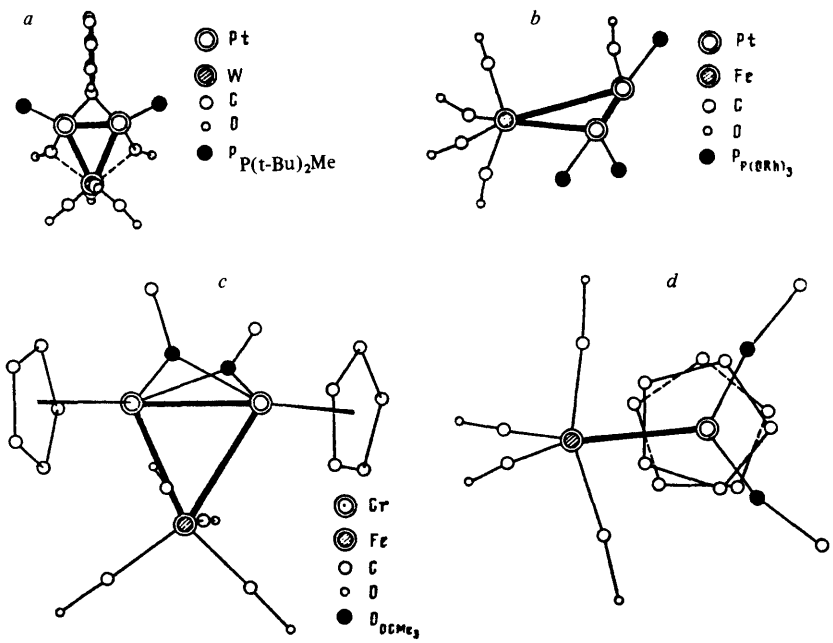

Figure 8. The structure of clusters each having 44 CVE: *a*) $Pt_2W[\mu\text{-}C(OCH_3)C_6H_5](\mu\text{-}CO)_2(CO)_4\{P[C(CH_3)_3]_2CH_3\}_2$;[150] R(Pt–Pt) = 2.63 Å; R(Pt–W) = 2.83 Å; R(Pt–C_{CO}) = 1.87 Å; R(W–C_{CO}) = 2.43 Å; α-(Pt–C–O) = 148°; *b*) $Pt_2Fe(CO)_5[P(OC_6H_5)_3]_3$;[57] R(Pt–Pt) = 2.63 Å; R(Pt–Fe) = 2.57 Å; *c*) $Cr_2Fe[\mu\text{-}OC(CH_3)_3]_2(CO)_4(Cp)_2$;[149] R(Cr–Cr) = 2.64 Å; R(Cr–Fe) = 2.70 Å; *d*) projection along the Cr–Cr axis.

perpendicular to that of the Pt_3 ring and passes through the centre of the Pt–Pt bond.

The only 42-electron rhodium cluster listed in Table 8 is an example of a compound in which the electronically unsaturated metallic triangle is fully shielded by highly branched ligands (Fig. 9*b*). The Rh–Rh distance is increased owing to the presence of the bridging hydrogen atoms.

One must note that, among the three-membered metallocycles listed in Table 8, there are many examples of compounds without M–C bonds: here we encounter for the first time triangular clusters having only typical acido-ligands, which are characteristic of "inorganic" complexes. As an example, we shall consider the $Re_3(\mu\text{-}Cl)_3Cl_9$ cluster, whose structure is illustrated in Fig. 9*d*. Evidently the Re–Re distances are greatly diminished compared with, for example, the length of this bond in $Re_2(CO)_{10}$ (3.02 Å). It has been suggested that multiple M–M bonds are present in this and analogous compounds.[162]

It is striking that the chloride ligands in the above cluster compounds, like the carbonyl groups in compounds of the type $M_3(CO)_{12}$, where M = Ru or Os, give rise to a close-packed configuration and a ligand polyhedron analogous to that shown in Fig. 1 with the sole difference that the central hexagon has been rotated by an angle of 60° relative to the axis passing through the centre of the Re_3 triangle.

The question whether three-membered metallocycles having less than 42 CVE can exist should apparently be answered in the affirmative. The organometallic compound $Re_3(CH_3)_9$, containing 30 CVE and the product of the addition to the latter of phosphine ligands, namely $Re_3(CH_3)_9(PEt_2Ph)_3$, which has 36 CVE, are known.[163]

Thus the following conclusions characterising the relation between the structure and the number of CVE in triangular cluster compounds can be drawn from the data examined above:

1. Stable three-membered cluster compounds of transition metals with the d^6–d^{10} configuration and 48, 46, 44, 42, or fewer CVE are known. The close packing of the bulky ligands on the surface of the metallic framework, which results in the shielding of the M–M bond against the influence of external agents, becomes increasingly pronounced with decrease of the number of CVE.
2. No specific ligand preference in the formation of triangular cluster compounds has been discovered; among the examples listed in Tables 1–8, ligands of virtually all known types are encountered.
3. The smaller the number of CVE in the compound, the shorter the M–M bond; this conclusion is valid for metals with the d^6–d^7 configuration but does not extend to the triangular Pd and Pt clusters.
4. In the cluster compounds with 49 CVE the unpaired electron is located in a highly antibonding (in relation to the M–M bond of the metallic framework) non-degenerate MO. Such compounds have at least one μ_3-bridging ligand, which maintains the metal atoms at short distances from one another.
5. In cluster compounds with 50 CVE a second electron enters the antibonding non-degenerate MO, which leads to the rupture of one metal–metal bond; the triangle is opened and the metallic framework assumes the form of a bent chain made up of three metal atoms.
6. In a cluster having 53 CVE all three Ni...Ni bonds are greatly extended compared with the normal Ni–Ni distance. The stability of such a cluster is determined by the close packing of the ligands in the presence of two μ_3-S bridges spanning the metal atoms.
7. The presence in the cluster framework of each Pt, Pd, and Au atom as a rule reduces the number of CVE by two. A typical number of CVE in the triangle of Pt or Pd atoms is 42 (sometimes 44). In the presence of a greater number

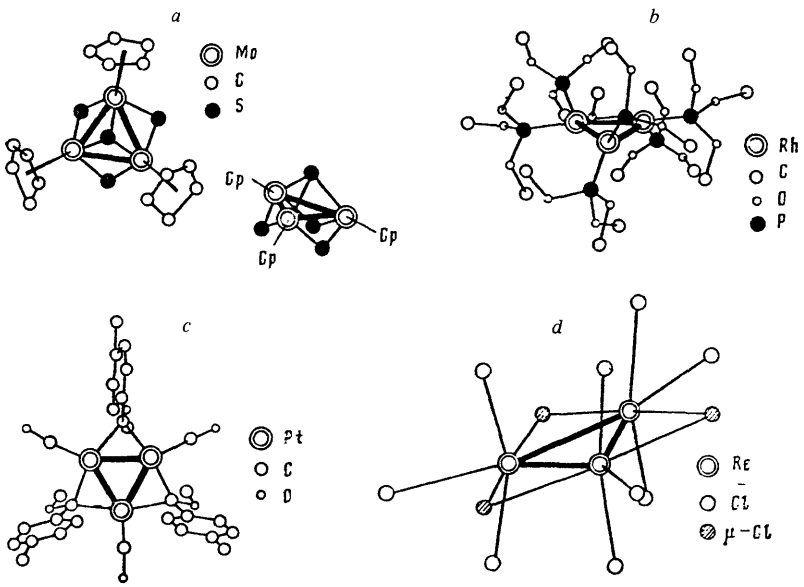

Figure 9. The structure of clusters each having 42 CVE: *a*) $[Mo_3(\mu\text{-}S)_3(\mu_3\text{-}S)(Cp)_3]^+$;[156] R(Mo–Mo) = 2.81 Å; R(Mo–S_μ) = 2.29 Å; R(Mo–S_{μ_3}) = 2.31 Å; *b*) $Rh_3(\mu\text{-}H)_3[P(OCH_3)_3]_6$;[158] R(Rh–Rh) = 2.82 Å; *c*) $Pt_3[\mu\text{-}C(OCH_3)C_6H_4CH_3\text{-}p]_3(CO)_3$;[157] R(Pt–Pt) = 2.62 Å; *d*) $[Re_3(\mu\text{-}Cl)_3Cl_9]^{3-}$; R(Re–Re) = 2.47 Å.[151]

of CVE the homometallic triangle made up of Pt or Pd atoms is open.

V. THE ELECTRONIC STRUCTURE OF THREE-MEMBERED METALLOCYCLES

In the formation of a metallocycle with a framework in the form of a regular triangle the three transition metal atoms each provide nine orbitals ($5d + 1s + 3p$), which results in a set of 27 MO (Fig.10); three of these (a_2' and e') have unduly high energies and are unsuitable for bonding.[164] Consequently in the metallic triangles there are only 24 cluster valence molecular orbitals (CVMO). In the three-membered metallocycles considered this set of MO is occupied in different ways by the electrons provided by the metal atoms and the ligands.

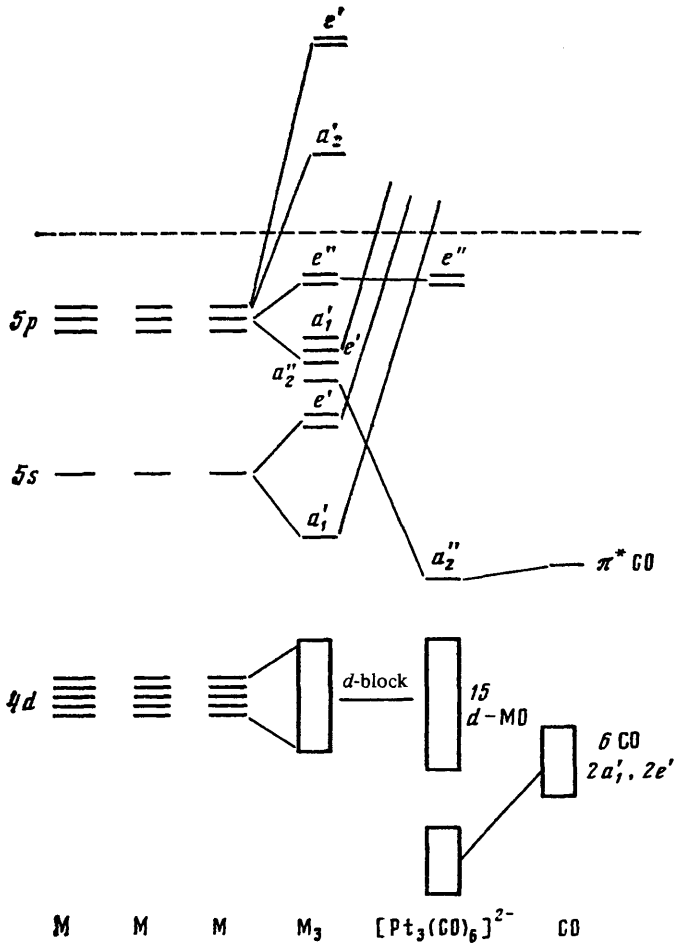

Figure 10 A qualitative scheme for the interaction of the AO of metals in the formation of a ligand-free M_3 triangle;[164] the changes occurring on formation of the anion $[Pt_3(CO)_6]^{2-}$ are shown on the right.

In the cluster compounds with 48 CVE all 24 CVMO are occupied, while in compounds of other types the situation is more complex. When the metallic triangle of the framework interacts with ligands (for example, with CO ligands) the cluster MO made up of the *s* and *p* AO undergo the greatest changes. Although the relative order in which the individual *d* orbitals are arranged changes somewhat on interaction with ligands (Figs.10 and 11), these changes are comparatively small, probably owing to the relatively small integrals, i.e. $[S] \leq 0.1$, for the overlap of the *d* orbitals of the metal with the orbitals of ligands such as the CO group.[165] Calculations have shown that the entire set of 27 MO of triangular clusters can be divided into four main groups, boundaries between which are approximate and vary as a function of the nature of the metals and the ligands. The molecular orbitals with the lowest energies are used mainly for bonding with the ligands because the combination of three *s* and nine *p* orbitals has the symmetry and directional properties suitable for bonding with ligands. The remaining five *d* orbitals form a set of MO having similar energies (the *d* block), through which the direct metal–metal interaction takes place. Next follow the so-called frontier orbitals, both HOMO and LUMO. Finally the antibonding orbitals with the highest energy belong to the fourth group.

This subdivision can be seen clearly in relation to the MO obtained as a result of EHM calculations for the $Ru_3(CO)_{12}$ molecule (Fig.11).[165] Examination of the character of the frontier orbitals of greatest importance for chemistry led to the conclusion that 48-electron metallocycles of the type of $M_3(CO)_{12}$ with D_{3h} symmetry are "inorganic" analogues of cyclopropane;[106] this analogy does not apply solely to the topological correspondence of the structures and the nature of the frontier orbitals; it is more profound and embraces also chemical behaviour: the similarity of $M_3(CO)_{12}$ to cyclopropane in the ring opening and closure reactions has been established in relation to $Os_3(CO)_{12}$.[167]

The $M_3(CO)_{12}$ clusters can be constructed by combining three octahedral $M(CO)_4$ fragments; the frontier orbitals of such fragments are illustrated in Fig.12. Two hybrid frontier orbitals of the a_1 and b_2 types, analogous to the σ and *p* orbitals of methylene, are located over a low-lying weakly split level mostly corresponding to the t_{2g} level in octahedral complexes. The $Fe(CO)_4$ and CH_2 fragments are isolobal and each has at least one pair of electrons in the two frontier orbitals indicated. The formation of the frontier orbitals of $Fe_3(CO)_{12}$ by combining the orbitals of the three $Fe(CO)_4$ groups, analogous to the formation of the orbitals of cyclopropane from those of the three CH_2 groups, is illustrated in Fig.12.[106] Evidently the orbitals of the t_{2g} level interact weakly with one another, forming the orbitals of the cluster *d* block, while the a_1 and b_2 orbitals give rise to a set of MO of the Walsh type. The difference from cyclopropane consists in the fact that both in the initial $Fe(CO)_4$ fragments and in the $Fe_3(CO)_{12}$ cluster the orbitals of the a_1 type have a higher energy than the b_2 orbitals, while in the cyclopropane the opposite situation obtains. It is believed[106] that this order in the arrangement of the orbitals is confirmed by the results of the investigation of the electronic and photoelectron spectra of $M_3(CO)_{12}$, where M = Ru or Os,[59] indicating the non-degenerate character of the HOMO in these compounds.

An analogous set of frontier orbitals of another 48-electron metallocycle, namely $Co_3(CO)_9(\mu_3\text{-}CH)$, is obtained by combining the orbitals of the $Co_3(CO)_9$ and CH fragments (Fig.4). It can be assumed that in other 48-electron triangular cluster compounds the qualitative scheme for the arrangement of the MO and their occupation by electrons is the same as for the molecules examined above. Information about the

character of the LUMO in such systems has been obtained in studies of the EPR spectra of certain 49-electron compounds presented in Table 5. Unfortunately there are as yet no experimental data which would permit the estimation of the energy gap between the HOMO and LUMO. The entry of a second electron into the LUMO results in the rupture of one metal–metal bond in the triangle.

Thus the scheme for the electronic structure of 48-electron triangular clusters put forward in a number of studies explains satisfactorily the existing experimental data. From this scheme, it follows without a doubt that triangular cluster compounds in which the number of CVE is greater than 48 should have greatly "loosened" metal–metal bonds up to an appreciable weakening of the direct interaction between the metal atoms. The stability of such cluster compounds is determined mainly by the μ_3-ligands which span the metallic triangle. For example, there are 53 CVE in the $Ni_3(\mu_3\text{-}S)_2.(Cp)_3$ cluster; the Ni–Ni bond length in this cluster is 2.80 Å,[159] which is greater by 0.4 Å than in the compound $Ni_3(\mu_3\text{-}CO)_2(Cp_3)$ with an analogous structure,[57] which has 4 CVE less [R(Ni–Ni) = 2.39 Å]; the five excess electrons in the $Ni_3(\mu_3\text{-}S)_3(Cp)_3$ cluster occupy three antibonding orbitals, while the weak Ni...Ni bonding is determined mainly by the exchange interaction involving the single unpaired electron ($\mu_{eff} = 1.7\ \mu_B$).

The data examined in Section II show that three-membered metallocycles with 48 CVE are characteristic of metals with the d^8 configuration or one close to it. However, clusters with fewer CVE are just as common; they can be divided into two groups—three-membered metallocycles made up of the atoms of the metal at the beginning of the transition series and triangles made up of the atoms of platinum group metals. It is striking that sometimes formally the same number of CVE can be attained by a different pathway—by introducing platinum metals or Group VI metals (Cr, Mo, and W). However, the electronic structure of the metallic framework in such cluster compounds is different. In platinum metallocycles the Pt–Pt distances (2.65–2.79 Å) differ little from the metal–metal distance in metallic platinum (2.77 Å), while in triangles made up of Group VI metal atoms the metal–metal distances are significantly shortened.

It might have been supposed that multiple metal–metal bonds are formed in triangles made up of atoms of metals having the d^6 or lower configuration, particularly since the existence of multiple bonds in dinuclear compounds of the same metals is a well established fact. For example, the results of quantum-calculations for model Cr, Mo, Ru, and Rh dimers, in which the metal atoms are linked by four identical planar bridges (O_2CH) located in pairs in mutually perpendicular planes and shielding fairly densely the space between the metal atoms, have been described;[3] the real molecules can each have in addition two two-electron axial ligands L. In the rhodium dimer each metal atom has a filled electron shell (taking into account the two electrons from the axial ligands L). The metal–metal bond orders are unity. In the isostructural ruthenium dimers there are two fewer electrons, while in the chromium and molybdenum dimers there are six fewer electrons. The rigid configuration of the dimers makes it impossible to attach additional ligands and make good from outside this electron deficit. The 18-electron shell in each metal atom in these compounds is therefore produced as a result of the formation of metal–metal multiple bonds; the bond multiplicity is 2 in the ruthenium dimer and 4 in the chromium and molybdenum dimers. In terms of the chosen coordinate system,[3] in the rhodium dimer the HOMO with $2b_{1u}$ symmetry is at the same time the antibonding δ^* orbital in relation to the metal–metal δ-bond; when it is filled with electrons, the δ-bond is ruptured and, conversely, a decrease of the number of electrons in this orbital leads to the appearance of a δ-bond

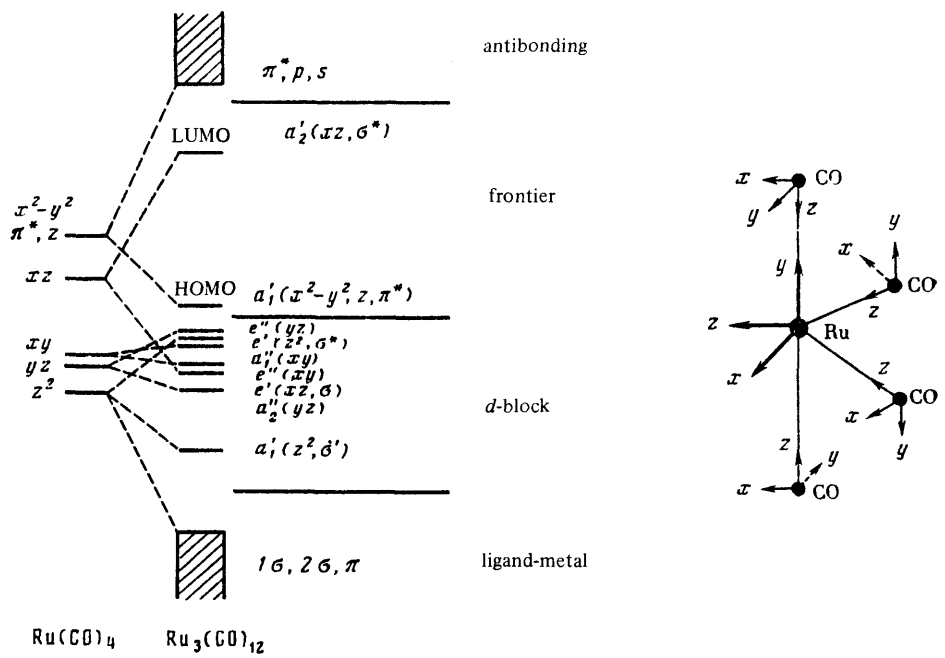

Figure 11. The formation of the molecular orbitals of $Ru_3(CO)_{12}$ from the MO of the $Ru(CO)_4$ fragment; HOMO = xz and LUMO = π^*, z for the $Ru(CO)_4$ fragment; the coordinate system for the $Ru(CO)_4$ fragment is shown on the right.[165]

between the metal atoms on moving along the above series of dimers from right to left; the same considerations are applicable to the π orbital which follows the δ^* orbital (see Cotton and Walton[3], pp.366–382).

One cannot rule out the possibility of a similar approach to the consideration of the electronic structures of three-membered metallocycles. The decrease of the number of intrinsic *d* electrons in the metal atoms and the impossibility of making good this deficit by attaching ligands should result in the occurrence of additional interaction between the AO of the metals with formation of multiple bonds.

Among electron-deficient clusters, quantum-chemical calculations have been made mainly for the Re_3 metallocycle;[59] they agree well with the hypothesis that multiple bonds are present in this and similar compounds. For example, the results of EHM calculations for the $(Re_3Cl_{12})^{3-}$ ion led the authors[166] to the conclusion that the two-centre bonds between the rhenium atoms can be described as double bonds.

Thus there are grounds for the assumption that, for the majority of the compounds listed in Tables 6–8 subject to the condition that the normal geometry of the framework and of the ligand environment is conserved, a decrease of the number of CVE compared with 48 for metals to the left of the iron group in the Periodic System can involve the formation of metal–metal multiple bonds in the metallocycle.

The normal multiplicity of each metal–metal bond (q) in a three-membered metallocycle can be calculated from the formula

$$q = \frac{54 - n}{6}$$

where 54 is the maximum number of electrons when all the 27 MO of the trinuclear cluster are occupied, n the number of CVE in the given three-membered metallocycle, and 6 the number of electrons capable of being accommodated in the three residual vacant CVMO in clusters with a filled shell having 48 CVE and a metal–metal bond multiplicity of unity.

Thus in the presence of 46 CVE the multiplicity of each metal–metal bond is 1 + 1/3, when all the bonds are equalised, or two M–M bonds have a multiplicity of unity and a third a multiplicity of two. This situation obtains, for example, in the 46-electron cluster $Os_3(\mu\text{-}H)_2(CO)_{10}$, where the bond between the two Os atoms spanned by two μ-H bridges has a multiplicity of 2, while the other two bonds have a multiplicity of unity; see also Cotton.[162]

From general considerations, it is understandable that the decrease of the bond lengths with increasing multiplity of the metal–metal bond in trinuclear metallocycles should be relatively smaller than in dimers. The difference between

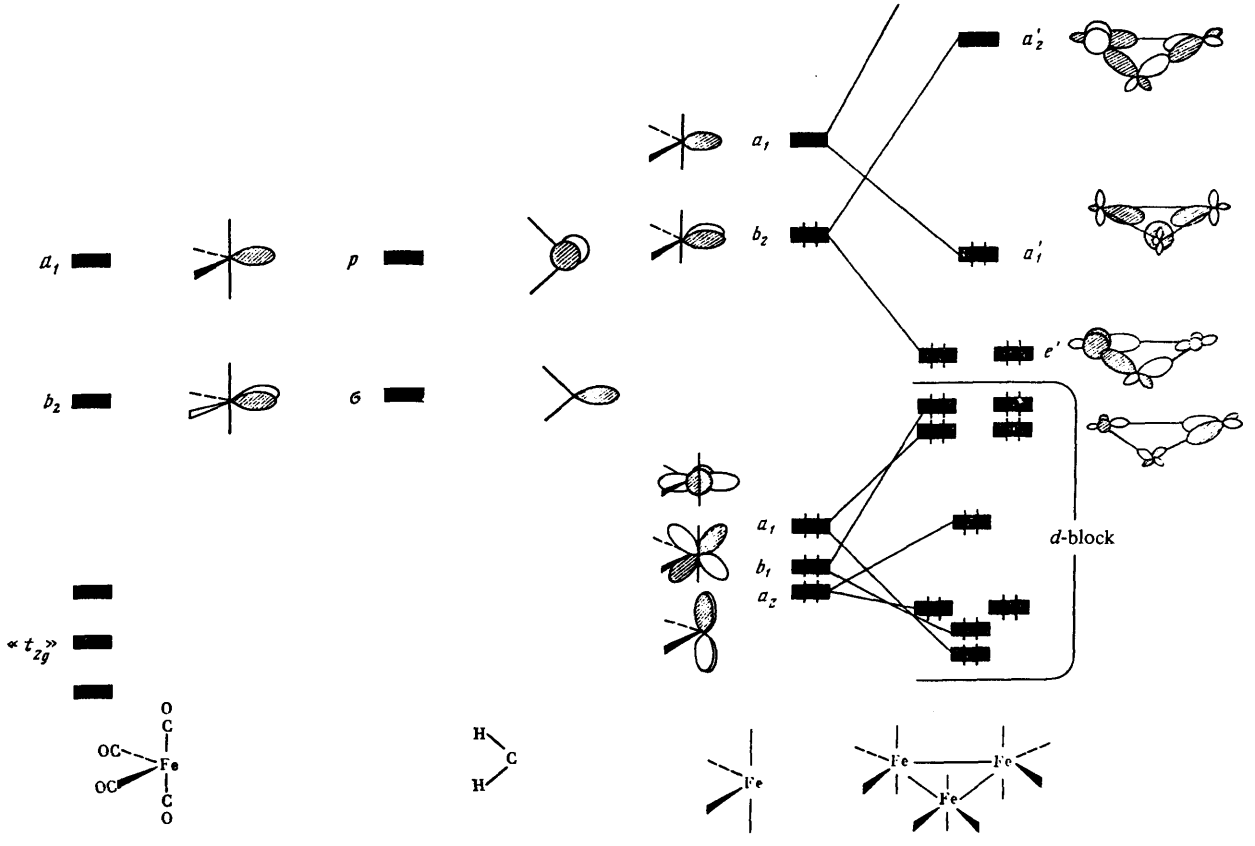

Figure 12. The group orbitals of the $Fe(CO)_4$ and CH_2 fragments; the formation of the MO of the $Fe_3(CO)_{12}$ molecule (idealised geometry with D_{3h} symmetry) from the orbitals of the $Fe(CO)_4$ fragments is shown on the right-hand side.[106]

the lengths of bonds of different multiplicity probably becomes increasingly less appreciable with increasing nuclearity of the clusters.

It follows from the calculated and experimental results presented above that triangular clusters based on platinum and palladium with a deficiency of electrons are as a rule coordination unsaturated and it would appear that they could combine with one or two more ligands in order to build up their electron shell to a stable state, but this does not occur in reality. In other words a triangle of Pt or Pd atoms can combine with a smaller number of ligands than the triangles made up of atoms of the other metals examined above. Furthermore, in heterometallic triangles each Pt or Pd atom reduces the total number of two-electron ligands by unity.

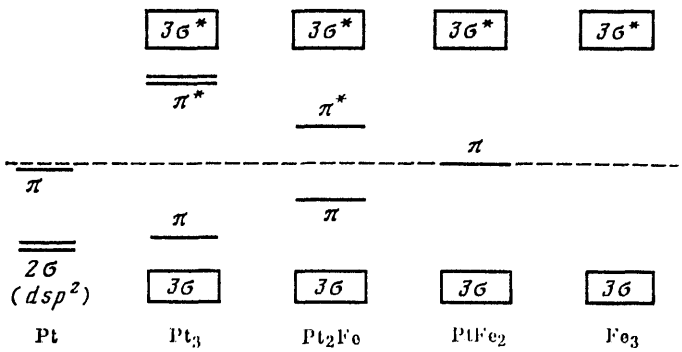

Figure 13. A qualitative scheme for the π-interactions in three-membered metallocycles with participation of platinum.[94]

It has come to be assumed that the energy of one of the *p* orbitals of the Pt or Pd atoms is unduly high and the orbital cannot participate in the formation of a bond with the ligand. Three such orbitals, extended along an axis perpendicular to the plane of the M_3 ring form as a rule in such cases the set of three MO illustrated schematically in Fig.13.[94] It is believed that these orbitals should have energies within the energy gap between the HOMO and LUMO for clusters with a filled electron shell. The changes occurring in the region of the frontier orbitals in the regular transition from Fe_3 to Pt_3 clusters are shown schematically in Fig.13. As a result of this interaction, one of the π MO becomes weakly bonding and two others become weakly antibonding.

This qualitative scheme agrees in the main with the results of an EHM calculation for the planar dianion $[Pt_3(CO)_6]^{2-}$, which are presented in Fig.10. Evidently all the 15 MO of the *d* block are occupied and the two excess electrons are in the a_2'' orbital, which has predominantly the π^*_{CO} character. The unoccupied non-bonding orbitals of the e'' set are in essence the almost unchanged *p* orbitals of the M_3 framework; calculations have shown that, in compounds with 42 CVE, all the orbitals having the *p* character ($a_2'' + e''$) are unoccupied.[164]

Thus an additional interaction of the π type also occurs in triangles based on platinum and its analogues, however, it does not involve the *d* orbitals, as in the previous case, but the MO made up of orbitals of the *p* type. However, in connection with the weakly bonding character of these MO, an appreciable decrease of the metal–metal distances does not as a rule occur.

The ability of platinum triangles to be coordinated to one another with formation of prismatic structures of different lengths, which are characterised by a weak interaction between the rings (the Pt–Pt bond length is greater than 3 Å) has been explained by the presence of orbitals of this type.

--o0o---

Thus comparison of the structures and numbers of CVE in a wide range of three-membered metallocycles permits the conclusion that the magic number of 48 CVE for triangular clusters means merely that in the presence of a large number of CVE, the triangular structure of the framework with short metal–metal bonds cannot be retained; on the other hand, experience has shown that, when the number of CVE is reduced, the extent by which it differs from the magic number for triangular clusters can vary within fairly broad limits.

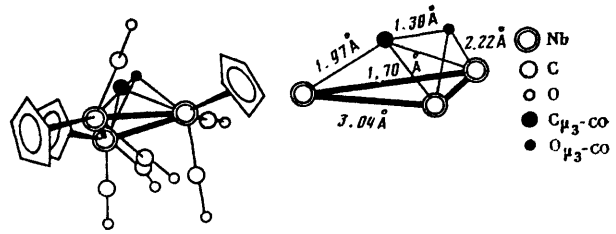

Figure 14. The structure of the $Nb_3(\mu_3\text{-CO})(CO)_6(Cp)_3$ cluster.[168]

On the other hand, one should note that in the chemistry of cluster compounds there is apparently no rigid specification whatsoever of the numbers of CVE for particular types of metals and ligands. It was noted above that, as one moves to the left along the Periodic System and the number of electrons in the valence shell of the metal atom falls, the number of CVE in the corresponding triangular compound differs to an increasing extent from the magic number. However, the $Cp_3Nb_3(CO)_7$ triangular niobium cluster with 48 CVE has been obtained, its structure being shown in Fig.14.[168] For this compound to have 48 CVE, the seventh CO group must supply six electrons for the formation of bonds with the metal atoms and for this to happen it must be located parallel to the plane of the Nb_3 ring. Fig.14 shows that this condition is fulfilled with adequate precision. The stretching vibration frequency of the seventh CO group is then displaced so much (to 1330 cm^{-1}) that in this case one can apparently envisage two ligands (C and O) weakly interacting with one another on the surface of the metallocycle. Consequently, if the ligand environment, occupying almost the same volume around the M_3 ring, can supply a greater number of electrons, a configuration with a filled electron shell obtains even for an element such as niobium, which has only five *d* electrons.

The same picture has been observed for the cluster compounds of metals having a filled *d* shell. Although triangular Pd and Pt clusters having 48 CVE have not so far been

obtained, one may quote an example from the chemistry of tetrahedral clusters. The magic number for the tetrahedron is 60 CVE; the majority of tetrahedral Pd and Pt compounds have, like the corresponding triangles, a significantly smaller number of CVE, but the $Pd_4(\mu\text{-}CO)_6(PBu_3)_4$ cluster with a tetrahedral structure of the framework has 60 CVE.[169]

In the formation of each given cluster compound there probably exist limited possibilities for the selection of ligands; a tendency is observed towards the construction of the most compact molecule with a preferential filling of the space around the metallic framework. Since the metallic framework itself is fairly stable, for example, in the form of ultradisperse metallic particles,[52] the electronic requirements which must be met by the ligand in the formation of a cluster on its basis are not rigorous, permitting deviations from the magic numbers. The number of examples in which the number of CVE differs from the magic number will apparently increase in the future as experimental data accumulate, particularly for cluster compounds with a high nuclearity.

The Structure of Cluster Compounds of Transition Metals and the Limits of Applicability of the Electron Counting Rules for Polyhedral Molecules

Yu.L.Slovokhotov and Yu.T.Struchkov

The current theoretical ideas concerning the electronic structure of clusters and electron counting schemes for them derivable from molecular orbital analysis, whereby one can determine magic numbers of valence and skeletal electrons corresponding to energetically favourable characteristic geometrical configurations of cluster polyhedra, are examined. Among the multiplicity of polynuclear compounds, the class of superaromatic clusters obeying Wade's rule (the $2n + 2$ rule) has been isolated. The structures of transition metal clusters M_n with $n = 3-38$, including small, trigonal-bipyramidal, and octahedral clusters, polyhedra of medium dimensions, and large clusters, are considered and the applicability of the existing schemes to the determination of magic numbers for each of these groups of compounds is discussed.
The bibliography includes 150 references.

II. Qualitative theoretical schemes for the electronic structures of cluster compounds of transition metals 323
III. The structure of transition metal clusters 331

I. INTRODUCTION

The present state of transition metal cluster chemistry can be best defined as the stage involving a vigorous search for regularities in order to arrange systematically and explain the entire extensive and varied experimental data. The unusual structure of the polyhedra made up to metal atoms in cluster molecules, the existence in the latter of a new type of bonding not observed in classical chemistry, and the increasing prospects for the use of clusters in catalysis—all these factors have been responsible for the continued rapid expansion of synthetic and structural research in this field.[1-9] Questions concerning the electronic structure of transition metal clusters[10] and related polyhedral molecules[11] have been frequently discussed also in Soviet chemical literature.

At the same time current theoretical ideas in cluster compound chemistry do not yet enable experimenters to predict the structures and reactivities of most of the newly obtained clusters and to estimate even in broad outline the most probable composition of the products of the reactions involving polynuclear molecules. The first fundamental studies designed to find correlations between the stoichiometry of cluster compounds and their geometrical and electronic structures were published more than ten years ago,[2,3] but the task of constructing a non-contradictory theory of the chemical bonds in clusters is still (despite the large number of studies carried out in recent years) far from complete and each of the existing theoretical concepts can account for the experimental facts relating to only a comparatively narrow class of compounds and is usually not concerned with the discussion of the numerous exceptions to a particular suggested rule. We therefore thought it timely to write this review, with the aim of introducing the reader to the range of theoretical problems in cluster chemistry, to give a critical survey of the existing models of the electronic structure of cluster compounds, and to define the limits of applicability of these models on the basis of experimental data.

The first part of the review deals with the theoretical schemes for the electronic structures of transition metal clusters current in the present-day chemical literature, while in the second predictions based on these theoretical schemes are compared with existing structural data. Among theoretical studies, those of a generalising character as well as calculations of the electronic structures of specific clusters, which enabled their authors to reach conclusions applicable to a certain group of polynuclear compounds, were considered in the first place. According to the estimates in Raithby's review,[7] the number of structural studies already exceeded 400 by 1980 and has continued to increase rapidly, which makes an exhaustive consideration of ali the available X-ray diffraction data cumbersome and obsolescent. We have therefore carried out a compilation of structural clusters only to the extent that this has been necessary to illustrate the adequacy or inadequacy of theoretical models for such clusters and the compilation embraces mainly recent studies.

II. QUALITATIVE THEORETICAL SCHEMES FOR THE ELECTRONIC STRUCTURES OF CLUSTER COMPOUNDS OF TRANSITION METALS

The primary task in the chemistry of cluster compounds has been from its inception the explanation of the clear preference for the formation of specific metallopolyhedra containing so-called "magic numbers" of valence electrons. Subsequently, we shall use the term "magic numbers" of electrons in the clusters (the valence electrons) determined from the stoichiometry of the latter as well as electrons assigned to the molecular orbital subsystem characteristic of the clusters—the so-called "skeletal" electrons (see below). These magic numbers have proved in many instances to be a stable characteristic of clusters differing in composition but having similar structures, i.e. a characteristic of a given classified metallopolyhedron. Thus in the majority of trinuclear clusters a closed triangular fragment M_3 (where M is a transition metal) contains 48 valence electrons, a 60-electron configuration is typical for tetranuclear tetrahedral clusters, an 86-electron configuration is typical for hexanuclear octahedral clusters, etc. The total number of valence electrons is then determined in accordance with the scheme usual in organometallic and coordination chemistry: the number of electrons provided by all the ligands in accordance with the usual rules

and in the case of charged clusters also the charge with the sign reversed are added to the total number of electrons in the valence shells of the atoms forming the cluster.†

The molecular orbital (MO) schemes widely employed in the chemistry of organometallic and complex compounds have been used since the beginning of the 1960's to interpret the electronic structure of clusters and to justify their magic numbers.[12,13] These schemes, to be referred to in the subsequent exposition as qualitative (bearing in mind their descriptive character), have remained hitherto the principal element of theoretical analysis in the chemistry of clusters—frequently owing to the difficulty of rigorous quantum-chemical calculations but in the first place because of the possibility of discovering in the simple model the fundamental properties of the molecule. However, the principle underlying the construction of the MO scheme is different in different approaches.

In its classical form, the diagram of one-electron levels of the cluster is constructed from the atomic orbitals (AO) of its constituent metal atoms and the frontier orbitals of the ligands which are used to make up linear combinations transformed in accordance with the irreducible representations of the symmetry point group of the molecule. The relative positions of the energy levels are then determined on the basis of particular qualitative (in reality rather intuitive) considerations. This approach, which was common in the chemical literature of the 1960's and is still sometimes used, appears, however, to be rather useless for the mononuclear transition metal complexes; in reality the number of MO is too large to regard any one of their dispositions as uniquely correct without resorting to additional data. It is therefore not surprising that the molecular-orbital models of the electronic structure of polynuclear complexes almost always involve an appeal to the results of calculations mostly carried out by the extended Hückel method (EHM). The models, with the aid of which certain important generalisations have been achieved, will be examined below in order of increasing complexity.

1. Clusters with Localised Bonds and the Effective Atomic Number (EAN) Rule

Soon after the start of systematic studies on clusters with carbonyl and olefin ligands, it was established that the magic numbers for some of them can be readily obtained by extending Sidgwick's rule [the 18-electron shell or the effective atomic number (EAN) rule] to some of them. This extension is based on the important postulate of the localised, i.e. two-electron two-centre, character of the metal–metal bonds in the polynuclear derivatives considered. Clusters satisfying this postulate are illustrated in Fig.1, which also presents the corresponding numbers of valence electrons N_{val}.

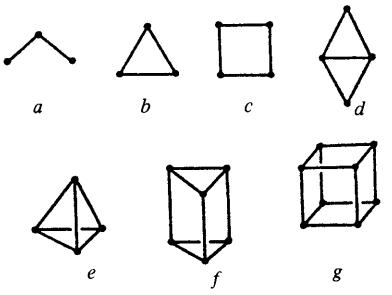

Figure 1. Clusters satisfying the EAN rule and the numbers of valence electrons N_{val} in their metallopolyhedra: *a*) $Os_3(CO)_{10}(\mu_3\text{-}Br)_2$,[15] 50ē; *b*) $Fe_3(CO)_{12}$,[14] 48ē; *c*) $Pt_4(OAc)_8$,[16] 64ē; *d*) $[Re_4(CO)_{16}]^{2-}$,[17] 62ē; *e*) $M_4(CO)_{12}$ (M = Co or Rh),[18] $Cp_3Cr_3Co(CO)(\mu_3\text{-}S)_4$,[19] 60ē; *f*) $[Rh_6C(CO)_{15}]^{2-}$,[20] 90ē; *g*) $Ni_8(CO)_8(PPh)_6$,[21] 120ē (OAc = $OOCCH_3$, Cp = $\eta^5\text{-}C_5H_5$).

The approach based on the EAN rule in essence reduces the electronic structure of clusters to the structure of their simplest analogues—organic or inorganic compounds (tetrahedrane, cubane, prismane, etc.—see Fig.1).# This analogy has been justified also in quantum-chemical calculations: many workers[3,22–25] have established that in model "naked" clusters M_n with M–M distances amounting to 2.5–3.0 Å and characteristic of real transition metal clusters, the splitting of the AO of the *d* block as a result of the formation of metal–metal bonds is insignificant compared with the splitting of the *s* and *p* AO of the valence shell. As a consequence of this, the *s* and *p* AO of the metal atoms make a dominant contribution to the bonding orbitals of the cluster and also to its high antibonding molecular orbitals, the filling of which with electrons leads to the breakdown of the M_n polyhedron. Thus in the stable M_4 tetrahedron with six localised metal–metal bonds the six corresponding antibonding MO should remain vacant, which in fact accounts for the magic numbers for this cluster: $N_{val} = 60$ ($18 \times 4 - 2 \times 6 = 60$).

The EAN rule makes it possible to isolate from the multiplicity of polynuclear complexes and clusters polyhedra related to skeletal compounds in organic chemistry. It is important to note that not more than three edges converge in the vertices in all the clusters illustrated in Fig.1. This geometrical characteristic of clusters with localised bonds probably has a profound topological significance.

†Another scheme for counting electrons in which one begins with a formal ionic structure for the complex and a d^n configuration usually attributed to the residual valence electrons in the transition metal, is current in inorganic chemistry. Clearly there is a rigorous relation between the total number of electrons in the cluster in such an "inorganic" scheme and the total number of valence electrons of the cluster determined in accordance with the "organometallic" scheme, but the numbers are different. This self-evident factor is sometimes forgotten in the consideration of cluster systems, the number of *d* electrons of the model ion (d^n) being used incorrectly in Wade's scheme (see Section II below). The "inorganic" scheme is usually employed in studies of the structure of clusters with halide ligands; in the chemistry of carbonyl clusters and their derivatives, the total number of all the valence electrons is usually considered. To avoid confusion, we shall use in the subsequent exposition only the "organometallic" approach (with the exceptions examined in subsections 1 and 3 of Section II).

#In contrast to skeletal organic compounds, the atom of a light element (H or C) can be incorporated in trigonal-prismatic metal clusters {as in the 90-electron cluster $[Rh_6C(CO)_{15}]^{2-}$ (Fig.1)}. In such derivatives the inserted atom supplies to the polyhedron all the electrons of its valence shell to be used for bonding.

2. Clusters with Many-Centre Bonds and the 2*n* + 2 Rule

Despite its simplicity and effectiveness, the EAN rule is unfortunately not entirely general and embraces only one class of polyhedra with localised metal–metal bonds. On the other hand, structural and chemical studies have made it possible to establish umambiguously that the chemical bond in the majority of cluster compounds is delocalised (many-centre) and does not reduce to the sum of two-centre two-electron interactions.[2] Thus, by placing along each edge of the polyhedron a two-centre two-electron bond even in hexanuclear octahedral clusters, we obtain 12 antibonding MO, the condition for the latter being unoccupied requiring the presence of 84 valence electrons in the cluster ($18 \times 6 - 2 \times 12$), while a magic number of 86$\bar{e}$ is characteristic of the vast majority of such clusters with carbonyl and olefin ligands. On the other hand, another hexanuclear cluster (a trigonal prism) does indeed have $N_{val} = 90$ ($18 \times 6 - 2 \times 9$) in conformity with EAN rules. Thus the transition from a polyhedron with third-order vertices, i.e. vertices joined to three other vertices (for example a trigonal prism), to a polyhedron with fourth-order vertices (for example, an octahedron) alters radically the character of the chemical bond in the cluster.

A magic number of 86$\bar{e}$ was noted in the 1960's virtually in each structural study on octahedral transition metal clusters (see, for example, Cotton and Haas[12] and Corey et al[13]), usually illustrated by a qualitative MO scheme in which numerous electronic levels, both degenerate and non-degenerate, are considered. A logical explanation and a scheme permitting the calculation of the magic numbers for clusters of a specific type with an arbitrary number of vertices were first proposed by Wade.[2,26] In his studies, initially devoted to the electronic structure of polyhedral boron hydrides and carbaboranes,[26] these compounds were subsequently proposed as a correct model for the description of the bonding in metal clusters with electron delocalisation—just as the skeletal organic molecules indicated above can serve as models for clusters satisfying the EAN rule.

Wade's scheme is based on the extremely important hypothesis that the electron system of the polyhedral molecule (carbaborane or metal cluster) is divided into two independent subsystems: the exopolyhedral and skeletal subsystems, which greatly resembles the familiar differentiation of the σ- and π-electron systems in planar aromatic molecules. Such subdivision was first established as a result of quantum-chemical calculations for the simplest polyhedral boron hydrides.[27] The calculations showed that polyhedral molecules with *n* vertices and triangular faces (*closo-n*-gons or deltahedra) contain *n* + 1 bonding MO made up predominantly of the AO of the atoms in the polyhedral skeleton distributed in the scheme in the "upper" (with a higher energy) part of the block of the bonding MO and separated from the antibonding MO by a considerable energy gap.

After comparing the results of structural and computational studies, Wade proposed the "2*n* + 2" rule,[26] according to which any *closo-n*-gon contains *n* + 1 skeletal bonding MO in which 2*n* + 2 skeletal electrons can be accommodated after the attainment of the closed configuration. The presence of a non-triangular ("open") face leads to an increase of the number of skeletal bonding MO by one and hence to the existence of 2*n* + 4 skeletal electrons in the *nido-n*-gon with one open face, of 2*n* + 6 skeletal electrons in the *arachno-n*-gon with two open faces, of 2*n* + 8 skeletal electrons in the *hypho-n*-gon with three open faces, etc. The appearance of a "cap", i.e. of an additional vertex located above the triangular face, in the polyhedron, which is frequently observed in metal clusters, does not increase the number of skeletal MO of the main polyhedron and the number of skeletal electrons supplied by this vertex is calculated in the same way as for the other vertices in metal clusters. The additional atom inserted into the polyhedral cavity also does not alter the number of skeletal MO and supplies its valence electrons to the skeletal bonding system in the cluster.

The scheme which Wade proposed[26] for counting electrons in a cluster employs the additional postulate of the involvement of three AO of the atom occupying the vertex of the polyhedron and the formation of skeletal MO. In the exopolyhedral system of orbitals of this atom (which is responsible for bonding with the ligands and which accommodates the unshared electron pairs) there remain respectively one AO in the case of a non-transition element and six AO in the case of a transition element. Thus the number of electrons introduced into the polyhedron for "skeletal" bonding by the mononuclear fragment located at its vertex is $x + l - 2$ for an atom of a non-transition element at the vertex of the polyhedron and $x + l - 12$ in the case of a transition metal atom, where x is the number of valence electrons of the given atom and l the number of electrons supplied by the ligands bound to the given atom.

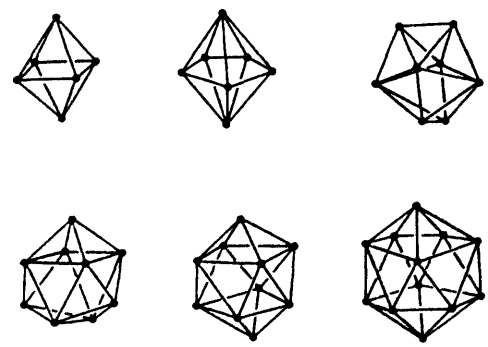

Figure 2. Types of metallopolyhedra in clusters with delocalisation of skeletal electrons.

According to this scheme, the $(OC)_3Fe$ and CpCo fragments each supply two electrons to the skeletal bonding system of the polyhedron, while the $(OC)_3Co$ fragments supply three electrons—in the former case analogously to the BH fragment and in the latter analogously to the CH fragment. The total number of skeletal electrons in an *n*-nuclear homoatomic cluster made up of transition metal atoms is then $n(x + l - 12) - q$, where q is the charge of the cluster, and is related to the number of vertices and open faces of the polyhedron by Wade's rule. The number of skeletal electrons can be found from the number of valence electrons and conversely (in the case of clusters made up of transition metal atoms $N_{val} = N_{sk} + 12n$, where n is the number of transition metal atoms). Thus octahedral clusters with 86 valence electrons contain 14 skeletal electrons, i.e. $86-12 \times 6$, in conformity with Wade's rule (*closo*-6-gon, $2n + 2 = 2 \times 6 + 2$). The magic number 86$\bar{e}$ for an octahedral cluster has thus been accounted for.

The 2*n* + 2 rule and the associated scheme for the counting of electrons, nowadays frequently referred to as the theory of skeletal electron pairs, has made a significant contribution to the theoretical ideas in the chemistry of clusters. The similarity of the structures of metal clusters and polyhedral

molecules such as those of boranes, carbaboranes, metalloboranes, and metallocarbaboranes, π-complexes, and nonclassical cations has been established on their basis.[2,3] With the aid of the $2n + 2$ rule, chemists have been able to predict the structure of a cluster on the basis of its stoichiometric composition.

The relation between the $2n + 2$ and EAN rules can be readily accounted for in terms of the postulate, adopted by Wade, that three AO of the atom at the vertex are involved in polyhedral skeletal bonding. Conditions for the formation of localised bonds are indeed fulfilled in clusters where all the vertices have an order $n \leq 3$ as a consequence of the overlap of the AO of neighbouring vertices in pairs. An increase of the order of the vertices in the polyhedron leads to a delocalised skeletal bonding system. Examples of the polyhedra encountered in the structures of carbaboranes and metal clusters are illustrated in Fig.2. We may note that the vertices of all these polyhedra have an order of four and above.

3. Lauher's CVMO Scheme and Other Approaches Based on EHM Calculations

The $2n + 2$ rule, which makes it possible to treat systematically the structures of a large number of clusters, has now become widely popular. The region of its applicability has proved, however, to be restricted to polyhedra of medium size, mainly made up of the atoms of Fe, Co, and their analogues with carbonyl ligands, some of which can be substituted by other "soft" ligands. Thus numerous clusters of other types remained outside the limits of Wade's scheme. Furthermore, Wade's rule itself is more in the nature of an empirical generalisation, leaving room for further development of the theory. The latest studies in the theoretical chemistry of clusters have accordingly developed in two directions: in ne of these the aim was to seek analogous schemes for the counting of electrons in other types of clusters and in the other the aim was to find a theoretical justification of the validity of the $2n + 2$ rule. In this subsection we shall consider the most widely used schemes developed in accordance with the first approach, while in the next subsection the results of the development of the second approach will be described.

The close relationship between clusters with localised and delocalised bonds which follows from the $2n + 2$ rule justifies the application to the latter of the model which made it possible previously to extend the EAN rule to clusters with localised bonds. According to this model, which we examined above, the highest antibonding MO of an isolated polyhedral M_n fragment are most important for the description of the electronic structure and for the determination of the magic numbers of the cluster; the filling of these MO by electrons is accompanied by the disruption of the cluster structure.[3,22] In contrast to clusters with localised bonds, such MO cannot be clearly represented by the sum of two-centre interactions; furthermore, for clusters of arbitrary type no *a priori* considerations are known at present which would permit a rigorous determination of the number of these MO. The significantly many-centre character of the bond in the clusters considered has given rise to a tendency to construct "canonical forms" with three-, four-, six-centre, etc. two-electron bonds and the resonance between such forms can evidently account for any number of valence electrons observed in reality. However, the predictive power of this scheme, described in Johnson and Benfield's review,[6] appears to us to be extremely insignificant, because procedures for a quantitative estimation of the contributions of the canonical forms considered to the overall resonance hybrid are not then defined (on the other hand, the main part of Johnson and Benfield's review,[6] devoted to studies of the configurations of ligands in carbonyl clusters, is extremely relevant and interesting). An attempt may be made to obviate the difficulties caused by the lack of rigorous theoretical principles for the prediction of the number of configurations of the antibonding MO of the cluster by constructing a MO diagram with the aid of quantum-chemical calculations. The first important results on these lines have been obtained by Mingos,[3] who confirmed by means of EHM calculations the validity of the selection of polyhedral B_6 molecules as a model of the Co_6 cluster. The calculated disposition of the highest antibonding MO made up of s and p AO in the B_6 and Co_6 clusters is indeed the same (Fig.3); the MO of the $3d$ type in the Co_6 cluster then constitute an extremely narrow band as a consequence of the less effective overlap of the corresponding AO.[3] The diagram obtained illustrates satisfactorily the applicability of the $2n + 2$ rule, derived for carbaboranes, to clusters of the metals in the centres of the transition series.

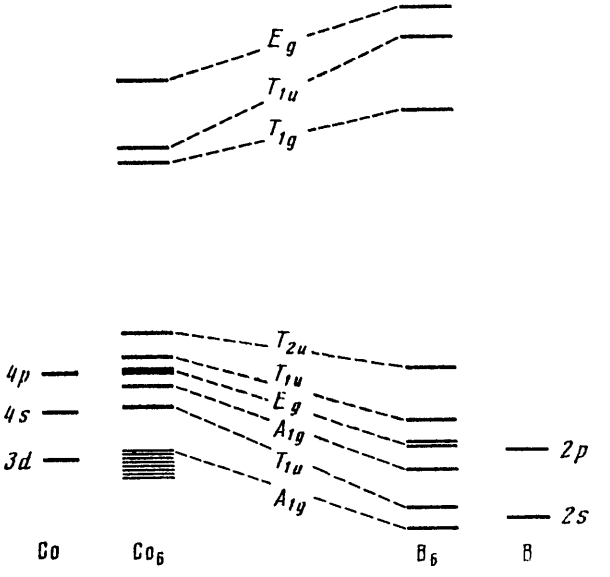

Figure 3. MO schemes for model Co_6 and B_6 clusters.[3]

The next step in the analysis of the MO with an isolated metal cluster was the scheme proposed by Lauher in a series of communications,[22,23] which is frequently referred to as the theory of valence MO of the cluster (CVMO) or of the valence electrons of the cluster. Lauher's scheme divides the MO of the cluster into low-lying CVMO and the antibonding MO (HLAO), designated here by AMO, separated from them by an energy gap. When ligands are coordinated to the cluster nucleus, the CVMO are modified as a consequence of their involvement in bonding while the AMO undergoes smaller changes (owing to the greater difference between their energies and those of the ligand orbitals) and remain unoccupied in the molecule of a real cluster. After differentiating the AMO on the molecular orbital diagram of the M_n cluster, calculated with the aid of EHM, the magic numbers of electrons

which can be accommodated in the CVMO of the given polyhedron when it is coordinated to the ligands are obtained. Specific calculations enable the author[23] to introduce the following semiquantitative criterion for the separation of the AMO from the CVMO: the antibonding MO of the cluster usually have higher energies than the unoccupied p AO of the metal atom.[23]

In contrast to Wade's scheme which operates with the intrapolyhedral (skeletal) electronic configuration, Lauher's scheme includes all the valence electrons of the cluster and is applicable in principle to metallopolyhedra having structures of any complexity, provided that the computational method employed in the scheme is sufficiently correct. Although a useful aspect of the qualitative scheme, namely the possibility of finding the magic number for a polyhedron of any structure without quantum-chemical calculations, is lost in this approach, it also makes it possible to determine the number of valence electrons in a specific M_n cluster with an arbitrary disposition of ligands in terms of a uniquely calculated MO scheme, although it does not provide a unique explanation of such numbers. On the other hand, in his first study,[22] Lauher reproduced, for example, the stable 170-electron configuration of the $[Rh_{13}(CO)_{24}H_3]^{2-}$ cluster with an Rh atom incorporated within the polyhedron, which cannot be interpreted in terms of other schemes, and carried out calculations for a series of M_n clusters with $n = 3 - 15$.

The total number of CVMO is expressed in Lauher's method as $6n + X$, where X is a quantity which assumes values from 3 to 13 depending on the geometry of the M_n polyhedron. The number of CVMO corresponding to one metal atom varies in conformity with this, converging slowly to 5.3, a value characteristic of an infinite metallic lattice, as the size of the cluster increases.

It appears that the CVMO scheme still suffers from the disadvantage that the prediction of the order in which the MO of the cluster are distributed on the basis of qualitative considerations is difficult and hence the results depend on the adequacy or inadequacy of the computational method employed. The extended Hückel method employed by Lauher (the simplest and therefore hitherto the only semiempirical quantum-chemical method used in calculations for systems such as polynuclear transition metal clusters) is by no means universal; its fundamental validity has been questioned even in calculations for mononuclear transition metal complexes.[28] An advantage of the EHM is that it takes into account the topology of the molecule by introducing into the matrix of the model Hamiltonian non-diagonal elements proportional to the overlap integrals. However, the question of the applicability of the given method to calculations for the molecules of organometallic and also cluster compounds is complex and requires further investigation.

In Lauher's study[22] the CVMO scheme reproduced correctly, in conformity with the predictions of the EAN or $2n + 2$ rule, the magic numbers for a series of common polyhedra (tetrahedron, trigonal prism, octahedron, cube, two-cap Archimedes antiprism, eicosahedron). However, results in conflict with the existing qualitative schemes and inconsistent with the magic numbers of the carbaborane analogues have been obtained for certain polyhedra (pentagonal pyramid, dodecahedron with trigonal faces, and square antiprism without caps). It is of interest to note that the real structure of transition metal clusters with such polyhedra of medium dimensions exhibits in reality deviations also from the predictions based on the $2n + 2$ rule, although this structure is not in fact fully consistent with Lauher's magic numbers either (see section II). For the octahedron with four caps, located in accordance with a tetrahedral motif, the predictions of the CVMO scheme ($N_{val} = 140$) have also not been confirmed: the corresponding osmium clusters of the type $[Os_{10}C(CO)_{24}]^{2-}$ contain 134 valence electrons in conformity with Wade's scheme.[29]§

The advantages and disadvantages of Lauher's approach are well illustrated by a study of Italian workers,[24] who quote the results of the calculation for more than 100 M_n metal clusters containing fragments of close-packed metal atoms. Calculation for eight Rh clusters of known structure, which served as models, made it possible (in some conflict with Lauher's data) to specify unambiguously the set of CVMO, corresponding to the real number of valence electrons, only for the three polyhedra of highest symmetry. In the remaining cases the numbers of valence electrons predicted did not agree with the real composition or a uniform distribution of levels was observed on the MO diagram, so that their separation into CVMO and AMO with respect to the energy of an isolated metal atom proved to be fairly arbitrary. In order to reduce the discrepancies between the calculated and observed numbers of electrons in planar trinuclear and tetranuclear clusters, it was necessary to choose as the AMO the orbitals whose energies were much higher than that of the unoccupied p level. Nevertheless, the authors[24] believe that the agreement between the calculated and experimental magic numbers is adequate for a qualitative consideration of the structure of transition metal clusters.

The numbers of CVMO determined by the above investigators[24] correspond to the formula $6n + X$ where X varies from 6 to 11. $X = 7$ was found for approximately half of the structures for which calculations had been made and $X = 8$ was found for one-quarter of the structures. Since the formal validity of the $2n + 2$ rule requires the existence of $2n - 1$ skeletal AMO and correspondingly $7n + 1$ CVMO, the authors[24] concluded that Wade's rule is inadequate for the class of systems which they investigated and proposed a $6n + X$ rule for an arbitrary n-atomic cluster, where in the majority of cases $X = 7$. This modification of Lauher's formula, which has been quoted recently in a number of communications, is in our view erroneous. The discrepancy between the number of CVMO of an n-vertex cluster and the

---

§ In certain recently published communications (B.K.Teo, Inorg.Chem., 1984, **23**, 1251; B.K.Teo, G.Longoni, and F.R.K.Chung, Inorg.Chem., 1984, 23, 1258) the number of CVMO of an arbitrary M_n metal cluster has been determined without a preliminary calculation, solely on the basis of the EAN rule and Euler's theorem by means of the formula $8V + 2 - F + X$, where V is the number of vertices of the cluster, F the number of its faces, and X the number of "additional" electron pairs necessary to create a stable electronic configuration, in excess of the number required in accordance with the EAN rule for a cluster with localised M–M bonds. The introduction of the term X reflects the many-centre character of the bonding in the cluster; $X = 0$ in all polyhedra with third-order vertices. The values of X for stable clusters, including those made up of several polyhedra, are determined by a set of seven rules (supported by a qualitative examination of the MO). These rules make it possible to find the numbers of valence electrons N_{val} for a large number of clusters with carbonyl ligands which have been investigated. The discrepancies between the calculated and real values of N_{val} are then observed mainly for cluster compounds of the elements at the end of the transition series and for the majority of metal clusters. The empirical character of the rules, which frequently specify 2–3 magic numbers of valence electrons for the metallopolyhedra most frequently encountered (trigonal bipyramid, octahedron, the Archimedes antiprism, and a three-cap triangular prism) can apparently be regarded as one of the disadvantages of the proposed scheme.

"Wade" value of $7n + 1$ can in general indicate the inapplicability of the $2n + 2$ rule to the given polyhedron, because the rule is not universal. However, $X = 7$ is also not of general validity (see Table 2 in Lauher's paper[22]) and its frequent appearance in the results of calculations reflects mainly the fact that more than half of the metal clusters considered[24] are constructed on the basis of an octahedron or a tetragonal pyramid supplemented by different numbers of "caps" or other condensed polyhedra. In conformity with Wade's rule, the octahedron (*closo*-hexagon) or tetragonal pyramid (*nido*-pentagon) with an arbitrary number of caps should have seven skeletal electron pairs, which, when added together to the $6n$ exopolyhedral MO, yields precisely $6n + 7$ CVMO. In this case X is exactly equal to 7 (Wade's formula includes the number of vertices not centred on trigonal faces and not the total number of vertices of the polyhedron[2]).

The results of the above study[24] illustrate in a somewhat unexpected fashion the, on the whole, correct evaluation of the number of CVMO (and hence of the valence electrons) by EHM calculations for clusters where they can be calculated independently in accordance with the $2n + 2$ rule. However, for a series of clusters including the four-cap octahedron discussed above, numbers N_{val} inconsistent with the real values (see Section III) were obtained. The reasons for the adequacy of the computational scheme under consideration in the case of some polyhedra and its inadequacy for their closest analogues are not entirely clear and we believe that so far the results of EHM calculations should be treated with a certain amount of caution.

It might have been expected that the results of EHM calculations will become more applicable with increase of the number of atoms in the cluster and on transition to an infinite crystal lattice of the metal in the limit, because in this region of large clusters the qualitative chemical rules governing the electronic structure are so far unknown. However, in calculations for large M_n metal clusters with $n = 16$–22[22,24] it was shown that, with increase of the number of metal atoms, the MO system approaches ever more closely the continuous region where no subdivision into AMO and CVMO is observed.

The CVMO method has been criticised also from the standpoint of a physical approach in which clusters are treated within the framework of band theory. According to Wooley,[9] who describes the physical point of view on clusters, the extended Hückel method yields an unduly small d band width in polyatomic transition metal aggregates (~1 eV in Mingos's calculations and ~3eV according to the estimates of band theory) and generates a bonding pattern inconsistent with the limiting case of a metallic lattice in which the bonding electrons occupy the d band and the s and p electrons (the probability of finding such electrons in the inner shells of a neighbouring atom is not zero as a consequence of the diffuseness of the corresponding AO) are antibonding because of orthogonality factors. There is no doubt about the value of the approach to the structures of large metal clusters from the standpoint of the ideas of solid state physics (band theory), but one should note that in this field the interests of physicists and chemists sometimes do not coincide and studies of correlations of the "composition–structure–properties" type must nevertheless be based on theoretical considerations derived from fairly approximate chemical models.

As in other theoretical schemes in the chemistry of clusters, the CVMO method is not universal even when the EHM calculation is correct.[23] In particular, with its aid it is impossible to interpret the electronic structures of polynuclear platinum and gold compounds (although these admittedly cannot be described satisfactorily within the framework of other theoretical schemes either). Thus the octahedral cluster $\{Au_6[P(C_6H_4Me)_3]_6\}^{2+}$, containing 76 valence electrons, i.e. four skeletal electrons, does not fit any of the existing models.

The electronic structures of the numerous unusual platinum and gold clusters obtained in recent years have been interpreted by Mingos using the results of EHM calculations.[31–36] Gold clusters of medium dimensions ($n = 6$–13) have been considered taking into account two findings by the same investigator: (1) the slight overlap of the occupied d AO leading to the formation of a narrow d band of a weakly antibonding character and (2) the small contribution of high-energy unoccupied p AO of the Au atoms to the bonding in the cluster. As a zeroth approximation, Mingos adopted a simplified model taking into account only the interaction of the valence s AO of the Au atoms in the clusters; in essence, this model is analogous to that of the simple Hückel method, where account is taken only of the overlap between the orbitals of neighbouring atoms and the p AO of the π-system are replaced by the s AO of the atoms making up the polyhedron.[31] The simple orbital diagram obtained for this model agrees with the relative disposition of the s MO in a more complex schematic arrangement of levels calculated using valence s, p, and d AO as the basis. The s MO schemes for the octahedral and eicosahedral clusters are presented in Fig. 4.

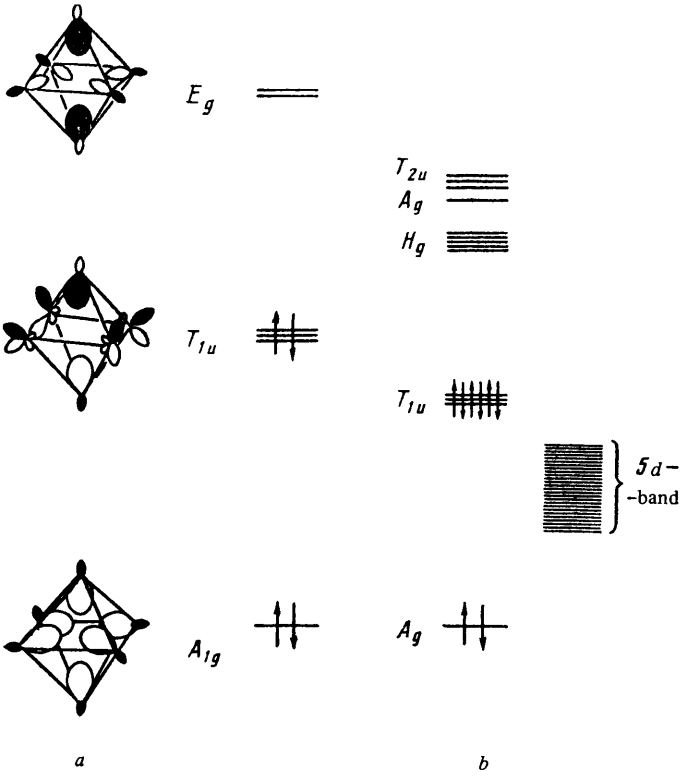

Figure 4. MO schemes for the Au_6 octahedral cluster (a) and the centred Au_{13} eicosahedral cluster (b).[31]

Mingos[31] demonstrated that the structures of the Au_n clusters based on a centred eicosahedron with the greatest contribution to the bonding by the interaction between the central and peripheral Au atoms are preferable. The coordination of n phosphine ligands at the vertices of such a

polyhedron results in the formation of n strongly bonding MO of the exopolyhedral type and the corresponding increase of the energy of the cluster s MO with retention of their relative positions.

The stable electronic configuration predicted by this calculation corresponds to the composition of the $[Au_{13}(PPh_3)_{12}]^{5+}$ cluster. This prediction was confirmed by the successful synthesis of the isoelectronic cluster $[Au_{13}L_{10}Cl_2]^{3+}$ with the *trans*-disposition of the Cl ligands in the eicosahedron.[32] Calculations for the octahedral $[Au_6L_6]^{2+}$ cluster predict an open electron shell [only two electrons are located in the triply degenerate T_{1u} MO (Fig. 4)], which subsequently led Evans and Mingos[33] to doubt the validity of the structural study of Bellon et al.[30] and the correctness of the composition established. The prediction of the stability of the octagonal dodecahedral Au_8C clusters with a carbide carbon atom at the centre of the polyhedron[31] has not so far been confirmed experimentally.

In the theoretical schemes examined above the cluster molecule is subdivided into the metallopolyhedron proper and its ligand environment and the electronic characteristics of the polyhedron, which depend little on the configuration of the ligands, are analysed. There exists also an alternative approach to the determination of the electronic structure of the clusters in which the MO scheme for the polyhedral molecule is constructed from the frontier orbitals of the mononuclear ML_k fragments. The idea, that the fragments of different nature whose frontier orbitals have similar energies and have the same nodal properties are stereochemically similar, occupies a major place in this approach. These considerations are to some extent already contained in Wade's classification of the mononuclear fragments of the cluster in terms of the number of electrons which they supply to the polyhedron, have been generalised in the familiar principle of isolobal correspondence,[36] and are widely used in interpreting the results of EHM calculations.[33–35] In this interpretation the analogy between the metal carbonyl clusters and polyhedral boranes and carbaboranes is justified by the isolobality of the $M(CO)_3$ and MCp fragments (where M is a transition metal) in relation to the BH and CH fragments. The development of schemes for the counting of electrons in polyhedral molecules outside the region of applicability of the EAN and $2n + 2$ rules, in this type of treatment is an expected result of the analysis of the correlation diagram of a cluster made up of mononuclear fragments such as $M(CO)_4$, ML_2, or ML, where L is a phosphine ligand, which are not isolobal with respect to the BH group. The last two fragments are encountered mainly in "non-Wade" Pt and Au clusters respectively; the magic numbers for small polyhedra with the number of vertices n between 3 and 6, which have been proposed on the basis of EHM results, were interpreted on the basis of the isolobal analogies of the given fragments.[33–35]

Nevertheless, the calculations have demonstrated the absence of adequate models for the AuL or PtL_2 fragments among the compounds of other elements. In the case of small Pt clusters, the electronic structure and the magic number derived from it proved to be different for different orientations of the ligands L relative to the Pt_n metallopolyhedra.[34] On the other hand, the energy of formation of Au clusters of different structure proved virtually identical in EHM calculations.[33] The isolobal analogy between the $Pt(PH_3)_2$ "corner" fragment and the $M(CO)_3$ "conical" fragment proved to be incomplete as a consequence of the energy splitting of the $hy(xz)$ hybrid orbital and the $p(y)$ atomic orbital, whose equivalents are degenerate in the case of $M(CO)_3$ (it is of interest to note that the frontier orbitals obtained in the studies quoted usually contain a significant contribution from d AO). The isolobal correspondence between the $AuPR_3$ fragment and the hydride ligand H has been postulated[33] for small Au clusters. It was deduced from structural data for the mixed clusters of the type $Os_3(CO)_{10}\cdot(AuPEt_3)_2$ [37] and $Ru_4(CO)_{12}(AuPR_3)_3H$, [38] where the $AuPR_3$ fragment as it were occupies the place of the μ-H ligand in the hydride derivatives, which have been synthesised recently. However, this analogy is incomplete and the authors stipulate the possibility in principle of the involvement in bonding also of the 6p AO of the Au atoms.[33]

On the whole, we believe that, with all its undoubted clarity and popularity, the analysis of the frontier orbitals of the fragments is in essence insufficiently effective for the prediction of the characteristics of the structure of polyhedral molecules which are at present not susceptible to description in terms of other schemes. The results of a number of studies[33–36] represent essentially the expression of experimental structural data in terms of frontier MO schemes and their explanation on the basis of a more detailed specification of the postulates which had already been put forward in earlier studies[31] and which involves certain controversial claims—the existence of two instead of three metal–metal bonds in 44-electron trinuclear Pt complexes[35] in the presence of 54 instead of 58 valence electrons in the $Au_4(\mu\text{-}I)_2(PR_3)_4$ tetrahedral cluster.[33] There is no doubt that consideration of a specific type of MO of the clusters gives rise to extensive possibilities for the interpretation of experimental data but the value of the theoretical scheme is largely determined by its predictive power. We believe that in this sense the principle of isolobal correspondence, which is extremely useful for the systematic treatment of a large number of molecular structures, may in many instances prove to be relatively inapplicable to the real structural-chemical problem.

4. The Topological Interpretation of the Electronic Structure of Cluster Systems

The ideas borrowed from topology and the graph theory have nowadays penetrated structural and quantum chemistry to an increasing extent. The development of studies on cluster molecules and the wide variety and unusual nature of the polyhedra present in them have led to a kind of fascination with the topological terminology, the employment of which in most of the studies published hitherto makes the interpretation of the results more novel than fruitful. Advances in theoretical chemistry and in the first place the study of the MO of planar aromatic systems by the graph theory method[39] have shown, however, that the application of the procedures of this, one of the most modern and abstract fields of mathematics, to chemical problems can be extremely useful and the possibilities for the introduction of topological ideas into the chemistry of cluster molecules are apparently much wider than the mere determination of the number of edges from the number of faces (or conversely) in an n-vertex cluster in terms of Euler's scheme. Topological ideas have been used to some extent in studies carried out in recent years whose aim was a theoretical justification of the $2n + 2$ rule.[40,41]

The book of King and Rouvray[40] deals, like other theoretical studies of the electronic structure of clusters, with a qualitative diagram of the Hückel MO of a polyhedral molecule. The novelty of this study consists in the analysis of the energies of the MO in a polyhedron of arbitrary type of symmetry solely on the basis of a scheme for the chemical bonds present in the molecule (i.e. the molecular graph). This approach is possible because the energies of the levels (i.e. the eigenvalues of the matrix of the model Hamiltonian H) in the Hückel model can be expressed in terms of the eigenvalues of another very simple matrix—the adjoint matrix A of the molecular graph whose elements are 1 for the pair of vertices

joined by a chemical bond and 0 for any other pair of vertices. The set of eigen-values of the adjoint matrix of a cyclic molecular graph C_n defines, for example, the MO diagram for aromatic π-systems, which constitutes the basis of the Hückel rule. The molecular orbital diagrams whereby it is possible to justify the $2n + 2$ rule can be derived analogously from the molecular graphs reflecting the bonding in the skeletal electron system of the cluster.

Starting with Wade's hypothesis of the involvement of three orbitals of the mononuclear fragment of a *closo*-polyhedron in the skeletal bonding system, it has been suggested[40] that two tangential orbitals (of the τ type), located along the tangent to the surface of the polyhedron, and one internal orbital (of the *i* type), directed to the centre of the cluster, be constructed from them. In an *n*-vertex cluster *n* bonding and *n* antibonding τ MO are formed from $2n$ τ AO, while a single bonding and $n - 1$ antibonding MO are formed from *n i* AO (the region of the mutual overlap of which is in the central part of the polyhedron) in conformity with the eigenvalues of the adjoint matrix of the graph of the *i* AO system, which represents the complete graph K_n (each vertex is connected to all the others). The bonding MO, the total number of which is thus $n + 1$, can accommodate $2n + 2$ skeletal electrons, which is consistent with Wade's rule. The cluster with triangular faces, which obeys the $2n + 2$ rule, is regarded as a three-dimensional superaromatic system with electron delocalisation, which represents a generalisation of the π-systems of planar aromatic molecules.

Thus, in addition to Wade's hypothesis of the separation of the exo- and endopolyhedral electron systems, the King and Rouvray scheme considers the τ and *i* MO also as independent of one another. These postulates appear to be fairly natural but cannot be rigorously derived from the symmetry properties of the cluster, which are altogether disregarded in this approach. The appearance of an additional pair of skeletal electrons in clusters with an open face has been justified[40] by introducing yet another hypothesis, this time the hypothesis of the separation of the system of *n i* AO of a *nido*-*n*-gon into the ν orbitals of the atoms surrounding the open face and the $n - \nu$ orbitals of the remaining atoms of the polyhedron. Each of these subsystems is assumed to be represented by its complete graph (K_ν and $K_{n-\nu}$ respectively), as a consequence of which two bonding orbitals of the *i* type arise in the system of skeletal MO instead of one such orbital. The increase of the number of open faces ("breaks") (on a *closo*-surface) as well as the introduction of "caps" in super-electron-deficient clusters lead, according to the authors,[40] to an increase of the degree of localisation of the bonds in the polyhedron.¶

Despite the importance of the results obtained, King and Rouvray's study[40] does not nevertheless provide an exhaustive description of three-dimensional superaromatic systems and does not contain a justification of the extremely significant initial postulates. The authors relate the degree of delocalisation of electrons in the cluster to the fraction of triangular faces on the total surface of the polyhedron, but the physical causes of this relation are not discussed. Finally, the results of graph theory have been applied in this instance only in terms of the simplest quantum-chemical Hückel method.

The strong aspects of the EHM are then clearly revealed: for example, it becomes understandable why calculations of this type have yielded such satisfactory results in the study of the polyhedral $B_nH_n^{2-}$ ions[27] but it has not been ultimately elucidated to what extent the relations obtained depend on the specific method of calculation employed.

Some of the questions enumerated above have been eliminated by Stone,[41] who developed a different much more general and physically well-founded model of the bonding interaction in the cluster. Having refrained from *a priori* assumptions about the number and form of the AO occupied in the exopolyhedral electron system, Stone employed in his study a single postulate, according to which the atoms making up the cluster polyhedron are approximately at equal distances from its centre. On this basis, he constructed a simple model of the polyhedral molecule whose atoms are uniformly distributed on the surface of a sphere. Thus, whereas the molecular symmetry is not considered at all in King and Rouvray's book, Stone's model has a spherical symmetry, which is the highest possible in a three-dimensional space. Nevertheless, with the aid of this model, it is possible to derive relations suitable for any clusters however low their symmetry.

In his study[41] Stone employed the wave function of a spherically symmetrical shell, which can be transformed into $R(r)Y_{lm}(\theta,\phi)$ in terms of polar coordinates, where the angular component Y_{lm} represents spherical functions, well known in quantum mechanics, which are defined in terms of two quantum numbers (the orbital momentum *l* and the magnetic momentum *m*) and which are degenerate by a factor $2l + 1$, like the sublevels of an isolated atom (see, for example, Messia[42]). Stone constructed the wave function of the cluster in accordance with the LCAO MO scheme in the form of a sum of the basis AO of the constituent atoms $\psi = \Sigma c_i\chi_i$; he employed the spherical functions Y_{lm} as the coefficients of the c_i in the expansion of ψ in terms of the basis functions $\{\chi_i\}$. This makes it possible to classify the resulting MO cluster in terms of the quantum number *l*, as is done for an isolated atom, by introducing the one-cluster *S* MO ($l = 0$), the three cluster *P* MO ($l = 1$), the five-cluster *D* MO ($l = 2$), etc. However, not all these MO exist in a specific cluster, because the spherical functions Y_{lm}, which appear in the expansion of the wave functions ψ for certain values of *l*, can become zero at the vertices of the polyhedron.

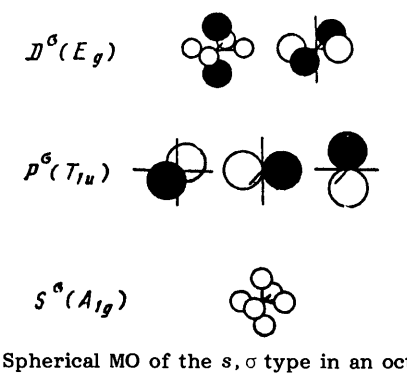

Figure 5. Spherical MO of the s,σ type in an octahedral cluster.[41]

In reality, only *n* linearly independent cluster MO can be made up of *n* basis functions χ_i. Thus it is possible to set up six independent MO of the σ type from six *s* AO of the metal atom (Fig.5): one fully symmetrical S^σ MO, three

¶The method developed by King and Rouvray[40] has been discussed in detail by Yanovskii (see this issue of the Journal). For our purposes, the use of postulates of a topological character in King and Rouvray's proof of the validity of the $2n + 2$ rule rather than the proof itself, is most significant.

degenerate P^{σ} MO antisymmetric with respect to inversion, and two of the five D^{σ} MO, since the other D^{σ} MO become zero (because the corresponding functions Y_{2m} at the vertices of the octahedron are zero).[41] The distribution of the cluster MO in terms of energy can be derived qualitatively from the number of nodal surfaces and is consistent with the usual pattern: the bonding A_{1g} MO, the non-bonding T_{1u} MO, and the antibonding E_g MO for an octahedral cluster (Fig. 4a).

The difference between the MO of a "spherical" cluster and the AO of an isolated atom consists in the fact that they have different forms depending not only on the quantum numbers l and m but also on the types of the basis functions (s, p, and d) and their overlap (σ, π, and δ). Accordingly, it is possible to isolate the following series of levels for a cluster made up to transition metal atoms: S_s^{σ}, P_s^{σ}, D_s^{σ}, ..., S_p^{σ}, P_p^{σ}, D_p^{σ}, ..., P_p^{π}, D_p^{π}, S_p^{π}, ..., P_d^{π}, D_d^{π}, F_d^{π}, ..., D_d^{δ}, δ_d, G_d^{δ}, ..., etc. The transition from cluster MO of the σ type to the MO of the π and δ types required also appropriate changes in the mathematical procedures, namely the introduction of the corresponding vector and tensor spherical functions instead of the corresponding scalar spherical functions Y_{lm}. The main consequence of such a change is the subdivision of $2n$ linearly independent π or δ MO into n low-energy even (i.e. symmetrical relative to the inversion operation) and n high-energy odd (antisymmetric in relation to inversion) orbitals. Thus pairs of MO made up of the even P_p^{π} and odd $\bar{P}_p^{\pi}$ orbitals, the even D_d^{δ} and odd $\bar{D}_d^{\delta}$ orbitals, etc., in which the first MO is in general bonding while the second is antibonding, appear.

Despite the large number of cluster MO of different types, their relative disposition as regards energy is extremely consistent. Thus, among all the MO of the σ type, only the S_s^{σ} orbital is bonding, while the others are antibonding. In the n-vertex cluster the P^{π} MO are divided into two groups: n even bonding P_p^{π} MO and n odd anti-bonding $\bar{P}_p^{\pi}$ MO, which is analogous to the formation of n molecular orbitals of the τ type and n orbitals of the τ^* type in the book of King and Rouvray. The cluster made up of n atoms of the elements in the Second Period thus contains $n + 1$ bonding MO. The splitting of the even and odd constituent π and δ MO, made up of d AO, is insignificant according to Stone's calculations[41] and all the MO of this type in the cluster are occupied by electrons (as shown above, the same result has been obtained in EHM calculations). Thus in this instance the $2n + 2$ rule has been justified (the presence of n bonding P_p^{π} MO and one bonding S_s^{σ} MO in the cluster). The expression for the bond energy in the cluster based on Stone's model contains a product of the type $Af(\omega)$, where $f(\omega)$ depends solely on the angular distance between neighbouring atoms on the surface of the sphere and the factor A is the ratio of the number of edges of the cluster to the number of its vertices and is a maximum for the *closo*-polyhedron with triangular faces. In this case the preference for cluster *closo*-structures is likewise well-founded.

At first sight Stone's scheme has no bearing on topology, because it uses the spherical shell model, which has been well developed in quantum mechanics. However, the very fact that the systematic treatment of the MO in accordance with the orbital quantum numbers l for an idealised spherical system is applicable to an arbitrary polyhedral molecule apparently demonstrates that the symmetry of the model is not itself of decisive importance in this instance and in a certain sense it merely complicates the description of the bonding, generating a large number of multiplets. Stone[41] emphasises the kinship between the spherical shell model and other simple models of systems with electron delocalisation—such as the linear potential box for conjugated polyenes and a closed conducting ring for cyclic π-systems. The latter model is purely topological: indeed Hückel's rule can be most simply derived for an ideal annular potential box with $D_{\infty h}$ symmetry (the lowest non-degenerate Σ_u level and an infinite sequence of doubly degenerate Π, Δ, etc. levels require the presence of $4n + 2$ π-electrons in a system with paired spins), but it is valid for all planar aromatic molecules however low their symmetry and is determined precisely by the fact that the π-electron system is closed. Analogously the adquacy of Stone's model in describing clusters is apparently determined by the same properties, namely the closed nature of the three-dimensional electron shell of the cluster, its homogeneous conductivity, and the presence of an inner cavity (we may note that the same properties of a superaromatic cluster with the additional hypothesis concerning the number of skeletal orbitals have been used in the studies by King and Rouvray).

In analysing cluster MO, Stone does not consider the consequences of the appearance of open faces in the polyhedron (i.e. the breakdown of the principle of the uniform distribution of atoms on the sphere underlying the model) and in essence proposes the same $2n + 2$ rule for every cluster, beginning with the diatomic molecule (as an example, he considered[41] the N_2 molecule). Despite the use of complex mathematical procedures, the scheme includes also significantly qualitative considerations, which are in many instances resorted to to account for the discrepancy between the predicted and true numbers of valence electrons in the molecule. The postulate of a weak interaction of the MO localised in various regions of the polyhedron (internal, surface, and exopolyhedral), which in fact corresponds to the postulate of the subdivision of the cluster MO into sybsystems (however, with a difference from the studies of Wade[2] and King and Rouvray[40] consisting in the fact that in Stone's work this postulate is a computational fact arising from the proposed model), is of special interest. The subdivision of the MO referring to topologically different regions of the cluster has been confirmed at the present time also experimentally;[9] however, quantum chemistry does not apparently as yet possess mathematical methods suitable for the analysis of this extremely interesting phenomenon.

Thus qualitative MO schemes make it possible not only to bring order into the experimental findings in the chemistry of clusters but also to achieve significant progress in the understanding of the causes of these findings. One may note further that principal advances in the theoretical description have been attained for clusters obeying the $2n + 2$ rule, which are nowadays regarded as three-dimensional superaromatic systems with a predominance of multicentre bonding. However, the electron count rules derived for such systems are applicable only to a limited range of skeletal compounds. In the next Section certain specific structures of metal clusters are considered in order to establish more definitely the limits of applicability of the qualitative theoretical structural schemes described above.

III. THE STRUCTURE OF TRANSITION METAL CLUSTERS

1. Trinuclear and Tetranuclear Clusters†

In these simplest polynuclear derivatives all the metal–metal bonds can be regarded as of the two-electron two-centre types; the magic numbers of the valence electrons of the

†The electronic structure of trinuclear metallocycles is examined in detail in S.P.Gubin's review (see this issue of the Journal).

cluster can therefore be determined in accordance with the EAN rule (Fig.1). The bonding and antibonding (in relation to the metal atoms) MO in these clusters are of course delocalised throughout the polyhedron, but they can be expressed mathematically by the combination of localised two-electron two-centre interactions. Many trinuclear and tetranuclear clusters of Group VI–VIII transition metals with carbanion π-olefin ligands obey the EAN rule (see, for example, Chini et al.[1] and Wade[2]).

However, in the present discussion we shall be interested in precisely those clusters which do not correspond to the commonest magic numbers and for this reason are more rarely dealt with in review communications. Certain representatives of the extremely numerous group of such compounds are compiled in Table 1, which also lists the principal characteristics of the cluster fragment in the molecule. Comparison of the M–M distances in the cluster and in the crystal lattice of the metal does not yield an unambiguous criterion for the existence (and even more so the multiplicity) of the metal–metal bond, although the sums of the Pauling metal atom radii are also listed in Table 1 to characterise the general trends in the variation of the interatomic distances.

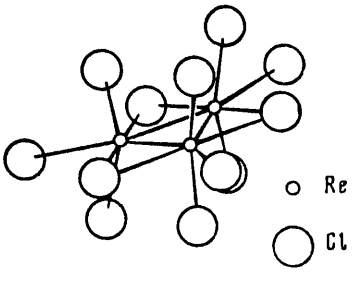

Figure 6. The structure of the $[Re_3(\mu_2\text{-}Cl)_3Cl_6]^{3-}$ cluster.[49]

Trinuclear and tetranuclear complexes of transition metals which do not obey the EAN rule can be arbitrarily divided into three non-equivalent groups. The first least numerous of these comprises clusters of the type $Os_3(CO)_{10}H_2$ in which the consequences of the deviation from the EAN rule can be readily interpreted within the framework of this same rule. Thus, the short Os–Os distance (2.680 Å) in $Os_3(CO)_{10}H_2$ can be attributed to a metal–metal double bond; multiplicities of 4/3 and 3/4 can be attributed to the Re–Re bonds (2.913 Å) in $Re_4(CO)_{12}H_4$ and the Ni–Ni bond (2.464 Å) in $Cp_4Ni_4H_3$ respectively; indeed, the average Re–Re distance (3.111 Å) in the 60-electron dianion $[Re_4(CO)_{12}H_6]^{2-}$ is greater by 0.20 Å than that observed in $Re_4(CO)_{12}H_4$.[47] The situation in the nickel derivative is somewhat more complex because the average Co–Co bond length in the 60-electron $Cp_4Co_4H_4$ cluster is 2.467 Å,[47] while the covalent radii of the cobalt and nickel atoms are similar; there exist also other nickel derivatives with an electron excess, for example, nickelocene, in which the presence of "superfluous" electrons does not lead to a structurally significant loosening of the bonds. The $Os_3(CO)_{10}H_2$ and $Re_4(CO)_{12}H_4$ clusters, which constitute an infrequent instance of the exception proving the rule, are regularly mentioned in theoretical studies.[2,23,25]

The trinuclear (Fig.6) complexes of Group II elements with halide and chalcogenide ligands of the type of $[Re_3Cl_{12}]^{3-}$ [49] or $[W_3O(OAc)_6(OH_2)_3]^{4+}$ [50] are discussed much more rarely in the literature devoted to the electronic structure of clusters. The number of valence electrons in these clusters (42ē) formally agrees with the existence of M=M double bonds, but such bonds in $[Re_3(\mu_2\text{-}Cl)_3Cl_9]^{3-}$ are shorter by 0.4 Å than the Re–Re bond in the dinuclear $H_2Re_2(CO)_8$ cluster (2.896 Å),[52] which can also be regarded as the double bond judging from the total number of electrons in the molecule. In terms of the "inorganic" (see above) electron counting scheme, the presence of double bonds has also been postulated in the trinuclear complexes considered.[49] Even more electron deficient clusters, for example $Re_3Cl_3(CH_2SiMe_3)_6$, in which the triangular $Re_3(\mu_2\text{-}Cl)_3$ fragment contains Re=Re double bonds 2.384–2.389 Å long according to the calculation based on the "inorganic" scheme, have been synthesised. However, according to the "organometallic" counting scheme, on the basis of the total number of valence electrons a multiplicity of 3 should be attributed to the same bonds. While it has certain advantages in the consideration of electronic structure, the existence of two electron counting schemes yielding inconsistent results nevertheless demonstrates that the description of the chemical bonds in clusters with halide and chalcogenide ligands has not been fully elaborated at the present time.

*Notation: k_{M-M} is the number of metal–metal bonds in the cluster, R(M–M) the average metal–metal distance, and R^M the sum of the Pauling metal atom radii.[43]

The third and most varied group of "irregular" trinuclear and tetranuclear clusters consists of derivatives of pallidium, platinum, and copper subgroup metals. In contrast to the halide complexes, these clusters have recently attracted the attention of theoreticians,[23,33,35] but it would be premature at present to speak of the development of an electron counting scheme for such clusters. Certain analogues of magic numbers can be established empirically in palladium and platinum derivatives—they are usually smaller than in the corresponding complexes of the metals in the middle of the transition series, just as in the mononuclear derivatives of these elements the 16-electron shell is more stable than the 18-electron shell. Trinuclear 42- and 44-electron platinum and

palladium complexes, 56-electron tetrahedral clusters, and 58-electron clusters with the "butterfly" configuration are known (Table 1). The situation is complicated by the frequent deviations from these empirical magic numbers as well. Thus there exist the 50-electron tetrahedral $Pt_4.H_2[P(t\text{-}Bu)_3]_4$ and the 60-electron tetrahedral $Pd_4(CO)_6.[P(n\text{-}Bu)_3]_4$ clusters (the latter, included in Table 1, obeys the EAN rule in contradiction of the Table heading, which is more in the nature of an exception in the class of palladium and platinum derivatives). Assuming that the exopolyhedral Pt–Pt bonds in the pentanuclear $Pt_5(CO)_6(PPh_3)_4$ cluster (Fig.7) are two-electron two-centre bonds, we obtain yet another magic number—58ē for the Pt_4 tetrahedron.[61]

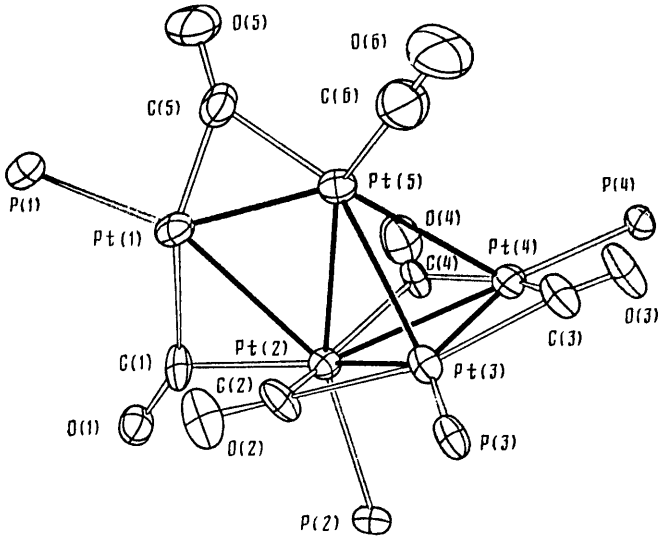

Figure 7. The $Pt_5(CO)_6(PPh_3)_4$ molecule (the phenyl substituents are not shown).[61]

The thermodynamically stable palladium and platinum clusters are able, in addition, to expand the coordination sphere of the metal atom, reacting under mild conditions with metallic mercury or its derivatives. Thus the bitetrahedral $\{[Ph(iso\text{-}Pr)_2P]_3Pt_3(CO)_3Hg\}_2$ cluster (Fig.8), which contains 54 or 53 electrons depending on whether the Hg...Hg contact 3.225 Å long is or is not regarded as a chemical bond,[62] the $[L_3Pt_3.(\mu_2\text{-}L)_3]_2Hg$ (where $L = Me_2C_6H_3NC$) *commo*-cluster of the sandwich type,[63] and the edge-condensed $Pd_4Hg_2Br_2(\mu_2\text{-}CO)_4.(PEt_3)_4$ cluster[64] have been obtained. Their electronic structure is difficult to interpret at the existing level of theoretical ideas.

The structures of the tetranuclear copper, silver, and gold complexes are even less susceptible to classification. The existence of the planar M_4 tetragon, which exhibits a tendency towards the formation of four additional M...Fe bonds in the ferrocenyl derivative $Cu_4(C_5H_4FeC_5H_4R)_4$ ($R = CH_2.NMe_2$) [66] (and in its silver analogue[67]), is characteristic of copper derivatives. The Cu–Cu distance in the 56-electron $Cu_4[O(t\text{-}Bu)]_4$ cluster (parallelogram) and in the 64-electron $[Cu_4(SPh)_6]^{2-}$ cluster (tetrahedron) is greater than in the formally 72-electron $Cu_4(\mu_3\text{-}I_4)Py_4$ complex, where metal–metal bonds should be absent according to the EAN rule. The Cu–Cu distances in the isoelectronic cubane-like clusters of the latter type vary in the range 2.65–3.21 Å.[70] The Cu–Cu contacts 2.6–2.8 Å long are not usually assumed to correspond to a direct metal–metal interaction.[68–70]

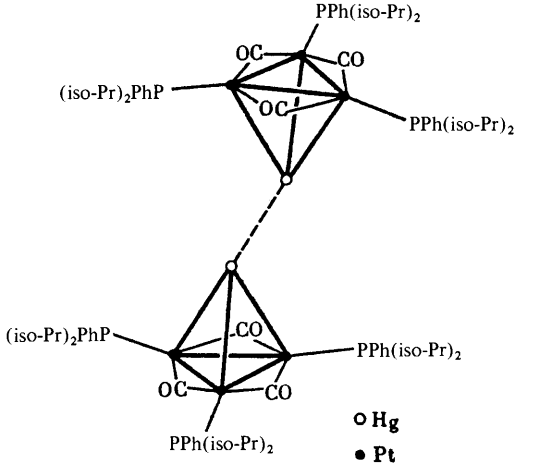

Figure 8. The $\{[Ph(iso\text{-}Pr)_2P]_3Pt_3(CO)_3Hg\}_2$ cluster (the hydrocarbon fragments are not shown).[62]

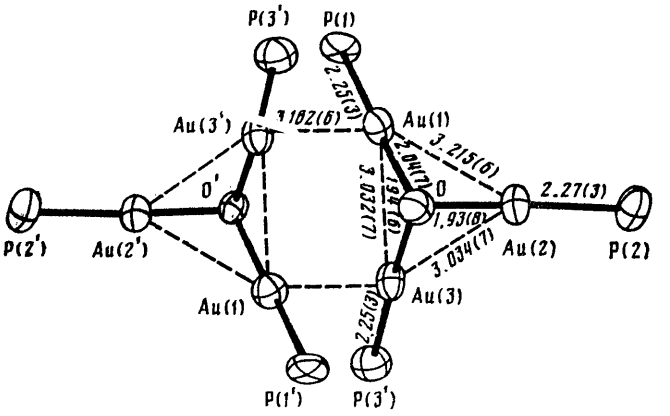

Figure 9. The structure of the $[(Ph_3PAu)_3O]_2^{2+}$ cation[74] (the phenyl substituents are not shown).

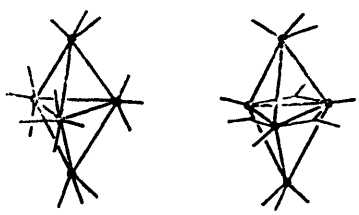
Somewhat in contrast to this, the gold derivatives definitely manifest a tendency towards a weak "secondary" Au...Au interaction at distances of 3.0–3.5 Å, which is observed, for example, in $C_5H_{10}NAuCl_4$.[71] The $Au_4(\mu_2\text{-}I)_2(PPh_3)_4$ structure contains the 58-electron Au_4 tetrahedron, while the formally 56-electron Au_4 tetrahedron in the pentanuclear $[Au_5(PPh_2.CH_2PPh_2)_3CH(PPh_2)_2]^{2+}$ dication is linked via one of its vertices to the 14-electron linearly coordinated Au atom.[73] Finally, two 42-electron $(LAu)_3E^+$ cations in the series of $[(LAu)_3E]_2^{2+}$ dimers (where $L = PPh_3$ and E = chalcogen atom[74,75]) are linked in pairs by secondary Au...Au interactions over distances of 3.15–3.40 Å (Fig.9).

We believe that the data examined suggest that the trinuclear and tetranuclear clusters of post-transition metals, palladium, and platinum do not on the whole exhibit an

unambiguous relation between the geometrical characteristics of the polyhedra present in their molecules and the numbers of valence electrons.

2. Trigonal-Bipyramidal Clusters

The trigonal-bipyramidal fragment is believed to be the first "Wade" *closo*-polyhedron and exists as such in the structures of a series of clusters satisfying the $2n + 2$ rule (Table 2, left half). According to this rule, clusters with 12 skeletal electrons, made up of the atoms of transition or non-transition elements are analogues of the *closo*-carbaborane $C_2B_3H_5$ (Fig.10). A characteristic feature of structures of the trigonal-bipyramidal type is, however, their intermediate position between polyhedra with localised and many-centre bonds, because the trigonal bipyramid can be equally well regarded as a one-cap tetrahedron, the localised bonding in which also requires twelve electrons. As a consequence of this, derivatives of the type $Os_4(CO)_{12}NMe$, for example, where the M_4 is a tetrahedron coordinated via a triangular face to the μ_3-NMe ligand, the M_4C or M_4N "butterfly" in which a non-metal atom is incorporated, or the M_3 triangle and two μ_3-X ligands, are sometimes classified as mixed trigonal-bipyramidal clusters.



a *b*

Figure 10. Examples of the "Wade" (*a*) and "non-Wade" (*b*) trigonal-bipyramidal clusters and the numbers of skeletal electrons in the latter: *a*) $Os_5(CO)_{16}$, $12\bar{e}$; *b*) $[Ni_5(CO)_{12}]^{2-}$, $16\bar{e}$.

This kind of borderline position of trigonal-bipyramidal structures is also expressed by the existence among them of a large number of exceptions to the $2n + 2$ rule (Table 2, right half) and these exceptions cannot at present be confidently ascribed to the presence in the polyhedron of the atoms of a post-transition element. The $[PtRh_4(CO)_{12}]^2$ ($12\bar{e}$) and $[PtRh_4(CO)_{14}]^{2-}$ ($16\bar{e}$) mixed clusters exhibit, for example, an isomeric behaviour of the cluster nucleus which depends on whether the Pt atom occupies the apical or equatorial position.

The characteristic features of the trigonal-bipyramidal complexes made it necessary to postulate the existence in them of two magic numbers (12 and 16) of skeletal electrons or (for clusters made up of transition metal atoms) of 72 and 76 valence electrons.[22,88] The experimentally observed increase in the length of the equatorial-apical metal–metal bonds compared with the equatorial-equatorial bonds in the 76-electron derivatives has been explained with the aid of EHM calculations.[22] However, Table 2 shows that there exist also clusters with ten and fourteen skeletal electrons. Among the polynuclear complexes of metals of the iron and cobalt subgroup trigonal bipyramidal derivatives are encountered much more rarely than the octahedral complexes.

3. Derivatives of Octahedral Clusters

The $2n + 2$ rule holds most rigorously for the octahedral clusters of transition metals of the iron and cobalt subgroups with carbonyl ligands, some of which can be substituted by other "soft" ligands (η^n-olefin, phosphine, and nitrosyl ligands). The examples in Table 3 show that the polyhedron in these clusters can consist of atoms of different elements [the heteronuclear $Ru_4C_2Me_2(CO)_{12}$ complex (Fig.11), in which the $Ru_4(CO)_{12}$ "butterfly" has been built onto the octahedron via the acetylene ligand of the complex bridging functional group is especially interesting[92]] or can incorporate a C or H atom within the cavity of the polyhedron. It is noteworthy that even the $Cp_6Ti_6O_8$ titanium cluster with μ_3-oxo-bridges and the heteronuclear carbide cluster $(Et_3PAu)_2.Fe_4C(CO)_{12}$ each have 14 skeletal electrons, differing in this respect from the majority of the polynuclear compounds at the beginning and end of the transition series which have been investigated. Pentanuclear *nido*- and *arachno*-derivatives which can be synthesised from octahedral clusters, are also known. Thus a 14-electron tetragonal pyramid can be obtained by removing one vertex of the octahedron (this leads to a general method of synthesis of heteronuclear clusters, as a result of the successive introduction of atoms of other transition elements in place of the missing vertex[94]), while a 16-electron *arachno*-cluster can be obtained by adding two-electron donors to the corresponding *nido*-derivatives (Fig.12).

$[Fe_6S_8(PEt_3)_6]^{2+}$	90	18	2.62	2.49	[98]

The cyclopentadienylnickel cluster Cp_6Ni_6 (its monocation is also known[97]) and the iron cluster[98] $Fe_6S_8(PEt_3)_6$ with phosphine and μ_3-sulphide ligands, in which there is a significant loosening of the metal–metal bonds, are exceptions to Wade's

rule. It is of interest to note that, in contrast to its analogues in the Periodic System, clusters with an electron excess are fairly characteristic of nickel, namely $Cp_4Ni_4H_3$,[46] $[Ni_5.(CO)_{12}]^{2-}$,[87] and Cp_6Ni_6.[97]

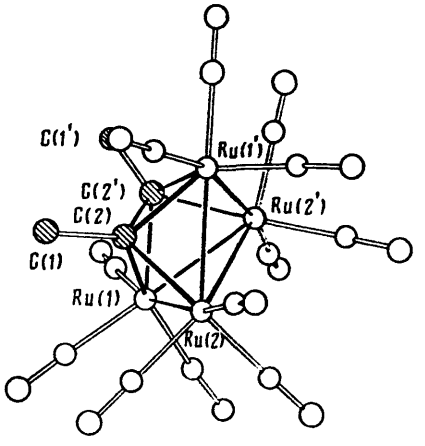

Figure 11. The structure of $Ru_4C_2Me_2(CO)_{12}$.[92]

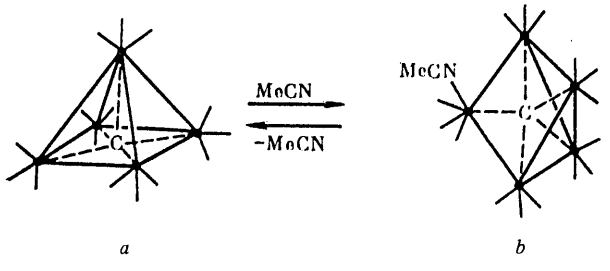

Figure 12. The interconversions of the *nido*- and *arachno*-clusters of ruthenium: *a*) $Ru_5C(CO)_{15}$, 14ē; *b*) $Ru_5C(CO)_{15}.(MeCN)$, 16ē.

Among octahedral clusters, there exist also numerous "non-Wade" derivatives, including, in particular, the halide complexes of Group III-VI transition metals (Table 4). The $M_6(\mu_2\text{-}X)_{12}$ and $M_6(\mu_3\text{-}X)_8$ motifs, where the halogen atoms form bridges along all the edges or along all the faces of the octahedron with additional apical coordination of the ligands to its vertices, occur widely in these clusters, which are distinguished by a fixed configuration of the ligand environment relative to the metallopolyhedron. The chemical bonds in the cluster nuclei of such compounds are usually described qualitatively in terms of the "inorganic" electron counting scheme which is not identical to the "organometallic" scheme adopted in this review.

Wade attempted to combine the two approaches[2] by postulating the involvement of four AO from each metal atom in skeletal bonding in "non-Wade" clusters. The bonds in the $[Nb_6(\mu_2\text{-}Cl)_{12}]^{2+}$ and $[Mo_6(\mu_3\text{-}Cl)_8]^{4+}$ model clusters are then assumed to be respectively two-electron three-centre bonds (eight bonds, 16ē) or two-electron two-centre bonds (twelve bonds, 24ē). Apart from the reduction of the predictive power of such a model as a consequence of the introduction of bonds with different degrees of localisation into isotypical compounds, one should note that the formal charge separation in the molecule by no means allows the isolation of the cluster fragments of the above types in all the existing octahedral metal complexes with halide ligands.

Table 4. Cluster transition metal halides.

$Mo_6(\mu_3\text{-}Cl)_8Br_6]^{2-}$	84	2.62	2.72	[105]

*The fractional subscripts correspond to compounds in the crystals of which the vertices of two neighbouring clusters are linked by bridging halide ligands.

The evaluation of the number of valence electrons in the metallopolyhedra of the compounds listed in Table 4 suggests that a characteristic feature of these polynuclear complexes is the absence of magic numbers as such rather than the existence of magic numbers (they could be found empirically from the available experimental data) other than in the carbonyl clusters. We believe that the reason for this may lie in the "super-electron deficiency" of the cluster derivatives of metals at the beginning of the transition series as a result of which the corresponding metallopolyhedron is coordination-saturated even before its ability to receive the electrons supplied by the ligand has been exhausted, i.e. before all its low-energy CVMO have been occupied. It is noteworthy that the $Cp_6Ti_6O_8$ cluster with many-electron ligands satisfies the $2n + 2$ rule.[91]

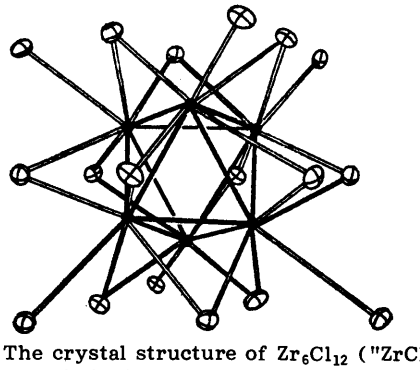

Figure 13. The crystal structure of Zr_6Cl_{12} ("$ZrCl_2$"). The metallopolyhedron is indicated; the Cl atoms in the equatorial belt are coordinated to the vertices of neighbouring octahedral clusters.

Yet another feature of the cluster transition metal halides is the breakdown of the principle of the uniform occupation of the coordination sphere of the metallopolyhedron by ligands,

which is valid for the corresponding carbonyl analogues.[6] Thus an arrangement of Cl ligands in layers is observed (Fig.13) in the Zr_6Cl_{12} structure, while the μ_2-Cl ligands in the equatorial component of the coordination shell are additionally coordinated along the vertices of neighbouring octahedra. The structural motifs examined are also common in organic clusters with chalcogenide ligands (Chevrel phases); metallo-octahedra with a mixed halide-chalcogenide environment are also known.

Derivatives of post-transition metals constitute yet another group of non-Wade octahedral clusters by analogy with the trinuclear and tetranuclear structures which do not obey the EAN rule. Few structural studies have so far been made on polynuclear compounds of this class, where (Table 5) the absence of magic numbers rather than an appreciable preference for particular electronic configurations is to be seen in the cluster halides of metals at the beginning of the transition series. The ammine, phosphine, and σ-aryl (more rarely σ-alkyl) groups are characteristic ligands for the elements of the copper subgroup.

Table 5. Hexanuclear clusters of post-transition elements.

Formula	N_{val}	N_{sk}	R (M–M), Å	r^M, Å	Refs.
$Ir_2Cu_4(\sigma,\eta\text{-}C{\equiv}CPh)_8(PPh_3)_2$	90	18	2.74 (Cu—Cu) 2.87 (Cu—Ir)	2.52 (Cu) 2.71 (Ir)	[106]
$H_6Cu_6(PPh_3)_6$	84	12	2.60	2.55	[107]

$[(Ph_3P)_2Au_3(\mu_3\text{-}O)]_2^{2+}$	84	12	3.11	2.88	[74]

*The $Co(CO)_4$ fragments play the role of ligands, forming exopolyhedral Au–Co bonds.

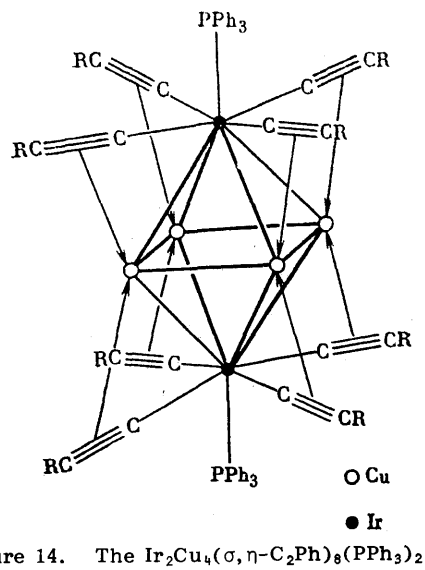

Figure 14. The $Ir_2Cu_4(\sigma,\eta\text{-}C_2Ph)_8(PPh_3)_2$ cluster.

Thus the $Ir_2Cu_4(C_2Ph)_8(PPh_3)_2$ cluster (Fig.14) contains 18 skeletal electrons, if each σ,π-acetylide is regarded as the donor of five electrons, or proves to be super-electron-deficient if it is assumed that these ligands each supply three electrons (this is more usual in the case of one-centre π-coordination of alkynes). The task of explaining the existence, inconsistent with calculated data, of the octahedral $[Au_6(PTol_3)_6]^{2+}$ (Tol = *p*-tolyl) cluster and the isoelectronic bitetrahedral $Au_6(PPh_3)_4[Co(CO)_4]_2$ cluster is made still more difficult by the presence of a bitetrahedral configuration, analogous to that in the latter cluster, in the 82-electron polyhedron (discussed above) in $Pd_2Hg_2Br_2(CO)_4(PEt_3)_4$. On the other hand, dications of the type $[(Ph_3PAu)_3E]_2^{2+}$ (E = S, Se, or Te—see Fig.9), which are isoelectronic with the octahedral copper clusters $H_6Cu_6(PPh_3)_6$ and $Cu_6(o\text{-}Me_2NC_6H_4)_4(\mu_2\text{-}Br)_2$, contain an open tricyclic Au_6 skeleton. Finally, distorted Ag_6 octahedra with Ag...Ag contacts 3.01 and 3.74 Å long, which are a general characteristic of polynuclear silver compounds normally containing complex polyatomic skeletons, are present in the $\{Ag_6[S_2C{=}C(CN)_2]_6\}^{6-}$ structure.[110]

Notation: N_{val} is the number of valence electrons in the cluster, N^{val}_{CVMO} the number of valence electrons calculated in accordance with Lauher's scheme, N_{sk} the number of skeletal electrons in the cluster, and $N^{sk}_{(2n+2)}$ the number of skeletal electrons predicted by Wade's rule.

Evaluation of the number of skeletal electrons in fairly representative groups of clusters with an octahedral structure based on different transition and post-transition elements thus demonstrates a consistent character of the electronic structure in derivatives of metals in the middle of transition series and the apparent absence of such regularities in clusters of the elements at the beginning and end of the transition series. The causes of the failure of the magic number (2*n* + 2) rule for elements to the left and right of Fe and Co as well as their analogues are evidently various, but we believe that the very fact of such behaviour of metal clusters reveals a close relation between the 2*n* + 2 and EAN rules, because the regions of their applicability in the series of transition elements are virtually identical.

4. Clusters Based on Polyhedra of Medium Dimensions

Metal clusters containing M_n polyhedra with a number of vertices n between 7 and 12 will be assigned to this group of polynuclear compounds. Most of such clusters consist of osmium and rhodium derivatives; cobalt, palladium, and gold compounds have also been investigated. Table 6 presents examples of such clusters; the numbers of their valence electrons are compared with the numbers found in accordance with the $2n + 2$ rule and calculated on the basis of the CVMO scheme.[22-24] Among the compounds considered, it is possible to differentiate several types of structures differing in the "reference" polyhedra which can have one or several caps. We shall consider subsequently the polyhedra of each type in order of increasing complexity of their reference polyhedron.

(a) Octahedra with centred faces. Clusters of this type have no analogies in the structures of boranes and carbaboranes. According to the $2n + 2$ scheme, the addition of a cap (i.e. a vertex over the centre of a triangular face) to an octahedral cluster does not increase the number of skeletal electrons of the octahedron. Accordingly, in the known clusters of metal-analogues, namely manganese, iron, and cobalt, having the structures of one-, two-, and four-cap octahedra, the magic number of skeletal electrons $N_{sk} = 14$ obtains. The electronic structure of the ten-vertex cluster $[Os_{10}C(CO)_{24}]^{2-}$,[29] which cannot be interpreted within the framework of the CVMO scheme on the basis of the results of EHM calculations, is in reality rigorously consistent with Wade's rule, which has been confirmed in a series of recent studies on derivatives of clusters of this type.[115]

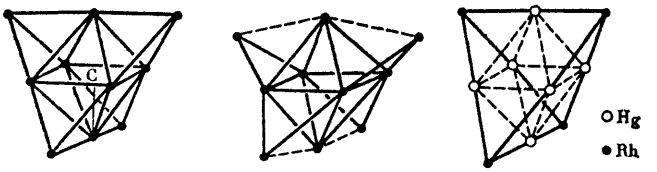

Figure 15. Decagonal clusters with a four-cap octahedron made up of metal atoms and the numbers of skeletal electrons in them: *a*) $[Os_{10}C(CO)_{24}]^{2-}$, 14$\bar{e}$;[29] *b*) $Pd_{10}(CO)_{12}(PBu_3)_6$, 16$\bar{e}$;[60] *c*) $Hg_6Rh_4(PMe_3)_{12}$, 12$\bar{e}$.[117]

Deviations from Wade's rule appear in the analogous palladium derivatives: the observed "opening of caps" requires the appearance of additional electrons relative to the closed electronic configuration, namely two in $Pd_7(CO)_7(PMe_3)_7$ and eight in $Pd_{10}(CO)_{12}[P(n\text{-}Bu)_3]_6$, which is inconsistent with the real numbers of valence electrons in these clusters. The number $N_{val} = 160$ in the dodecanuclear cluster $[Pd_6Fe_6.(CO)_{24}H]^{3-}$ [118] corresponds to $N_{sk} = 16$, which is inconsistent with the $2n + 2$ rule, but can be reproduced in terms of the CVMO scheme; at present it is not entirely clear whether the observed distortions of the trigonal-antiprismatic type in the internal Pd_6 octahedron are a result of the deviation from Wade's magic number $N_{sk} = 14$. For the $Hg_6Rh_4.(PMe_3)_{12}$ cluster, the establishment of a correlation between the number of electrons and the geometrical characteristics of the polyhedra constitutes a still more difficult task. Examples of decanuclear clusters (Fig.15) illustrate yet again the loss of predictive power by Wade's rule for clusters of metals at the end of the transition series.

(b) Polyoctahedral clusters. The $2n + 2$ rule can apparently be extended (provided that it is valid for the constituent polyhedra) to clusters consisting of two or several polyhedra having common vertices (*commo*-clusters, polyhedra with a common edge and a common face); by relating the number of skeletal electrons in such compounds to the number of non-common vertices, i.e. vertices which do not belong simultaneously to two or several polyhedra. Accordingly, the numbers of skeletal electrons in the recently synthesised $[Rh_9(CO)_{19}]^{3-}$ and $[Ru_{10}(C)_2(CO)_{24}]^{2-}$ clusters and also in the mixed cluster $Os_6C(CO)_{16}(C_2Me_2)$[121] are analogous to those required for the corresponding *closo*-hexagon, *closo*-octagon, and *arachno*-hexagon (Fig.16).

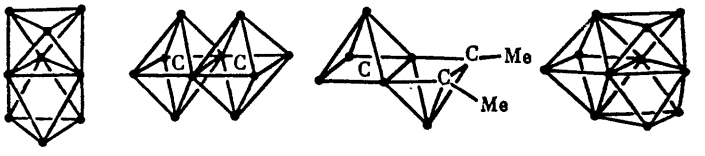

Figure 16. Polyoctahedral clusters and the numbers of skeletal electrons observed in them: *a*) $[Rh_9(CO)_{15}]^{3-}$, 14$\bar{e}$;[121] *b*) $[Ru_{10}(C)_2(CO)_{24}]^{2-}$, 18e;[122] *c*) $Os_6C(CO)_{16}C_2Me_2$, 18$\bar{e}$;[123] *d*) $[Rh_{11}(CO)_{23}]^{3-}$, 16$\bar{e}$.[124]

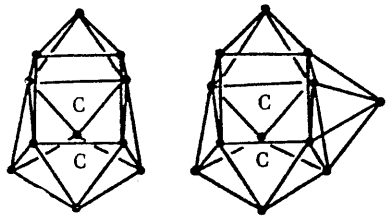
A more general rule for the calculation of the magic numbers of valence electrons for any multipolyhedral clusters has now been proposed by Mingos;[120] the total magic number of valence electrons of the cluster is equal to the sum of the magic numbers of its constituent polyhedra minus the sum of the magic numbers of the boundary fragments (18$\bar{e}$ for a single atom in *commo*-clusters, 34$\bar{e}$ for two atoms located on a common edge of the cluster, and 48$\bar{e}$ for three atoms on a common triangular face or 50$\bar{e}$ for a common face in polyhedra with electron delocalisation). Mingos's rule makes it possible, for example, to obtain the magic number of valence electrons in a trigonal bipyramid regarded as two tetrahedra with a common fact ($60 + 60 - 48 = 72\bar{e}$) and is valid for a large number of clusters of a wide variety of types.# We may recall that the numbers of valence and skeletal electrons in the cluster differ by $12n$, where n is the number of atoms in the cluster.

It is noteworthy that Wade's magic numbers characterise a trend rather than a rigorous rule in the geometrical structures of clusters in the case of compound polyhedra: thus the distances between the apical atoms of the two octahedra in $Ru_{10}(C)_2(CO)_{24}]^{2-}$ not linked by valence forces (Ru...Ru contacts 3.112 and 3.138 Å long) exceed only slightly the

#Analogous rules have been proposed in a recent study by Mingos and Evans[148] for platinum clusters. In this case the magic numbers of boundary fragments are 16$\bar{e}$ for a common vertex, 30$\bar{e}$ for a common edge, and 44$\bar{e}$ for a common triangular face. For the pentanuclear cluster $Pt_5(CO)_6(PPh_3)_4$, the scheme predicts the number 70$\bar{e}$, which agrees with the true number (see, however, Section III, 2 of the present review).

lengths of certain edges (2.803–3.098 Å). However, the CVMO scheme yields for these clusters numbers of valence electrons which are inconsistent with the observed numbers.[24] The trisoctahedral cluster having the composition $[Rh_{11}(CO)_{23}]^{3-}$ indicated in Table 6 deviates from the 2*n* + 2 rule; calculations of its electronic structure on the basis of the CVMO scheme have not been carried out. The presence of five long edges (2.96–3.06 Å) in the Rh_{11} polyhedron has been rationally explained [124] by the deformation of its constituent condensed octahedra, because in this case octahedra do not fill the three-dimensional space.

(c) Clusters based on a tetragonal (Archimedes) antiprism. The recently synthesised derivatives of this type with one (*nido*-M_9) or two (*closo*-M_{10}) caps over the "open" tetragonal faces of the reference polyhedron contain 22 skeletal electrons in conformity with the 2*n* + 2 rule. The inner cavity of the rhodium clusters contains P, S, or As atoms. It is of interest that the specific metal–metal distances in this group of clusters can vary within fairly wide limits (particularly in the polyhedral anions Sn_8Tl^{3-} and Sn_9Tl^{3-}).[128] In essence, on the basis of the 2*n* + 2 rule, it is possible to predict in compounds of the given type only an idealised configuration of the polyhedron, which in the real structure may undergo considerable distortions. It is noteworthy that in the carbaborane derivatives of analogous structure the 2*n* + 2 rule holds extremely rigorously.[2]



a *b*

Figure 17. *a*) $[Co_{11}C_2(CO_{22})]^{3-}$; *b*) $Rh_{12}C_2(CO)_{25}$.

(d) Polyhedra with an irregular structure. We understand this term to mean metal clusters of complex form in the structures of which it is possible to isolate the reference polyhedron only tentatively. Such compounds are usually characterised by fairly significant deviations from the 2*n* + 2 rule. The $[Co_8C(CO)_{18}]^{2-}$ cluster occupies an intermediate position between those examined in the present and previous Sections: it has a tetragonal antiprismatic type of structure, but, as a consequence of distortion, it is also close to a two-cap trigonal prism (one of the open faces of the antiprism is "pierced" by the Co...Co contact 3.225 Å long); the number of skeletal electrons in this cluster does not agree with Wade's rule (but is correctly reproduced in terms of the CVMO scheme[22]). The distortions of the polyhedron considered have been explained[1] as a result of the discrepancy between the covalent radius of the carbon atom (0.77 Å) and the somewhat larger internal cavity in clusters of the tetragonal-antiprismatic type (capable of incorporating the atoms of non-metals in the Third and Fourth Period, as can be seen from the previous Section).

The undecanuclear $[Co_{11}C_2(CO)_{22}]^{3-}$ cluster[130] and the dodecanuclear $Rh_{12}C_2(CO)_{25}$ cluster[131] (Fig.17), containing in the inner cavities the diatomic C_2 group with C–C distances of 1.62 and 1.48 Å respectively, are even less susceptible to an "idealised" description. In the complex polyhedra of these clusters, each of which has two open tetragonal faces, there are 22 skeletal electrons in each case, i.e. the number N_{sk} characteristic of a *closo*-decagon holds. The presence of open faces thus ceases to affect the total number of skeletal electrons, which also remain unchanged following the appearance of a cap over each face.

The heteronuclear nitride cluster $[PtRh_{10}N(CO)_{21}]^{3-}$ can be represented by a three-cap trigonal prism with two additional caps, each of which constitutes simultaneously the centre of two rectangular faces; however, the lateral edges of such a prism are lengthened up to "non-bonding" Rh...Rh distances and amount to ~3.50 Å (Fig.18). The super-electron-deficient metalloborane and metallocarbaborane clusters have an analogous structure (see Yanovskii's review in this Journal).

Distortions of the type indicated are a general characteristic of trigonal-prismatic clusters with caps, which can be illustrated by the structure of Bi_9^{5+}.[133] In this polynuclear cation the lateral edges of the reference prism have been lengthened to 3.704–3.979 Å, while the other Bi–Bi distances in the polyhedron are in the range 3.078–3.286 Å. The number of electrons in Bi_9^{5+} is greater than the Wade number by 2, which is consistent with the predictions of the CVMO scheme for rhodium clusters.[22]

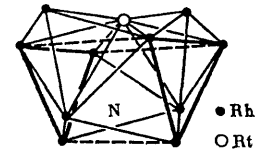


Figure 18. The $[PtRh_{10}N(CO)_{21}]^{3-}$ cluster[132] (the reference polyhedron is indicated).

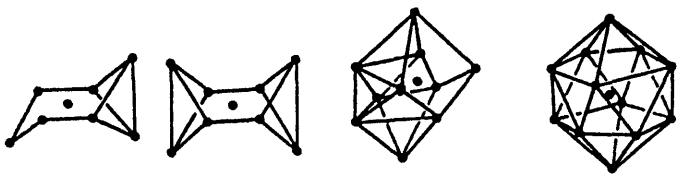
(e) Clusters based on a centred eicosahedron. Among carbaboranes and metallo-carbaboranes, eicosahedral derivatives constitute the largest class which is most consistent with the 2*n* + 2 rule.[134] On the other hand, with increase of the size of the polyhedron in metal clusters a tendency arises towards the breakdown of this rule. In the single structurally investigated distorted eicosahedral rhodium cluster $[Rh_{12}Sb(CO)_{27}]^{3-}$ the inner cavity is occupied by an Sb atom (the Sb–Rh distances are 2.712 and 2.922 Å) and, for the average Rh–Rh bonding distance in the polyhedron of 2.912 Å, three edges of the cluster are extended to 3.334 Å.[135] Despite the existence of "semiopen" faces, the cluster contains 26 skeletal electrons, which is typical for a *closo*-eicosahedron. The closeness of the covalent radii of the Sb (1.36 Å) and Rh (1.32 Å) atoms[43] is responsible for the possibility of the existence of homoatomic centred polyhedra. Indeed, long before the synthesis of $[Rh_{12}Sb(CO)_{27}]^{3-}$ its isoelectronic derivatives $[Rh_{13}(CO)_{24}H_n]^{(5-n)-}$ were obtained.[1] Their structures will be examined in the next Section (in view of their close relationship with the large carbonyl clusters).

Yet another extremely interesting class of polynuclear complexes, constructed in accordance with the eicosahedral motif, is known, namely the gold clusters (Fig.19). The oldest representative of this series, the $[Au_{13}(PMe_2Ph)_{10}Cl_2]^{3+}$ cluster,[32] was initially predicted by Mingos on the basis of EHM calculations.[31] The clusters whose structures have been

investigated so far and whose polyhedra can be represented by an eicosahedron with different numbers of missing vertices are compiled in Table 7 (L is a phosphine ligand). §

Table 7 shows that, in contrast to the gold derivatives examined previously, clusters of this type exhibit a definite tendency towards the retention of the magic number N_{sk} = 18, which is inconsistent with the number N_{sk} = 26 required for the eicosahedron according to the $2n + 2$ rule. For $[Au_8PPh_3)_8]^{2+}$, this is achieved by virtue of the weak coordination of one of the Ph_3P ligands to the central Au atom.[136]



a *b* *c* *d*

Figure 19. Centred gold clusters: *a*) $Au_8L_7^{2+}$; *b*) $Au_9L_8^{3+}$; *c*) $Au_{11}L_{10}^{3+}$; *d*) $Au_{13}L_{10}Cl_2^{3+}$.

On the basis of the preferential contribution of the interaction between the central and peripheral Au atoms to the bonding in the given cluster (this has been established both by calculations[131] and experimentally[139]), one can assume that the magic number N_{sk} = 18 characterises the tendency of the electron shell of the central Au atom in compounds of this type to assume the inert gas configuration.

Table 7. Centred gold clusters based on the eicosahedron.*

Formula	n_{miss}	N_{val}	N_{sk}	Refs.
$[Au_8L_7]^{2+}$	5	100	16	[136]
$[Au_8L_8]^{2+}$	5	102	18	[136]
$[Au_9L_8]^{3+}$	4	112	16	[137]
$[Au_{11}L_{10}]^{3+}$	2	138	18	[138]
$[Au_{13}L_{10}Cl_2]^{3+}$	0	162	18	[32]

*n_{miss} is the number of missing vertices.

In contrast to the mononuclear Au complexes, where a linear configuration and a 14-electron shell are characteristic of many of such compounds, the peripheral Au atoms in the clusters listed in Table 7 occupy fairly uniformly the coordination shell of the central atom, which apparently constitutes a condition for the fulfilment of the EAN rule in mononuclear transition metal complexes. This makes it possible to expect the existence of the clusters, not as yet obtained, $[Au_{10}L_9]^{2+}$ and $[Au_{12}L_{11}]^{4+}$ (or their isoelectronic derivatives involving the substitution of some of the phosphine ligands by halide ligands, which reduces the overall positive charge) and possibly cations of the type $[Au_{14}L_{11}X_2]^{4+}$ or $[Au_{14}L_{10}X_3]^{3+}$ (where X = halogen) with an 18-electron configuration of the central Au atom in all such hypothetical structures. In the case of the 16-electron clusters $Au_9L_8^{3+}$ the somewhat more open flattened Au_9 skeleton (Fig. 19b) is apparently capable of rearranging to a structure with a centred crown.[140]

§A preliminary communication[149] concerning the synthesis and structural study of the mixed $[(Ph_3P)_{12}Au_{13}Ag_{12}(\mu\text{-}Cl_6]^{m+}$ cluster, constructed from three interpenetrating eicosahedra and containing three intrapolyhedral Au atoms, has been published.

5. Lattice Clusters

Here we denote by this term polynuclear transition metal anions, predominantly those of Rh and Pt, where the M_n polyhedron actually represent a fragment of the crystal lattice of the metal. Clusters of the type $[Os_{10}C(CO)_{24}]^{2-}$ or $[Pd_6Fe_6(CO)_{24}H]^{3-}$ (Table 6), which have already been examined, may be assumed to contain layers of metal atoms, with hexagonal close packing, but it is still possible to interpret their electronic structure rationally in terms of a model of the reference octahedron with electron delocalisation over which caps with localised bonds have been constructed. In contrast to this, the examples of large clusters with carbonyl ligands listed in Table 8 cannot be arranged systematically on the basis of the $2n + 2$ rule and even less so the EAN rule. For some of these, the real numbers of valence electrons can be found by means of the CVMO scheme, but, generally speaking, precisely in this class of polynuclear compounds the above scheme starts to become inadequate for the task formulated (see Section II). Comparison of the theoretical magic numbers of valence electrons with the numbers for specific structures is complicated in this instance also by the difficulty of detecting carbonyl (and even more so hydride) ligands in the X-ray diffraction study of large clusters owing to the high scattering capacity of the metal atoms and the intense absorption, as a result of which, for example, the number of CO ligands in the last cluster in Table 8, namely $[Pt_{38}(CO)_{44}]^{2-}$, was established only tentatively

Table 8. Certain Rh and Pt lattice clusters.

Formula	n_{int}	n_{cap}	n_o	N_{val}	N_{sk}	$N^{sk}_{(2n+2)}$	N^{val}_{CVMO}	Refs.

$[Rh_{22}(CO)_{35}H_x]^{5-}$	2	8	2	$273 + x$	$33 + x$	46	—	[146]
$[Pt_{19}(CO)_{22}]^{4-}$	2	0	10	238	34	56	—	[147]
$[Pt_{26}(CO)_{32}]^{2-}$	3	0	6	326	50	60	—	[4]
$[Pt_{38}(CO)_{44}]^{2-}$	6	0	6	470	86	78	—	[4]

Notation: n_{int} is the number of internal atoms, n_{cp} the number of caps, n_o the number of open faces; for the significance of the remaining notation, see previous tables.

In relation to quantitative theoretical schemes, the lattice clusters in general exhibit fully the tendency already mentioned above for polyhedra of medium dimensions: with increase of the size of the polyhedron, its idealised form, consistent with the $2n + 2$ rule, is found to be capable of undergoing increasing distortions, which do not alter the number of valence (or skeletal) electrons. Accordingly, the

$[Rh_{13}(CO)_{24}H_3]^{2-}$ cluster, which can be obtained from a cubo-octahedron by rotating by 180° one of the triangular faces (to reproduce the so-called "twin of the cubo-octahedron"), is isoelectronic with a *closo*-eicosahedron, despite the presence of six open faces, which formally require additional twelve skeletal electrons.

Analysis of structures with Rh_{14}–Rh_{17} polyhedra (Fig. 20), which arise after the addition of caps to the initial Rh_{13} cluster, shows that in the case of large carbonyl clusters there is in essence no difference between the triangular and non-triangular faces as regards the influence on the number of skeletal electrons of the polyhedron. However, these numbers are not predicted by any of the existing theoretical schemes and can apparently be different for polyhedra of isotypical structure. Thus a satisfactory theoretical scheme for large transition metal clusters with carbonyl ligands has not as yet been developed.¶

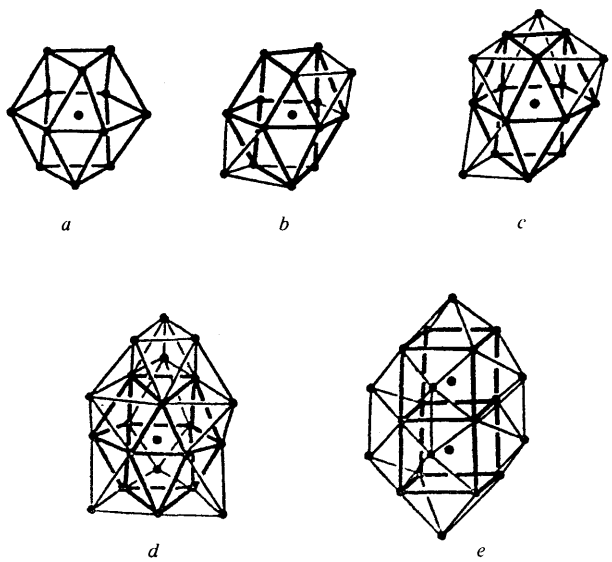

Figure 20. Examples of the structures of large metal clusters (the reference centred polyhedron is indicated): *a*) $[Rh_{13}.H_3(CO)_{24}]^{2-}$; *b*) $[Rh_{15}(CO)_{27}]^{3-}$; *c*) $[Rh_{17}(CO)_{30}]^{3-}$; *d*) $[Rh_{22}(CO)_{37}]^{4-}$; *e*) $[Rh_{22}(CO)_{35}H_x]^{5-}$.

- - - o 0 o - - -

On the basis of the structures of transition metal clusters examined above, it is possible to outline the limits of applicability of the existing schemes for the evaluation of the number of electrons in polyhedra. It follows from the examples in Section II that the "ordered region" in polynuclear transition metal complexes occurs in general in the vicinity of elements in the middle of transition series (Group VI–VIII metals), for "soft" ligands (in the first place CO), and for relatively simple M_n polyhedra with the number of vertices n in the range from 3 to 12. The $2n + 2$ rule or the EAN rule closely related to it (representing the special case for clusters with vertices of order ≤ 3 in which localised bonds can exist) yields the best results for such clusters.

The application of the $2n + 2$ scheme to octahedral metal clusters appears to be the most correct; an increase in the dimensions of the metallopolyhedron leads to increasing deviations of the structures of the clusters from the Wade structures and the corresponding magic numbers (somewhat in contrast to carbaborane derivatives, where eicosahedral clusters approximate most closely to the Wade structures).

The empirical-computational CVMO scheme which in general reproduces satisfactorily the numbers of valence electrons in clusters in the region of applicability of the $2n + 2$ rule, provides a somewhat better description of the electronic structure of clusters of medium dimensions, which sometimes deviates from this rule, and extends a little further into the region of large clusters; however, for a series of Wade polyhedra, this scheme can predict magic numbers which are incorrect. The search for general regularities outside the limits of the range of compounds indicated above and differentiated empirically has not so far achieved notable advances. Because of this, the hypothesis that clusters whose atomic and geometrical structures are governed by the $2n + 2$ rule contain a special type of chemical bond, which is absent from other clusters and which is taken into account explicitly or implicitly by electron counting schemes, appears to be fairly logical. According to all the theoretical and experimental studies, the chemical bond of this type in Wade clusters (and only in such clusters) makes it possible to differentiate independent topologically different exopolyhedral, surface, and intrapolyhedral electron systems with full localisation of electrons in the last two systems, which constitute overall the skeletal system of linkages in the clusters.[40] Thus Wade clusters (and only such clusters) apparently possess a closed configuration with skeletal delocalisation of the electron system, i.e. have the property of "three-dimensional" superaromaticity, which is nowadays attributed, not always with prejustification, to any polyhedral molecule.
